Acute respiratory distress syndrome (ARDS), first described in 1967, is a devastating syndrome of acute lung injury. Initially called the *adult respiratory distress syndrome*, it is now called the *acute respiratory distress syndrome* because it also affects children. ARDS affects approximately 150,000 to 200,000 persons each year; at least 50% to 60% of these persons die, despite the most sophisticated intensive care.³¹

ARDS is the final common pathway through which many serious localized and systemic disorders produce diffuse injury to the alveolar-capillary membrane. It may result from a number of conditions, including aspiration of gastric contents, major trauma (with or without fat emboli), sepsis secondary to pulmonary or nonpulmonary infections, acute pancreatitis, hematologic disorders, metabolic events, and reactions to drugs and toxins^{31,32} (Chart 21-3).

Although a number of conditions may lead to ARDS, they all produce similar pathologic lung changes that include diffuse endothelial and epithelial cell injury with increased permeability of the alveolar-capillary membrane (Fig. 21-14). The increased permeability permits fluid, protein, cellular debris and blood cells to move out of the vascular compartment into the interstitium and alveoli of the lung. Alveolar cell damage leads to accumulation of edema fluid, surfactant inactivation, and formation of a hyaline membrane that is impervious to gas exchange. The lungs become very stiff and difficult to inflate. There is increased intrapulmonary shunting of blood, impaired gas exchange, and profound hypoxia. Gas exchange is further compromised by alveolar collapse resulting from abnormalities in surfactant production. When injury to the alveolar epithelium is severe, disorganized epithelial repair may lead to fibrosis.

The pathogenesis of ARDS is unclear. Neutrophils accumulate early in the course of the disorder and are thought to play a role in the pathogenesis of ARDS. Activated neutrophils release a variety of products, including oxidants, proteases, platelet activating factor, and leukotrienes that damage the alveolar capillary endothelium and alveolar cells.

Clinically, the syndrome consists of progressive respiratory distress, an increase in respiratory rate, and signs of respiratory failure. Radiologic findings usually show extensive bilateral consolidation of the lung tissue. Severe hypoxia persists despite increased inspired oxygen levels.

The treatment goals in ARDS are to supply oxygen to vital organs and provide supportive care until the condition causing the pathologic process has been reversed and the lungs have had a chance to heal. Assisted ventilation using high concentrations of oxygen may be required to overcome the hypoxia.

■ FIGURE 21-14 ■ The mechanism of lung changes in ARDS. Injury and increased permeability of the alveolar capillary membrane allow fluid, protein, cellular debris, platelets, and blood cells to move out of the vascular compartment and enter the interstitium and alveoli. Activated neutrophils release a variety of products that damage the alveolar cells and lead to edema, surfactant inactivation, and formation of a hyaline membrane.

Positive end-expiratory pressure breathing, which increases the pressure in the airways during expiration, may be used to assist in reinflating the collapsed areas of the lung and to improve the matching of ventilation and perfusion.

In summary, pulmonary vascular disorders include pulmonary embolism and pulmonary hypertension. Pulmonary embolism develops when a blood-borne substance lodges in a branch of the pulmonary artery and obstructs blood flow. The embolus can consist of a thrombus, air, fat, or amniotic fluid. The most common form is a thromboembolus arising from the deep venous channels of the lower extremities. Pulmonary hypertension is the elevation of pulmonary arterial pressure. It can be caused by an elevated left atrial pressure, increased pulmonary blood flow, or increased pulmonary vascular resistance secondary to lung disease. The term *cor pulmonale* describes right heart failure caused by primary pulmonary disease and longstanding pulmonary hypertension.

ARDS is a devastating syndrome of acute lung injury resulting from a number of serious localized and systemic disorders that damage the alveolar-capillary membrane of the lung. It results in interstitial edema of lung tissue, an increase in surface tension caused by inactivation of surfactant, collapse of the alveolar structures, a stiff and noncompliant lung that is difficult to inflate, and impaired diffusion of the respiratory gases with severe hypoxia that is resistant to oxygen therapy.

RESPIRATORY FAILURE

Respiratory failure is a condition in which the lungs fail to oxygenate the blood adequately and prevent carbon dioxide retention. It is not a specific disease but the result of a number of conditions that impair ventilation, compromise the matching of ventilation and perfusion, or disrupt blood flow in the lung. These conditions include impaired ventilation caused by impaired function of the respiratory center, weakness and paralysis of the respiratory muscles, chest wall deformities, airway obstruction, and disease of the airways and lungs. It may occur in previously healthy persons as the result of acute disease or trauma involving the respiratory system, or it may develop in the course of a chronic neuromuscular or respiratory disease. The causes of respiratory failure are summarized in Chart 21-4.

Alterations in Blood Gases

The term *hypoxia* refers to a reduction in oxygen supply to the tissues; *hypoxemia*, to a low level of oxygen in the blood; and *hypercapnia* (sometimes referred to as *hypercarbia*), to excess carbon dioxide in the blood. The abbreviation PO₂ often is used to indicate the partial pressure of oxygen in arterial blood, and the abbreviation PCO₂, the partial pressure of carbon dioxide. The common manifestations of respiratory failure are hypoxemia and hypercapnia. There is no absolute definition of the levels of arterial PO₂ and PCO₂ that indicate respiratory failure. As a general rule, *respiratory failure* refers to an arterial PO₂ level of 50 mm Hg or less and an arterial PCO₂ level greater than 50 mm Hg. However, these values are not reliable when dealing with persons who have chronic lung disease because many of these persons are alert and functioning with blood gas levels outside this range.

Mechanisms of Altered Gas Exchange

Various types of respiratory failure are associated with different degrees of hypoxemia or hypercapnia.³³ For example, pure hypoventilation, as occurs in conditions such as drug overdose, favors retention of CO₂. Severe ventilation-perfusion mismatching that is inadequate to maintain the PO₂ results in

hypoxemia that is more severe in relation to hypercapnia. This pattern of respiratory failure is seen most commonly in persons with advanced COPD. In interstitial lung disease, there is severe hypoxemia but no hypercapnia because of increased ventilation. In ARDS, the arterial PCO_2 is typically

KEY CONCEPTS

DISORDERS OF BLOOD GASES IN RESPIRATORY FAILURE

- Respiratory failure represents failure of the lungs to adequately oxygenate the blood and prevent carbon dioxide retention.
- Hypoxemia results from decreased concentration of oxygen in the inspired air, airway diseases that impair ventilation, respiratory disorders that impair ventilation and/or perfusion, and cardiovascular disorders that impair movement of blood through the respiratory portions of the lung.
- Carbon dioxide retention is characteristic of conditions that produce hypoventilation.
- Conditions such as acute respiratory distress syndrome that impede the diffusion of gases in the lung impair the oxygenation of blood but do not interfere with the elimination of carbon dioxide.

low, but hypoxemia is severe. In this case, administration of oxygen can produce an increase in PO_2 without producing an increase in PCO_2 .

Hypoventilation. Hypoventilation occurs when the volume of "fresh" air moving into and out of the lung is significantly reduced. Hypoventilation is commonly caused by conditions outside the lung such as depression of the respiratory center (*e.g.*, drug overdose), diseases of the nerves supplying the respiratory muscles (*e.g.*, Guillain-Barré syndrome), disorders of the respiratory muscles (*e.g.*, muscular dystrophy), or thoracic cage disorders (*e.g.*, severe scoliosis or crushed chest).

Hypoventilation has two important effects on arterial blood gases. First, hypoventilation almost always causes an increase in PCO₂. The rise in PCO₂ is directly related to the level of ventilation. For example, the PCO₂ doubles when alveolar ventilation is reduced by one half. Thus, the PCO₂ level is a good diagnostic measure for hypoventilation. Second, hypoxemia caused by hypoventilation can be easily corrected by increasing the oxygen content of the inspired air.³³

Ventilation-Perfusion Mismatching. The mismatching of ventilation and perfusion occurs when areas of the lung are ventilated but not perfused or when areas are perfused but not ventilated. Usually the hypoxemia that is seen in situations of ventilation-perfusion mismatching is more severe in relation to hypercapnia than that seen in hypoventilation. Severe mismatching of ventilation and perfusion often is seen in persons with advanced COPD. These disorders contribute to the retention of carbon dioxide by reducing the effective alveolar ventilation, even when total ventilation is maintained. This occurs because a region of the lung is not perfused and gas exchange cannot take place or because an area of the lung is not being ventilated. Maintaining a high ventilation rate effectively prevents hypercapnia but also increases the work of breathing.

The hypoxemia associated with ventilation-perfusion disorders often is exaggerated by conditions such as hypoventilation and decreased cardiac output. For example, sedation can cause hypoventilation in persons with severe COPD, resulting in further impairment of ventilation. Likewise, a decrease in cardiac output because of myocardial infarction can exaggerate the ventilation-perfusion impairment in a person with mild pulmonary edema.

The beneficial effect of oxygen administration on PO_2 levels in ventilation-perfusion disorders depends on the degree of mismatching that is present. Because oxygen administration increases the diffusion gradient in ventilated portions of the lung, it usually is effective in raising arterial PO_2 levels but may decrease the respiratory drive and produce an increase in PCO_2 .

Impaired Diffusion. Diffusion impairment describes a condition in which gas exchange between the alveoli and the red blood cells is impeded because of an increase in the distance for diffusion or a decrease in the permeability of the alveolar capillary membrane to movement of gases. Impaired diffusion is caused by conditions such as interstitial lung disease, ARDS, pulmonary edema, and pneumonia. These conditions alter the thickness or permeability of the alveolar capillary membrane, rather than the time that the blood spends in pulmonary capillaries.

Hypoxemia resulting from impaired diffusion can be partially or completely corrected by the administration of 100% oxygen. This occurs because the increase in alveolar oxygen establishes a large alveolar-capillary diffusion gradient that overcomes the resistance to diffusion.

Shunt. Shunt occurs when blood reaches the arterial system without passing through the ventilated portion of the lung. Most shunts, such as those that occur with congenital heart disease, are extrapulmonary. However, a completely unventilated portion of the lung, as occurs with atelectasis, can result in the shunting of blood in the pulmonary circulation. Administration of oxygen usually increases arterial oxygen levels with intrapulmonary shunting but not with extrapulmonary shunting, such as occurs in children with intracardiac shunts. Because unoxygenated venous blood is being mixed with oxygenated blood in persons with intrapulmonary shunts, the rise in PO₂ levels depends on the degree of shunt.

Hypoxemia

Hypoxemia refers to a reduction in blood oxygen levels. Hypoxemia can result from an inadequate amount of oxygen in the air, disease of the respiratory system, or alterations in circulatory function. The mechanisms whereby respiratory disorders lead to a significant reduction in PO₂ are hypoventilation, impaired diffusion of gases, shunt, and mismatching of ventilation and perfusion.33 Another cause of hypoxemia, reduction of the partial pressure of oxygen in the inspired air, occurs only under special circumstances, such as at high altitudes. Often more than one mechanism contributes to hypoxemia in a person with respiratory or cardiac disease.

Clinical Manifestations. Hypoxemia produces its effects through tissue hypoxia and the compensatory mechanisms that the body uses to adapt to the lowered oxygen level. Body tissues vary considerably in their vulnerability to hypoxia; those with the greatest need are the nervous system and heart. Cessation of blood flow to the cerebral cortex results in loss of consciousness within 10 to 20 seconds. If the PO₂ of the tissues falls below a critical level, aerobic metabolism ceases and anaerobic metabolism takes over, with the formation and release of lactic acid.

The signs and symptoms of hypoxemia can be grouped into two categories: those resulting from impaired function of vital centers and those resulting from activation of compensatory mechanisms. Mild hypoxemia produces few manifestations. There may be slight impairment of mental performance and visual acuity and sometimes hyperventilation. This is because hemoglobin saturation still is approximately 90% when the PO₂ is only 60 mm Hg (see Chapter 19, Fig. 19-18). More pronounced hypoxemia may produce personality changes, restlessness, agitated or combative behavior, muscle incoordination, euphoria, impaired judgment, delirium, and, eventually, stupor and coma. Recruitment of sympathetic compensatory mechanisms produces tachycardia, cool skin (i.e., peripheral vasoconstriction), diaphoresis, and a mild increase in blood pressure. Profound acute hypoxemia can cause convulsions, retinal hemorrhages, and permanent brain damage. Hypotension and bradycardia often are preterminal events in persons with hypoxemia, indicating the failure of compensatory mechanisms.

In conditions of chronic hypoxemia, the manifestations may be insidious in onset and attributed to other causes, particularly in chronic lung disease. There may be a gradual increase in red blood cells (polycythemia) and development of pulmonary hypertension. Polycythemia increases the red blood cell concentration and the oxygen-carrying capacity of the blood. Pulmonary vasoconstriction occurs as a local response to alveolar hypoxia; it increases pulmonary arterial pressure and improves the matching of ventilation and blood flow.

Cyanosis. Cyanosis refers to the bluish discoloration of the skin and mucous membranes that results from an excessive concentration of reduced or deoxygenated hemoglobin in the small blood vessels. It usually is most marked in the lips, nail beds, ears, and cheeks. The degree of cyanosis is modified by the amount of cutaneous pigment, skin thickness, and the state of the cutaneous capillaries. Cyanosis is more difficult to distinguish in persons with dark skin and in areas of the body with increased skin thickness.

Although cyanosis may be evident in persons with respiratory failure, it often is a late sign. A concentration of approximately 5 g/dL of deoxygenated hemoglobin is required in the circulating blood for cyanosis to occur.³⁴ The absolute quantity of reduced hemoglobin, rather than the relative quantity, is important in producing cyanosis. Persons with anemia and low hemoglobin levels are less likely to exhibit cyanosis (because they have less hemoglobin to deoxygenate), even though they may be relatively hypoxic because of their decreased ability to transport oxygen, than persons who have high hemoglobin concentrations. Someone with a high hemoglobin level because of polycythemia may be cyanotic without being hypoxic.

Cyanosis can be divided into two types: central or peripheral. Central cyanosis is evident in the tongue and lips. It is caused by an increased amount of deoxygenated hemoglobin in the arterial blood. Peripheral cyanosis occurs in the extremities and on the tip of the nose or ears. It is caused by slowing of blood flow to an area of the body, with increased extraction of oxygen from the blood. It results from vasoconstriction and diminished peripheral blood flow, as occurs with cold exposure, shock, congestive heart failure, and peripheral vascular disease.

Diagnosis. Diagnosis of hypoxemia is based on clinical observation and diagnostic tests to determine blood oxygen levels. The analysis of arterial blood gases provides a direct measure of the oxygen content of the blood and is a good indicator of the lungs' ability to oxygenate the blood. Noninvasive measurement of hemoglobin saturation can be obtained using the pulse oximeter. The pulse oximeter uses light-emitting diodes and light-receiving sensors to quantify the light absorbed by oxygenated/deoxygenated hemoglobin in arterial blood.⁸⁵ Sensors that can be placed on the ear, finger, toe, or forehead are available. Pulse oximetry cannot distinguish between oxygen-carrying hemoglobin and carbon monoxide-carrying hemoglobin, a factor that should be considered when treating persons with carbon monoxide poisoning. It is also inaccurate in persons with pronounced vasoconstriction.

Hypercapnia

Hypercapnia refers to an increase in the carbon dioxide content of the blood. The diagnosis of hypercapnia is based on physiologic manifestations, arterial pH, and blood gas levels. The carbon dioxide level in the arterial blood, or PCO₂, is proportional to carbon dioxide production and inversely related to alveolar ventilation. The diffusing capacity of carbon dioxide is 20 times that of oxygen; therefore, hypercapnia is observed only in situations of hypoventilation sufficient to cause hypoxia.

Causes. Hypercapnia can occur in a number of disorders that cause hypoventilation or mismatching of ventilation and perfusion. Hypoventilation is a cause of hypercapnia in respiratory failure caused by depression of the respiratory center in drug overdose, neuromuscular diseases such as Guillain-Barré syndrome, or chest wall deformities such as those seen with severe scoliosis. Hypercapnia caused by ventilation-perfusion inequalities is seen most commonly in persons with COPD.

The respiratory center, which controls the activity of the muscles of respiration, is a crucial determinant of ventilation and elimination of carbon dioxide. It is composed of widely dispersed groups of neurons located in the medulla oblongata and pons (see Chapter 19). The activity of the respiratory center is regulated by chemoreceptors that monitor changes in the chemical composition of the blood. The most important chemoreceptors in terms of the minute-by-minute control of ventilation are the central chemoreceptors that respond to changes in the hydrogen ion (H⁺) concentration of the cerebrospinal fluid. Although the blood-brain barrier is impermeable to H^+ ions, CO_2 crosses it with ease. The CO_{21} in turn, reacts with water to form carbonic acid, which dissociates to form H^+ and bicarbonate (HCO₃⁻) ions. When the CO₂ content of the blood rises, CO₂ crosses the blood-brain barrier, liberating H⁺ ions that stimulate the central chemoreceptors. The excitation of the respiratory center caused by CO₂ is greatest during the first 1 to 2 days that blood levels are elevated, but it gradually declines during the next 1 to 2 days.34

In persons with respiratory problems that cause chronic hypoxia and hypercapnia, the peripheral chemoreceptors become the driving force for ventilation. These chemoreceptors, which are located in the bifurcation of the common carotid arteries and in the aortic arch, respond to changes in PO₂. Administration of high-flow oxygen to these persons can abolish the input from these peripheral receptors, causing a decrease in alveolar ventilation and a further increase in PCO₂ levels.

Respiratory muscle fatigue can contribute to carbon dioxide retention in persons with various primary respiratory diseases and in those with neuromuscular disorders. In these persons, respiratory muscle fatigue develops when energy requirements exceed the energy supply. A number of factors increase energy requirements or decrease the energy supply. The energy demands of the respiratory muscles are increased by high levels of ventilation or by factors that increase the work of breathing, such as high levels of airway resistance. The energy supply depends on blood flow and the oxygen content of the blood. Low cardiac output, anemia, and decreased oxygen saturation contribute to a decreased energy supply and increase the likelihood of respiratory muscle fatigue. With malnutrition, the energy stores of the muscles are diminished, and there may be structural changes in the muscle as well. Electrolyte imbalances, especially hypokalemia and hypophosphatemia, contribute to respiratory muscle weakness.³⁶

Clinical Manifestations. Hypercapnia affects many body functions, including renal, neural, and cardiovascular function, as well as the acid-base balance. Elevated levels of PCO_2 produce a decrease in pH and respiratory acidosis (see Chapter 6). The body normally compensates for an increase in PCO_2 by increasing renal bicarbonate retention. As long as the pH is in an acceptable range, the main complications of hypercapnia are those resulting from the accompanying hypoxia. Because the body compensates for chronic increases in blood levels of carbon dioxide, persons with chronic hypercapnia may not have symptoms until the PCO_2 is markedly elevated.

Carbon dioxide has a direct vasodilatory effect on many blood vessels and a sedative effect on the nervous system. When the cerebral vessels are dilated, headache develops. The conjunctivae are hyperemic and the skin flushed. Hypercapnia has nervous system effects similar to those of an anesthetic, thus the term *carbon dioxide narcosis*. There is progressive somnolence, disorientation, and if the condition is untreated, coma. Mild to moderate increases in blood pressure are common. Air hunger and rapid breathing occur when alveolar PCO₂ levels rise to approximately 60 to 75 mm Hg; as PCO₂ levels reach 80 to 100 mm Hg, the person becomes lethargic and sometimes becomes semicomatose. Anesthesia and death can result when PCO₂ levels reach 100 to 150 mm Hg.

Treatment of Respiratory Failure

The treatment of respiratory failure focuses on correcting the problems causing impaired gas exchange when possible and on relieving the hypoxemia and hypercapnia. A number of treatment modalities are available, including treatment of drug overdose, use of bronchodilating drugs, and antibiotics to treat severe respiratory tract infections. The insertion of an artificial airway and use of mechanical ventilation may be necessary.

Therapy for hypercapnia is directed at decreasing the work of breathing and improving the ventilation-perfusion balance. Intermittent rest therapy, such as nocturnal negative-pressure ventilation, applied to patients with hypercapnia and chronic obstructive disease or chest wall disease may be effective in increasing the strength and endurance of the respiratory muscle and improving the PCO₂. Respiratory muscle retraining aimed at improving the respiratory muscles, their endurance, or both has been used to improve exercise tolerance and diminish the likelihood of respiratory fatigue.

Hypoxemia is usually treated with oxygen therapy. Oxygen may be delivered by nasal cannula or mask. It also may be administered directly into an endotracheal or tracheostomy tube in persons who are being ventilated. The oxygen must be humidified as it is being administered. The concentration of oxygen that is being administered (usually determined by the flow rate) is based on the PO₂. The rate must be carefully monitored in persons with chronic lung disease because increases in PO₂ above 60 mm Hg are likely to depress the ventilatory drive. There also is the danger of oxygen toxicity with high concentrations of oxygen. Continuous breathing of oxygen at high concentrations can lead to diffuse parenchymal lung injury.

In summary, the lungs enable inhaled air to come in proximity to the blood flowing through the pulmonary capillaries so that the exchange of gases between the internal environment of the body and the external environment can take place. Respiratory failure is a condition in which the lungs fail adequately to oxygenate the blood or prevent undue retention of carbon dioxide. The causes of respiratory failure are many. It may arise acutely in persons with previously healthy lungs, or it may be superimposed on chronic lung disease. Respiratory failure is defined as a PO₂ of 50 mm Hg or less and a PCO₂ of 50 mm Hg or more.

Hypoxia refers to an acute or chronic reduction in tissue oxygenation. It can occur as the result of hypoventilation, diffusion impairment, shunt, and ventilation-perfusion impairment. Acute hypoxemia incites sympathetic nervous system responses such as tachycardia and produces symptoms that are similar to those of alcohol intoxication. In conditions of chronic hypoxia, the manifestations may be insidious in onset and attributed to other causes, particularly in chronic lung disease. The development of cyanosis requires a concentration of 5 g/dL of deoxygenated hemoglobin.

Hypercapnia refers to an increase in carbon dioxide levels. In the clinical setting, four factors contribute to hypercapnia: alterations in carbon dioxide production, disturbance in the gas exchange function of the lungs, abnormalities in respiratory function of the chest wall and respiratory muscles, and changes in neural control of respiration. The manifestations of hypercapnia consist of those associated with the vasodilation of blood vessels, including those in the brain, and depression of the central nervous system (*e.g.*, carbon dioxide narcosis).

REVIEW QUESTIONS

Differentiate among the causes and manifestations of spontaneous pneumothorax, secondary pneumothorax, and tension pneumothorax.

Describe the causes and manifestations of atelectasis.

Describe the physiology of bronchial smooth muscle as it relates to the early phase and late phase responses in the pathogenesis of bronchial asthma.

Explain the distinction between chronic bronchitis and emphysema in terms of pathology and clinical manifestations.

Describe the genetic abnormality responsible for cystic fibrosis and state the disorder's effect on lung function.

Compare the physiology changes that occur with COPD and interstitial lung diseases.

State the most common cause of pulmonary embolism and the clinical manifestations of the disorder.

Describe the pathophysiology of pulmonary arterial hypertension and three causes of secondary pulmonary hypertension. Describe the pathologic lung changes that occur in acute respiratory distress syndrome and relate them to the clinical manifestations of the disorder.

Define the terms hypoxia, hypoxemia, and hypercapnia and characterize the mechanisms whereby respiratory disorders cause hypoxemia and hypercapnia.

Compare the manifestations of hypoxia and hypercapnia.

CHAPTER

Tests of Renal Function Urine Tests Glomerular Filtration Rate Blood Tests Serum Creatinine Blood Urea Nitrogen

 It is no exaggeration to say that the composition of the blood is determined not so much by what the mouth takes in as by what the kidneys keep.
 Homer Smith, From Fish to Philosopher

he kidneys are remarkable organs. Each is smaller than a person's fist, but in a single day the two organs process approximately 1700 L of blood and combine its waste products into approximately 1.5 L of urine. As part of their function, the kidneys filter physiologically essential substances, such as sodium and potassium ions, from the blood and selectively reabsorb those substances that are needed to maintain the normal composition of internal body fluids. Substances that are not needed for this purpose or are in excess pass into the urine. In regulating the volume and composition of body fluids, the kidneys perform excretory and endocrine functions. The renin-angiotensin mechanism participates in the regulation of blood pressure and the maintenance of circulating blood volume, and erythropoietin stimulates red blood cell production.

KIDNEY STRUCTURE AND FUNCTION

Gross Structure and Location

The kidneys are paired, bean-shaped organs that lie outside the peritoneal cavity in the back of the upper abdomen, one on each side of the vertebral column at the level of the 12th thoracic to 3rd lumbar vertebrae (Fig. 22-1). The right kidney normally is situated lower than the left, presumably because of the position of the liver. In the adult, each kidney is approximately 10 to 12 cm long, 5 to 6 cm wide, and 2.5 cm deep and weighs approximately 113 to 170 g. The medial border of the kidney is indented by a deep fissure called the hilus. It is here that blood vessels and nerves enter and leave the kidney. The ureters, which connect the kidneys with the bladder, also enter the kidney at the hilus.

The kidney is a multilobular structure, composed of up to 18 lobes. Each lobule is composed of nephrons, which are the functional units of the kidney. Each nephron has a glomerulus that filters the blood and a system of tubular structures that selectively reabsorb material from the filtrate back into the blood and secrete materials from the blood into the filtrate as urine is being formed.

On longitudinal section, a kidney can be divided into an outer cortex and an inner medulla (Fig. 22-2). The cortex, which is reddish-brown, contains the glomeruli and convoluted tubules of the nephron and blood vessels. The medulla consists of light-colored, cone-shaped masses-the renal pyramids—that are divided by the columns of the cortex (i.e., columns of Bertin) that extend into the medulla. Each pyramid,

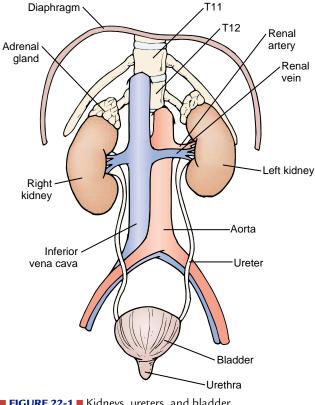

FIGURE 22-1 Kidneys, ureters, and bladder.

topped by a region of cortex, forms a lobe of the kidney. The apices of the pyramids form the papillae, which are perforated by the openings of the collecting ducts. The renal pelvis is a wide, funnel-shaped structure at the upper end of the ureter. It is made up of the calices or cuplike structures that drain the upper and lower halves of the kidney.

The kidney is ensheathed in a fibrous external capsule and surrounded by a mass of fatty connective tissue, especially at its ends and borders. The adipose tissue protects the kidney from mechanical blows and assists, together with the attached blood vessels and fascia, in holding the kidney in place. Although the kidneys are relatively well protected, they may be bruised by blows to the loin or by compression between the lower ribs and the ilium. Because the kidneys are outside the peritoneal cavity, injury and rupture do not produce the same threat of peritoneal involvement as rupture of organs such as the liver or spleen.

Each kidney is supplied by a single renal artery that arises on either side of the aorta. As the renal artery approaches the kidney, it divides into five segmental arteries that enter the hilus of the kidney. In the kidney, each segmental artery subdivides and branches several times. The smallest branches, the intralobular arteries, give rise to the afferent arterioles that supply the glomeruli (Fig. 22-3).

The Nephron

Each kidney is composed of more than 1 million tiny, closely packed functional units called nephrons. Each nephron consists of a glomerulus, where blood is filtered, and a tubular component. Here, water, electrolytes, and other substances needed to maintain the constancy of the internal environment are reabsorbed into the bloodstream while other unneeded materials are secreted into the tubular filtrate for elimination (see Fig. 22-4).

The Glomerulus

The glomerulus consists of a compact tuft of capillaries encased in a thin, double-walled capsule, called Bowman's capsule. Blood flows into the glomerular capillaries from the afferent arteriole and flows out of the glomerular capillaries into the efferent arteriole, which leads into the peritubular capillaries. Fluid and particles from the blood are filtered through the capillary membrane into a fluid-filled space in Bowman's capsule, called Bowman's space. The portion of the blood that is filtered into the capsule space is called the filtrate. The mass of capillaries and its surrounding epithelial capsule are collectively referred to as the renal corpuscle (Fig. 22-5A). The glomerular capillary membrane is composed of three layers: the capillary endothelial layer, the basement membrane, and the single-celled capsular epithelial layer (see Fig. 22-5B). The endothelial layer lines the glomerulus and interfaces with blood as it moves through the capillary. This layer contains many small perforations, called fenestrations.

The epithelial layer that covers the glomerulus is continuous with the epithelium that lines Bowman's capsule. The cells of the epithelial layer have unusual octopus-like structures that possess a large number of extensions, or foot processes (i.e., podocytes), which are embedded in the basement membrane. These foot processes form slit pores through which

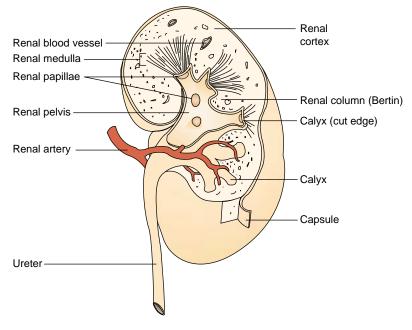

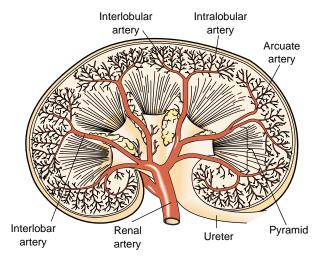

FIGURE 22-2 Internal structure of the kidney.

the glomerular filtrate passes. The *basement membrane* consists of a homogeneous acellular meshwork of collagen fibers, glycoproteins, and mucopolysaccharides (see Fig. 22-5C). Because the endothelial and the epithelial layers of the glomerular capillary have porous structures, the basement membrane determines the permeability of the glomerular capillary membrane. The spaces between the fibers that make up the basement membrane represent the pores of a filter and determine the size-dependent permeability barrier of the glomerulus. The size of the pores in the basement membrane normally prevents red blood cells and plasma proteins from passing through the glomerular membrane into the filtrate. There is evidence that the epithelium plays a major role in producing the basement membrane components, and it is

■ **FIGURE 22-3** ■ Simplified illustration of the arterial supply of the kidney. (Cormack D.H. [1987]. *Ham's histology* [9th ed.]. Philadelphia: J.B. Lippincott)

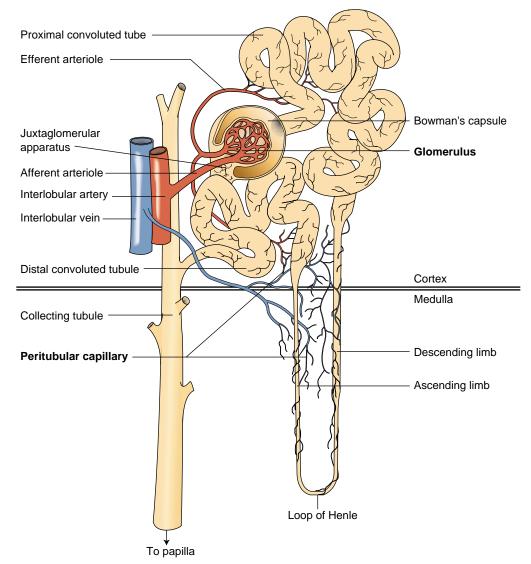

probable that the epithelial cells are active in forming new basement membrane material throughout life. Alterations in the structure and function of the glomerular basement membrane are responsible for the leakage of proteins and blood cells into the filtrate that occurs in many forms of glomerular disease.

Another important component of the glomerulus is the mesangium. In some areas, the capillary endothelium and the basement membrane do not completely surround each capillary. Instead, the mesangial cells, which lie between the capillary tufts, provide support for the glomerulus in these areas (see Fig. 22-5B). The mesangial cells produce an intercellular substance similar to that of the basement membrane. This substance covers the endothelial cells where they are not covered by basement membrane. The mesangial cells possess (or can develop) phagocytic properties and remove macromolecular materials that enter the intercapillary spaces. Mesangial cells also exhibit contractile properties in response to neurohumoral substances and are thought to contribute to the regulation of blood flow through the glomerulus. In normal glomeruli, the mesangial area is narrow and contains only a small number of cells. Mesangial hyperplasia and increased mesangial matrix occur in a number of glomerular diseases.

Tubular Components of the Nephron

The nephron tubule is divided into four segments: a highly coiled segment called the *proximal convoluted tubule*, which drains Bowman's capsule; a thin, looped structure called the *loop of Henle*; a distal coiled portion called the *distal convoluted tubule*; and the final segment called the *collecting tubule*, which joins with several tubules to collect the filtrate (Fig. 22-4). The filtrate passes through each of these segments before reaching the pelvis of the kidney.

Nephrons can be roughly grouped into two categories. Approximately 85% of the nephrons originate in the superficial part of the cortex and are called *cortical nephrons*. They have

■ FIGURE 22-4 ■ Nephron, showing the glomerular and tubular structures along with the blood supply.

KEY CONCEPTS

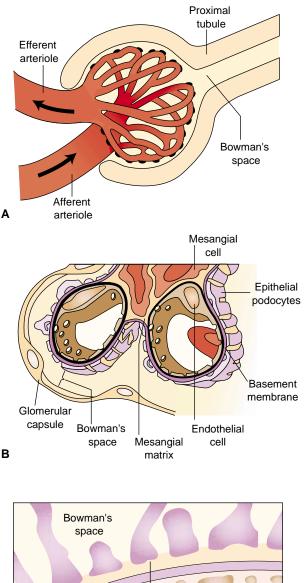

THE NEPHRON

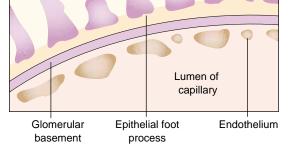

- The nephron, which contains a glomerulus and tubular structures, is the functional unit of the kidney.
- Each nephron is closely associated with two capillary beds: the glomerulus, where water-soluble nutrients, wastes, and other small particles are filtered from the blood, and the peritubular capillaries that surround the tubular structures.
- Tubular structures process the glomerular (urine) filtrate, selectively reabsorbing substances from the tubular fluid into the peritubular capillaries and secreting substances from the peritubular capillaries into the urine filtrate.

short, thick loops of Henle that penetrate only a short distance into the medulla. The remaining 15% are called *juxtamedullary nephrons*. They originate deeper in the cortex and have longer and thinner loops of Henle that penetrate the entire length of the medulla. The juxtamedullary nephrons are largely concerned with urine concentration.

The proximal tubule is a highly coiled structure that dips toward the renal pelvis to become the descending limb of the loop of Henle. The ascending loop of Henle returns to the region of the renal corpuscle, where it becomes the distal tubule. The distal convoluted tubule, which begins at the juxtaglomerular complex, is divided into two segments: the *diluting segment* and the *late distal tubule*. The late distal tubule fuses with the collecting tubule. Like the distal tubule, the collecting duct is divided into two segments: the *cortical collecting tubule* and the *inner medullary collecting tubule*.

Throughout its course, the tubule is composed of a single layer of epithelial cells resting on a basement membrane. The structure of the epithelial cells varies with tubular function.

C membrane

The cells of the proximal tubule have a fine villous structure that increases the surface area for reabsorption; they also are rich in mitochondria, which support active transport processes. The epithelial layer of the thin segment of the loop of Henle has few mitochondria, indicating minimal metabolic activity and passive reabsorptive function.

Nephron Blood Supply

The nephron is supplied by two capillary systems, the glomerulus and the peritubular capillary network (Fig. 22-4). The glomerulus is a unique, high-pressure capillary filtration system located between two arterioles-the afferent and the efferent arterioles-that selectively dilate or constrict to regulate glomerular capillary pressure and consequently their filtration. The peritubular capillary network is a low-pressure reabsorptive system that originates from the efferent arteriole. These capillaries surround all portions of the tubules, an arrangement that permits rapid movement of solutes and water between the fluid in the tubular lumen and the blood in the capillaries. The medullary nephrons are supplied with two types of capillaries: the peritubular capillaries, which are similar to those in the cortex, and the vasa recta, which are long, straight capillaries. The vasa recta accompany the long loops of Henle in the medullary portion of the kidney to assist in exchange of substances flowing in and out of that portion of the kidney and play an important role in concentrating the urine. The peritubular capillaries rejoin to form the venous channels by which blood leaves the kidneys and empties into the inferior vena cava.

Although nearly all the blood flow to the kidneys passes through the cortex, less than 10% is directed to the medulla and only approximately 1% goes to the papillae. Under conditions of decreased perfusion or increased sympathetic nervous system stimulation, blood flow is redistributed away from the cortex toward the medulla. This redistribution of blood flow decreases glomerular filtration while maintaining the urine concentrating ability of the peritubular capillaries, a factor that is important during conditions such as shock.

Urine Formation

Urine formation involves the filtration of blood by the glomerulus to form an *ultrafiltrate of urine* and the tubular reabsorption of electrolytes and nutrients needed to maintain the constancy of the internal environment while eliminating waste materials.

Glomerular Filtration

Urine formation begins with the filtration of essentially protein-free plasma through the glomerular capillaries into Bowman's space. The movement of fluid through the glomerular capillaries is determined by the same factors (*i.e.*, capillary filtration pressure, colloidal osmotic pressure, and capillary permeability) that affect fluid movement through other capillaries in the body (see Chapter 6). The glomerular filtrate has a chemical composition similar to plasma, but it contains almost no proteins because large molecules do not readily cross the glomerular wall. Approximately 125 mL of filtrate is formed each minute. This is called the *glomerular filtration rate* (*GFR*). This rate can vary from a few milliliters per minute to as high as 200 mL/minute.

The location of the glomerulus between two arterioles allows for maintenance of a high-pressure filtration system. The capillary filtration pressure (approximately 60 mm Hg) in the glomerulus is approximately two to three times higher than that of other capillary beds in the body. The filtration pressure and the GFR are regulated by the constriction and relaxation of the afferent and efferent arterioles. Constriction of the efferent arteriole increases resistance to outflow from the glomeruli and increases the glomerular pressure and the GFR. Constriction of the afferent arteriole causes a reduction in the renal blood flow, glomerular filtration pressure, and GFR. The afferent and the efferent arterioles are innervated by the sympathetic nervous system and also are sensitive to vasoactive hormones, such as angiotensin II. During periods of strong sympathetic stimulation, such as occurs during shock, constriction of the afferent arteriole causes a marked decrease in renal blood flow and thus glomerular filtration pressure. Consequently, urine output can fall almost to zero.

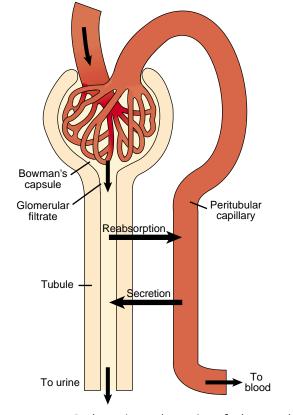

Tubular Reabsorption and Secretion

From Bowman's capsule, the glomerular filtrate moves into the tubular segments of the nephron. In its movement through the lumen of the tubular segments, the glomerular filtrate is changed considerably by the tubular transport of water and solutes. Tubular transport can result in reabsorption of substances from the tubular fluid into the blood or secretion of substances from the blood into the tubular fluid (Fig. 22-6). Segments of the renal tubule are adapted to reabsorb or secrete specific substances, using particular modes of transport.

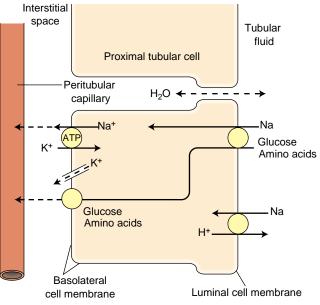

The basic mechanisms of transport across the tubular epithelial cell membrane are similar to those of other cell membranes in the body and include active and passive transport mechanisms (see Chapter 1). Water and urea are passively absorbed along concentration gradients. Sodium, potassium, chloride, calcium, and phosphate ions, as well as urate, glucose, and amino acids are reabsorbed using primary or secondary active transport mechanisms to move across the tubular membrane. Some substances, such as hydrogen, potassium, and urate ions, are secreted into the tubular fluids. Under normal conditions, only approximately 1 mL of the 125 mL of glomerular filtrate that is formed each minute is excreted in the urine. The other 124 mL is reabsorbed in the tubules. This means that the average output of urine is approximately 60 mL/hour.

Renal tubular cells have two membrane surfaces through which substances must pass as they are reabsorbed from the tubular fluid. The side of the cell that is in contact with the tubular lumen and tubular filtrate is called the *luminal membrane*. The outside membrane that lies adjacent to the interstitial fluid and the peritubular capillaries is called the *basolateral membrane*. In most cases, substances move from the tubular filtrate into the tubular cell along a concentration gradient, but they require facilitated transport or carrier systems to move across the basolateral membrane into the interstitial fluid, where they are absorbed into the peritubular capillaries.

The bulk of energy used by the kidney is for active transport mechanisms that facilitate sodium reabsorption and cotransport of other electrolytes and substances such as glucose and amino acids (Fig. 22-7). Cotransport uses a carrier system in which two substances move in the same direction. The active transport of one substance such as sodium is coupled to the movement of a second substance such as glucose or an amino acid. A few substances, such as hydrogen, are secreted into the tubule using countertransport, in which the movement of one substance, such as sodium, enables the movement of a second substance in the opposite direction.

■ **FIGURE 22-6** ■ Reabsorption and secretion of substances between the renal tubules and peritubular capillaries.

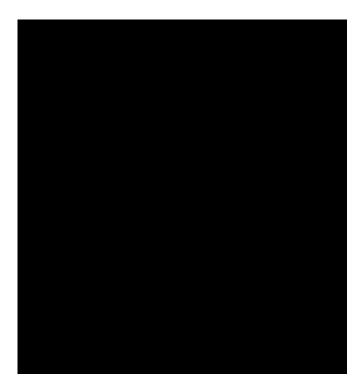

■ FIGURE 22-7 ■ Mechanism for secondary active transport or cotransport of glucose and amino acids in the proximal tubule. The energy-dependent sodium-potassium pump on the basal lateral surface of the cell maintains a low intracellular gradient that facilitates the downhill movement of sodium and glucose or amino acids (cotransport) from the tubular lumen into the tubular cell and then into the peritubular capillary.

Proximal Tubule. Although tubular transport occurs throughout the renal tubule, most of it occurs in the proximal tubule. Approximately 65% of all reabsorptive and secretory processes that occur in the tubular system take place in the proximal tubule. There is almost complete reabsorption of nutritionally important substances, such as glucose, amino acids, lactate, and water-soluble vitamins. Electrolytes, such as sodium, potassium, chloride, and bicarbonate, are 65% to 80% reabsorbed. As these solutes move into the tubular cells, their concentration in the tubular lumen decreases, providing a concentration gradient for the osmotic reabsorption of water and urea. The proximal tubule is highly permeable to water, and the osmotic movement of water occurs so rapidly that the concentration difference of solutes on either side of the membrane seldom is more than a few milliosmoles.

Many substances, such as glucose, are freely filtered in the glomerulus and reabsorbed by energy-dependent cotransport carrier mechanisms. The maximum amount of substance that these transport systems can reabsorb per unit time is called the transport maximum. The transport maximum is related to the number of carrier proteins that are available for transport and usually is sufficient to ensure that all of a filtered substance such as glucose can be reabsorbed, rather than being eliminated in the urine. The plasma level at which the substance appears in the urine is called the *renal threshold* (Fig. 22-8). Under some circumstances, the amount of substance filtered in the glomerulus exceeds the transport maximum. For example, when the blood glucose level is elevated in uncontrolled diabetes mellitus, the amount that is filtered in the glomerulus often exceeds the transport maximum (approximately 320 mg/minute), and glucose spills into the urine.

The Loop of Henle. The loop of Henle is divided into three segments: the thin descending segment, the thin ascending segment, and thick ascending segment. The loop of Henle, taken

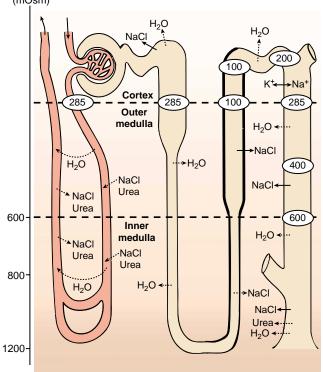

as whole, always reabsorbs more sodium and chloride than water. This is in contrast to the proximal tubule, which reabsorbs sodium and water in equal proportions.

The thin descending limb is highly permeable to water and moderately permeable to urea, sodium, and other ions. As the urine filtrate moves down the descending limb, water moves out of the filtrate into the surrounding interstitium (Fig. 22-9). Thus, the osmolality of the filtrate reaches its highest point at the elbow of the loop of Henle. In contrast to the descending limb, the ascending limb of the loop of Henle is impermeable to water. In this segment, solutes are reabsorbed, but water cannot follow; as a result, the tubular filtrate becomes more and more dilute, often reaching an osmolality of 100 mOsm/kg of H₂O as it enters the distal convoluted tubule, compared with the 285 mOsm/kg of H₂O in plasma. This allows for excretion of free water from the body. For this reason, it is often called the *diluting segment*.

The thick segment of the loop of Henle begins in the ascending limb where the epithelial cells become thickened. The beginning of the thick ascending limb marks the border between the outer and inner medulla; thus, the thick ascending limb is found only in the cortex and outer medulla. As with the thin ascending limb, this segment is relatively impermeable to

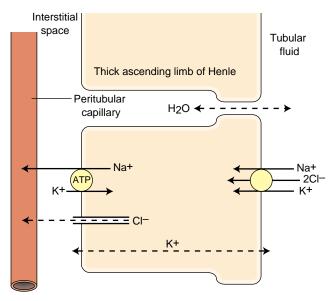

■ FIGURE 22-9 ■ Summary of movements of ions, urea, and water in the kidney during production of a maximally concentrated urine (1200 mOsm/kg H₂O). *Solid arrows* indicate active transport; *dashed arrows* indicate passive transport. The heavy outlining along the ascending limb of Henle's loop indicates decreased water permeability in that tubule segment. Note the osmotic gradient in the medulla from the outer to the inner medulla. (Modified from Rhoades R.A., Tanner G.A. [1996]. *Medical physiology* [p. 441]. Boston: Little, Brown)

408 Unit Six: Alterations in the Urinary System

water. The epithelium of the thick segment has a Na⁺-K⁺-2Cl⁻ cotransport system that moves these ions out of the urine filtrate into the surrounding interstitium and peritubular capillaries (Fig. 22-10). Approximately 20% to 25% of the filtered load of sodium, potassium, and chloride is reabsorbed in the thick loop of Henle. This transport system is selectively blocked by diuretic agents known as *loop diuretics*. The Na⁺-K⁺-2Cl⁻ cotransport system also provides the electrochemical gradient needed for the passive reabsorption of the divalent magnesium and calcium ions. Thus, the inhibition of sodium transport in the thick loop of Henle by the loop diuretics causes an increase in the urinary excretion of these divalent ions in addition to sodium chloride.

In approximately one fifth of the juxtamedullary nephrons, the loops of Henle and special hairpin-shaped capillaries called the *vasa recta* descend into the medullary portion of the kidney. A countercurrent mechanism controls water and solute movement so that water is kept out of the area surrounding the tubule and sodium and urea are retained (see Fig. 22-9). The term countercurrent refers to a flow of fluids in opposite directions in adjacent structures. In this case, there is an exchange of solutes between the adjacent descending and ascending loops of Henle and between the ascending and descending sections of the vasa recta. Because of these exchange processes, a high concentration of osmotically active particles (approximately 1200 mOsm/kg of H_2O) collects in the interstitium of the kidney medulla. The presence of these osmotically active particles in the interstitium surrounding the medullary collecting tubules facilitates the antidiuretic hormone (ADH)-mediated reabsorption of water.

Distal Convoluted Tubule. Like the thick ascending loop of Henle, the distal convoluted tubule is relatively impermeable to water, and reabsorption of sodium chloride from this segment further dilutes the tubular fluid. Sodium reabsorption occurs through a sodium and chloride cotransport mechanism. Approximately 10% of filtered sodium chloride is reabsorbed

■ **FIGURE 22-10** Sodium, chloride, and potassium reabsorption in the thick segment of the loop of Henle.

in this section of the tubule. Unlike the thick ascending loop of Henle, neither calcium nor magnesium is passively absorbed in this segment of the tubule. Instead, calcium ions are actively reabsorbed in a process that is largely regulated by parathyroid hormone and possibly by vitamin D. The thiazide diuretics exert their action by inhibiting sodium chloride reabsorption in this segment of the renal tubules.

Distal Tubule and Cortical Collecting Tubule. The late distal tubule and the cortical collecting tubule constitute the site where aldosterone exerts its action on sodium and potassium reabsorption. Although responsible for only 2% to 5% of so-dium chloride reabsorption, this site is largely responsible for determining the final sodium concentration of the urine. The late distal tubule with the cortical collecting tubule also is the major site for regulation of potassium excretion by the kidney. When the body is confronted with a potassium excess, as occurs with a diet high in potassium content, the amount of potassium secreted at this site may exceed the amount filtered in the glomerulus.

The mechanism for sodium reabsorption and potassium secretion by this section of the kidney is distinct from other tubular segments. This tubular segment is composed of two types of cells, the *intercalated cells*, where potassium is reabsorbed and hydrogen is secreted, and the *principal cells*, where aldosterone exerts its action. The secretion of hydrogen ions into the tubular fluid by the intercalated cells is accompanied by the reabsorption of bicarbonate ions. The intercalated cells can also reabsorb potassium ions. The principal cells reabsorb sodium and facilitate the movement of potassium into the urine filtrate. Under the influence of aldosterone, sodium moves from the urine filtrate into principal cells; from there it moves into the surrounding interstitial fluid and peritubular capillaries. Potassium moves from the peritubular capillaries into the principal cells and then into the urine filtrate.

Medullary Collecting Duct. The epithelium of the inner medullary collecting duct is well designed to resist extreme changes in the osmotic or pH characteristics of tubular fluid, and it is here that the urine becomes highly concentrated, highly diluted, highly alkaline, or highly acidic. During periods of water excess or dehydration, the kidneys play a major role in maintaining water balance.

ADH exerts its effect in the medullary collecting ducts. ADH maintains extracellular volume by returning water to the vascular compartment and leads to the production of a concentrated urine by removing water from the tubular filtrate. Osmoreceptors in the hypothalamus sense the increase in osmolality of extracellular fluids and stimulate the release of ADH from the posterior pituitary gland (see Chapter 6). The permeability of the collecting ducts to water is determined mainly by the concentration of ADH. In exerting its effect, ADH, also known as vasopressin, binds to vasopressin receptors on the blood side of the tubular cells. Binding of ADH to the vasopressin receptors leads to the opening of water channels on the luminal side of the tubular cells, producing a marked increase in water permeability. After the permeability of the collecting tubules has been established, water moves out of the tubular lumen and into the hyperosmotic interstitium of the medullary area, where it enters the peritubular capillaries for return to the vascular system. In the absence of ADH, the water channels are closed, the tubular cells lose their water permeability, and a dilute urine is formed.

Regulation of Renal Blood Flow

In the adult, the kidneys are perfused with 1000 to 1300 mL of blood per minute, or 20% to 25% of the cardiac output. This large blood flow is mainly needed to ensure a sufficient GFR for the removal of waste products from the blood, rather than for the metabolic needs of the kidney. Feedback mechanisms intrinsic to the kidney normally keep blood flow and GFR constant despite changes in arterial blood pressure.

Neural and Humoral Control Mechanisms

The kidney is richly innervated by the sympathetic nervous system. Increased sympathetic activity causes constriction of the afferent and efferent arterioles and thus a decrease in renal blood flow. Intense sympathetic stimulation such as occurs in shock and trauma can produce marked decreases in renal blood flow and GFR, even to the extent of causing blood flow to cease altogether.

Several humoral substances, including angiotensin II, ADH, and endothelins, produce vasoconstriction of renal vessels. The endothelins are a group of peptides released from damaged endothelial cells in the kidney and other tissues. Although not thought to be important regulators of renal blood flow during everyday activities, endothelin I may play a role in reduction of blood flow in conditions such as postischemic acute renal failure (see Chapter 24).

Other substances such as dopamine, nitric oxide, and prostaglandins (*i.e.*, E_2 and I_2) produce vasodilation. Nitric oxide, a vasodilator produced by the vascular endothelium, appears to be important in preventing excessive vasoconstriction of renal blood vessels and allowing normal excretion of sodium and water. Prostaglandins are a group of mediators of cell function that are produced locally and exert their effects locally. Although prostaglandins do not appear to be of major importance in regulating renal blood flow and GFR under normal conditions, they may protect the kidneys against the vasoconstricting effects of sympathetic stimulation and angiotensin II. Salicylates and the nonsteroidal antiinflammatory drugs that inhibit prostaglandin synthesis may cause reduction in renal blood flow and GFR under certain conditions.

Autoregulation

The constancy of renal blood flow is maintained by a process called autoregulation (see Chapter 14). Normally, autoregulation of blood flow is designed to maintain blood flow at a level consistent with the metabolic needs of the tissues. In the kidney, autoregulation of blood flow also must allow for precise regulation of water and solute secretion. For autoregulation to occur, the resistance to blood flow through the kidneys must be varied in direct proportion to the arterial pressure. The exact mechanisms responsible for the intrarenal regulation of blood flow are unclear. One of the proposed mechanisms is a direct effect on vascular smooth muscle that causes the blood vessels to relax when there is an increase in blood pressure, and to constrict when there is a decrease in pressure. A second proposed mechanism is the feedback regulation exerted by the juxtaglomerular complex.

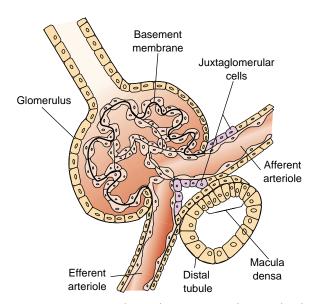

The Juxtaglomerular Complex. The juxtaglomerular complex is thought to represent a feedback control system that links changes in the GFR with renal blood flow. The juxtaglomerular complex is located at the site where the distal tubule extends back to the glomerulus and then passes between the afferent and efferent arteriole (Fig. 22-11). The distal tubular site that is nearest the glomerulus is characterized by densely nucleated cells called the macula densa.

In the adjacent afferent arteriole, the smooth muscle cells of the media are modified as special secretory cells called juxtaglomerular cells. These cells contain granules of inactive renin, an enzyme that functions in the conversion of angiotensinogen to angiotensin. Renin functions by means of angiotensin II to produce vasoconstriction of the efferent arteriole as a means of preventing serious decreases in the glomerular filtration rate (see Chapter 16). Angiotensin II also increases sodium reabsorption indirectly by stimulating aldosterone secretion from the adrenal gland and directly by increasing sodium reabsorption by the proximal tubule cells.

Because of its location between the afferent and efferent arteriole, the juxtaglomerular complex is thought to play an essential feedback role in linking the level of arterial blood pressure and renal blood flow to the GFR and the composition of the distal tubular fluid. The juxtaglomerular complex monitors the systemic blood pressure by sensing the stretch of the afferent arteriole, and it monitors the concentration of sodium chloride in the tubular filtrate as it passes through the macula densa. This information is then used in determining how much renin should be released to keep the arterial blood pressure in its normal range and maintain a relatively constant GFR.

Elimination Functions of the Kidney

The functions of the kidney focus on elimination of water, waste products, excess electrolytes, and unwanted substances from the blood. Blood tests can provide valuable information

■ FIGURE 22-11 ■ Juxtaglomerular apparatus, showing the close contact of the distal tubule with the afferent arteriole, the macula densa, and the juxtaglomerular cells.

about the kidneys' ability to remove metabolic wastes from the blood and maintain normal electrolyte and pH composition of the blood. As renal function declines, serum levels of substances such urea, creatinine, phosphate, and potassium increase. The effect of renal failure on the concentration of serum electrolytes and metabolic end products is discussed in Chapter 24.

Renal Clearance

Renal clearance is the volume of plasma that is completely cleared each minute of any substance that finds its way into the urine. It is determined by the ability of the substance to be filtered in the glomeruli and the capacity of the renal tubules to reabsorb or secrete the substance. Every substance has its own clearance rate, the units of which are expressed as the volume of plasma that is cleared per unit time. It can be determined by measuring the amount of a substance that is excreted in the urine (*i.e.*, urine concentration × urine flow rate in milliliters per minute) and dividing by its plasma concentration. Inulin, a large polysaccharide, is freely filtered in the glomeruli and neither reabsorbed nor secreted by the tubular cells. After intravenous injection, the amount that appears in the urine is equal to the amount that is filtered in the glomeruli (i.e., the clearance rate is equal to the GFR). Because of these properties, inulin can be used as a laboratory measure of the GFR.

Creatinine is a product of creatine metabolism in muscles; its formation and release are relatively constant and proportional to the amount of muscle mass present. Creatinine is freely filtered in the glomeruli, is not reabsorbed from the tubules into the blood, and is only minimally secreted into the tubules from the blood; therefore, its serum values depend closely on the GFR. Serum creatinine levels are often used as a measure of renal function. A normal serum creatinine level usually indicates normal renal function.

Some substances, such as urea, are freely filtered in the glomeruli, but the volume that is cleared from the plasma is less than the GFR, indicating that at least some of the substance is being reabsorbed. At normal plasma levels, glucose has a clearance of zero because it is reabsorbed in the tubules and none appears in the urine.

Regulation of Sodium and Potassium Elimination

Elimination of sodium and potassium is regulated by the GFR and by humoral agents that control reabsorption. Aldosterone functions in the regulation of sodium and potassium elimination. Atrial natriuretic peptide (ANP) contributes to the regulation of sodium elimination.

Aldosterone. Sodium reabsorption in the distal tubule and collecting duct is highly variable and depends on the presence of aldosterone, a hormone secreted by the adrenal gland. In the presence of aldosterone, almost all the sodium in the distal tubular fluid is reabsorbed, and the urine essentially becomes sodium free. In the absence of aldosterone, virtually no sodium is reabsorbed from the distal tubule. The remarkable ability of the distal tubular and collecting duct cells to alter sodium reabsorption in relation to changes in aldosterone allows the kidneys to excrete urine with sodium levels that range from a few tenths of a gram to 40 g per day. Like sodium, potassium is reabsorbed from and secreted into the tubular fluid. The se-

cretion of potassium into the tubular fluid occurs in the distal tubule and, like that of sodium, is regulated by aldosterone. Only approximately 70 mEq of potassium is delivered to the distal tubule each day, but the average person consumes this much and more potassium in the diet. Excess potassium that is not filtered in the glomerulus and delivered to the collecting tubule therefore must be secreted (*i.e.*, transported from the blood) into the tubular fluid for elimination from the body. In the absence of aldosterone (as in Addison's disease; see Chapter 31), potassium secretion becomes minimal. In these circumstances, potassium reabsorption exceeds secretion, and blood levels of potassium increase.

Atrial Natriuretic Peptide. Atrial natriuretic peptide, discovered in 1981, is a hormone believed to have an important role in salt and water excretion by the kidney. It is synthesized in muscle cells of the atria of the heart and released when the atria are stretched. The actions of ANP include vasodilation of the afferent and efferent arterioles, which results in an increase in renal blood flow and glomerular filtration rate. ANP also inhibits sodium reabsorption from the collecting tubules through its inhibition of aldosterone secretion and through direct action on the tubular cells. It also inhibits ADH release from the posterior pituitary gland, thereby increasing excretion of water by the kidneys. ANP also has vasodilator properties. Whether these effects are sufficient to produce long-term changes in blood pressure is uncertain.

Regulation of pH

The kidneys regulate body pH by conserving base bicarbonate (HCO_3^{-}) and eliminating hydrogen ions (H^+) . Neither the blood buffer systems nor the respiratory control mechanisms for carbon dioxide elimination can eliminate H⁺ from the body. This is accomplished by the kidneys. The average North American diet results in the liberation of 40 to 80 mmol of H+ each day. Virtually all the H⁺ excreted in the urine is secreted into the tubular fluid by means of tubular secretory mechanisms. The lowest tubular fluid pH that can be achieved is 4.4 to 4.5. The ability of the kidneys to excrete H⁺ depends on buffers in the urine that combine with the H⁺. The three major urine buffers are HCO_3^- , phosphate (HPO₄⁻), and ammonia (NH_3) . The HCO₃⁻ ions, which are present in the urine filtrate, combine with H⁺ ions that have been secreted into the tubular fluid; this results in the formation of carbon dioxide and water. The carbon dioxide is then absorbed into the tubular cells, and bicarbonate is regenerated. The HPO_4^- ion is a metabolic end product that is filtered into the tubular fluid; it combines with a secreted H⁺ ion and is not reabsorbed. Ammonia is synthesized in tubular cells by deamination of the amino acid glutamine; it diffuses into the tubular fluid and combines with the H⁺ ion. An important aspect of this buffer system is that the deamination process increases when the body's H⁺ ion concentration remains elevated for 1 to 2 days. These mechanisms for pH regulation are described more fully in Chapter 6.

pH-Dependent Elimination of Organic Ions

The proximal tubule actively secretes large amounts of different organic anions. Foreign anions (*e.g.*, salicylates, penicillin) and endogenously produced anions (*e.g.*, bile acids, uric acid) are actively secreted into the tubular fluid. Most of the anions that are secreted use the same transport system, allowing the kidneys to rid the body of many different drugs and environmental agents. Because the same transport system is shared by different anions, there is competition for transport such that elevated levels of one substance tend to inhibit the secretion of other anions. The proximal tubules also possess an active transport system for organic cations that is analogous to that for organic ions.

Uric Acid Elimination

Uric acid is a product of purine metabolism (see Chapter 43). Excessively high blood levels (*i.e.*, hyperuricemia) can cause gout, and excessive levels in the urine can cause kidney stones. Uric acid is freely filtered in the glomerulus and is reabsorbed and secreted into the proximal tubules. Uric acid is one of the anions that uses the previously described anion transport system in the proximal tubule. Tubular reabsorption normally exceeds secretion, and the net effect is removal of uric acid from the filtrate. Although the rate of reabsorption exceeds secretion, the secretory process is homeostatically controlled to maintain a constant plasma level. Many persons with elevated uric acid levels.

Uric acid uses the same transport systems as other anions, such as aspirin, sulfinpyrazone, and probenecid. Small doses of aspirin compete with uric acid for secretion into the tubular fluid and reduce uric acid secretion, and large doses compete with uric acid for reabsorption and increase uric acid excretion in the urine. Because of its effect on uric acid secretion, aspirin is not recommended for treatment of gouty arthritis. Thiazide and loop diuretics (*i.e.*, furosemide and ethacrynic acid) also can cause hyperuricemia and gouty arthritis, presumably through a decrease in extracellular fluid volume and enhanced uric acid reabsorption.

Urea Elimination

Urea is an end product of protein metabolism. The normal adult produces 25 to 30 g/day; the quantity rises when a highprotein diet is consumed, when there is excessive tissue breakdown, or in the presence of gastrointestinal bleeding. With gastrointestinal bleeding, the blood proteins are broken down to form ammonia in the intestine; the ammonia is then absorbed into the portal circulation and converted to urea by the liver before being released into the bloodstream. The kidneys, in their role as regulators of blood urea nitrogen (BUN) levels, filter urea in the glomeruli and then reabsorb it in the tubules. This enables maintenance of a normal BUN, which is in the range of 8 to 20 mg/dL. During periods of dehydration, the blood volume and GFR drop, and BUN levels increase. The renal tubules are permeable to urea, which means that the longer the tubular fluid remains in the kidneys, the greater is the reabsorption of urea into the blood. Only small amounts of urea are reabsorbed into the blood when the GFR is high, but relatively large amounts of urea are returned to the blood when the GFR is reduced.

Drug Elimination

Many drugs are eliminated in the urine. These drugs are selectively filtered in the glomerulus and reabsorbed or secreted into the tubular fluid. Only drugs that are not bound to plasma proteins are filtered in the glomerulus and therefore able to be eliminated by the kidneys.

Many drugs are weak acids or weak bases and are present in the renal tubular fluid partly as water-soluble ions and partly as nonionized lipid-soluble molecules. The nonionized lipid-soluble form of a drug diffuses more readily through the lipid membrane of the tubule and then back into the bloodstream. The water-soluble ionized form remains in the urine filtrate. The ratio of ionized to nonionized drug depends on the pH of the urine. For example, aspirin is highly ionized in alkaline urine and in this form is rapidly excreted in the urine. Aspirin is largely nonionized in acid urine and is reabsorbed, rather than excreted. Alkaline or acid diuresis may be used to increase elimination of drugs in the urine, particularly in situations of drug overdose.

Endocrine Functions of the Kidney

In addition to their function in regulating body fluids and electrolytes, the kidneys function as an endocrine organ in that they produce chemical mediators that travel through the blood to distant sites where they exert their actions. The kidneys participate in control of blood pressure by way of the renin-angiotensin mechanism, in calcium metabolism by activating vitamin D, and in regulating red blood cell production through the synthesis of erythropoietin.

The Renin-Angiotensin-Aldosterone Mechanism

The renin-angiotensin-aldosterone mechanism plays an important part in the short-term and long-term regulation of blood pressure (see Chapter 16). Renin is synthesized and stored in the juxtaglomerular cells of the kidney. This enzyme is released in response to a decrease in renal blood flow or a change in the composition of the distal tubular fluid, or as the result of sympathetic nervous system stimulation. Renin itself has no direct effect on blood pressure. Rather, it acts enzymatically to convert a circulating plasma protein called angiotensinogen to angiotensin I. Angiotensin I, which has few vasoconstrictor properties, leaves the kidneys and enters the circulation; as it is circulated through the lungs, *angiotensinconverting enzyme* catalyzes the conversion of angiotensin I to angiotensin II. Angiotensin II is a potent vasoconstrictor, and it acts directly on the kidneys to decrease salt and water

KEY CONCEPTS

FUNCTIONS OF THE KIDNEY

- Long-term regulation of blood pressure is facilitated through the kidney's activation of the reninangiotensin system and regulation of sodium and water balance.
- The activation of vitamin D, which is important for intestinal absorption of calcium, occurs in the kidney.
- The kidney synthesizes erythropoietin, which stimulates bone marrow production of red blood cells.

excretion. Both mechanisms have relatively short periods of action. Angiotensin II also stimulates aldosterone secretion by the adrenal gland. Aldosterone acts on the distal tubule to increase sodium reabsorption and exerts a longer-term effect on the maintenance of blood pressure. Renin also functions by means of angiotensin II to produce constriction of the efferent arteriole as a means of preventing a serious decrease in glomerular filtration pressure.

Erythropoietin

Erythropoietin is a polypeptide hormone that regulates the differentiation of red blood cells in the bone marrow (see Chapter 13). Between 89% and 95% of erythropoietin is formed in the kidneys. The synthesis of erythropoietin is stimulated by tissue hypoxia, which may be brought about by anemia, residence at high altitudes, or impaired oxygenation of tissues caused by cardiac or pulmonary disease. Persons with endstage kidney disease often are anemic because of an inability of the kidneys to produce erythropoietin. This anemia usually is managed by the administration of epoetin-alfa, a synthetic form of erythropoietin produced through DNA technology, to stimulate erythropoiesis.

Vitamin D

Activation of vitamin D occurs in the kidneys. Vitamin D increases calcium absorption from the gastrointestinal tract and helps to regulate calcium deposition in bone. It also has a weak stimulatory effect on renal calcium absorption. Although vitamin D is not synthesized and released from an endocrine gland, it often is considered as a hormone because of its pathway of molecular activation and mechanism of action.

It exists in several forms: natural vitamin D (cholecalciferol), which results from ultraviolet irradiation of the skin, and synthetic vitamin D (ergocalciferol), which is derived from irradiation of ergosterol. The active form of vitamin D is 1,25-dihydroxycholecalciferol. Cholecalciferol and ergocalciferol must undergo chemical transformation to become active: first to 25-hydroxycholecalciferol in the liver and then to 1,25-dihydroxycholecalciferol in the kidneys. Persons with end-stage renal disease are unable to transform vitamin D to its active form and must rely on pharmacologic preparations of the active vitamin (calcitriol) for maintaining mineralization of their bones.

In summary, the kidneys perform excretory and endocrine functions. In the process of excreting wastes, the kidneys filter the blood and then selectively reabsorb those materials that are needed to maintain a stable internal environment. The kidneys rid the body of metabolic wastes, regulate fluid volume, regulate the concentration of electrolytes, assist in maintaining acid-base balance, aid in the regulation of blood pressure through the renin-angiotensinaldosterone mechanism and control of extracellular fluid volume, regulate red blood cell production through erythropoietin, and aid in calcium metabolism by activating vitamin D.

The kidneys selectively eliminate water, waste products, excess electrolytes, and other substances that are not needed to maintain the constancy of the internal environment. Renal clearance is the volume of plasma that is completely cleared each minute of any substance that finds its way into the urine. It is determined by the ability of the substance to be filtered in the glomeruli and the capacity of the renal tubules to reabsorb or secrete the substance. The GFR is the amount of filtrate that is formed each minute as blood moves through the glomeruli. It is regulated by the arterial blood pressure and renal blood flow in the normally functioning kidney. The juxtaglomerular complex is thought to represent a feedback control system that links changes in the GFR with renal blood flow.

In addition to their function in regulating body fluids and electrolytes, the kidneys function as an endocrine organ in that they produce chemical mediators that travel through the blood to distant sites where they exert their actions. The kidneys participate in control of blood pressure by way of the renin-angiotensin mechanism, in calcium metabolism by activating vitamin D, and in regulating red blood cell production through the synthesis of erythropoietin.

TESTS OF RENAL FUNCTION

The functions of the kidney are to filter the blood and selectively reabsorb those substances that are needed to maintain the constancy of body fluids and excrete metabolic wastes. Laboratory tests of the urine and blood can provide valuable information about kidney pathology and the adequacy of renal function.

Urine Tests

Urine is a clear, amber-colored fluid that is approximately 95% water and 5% dissolved solids. The kidneys normally produce approximately 1.5 L of urine each day. Normal urine contains metabolic wastes and few or no plasma proteins, blood cells, or glucose molecules.

Urine tests can be performed on a single urine specimen or on a 24-hour urine specimen. First-voided morning specimens are useful for qualitative protein and specific gravity testing. A freshly voided specimen is most reliable. Urine specimens that have been left standing may contain lysed red blood cells, disintegrating *casts*, and rapidly multiplying bacteria.

Casts are molds of the distal nephron lumen. A gel-like substance called *Tamm-Horsfall mucoprotein*, which is formed in the tubular epithelium, is the major protein constituent of urinary casts. Casts composed of this gel but devoid of cells are called *hyaline casts*. These casts develop when the protein concentration of the urine is high (as in nephrotic syndrome), urine osmolality is high, and urine pH is low. The inclusion of granules or cells in the matrix of the protein gel leads to the formation of various other types of casts.

Because of the glomerular capillary filtration barrier, less than 150 mg of protein is excreted in the urine during 24 hours in a healthy person. Qualitative and quantitative tests to determine urinary protein content are important tools to assess the extent of glomerular disease. pH-sensitive reagent strips are used to test for the presence of proteins, whereas immunoassay methods are used to test for microalbuminuria (30 to 300 mg albumin/24 hours).

The specific gravity (or osmolality) of urine varies with its concentration of solutes. Urine specific gravity provides a valuable index of the hydration status and functional ability of the kidneys. Healthy kidneys can produce a concentrated urine with a specific gravity of 1.030 to 1.040. During periods of marked hydration, the specific gravity can approach 1.000. With the loss of nephrons and diminished renal function, there is a loss of renal concentrating ability, and the urine specific gravity may fall to levels of 1.006 to 1.010 (usual range is 1.010 to 1.025 with normal fluid intake). These low levels are particularly significant if they occur during periods that follow a decrease in water intake (e.g., during the first urine specimen on arising in the morning). The ability to concentrate urine also depends on the availability of and renal response to ADH. The urine specific gravity is decreased when ADH levels are decreased, such as in diabetes insipidus, and it is increased when ADH levels are inappropriately elevated, such as in the syndrome of inappropriate ADH.

Glomerular Filtration Rate

The GFR provides a gauge of renal function. It can be measured clinically by collecting timed samples of blood and urine. *Creatinine*, a product of creatine metabolism by the muscle, is filtered by the kidneys but not reabsorbed in the renal tubule. Creatinine levels in the blood and urine can be used to measure GFR. The clearance rate for creatinine is the amount that is completely cleared by the kidneys in 1 minute. The formula is expressed as C = UV/P, in which C is the clearance rate (mL/minute), U is the urine concentration (mg/dL), V is the urine volume excreted (mL/minute or 24 hours), and P is plasma concentration (mg/dL).

Normal creatinine clearance is 115 to 125 mL/minute. This value is corrected for body surface area, which reflects the muscle mass where creatinine metabolism takes place. The test may be done on a 24-hour basis, with blood being drawn when the urine collection is completed. In another method, two 1-hour urine specimens are collected, and a blood sample is drawn in between.

Blood Tests

Blood tests can provide valuable information about the kidneys' ability to remove metabolic wastes from the blood and maintain normal electrolyte and pH composition of the blood. Normal blood values are listed in Table 22-1. Serum levels of potassium, phosphate, BUN, and creatinine increase in renal failure. Serum pH, calcium, and bicarbonate levels decrease in renal failure. The effect of renal failure on the concentration of serum electrolytes and metabolic end products is discussed in Chapter 24.

Serum Creatinine

Serum creatinine levels reflect the glomerular filtration rate. Because these measurements are easily obtained and relatively inexpensive, they often are used as a screening measure of renal function. Creatinine is a product of creatine metabolism in muscles; its formation and release are relatively constant and proportional to the amount of muscle mass present. Creatinine is freely filtered in the glomeruli, is not reabsorbed from the tubules into the blood, and is only minimally secreted into the

TABLE 22-1	Normal Blood			
Chemistry Levels				
Substance	Normal Value*			
Blood urea nitroge Creatinine	en 8.0–20.0 mg/dL (2.9–7.1 mmol/L) 0.6–1.2 mg/dL (50–100 μmol/L)			
Sodium	135–145 mEq/L (135–148 mmol/L)			
Potassium	3.5–5 mEq/L (3.5–5 mmol/L)			
(CO ₂ content)				
Phosphate	2.5–4.5 mg/dL (0.77–1.45 mmol/L)			
Uric acid pH	1.4–7.4 mg/dL (0.154–0.42 mmol/L) 7.35–7.45			
Sodium Chloride Potassium Carbon dioxide (CO ₂ content) Calcium Phosphate Uric acid	135–145 mEq/L (135–148 mmol/L) 98–106 mEq/L (98–106 mmol/L) 3.5–5 mEq/L (3.5–5 mmol/L) 24–29 mEq/L (24–29 mmol/L) 8.5–10.5 mg/dL (2.1–2.6 mmol/L) 2.5–4.5 mg/dL (0.77–1.45 mmol/L) 1.4–7.4 mg/dL (0.154–0.42 mmol/L)			

*Values may vary among laboratories, depending on the method of analysis used.

tubules from the blood; therefore, its blood values depend closely on the GFR.

The normal creatinine value is approximately 0.6 mg/dL of blood for a woman with a small frame, approximately 1.0 mg/dL of blood for a normal adult man, and approximately 1.2 mg/dL of blood for a muscular man. There is an age-related decline in creatinine clearance in many elderly persons because muscle mass and the GFR decline with age (see Chapter 24). A normal serum creatinine level usually indicates normal renal function. In addition to its use in calculating the GFR, the serum creatinine level is used in estimating the functional capacity of the kidneys (Fig. 22-12). If the serum creatinine value doubles, the GFR—and renal function—probably has fallen to one half of its normal state. A rise in the serum creatinine level to three times its normal value suggests that there is a 75% loss of renal function, and with creatinine values of 10 mg/dL or more, it can be assumed that approximately 90% of renal function has been lost.

Blood Urea Nitrogen

Urea is formed in the liver as a by-product of protein metabolism and is eliminated entirely by the kidneys. Therefore,

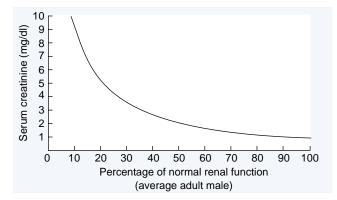

FIGURE 22-12 Relation between the percentage of renal function and serum creatinine levels.

414 Unit Six: Alterations in the Urinary System

BUN is related to the GFR but, unlike creatinine, also is influenced by protein intake, gastrointestinal bleeding, and hydration status. Increased protein intake and gastrointestinal bleeding increase urea by means of protein metabolism. In gastrointestinal bleeding, the blood is broken down by the intestinal flora, and the nitrogenous waste is absorbed into the portal vein and transported to the liver, where it is converted to urea. During dehydration, elevated BUN levels result from increased concentration. Approximately two thirds of renal function must be lost before a significant rise in the BUN level occurs.

The BUN is less specific for renal insufficiency than creatinine, but the *BUN–creatinine ratio* may provide useful diagnostic information. The ratio normally is approximately 10:1. Ratios greater than 15:1 represent prerenal conditions, such as congestive heart failure and upper gastrointestinal tract bleeding, that produce an increase in BUN but not in creatinine. A ratio of less than 10:1 occurs in persons with liver disease and in those who receive a low-protein diet or chronic dialysis because BUN is more readily dialyzable than creatinine.

In summary, urinalysis and blood tests that measure levels of by-products of metabolism and electrolytes provide information about renal function. Serum creatinine reflects the glomerular filtration rate and can be used as an estimate of renal function. Measurements of BUN, which is formed in liver as a by-product of protein metabolism and eliminated almost entirely by the kidney, are also a measure of renal function.

REVIEW QUESTIONS

Describe the location and gross structure of the kidney and explain why kidney injury does not produce peritonitis.

Explain the structure and function of the capillary structures of the nephron (glomerulus and peritubular capillaries) and the tubular components of the nephron in terms of filtering and reabsorbing nutrients, eliminating waste products, and maintaining the acid-base and electrolyte composition of the extracellular fluid.

Describe the kidney blood supply and mechanisms for regulating blood flow.

Use the concept of the countercurrent mechanism and the actions of the antidiuretic hormone to explain how the kidney produces a concentrated or dilute urine.

Characterize the function of the juxtaglomerular complex.

Explain the endocrine functions of the kidney.

Use the concepts of glomerular filtration, tubular reabsorption, and tubular secretion to explain why serum creatinine is a better indicator of the glomerular filtration rate than blood urea nitrogen.

CHAPTER

2

Tubulointerstitial Disorders Pyelonephritis Drug-Related Nephropathies Neoplasms Wilms' Tumor Renal Cell Carcinoma

ore than 20 million North Americans have diseases of the kidneys and urinary tract. Each year, more than million people receive diagnoses of acute urinary tract disorders, and approximately 50,000 die of these diseases.¹

The kidneys are subject to many of the same types of disorders that affect other body structures, including developmental defects, infections, altered immune responses, and neoplasms. The kidneys filter blood from all parts of the body, and although many forms of kidney disease originate in the kidneys, others develop secondary to disorders such as hypertension, diabetes mellitus, and systemic lupus erythematosus (SLE).

CONGENITAL AND HEREDITARY DISORDERS OF THE KIDNEY

Some abnormality of the kidneys and ureters occurs in approximately 3% to 4% of newborn infants.² Anomalies in shape and position are the most common. Less common are disorders involving a decrease in renal mass (*e.g.*, agenesis, hypogenesis) or a change in renal structure (*e.g.*, renal cysts). Many fetal anomalies can be detected before birth by ultrasonography. In the normal fetus, the kidneys can be visualized as early as 12 weeks.

Agenesis and Hypoplasia

The kidneys begin to develop early in the fifth week of gestation and start to function approximately 3 weeks later. Formation of urine is thought to begin in the 9th to 12th weeks of gestation; by the 32nd week, fetal production of urine reaches approximately 28 mL/hour.³ Urine is the main constituent of amniotic fluid. The relative amount of amniotic fluid can provide information about the status of fetal renal function.

416 Unit Six: Alterations in the Urinary System

The term *dysgenesis* refers to a failure of an organ to develop normally. *Agenesis* is the complete failure of an organ to develop. Total agenesis of both kidneys is incompatible with extrauterine life. Infants are stillborn or die shortly after birth of pulmonary hypoplasia. Newborns with renal agenesis often have characteristic facial features, termed *Potter's syndrome*.⁴ The eyes are widely separated and have epicanthic folds, the ears are low set, the nose is broad and flat, the chin is receding, and limb defects often are present.^{4,5} Other causes of neonatal renal failure with the Potter phenotype include cystic renal dysplasia, obstructive uropathy, and autosomal recessive polycystic disease. Unilateral agenesis is an uncommon anomaly that is compatible with life if no other abnormality is present. The opposite kidney usually is enlarged as a result of compensatory hypertrophy.

In *renal hypoplasia*, the kidneys do not develop to normal size. Like agenesis, hypoplasia more commonly affects only one kidney. When both kidneys are affected, there is progressive development of renal failure. It has been suggested that true hypoplasia is extremely rare; most cases probably represent acquired scarring caused by vascular, infectious, or other kidney diseases, rather than an underlying developmental failure.^{5,6}

In pregnancies that involve infants with nonfunctional kidneys or outflow obstruction of the kidneys, the amount of amniotic fluid is small—a condition called *oligohydramnios*. The cause of fetal death in these infants is thought to be cord compression caused by the oligohydramnios.²

Disorders of Kidney Position and Form

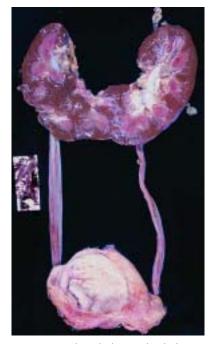

The development of the kidneys during embryonic life can result in kidneys that lie outside their normal position, usually just above the pelvic brim or within the pelvis. Because of the abnormal position, kinking of the ureters and obstruction of urine flow may occur.

One of the most common alterations in kidney form is an abnormality called a *horseshoe kidney*. This abnormality occurs in approximately 1 in every 500 to 1000 persons.^{4,5} In this disorder, the upper or lower poles of the two kidneys are fused, producing a horseshoe-shape structure that is continuous along the midline of the body anterior to the great vessels. Most horseshoe kidneys are fused at the lower pole⁶ (Fig. 23-1). The condition usually does not cause problems unless there is an associated defect in the renal pelvis or other urinary structures that obstruct urine flow.

Polycystic Kidney Disease

Renal cysts are fluid-filled sacs or segments of a dilated nephron. The cysts may be single or multiple and can vary in size from microscopic to several centimeters in diameter. The most common form of renal cystic disease is polycystic kidney disease, which is the result of a hereditary trait. It is one of the most common hereditary diseases in the United States, affecting more than 600,000 Americans.¹ There are two types of inherited polycystic disease: autosomal recessive and autosomal dominant.

Autosomal recessive polycystic kidney disease, which is present at birth, is rare compared with the adult variety.^{5,6} The disorder is inherited as a recessive trait, meaning that both parents are carriers of the gene and that there is a one in four chance of

■ FIGURE 23-1 ■ Horseshoe kidney. The kidneys are fused at the lower poles. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 865]. Philadelphia: Lippincott Williams & Wilkins)

the parents having another child with the disorder. Because the condition is present at birth, it formerly was called *infantile* or *childhood polycystic disease*. The condition is bilateral, and significant renal dysfunction usually is present, accompanied by variable degrees of liver fibrosis and portal hypertension. The disorder can be diagnosed by ultrasonography. There is no known treatment for the disease. Approximately 75% of infants die during the perinatal period, often because the large kidneys compromise expansion of the lungs.⁶ Some children may present with less severe kidney problems and more severe liver disease.

Autosomal dominant polycystic kidney disease, also called adult polycystic kidney disease, affects children and adults in the prime of life and accounts for 10% of persons who require treatment for end-stage renal disease. This disorder is transmitted as an autosomal dominant trait. There is considerable variability in gene expression, and many affected persons do not have clinical symptoms, or if they do, the symptoms occur later in life.

Three mutant genes have been implicated in the disorder.⁵⁻⁷ A polycystic kidney disease gene called PKD1, located on chromosome 16, is responsible for approximately 85% of cases. It encodes a large membrane protein called *polycystin 1* that has domains similar to proteins involved in cell-to-cell and cell-toextracellular matrix interactions.^{5,7} A second gene, called *PKD2*, which is located on chromosome 4, is responsible for a milder form of the disease. It encodes for a product called *polycystin 2*, which is an integral membrane protein that is similar to certain calcium and sodium channel proteins as well as to a portion of polycystin 1. A third gene, *PKD3*, is responsible for a minority of cases and has yet to be mapped.

How the genetic defects in the polycystin proteins cause cyst formation is largely speculative. It is thought that the membrane proteins may play a role in extracellular matrix interactions that are important in tubular epithelial cell growth and differentiation. In addition, cyst fluids have been shown to harbor mediators that enhance fluid secretion and induce inflammation, resulting in further enlargement of the cysts and the interstitial fibrosis that is characteristic of progressive polycystic kidney disease.

The disease is characterized by tubular dilatation with cyst formation interspersed between normally functioning nephrons. Fluid collects in the cyst while it is still part of the tubular lumen, or it is secreted into the cyst after it has separated from the tubule. As the fluid accumulates, the cysts gradually increase in size, with some becoming as large as 5 cm in diameter. The kidneys of persons with polycystic kidney disease eventually become enlarged because of the presence of multiple cysts (Fig. 23-2). Cysts also may be found in the liver and, less commonly, the pancreas and spleen. Mitral valve prolapse and other valvular heart diseases occur in 20% to 25% of persons, but are largely asymptomatic. Most persons with polycystic disease also have colonic diverticula. One of the most devastating extrarenal manifestations is a weakness in the walls of the cerebral arteries that can lead to aneurysm formation. Approximately 20% of persons with polycystic kidney disease have an associated aneurysm, and subarachnoid hemorrhage is a frequent cause of death.6

The manifestations of polycystic kidney disease include pain from the enlarging cysts that may reach debilitating levels, episodes of gross hematuria from bleeding into a cyst, infected cysts from ascending urinary tract infections, and hypertension resulting from compression of intrarenal blood vessels with activation of the renin-angiotensin mechanism.8 Persons with polycystic kidney disease also are at risk for the development of renal cell carcinoma. The progress of the disease is slow, and end-stage renal failure is uncommon before 40 years of age.

The diagnosis of autosomal polycystic kidney disease can be made by radiologic studies, ultrasonography, and computed tomography (CT). Ultrasonography is particularly useful as a screening test for the disease.

The treatment of polycystic kidney disease is largely supportive. Control of hypertension and prevention of ascending urinary tract infections are important. The cysts may be surgically decompressed in persons with severe, disabling pain.⁸ The procedure permits removal of fluid from the cyst. Although affording pain relief, the procedure does not appear to alter the course of the disease.8 Dialysis and kidney transplantation are reserved for those who have end-stage renal disease.

In summary, approximately 10% of infants are born with potentially significant malformations of the urinary system. These abnormalities can range from bilateral renal agenesis, which is incompatible with life, to hypogenesis of one kidney, which usually causes no problems unless the function of the remaining kidney is impaired. The developmental process can result in kidneys that lie outside their normal position. Because of the abnormal position, kinking of the ureters and obstruction of urine flow can occur.

Renal cystic disease is a condition in which there is dilatation of tubular structures with cyst formation. Polycystic kidney disease is an inherited form of renal cystic disease; it can also be inherited as an autosomal recessive or an autosomal dominant trait. Autosomal recessive polycystic kidney disease is rare and usually presents as severe renal dysfunction during infancy. Autosomal dominant polycystic disease usually does not become symptomatic until later in life, often after 40 years of age.

FIGURE 23-2 Adult polycystic disease. The kidney is enlarged. and the parenchyma is almost entirely replaced by cysts of varying size. (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 867]. Philadelphia: Lippincott Williams & Wilkins)

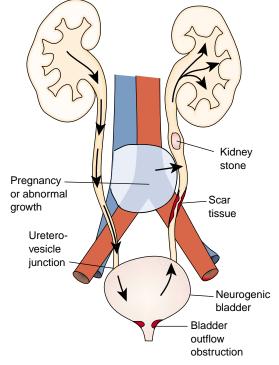

OBSTRUCTIVE DISORDERS

Urinary obstruction can occur in persons of any age and can involve any level of the urinary tract from the urethra to the renal pelvis (Fig. 23-3). The conditions that cause urinary tract obstruction include developmental defects, pregnancy, benign prostatic hyperplasia, tumors, and kidney stones. The causes of urinary tract obstructions are summarized in Table 23-1.

The two most damaging effects of urinary obstruction are stasis of urine, which predisposes to infection and stone formation, and development of backpressure, which interferes with renal blood flow, destroys kidney tissue, and predisposes to hydronephrosis. The destructive effects of urinary obstruction on kidney structures are determined by the degree (*i.e.*, partial vs. complete, unilateral vs. bilateral) and the duration of the obstruction.9

The manifestations of urinary obstruction depend on the site of obstruction, the cause, and the rapidity with which the condition developed. Most commonly, the person has pain, signs and symptoms of urinary tract infection, and manifestations of renal dysfunction, such as an impaired ability to concentrate urine. Changes in urine output may be misleading because output may be normal or even high in cases of partial obstruction.

418 Unit Six: Alterations in the Urinary System

■ FIGURE 23-3 ■ Locations and causes of urinary tract obstruction.

Pain, which often is the factor that causes a person to seek medical attention, is the result of distention of the bladder, collecting system, or renal capsule. Its severity is related most closely to the rate, rather than the degree, of distention. Pain most often occurs with acute obstruction, in which the distention of urinary structures is rapid. This is in contrast to chronic obstruction, in which distention is gradual and may not cause pain. Instead, gradual obstruction may produce only vague abdominal or back discomfort. When pain occurs, it is related to the site of obstruction. Obstruction of the renal pelvis or upper ureter causes pain and tenderness over the flank area. With

lower levels of obstruction, the pain may radiate to the testes in the male or the labia in the female. With partial obstruction, particularly of the ureteropelvic junction, pain may occur during periods of high fluid intake, when a high rate of urine flow causes an acute distention of the renal pelvis. Because of its visceral innervation, ureteral obstruction may produce reflex impairment of gastrointestinal tract peristalsis and motility with abdominal distention and, in severe cases, paralytic ileus.

Hypertension is an occasional complication of urinary tract obstruction. It is more common in cases of unilateral obstruction in which renin secretion is enhanced, probably secondary to impaired renal blood flow. In these circumstances, removal of the obstruction often leads to a reduction in blood pressure. When hypertension accompanies bilateral obstruction, renin levels usually are normal, and the elevated blood pressure probably is volume related. The relief of bilateral obstruction leads to a loss of volume and a decrease in blood pressure. In some cases, relieving the obstruction does not correct the hypertension.

Renal Calculi

The most common cause of upper urinary tract obstruction is urinary calculi. Although stones can form in any part of the urinary tract, most develop in the kidneys. Approximately 1 million North Americans are hospitalized each year with kidney stones, and an equal number are treated for stones without hospitalization.¹ Men are more frequently affected than women, with a ratio of $4:1.^{10}$

Kidney stones are crystalline structures made up of materials that the kidneys normally excrete in the urine. The etiology of urinary stone formation is complex, and not all aspects are well understood. It is thought to encompass a number of factors, including increases in blood and urinary levels of stone components and interactions among the components; anatomic changes in urinary tract structures; metabolic and endocrine influences; dietary and intestinal absorption factors; and urinary tract infections. To add to the mystery of stone formation is the fact that although both kidneys are exposed to the same urinary constituents, kidney stones tend to form in only one kidney. Three major theories are used to explain stone formation: the saturation theory, the matrix theory, and the inhibitor deficiency theory.^{11,12} One or more of these theories may apply to stone formation in the same person.

KEY CONCEPTS

KIDNEY STONES

- Kidney stones are crystalline structures that form from components of the urine.
- Stones require a nidus to form and a urinary environment that supports continued crystallization of stone components.
- Stone formation is influenced by the concentration of stone components in the urine, the ability of the stone components to complex and form stones, and the presence of substances that inhibit stone formation.

Kidney stones require a nidus, or nucleus, to form and a urinary environment that supports continued precipitation of stone components to grow. The *saturation theory* states that the risk of stone formation is increased when the urine is supersaturated with stone components (*e.g.*, calcium salts, uric acid, magnesium ammonium phosphate, cystine). Supersaturation depends on urinary pH, solute concentration, ionic strength, and complexation. The greater the concentration of two ions, the more likely they are to precipitate. Complexation influences the availability of specific ions. For example, sodium complexes with oxalate, decreasing its free ionic form and increasing the amount that is available to participate in stone formation.

The *matrix theory* proposes that organic materials, such as mucopolysaccharides derived from the epithelial cells that line the tubules, act as a nidus for stone formation. This theory is based on the observation that organic matrix materials can be found in all layers of kidney stones. It is not known whether the matrix material contributes to the initiation of stone formation or if the material is merely entrapped as the stone forms.

Kidney proteins inhibit all phases of crystallization. The *inhibitor theory* suggests that persons who have a deficiency of proteins that inhibit stone formation in their urine are at increased risk for stone formation. Kidney cells produce at least three proteins that are thought to slow the rate of calcium oxalate crystallization: nephrocalcin, Tamm-Horsfall mucoprotein, and uropontin.^{11,13} Nephrocalcin inhibits nucleation, aggregation, and growth of calcium oxalate stones. *Tamm-Horsfall mucoprotein* is thought to exert a minor effect on crystal aggregation. Uropontin inhibits the growth of calcium oxalate crystals.

Urinary obstruction and stagnation of urine predisposes to infection. When present, urinary calculi serve as foreign bodies and contribute to the infection. Once established, the infection is difficult to treat. It often is caused by urea-splitting organisms (*e.g.*, *Proteus*, staphylococci) that increase ammonia production and cause the urine to become alkaline.⁹ Calcium salts precipitate more readily in stagnant alkaline urine; thus, urinary tract obstructions also predispose to stone formation.

Types of Stones

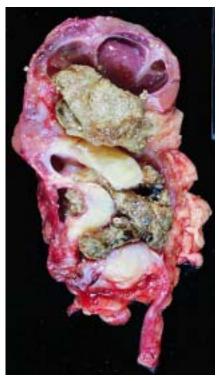

There are four basic types of kidney stones: calcium stones (*i.e.*, oxalate or phosphate), magnesium ammonium phosphate stones, uric acid stones, and cystine stones. The causes and treatment measures for each of these types of renal stones are described in Table 23-2.

Calcium Stones. Most kidney stones (70% to 80%) are calcium stones—calcium oxalate, calcium phosphate, or a combination of the two materials. Calcium stones usually are associated with increased concentrations of calcium in the blood and urine. Excessive bone resorption caused by immobility, bone disease, hyperparathyroidism, and renal tubular acidosis all are contributing conditions. High oxalate concentrations in the blood and urine predispose to formation of calcium oxalate stones. A recent addition to the spectrum of kidney stones are those seen in persons with human immunodeficiency virus (HIV) infection who are being treated with indinavir, a protease inhibitor. The calcium-containing calculi develop in as many as 6% of persons treated with the drug.⁹

Magnesium Ammonium Phosphate Stones. Magnesium ammonium phosphate stones, also called *struvite stones*, form only in alkaline urine and in the presence of bacteria that possess an enzyme called *urease*, which splits the urea in the urine into ammonia and carbon dioxide. The ammonia that is formed takes up a hydrogen ion to become an ammonium ion, increasing the pH of the urine so that it becomes more alkaline. Because phosphate levels are increased in alkaline urine and because magnesium always is present in the urine, struvite stones form. These stones enlarge as the bacterial count grows, and they can increase in size until they fill an entire renal pelvis (Fig. 23-4). Because of their shape, they often are called *staghorn stones*. Staghorn stones almost always are associated with

TABLE 23-2 Composition, Contributing Factors, and Treatment of Kidney Stones			
Type of Stone		Contributing Factors	Treatment

Uric acid (urate)		Formed in acid urine with pH of approximately 5.5 Gout High-purine diet	Increased fluid intake Allopurinol for hyperuricuria Alkalinization of urine
Cystine		Cystinuria (inherited disorder of amino acid metabolism)	Increased fluid intake Alkalinization of urine

420 Unit Six: Alterations in the Urinary System

■ FIGURE 23-4 ■ Staghorn calculi. The kidney shows hydronephrosis and stones that are casts of the dilated calyces. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 909]. Philadelphia: Lippincott Williams & Wilkins)

urinary tract infections and persistently alkaline urine. Because these stones act as a foreign body, treatment of the infection often is difficult. Struvite stones usually are too large to be passed and require lithotripsy or surgical removal.

Uric Acid Stones. Uric acid stones develop in conditions of gout and high concentrations of uric acid in the urine. Hyperuricosuria also may contribute to calcium stone formation by acting as a nucleus for calcium oxalate stone formation. Unlike radiopaque calcium stones, uric acid stones are not visible on x-ray films. Uric acid stones form most readily in urine with a pH of 5.1 to 5.9.¹¹ Thus, these stones can be treated by raising the urinary pH to 6 to 6.5 with potassium alkali salts.

Cystine Stones. Cystine stones are rare. They are seen in cystinuria, which results from a genetic defect in renal transport of cystine. These stones resemble struvite stones except that infection is unlikely to be present.

Manifestations

One of the major manifestations of kidney stones is pain. Depending on location, there are two types of pain associated with kidney stones: renal colic and noncolicky renal pain.⁹ *Renal colic* is the term used to describe the colicky pain that accompanies stretching of the collecting system or ureter. The symptoms of renal colic are caused by stones 1 to 5 mm in diameter that can move into the ureter and obstruct flow. Classic ureteral colic is manifested by acute, intermittent, and excruciating pain in the flank and upper outer quadrant of the abdomen on the affected side. The pain may radiate to the lower

abdominal quadrant, bladder area, perineum, or scrotum in the male. The skin may be cool and clammy, and nausea and vomiting are common. Noncolicky pain is caused by stones that produce distention of the renal calices or renal pelvis. The pain usually is a dull, deep ache in flank or back that can vary in intensity from mild to severe. The pain may be exaggerated by drinking large amounts of fluid.⁹

Diagnosis and Treatment

Persons with kidney stones often present with acute renal colic, and the diagnosis is based on symptomatology and diagnostic tests, which include urinalysis, abdominal radiographs, and excretory urography. Urinalysis provides information related to hematuria, infection, the presence of stone-forming crystals, and urine pH. At least 90% of stones are radiopaque and readily visible on a plain radiograph of the abdomen. Excretory urography uses an intravenously injected contrast medium that is filtered in the glomeruli to visualize the collecting system and the ureters of the kidneys. Retrograde urography, ultrasonography, and CT scanning also may be used.

Treatment of acute renal colic usually is supportive. Pain relief may be needed during acute phases of obstruction, and antibiotic therapy may be necessary to treat urinary infections. Most stones that are less than 5 mm in diameter pass spontaneously. All urine should be strained during an attack in the hope of retrieving the stone for chemical analysis and determination of stone type.

A major goal of treatment in persons who have passed kidney stones or have had them removed is to prevent their recurrence (see Table 23-2). Adequate fluid intake reduces the concentration of stone-forming crystals in the urine and needs to be encouraged. Depending on the type of stone that is formed, dietary changes, medications, or measures to change the pH of the urine may be used to alter the concentration of stone-forming elements in the urine.

In some cases, stone removal may be necessary. Several methods, including ureteroscopic removal and extracorporeal lithotripsy, are available for removing kidney stones. Ureteroscopic removal involves the passage of an instrument through the urethra into the bladder and then into the ureter. *Extracorporeal shock-wave lithotripsy* uses acoustic shock waves to break up the stones so they can be passed in the urine. All these procedures eliminate the need for an open surgical procedure. Open stone surgery may be required to remove large calculi or those that are resistant to other forms of removal.

Hydronephrosis

Hydronephrosis refers to urine-filled dilatation of the renal pelvis and calices, with accompanying atrophy of renal tissue, caused by obstruction of urine flow. The obstruction may be sudden or insidious and may occur at any level of the urinary tract. The most common causes are congenital disorders of the urethra or ureters, kidney stones, tumors that compress the urethra or ureters, prostatitis, inflammatory conditions of the urethra, and neurogenic bladder.

In situations of marked or complete obstruction, backpressure develops because of a combination of continued glomerular filtration and obstruction of urine flow. Depending on the degree of obstruction, pressure builds up, beginning at the site of obstruction and moving backward from the ureter or renal pelvis into the calices and collecting tubules. Typically, the most severe effects occur at the level of the papillae because these structures are subjected to the greatest pressure. Damage to the nephrons and other functional components of the kidney is caused by compression from increased intrapelvic pressure and ischemia from disturbances in blood flow.

The degree of hydronephrosis depends on the duration, degree, and site of obstruction. Bilateral hydronephrosis occurs only when the obstruction is below the level of the ureters. If the obstruction occurs at the level of the ureters or above, hydronephrosis is unilateral. Unfortunately, unilateral hydronephrosis may remain silent for long periods of time. Often the enlarged kidney is discovered on routine exam. If the obstruction is removed within a few weeks, return of function is possible. Prolonged or severe partial obstruction causes irreversible kidney damage. The kidney eventually is destroyed and appears as a thin-walled shell that is filled with fluid (Fig. 23-5).

In summary, obstruction of urine flow can occur at any level of the urinary tract. Among the causes of urinary tract obstruction are developmental defects, pregnancy, infection and inflammation, kidney stones, neurologic defects, and prostatic hypertrophy. Obstructive disorders produce stasis of urine, increasing the risk of infection and calculi formation and resulting in back pressure that is damaging to kidney structures.

Kidney stones are a major cause of upper urinary tract obstruction. There are four types of kidney stones: calcium (i.e., oxalate and phosphate) stones, which are associated with increased serum calcium levels; magnesium ammonium phosphate (i.e., struvite) stones, which are associated with urinary tract infections; uric acid stones, which are related to elevated uric acid levels; and cystine stones, which are seen in cystinuria. A major goal of treatment for persons who have passed kidney stones or have had them removed is to identify stone composition and prevent their recurrence. Treatment measures depend on stone type and include adequate fluid intake to prevent urine saturation, dietary modification to decrease intake of stone-forming constituents, treatment of urinary tract infections, measures to change urine pH, and the use of diuretics that decrease the calcium concentration of urine.

Hydronephrosis refers to dilation of the renal pelvis and calices, with atrophy of renal tissue, that is caused by obstruction to the outflow of urine. The obstruction may be sudden or insidious in onset and may occur at any level of the urinary tract.

URINARY TRACT INFECTIONS

Urinary tract infections (UTIs) are the second most common type of bacterial infections seen by health care providers (respiratory tract infections are first). UTIs can include several distinct entities, including asymptomatic bacteriuria, symptomatic infections, lower UTIs such as cystitis, and upper UTIs such as pyelonephritis. Because of their ability to cause renal damage, upper UTIs are considered more serious than lower UTIs.

■ FIGURE 23-5 ■ Hydronephrosis. Bilateral urinary tract obstruction has led to conspicuous dilatation of the ureters, pelves, and calyces. The kidney on the right shows severe cortical atrophy. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 910]. Philadelphia: Lippincott Williams & Wilkins)

Etiologic Factors

Most UTIs are caused by *Escherichia coli*. Other common pathogens include *Staphylococcus saprophyticus*, *Proteus mirabilis*, *Klebsiella pneumoniae*, and *Enterococcus* species.^{14–18} Bacteria can enter the kidneys either through the bloodstream or as an ascending infection from the lower urinary tract. Most infections are of the ascending type. Although the distal portion of the urethra often contains pathogens, the urine formed in the kidneys and found in the bladder normally is sterile or free of bacteria. This is because of the *washout phenomenon*, in which urine from the bladder normally washes bacteria out of the urethra. When a UTI occurs, the bacteria that have colonized the urethra, vagina, or perineal area often are responsible.

There is an increased risk of UTI in persons with urinary obstruction and reflux; in people with neurogenic disorders that impair bladder emptying; in women who are sexually active, especially if they use a diaphragm or spermicide for contraception; in postmenopausal women; in men with diseases of the prostate; and in elderly persons. Instrumentation and urinary catheterization are the most common predisposing factors for nosocomial UTIs.

KEY CONCEPTS

URINARY TRACT INFECTIONS

- Urinary tract infections involve both the lower and upper urinary tract structures.
- In lower urinary tract infections, the infecting pathogens tend to propagate in the urine and cause irritative voiding symptoms, often with minimal systemic signs of infection.
- Upper urinary tract infections tend to invade the tissues of the kidney pelvis, inciting an acute inflammatory response with marked systemic manifestations of infection.

Because certain people tend to be predisposed to the development of UTIs, considerable interest has been focused on host-agent interactions and factors such as urinary tract obstruction and reflux that increase the risk of UTI.

Host Defenses

In the development of a UTI, host defenses are matched against the virulence of the pathogen. The host defenses of the bladder have several components, including the washout phenomenon, in which bacteria are removed from the bladder and urethra during voiding; the protective mucin layer that lines the bladder and protects against bacterial invasion; and local immune responses. In the ureters, peristaltic movements facilitate the movement of urine from the renal pelvis through the ureters and into the bladder. Immune mechanisms, particularly secretory immunoglobulin A (IgA), appear to provide an important antibacterial defense. Phagocytic blood cells further assist in the removal of bacteria from the urinary tract.

There has been a growing appreciation of the protective function of the bladder's mucin layer.¹⁴ It is thought that the epithelial cells that line the bladder synthesize protective substances that subsequently become incorporated into the mucin layer that adheres to the bladder wall. One theory proposes that the mucin layer acts by binding water, which then constitutes a protective barrier between the bacteria and the bladder epithelium. Elderly and postmenopausal women produce less mucin than younger women, suggesting that estrogen may play a role in mucin production in women.

Pathogen Virulence

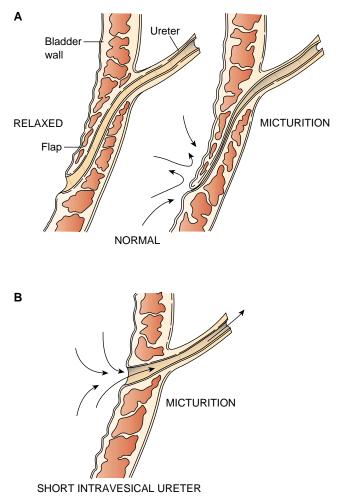

Investigations are focusing on the adherence properties of the bacteria that infect the urinary tract. These bacteria have fine protein filaments that help them adhere to receptors on the lining of urinary tract structures.^{14,15} These filaments are called *fimbriae* or *pili*. Among the factors that contribute to bacterial virulence, the type of fimbriae that the bacteria possess may be the most important. Bacteria with certain types of fimbriae are associated primarily with cystitis, and those with other types are associated with a high incidence of pyelonephritis. The bacteria that bind to carbohydrates that are specific to the surfaces of epithelial cells in this part of the urinary tract.

Obstruction and Reflux

Obstruction and reflux are important contributing factors in the development of UTIs. Any microorganisms that enter the bladder normally are washed out during voiding. When outflow is obstructed, urine remains in the bladder and acts as a medium for microbial growth; the microorganisms in the contaminated urine can then ascend along the ureters to infect the kidneys. The presence of residual urine correlates closely with bacteriuria and with its recurrence after treatment. Another aspect of bladder outflow obstruction and bladder distention is increased intravesicular pressure, which compresses blood vessels in the bladder wall, leading to a decrease in the mucosal defenses of the bladder.

In UTIs associated with stasis of urine flow, the obstruction may be anatomic or functional. Anatomic obstructions include urinary tract stones, prostatic hyperplasia, pregnancy, and malformations of the ureterovesical junction. Functional obstructions include neurogenic bladder, infrequent voiding, detrusor (bladder) muscle instability, and constipation. Reflux occurs when urine from the urethra moves into the bladder (*i.e.*, urethrovesical reflux) or from the bladder into the ureters (*i.e.*, vesicoureteral reflux). In women, *urethrovesical* reflux can occur during activities such as coughing or squatting, in which an increase in intra-abdominal pressure causes the urine to be squeezed into the urethra and then to flow back into the bladder as the pressure decreases. This also can happen when voiding is abruptly interrupted. Because the urethral orifice frequently is contaminated with bacteria, the reflux mechanism may cause bacteria to be drawn back into the bladder.

A second type of reflux mechanism, *vesicoureteral reflux*, occurs at the level of the bladder and ureter. Normally, the distal portion of the ureter courses between the muscle layer and the mucosal surface of the bladder wall, forming a flap. The flap is compressed against the bladder wall during micturition, preventing urine from being forced into the ureter (Fig. 23-6). In

■ FIGURE 23-6 ■ Anatomic features of the bladder and kidney in pyelonephritis caused by vesicoureteral reflux. Bladder. (A) In the normal bladder, the distal portion of the intravesical ureter courses between the mucosa and the muscularis of the bladder. A mucosal flap is thus formed. On micturition, the elevated intravesicular pressure compresses the flap against the bladder wall, thereby occluding the lumen. (B) Persons with a congenitally short intravesical ureter have no mucosal flap, because the entry of the ureter into the bladder approaches a right angle. Thus, micturition forces urine into the ureter. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 903]. Philadelphia: Lippincott Williams & Wilkins.) (Courtesy of Dmitri Karetnikov, artist) persons with vesicoureteral reflux, the ureter enters the bladder at an approximate right angle such that urine is forced into the ureter during micturition.⁶ It is seen most commonly in children with UTIs and is believed to result from congenital defects in length, diameter, muscle structure, or innervation of the submucosal segment of the ureter. Vesicoureteral reflux also is seen in adults with obstruction to bladder outflow, primarily because of increased bladder volume and pressure.

Catheter-Induced Infection

Urinary catheters are tubes made of latex or plastic. They are inserted through the urethra into the bladder for the purpose of draining urine. They are a source of urethral irritation and provide a means for entry of microorganisms into the urinary tract.

Catheter-associated bacteriuria remains the most frequent cause of gram-negative septicemia in hospitalized patients. Studies have shown that bacteria adhere to the surface of the catheter and initiate the growth of a biofilm that then covers the surface of the catheter.¹⁴ The biofilm tends to protect the bacteria from the action of antibiotics and makes treatment difficult. A closed drainage system (*i.e.*, closed to air and other sources of contamination) and careful attention to perineal hygiene (*i.e.*, cleaning the area around the urethral meatus) help to prevent infections in persons who require an indwelling catheter. Careful hand washing and early detection and treatment of UTIs also are essential.

Manifestations

The manifestations of UTI depend on whether the infection involves the lower or upper urinary tract. An acute episode of cystitis (bladder infection) or lower UTI is characterized by frequency of urination (sometimes as often as every 20 minutes), lower abdominal or back discomfort, and burning and pain on urination (*i.e.*, dysuria). Occasionally the urine is cloudy and foul smelling. In adults, fever and other signs of infection usually are absent. If there are no complications, the symptoms disappear within 48 hours of treatment. This type of UTI is common in younger women. The symptoms of cystitis also may represent urethritis caused by *Chlamydia trachomatis, Neisseria gonorrhoeae*, or herpes simplex virus, or vaginitis attributable to *Trichomonas vaginalis* or *Candida* species.

Upper UTIs affect the parenchymal tissues of kidney pelvis (pyelonephritis). They tend to produce more systemic signs of infection than lower UTIs because of closer proximity to the vascular compartment and blood cells (*e.g.*, neutrophils) that incite the inflammatory response. Acute pyelonephritis tends to present with an abrupt onset of shaking chills, moderate to high fever, and constant ache in the loin area of the back that is unilateral or bilateral.^{13,14} Lower urinary tract symptoms, including dysuria, frequency, and urgency, also are common. There may be significant malaise, and the person usually looks and feels ill. Nausea and vomiting may occur along with abdominal pain. Palpation or percussion over the costovertebral angle on the affected side usually causes pain. Pyelonephritis occurs more frequently in children and adults with urinary tract obstructions or other predisposing conditions.

Diagnosis and Treatment

The diagnosis of UTI usually is based on symptoms and on examination of the urine for the presence of microorganisms. When necessary, x-ray films, ultrasonography, and CT and renal scans are used to identify contributing factors, such as obstruction.

Microscopic urine tests are used establish the presence of bacteria and blood cells in the urine.⁹ A commonly accepted criterion for diagnosis of a UTI is the presence of 10⁵ or more bacteria per milliliter of urine.⁹ Colonization usually is defined as the multiplication of microorganisms in or on a host without apparent evidence of invasiveness or tissue injury. Pyuria (the presence of less than five to eight leukocytes per highpower field) indicates a host response to infection, rather than asymptomatic bacterial colonization. A Gram's stain may be done to determine the type of organism that is present (gram positive or gram negative).

Chemical screening (urine dipstick) for markers of infection may provide useful information but is less sensitive than microscopic analysis. A urine culture confirms the presence of pathogenic bacteria in urine specimens, allows for their identification, and permits the determination of their sensitivity to specific antibiotics.

The treatment of acute UTI is based on the type of infection that is present (lower or upper UTI), the pathogen causing the infection, and the presence of contributing host-agent factors. Other considerations include whether the infection is acute, recurrent, or chronic. Most acute lower UTIs are treated successfully with antimicrobial therapy and increased fluid intake. Because there is risk of permanent kidney damage, upper urinary tract infections (*e.g.*, pyelonephritis) are treated more aggressively. Hospitalization may be recommended during the early stages of infection until a response to treatment is observed.¹⁶

Recurrent lower UTIs are those that recur after treatment. They are attributable either to bacterial persistence or reinfection. Bacterial persistence usually is curable by removal of the infectious source (*e.g.*, urinary catheter or infected bladder stones).

Chronic UTIs are more difficult to treat. Because they often are associated with obstructive uropathy or reflux flow of urine, diagnostic tests usually are performed to detect such abnormalities. When possible, the condition causing the reflux flow or obstruction is corrected. Men in particular should be investigated for obstructive disorders or a prostatic focus of infection.

Infections in Special Populations

Urinary Tract Infections in Women

In women, the urethra is short and close to the vagina and rectum, offering little protection against entry of microorganisms into the bladder. There is a peak incidence of these infections in the 15- to 24-year-old age group, suggesting that hormonal and anatomic changes associated with puberty and sexual activity contribute to UTIs.

The role of sexual activity in the development of urethritis and cystitis is a matter of controversy. The anterior urethra usually is colonized with bacteria; urethral massage or sexual intercourse can force these bacteria back into the bladder. Using a diaphragm and spermicide enhances the susceptibility to infection.¹⁷ A nonpharmacologic approach to the treatment of frequent UTIs associated with sexual intercourse is to increase fluid intake before intercourse and to void soon after intercourse. This procedure uses the washout phenomenon to remove bacteria from the bladder. Pregnant women are at increased risk for UTIs. Normal changes in the functioning of the urinary tract that occur during pregnancy predispose to UTIs.¹⁸ These changes involve the collecting system of the kidneys and include dilatation of the renal calices, pelves, and ureters that begins during the first trimester and becomes most pronounced during the third trimester. This dilatation of the upper urinary system is accompanied by a reduction in the peristaltic activity of the ureters that is thought to result from the muscle-relaxing effects of progesterone-like hormones and mechanical obstruction from the enlarging uterus. In addition to the changes in the kidneys and ureters, the bladder becomes displaced from its pelvic position to a more abdominal position, producing further changes in ureteral position.

UTIs are commonly asymptomatic in pregnant women. The complications of asymptomatic UTIs during pregnancy include persistent bacteriuria, acute and chronic pyelonephritis, toxemia of pregnancy, and premature delivery. Evidence suggests that few women become bacteriuric during pregnancy. Rather, it appears that symptomatic UTIs during pregnancy reflect preexisting asymptomatic bacteriuria, and that changes occurring during pregnancy simply permit the prior urinary colonization to lead to symptomatic infection and invasion of the kidneys.¹⁹ Because bacteriuria may occur as an asymptomatic condition in pregnant women, the American College of Obstetricians and Gynecologists recommends that a urine culture be obtained at the first prenatal visit.^{18,19} A repeat culture should be obtained during the third trimester. Women with bacteriuria should be followed up closely, and infections should be properly treated to prevent complications. The choice of antimicrobial agent should address the common infecting organisms and should be safe for the woman and fetus.

Urinary Tract Infections in Children

Urinary tract infections occur in as many as 3% to 5% of female and 1% of male children.⁴ In girls, the average age at first diagnosis is 3 years, which coincides with onset of toilet training. In boys, most UTIs occur during the first year of life; they are more common in uncircumcised than in circumcised boys. Children who are at increased risk for bacteriuria or symptomatic UTIs are premature infants discharged from neonatal intensive care units; children with systemic or immunologic disease or urinary tract abnormalities such as neurogenic bladder or vesicoureteral reflux; those with a family history of UTI or urinary tract anomalies with reflux; and girls younger than 5 years of age with a history of UTI.²⁰

UTIs in children frequently involve the upper urinary tract (pyelonephritis). In children in whom renal development is not complete, pyelonephritis can lead to renal scarring and permanent kidney damage. It has been reported that more than 75% of children younger than 5 years of age with febrile UTIs have pyelonephritis, and that renal scarring occurs in 27% to 64% of children with pyelonephritis.²⁰ Most UTIs that lead to scarring and diminished kidney growth occur in children younger than 4 years, especially infants younger than 1 year of age. The incidence of scarring is greatest in children with gross vesicoureteral reflux or obstruction, in children with recurrent UTIs, and those with a delay in treatment.

Unlike adults, children frequently do not present with the typical signs of a UTI.^{20,21} Many neonates with UTIs have bac-

teremia and may show signs and symptoms of septicemia, including fever, hypothermia, apneic spells, poor skin perfusion, abdominal distention, diarrhea, vomiting, lethargy, and irritability. Older infants may present with feeding problems, failure to thrive, diarrhea, vomiting, fever, and foul-smelling urine. Toddlers often present with abdominal pain, vomiting, diarrhea, abnormal voiding patterns, foul-smelling urine, fever, and poor growth. In older children with lower UTIs, the classic features—enuresis, frequency, dysuria, and suprapubic discomfort—are more common. Fever is a common sign of UTI in children, and the possibility of UTI should be considered in children with unexplained fever.

Diagnosis is based on a careful history of voiding patterns and symptomatology; physical examination to determine fever, hypertension, abdominal or suprapubic tenderness, and other manifestations of UTI; and urinalysis to determine bacteriuria, pyuria, proteinuria, and hematuria. A positive urine culture that is obtained correctly is essential for the diagnosis. Additional diagnostic methods may be needed to determine the cause of the disorder. Vesicoureteral reflux is the most commonly associated abnormality in UTIs, and reflux nephropathy is an important cause of end-stage renal disease in children and adolescents. Children with a relatively uncomplicated first UTI may turn out to have significant reflux. Therefore, even a single documented UTI in a child requires careful diagnosis. Urinary symptoms in the absence of bacteriuria suggest vaginitis, urethritis, sexual molestation, the use of irritating bubble baths, pinworms, or viral cystitis. In adolescent girls, a history of dysuria and vaginal discharge makes vaginitis or vulvitis a consideration.

The approach to treatment is based on the clinical severity of the infection, the site of infection (*i.e.*, lower vs. upper urinary tract), the risk of sepsis, and the presence of structural abnormalities. The immediate treatment of infants and young children is essential. Most infants with symptomatic UTIs and many children with clinical evidence of acute upper UTIs require hospitalization and intravenous antibiotic therapy. Follow-up is essential for children with febrile UTIs to ensure resolution of the infection. Follow-up urine cultures often are done at the end of treatment. Imaging studies often are recommended for all children after first UTIs to detect renal scarring, vesicoureteral reflux, or other abnormalities.^{20,21}

Winary Tract Infections in the Elderly

Urinary tract infections are relatively common in elderly persons. It has been reported that 5% to 20% of the elderly living at home have bacteriuria. These numbers increase to 15% to 25% for the elderly living in nursing homes or extended-care facilities.²²

Most of these infections follow invasion of the urinary tract by the ascending route. Several factors predispose elderly persons to UTIs: immobility resulting in poor bladder emptying, bladder outflow obstruction caused by prostatic hyperplasia or kidney stones, bladder ischemia caused by urine retention, senile vaginitis, constipation, and diminished bactericidal activity of urine and prostatic secretions. Added to these risks are other health problems that necessitate instrumentation of the urinary tract. UTIs develop in 1% of ambulatory patients after a single catheterization and within 3 to 4 days in essentially all patients with indwelling catheters.²³

Elderly persons with bacteriuria have varying symptoms, ranging from the absence of symptoms to the presence of typ-

ical UTI symptoms. Even when symptoms of lower UTIs are present, they may be difficult to interpret because elderly persons without UTIs commonly experience urgency, frequency, and incontinence. Alternatively, elderly persons may have vague symptoms such as anorexia, fatigue, weakness, or change in mental status. Even with more serious upper UTIs (*e.g.*, pyelonephritis), the classic signs of infection such as fever, chills, flank pain, and tenderness may be altered or absent in elderly persons.²² Sometimes, no symptoms occur until the infection is far advanced.

In summary, UTI is the second most common type of bacterial infection seen by health care professionals. Infections can range from simple bacteriuria to severe kidney infections that cause irreversible kidney damage. Predisposition to infection is determined by host defenses and pathogen virulence. Host defenses include the washout phenomenon associated with voiding, the protective mucin lining of the bladder, and local immune defenses. Pathogen virulence is enhanced by the presence of fimbriae that facilitate adherence to structures in the urinary tract.

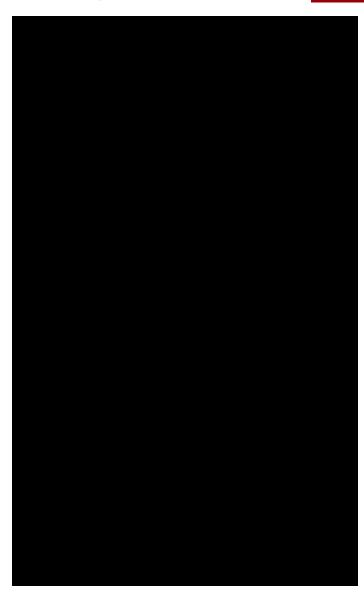

Most UTIs ascend from the urethra and bladder. A number of factors interact in determining the predisposition to development of UTIs, including urinary tract obstruction, urine stasis and reflux, pregnancy-induced changes in urinary tract function, age-related changes in the urinary tract, changes in the protective mechanisms of the bladder and ureters, impaired immune function, and virulence of the pathogen. Urinary tract catheters and urinary instrumentation contribute to the incidence of UTIs. Early diagnosis and treatment of UTIs are essential to preventing permanent kidney damage.

DISORDERS OF GLOMERULAR FUNCTION

The glomeruli are tufts of capillaries that lie between the afferent and efferent arterioles. The capillaries of the glomeruli are arranged in lobules and supported by a stalk consisting of mesangial cells and a basement membrane-like extracellular matrix (Fig. 23-7). The glomerular membrane is composed of three layers: an endothelial layer lining the capillary, a basement membrane, and a layer of epithelial cells forming the outer surface of the capillary and lining Bowman's capsule (see Chapter 22, Fig. 22-5). The epithelial cells are attached to the basement membrane by discrete cytoplasmic extensions, the foot processes (i.e., podocytes). In the glomeruli, blood is filtered, and the urine filtrate formed. The capillary membrane is selectively permeable: it allows water, electrolytes, and dissolved particles, such as glucose and amino acids, to leave the capillary and enter Bowman's space and prevents larger particles, such as plasma proteins and blood cells, from leaving the blood.

Mechanisms of Glomerular Injury

Glomerulonephritis, an inflammatory process that involves glomerular structures, is the leading cause of chronic renal failure in the United States, accounting for one half of persons with end-stage renal disease.²⁴ There are many causes of

KEY CONCEPTS

GLOMERULAR DISEASE

- Glomerular disorders affect the glomerular capillary membrane structures that filter materials from the blood.
- Nephritic syndromes are caused by diseases that produce proliferative inflammatory responses that decrease the permeability of the glomerular capillary membrane.
- The nephrotic syndrome is caused by disorders that increase the permeability of the glomerular capillary membrane, causing massive loss of protein in the urine.

426 Unit Six: Alterations in the Urinary System

glomerular disease. The disease may occur as a primary condition in which the glomerular abnormality is the only disease present, or it may occur as a secondary condition in which the glomerular abnormality results from another disease, such as diabetes mellitus or SLE. An understanding of the various forms of glomerular disease has emerged only recently. Much of this knowledge can be attributed to advances in immunobiology and electron microscopy, development of animal models, and increased use of renal biopsy during the early stages of glomerular disease.

Although little is known about the causative agents or triggering events that produce glomerular disease, most cases of primary and many cases of secondary glomerular disease probably have an immune origin.^{5,6,24} Two types of immune mechanisms have been implicated in the development of glomerular disease: injury resulting from antibodies reacting with fixed glomerular antigens, and injury resulting from circulating antigen-antibody complexes that become trapped in the glomerular membrane (Fig. 23-8). Antigens responsible for development of the immune response may be of endogenous origin, such as DNA in SLE, or they may be of exogenous origin, such as streptococcal membrane antigens in poststreptococcal glomerulonephritis. Frequently, the source of the antigen is unknown.

The cellular changes that occur with glomerular disease include proliferative, sclerotic, and membranous changes. The term *proliferative* refers to an increase in the cellular components of the glomerulus, regardless of origin; *sclerotic* to an increase in the noncellular components of the glomerulus, primarily collagen; and *membranous* to an increase in the thickness of the glomerular capillary wall, often caused by immune complex deposition. Glomerular changes can be *diffuse*, involving all glomeruli and all parts of the glomeruli; *focal*, in which only some glomeruli are affected and others are essentially normal; *segmental*, involving only a certain segment of each glomeruli; or *mesangial*, affecting only the mesangial cell. Figure 23-8 shows changes associated with various types of glomerular disease.

Among the different types of glomerular diseases are the nephritic syndromes, which produce a proliferative inflammatory response; the nephrotic syndromes, which involve increased permeability of the glomerulus; and chronic glomerulonephritis, which represents the chronic phase of a number of glomerular disorders.

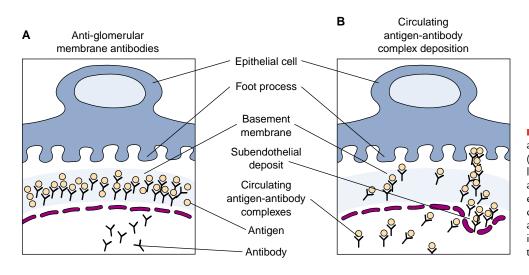

Nephritic Syndromes

Glomerulonephritis is characterized by hematuria with red cell casts, a diminished glomerular filtration rate (GFR), azotemia (presence of nitrogenous wastes in the blood), oliguria, and hypertension. It is caused by diseases that provoke a proliferative inflammatory response of the endothelial, mesangial, or epithelial cells of the glomeruli. The inflammatory process damages the capillary wall, permitting red blood cells to escape into the urine and producing hemodynamic changes that decrease the GFR. The nephritic syndromes include acute proliferative glomerulonephritis and rapidly progressive glomerulonephritis.

Acute Proliferative Glomerulonephritis

The most commonly recognized form of acute glomerulonephritis is diffuse proliferative glomerulonephritis, which follows infections caused by strains of group A β-hemolytic streptococci. Diffuse proliferative glomerulonephritis also may occur after infections by other organisms, including staphylococci and a number of viral agents, such as those responsible for mumps, measles, and chickenpox. With this type of nephritis, the inflammatory response is caused by an immune reaction that occurs when circulating immune complexes become entrapped in the glomerular membrane. Proliferation of the endothelial cells lining the glomerular capillary (i.e., endocapillary form of the disease) and the mesangial cells lying between the endothelium and the epithelium follows (see Fig. 23-8). The capillary membrane swells and becomes permeable to plasma proteins and blood cells. Although the disease is seen primarily in children, adults of any age also can be affected.

The classic case of poststreptococcal glomerulonephritis follows a streptococcal infection by approximately 7 to 12 days the time needed for the development of antibodies.²⁴ Oliguria, which develops as the GFR decreases, is one of the first symptoms. Proteinuria and hematuria follow because of increased glomerular capillary wall permeability. The blood is degraded by materials in the urine, and a cola-colored urine may be the first sign of the disorder. Sodium and water retention gives rise to edema, particularly of the face and hands, and hypertension. Important laboratory findings include an elevated streptococcal exoenzyme (antistreptolysin O) titer, a decline in C3 com-

■ FIGURE 23-8 ■ Immune mechanisms of glomerular disease. (A) Antiglomerular antibodies leave the circulation and interact with antigens that are present in the basement membrane of the glomerulus. (B) Antigenantibody complexes circulating in the blood become trapped as they are filtered in the glomerulus. plement (see Chapter 10), and cryoglobulins (*i.e.*, large immune complexes) in the serum.

Treatment for acute poststreptococcal glomerulonephritis is largely symptomatic. The acute symptoms usually begin to subside in approximately 10 days to 2 weeks, although in some children the proteinuria may persist for several months. The immediate prognosis is favorable, and approximately 95% of children recover spontaneously.⁵ The outlook for adults is less favorable; approximately 60% recover completely. In the remainder of cases, the lesions eventually resolve, but there may be permanent kidney damage.

Rapidly Progressive Glomerulonephritis

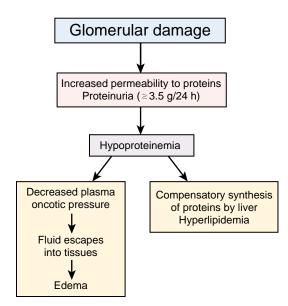

Rapidly progressive glomerulonephritis is a clinical syndrome characterized by signs of severe glomerular injury that does not have a specific cause. As its name indicates, this type of glomerulonephritis is rapidly progressive, often within a matter of months. The disorder involves focal and segmental proliferation of glomerular cells and recruitment of monocytes (macrophages) with formation of crescent-shaped structures that obliterate Bowman's space.⁵ Rapidly proliferative glomerulonephritis may be caused by a number of immunologic disorders, some systemic and others restricted to the kidney. Among the diseases associated with this form of glomerulonephritis are immune complex disorders such as SLE, the small vessel vasculitides (*e.g.*, microscopic polyangiitis), and an immune disorder condition called *Goodpasture's syndrome*.

Goodpasture's syndrome, which is caused by antibodies to the glomerular basement membrane (GBM), accounts for approximately 5% of cases of rapidly progressive glomerulonephritis. It is a rare disease and is associated with a triad of pulmonary hemorrhage, iron-deficiency anemia, and glomerulonephritis. All of these manifestations result from anti-GBM antibody deposition in the lungs and glomeruli. The cause of the disorder is unknown, although influenza infection and exposure to hydrocarbon solvent (found in paints and dyes) have been implicated in some persons, as have various drugs and cancers. There is a high prevalence of certain human leukocyte antigen subtypes (e.g., HLA-DRB1), suggesting a genetic predisposition.⁵ Treatment includes plasmapheresis to remove circulating anti-GBM antibodies and immunosuppressive therapy (i.e., corticosteroids and cyclophosphamide) to inhibit antibody production.

Nephrotic Syndrome

Nephrotic syndrome is not a specific glomerular disease but a constellation of clinical findings that result from increased glomerular permeability to the plasma proteins (Fig. 23-9). The glomerular derangements that occur with nephrosis can develop as a primary disorder or secondary to changes caused by systemic diseases such as diabetes mellitus, amyloidosis, and SLE. Among the primary glomerular lesions leading to nephrotic syndrome are minimal change disease (lipoid nephrosis), focal segmental glomerulosclerosis, and membranous glomerulonephritis. The relative frequency of these causes varies with age. In children younger than 15 years of age, nephrotic syndrome almost always is caused by primary glomerular disease, whereas in adults it often is a secondary disorder.⁵

The nephrotic syndrome is characterized by massive proteinuria (>3.5 g/day) and lipiduria (*e.g.*, free fat, oval bodies,

■ FIGURE 23-9 ■ Pathophysiology of the nephrotic syndrome.

fatty casts), along with an associated hypoalbuminemia (<3 g/dL), generalized edema, and hyperlipidemia (cholesterol >300 mg/dL).^{6,25,26} The initiating event in the development of nephrosis is a derangement in the glomerular membrane that causes increased permeability to plasma proteins. The glomerular membrane acts as a size and charge barrier through which the glomerular filtrate must pass. Any increased permeability allows protein to escape from the plasma into the glomerular filtrate.

Generalized edema, which is a hallmark of nephrosis, results from salt and water retention and a loss of serum albumin below that needed to maintain the colloid osmotic pressure of the vascular compartment.⁵ The sodium and water retention appears to be caused by several factors, including a compensatory increase in aldosterone, stimulation of the sympathetic nervous system, and a reduction in secretion of natriuretic factors. Initially, the edema presents in dependent parts of the body, such as the lower extremities, but becomes more generalized as the disease progresses. Dyspnea caused by pulmonary edema, pleural effusions, and diaphragmatic compromise attributable to ascites can develop in persons with nephrotic syndrome.¹⁵

Although the largest proportion of plasma protein loss is in albumin, globulins also are lost. As a result, persons with nephrosis are particularly vulnerable to infections, particularly those caused by staphylococci and pneumococci.⁵ This decreased resistance to infection probably is related to loss of both immunoglobulins and low-molecular-weight complement components in the urine. Many binding proteins also are lost in the urine. Consequently, the plasma levels of many ions (iron, copper, zinc), hormones (thyroid and sex hormones), and drugs may be low because of decreased binding proteins. Many drugs require protein binding for transport. Hypoalbuminemia reduces the number of available protein binding sites, thereby producing a potential increase in the amount of free (active) drug that is available.²⁷

Thrombotic complications also have evolved as a risk in persons with nephrotic syndrome. These disorders are thought to be related to a disruption in the function of the coagulation system brought about by a loss of coagulation and anticoagulation factors.^{15,27} Renal vein thrombosis, once thought to be a cause of the disorder, is more likely a consequence of the hypercoagulable state.⁵ Other thrombotic complications include deep vein thrombosis and pulmonary emboli.

The hyperlipidemia that occurs in persons with nephrosis is characterized by elevated levels of triglycerides and low-density lipoproteins (LDL). Levels of high-density lipoproteins (HDL) usually are normal. These abnormalities are thought to be related, in part, to increased synthesis of lipoproteins in the liver secondary to a compensatory increase in albumin production. Because of the elevated LDL levels, persons with nephrotic syndrome are at increased risk for development of atherosclerosis.

Membranous Glomerulonephritis

Membranous glomerulonephritis is the most common cause of primary nephrosis in adults, most commonly people in their sixth or seventh decade. The disorders are caused by diffuse thickening of the GBM attributable to deposition of immune complexes. The disorder may be idiopathic or associated with a number of disorders, including autoimmune diseases such as SLE, infections such as chronic hepatitis B, metabolic disorders such as diabetes mellitus and thyroiditis, and use of certain drugs such as gold, penicillamine, and captopril.⁵ Because of the presence of immunoglobulins and complement in the subendothelial deposits, it is thought that the disease represents a chronic antigen-antibody complex-mediated disorder.

The disorder is treated with corticosteroids. Cytotoxic drugs may be added to the treatment regimen. The progress of the disease is variable; approximately one half of persons sustain a slow but progressive loss of renal function.

Minimal Change Disease (Lipoid Nephrosis)

Minimal change disease is characterized by diffuse loss (through fusion) of the foot processes from the epithelial layer of the glomerular membrane. The peak incidence is between 2 and 6 years of age. The cause of minimal change nephrosis is unknown; however, children in whom the disease develops often have a history of recent upper respiratory infections or of receiving routine immunizations.⁵ Although minimal change disease does not progress to renal failure, it can cause significant complications, including predisposition to infection with gram-positive organisms, a tendency toward thromboembolic events, hyperlipidemia, and protein malnutrition. There usually is a dramatic response to corticosteroid therapy.⁵

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis is characterized by sclerosis (*i.e.*, increased collagen deposition) of some but not all glomeruli, and in the affected glomeruli, only a portion of the glomerular tuft is involved. Although focal segmental sclerosis often is an idiopathic syndrome, it may be associated with reduced oxygen in the blood (*e.g.*, sickle cell disease and cyanotic congenital heart disease), HIV infection, or intravenous drug abuse, or it may be a secondary event reflecting glomerular scarring caused by other forms of glomerulonephritis or reflux nephropathy.^{5,6} The presence of hypertension and decreased renal function distinguishes focal sclerosis from minimal change disease. The disorder usually is treated with corticosteroids. Most persons with focal segmental glomerulosclerosis progress to end-stage renal disease within 5 to 10 years.

Chronic Glomerulonephritis

Chronic glomerulonephritis represents the chronic phase of a number of specific types of glomerulonephritis.⁵ Some forms of glomerulonephritis (*e.g.*, poststreptococcal glomerulonephritis) undergo complete resolution, whereas others progress at variable rates to chronic glomerulonephritis. Some persons who present with chronic glomerulonephritis have no history of glomerular disease. These cases may represent the end result of relatively asymptomatic forms of glomerulonephritis. Histologically, the condition is characterized by small kidneys with sclerosed glomeruli. In most cases, chronic glomerulonephritis develops insidiously and slowly progresses to end-stage renal disease over a period of years (see Chapter 24).

Glomerular Lesions Associated With Systemic Disease

Many immunologic, metabolic, or hereditary systemic diseases are associated with glomerular injury. In some diseases, such as systemic lupus erythematosus and diabetes mellitus, the glomerular involvement may be a major clinical manifestation. The glomerular lesions associated with diabetes mellitus and hypertension are discussed in this chapter.

Diabetic Glomerulosclerosis

Diabetic nephropathy, or kidney disease, is a major complication of diabetes mellitus. It affects approximately 30% of persons with type 1 diabetes and accounts for 20% of deaths in diabetic patients younger than 40 years of age.⁵

The glomerulus is the most commonly affected structure in diabetic nephropathy, evidenced by three glomerular syndromes: non-nephrotic proteinuria, nephrotic syndrome, and renal failure. Widespread thickening of the glomerular capillary basement membrane occurs in almost all persons with diabetes and can occur without evidence of proteinuria.⁵ This is followed by a diffuse increase in mesangial matrix, with mild proliferation of mesangial cells. In nodular glomerulosclerosis, also known as *Kimmelstiel-Wilson syndrome*, there is nodular deposition of hyaline in the mesangial portion of the glomerulus. As the sclerotic process progresses in both the diffuse and nodular forms of glomerulosclerosis, there is complete obliteration of the glomerulus, with impairment of renal function.

Although the mechanisms of glomerular change in diabetes are uncertain, they are thought to represent enhanced or defective synthesis of the glomerular basement membrane and mesangial matrix with an inappropriate incorporation of glucose into the noncellular components of these glomerular structures. Alternatively, hemodynamic changes that occur secondary to elevated blood glucose levels may contribute to the initiation and progression of diabetic glomerulosclerosis. It has been hypothesized that elevations in blood glucose produce an increase in GFR and glomerular intracapillary pressure that leads to an enlargement of glomerular capillary pores by a mechanism that is at least partly mediated by angiotensin II. This enlargement impairs the size-selective function of the membrane so that the protein content of the glomerular filtrate increases, which in turn requires increased endocytosis of protein by the tubular endothelial cells, a process that ultimately leads to nephron destruction and progressive deterioration of renal function.28,29

The clinical manifestations of diabetic glomerulosclerosis are closely linked to those of diabetes. The increased GFR that occurs in persons with early alterations in renal function is associated with microalbuminuria, defined as urinary albumin excretion greater than 30 mg/24 hours and no more than 300 mg/ 24 hours.²⁹ Microalbuminuria is an important predictor of future diabetic nephropathies.^{5,29} In many cases, these early changes in glomerular function can be reversed by careful control of blood glucose levels (see Chapter 32).29 Inhibition of angiotensin by angiotensin-converting enzyme inhibitors (e.g., captopril) has been shown to have a beneficial effect, possibly by reversing increased glomerular pressure.6,29 Hypertension and cigarette smoking have been implicated in the progression of diabetic nephropathy. Thus, control of high blood pressure and smoking cessation are recommended as primary and secondary prevention strategies in persons with diabetes.

Hypertensive Glomerular Disease

Hypertension can be viewed as both a cause and an effect of kidney disease. Most persons with advanced kidney disease have hypertension, and many persons with long-standing hypertension eventually sustain changes in kidney function. Renal failure and azotemia occur in 1% to 5% of persons with long-standing hypertension (see Chapter 16). Hypertension is associated with a number of changes in glomerular structures, including sclerotic changes. As the glomerular vascular structures thicken and perfusion diminishes, the blood supply to the nephron decreases, causing the kidneys to lose some of their ability to concentrate the urine. This may be evidenced by nocturia. Blood urea nitrogen levels also may become elevated, particularly during periods of water deprivation. Proteinuria may occur as a result of changes in glomerular structure.

In summary, diseases of the glomerulus disrupt glomerular filtration and alter the permeability of glomerular capillary membrane to plasma proteins and blood cells. *Glomerulonephritis* is a term used to describe a group of diseases that result in inflammation and injury of the glomerulus. These diseases disrupt the capillary membrane and cause proteinuria, hematuria, pyuria, oliguria, edema, hypertension, and azotemia. Almost all types of glomerulonephritis are caused by immune mechanisms.

Glomerular diseases have been grouped into two categories: the nephritic and the nephrotic syndromes. The nephritic syndrome evokes an inflammatory response in the glomeruli and is characterized by hematuria with red cell casts in the urine, a diminished GFR, azotemia, oliguria, and hypertension. The nephrotic syndrome affects the integrity of the glomerular capillary membrane and is characterized by massive proteinuria, hypoalbuminemia, generalized edema, lipiduria, and hyperlipidemia. Both conditions can lead to progressive loss of glomerular function and eventual development of endstage renal disease. Among the secondary causes of glomerular kidney disease are diabetes and hypertension. Kidney disease is a major complication of diabetes mellitus and is thought to be related to hemodynamic changes associated with defective synthesis of glomerular structures associated with increased blood glucose levels. Hypertension is closely linked with kidney disease, and kidney disease can be a cause or effect of elevated blood pressure.

TUBULOINTERSTITIAL DISORDERS

Several disorders affect renal tubular structures, including the proximal and distal tubules. Most of these disorders also affect the interstitial tissue that surrounds the tubules. These disorders, which sometimes are referred to as *tubulointerstitial disorders*, include acute tubular necrosis (see Chapter 24), pyelonephritis, and drug-induced nephropathies.

Tubulointerstitial renal diseases may be divided into acute and chronic disorders. The acute disorders are characterized by their sudden onset and by signs and symptoms of interstitial edema; they include acute pyelonephritis and acute hypersensitivity reaction to drugs. The chronic disorders produce interstitial fibrosis, atrophy, and mononuclear infiltrates; most persons are asymptomatic until late in the course of the disease. In the early stages, tubulointerstitial diseases commonly are manifested by fluid and electrolyte imbalances that reflect subtle changes in tubular function. These manifestations can include the inability to concentrate urine, as evidenced by polyuria and nocturia; interference with acidification of urine, resulting in metabolic acidosis; and diminished tubular reabsorption of sodium and other substances.⁵

Pyelonephritis

Acute pyelonephritis refers to an inflammation of the kidneys and renal pelves. There are two forms of pyelonephritis: acute and chronic. *Acute pyelonephritis* represents a patchy interstitial suppurative inflammatory process, with abscess formation and tubular necrosis. Infection may occur through bloodstream or ascend from the bladder. Factors that contribute to the development of acute pyelonephritis are catheterization and urinary tract instrumentation, vesicoureteral reflux, pregnancy, and neurogenic bladder. A second less frequent and more serious type of acute pyelonephritis, called *necrotizing papillitis*, is characterized by necrosis of the renal papillae. It is particularly common in persons with diabetes and may also complicate acute pyelonephritis when there is significant urinary tract obstruction.

The onset of acute pyelonephritis typically is abrupt, with chills, fever, headache, back pain, tenderness over the costovertebral angle, and general malaise. It usually is accompanied by symptoms of bladder irritation, such as dysuria, frequency, and urgency. Pyuria occurs but is not diagnostic because it also occurs in lower UTIs. The development of necrotizing papillitis is associated with much poorer prognosis. These persons have evidence of overwhelming sepsis and, often, renal failure.

Acute pyelonephritis is treated with appropriate antimicrobial drugs. Unless obstruction or other complications occur, the symptoms usually disappear within several days. Hospitalization during initial treatment may be necessary. Depending on the cause, recurrent infections are possible.

Chronic pyelonephritis represents a progressive process. There is scarring and deformation of the renal calices and pelvis⁶ (Fig. 23-10). The disorder appears to involve a bacterial infection superimposed on obstructive abnormalities or vesicoureteral reflux. Chronic obstructive pyelonephritis is associated with recurrent bouts of inflammation and scarring, which eventually lead to chronic pyelonephritis. Reflux, which is the most 0 Unit Six: Alterations in the Urinary System

■ FIGURE 23-10 Chronic pyelonephritis. Marked dilatation of calcyces caused by inflammatory destruction of papillae, with atrophy and scarring of the overlying cortex. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 905]. Philadelphia: Lippincott Williams & Wilkins)

common cause of chronic pyelonephritis, results from superimposition of infection on congenital vesicoureteral reflux or intrarenal reflux. Reflux may be unilateral with involvement of a single kidney or bilateral leading to scarring and atrophy of both kidneys with the eventual development of chronic renal insufficiency.

Chronic pyelonephritis may cause many of the same symptoms as acute pyelonephritis, but its onset may be more insidious. Loss of tubular function and the ability to concentrate urine give rise to polyuria and nocturia, and mild proteinuria is common. Severe hypertension often is a contributing factor in the progress of the disease. Chronic pyelonephritis is a significant cause of renal failure. It is thought to be responsible for 11% to 20% of all cases of end-stage renal disease.⁵

Drug-Related Nephropathies

Drug-related nephropathies involve functional or structural changes in the kidneys that occur after exposure to a drug. The kidneys are exposed to a high rate of delivery of any substance in the blood because of their large blood flow and high filtration pressure. The kidneys also are active in the metabolic transformation of drugs and therefore are exposed to a number of toxic metabolites. Some drugs and toxic substances damage the kidneys by causing a decrease in blood flow; others directly damage tubulointerstitial structures; and still others cause damage by producing hypersensitivity reactions.

The tolerance to drugs varies with age and depends on renal function, state of hydration, blood pressure, and the pH of the urine. Because of a decrease in physiologic function, elderly persons are particularly susceptible to kidney damage caused by drugs and toxins. The dangers of nephrotoxicity are increased when two or more drugs capable of producing kidney damage are given at the same time.

Acute drug-related hypersensitivity reactions produce tubulointerstitial nephritis, with damage to the tubules and interstitium. This condition was observed initially in persons who were sensitive to the sulfonamide drugs; currently, it is observed most often with the use of methicillin and other synthetic antibiotics, and with the use of furosemide and the thiazide diuretics in persons sensitive to these drugs. The condition begins approximately 15 days (range, 2-40 days) after exposure to the drug.^{5,6} At the onset, there is fever, eosinophilia, hematuria, mild proteinuria, and in approximately one fourth of cases, a rash. In approximately 50% of cases, signs and symptoms of acute renal failure develop. Withdrawal of the drug commonly is followed by complete recovery, but there may be permanent damage in some persons, usually in older persons. Drug nephritis may not be recognized in its early stage because it is uncommon.

Chronic analgesic nephritis, which is associated with analgesic abuse, causes interstitial nephritis with renal papillary necrosis. When first observed, it was attributed to phenacetin, a then-common ingredient of over-the-counter medications containing aspirin, phenacetin, and caffeine. Although phenacetin is no longer contained in these preparations, it has been suggested that other ingredients, such as aspirin and acetaminophen, also may contribute to the disorder. How much analgesic it takes to produce papillary necrosis is unknown.

Nonsteroidal anti-inflammatory drugs (NSAIDs) also have the potential for damaging renal structures, including medullary interstitial cells. Prostaglandins (particularly PGI₂ and PGE₂) contribute to regulation of tubular blood flow.³⁰ The deleterious effects of NSAIDs on the kidney are thought to result from their ability to inhibit prostaglandin synthesis. Persons who are particularly at risk are the elderly because of age-related changes in renal function, persons who are dehydrated or have a decrease in blood volume, and persons with pre-existing kidney disease or renal insufficiency.

In summary, tubulointerstitial diseases affect the tubules and the surrounding interstitium of the kidneys. These disorders include pyelonephritis and the effects of drugs and toxins. Pyelonephritis, or infection of the kidney and kidney pelvis, can occur as an acute or a chronic condition. Acute pyelonephritis typically is caused by ascending bladder infections or infections that come from the bloodstream; it usually is successfully treated with appropriate antimicrobial drugs. Chronic pyelonephritis is a progressive disease that produces scarring and deformation of the renal calices and pelvis. Druginduced impairment of tubulointerstitial structure and function usually is the result of direct toxic injury, decreased blood flow, or hypersensitivity reactions.

NEOPLASMS

There are two major groups of renal neoplasms: embryonic kidney tumors (*i.e.*, Wilms' tumor), which occur during childhood, and renal cell carcinoma, which is the main kidney cancer in adults.

Wilms' Tumor

Wilms' tumor (*i.e.*, nephroblastoma) is one of the most common primary neoplasms of young children. The median age at time of diagnosis of unilateral Wilms' tumor is approximately 3 years.³¹ It is a mixed tumor, composed of epithelial and mesenchymal embryonic tissue elements.32 An important feature of Wilms' tumor is its association with congenital anomalies, the most frequent being those affecting genitourinary structures.³¹ Deletions involving at least two loci on chromosome 11 have been found in approximately 30% of children with Wilms' tumors. Some familial cases of Wilms' tumor are not associated with identifiable chromosomal deletions or mutations, suggesting a third locus may be involved.

Wilms' tumor usually is a solitary mass that occurs in any part of the kidney. It usually is sharply demarcated and variably encapsulated.6 The tumors grow to a large size, distorting kidney structure. The tumors usually are staged using the Wilms' Tumor Study Group classification.³¹ Stage I tumors are limited to the kidney and can be excised with the capsular surface intact. Stage II tumors extend into the kidney but can be excised. In stage III, extension of the tumor is confined to the abdomen, and in stage IV, hematogenous metastasis most commonly involves the lung. Bilateral kidney involvement occurs in 5% to 10% of cases.

The common presenting signs are a large asymptomatic abdominal mass and hypertension. Approximately 50% of children have abdominal pain, vomiting, or both.³¹ Microscopic and gross hematuria are present in 10% to 25% of children. CT scans are used to confirm the diagnosis.

Treatment involves surgery, chemotherapy, and sometimes radiation therapy. Long-term survival rates have increased to approximately 90% with an aggressive treatment plan.³¹

Renal Cell Carcinoma

Kidney cancer accounts for 2% of all adult cancer incidence and mortality in the United States.³³ The increased use of imaging procedures such as ultrasonography, CT scanning, and magnetic resonance imaging (MRI) has contributed significantly to earlier diagnosis and more accurate staging of kidney cancers.³³

Renal cell carcinoma originates in the renal cortex and accounts for approximately 80% to 85% of kidney tumors, with transitional or squamous cell cancers of the renal pelvis accounting for most of the remaining cancers.³⁴ The cause of renal cell carcinoma remains unclear. It occurs most often in older persons in the sixth to seventh decade. Men are affected twice as frequently as women. Some of these tumors may occur as a result of chronic irritation associated with kidney stones. Epidemiologic evidence suggests a correlation between smoking and kidney cancer. Obesity also is a risk factor, particularly in women.34 Additional risk factors include occupational exposure to petroleum products, heavy metals, and asbestos. The risk of renal cell carcinoma also is increased in persons with acquired cystic kidney disease associated with chronic renal insufficiency.^{34,35} Most cases of renal cell carcinoma occur without a recognizable hereditary pattern. However, there are several rare forms of renal cell cancer that are characterized by an autosomal dominant pattern of inheritance, young age at onset (third and fourth decade), and bilateral or multifocal tumors.34,35

Kidney cancer is largely a silent disorder during its early stages, and symptoms usually denote advanced disease. Presenting features include hematuria, costovertebral pain, presence of a palpable flank mass, polycythemia, and fever. Hematuria, which occurs in 70% to 90% of cases, is the most reliable sign. However, it is intermittent and may be microscopic; as a result, the tumor may reach considerable size before it is detected. In approximately one third of cases, metastases are present at the time of diagnosis.

Kidney cancer is suspected when there are findings of hematuria and a renal mass. Ultrasonography, CT scanning, excretory urography, and renal angiography are used to confirm the diagnosis. MRI with intravenous gadolinium may be used when involvement of the inferior vena cava is suspected.

Surgery (radical nephrectomy with lymph node dissection) is the treatment of choice for all resectable tumors. Nephronsparing surgery may be done when both kidneys are involved or when the contralateral kidney is threatened by an associated disease such as hypertension or diabetes mellitus. Single-agent and combination chemotherapy have been used with limited success. The prognosis depends on the stage of the cancer; the 5-year survival rate associated with stage I tumors is 65% to 85%; for stage IV tumors, it is 0% to 10%.34,35

In summary, there are two major groups of renal neoplasms: embryonic kidney tumors (i.e., Wilms' tumor) that occur during childhood and adult renal cell carcinomas. Wilms' tumor is the most common malignant tumor of children. The most common presenting signs are a large abdominal mass and hypertension. Treatment is surgery, chemotherapy, and sometimes radiation therapy. The long-term survival rate for children with Wilms' tumor is approximately 90% with an aggressive plan of treatment.

Renal cell carcinoma accounts for 2% of all adult cancers. These tumors are characterized by a lack of early warning signs, diverse clinical manifestations, and resistance to chemotherapy and radiation therapy. Because of the lack of early warning signs, the tumors often are far advanced at the time of diagnosis. Diagnostic methods include ultrasonography and CT scans. The treatment of choice is surgical resection.

REVIEW QUESTIONS

Define the terms agenesis, dysgenesis, and hypoplasia as they refer to the development of the kidney.

Describe the genetic basis for renal cystic disease, the pathology of the disorder, and its signs and symptoms.

Describe the effects of urinary tract obstruction on renal structure and function.

Cite three theories that are used to explain the formation of kidney stones.

Explain the mechanisms of pain and infection that occur with kidney stones.

Cite the organisms most responsible for UTIs and state why urinary catheters, obstruction, and reflux predispose to infections.

List three physiologic mechanisms that protect against UTIs.

Compare the manifestations of UTIs in different age groups, including infants, toddlers, adolescents, adults, and older adults.

Use the terms *proliferation, sclerosis, membranous, diffuse, focal, segmental,* and *mesangial* to explain changes in glomerular structure that occur with glomerulonephritis.

Relate the proteinuria, hematuria, pyuria, oliguria, edema, hypertension, and azotemia that occur with glomerulonephritis to changes in glomerular structure.

Cite a definition of tubulointerstitial kidney disease.

Explain the vulnerability of the kidneys to injury caused by drugs and toxins.

Characterize Wilms' tumor in terms of age of onset, possible oncogenic origin, manifestations, and treatment.

Cite the risk factors for renal cell carcinoma, describe the manifestations, and explain why the 5-year survival rate has been so low.

CHAPTER

76

Renal failure is a condition in which the kidneys fail to remove metabolic end-products from the blood and regulate the fluid, electrolyte, and pH balance of the extracellular fluids. The underlying cause may be renal disease, systemic disease, or urologic defects of nonrenal origin. Renal failure can occur as an acute or a chronic disorder. Acute renal failure is abrupt in onset and often is reversible if recognized early and treated appropriately. In contrast, chronic renal failure is the end result of irreparable damage to the kidneys. It develops slowly, usually over the course of a number of years.

ACUTE RENAL FAILURE

Acute renal failure represents a rapid decline in renal function sufficient to increase blood levels of nitrogenous wastes and impair fluid and electrolyte balance. It is a common threat to seriously ill persons in intensive care units, with a mortality rate ranging from 42% to 88%.¹ Although treatment methods such as dialysis and renal replacement methods are effective in correcting life-threatening fluid and electrolyte disorders, the mortality rate associated with acute renal failure has not changed substantially since the 1960s.^{2,3} This probably is because acute renal failure is seen more often in older persons than before, and because it frequently is superimposed on other life-threatening conditions, such as trauma, shock, and sepsis.

The most common indicator of acute renal failure is *azotemia*, an accumulation of nitrogenous wastes (urea nitrogen, uric acid, and creatinine) in the blood. In acute renal failure the glomerular filtration rate (GFR) is decreased. As a result, excretion of nitrogenous wastes is reduced and fluid and electrolyte balance cannot be maintained. Persons with acute renal failure often are asymptomatic, and the condition is diagnosed by observation of elevations in blood urea nitrogen (BUN) and creatinine.

Types of Acute Renal Failure

Acute renal failure can be caused by several types of conditions, including a decrease in blood flow without ischemic injury; ischemic, toxic, or obstructive tubular injury; and obstruction of urinary tract outflow. The causes of acute renal failure commonly are categorized as prerenal (55% to 60%), postrenal

KEY CONCEPTS

ACUTE RENAL FAILURE

- Acute renal failure is caused by conditions that produce an acute shutdown in renal function.
- It can result from decreased blood flow to the kidney (prerenal failure), disorders that interfere with the elimination of urine from the kidney (postrenal failure), or disorders that disrupt the structures in the kidney (intrinsic or intrarenal failure).
- Acute renal failure, although it causes an accumulation of products normally cleared by the kidney, is a reversible process if the factors causing the condition can be corrected.

(<5%), and intrinsic (35% to 40%).³ Causes of renal failure within these categories are summarized in Chart 24-1.

Prerenal Failure

Prerenal failure, the most common form of acute renal failure, is characterized by a marked decrease in renal blood flow. It is reversible if the cause of the decreased renal blood flow can be identified and corrected before kidney damage occurs. Causes of prerenal failure include profound depletion of vascular volume (*e.g.*, hemorrhage, loss of extracellular fluid volume), im-

Bladder outlet obstruction				

paired perfusion caused by heart failure and cardiogenic shock, and decreased vascular filling because of increased vascular capacity (*e.g.*, anaphylaxis or sepsis). Elderly persons are particularly at risk because of their predisposition to hypovolemia and their high prevalence of renal vascular disorders.

Some vasoactive mediators, drugs, and diagnostic agents stimulate intense intrarenal vasoconstriction and induce glomerular hypoperfusion and prerenal failure.3 Examples include hypercalcemia, endotoxins, and radiocontrast agents such as those used for cardiac catheterization.³ Many of these agents also cause acute tubular necrosis (discussed later). In addition, several commonly used classes of drugs impair renal adaptive mechanisms and can convert compensated renal hypoperfusion into prerenal failure. Angiotensin-converting enzyme (ACE) inhibitors reduce the effects of renin on renal blood flow; when combined with diuretics, they may cause prerenal failure in persons with decreased blood flow caused by large-vessel or smallvessel renal vascular disease. Prostaglandins have a vasodilatory effect on renal blood vessels. Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce renal blood flow through inhibition of prostaglandin synthesis. In some persons with diminished renal perfusion, NSAIDs can precipitate prerenal failure.

Normally, the kidneys receive 20% to 25% of the cardiac output.⁴ This large blood supply is required to remove metabolic wastes and regulate body fluids and electrolytes. Fortunately, the normal kidney can tolerate relatively large reductions in blood flow before renal damage occurs. As renal blood flow is reduced, the GFR drops, the amount of sodium and other substances that is filtered by the glomeruli is reduced, and the need for energy-dependent mechanisms to reabsorb these substances is reduced. As the GFR and urine output approach zero, oxygen consumption by the kidney approximates that required to keep renal tubular cells alive.4 When blood flow falls below this level, which is about 20% of normal, ischemic changes occur. Because of their high metabolic rate, the tubular epithelial cells are most vulnerable to ischemic injury. Improperly treated, prolonged renal hypoperfusion can lead to ischemic tubular necrosis with significant morbidity and mortality.

Acute renal failure is manifested by a sharp decrease in urine output and a disproportionate elevation of BUN in relation to serum creatinine levels. The kidney normally responds to a decrease in the GFR with a decrease in urine output. An early sign of prerenal failure is a sharp decrease in urine output. BUN levels also depend on the GFR. A low GFR allows more time for small particles such as urea to be reabsorbed into the blood. Creatinine, which is larger and nondiffusible, remains in the tubular fluid, and the total amount of creatinine that is filtered, although small, is excreted in the urine. Thus, there also is a disproportionate elevation in the ratio of BUN to serum creatinine to greater than 20:1 (normal, approximately 10:1).

Postrenal Failure

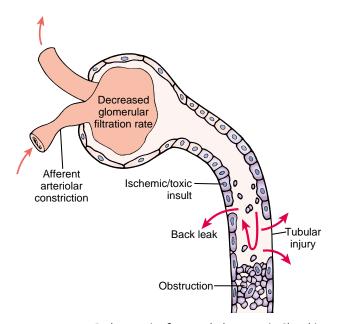

Postrenal failure results from obstruction of urine outflow from the kidneys. The obstruction can occur in the ureter (*i.e.*, calculi and strictures), bladder (*i.e.*, tumors or neurogenic bladder), or urethra (*i.e.*, prostatic hypertrophy). Prostatic hyperplasia is the most common underlying problem. Because both ureters must be occluded to produce renal failure, obstruction of the bladder rarely causes acute renal failure unless one of the kidneys already is damaged or a person has only one kidney. The treatment of acute postrenal failure consists of treating the underlying cause of obstruction so that urine flow can be re-established before permanent nephron damage occurs.

Intrinsic Renal Failure

Intrinsic or intrarenal renal failure results from conditions that cause damage to structures within the kidney-glomerular, tubular, or interstitial. Injury to the tubules is most common and often is ischemic or toxic in origin. The major causes of intrarenal failure are ischemia associated with prerenal failure, toxic insult to the tubular structures of the nephron, and intratubular obstruction. Acute glomerulonephritis and acute pyelonephritis also are intrarenal causes of acute renal failure.

Acute Tubular Necrosis. Acute tubular necrosis (ATN) is characterized by destruction of tubular epithelial cells with acute suppression of renal function (Fig. 24-1).^{3,5} It is the most common cause of intrinsic renal failure. ATN can be caused by a variety of conditions, including acute tubular damage caused by ischemia, the nephrotoxic effects of drugs, tubular obstruction, and toxins from a massive infection. The tubular injury that occurs in ATN frequently is reversible. The process depends on the recovery of the injured cells, removal of the necrotic cells and intratubular casts, and regeneration of renal cells to restore the normal continuity of the tubular epithelium. However, if the ischemia is severe enough to cause cortical necrosis, irreversible renal failure occurs.

Ischemic ATN occurs most frequently in persons who have major surgery, severe hypovolemia, overwhelming sepsis, trauma, and burns.3 Sepsis produces ischemia by provoking a

■ FIGURE 24-1 ■ Pathogenesis of acute tubular necrosis. Sloughing and necrosis of tubular epithelial cells leading to obstruction and increased intraluminal pressure, which reduces glomerular filtration. Afferent arteriolar vasoconstriction, caused in part by tubuloglomular feedback, results in decreased glomerular capillary filtration pressure. Tubular injury and increased intraluminal pressure cause fluid to move from the tubular lumen into the interstitium (backleak). (Modified from Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 901]. Philadelphia: Lippincott Williams & Wilkins)

combination of systemic vasodilation and intrarenal hypoperfusion. In addition, sepsis results in the generation of toxins that sensitize renal tubular cells to the damaging effects of ischemia. ATN complicating trauma and burns frequently is multifactorial in origin and caused by the combined effects of hypovolemia and myoglobin or other toxins released from damaged tissue. In contrast to prerenal failure, the GFR does not improve with the restoration of renal blood flow in acute renal failure caused by ischemic ATN.

Nephrotoxic ATN complicates the administration of or exposure to many structurally diverse drugs and other toxic agents. Nephrotoxic agents cause renal injury by inducing varying combinations of renal vasoconstriction, direct tubular damage, or intratubular obstruction. The kidney is particularly vulnerable to nephrotic injury because of its rich blood supply and ability to concentrate toxins to high levels in the medullary portion of the kidney. In addition, the kidney is an important site for metabolic processes that transform relatively harmless agents into toxic metabolites. Pharmacologic agents that are directly toxic to the renal tubule include antimicrobial agents such as the aminoglycosides, chemotherapeutic agents such as cisplatin and ifosfamide, and the radiocontrast agents used during cardiac catheterization and other diagnostic procedures.^{5,6} Radiocontrast media-induced nephrotoxicity is thought to result from direct tubular toxicity and renal ischemia.⁷ The risk of renal damage caused by radiocontrast media is greatest in elderly persons, in persons with diabetes mellitus, and in persons who, for various reasons, are susceptible to kidney disease.3 Heavy metals (e.g., lead, mercury) and organic solvents (e.g., carbon tetrachloride, ethylene glycol) are other nephrotoxic agents.

Myoglobin, hemoglobin, uric acid, and myeloma light chains are the most common cause of ATN attributable to intratubular obstruction. Deposits of immunoglobulins and urine acid crystals usually are seen in the setting of widespread malignancy or massive tumor destruction by therapeutic agents.³ Hemoglobinuria results from blood transfusion reactions and other hemolytic crises. Skeletal and cardiac muscles contain myoglobin, which accounts for their red color. Myoglobin corresponds to hemoglobin in function, serving as an oxygen reservoir in the muscle fibers. Myoglobin normally is not found in the serum or urine. Myoglobinuria most commonly results from muscle trauma but may result from extreme exertion, hyperthermia, sepsis, prolonged seizures, potassium or phosphate depletion, and alcoholism or drug abuse. Both myoglobin and hemoglobin discolor the urine, which may range from the color of tea to red, brown, or black.

Clinical Course

The course of acute renal failure can be divided into three phases: the onset or initiating phase, the maintenance phase, and the recovery or convalescent phase.³ The onset or initiating phase, which lasts hours or days, is the time from the onset of the precipitating event (e.g., ischemic phase of prerenal failure or toxin exposure) until tubular injury occurs.

The maintenance phase is characterized by a marked decrease in the GFR, causing sudden retention of endogenous metabolites such as urea, potassium, sulfate, and creatinine that normally are cleared by the kidneys. The urine output usually is lowest at this point. Fluid retention gives rise to edema, water

436 Unit Six: Alterations in the Urinary System

intoxication, and pulmonary congestion. If the period of oliguria is prolonged, hypertension frequently develops and with it signs of uremia. When untreated, the neurologic manifestations of uremia progress from neuromuscular irritability to seizures, somnolence, coma, and death. Hyperkalemia usually is asymptomatic until serum levels of potassium rise above 6.0 to 6.5 mEq/L, at which point characteristic electrocardiographic changes and symptoms of muscle weakness are seen.

The *recovery phase* is the period during which repair of renal tissue takes place. Its onset usually is heralded by a gradual increase in urine output and a fall in serum creatinine, indicating that the nephrons have recovered to the point where urine excretion is possible. Diuresis often occurs before renal function has fully returned to normal. Consequently, BUN and serum creatinine, potassium, and phosphate levels may remain elevated or continue to rise even though urine output is increased. In some cases, the diuresis may result from impaired nephron function and may cause excessive loss of water and electrolytes. Eventually, renal tubular function is restored with improvement in urine concentrating ability. At about the same time, the BUN and creatinine begin to return to normal. In some cases, mild to moderate kidney damage persists.

Diagnosis and Treatment

Given the high morbidity and mortality rates associated with acute renal failure, attention should be focused on prevention and early diagnosis. This includes assessment measures to identify persons at risk for the development of acute renal failure, including those with pre-existing renal insufficiency and diabetes. Elderly persons are susceptible to all forms of acute renal failure because of the effects of aging on renal reserve.

Careful observation of urine output is essential for persons at risk for the development of acute renal failure. Urine output and urine osmolality or specific gravity should be carefully monitored. One of the earliest manifestations of tubular damage is the inability to concentrate the urine. Further diagnostic information that can be obtained from the urinalysis includes evidence of proteinuria, hemoglobinuria, and casts or crystals in the urine. Blood tests for BUN and creatinine provide information regarding the ability to remove nitrogenous wastes from the blood.

A major concern in the treatment of acute renal failure is identifying and correcting the cause (*e.g.*, improving renal perfusion, discontinuing nephrotoxic drugs). Fluids are carefully regulated in an effort to maintain normal fluid volume and electrolyte concentrations. Adequate caloric intake is needed to prevent the breakdown of body proteins, which increases the need for elimination of nitrogenous wastes. Parenteral hyperalimentation may be used for this purpose. Because secondary infections are a major cause of death in persons with acute renal failure, constant effort is needed to prevent and treat such infections.

Dialysis or continuous renal replacement therapy (CRRT) may be indicated when nitrogenous wastes and the water and electrolyte balance cannot be kept under control by other means.

In summary, acute renal failure is an acute, reversible suppression of kidney function. It is a common threat to seriously ill persons in intensive care units and is associated with a high mortality rate. Acute renal failure is characterized by an accumulation of nitrogenous wastes in the blood (*i.e.*, azo-temia) and alterations in body fluids and electrolytes. Acute renal failure is classified as prerenal, postrenal, or intrarenal in origin. Prerenal failure is caused by decreased blood flow to the kidneys; postrenal failure by obstruction to urine output; and intrinsic renal failure by disorders in the kidney itself. ATN, caused by ischemia or nephrotoxic agents, is a common cause of acute intrinsic renal failure. Acute renal failure typically progresses through three phases: the initiation phase, during which tubular injury is induced; the maintenance phase, during which the GFR falls, nitrogenous wastes accumulate, and urine output decreases; and the recovery or reparative phase, during which the GFR, urine output, and blood levels of nitrogenous wastes return to normal.

Because of the high morbidity and mortality rates associated with acute renal failure, identification of persons at risk is important to clinical decision making. Acute renal failure often is reversible, making early identification and correction of the underlying cause (*e.g.*, improving renal perfusion, discontinuing nephrotoxic drugs) important. Treatment includes the judicious administration of fluids and dialysis or CRRT.

CHRONIC RENAL FAILURE

Unlike acute renal failure, chronic renal failure represents progressive and irreversible destruction of kidney structures. As recently as 1965, many patients with chronic renal failure pro-

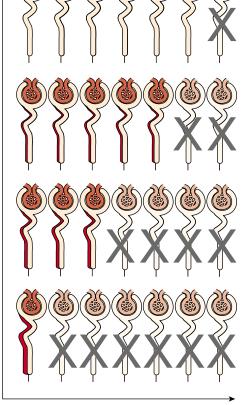

KEY CONCEPTS CHRONIC RENAL FAILURE

- Chronic renal failure represents the end result of conditions that greatly reduce renal function by destroying renal nephrons and producing a marked decrease in the glomerular filtration rate (GFR).
- Signs of renal failure begin to appear as renal function moves from renal insufficiency (GFR 50% to 20% normal), to renal failure (20% to 5% normal), to end-stage renal disease (<5% normal). When the GFR decreases to less than 5% of normal, dialysis or kidney transplantation is necessary for survival.
- The manifestations of chronic renal failure represent the inability of the kidney to perform its normal functions in terms of regulating fluid and electrolyte balance, controlling blood pressure through fluid volume and the renin-angiotensin system, eliminating nitrogenous and other waste products, governing the red blood cell count through erythropoietin synthesis, and directing parathyroid and skeletal function through phosphate elimination and activation of vitamin D.

gressed to the final stages of the disease and then died. The high mortality rate was associated with limitations in the treatment of renal disease and with the tremendous cost of ongoing treatment. In 1972, federal support began for dialysis and transplantation through a Medicare entitlement program.⁸ Technologic advances in renal replacement therapy (*i.e.*, dialysis therapy and transplantation) have improved the outcomes for persons with renal failure. In the United States, there are approximately 400,000 persons with end-stage renal disease who are living today, a product of continued research and advances in treatment methods.⁹

Chronic renal failure can result from a number of conditions that cause permanent loss of nephrons, including diabetes, hypertension, glomerulonephritis, and polycystic kidney disease. Typically, the signs and symptoms of renal failure occur gradually and do not become evident until the disease is far advanced. This is because of the amazing compensatory ability of the kidneys. As kidney structures are destroyed, the remaining nephrons undergo structural and functional hypertrophy, each increasing its function as a means of compensating for those that have been lost (Fig. 24-2). It is only when the few remaining nephrons are destroyed that the manifestations of renal failure become evident.

Glomerular filtration rate

Number of functioning nephrons

■ **FIGURE 24-2** ■ Relation of renal function and nephron mass. Each kidney contains 1 million tiny nephrons. A proportional relation exists between the number of nephrons affected by disease and the resulting glomerular filtration rate. Regardless of cause, chronic renal failure results in progressive deterioration of glomerular filtration, tubular reabsorptive capacity, and endocrine functions of the kidneys. All forms of renal failure are characterized by a reduction in the GFR, reflecting a corresponding reduction in the number of functional nephrons.

Stages of Progression

The rate of nephron destruction differs from case to case, ranging from several months to many years. The progression of chronic renal failure usually occurs in four stages: diminished renal reserve, renal insufficiency, renal failure, and end-stage renal disease.⁵

Diminished Renal Reserve

Diminished renal reserve occurs when the GFR drops to approximately 50% of normal. At this point, the serum BUN and creatinine levels still are normal, and no symptoms of impaired renal function are evident. This is supported by the fact that many persons survive an entire lifetime with only one kidney. Because of the diminished reserve, the risk for development of azotemia increases with an additional renal insult, such as that caused by nephrotoxic drugs.

Renal Insufficiency

Renal insufficiency represents a reduction in the GFR to 20% to 50% of normal. During this stage, azotemia, anemia, and hypertension appear. Signs and symptoms of renal insufficiency do not begin to appear until more than 50% of the function in both kidneys is lost. As nephrons are destroyed, the remaining nephrons compensate for those that are lost by filtering more solute particles from the blood. Because the solute particles are osmotically active, they cause additional water to be lost in the urine. One of the earliest symptoms of renal insufficiency is isosthenuria or polyuria with urine that is almost isotonic with plasma.⁴

Conservative treatment during this stage includes measures to retard the deterioration of renal function and assist the body in managing the effects of impaired function. Because the kidneys have difficulty eliminating the waste products of protein metabolism, a restricted-protein diet usually produces fewer symptoms and slows progression of renal failure. The few remaining nephrons that constitute the functional reserve of the kidneys can be easily disrupted; at that point, renal failure progresses rapidly.

Renal Failure

Renal failure develops when the GFR is less than 20% of normal. At this point, the kidneys cannot regulate volume and solute composition, and edema, metabolic acidosis, and hyperkalemia develop. These alterations affect other body systems to cause neurologic, gastrointestinal, and cardiovascular manifestations.

End-Stage Renal Disease

End-stage renal disease (ESRD) occurs when the GFR is less than 5% of normal. Histologic findings of an end-stage kidney include a reduction in renal capillaries and scarring in the glomeruli. Atrophy and fibrosis are evident in the tubules. The mass of the kidneys usually is reduced. At this final phase of renal failure, treatment with dialysis or transplantation is necessary for survival.

Clinical Manifestations

The clinical manifestations of renal failure include alterations in water, electrolyte, and acid-base balance; mineral and skeletal disorders; anemia and coagulation disorders; hypertension and alterations in cardiovascular function; gastrointestinal disorders; neurologic complications; disorders of skin integrity; and immunologic disorders (Fig. 24-3). *Uremia*, which literally means "urine in the blood," is the term used to describe the clinical manifestations of ESRD. Uremia differs from azotemia, which merely indicates the accumulation of nitrogenous wastes in the blood and can occur without symptoms.

There currently are four target populations that comprise the entire population of persons with chronic renal failure: persons with chronic renal insufficiency, those with ESRD being treated with hemodialysis, those being treated with peritoneal dialysis, and renal transplant recipients. The manifestations of renal failure are determined largely by the extent of renal function that is present (*e.g.*, renal insufficiency, ESRD), coexisting disease conditions, and the type of renal replacement therapy the person is receiving.

Accumulation of Nitrogenous Wastes

The accumulation of nitrogenous wastes is an early sign of renal failure, usually occurring before other symptoms become evident. Urea is one of the first nitrogenous wastes to accumulate in the blood, and the BUN level becomes increasingly elevated as renal failure progresses. The normal concentration of urea in the plasma is usually less than 20 mg/dL. In renal failure, this level may rise to as high as 800 mg/dL. Creatinine, a by-product of muscle metabolism, is freely filtered in the glomerulus and is not reabsorbed in the renal tubules. Creatinine is produced at a relatively constant rate, and any creatinine that is filtered in the glomerulus is lost in the urine, rather than being reabsorbed into the blood. Thus, serum creatinine can be used as an indirect method for assessing the GFR and the extent of renal damage that has occurred in renal failure. Because creatinine is a by-product of muscle metabolism, serum values vary with age and muscle mass. An increase in serum creatinine to three times its normal value suggests that there is a 75% loss of renal function, and with creatinine levels of 10 mg/dL or more, it can be assumed that 90% of renal function has been lost. (See Chapter 22, Fig. 22-12.)

Disorders of Water, Electrolyte, and Acid-Base Balance

The kidneys function in the regulation of extracellular fluid volume. They do this by either eliminating or conserving sodium and water. Chronic renal failure can produce dehydration or fluid overload, depending on the pathology of the renal disease. In addition to volume regulation, the ability of the kidneys to concentrate the urine is diminished. With early losses in renal function, the specific gravity of the urine becomes fixed (1.008 to 1.012) and varies little from voiding to voiding. Polyuria and nocturia are common.

As renal function declines further, the ability to regulate sodium excretion is reduced. There is impaired ability to adjust to a sudden reduction in sodium intake and poor tolerance of an acute sodium overload. Volume depletion with an accompanying decrease in the GFR can occur with a restricted sodium intake or excess sodium loss caused by diarrhea or vomiting. Salt wasting is a common problem in advanced renal failure because of impaired tubular reabsorption of sodium. Increas-

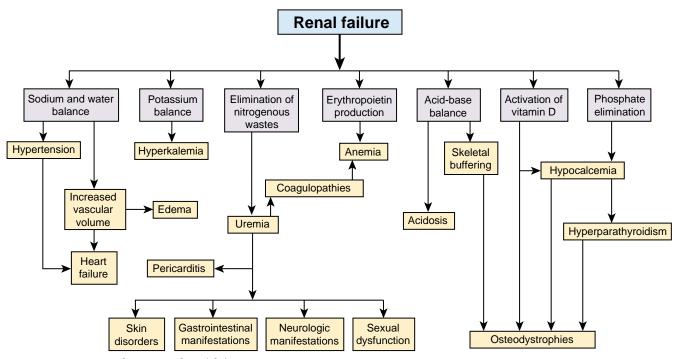

FIGURE 24-3 Manifestations of renal failure.

ing sodium intake in persons with chronic renal failure often improves the GFR and whatever renal function remains. In patients with associated hypertension, the possibility of increasing blood pressure or production of congestive heart failure often excludes supplemental sodium intake.

Approximately 90% of potassium excretion is through the kidneys. In renal failure, potassium excretion by each nephron increases as the kidneys adapt to a decrease in the GFR. As a result, hyperkalemia usually does not develop until renal function is severely compromised. Because of this adaptive mechanism, it usually is not necessary to restrict potassium intake in patients with chronic renal failure until the GFR has dropped below 5 mL/minute. In persons with ESRD, hyperkalemia often results from the failure to follow dietary potassium restrictions and ingestion of medications that contain potassium, or from an endogenous release of potassium, as in trauma or infection.

The kidneys normally regulate blood pH by eliminating hydrogen ions produced in metabolic processes and regenerating bicarbonate. This is achieved through hydrogen ion secretion, sodium and bicarbonate reabsorption, and the production of ammonia, which acts as a buffer for titratable acids (see Chapter 6). With a decline in renal function, these mechanisms become impaired, and metabolic acidosis results. In chronic renal failure, acidosis seems to stabilize as the disease progresses, probably as a result of the tremendous buffering capacity of bone. However, this buffering action is thought to increase bone resorption and contribute to the skeletal defects present in chronic renal failure.

Mineral Metabolism and Skeletal Disorders

Abnormalities of calcium, phosphate, and vitamin D occur early in the course of chronic renal failure.¹⁰ They involve the renal regulation of serum calcium and phosphate levels, activation of vitamin D, and regulation of parathyroid hormone (PTH) levels.

The regulation of serum phosphate levels requires a daily urinary excretion of an amount equal to that absorbed from the diet. With deteriorating renal function, phosphate excretion is impaired, and as a result, serum phosphate levels rise. At the same time, serum calcium levels fall because serum calcium is inversely regulated in relation to serum phosphate levels (see Chapter 6). The drop in serum calcium, in turn, stimulates PTH release, with a resultant increase in calcium resorption from bone. Most persons with ESRD develop secondary hyperparathyroidism, the result of chronic stimulation of the parathyroid glands. Although serum calcium levels are maintained through increased PTH function, this adjustment is accomplished at the expense of the skeletal system and other body organs.

The kidneys regulate vitamin D activity by converting the inactive form of vitamin D [25(OH) vitamin D₃] to its active form $(1,25-OH_2 \text{ vitamin } D_3)$. Decreased levels of active vitamin D lead to a decrease in intestinal absorption of calcium with a resultant increase in parathyroid hormone levels. Vitamin D also regulates osteoblast differentiation, thereby affecting bone matrix formation and mineralization.

Skeletal Disorders. The term renal osteodystrophy is used to describe the skeletal complications of ESRD.^{10,11} Several factors are thought to contribute to the development of renal osteodystrophy, including elevated serum phosphate levels, decreased serum calcium levels, impaired renal activation of vitamin D, and hyperparathyroidism. The skeletal changes that occur with renal failure have been divided into two major types of disorders: high-turnover and low-turnover osteodystrophy.5 Inherent to both of these conditions is abnormal reabsorption and defective remodeling of bone.

High-bone-turnover osteodystrophy, sometimes referred to as osteitis fibrosa,¹¹ is characterized by increased bone resorption and formation, with bone resorption predominating. The disorder is associated with secondary hyperparathyroidism; altered vitamin D metabolism along with resistance to the action of vitamin D; and impaired regulation of locally produced growth factors and inhibitors. There is an increase in both osteoblast and osteoclast numbers and activity. Although the osteoblasts produce excessive amounts of bone matrix, mineralization fails to keep pace, and there is a decrease in bone density and formation of porous and coarse-fibered bone. Cortical bone is affected more severely than cancellous bone. Marrow fibrosis is another component of osteitis fibrosa; it occurs in areas of increased bone cell activity. In advanced stages of the disorder, cysts may develop in the bone, a condition called osteitis fibrosa cystica.¹²

Low-bone-turnover osteodystrophy is characterized by decreased numbers of osteoblasts and low or reduced numbers of osteoclasts, a low rate of bone turnover, and an accumulation of unmineralized bone matrix.12 There are two forms of low-turnover osteodystrophy: osteomalacia and adynamic osteodystrophy. Osteomalacia, sometimes referred to as renal rickets, is characterized by a slow rate of bone formation and defects in bone mineralization. Until the 1980s, osteomalacia in ESRD resulted mainly from aluminum intoxication. Aluminum intoxication causes decreased and defective mineralization of bone by existing osteoblasts and more long-term inhibition of osteoblast differentiation. During the 1970s and 1980s, it was discovered that accumulation of aluminum from water used in dialysis and aluminum salts used as phosphate binders caused osteomalacia and advnamic bone disease.¹³ This discovery led to a change in the composition of dialysis solutions and substitution of calcium carbonate for aluminum salts as phosphate binders. As a result, the prevalence of osteomalacia in persons with ESRD is declining.

The second type of low-turnover osteodystrophy, advnamic osteodystrophy, is characterized by a low number of osteoblasts, the osteoclast number being normal or reduced.¹² In persons with adynamic bone disease, bone remodeling is greatly reduced, and the bone surfaces become hypocellular. Adynamic bone disease is associated with an increased fracture rate. The disease is associated with a "relative hypothyroidism." It has been suggested that hypersecretion of parathyroid hormone may be necessary to maintain normal rates of bone formation in persons with ESRD. Thus, this form of renal osteodystrophy is seen more commonly in persons with ESRD who do not have secondary hyperparathyroidism (i.e., those who have been treated with parathyroidectomy) or have been overtreated with calcium and vitamin D.

The symptoms of renal osteodystrophy, which occur late in the disease, include bone tenderness and muscle weakness. Proximal muscle weakness in the lower extremities is common, making it difficult to get out of a chair or climb stairs.¹¹ Fractures are more common with low-turnover osteomalacia and advnamic renal bone disease.

Early treatment of hyperphosphatemia and hypocalcemia is important to prevent or slow long-term skeletal complications.¹⁴ Activated forms of vitamin D and calcium supplements often are used to facilitate intestinal absorption of calcium, increase serum calcium levels, and reduce parathyroid hormone levels. Milk products and other foods high in phosphorus content are restricted in the diet. Oral phosphatebinding agents such as calcium carbonate may be prescribed to decrease absorption of phosphate from the gastrointestinal tract. Aluminum-containing antacids can contribute to the development of osteodystrophy and their use should be avoided except in acute situations.

Hematologic Disorders

Chronic anemia is the most profound hematologic alteration that accompanies renal failure. Anemia first appears when the GFR falls below 40 mL/minute and is present in most persons with ESRD.¹⁵ Several factors contribute to anemia in persons with chronic renal failure, including a erythropoietin deficiency, uremic toxins, and iron deficiency. The kidneys are the primary site for the production of the hormone *erythropoietin*, which controls red blood cell production. The accumulation of uremic toxins further suppresses red cell production in the bone marrow, and the cells that are produced have a shortened life span. Iron is essential for erythropoiesis. Many persons receiving maintenance hemodialysis also are iron deficient because of blood sampling and accidental loss of blood during dialysis. Other causes of iron deficiency include factors such as anorexia and dietary restrictions that limit intake.

When untreated, anemia causes or contributes to weakness, fatigue, depression, insomnia, and decreased cognitive function. There is also increasing concern regarding the physiologic effects of anemia on cardiovascular function. The anemia of renal failure produces a decrease in blood viscosity and a compensatory increase in heart rate. The decreased blood viscosity also exacerbates peripheral vasodilatation and contributes to decreased vascular resistance. Cardiac output increases in a compensatory fashion to maintain tissue perfusion. Echocardiographic studies after initiation of chronic dialysis have shown ventricular dilatation with compensatory left ventricular hypertrophy.¹⁵ Anemia also limits myocardial oxygen supply, particularly in persons with coronary heart disease, leading to angina pectoris and other ischemic events.¹⁶ Thus, anemia, when coupled with hypertension, may be a major contributing factor to the development of left ventricular dysfunction and congestive heart failure in persons with ESRD.

A remarkable advance in medical management of anemia in persons with ESRD occurred with the availability of recombinant human erythropoietin (rhEPO). Secondary benefits of treating anemia with rhEPO, previously attributed to the correction of uremia, include improvement in appetite, energy level, sexual function, skin color, and hair and nail growth, and reduced cold intolerance. Frequent measurements of hematocrit are necessary. Worsening hypertension and seizures have occurred when the hematocrit was raised too suddenly. Because iron deficiency is common among persons with chronic renal failure, iron supplementation often is needed. Iron can be given orally or intravenously. Intravenous iron may be used for treatment of persons who are not able to maintain adequate iron status with oral iron.

Bleeding disorders, which are manifested by epistaxis, menorrhagia, gastrointestinal bleeding, and bruising of the skin and subcutaneous tissues, are also common among persons with chronic renal failure. Although platelet production often is normal in ESRD, platelet function is impaired. Platelet function improves with dialysis but does not completely normalize, suggesting that uremia contributes to the problem. Anemia may accentuate the problem by changing the position of the platelets with respect to the vessel wall. Normally the red cells occupy the center of the bloodstream, and the platelets are in the skimming layer along the endothelial surface. In anemia, the platelets become dispersed, impairing the plateletendothelial cell adherence needed to initiate hemostasis.¹⁷

Cardiovascular Disorders

Cardiovascular disorders, including hypertension, left ventricular hypertrophy, and pericarditis, are a major cause of morbidity and mortality in patients with ESRD. Hypertension commonly is an early manifestation of chronic renal failure. The mechanisms that produce hypertension in ESRD are multifactorial; they include an increased vascular volume, elevation of peripheral vascular resistance, decreased levels of renal vasodilator prostaglandins, and increased activity of the reninangiotensin system.¹⁸ Early identification and aggressive treatment of hypertension has been shown to slow the rate of renal impairment in many types of renal disease. Treatment involves salt and water restriction and the use of antihypertensive medications to control blood pressure. Many persons with renal insufficiency need to take several antihypertensive medications to control blood pressure (see Chapter 16).

The spectrum of heart disease includes left ventricular hypertrophy and ischemic heart disease. People with ESRD tend to have an increased prevalence of left ventricular dysfunction, both with a depressed left ventricular ejection fraction, as in systolic dysfunction, as well as impaired ventricular filling, as in diastolic failure (see Chapter 18).¹⁹ There are multiple factors that lead to development of left ventricular dysfunction, including extracellular fluid overload, shunting of blood through an arteriovenous fistula for dialysis, and anemia. These abnormalities, coupled with the hypertension that often is present, cause increased myocardial work and oxygen demand, with eventual development of heart failure. Coexisting conditions that have been identified as contributing to the burden of cardiovascular disease include anemia, diabetes mellitus, dyslipidemia, and coagulopathies. Anemia, in particular, has been correlated with the presence of left ventricular hypertrophy.

Pericarditis occurs in approximately 20% of persons receiving chronic dialysis.²⁰ It can result from metabolic toxins associated with the uremic state or from dialysis. The manifestations of uremic pericarditis resemble those of viral pericarditis, with all its complications, including cardiac tamponade (see Chapter 17).

Gastrointestinal Disorders

Anorexia, nausea, and vomiting are common in patients with uremia, along with a metallic taste in the mouth that further depresses the appetite. Early-morning nausea is common. Ulceration and bleeding of the gastrointestinal mucosa may develop, and hiccups are common. A possible cause of nausea and vomiting is the decomposition of urea by intestinal flora, resulting in a high concentration of ammonia. Parathyroid hormone increases gastric acid secretion and contributes to gastrointestinal problems. Nausea and vomiting often improve with restriction of dietary protein and after initiation of dialysis and disappear after kidney transplantation.

Disorders of Neural Function

Many persons with chronic renal failure have alterations in peripheral and central nervous system function. Peripheral neuropathy, or involvement of the peripheral nerves, affects the lower limbs more frequently than the upper limbs. It is symmetric and affects both sensory and motor function. Neuropathy is caused by atrophy and demyelination of nerve fibers, possibly caused by uremic toxins. Restless legs syndrome is a manifestation of peripheral nerve involvement and can be seen in as many as two thirds of patients on dialysis. This syndrome is characterized by creeping, prickling, and itching sensations that typically are more intense at rest. Temporary relief is obtained by moving the legs. A burning sensation of the feet, which may be followed by muscle weakness and atrophy, is a manifestation of uremia.

The central nervous system disturbances in uremia are similar to those caused by other metabolic and toxic disorders. Sometimes referred to as *uremic encephalopathy*, the condition is poorly understood and may result, at least in part, from an excess of toxic organic acids that alter neural function. Electrolyte abnormalities, such as sodium shifts, also may contribute. The manifestations are more closely related to the progress of the uremic disorder than to the level of the metabolic endproducts. Reductions in alertness and awareness are the earliest and most significant indications of uremic encephalopathy. This often is followed by an inability to fix attention, loss of recent memory, and perceptual errors in identifying persons and objects. Delirium and coma occur late in the course; seizures are the preterminal event.

Disorders of motor function commonly accompany the neurologic manifestations of uremic encephalopathy. During the early stages, there often is difficulty in performing fine movements of the extremities; the gait becomes unsteady and clumsy with tremulousness of movement. Asterixis (dorsiflexion movements of the hands and feet) typically occurs as the disease progresses. It can be elicited by having the person hyperextend his or her arms at the elbow and wrist with the fingers spread apart. If asterixis is present, this position causes side-to-side flapping movements of the fingers.

Altered Immune Function

Infection is a common complication and cause of hospitalization and death of patients with chronic renal failure. Immunologic abnormalities decrease the efficiency of the immune response to infection. All aspects of inflammation and immune function may be affected adversely by the high levels of urea and metabolic wastes, including a decrease in granulocyte count, impaired humoral and cell-mediated immunity, and defective phagocyte function. The acute inflammatory response and delayed-type hypersensitivity response are impaired. Although persons with ESRD have normal humoral responses to vaccines, a more aggressive immunization program may be needed. Skin and mucosal barriers to infection also may be defective. In persons who are receiving dialysis, vascular access devices are common portals of entry for pathogens. Many persons with ESRD do not experience fever with infection, making the diagnosis more difficult.

Disorders of Skin Integrity

Skin manifestations are common in persons with ESRD. The skin often is pale because of anemia and may have a sallow, yellow-brown hue. The skin and mucous membranes often are dry, and subcutaneous bruising is common. Skin dryness is caused by a reduction in perspiration caused by the decreased size of sweat glands and the diminished activity of oil glands. Pruritus is common; it results from the high serum phosphate levels and the development of phosphate crystals that occur with hyperparathyroidism. Severe scratching and repeated needlesticks, especially with hemodialysis, break the skin integrity and increase the risk for infection. In the advanced stages of untreated renal failure, urea crystals may precipitate on the skin as a result of the high urea concentration in body fluids. The fingernails may become thin and brittle, with a dark band just behind the leading edge of the nail, followed by a white band. This appearance is known as Terry's nails.

Sexual Dysfunction

Alterations in physiologic sexual responses, reproductive ability, and libido are common. The cause probably is multifactorial and may result from high levels of uremic toxins, neuropathy, altered endocrine function, psychological factors, and medications (*e.g.*, antihypertensive drugs).

Impotence occurs in as many as 56% of male patients receiving dialysis.²¹ Derangements of the pituitary and gonadal hormones, such as decreases in testosterone levels and increases in prolactin and luteinizing hormone levels, are common and cause erectile difficulties and decreased spermatocyte counts. Loss of libido may result from chronic anemia and decreased testosterone levels. Several drugs, such as exogenous testosterone and bromocriptine, have been used in an attempt to return hormone levels to normal.

Impaired sexual function in women is manifested by abnormal levels of progesterone, luteinizing hormone, and prolactin. Hypofertility, menstrual abnormalities, decreased vaginal lubrication, and various orgasmic problems have been described.²² Amenorrhea is common among women who are receiving dialysis therapy.

Elimination of Drugs

The kidneys are responsible for the elimination of many drugs and their metabolites.⁶ Renal failure and its treatment can interfere with the absorption, distribution, and elimination of drugs. The administration of large quantities of phosphatebinding antacids to control hyperphosphatemia and hypocalcemia in patients with advanced renal failure interferes with the absorption of some drugs. Many drugs are bound to plasma proteins, such as albumin, for transport in the body; the unbound portion of the drug is available to act at the various receptor sites and is free to be metabolized. A decrease in plasma proteins, particularly albumin, that occurs in many persons with ESRD results in less protein-bound drug and greater amounts of free drug.

Decreased elimination by the kidneys allows drugs or their metabolites to accumulate in the body and requires that drug dosages be adjusted accordingly. Some drugs contain unwanted nitrogen, sodium, potassium, and magnesium and must be avoided in patients with renal failure. For example, penicillin contains potassium. Nitrofurantoin and ammonium chloride add to the body's nitrogen pool. Many antacids contain magnesium. Because of problems with drug dosing and elimination, persons with renal failure should be cautioned against the use of over-the-counter remedies.

Treatment

During the past several decades, an increasing number of persons have required renal replacement therapy with dialysis or transplantation. The growing volume is largely attributable to the improvement in treatment and more liberal policies regarding who is treated. Between 1980 and 1992, there was a twofold reported increase in treatment for ESRD.²³ In 1998, almost 245,910 persons were receiving dialysis therapy in the United States, and another 13,272 underwent kidney transplantation.²⁴

Medical Management

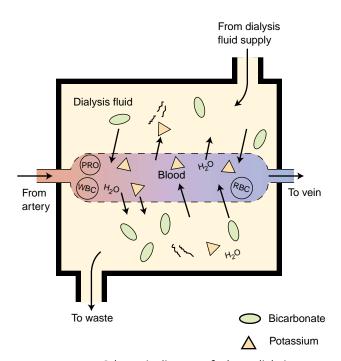

Chronic renal failure can be treated by conservative management of renal insufficiency and by renal replacement therapy with dialysis or transplantation. Conservative treatment consists of measures to prevent or retard deterioration in remaining renal function and to assist the body in compensating for the existing impairment. Interventions that have been shown to significantly retard the progression of chronic renal insufficiency include dietary protein restriction and blood pressure normalization. Various interventions are used to compensate for reduced renal function and correct the resulting anemia, hypocalcemia, and acidosis. These interventions often are used in conjunction with dialysis therapy for patients with ESRD.

Dialysis and Transplantation

Dialysis or renal replacement therapy is indicated when advanced uremia or serious electrolyte imbalances are present. The choice between dialysis and transplantation is dictated by age, related health problems, donor availability, and personal preference. Although transplantation often is the treatment preference, dialysis plays a critical role as a treatment method for ESRD. It is life sustaining for persons who are not candidates for transplantation or who are awaiting transplantation. There are two broad categories of dialysis: hemodialysis and peritoneal dialysis.

Hemodialysis. The basic principles of hemodialysis have remained unchanged throughout the years, although new technology has improved the efficiency and speed of dialysis.²⁵ A hemodialysis system, or artificial kidney, consists of three parts: a blood compartment, a dialysis fluid compartment, and a cellophane membrane that separates the two compartments. The cellophane membrane is semipermeable, permitting all molecules except blood cells and plasma proteins to move freely in both directions-from the blood into the dialyzing solution and from the dialyzing solution into the blood. The direction of flow is determined by the concentration of the substances contained in the two solutions. The waste products and excess electrolytes in the blood normally diffuse into the dialyzing solution. If there is a need to replace or add substances, such as bicarbonate, to the blood, these can be added to the dialyzing solution (Fig. 24-4).

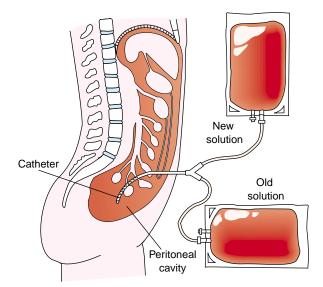

During dialysis, blood moves from an artery through the tubing and blood chamber in the dialysis machine and then

■ FIGURE 24-4 ■ Schematic diagram of a hemodialysis system. The blood compartment and dialysis solution compartment are separated by a cellophane membrane. This membrane is porous enough to allow all the constituents, except the plasma proteins and blood cells, to diffuse between the two compartments.

back into the body through a vein. Access to the vascular system is accomplished through an external arteriovenous shunt (*i.e.*, tubing implanted into an artery and a vein) or, more commonly, through an internal arteriovenous fistula (*i.e.*, anastomosis of a vein to an artery, usually in the forearm). Heparin is used to prevent clotting during the dialysis treatment; it can be administered continuously or intermittently.

Peritoneal Dialysis. Peritoneal dialysis uses the same principles of diffusion, osmosis, and ultrafiltration that apply to hemodialysis. The thin serous membrane of the peritoneal cavity serves as the dialyzing membrane. A silastic catheter is surgically implanted in the peritoneal cavity below the umbilicus to provide access. The catheter is tunneled through subcutaneous tissue and exits on the side of the abdomen (Fig. 24-5). The dialysis process involves instilling a sterile dialyzing solution (usually 2 L) through the catheter during a period of approximately 10 minutes. The solution then is allowed to remain, or dwell, in the peritoneal cavity for a prescribed amount of time, during which the metabolic endproducts and extracellular fluid diffuse into the dialysis solution. At the end of the dwell time, the dialysis fluid is drained out of the peritoneal cavity by gravity into a sterile bag. Glucose in the dialysis solution accounts for water removal. Commercial dialysis solution is available in 1.5%, 2.5%, and 4.25% dextrose concentrations. Solutions with higher dextrose levels increase osmosis, causing more fluid to be removed. The most common method is continuous ambulatory peritoneal dialysis (CAPD), a self-care procedure in which the person manages the dialysis procedure and the type of solution (*i.e.*, dextrose concentration) used at home.

■ FIGURE 24-5 ■ Peritoneal dialysis. A semipermeable membrane, richly supplied with small blood vessels, lines the peritoneal cavity. With dialysate dwelling in the peritoneal cavity, waste products diffuse from the network of blood cells into the dialysate.

Transplantation. Greatly improved success rates have made kidney transplantation the treatment of choice for many patients with chronic renal failure. The availability of donor organs continues to limit the number of transplantations performed each year. Donor organs are obtained from cadavers and living related donors (*e.g.*, parent, sibling). The success of transplantation depends primarily on the degree of histocompatibility, adequate organ preservation, and immunologic management.²⁶

In summary, chronic renal failure results from the destructive effects of many forms of renal disease. Regardless of the cause, the consequences of nephron destruction in ESRD are alterations in the filtration, reabsorption, and endocrine functions of the kidneys. The progression of chronic renal failure usually occurs in four stages: diminished renal reserve, renal insufficiency, renal failure, and ESRD. Renal insufficiency represents a reduction in the GFR to approximately 20% to 50% of normal; renal failure, a reduction to less than 20% to 25% of normal; and ESRD, a decrease in GFR to less than 5% of normal.

End-stage renal disease affects almost every body system. It causes an accumulation of nitrogenous wastes (*i.e.*, azotemia), alters sodium and water excretion, and alters regulation of body levels of potassium, phosphate, calcium, and magnesium. It also causes skeletal disorders, anemia, alterations in cardiovascular function, neurologic disturbances, gastrointestinal dysfunction, and discomforting skin changes.

The treatment of ESRD can be divided into two types: conservative management of renal insufficiency and renal replacement therapy with dialysis or transplantation. Conservative treatment consists of measures to prevent or retard deterioration in remaining renal function and to assist the body in compensating for the existing impairment.

RENAL FAILURE IN CHILDREN AND ELDERLY PERSONS

Although the spectrum of renal disease among children and elderly persons is similar to that of adults, several unique issues affecting these groups warrant further discussion.

Chronic Renal Failure in Children

The true incidence of chronic renal failure in infants and children is unknown. The data indicate that 2500 people in the United States who are younger than 20 years of age begin treatment for chronic renal failure each year; 100 of these children are younger than 2 years of age.²⁷ The most common cause of chronic renal failure in children is glomerulonephritis and congenital malformations, such as renal hypoplasia or dysplasia, obstructive uropathy, and reflux nephropathy.²⁸

Features of renal disease that are marked during childhood include severe growth impairment, developmental delay, delay in sexual maturation, bone abnormalities, and development of psychosocial problems.^{27,29} Critical growth periods occur during the first 2 years of life and during adolescence. Physical growth and cognitive development occur at a slower rate as consequences of renal disease, especially among children with congenital renal disease. Puberty usually occurs at a later age in children with renal failure, partly because of endocrine abnormalities. Renal osteodystrophy is more common and extensive in children than in adults because of the presence of open epiphyses. As a result, metaphyseal fractures, bone pain, impaired bone growth, short stature, and osteitis fibrosa cystica occur with greater frequency. Some hereditary renal diseases, such as medullary cystic disease, have patterns of skeletal involvement that further complicate the problems of renal osteodystrophy. Factors related to impaired growth include deficient nutrition, anemia, renal osteodystrophy, chronic acidosis, and cases of nephrotic syndrome that require high-dose corticosteroid therapy.

The success of treatment depends on the level of bone maturation at the initiation of therapy. Nutrition is believed to be the most important determinant during infancy. During childhood, growth hormone is important, and gonadotropic hormones become important during puberty.³⁰ Parental heights provide a means of assessing growth potential. For many children, catch-up growth is important because a growth deficit frequently is established during the first months of life. Recombinant human growth hormone therapy has been used to improve growth in children with ESRD.³⁰ Success of treatment depends on the level of bone maturation at the initiation of therapy.

All forms of renal replacement therapy can be safely and reliably used for children. Children typically are treated with CAPD or transplantation to optimize growth and development.²⁸ An alternative to CAPD is continuous cyclic peritoneal dialysis. The procedure reverses the schedule of CAPD by providing the exchanges at night, rather than during the day. The exchanges are performed automatically during sleep by a simple cycler machine. Renal transplantation is considered the best alternative for children.³¹ Early transplantation in young children is regarded as the best way to promote physical growth, improve cognitive function, and foster psychosocial development.³¹ Immunosuppressive therapy in children is similar to that used in adults. All of these immunosuppressive agents have side effects, including increased risk of infection. Corticosteroids, which have been the mainstay of chronic immunosuppressive therapy for decades, carry the risk of hypertension, orthopedic complications (especially aseptic necrosis), cataracts, and growth retardation.

Chronic Renal Failure in Elderly Persons

Since the mid-1980s, there have been increasing numbers of elderly persons accepted to ESRD programs. In 2001, 20.1% of persons being treated for ESRD were 65 to 74 years of age, and 14.4% were older than 75 years of age.³² Among elderly persons, the presentation and course of renal failure may be altered because of age-related changes in the kidneys and concurrent medical conditions.

Normal aging is associated with a decline in the GFR and subsequently with reduced homeostatic regulation under stressful conditions.³³ This reduction in GFR makes elderly persons more susceptible to the detrimental effects of nephrotoxic drugs, such as radiographic contrast compounds. The reduction in GFR related to aging is not accompanied by a parallel increase in the serum creatinine level because the serum creatinine level, which results from muscle metabolism, is significantly reduced in elderly persons because of diminished muscle mass and other age-related changes. Evaluation of renal function in elderly persons should include a measurement of creatinine clearance along with the serum creatinine level.

The prevalence of chronic disease affecting the cerebrovascular, cardiovascular, and skeletal systems is higher in this age group. Because of concurrent disease, the presenting symptoms of renal disease in elderly persons may be less typical than those observed in younger adults. For example, congestive heart failure and hypertension may be the dominant clinical features with the onset of acute glomerulonephritis, whereas oliguria and discolored urine more often are the first signs in younger adults. The course of renal failure may be more complicated in older patients with numerous chronic diseases.

Treatment options for chronic renal failure in elderly patients with ESRD include hemodialysis and peritoneal dialysis. Neither hemodialysis nor peritoneal dialysis has proven to be superior in the elderly. Many transplantation centers have increased the age for acceptance on transplant waiting lists, so renal transplantation provides another option. The general reduction in T-cell function that occurs with aging has been suggested as a beneficial effect that increases transplant graft survival.

In summary, there is approximately a 2% per year incidence of renal failure in children, most frequently resulting from congenital malformations and glomerulonephritis. Problems associated with renal failure in children include growth impairment, delay in sexual maturation, and more extensive bone abnormalities than in adults. Although all forms of renal replacement therapy can be safely and reliably used for children, CAPD or transplantation optimize growth and development. Adults 65 years of age and older account for close to one half of the new cases of ESRD each year. Normal aging is associated with a decline in the GFR, which makes elderly persons more susceptible to the detrimental effects of nephrotoxic drugs and other conditions that compromise renal function. Treatment options for chronic renal failure in elderly patients are similar to those for younger persons.

REVIEW QUESTIONS

Compare acute and chronic renal failure in terms of reversibility.

Differentiate the prerenal, intrinsic, and extrarenal forms of acute renal failure in terms of the mechanisms of development and manifestations.

Cite the two most common causes of acute tubular necrosis and describe the course of the disease in terms of the initiation, maintenance, and recovery phases.

State the definitions of renal impairment, renal insufficiency, renal failure, and end-stage renal disease.

List the common problems associated with end-stage renal disease, including alterations in fluid and electrolyte balance and disorders of skeletal, hematologic, cardiovascular, immune, neurologic, skin, and sexual function, and explain their physiologic significance.

Describe the scientific principles underlying dialysis treatment, and compare hemodialysis with peritoneal dialysis.

List the causes of renal failure in children and describe the special problems of children with ESRD.

Explain why renal failure is so common in the elderly, and describe measures to prevent or delay the onset of ESRD in this population.

CHAPTER

Ithough the kidneys control the formation of urine and regulate the composition of body fluids, it is the bladder that stores urine and controls its elimination from the body. Alterations in the storage and expulsion functions of the bladder can result in incontinence, with its accompanying social and hygienic problems, or obstruction of urine flow, which has deleterious effects on ureteral and, ultimately, renal function. The discussion in this chapter focuses on normal control of urine elimination, urinary obstruction and stasis, neurogenic bladder, incontinence, and bladder cancer. Urinary tract infections are discussed in Chapter 23.

CONTROL OF URINE ELIMINATION

The urinary bladder, also known as the urinary vesicle, is a freely movable organ located behind the pelvic bone in the male and in front of the vagina in the female. It consists of two parts: the fundus, or body, and the neck, or posterior urethra. In the man, the urethra continues anteriorly through the penis. Urine passes from the kidneys to the bladder through the ureters. The ureters enter the bladder obliquely through the *trigone*, a triangular area located above the bladder neck on the posterior wall of the bladder (Fig. 25-1). There are no valves at the ureteral openings, but because of their oblique position in the bladder wall, the pressure of the urine keeps the ends of the ureters compressed to prevent the backflow of urine from the bladder into the ureters.

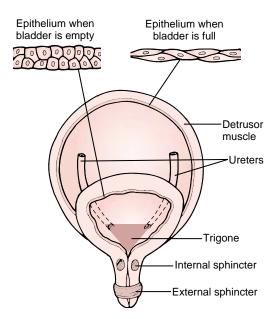

Bladder Structure

The bladder is composed of four layers. The first is an outer serosal layer, which covers the upper surface and is continuous with the peritoneum. The second is a network of smooth muscle fibers called the *detrusor muscle*. The third is a submucosal layer of loose connective tissue, and the fourth is an inner mucosal lining of transitional epithelium.

The tonicity of the urine often is quite different from that of the blood, and the transitional epithelial lining of the bladder acts as an effective barrier to prevent the passage of water between the bladder contents and the blood. The inner elements of the bladder form smooth folds, or rugae. As the bladder expands during filling, these rugae spread out to form a single layer without disrupting the integrity of the epithelial lining.

The detrusor muscle is the muscle of micturition (passage of urine). When it contracts, urine is expelled from the bladder. The abdominal muscles play a secondary role in micturition. Their contraction increases intra-abdominal pressure, which further increases intravesicular pressure.

Muscles in the bladder neck, sometimes referred to as the *internal sphincter*, are a continuation of the detrusor muscle. They run down obliquely behind the proximal urethra, forming the posterior urethra in males and the entire urethra in females. When the bladder is relaxed, these circular muscle fibers

■ FIGURE 25-1 ■ Diagram of the bladder, showing the detrusor muscle, ureters, trigone area, and urethral orifice. Note the flattening of epithelial cells when the bladder is full and the wall is stretched.

are closed and act as a sphincter. When the detrusor muscle contracts, the sphincter is pulled open by the changes that occur in bladder shape. In the female, the urethra (2.5 to 3.5 cm) is shorter than that in the male (16.5 to 18.5 cm) and usually affords less resistance to urine outflow.

Another muscle important to bladder function is the *external sphincter*, a circular muscle composed of striated muscle fibers that surrounds the urethra distal to the base of the bladder. The external sphincter operates as a reserve mechanism to stop micturition when it is occurring and to maintain continence in the face of unusually high bladder pressure. The skeletal muscles of the pelvic floor also contribute to the support of the bladder and the maintenance of continence.

Micturition

To maintain continence, or retention of urine, the bladder must function as a low-pressure storage system; the pressure in the bladder must remain lower than urethral pressure. To ensure that this condition is met, the increase in intravesicular pressure that accompanies bladder filling is almost imperceptible. An increase in bladder volume from 10 to 400 mL may be accompanied by only a 5 cm H₂O increase in pressure.¹ Sustained elevations in intravesicular pressures (>40 to 50 cm H₂O) often are associated with vesicoureteral reflux (*i.e.*, backflow of urine from the bladder into the ureter) and the development of ureteral dilatation (see Chapter 23). Although the pressure in the bladder is maintained at low levels, sphincter pressure remains high (45 to 65 cm H₂O) as a means of preventing loss of urine as the bladder fills.

Micturition involves both sensory and motor functions associated with bladder emptying. When the bladder is distended to 150 to 300 mL, the sensation of fullness is transmitted to the spinal cord and then to the cerebral cortex, allowing for conscious inhibition of the micturition reflex. During the act of micturition, the detrusor muscle of the bladder fundus and bladder neck contract down on the urine; the ureteral orifices are forced shut; the bladder neck is widened and shortened as it is pulled up by the globular muscles in the bladder fundus; the resistance of the internal sphincter in the bladder neck is decreased; and the external sphincter relaxes as urine moves out of the bladder.

Neural Control of Bladder Function

The control of bladder emptying is unique in that it involves both involuntary autonomic nervous system (ANS) reflexes and some voluntary control. The ANS and its neuromediators play a central role in micturition. The somatic nervous system controls the external sphincter and contributes to the voluntary control of bladder emptying.

The parasympathetic nervous system produces contraction of the detrusor muscle and bladder emptying. Parasympathetic innervation of the bladder is mediated by cholinergic (muscarinic) receptors and the neurotransmitter acetylcholine.²

Sympathetic innervation, although not essential to the act of micturition, allows the bladder to store a large volume without the involuntary escape of urine—a mechanism that is consistent with the fight-or-flight function subserved by the sympathetic nervous system. The bladder is supplied with α_1 - and β_2 -adrenergic receptors. The β_2 -adrenergic receptors are found in the detrusor muscle; they produce relaxation of the detrusor muscle, increasing the bladder volume at which the micturition reflex is triggered. The α_1 -adrenergic receptors are found in the trigone area, including the intramural ureteral musculature, bladder neck, and internal sphincter. The activation of α_1 receptors produces contraction of these muscles. Sympathetic activity ceases when the micturition reflex is activated. During male ejaculation, which is mediated by the sympathetic nervous system, the musculature of the trigone area and that of the

KEY CONCEPTS

BLADDER FUNCTION

- The storage and emptying of urine involve both involuntary (autonomic nervous system) and voluntary (somatic nervous system) control.
- The parasympathetic nervous system promotes bladder emptying. It produces contraction of the smooth muscle of the bladder wall and relaxation of the internal sphincter.
- The sympathetic nervous system promotes bladder filling. It produces relaxation of the smooth muscle of the bladder wall and contraction of the internal sphincter.
- The striated muscles in the external sphincter and pelvic floor, which are innervated by the somatic nervous system, provide for the voluntary control of urination and maintenance of continence.

bladder neck and prostatic urethra contracts and prevents the backflow of seminal fluid into the bladder.

There are three main levels of neurologic control for bladder function: (1) the spinal cord reflex centers, (2) the micturition center in the pons, and (3) the cortical and subcortical centers.

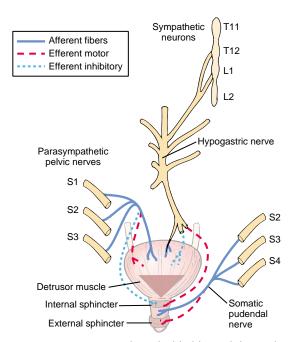

Spinal Cord Centers

The centers for reflex control of bladder emptying or micturition are located in the sacral (S1 through S4) and thoracolumbar (T11 through L2) segments of the spinal cord (Fig. 25-2). The parasympathetic motor neurons that innervate the detrusor muscle of the bladder are located in the sacral segments of the spinal cord; their axons travel to the bladder by way of the *pelvic nerve*. Motor neurons for the external sphincter also are located in the sacral segments of the spinal cord. These motor neurons receive their control from the motor cortex by way of the corticospinal tract and send impulses to the external sphincter through the *pudendal nerve*. The bladder neck and trigone area of the bladder are innervated by the sympathetic fibers from the thoracolumbar segments of the spinal cord.

The afferent or sensory input, which detects stretch of the bladder wall, is carried to the central nervous system (CNS) by way of fibers that travel with the parasympathetic (pelvic), somatic (pudendal), and sympathetic (hypogastric) nerves. The pelvic nerve carries sensory fibers from the stretch receptors in the bladder wall; the pudendal nerve carries sensory fibers from the external sphincter and pelvic muscles; and the hypogastric nerve carries sensory fibers from the trigone area.

Pontine Micturition Center

The immediate coordination of the normal micturition reflex occurs in the micturition center in the pons, facilitated by descending input from the forebrain and ascending input from the reflex centers in the spinal cord^{3,4} (Fig. 25-3). This center coordinates the activity of the detrusor muscle and the external

■ FIGURE 25-2 ■ Nerve supply to the bladder and the urethra.

sphincter. As bladder filling occurs, and the muscle stretch receptors are activated, ascending spinal afferents relay this information to the micturition center, which also receives important descending information from the forebrain concerning behavioral cues for bladder emptying. Descending pathways from the pontine micturition center produce coordinated inhibition of neurons controlling the internal and external sphincters. The onset of urinary flow through the urethra causes reflex contraction of the bladder.

Cortical and Subcortical Centers

Cortical brain centers enable inhibition of the micturition center in the pons and conscious control of urination. Neural influences from the subcortical centers in the basal ganglia, which are conveyed by extrapyramidal pathways, modulate the contractile response. They modify and delay the detrusor contractile response during filling and then modulate the expulsive activity of the bladder to facilitate complete emptying.

Development of Bladder Control in Children

In infants and young children, micturition is an involuntary act that is triggered by a spinal cord reflex; when the bladder fills to a given capacity, the detrusor muscle contracts and the external sphincter relaxes. As the bladder grows and increases in capacity, the tone of the external sphincter muscle increases. At 2 to 3 years of age, the child becomes conscious of the need to urinate and can learn to contract the pelvic muscles to maintain closure of the external sphincter and delay urination. As the nervous system continues to mature, inhibition of involuntary detrusor muscle activity takes place. After the child achieves continence, micturition becomes voluntary.

Evaluation of Bladder Function

Bladder structure and function can be assessed by a number of methods.⁵ Reports or observations of frequency, hesitancy, straining to void, and a weak or interrupted stream are suggestive of outflow obstruction. Palpation and percussion provide information about bladder distention.

Postvoided residual (PVR) urine volume provides information about bladder emptying. It can be estimated by abdominal palpation and percussion. Catheterization and ultrasonography can be used to obtain specific measurements of PVR. A PVR value of less than 50 mL is considered adequate bladder emptying, and more than 200 mL indicates inadequate bladder emptying.⁶

Pelvic examination is used in women to assess perineal skin condition, perivaginal muscle tone, genital atrophy, pelvic prolapse (*e.g.*, cystocele, rectocele, uterine prolapse), pelvic mass, or other conditions that may impair bladder function. Bimanual examination (*i.e.*, pelvic and abdominal palpation) can be used to assess PVR volume. Rectal examination is used to test for perineal sensation, sphincter tone, fecal impaction, and rectal mass. It is used to assess the contour of the prostate in men.

Urine tests provide information about kidney function and urinary tract infections. The presence of bacteriuria or pyuria suggests urinary tract infection and the possibility of urinary tract obstruction. Blood tests (*i.e.*, blood urea nitrogen and creatinine) provide information about renal function.

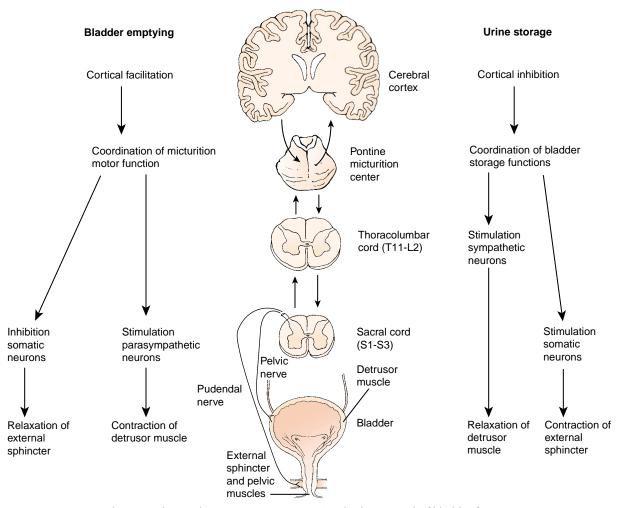

FIGURE 25-3 Pathways and central nervous system centers involved in control of bladder function. Efferent pathways for micturition (**left**) and urine storage (**right**).

Bladder structures can be visualized indirectly by taking x-ray films of the abdomen and by using excretory urography, which involves the use of a radiopaque dye, computed tomographic (CT) scanning, magnetic resonance imaging (MRI), or ultrasonography. Cystoscopy enables direct visualization of the urethra, bladder, and ureteral orifices. The ultrasound bladder scan provides a noninvasive method for estimating bladder volume. Urodynamic studies may be used to study bladder function and voiding problems.

In summary, although the kidneys function in the formation of urine and the regulation of body fluids, it is the bladder that stores and controls the elimination of urine. Micturition is a function of the peripheral ANS, subject to facilitation or inhibition from higher neurologic centers. The parasympathetic nervous system controls the motor function of the bladder detrusor muscle and the tone of the internal sphincter; its cell bodies are located in the sacral spinal cord and communicate with the bladder through the pelvic nerve. Efferent sympathetic control originates at the level of segments T11 through L2 of the spinal cord and produces relaxation of the detrusor muscle and contraction of the internal sphincter. Skeletal muscle found in the external sphincter and the pelvic muscles that support the bladder are supplied by the pudendal nerve, which exits the spinal cord at the level of segments S2 through S4. The micturition center in the brain stem coordinates the action of the detrusor muscle and the external sphincter, whereas cortical centers permit conscious control of micturition.

Bladder function can be evaluated using urodynamic studies that measure bladder, urethral, and abdominal pressures; urine flow characteristics; and skeletal muscle activity of the external sphincter.

ALTERATIONS IN BLADDER FUNCTION

Alterations in bladder function include urinary obstruction with retention or stasis of urine and urinary incontinence with involuntary loss of urine. Although the two conditions have almost opposite effects on urination, they can have similar causes. Both can result from structural changes in the bladder, urethra, or surrounding organs or from impairment of neurologic control of bladder function.

Urinary Obstruction and Stasis

In lower urinary tract obstruction and stasis, urine is produced normally by the kidneys but is retained in the bladder. Obstructions are classified according to cause (congenital or acquired), degree (partial or complete), duration (acute or chronic), and level (upper or lower urinary tract).⁷ Because it has the potential to produce vesicoureteral reflux and cause kidney damage, urinary obstruction and stasis is a serious disorder.

Congenital narrowing of the external meatus (*i.e.*, meatal stenosis) is more common in boys, and obstructive disorders of the posterior urethra are more common in girls. Another common cause of congenital obstruction is the damage to sacral nerves that occurs in spina bifida and meningomyelocele.

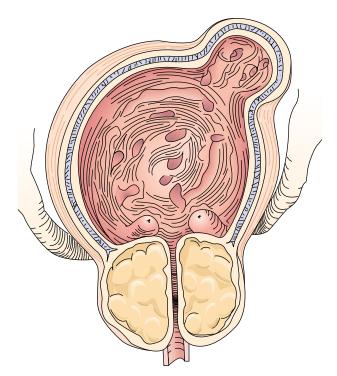

The acquired causes of lower urinary tract obstruction and stasis are numerous. In males, the most important cause of urinary obstruction is external compression of the urethra caused by the enlargement of the prostate gland. Gonorrhea and other sexually transmitted diseases contribute to the incidence of infection-produced urethral strictures. Bladder tumors and secondary invasion of the bladder by tumors arising in structures that surround the bladder and urethra can compress the bladder neck or urethra and cause obstruction. Constipation and fecal impaction can compress the urethra and produce urethral obstruction. This can be a particular problem in elderly persons.

The body compensates for the obstruction of urine outflow with mechanisms designed to prevent urine retention. These mechanisms can be divided into two stages: a compensatory stage and a decompensatory stage.⁷ The degree to which these changes occur and their effect on bladder structure and urinary function depend on the extent of the obstruction, the rapidity with which it occurs, and the presence of other contributing factors, such as neurologic impairment and infection.

During the early stage of obstruction, the bladder begins to hypertrophy and becomes hypersensitive to afferent stimuli arising from bladder filling. The ability to suppress urination is diminished, and bladder contraction can become so strong that it virtually produces bladder spasm. There is urgency, sometimes to the point of incontinence, and frequency during the day and at night.

With continuation and progression of the obstruction, compensatory changes begin to occur. There is further hypertrophy of the bladder muscle, the thickness of the bladder wall may double, and the pressure generated by detrusor contraction can increase from a normal 20 to 40 cm H_2O to 50 to 100 cm H_2O to overcome the resistance from the obstruction. As the force needed to expel urine from the bladder increases, compensatory mechanisms may become ineffective, causing muscle fatigue before complete emptying can be accomplished. After a few minutes, voiding can again be initiated and completed, accounting for the frequency of urination.

The inner bladder surface forms smooth folds. With continued outflow obstruction, this smooth surface is replaced with coarsely woven structures (*i.e.*, hypertrophied smooth muscle fibers) called *trabeculae*. Small pockets of mucosal tissue, called *cellules*, commonly develop between the trabecular ridges. These pockets form diverticula when they extend between the actual fibers of the bladder muscle (Fig. 25-4). Because the diverticula have no muscle, they are unable to contract and expel their urine into the bladder, and secondary infections caused by stasis are common.

■ FIGURE 25-4 ■ Destructive changes of the bladder wall with development of diverticula caused by benign prostatic hypertrophy.

Along with hypertrophy of the bladder wall, there is hypertrophy of the trigone area and the interureteric ridge, which is located between the two ureters. This causes backpressure on the ureters, the development of hydroureters, vesicourethral reflux, and eventually, kidney damage (see Chapter 23). Stasis of urine predisposes to urinary tract infections.

When compensatory mechanisms no longer are effective, signs of decompensation begin to appear. The period of detrusor muscle contraction becomes too short to completely expel the urine, and residual urine remains in the bladder. At this point, the symptoms of obstruction—frequency of urination, hesitancy, a need to strain to initiate urination, a weak and small stream, and termination of the stream before the bladder is completely emptied—become pronounced. The amount of residual urine may increase to 1000 to 3000 mL, and overflow incontinence occurs. There also may be acute retention of urine. The signs of urine retention are summarized in Chart 25-1.

CHART 25-1 Signs of Outflow Obstruction and Urine Retention

Bladder distention Hesitancy Straining when initiating urination Small and weak stream Frequency Feeling of incomplete bladder emptying Overflow incontinence

KEY CONCEPTS

NEUROGENIC BLADDER DISORDERS

- Neurogenic disorders of the bladder commonly are manifested by spastic bladder dysfunction, in which there is failure to store urine, or as flaccid bladder dysfunction, in which bladder emptying is impaired.
- Spastic bladder dysfunction results from neurologic lesions above the level of the sacral cord that allow neurons in the micturition center to function reflexively without control from higher central nervous system centers.
- Flaccid bladder dysfunction results from neurologic disorders affecting the motor neurons in the sacral cord or peripheral nerves that control detrusor muscle contraction and bladder emptying.

The immediate treatment of lower urinary obstruction and stasis is directed toward relief of bladder distention. This usually is accomplished through urinary catheterization (discussed later in this chapter). Constipation or fecal impaction should be corrected. Long-term treatment is directed toward correcting the problem causing the obstruction.

Neurogenic Bladder Disorders

The urinary bladder is unique in that it is probably the only ANS innervated visceral organ that is under CNS control. The neural control of bladder function can be interrupted at any level. It can be interrupted at the level of the peripheral nerves that connect the bladder to the reflex micturition center in the sacral cord, the ascending and descending tracts in the spinal cord, the pontine micturition center, or the cortical centers that are involved in voluntary control of micturition.^{8,9} Neurogenic disorders of bladder function commonly are manifested in one of two ways: failure to store urine (spastic bladder dysfunction) or failure to empty (flaccid bladder dysfunction). The neural pathways involved in the emptying and storage functions of the bladder are illustrated in Figure 25-3. Spastic bladder dysfunction usually results from neurologic lesions located above the level of the sacral micturition reflexes, whereas flaccid bladder dysfunction results from lesions at the level of sacral reflexes or the peripheral nerves that innervate the bladder. In addition to disorders of detrusor muscle function, disruption of micturition occurs when the neurologic control of external sphincter function is disrupted. Some disorders, such as stroke and Parkinson's disease, may affect both the storage and emptying functions of the bladder. Table 25-1 describes the characteristics of neurogenic bladder according to the level of the lesion.

Spastic Bladder: Failure to Store Urine

Failure to store urine results from conditions that cause reflex bladder spasm and a decrease in bladder volume. It commonly is caused by conditions that produce partial or extensive neural damage above the micturition reflex center in the sacral cord. As a result, bladder function is regulated by segmental reflexes, without control from higher brain centers. The degree of bladder spasticity and dysfunction depends on the level and extent of neurologic dysfunction. Usually both the ANS neurons controlling bladder function and the somatic neurons controlling the function of the striated muscles in the external sphincter are affected. In some cases, there is a detrusor-sphincter dyssynergia with uncoordinated contraction and relaxation of the detrusor and external sphincter muscles. The most common causes of spastic bladder dysfunction are spinal cord lesions such as spinal cord injury, herniated intervertebral disk, vascular lesions, tumors, and myelitis. Other neurologic conditions that affect voiding are stroke, multiple sclerosis, and brain tumors.

TABLE 25-1 Types and Characteristics of Neurogenic Bladder				
Level of Lesion	Change in Bladder Function	Common Causes		
Sensory cortex, motor cortex, or corticospinal tract	Loss of ability to perceive bladder filling; low-volume, physiologically normal micturition that occurs suddenly and is difficult to inhibit	Stroke and advanced age		
Basal ganglia or extrapyramidal tract	Detrusor contractions are elicited suddenly without warning and are difficult to control; bladder contraction is shorter than normal and does not produce full bladder emptying	Parkinson's disease		
Pontine micturition center or com- municating tracts in the spinal cord	Storage reflexes are provoked during filling, and external sphincter responses are heightened; uninhibited bladder contractions occur at a lower volume than normal and do not continue until the bladder is emptied; antagonistic activity occurs between the detrusor muscle and the external sphincter	Spinal cord injury		
Sacral cord or nerve roots	Areflexic bladder fills but does not contract; loss of external sphinc- ter tone occurs when the lesion affects the α-adrenergic motor neurons or pudendal nerve	Injury to sacral cord or spinal roots		
Pelvic nerve	Increased filling and impaired sphincter control cause increased intravesicular pressure	Radical pelvic surgery		
Autonomic peripheral sensory pathways	Bladder overfilling occurs owing to a loss of ability to perceive bladder filling	Diabetic neuropathies, multiple sclerosis		

452 Unit Six: Alterations in the Urinary System

Bladder Dysfunction Caused by Spinal Cord Injury. One of the most common types of spinal cord lesions is spinal cord injury (see Chapter 38). The immediate and early effects of spinal cord injury on bladder function are quite different from those that follow recovery from the initial injury. During the period immediately after spinal cord injury, a state of spinal shock develops, during which all the reflexes, including the micturition reflex, are depressed. During this stage, the bladder becomes atonic and cannot contract. Catheterization is necessary to prevent injury to urinary structures associated with overdistention of the bladder. Aseptic intermittent catheterization is the preferred method of catheterization. Depression of reflexes lasts from a few weeks to 6 months (usually 2 to 3 months), after which the spinal reflexes return and become hyperactive.⁹

After the acute stage of spinal cord injury, the micturition response changes from a long-tract reflex to a segmental reflex. Because the sacral reflex arc remains intact, stimuli generated by bladder stretch receptors during filling produce frequent spontaneous contractions of the detrusor muscle. This creates a small, hyperactive bladder subject to high-pressure and short-duration uninhibited bladder contractions. Voiding is interrupted, involuntary, or incomplete. Dilation of the internal sphincter and spasticity of the external sphincter and perineal muscles innervated by upper motoneurons occur, producing resistance to bladder emptying. Hypertrophy of the trigone develops, often leading to vesicoureteral reflux and kidney damage.

Uninhibited Neurogenic Bladder. A mild form of reflex neurogenic bladder, sometimes called *uninhibited bladder*, can develop after a stroke, during the early stages of multiple sclerosis, or as a result of lesions located in the inhibitory centers of the cortex or the pyramidal tract. With this type of disorder, the sacral reflex arc and sensation are retained, the urine stream is normal, and there is no residual urine. However, bladder capacity is diminished because of increased detrusor muscle tone and external sphincter spasticity.

Detrusor-Sphincter Dyssynergia. Depending on the level of the lesion, the coordinated activity of the detrusor muscle and the external sphincter may be affected. Lesions that affect the micturition center in the pons or impair communication between this center and spinal cord centers interrupt the coordinated activity of the detrusor muscle and the external sphincter. This is called *detrusor-sphincter dyssynergia*. Instead of relaxing during micturition, the external sphincter becomes more constricted. This condition can lead to elevated intravesicular pressures, vesicoureteral reflux, and kidney damage.

Treatment. Among the methods used to treat spastic bladder and detrusor-sphincter dyssynergia are the use of anticholinergic medications to decrease bladder hyperactivity and urinary catheterization to produce bladder emptying (discussed later). A sphincterotomy (surgical resection of the external sphincter) or implantable urethral stent may be used to decrease outflow resistance in persons whose condition cannot be managed with medications and catheterization procedures. An alternative to surgical resection of the external sphincter is the injection of botulinum-A toxin to produce paralysis of the striated muscles in the external sphincter. The effects of the injection last from 3 to 9 months, after which the injection must be repeated.⁸

Flaccid Bladder: Failure to Empty Urine

Failure to empty the bladder can be caused by flaccid bladder dysfunction, peripheral neuropathies that interrupt afferent or efferent communication between the bladder and the spinal cord, or conditions that prevent relaxation of the external sphincter.

Flaccid Bladder Dysfunction. Detrusor muscle areflexia, or flaccid neurogenic bladder, occurs when there is injury to the micturition center of the sacral cord, the cauda equina, or the sacral nerve roots that supply the bladder.⁹ Atony of the detrusor muscle and loss of the perception of bladder fullness permits overstretching of the detrusor muscle and contributes to weak and ineffective bladder contractions. External sphincter tone and perineal muscle tone are diminished. Voluntary urination does not occur, but fairly efficient emptying usually can be achieved by increased intra-abdominal pressure or manual suprapubic pressure. Among the causes of flaccid neurogenic bladder are spina bifida and meningomyelocele.

Bladder Dysfunction Caused by Peripheral Neuropathies. In addition to CNS lesions and conditions that disrupt bladder function, disorders of the peripheral (pelvic, pudendal, and hypogastric) neurons that supply the bladder can occur. These neuropathies can selectively interrupt sensory or motor pathways or involve both pathways.

Bladder atony and dysfunction is a frequently occurring complication of diabetes mellitus. The disorder initially affects the sensory axons of the urinary bladder without involvement of the pudendal nerve. This leads to large residual volumes after micturition, sometimes complicated by infection.¹⁰ There frequently is a need for straining, accompanied by hesitation, weakness of the stream, dribbling, and a sensation of incomplete bladder emptying.11 The chief complications are vesicoureteral reflux and ascending urinary tract infection. Because persons with diabetes are already at risk for development of glomerular disease, reflux can have serious effects on kidney function. Treatment consists of client education, including the need for frequent voidings (e.g., every 3 to 4 hours while awake), use of abdominal compression to effect more complete bladder emptying, and intermittent catheterization when necessary.11

Nonrelaxing External Sphincter. Another condition that affects micturition and bladder emptying is the nonrelaxing external sphincter.¹² This condition usually is related to a delay in maturation, developmental regression, psychomotor disorders, or locally irritative lesions. Inadequate relaxation of the external sphincter can be the result of anxiety or depression. Any local irritation can produce spasms of the sphincter by means of afferent sensory input from the pudendal nerve; included are vaginitis, perineal inflammation, and inflammation or irritation of the urethra. In men, chronic prostatitis contributes to the impaired relaxation of the external sphincter.

Treatment. The goals of treatment for conditions that interfere with bladder emptying focus on preventing bladder overdistention, urinary tract infections, and potentially life-threatening renal damage, and reducing the undesirable social and psychological effects of the disorder. The methods used in treatment of neurogenic bladder disorders are individualized based

on the type of neurologic lesion that is involved; information obtained through the health history, including fluid intake; report or observation of voiding patterns; presence of other health problems; urodynamic studies when indicated; and the ability of the person to participate in the treatment. Treatment methods include catheterization, bladder retraining, pharmacologic manipulation of bladder function, and surgery.

Urinary Incontinence

The Urinary Incontinence Guideline Panel defines urinary incontinence as an involuntary loss of urine that is sufficient to be a problem.¹³ This panel was convened by the Agency for Health Care Policy and Research in 1992 and again in 1996 for the purpose of developing specific guidelines to improve the care of persons with urinary incontinence.⁶

Urinary incontinence affects approximately 13 million Americans. Many body functions decline with age, and incontinence, although not a normal accompaniment of the aging process, is seen with increased frequency in elderly persons. For noninstitutionalized persons older than 60 years, the prevalence of urinary incontinence ranges from 15% to 35%, with women affected twice as often as men.⁶ The increase in health problems often seen in elderly persons probably contributes to the greater frequency of incontinence. Despite the prevalence of incontinence, most affected persons do not seek help for it, primarily because of embarrassment or because they are not aware that help is available.

Incontinence can be caused by a number of conditions. It can occur without the person's knowledge; at other times, the person may be aware of the condition but be unable to prevent it. The Urinary Incontinence Guideline Panel has identified four main types of incontinence: stress incontinence, urge incontinence, overflow incontinence, and mixed incontinence, which is a combination of stress and urge incontinence.⁶ Recently, the term *overactive bladder* has been designated as a term to replace *urge incontinence*.¹⁴ Table 25-2 summarizes the characteristics of stress, urge incontinence/overactive bladder, and overflow incontinence.

Incontinence may occur as a transient and correctable phenomenon, or it may not be totally correctable and occur with

TABLE 25-2 Types and Characteristics of Urinary Incontinence				
Туре	Characteristics			
Stress	Involuntary loss of urine associated with activities, such as coughing, that in- crease intra-abdominal pressure			
Overactive bladder/ urge incontinence	Urgency and frequency associated with hyperactivity of the detrusor muscle; may or may not involve involuntary loss of urine			
Overflow	Involuntary loss of urine when intravesi- cular pressure exceeds maximal ure- thral pressure in the absence of detrusor activity			

KEY CONCEPTS

INCONTINENCE

- Incontinence represents the involuntary loss of urine due to increased bladder pressures (overactive bladder with urge incontinence or overflow incontinence) or decreased ability of the vesicourethral sphincter to prevent the escape of urine (stress incontinence).
- Overactive bladder with urge incontinence is caused by neurogenic or myogenic disorders that result in hyperactive bladder contractions.
- Overflow incontinence results from overfilling of the bladder with escape of urine.
- Stress incontinence is caused by the decreased ability of the vesicourethral sphincter to prevent the escape of urine during activities, such as lifting and coughing, that raise bladder pressure above the sphincter closing pressure.

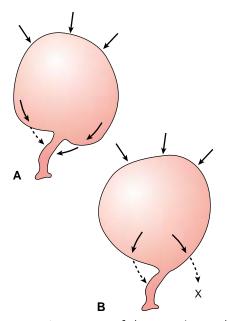

various degrees of frequency. Among the transient causes of urinary incontinence are confusional states; medications that alter bladder function or perception of bladder filling and the need to urinate; diuretics and conditions that increase bladder filling; restricted mobility; and stool impaction.¹⁵

Stress Incontinence

Stress incontinence is the involuntary loss of urine during coughing, laughing, sneezing, or lifting that increases intraabdominal pressure. The most common cause is hypermobility and significant displacement of the urethra during exertion.

In women, the angle between the bladder and the posterior proximal urethra (i.e., urethrovesical junction) is important to continence. This angle normally is 90 to 100 degrees, with at least one third of the bladder base contributing to the angle when not voiding¹⁶ (Fig. 25-5). During the first stage of voiding, this angle is lost as the bladder descends. In women, diminution of muscle tone associated with normal aging, childbirth, or surgical procedures can cause weakness of the pelvic floor muscles and result in stress incontinence by obliterating the critical posterior urethrovesical angle. In these women, loss of the posterior urethrovesical angle, descent and funneling of the bladder neck, and backward and downward rotation of the bladder occur, so that the bladder and urethra are already in an anatomic position for the first stage of voiding. Any activity that causes downward pressure on the bladder is sufficient to allow the urine to escape involuntarily.

Another cause of stress incontinence is intrinsic urethral deficiency, which may result from congenital sphincter weakness, as occurs with meningomyelocele. It also may be acquired as a result of trauma, irradiation, or sacral cord lesion. Stress incontinence in men may result from a congenital defect or from trauma or surgery to the bladder outlet, as occurs with prostatectomy. Neurologic dysfunction, as occurs with impaired sympathetic innervation of the bladder neck, impaired pelvic nerve

■ FIGURE 25-5 ■ Importance of the posterior urethrovesical (PU-V) angle to the continence mechanism. (A) In the presence of the normal PU-V angle, sudden changes in intra-abdominal pressure are transmitted optimally (indicated by the *arrows* with dotted lines) to all sides of the proximal urethra. In this way, intraurethral pressure is maintained higher than the simultaneously elevated intravesicular pressure. This prevents loss of urine with sudden stress. (B) Loss of the PU-V angle results in displacement of the vesicle neck to the most dependent portion of the bladder, preventing the equal transmission of sudden increases in intraabdominal pressure to the lumen of the proximal urethra. Thus, the pressure in the region of the vesicle neck rises considerably more than the intraurethral pressure just beyond it, and stress incontinence occurs. (Green J.T., Jr. [1968]. *Obstetrical and Gynecological Survey* 23, 603. Reprinted with permission)

innervation to the intrinsic sphincter, or impaired pudendal nerve innervation to the external sphincter, may be a contributing factor.

Urge Incontinence/Overactive Bladder

The Urinary Incontinence Guideline Panel has defined urge incontinence as the involuntary loss of urine associated with a strong desire to void (urgency).⁶ To expand the number and types of patients eligible for clinical trials, the U.S. Food and Drug Administration adopted the term *overactive bladder* to describe the clinical syndrome that describes urge incontinence, as well as urgency, frequency, dysuria, and nocturia.¹⁴ Overactive bladder, which often is associated with urge incontinence, can occur without incontinence.¹⁷

Although some cases of overactive bladder result from specific conditions such as acute or chronic urinary tract infections, in many cases the cause is unknown. Regardless of the primary cause of overactive bladder, two types of mechanisms are thought to contribute to its symptomatology: those involving CNS control of bladder sensation and emptying (neurogenic) and those involving the smooth muscle of the bladder itself (myogenic).¹⁷

The CNS functions as an on-off switching circuit for voluntary control of bladder function. Therefore, neurologic damage to central inhibitory pathways or sensitization of peripheral afferent terminals in the bladder may trigger bladder overactivity caused by uncontrolled voiding reflexes. Neurogenic causes of overactive bladder include stroke, Parkinson's disease, and multiple sclerosis. Other neurogenic causes of overactive bladder include increased peripheral afferent activity or increased peripheral sensitivity to efferent impulses.

Myogenic causes of overactive bladder result from changes in the excitability of smooth muscle of the bladder itself. One example is overactive bladder associated with bladder outlet obstruction. It is hypothesized that the sustained increase in intravesicular pressure that occurs with the outlet obstruction causes a partial destruction of the efferent nerve endings that control bladder excitability.¹⁷ The result is urgency and frequency of urination caused by spontaneous bladder contractions resulting from detrusor muscle hyperexcitability. Disorders of detrusor muscle structure and excitability also can occur as the result of the aging process or disease conditions such as diabetes mellitus. Overactive bladder symptoms usually are exaggerated by incomplete bladder emptying.

In persons with overactive bladder, urge incontinence may occur because the interval between knowing the bladder needs to be emptied and being able to stop it from emptying may be less than the time needed to reach the lavatory. Musculoskeletal disorders, such as arthritis and joint instability, also may prevent an otherwise continent person from reaching the toilet in time. Drugs such as hypnotics, tranquilizers, and sedatives can interfere with the conscious inhibition of voiding, leading to urge incontinence. Diuretics, particularly in elderly persons, increase the flow of urine and may contribute to incontinence, particularly in persons with diminished bladder capacity and in those who have difficulty reaching the toilet.

Treatment methods for overactive bladder include the use of behavioral methods and pharmacologic agents. Behavioral methods include fluid management, modification of voiding frequency, and bladder retraining.¹⁸ Bladder retraining and biofeedback techniques seek to re-establish cortical control over bladder function by having the person ignore urgency and respond only to cortical signals during waking hours. Two newer anticholinergic medications, tolterodine and extended-release oxybutynin, may be used to inhibit detrusor muscle hyperactivity and thereby increase overall bladder capacity.^{18,19}

Overflow Incontinence

Overflow incontinence is an involuntary loss of urine that occurs when intravesicular pressure exceeds the maximal urethral pressure because of bladder distention in the absence of detrusor activity. It can occur with retention of urine caused by nervous system lesions or obstruction of the bladder neck. With this type of incontinence, the bladder is distended and small amounts of urine are passed, particularly at night. In males, one of the most common causes of obstructive incontinence is enlargement of the prostate gland. Another cause that commonly is overlooked is fecal impaction (*i.e.*, dry, hard feces in the rectum). When a large bolus of stool forms in the rectum, it can push against the urethra and block the flow of urine.

Other Causes of Incontinence

Another cause of incontinence is decreased bladder compliance or distensibility. This abnormal bladder condition may result from radiation therapy, radical pelvic surgery, or interstitial cystitis. Many persons with this disorder have severe urgency related to bladder hypersensitivity that results in loss of bladder elasticity, such that any small increase in bladder volume or detrusor function causes a sharp increase in bladder pressure and severe urgency.

Treatment with drugs such as diuretics may cause the bladder to fill more rapidly than usual, making it difficult to reach the bathroom in time if there are problems with mobility or if a bathroom is not readily available. Night sedation may cause a person to sleep through the signal that normally would waken a person so he or she could get up and empty the bladder and avoid wetting the bed.

Diagnosis and Treatment

Urinary incontinence is a frequent and major health problem. It increases social isolation, frequently leads to institutionalization of elderly persons, and predisposes to infections and skin breakdown.

Urinary incontinence is not a single disease but a symptom with many possible causes. As a symptom, it requires full investigation to establish its cause. This usually is accomplished through a careful history, physical examination, blood tests, and urinalysis. A voiding record (*i.e.*, diary) may be used to determine the frequency, timing, amount of voiding, and other factors associated with the incontinence.^{13,14} Because many drugs affect bladder function, a full drug history is essential. Estimation of PVR volume is recommended for all persons with incontinence. Provocative stress testing, such as having a person relax and then cough vigorously, may be done when stress incontinence is suspected. Urodynamic studies may be needed to provide information about urinary pressures and urine flow rates.

Treatment or management depends on the type of incontinence, accompanying health problems, and the person's age. Exercises to strengthen the pelvic muscles and surgical correction of pelvic relaxation disorders often are used for women with stress incontinence. The α -adrenergic agonist drugs, such as pseudoephedrine, increase sympathetic relaxation of the detrusor muscle and internal sphincter tone and may be used in treating stress incontinence.^{6,16}

Noncatheter devices to obstruct urine flow or collect urine as it is passed may be used when urine flow cannot be controlled. Indwelling catheters, although a solution to the problem of urinary incontinence, usually are considered only after all other treatment methods have failed. In some types of incontinence, such as that associated with spinal cord injury or meningomyelocele, self-catheterization provides the means for controlling urine elimination.

Surgical intervention may be considered when other treatment methods have proved ineffective. Three types of surgical procedures are used: procedures that increase outlet resistance, surgeries that decrease detrusor muscle instability, and operations that remove outflow obstruction to reduce overflow incontinence and detrusor muscle instability.⁶ A minimally invasive procedure for the treatment of stress incontinence is periurethral injection of a bulking agent (glutaraldehyde cross-linked bovine collagen or carbon-coated beads). Both of these agents typically require multiple treatment sessions to achieve cure.¹⁴

Surgically implanted artificial sphincters are available for use in males and females. These devices consist of an inflatable cuff that surrounds the proximal urethra. The cuff is connected by tubing to an implanted fluid reservoir and an inflation bulb.

Special Needs of Elderly Persons

Urinary incontinence is a common problem in elderly persons. An estimated 15% to 35% of community-dwelling elders and 50% of institutionalized elders have severe urinary incontinence.^{20,21} Many factors contribute to incontinence in elderly persons, a number of which can be altered.

Physiologically, detrusor muscle function tends to decline with aging so there is a trend toward a reduction in the strength of bladder contraction and impairment in emptying that leads to larger PVR volumes.⁴ It has been proposed that many of these changes are attributable to degenerative detrusor muscle changes, rather than neurologic changes, as was once thought. The combination of involuntary detrusor contraction (detrusor hyperactivity) leading to urge incontinence along with impaired contractile function leads to incomplete bladder emptying.

Pelvic relaxation disorders are more frequent in older than in younger women, and prostatic hypertrophy is more common in older than in younger men. Many elderly persons have difficulty getting to the toilet in time. This can be caused by arthritis that makes walking or removing clothing difficult or by failing vision that makes trips to the bathroom precarious, especially in new and unfamiliar surroundings.

Medication prescribed for other health problems may prevent a healthy bladder from functioning normally. Potent, fast-acting diuretics are known for their ability to cause urge incontinence. Psychoactive drugs, such as tranquilizers and sedatives, may diminish normal attention to bladder cues. Impaired thirst or limited access to fluids predisposes to constipation with urethral obstruction and overflow incontinence and to concentrated and infected urine, which increases bladder excitability.

Treatment may involve changes in the physical environment so that the older person can reach the bathroom more easily or remove clothing more quickly. Habit training with regularly scheduled toileting—usually every 2 to 4 hours often is effective. Many elderly persons who void on a regular schedule can gradually increase the interval between toileting while improving their ability to suppress bladder instability. The treatment plan may require dietary changes to prevent constipation or a plan to promote adequate fluid intake to ensure adequate bladder filling and prevent urinary stasis and symptomatic urinary tract infections.

In summary, alterations in bladder function include urinary obstruction with retention of urine, neurogenic bladder, and urinary incontinence with involuntary loss of urine. Urine retention occurs when the outflow of urine from the bladder is obstructed because of urethral obstruction or impaired bladder innervation. Urethral obstruction causes bladder irritability, detrusor muscle hypertrophy, trabeculation and the formation of diverticula, development of hydroureters, and eventually, renal failure.

Neurogenic bladder is caused by interruption in the innervation of the bladder. It can result in spastic bladder dysfunction caused by failure of the bladder to fill or flaccid bladder dysfunction caused by failure of the bladder to empty. Spastic bladder dysfunction usually results from neurologic lesions that are above the level of the sacral micturition reflex center; flaccid bladder dysfunction results from lesions at the level of the sacral micturition reflexes or peripheral innervation of the bladder. A third type of neurogenic disorder involves a nonrelaxing external sphincter.

Urinary incontinence is the involuntary loss of urine in amounts sufficient to be a problem. It may manifest as stress incontinence, in which the loss of urine occurs as a result of coughing, sneezing, laughing, or lifting; overactive bladder, characterized by frequency and urgency associated with hyperactive bladder contractions; or overflow incontinence, which results when intravesicular pressure exceeds the maximal urethral pressure because of bladder distention. Other causes of incontinence include a small, contracted bladder or external environmental conditions that make it difficult to access proper toileting facilities.

The treatment of urinary obstruction, neurogenic bladder, and incontinence requires careful diagnosis to determine the cause and contributing factors. Treatment methods include correction of the underlying cause, such as obstruction caused by prostatic hyperplasia; pharmacologic methods to improve bladder and external sphincter tone; behavior methods that focus on bladder and habit training; exercises to improve pelvic floor function; and the use of catheters and urine collection devices.

CANCER OF THE BLADDER

Bladder cancer is the most common form of urinary tract cancer in the United States, accounting for more than 56,500 new cases and 12,600 deaths each year.²² Whites are twice as likely to have bladder cancer as African Americans.²² It occurs most commonly in people in their late seventh decade.²³ When detected and treated early, the chances for survival are very good. The 5-year survival rate for early noninvasive bladder cancers is approximately 94%.

Approximately 90% of bladder cancers are derived from the transitional (urothelial) cells that line the bladder.^{24,25} These tumors can range from low-grade noninvasive tumors to high-grade tumors that invade the bladder wall and metastasize frequently. The low-grade tumors, which may recur after resection, have an excellent prognosis, with only a small number (2% to 10%) progressing to higher-grade tumors.²⁶ The high-grade tumors tend to have greater invasive and metastatic potential and are potentially fatal in approximately 60% of cases within 10 years of diagnosis.²⁴

Although the cause of bladder cancer is unknown, evidence suggests that its origin is related to local influences, such as carcinogens that are excreted in the urine and stored in the bladder. These include the breakdown products of aniline dyes used in the rubber and cable industries. Smoking also deserves attention. Fifty percent to 80% of all bladder cancers in men are associated with cigarette smoking. Chronic bladder infections and bladder stones also increase the risk of bladder cancer. Bladder cancer occurs more frequently among persons harboring the parasite *Schistosoma haematobium* in their bladders. The parasite is endemic in Egypt and Sudan. It is not known whether the parasite excretes a carcinogen or produces its effects through irritation of the bladder.

The most common sign of bladder cancer is painless hematuria.^{24–26} Gross hematuria is a presenting sign in 75% of persons with the disease, and microscopic hematuria is present in most others. Frequency, urgency, and dysuria occasionally accompany the hematuria. Because hematuria often is intermittent, the diagnosis may be delayed. Periodic urine cytology is recommended for all persons who are at high risk for the development of bladder cancer because of exposure to urinary tract carcinogens. Ureteral invasion leading to bacterial and obstructive renal disease and dissemination of the cancer are potential complications and ultimate causes of death. The prognosis depends on the histologic grade of the cancer and the stage of the disease at the time of diagnosis.

Diagnosis and Treatment

Diagnostic methods include cytologic studies, excretory urography, cystoscopy, and biopsy. Ultrasonography, CT scans, and MRI are used as aids for staging the tumor. Cytologic studies performed on biopsy tissues or cells obtained from bladder washings may be used to detect the presence of malignant cells.

The treatment of bladder cancer depends on the extent of the lesion and the health of the patient. Endoscopic resection usually is done for diagnostic purposes and may be used as a treatment for superficial lesions. Diathermy (*i.e.*, electrocautery) may be used to remove the tumors. Segmental surgical resection may be used for removing a large single lesion. When the tumor is invasive, cystectomy with resection of the pelvic lymph nodes frequently is the treatment of choice. In males, the prostate and seminal vesicles often are removed as well. Cystectomy requires urinary diversion, an alternative reservoir, usually created from the ileum (*e.g.*, an ileal loop), which is designed to collect the urine. External beam radiation is an alternative to radical cystectomy in some persons with deeply infiltrating bladder cancers.

Although a number of chemotherapeutic drugs have been used in the treatment of bladder cancer, no chemotherapeutic regimens for the disease have been established. Perhaps of more importance is the increasing use of intravesicular chemotherapy, in which the cytotoxic drug is instilled directly into the bladder, thereby avoiding the side effects of systemic therapy.²⁶ The intervesicular administration of bacillus Calmette-Guérin (BCG) vaccine, made from a strain of *Mycobacterium bovis*, may be used to reduce the disease recurrence or progression. The vaccine is thought to act as a nonspecific stimulator of cellmediated immunity. Instillation into the bladder decreases the risk of systemic dissemination.²⁵

In summary, cancer of the bladder is the most common cause of urinary tract cancer in the United States. Bladder cancers fall into two major groups: low-grade noninvasive tumors and high-grade invasive tumors that are associated with metastasis and a worse prognosis. Although the cause of cancer of the bladder is unknown, evidence suggests that carcinogens excreted in the urine may play a role. Microscopic and gross, painless hematuria are the most common presenting signs of bladder cancer. The methods used in the treatment of bladder cancer depend on the cytologic grade of the tumor and the lesion's degree of invasiveness. The methods include surgical removal of the tumor, radiation therapy, and chemotherapy. In many cases, chemotherapeutic or immunotherapeutic agents can be instilled directly into the bladder, thereby avoiding the side effects of systemic therapy.

REVIEW QUESTIONS

Trace the innervation of the bladder and control of micturition from the detrusor muscle and external sphincter, the micturition centers in the sacral and thoracolumbar cord, the pontine micturition center, and the cerebral cortex.

Describe the causes of and compensatory changes that occur with urinary tract obstruction.

Differentiate lesions that produce storage dysfunction associated with spastic bladder from those that produce emptying dysfunction associated with flaccid bladder in terms of the level of the lesions and their effects on bladder function.

Define *incontinence* and list the categories of this condition.

Discuss the difference between superficial and invasive bladder cancer in terms of bladder involvement, extension of the disease, and prognosis.

State the most common sign of bladder cancer.

Digestion and Absorption Carbohydrates Fats Proteins Anorexia, Nausea, and Vomiting Anorexia Nausea Vomiting

Swith its lumen inside the body and its wall acting as an interface between the internal and external environments. The wall does not normally allow harmful agents to enter the body, nor does it permit body fluids and other materials to escape. The process of digestion and absorption of nutrients requires an intact and healthy gastrointestinal tract epithelial lining that can resist the effects of its own digestive secretions. The process also involves movement of materials through the gastrointestinal tract at a rate that facilitates absorption, and it requires the presence of enzymes for the digestion and absorption of nutrients.

As a matter of semantics, the gastrointestinal tract also is referred to as the *digestive tract*, the *alimentary canal*, and at times, the *gut*. The intestinal portion also may be called the *bowel*. For the purposes of this text, the salivary glands, the liver, and the pancreas, which produce secretions that aid in digestion, are considered *accessory organs*.

STRUCTURE AND ORGANIZATION OF THE GASTROINTESTINAL TRACT

In the digestive tract, food and other materials move slowly along its length as they are systematically broken down into ions and molecules that can be absorbed into the body. In the large intestine, unabsorbed nutrients and wastes are collected for later elimination. Although the gastrointestinal tract is located inside the body, it is a long, hollow tube, the lumen (*i.e.*, hollow center) of which is an extension of the external environment. Nutrients do not become part of the internal environment until they have passed through the intestinal wall and have entered the blood or lymph channels.

For simplicity and understanding, the digestive system can be divided into four parts (Fig. 26-1). The upper part—the mouth, esophagus, and stomach—acts as an intake source and receptacle through which food passes and in which initial digestive processes take place. The middle portion consists of the small intestine—the duodenum, jejunum, and ileum. Most digestive and absorptive processes occur in the small intestine. The lower segment—the cecum, colon, and rectum—serves as a storage channel for the efficient elimination of waste. The fourth part consists of the accessory organs—the salivary glands, liver, and pancreas. These structures produce digestive secretions that help dismantle foods and regulate the use and storage of nutrients. The discussion in this chapter focuses on the first three parts of the gastrointestinal tract. The liver and pancreas are discussed in Chapter 28.

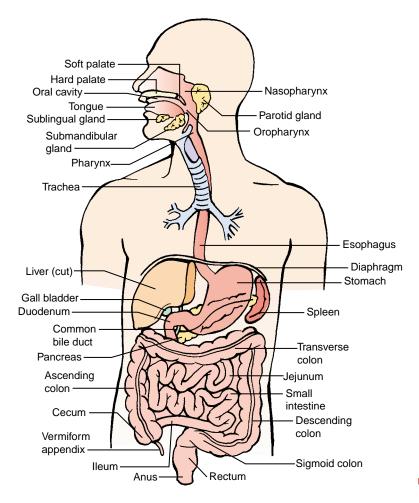

Upper Gastrointestinal Tract

The mouth forms the entryway into the gastrointestinal tract for food; it contains the teeth, used in the mastication of food, and the tongue and other structures needed to direct food toward the pharyngeal structures and the esophagus.

Esophagus

The esophagus is a tube that connects the oropharynx with the stomach. The esophagus begins at the lower end of the pharynx. It is a muscular, collapsible tube, approximately 25 cm (10 in) long, that lies behind the trachea. The muscular walls of the upper third of the esophagus are skeletal-type striated muscle; these muscle fibers are gradually replaced by smooth muscle fibers until, at the lower third of the esophagus, the muscle layer is entirely smooth muscle.

The esophagus functions primarily as a conduit for passage of food from the pharynx to the stomach, and the structures of its walls are designed for this purpose: the smooth muscle layers provide the peristaltic movements needed to move food along its length, and the epithelial layer secretes mucus, which protects its surface and aids in lubricating food. There are sphincters at either end of the esophagus: an upper esophageal

■ **FIGURE 26-1** ■ The digestive system.

STRUCTURE AND FUNCTION OF THE GASTROINTESTINAL TRACT

- The gastrointestinal tract is a long, hollow tube that extends from the mouth to the anus; food and fluids that enter the gastrointestinal tract do not become part of the internal environment until they have been broken down and absorbed into the blood or lymph channels.
- The wall of the gastrointestinal tract is essentially a five-layered tube: an inner mucosal layer; a supporting submucosal layer of connective tissue; a fourth and fifth layer of circular and longitudinal smooth muscle that functions to propel its contents in a proximal-to-distal direction; and an outer, twolayered peritoneum that encloses and prevents friction between the continuously moving segments of the intestine.
- The nutrients contained in ingested foods and fluids must be broken down into molecules that can be absorbed across the wall of the intestine. Gastric acids and pepsin from the stomach begin the digestive process: bile from the liver, digestive enzymes from the pancreas, and brush border enzymes break carbohydrates, fats, and proteins into molecules that can be absorbed from the intestine.

sphincter and a lower esophageal sphincter. The upper esophageal, or pharyngoesophageal, sphincter consists of a circular layer of striated muscle. The lower esophageal, or gastroesophageal, sphincter is an area approximately 3 cm above the junction with the stomach. The circular muscle in this area normally remains tonically contracted, creating a zone of high pressure that serves to prevent reflux of gastric contents into the esophagus. During swallowing, there is "receptive relaxation" of the lower esophageal sphincter, which allows easy propulsion of the esophageal contents into the stomach. The lower esophageal sphincter passes through an opening, or hiatus, in the diaphragm as it joins with the stomach, which is located in the abdomen. The portion of the diaphragm that surrounds the lower esophageal sphincter helps to maintain the zone of high pressure needed to prevent reflux of stomach contents into the esophagus.

Stomach

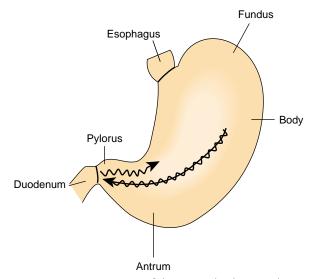

The stomach is a pouchlike structure that lies in the upper part of the abdomen and serves as a food storage reservoir during the early stages of digestion. Although the residual volume of the stomach is only approximately 50 mL, it can increase to almost 1000 mL before the intraluminal pressure begins to rise. The esophagus opens into the stomach through an opening called the *cardiac orifice*, so named because of its proximity to the heart. The part of the stomach that lies above and to the left of the cardiac orifice is called the *fundus*, the central portion is called the *body*, the orifice encircled by a ringlike muscle that opens into the small intestine is called the *pylorus*, and the portion between the body and pylorus is called the *antrum* (Fig. 26-2). The presence of a true pyloric sphincter is a matter of controversy. Regardless of whether an actual sphincter exists, contractions of the smooth muscle in the pyloric area control the rate of gastric emptying.

Middle Gastrointestinal Tract

The small intestine, which forms the middle portion of the digestive tract, consists of three subdivisions: the duodenum, the jejunum, and the ileum. The duodenum, which is approximately 22 cm (10 in) long, connects the stomach to the jejunum and contains the opening for the common bile duct and the main pancreatic duct. Bile and pancreatic juices enter the intestine through these ducts. It is in the jejunum and ileum, which together are approximately 7 m (23 ft) long and must be folded onto themselves to fit into the abdominal cavity, that food is digested and absorbed.

Lower Gastrointestinal Tract

The large intestine, which forms the lower gastrointestinal tract, is approximately 1.5 m (4.5 to 5 ft) long and 6 to 7 cm (2.4 to 2.7 in) in diameter. It is divided into the cecum, colon, rectum, and anal canal. The cecum is a blind pouch that projects down at the junction of the ileum and the colon. The ileocecal valve lies at the upper border of the cecum and prevents the return of feces from the cecum into the small intestine. The appendix arises from the cecum approximately 2.5 cm (1 in) from the ileocecal valve. The colon is further divided into ascending, transverse, descending, and sigmoid portions. The ascending colon extends from the cecum to the undersurface of the liver, where it turns abruptly to form the right colic (hepatic) flexure. The transverse colon crosses the upper half of the abdominal cavity from right to left and then curves sharply downward beneath the lower end of the spleen, forming the left colic

■ **FIGURE 26-2** ■ Structures of the stomach, showing the pacemaker area and the direction of chyme movement resulting from peristaltic contractions.

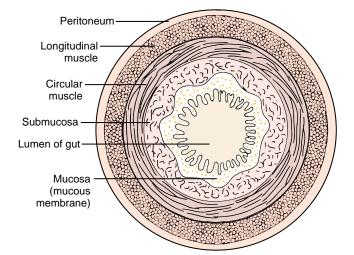

(splenic) flexure. The descending colon extends from the colic flexure to the rectum. The rectum extends from the sigmoid colon to the anus. The anal canal passes between the two medial borders of the levator ani muscles. Powerful sphincter muscles guard against fecal incontinence.

Gastrointestinal Wall Structure

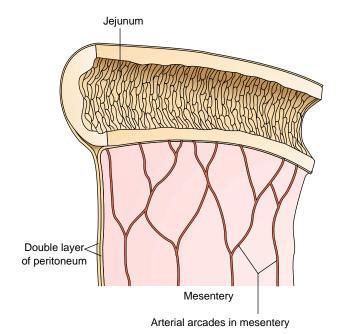

The digestive tract is essentially a five-layered tube (Fig. 26-3). The inner luminal layer, or *mucosal layer*, is so named because its cells produce mucus that lubricates and protects the inner surface of the alimentary canal. The epithelial cells in this layer have a rapid turnover rate and are replaced every 4 to 5 days. Approximately 250 g of these cells are shed each day in the stool. Because of the regenerative capabilities of the mucosal layer, injury to this layer of tissue heals rapidly without leaving scar tissue. The *submucosal layer* consists of connective tissue. This layer contains blood vessels, nerves, and structures responsible for secreting digestive enzymes. The third and fourth layers, the *circular* and *longitudinal muscle layers*, facilitate movement of the contents of the gastrointestinal tract. The outer layer, the *peritoneum*, is loosely attached to the outer wall of the intestine.

The peritoneum is the largest serous membrane in the body, having a surface area approximately equal to that of the skin. The peritoneum consists of two continuous layers—the parietal and the visceral peritoneum. The *parietal peritoneum* comes in contact with and is loosely attached to the abdominal wall, whereas the *visceral peritoneum* invests the viscera such as the stomach and intestines. A thin layer of serous fluid separates the parietal and visceral peritoneum, forming a potential space called the *peritoneal cavity*. The serous fluid forms a moist and slippery surface that prevents friction between the continuously moving abdominal structures. In certain pathologic states, the amount of fluid in the potential space of the peritoneal cavity is increased, causing a condition called *ascites*.

The jejunum and ileum are suspended by a double-layered fold of peritoneum called the *mesentery* (Fig. 26-4). The mesentery contains the blood vessels, nerves, and lymphatic vessels

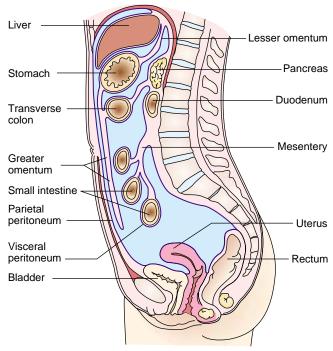

■ FIGURE 26-3 ■ Transverse section of the digestive system. (Thomson J.S. [1977]. *Core textbook of anatomy*. Philadelphia: J.B. Lippincott)

■ **FIGURE 26-4** ■ The attachment of the mesentery to the small bowel. (Thomson J.S. [1977]. *Core textbook of anatomy*. Philadel-phia: J.B. Lippincott)

that supply the intestinal wall. The mesentery is gathered in folds that attach to the dorsal abdominal wall along a short line of insertion, giving a fan-shaped appearance, with the intestines at the edge. A filmy, double fold of peritoneal membrane called the *greater omentum* extends from the stomach to cover the transverse colon and folds of the intestine (Fig. 26-5).

■ **FIGURE 26-5** ■ Reflections of the peritoneum as seen in sagittal section.

The greater omentum protects the intestines from cold. It always contains some fat, which in obese persons can be a considerable amount. The omentum also controls the spread of infection from gastrointestinal contents. In the case of infection, the omentum adheres to the inflamed area so that the infection is less likely to enter the peritoneal cavity. The lesser omentum extends between the transverse fissure of the liver and the lesser curvature of the stomach.

In summary, the gastrointestinal tract is a long, hollow tube, the lumen of which is an extension of the external environment. The digestive tract can be divided into four parts: an upper part, consisting of the mouth, esophagus, and stomach; a middle part, consisting of the small intestine; a lower part, consisting of the cecum, colon, and rectum; and the accessory organs, consisting of the salivary glands, the liver, and the pancreas. Throughout its length, except for the mouth, throat, and upper esophagus, the gastrointestinal tract is composed of five layers: an inner mucosal layer, a submucosal layer, a layer of circular smooth muscle fibers, a layer of longitudinal smooth muscle fibers, and an outer serosal layer that forms the peritoneum and is continuous with the mesentery.

INNERVATION AND MOTILITY

The motility of the gastrointestinal tract propels food products and fluids along its length, from mouth to anus, in a manner that facilitates digestion and absorption. Except in the pharynx and upper third of the esophagus, smooth muscle provides the contractile force for gastrointestinal motility (the actions of smooth muscle are discussed in Chapter 1). The rhythmic movements of the digestive tract are selfperpetuating, much like the activity of the heart, and are influenced by local, humoral (*i.e.*, blood-borne), and neural influences. The ability to initiate impulses is a property of the smooth muscle itself. Impulses are conducted from one muscle fiber to another.

The smooth muscle movements of the gastrointestinal tract are tonic and rhythmic. The *tonic movements* are continuous movements that last for minutes or even hours. Tonic contractions occur at sphincters. The *rhythmic movements* consist of intermittent contractions that are responsible for mixing and moving food along the digestive tract. *Peristaltic movements* are rhythmic propulsive movements that occur when the smooth muscle layer constricts, forming a contractile band that forces the intraluminal contents forward. During peristalsis, the segment that lies distal to, or ahead of, the contracted portion relaxes, and the contents move forward with ease. Normal peristalsis always moves in the direction from the mouth toward the anus.

Innervation

Gastrointestinal function is controlled by the *enteric nervous sys*tem, which lies entirely within the wall of the gastrointestinal tract, and by the parasympathetic and sympathetic divisions of the autonomic nervous system (ANS).

Enteric Nervous System

The intramural neurons (*i.e.*, those contained within the wall of the gastrointestinal tract) consist of two networks: the myenteric and submucosal plexuses. Both plexuses are aggregates of ganglionic cells that extend along the length of the gastrointestinal wall. The myenteric (Auerbach's) plexus is located between the circular muscle and longitudinal muscle layers, and the submucosal (Meissner's) plexus between the mucosal layer and the circular muscle layers (Fig. 26-6). The activity of the neurons in the myenteric and submucosal plexuses is regulated by local influences, input from the ANS, and by interconnecting fibers that transmit information between the two plexuses.

The myenteric plexus consists mainly of a linear chain of interconnecting neurons that extend the full length of the gastrointestinal tract. Because it extends all the way down the intestinal wall and because it lies between the two muscle layers, it is concerned mainly with motility along the length of the gut. The submucosal plexus, which lies between the mucosal and circular muscle layers of the intestinal wall, is mainly concerned with controlling the function of each segment of the intestinal tract. It integrates signals received from the mucosal layer into local control of motility, intestinal secretions, and absorption of nutrients.

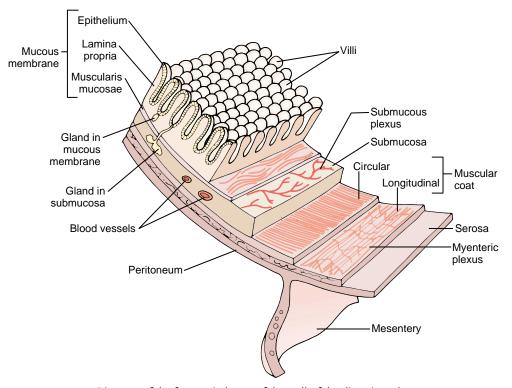

Intramural plexus neurons also communicate with receptors in the mucosal and muscle layers. Mechanoreceptors monitor the stretch and distention of the gastrointestinal tract wall, and chemoreceptors monitor the chemical composition (*i.e.*, osmolality, pH, and digestive products of protein and fat metabolism) of its contents. These receptors can communicate directly with ganglionic cells in the intramural plexuses or with visceral afferent fibers that influence ANS control of gastrointestinal function.

Autonomic Nervous System

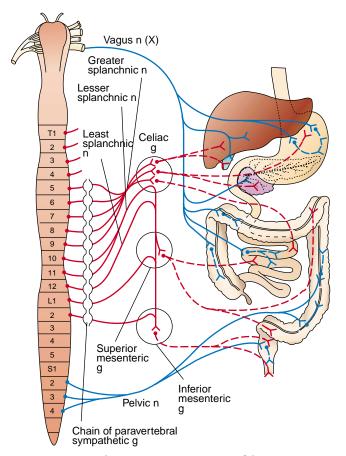

The gastrointestinal tract is innervated by both the sympathetic and parasympathetic nervous systems. Parasympathetic innervation to the stomach, small intestine, cecum, ascending colon, and transverse colon occurs by way of the vagus nerve (Fig. 26-7). The remainder of the colon is innervated by parasympathetic fibers that exit the sacral segments of the spinal cord by way of the pelvic nerve. Preganglionic parasympathetic fibers can synapse with intramural plexus neurons, or they can act directly on intestinal smooth muscle. Most parasympathetic fibers are excitatory. Numerous vagovagal reflexes influence motility and secretions of the digestive tract.

Sympathetic innervation of the gastrointestinal tract occurs through the thoracic chain of sympathetic ganglia and the celiac, superior mesenteric, and inferior mesenteric ganglia. Sympathetic control of gastrointestinal function is largely mediated by altering the activity of neurons in the intramural plexuses. The sympathetic nervous system exerts several effects on gastrointestinal function. It controls mucus secretion by the mucosal glands, reduces motility by inhibiting the activity of intramural plexus neurons, enhances sphincter function, and increases the vascular smooth muscle tone of the blood vessels that supply the gastrointestinal tract. The sympathetic fibers that supply the lower esophageal, pyloric, and internal and external anal sphincters are largely excitatory, but their role in controlling these sphincters is poorly understood.

Unit Seven: Alterations in the Gastrointestinal System

■ FIGURE 26-6 ■ Diagram of the four main layers of the wall of the digestive tube: mucosa, submucosa, muscular, and serosa (below the diaphragm).

■ **FIGURE 26-7** ■ The autonomic innervation of the gastrointestinal tract (g, ganglion; n, nerve).

Swallowing and Esophageal Motility

The movement of foods and fluids in the gastrointestinal tract begins with chewing, in the case of solid foods, and swallowing. Chewing begins the digestive process; it breaks the food into particles of a size that can be swallowed, lubricates it by mixing it with saliva, and mixes starch-containing food with salivary amylase. Although chewing usually is considered a voluntary act, it can be carried out involuntarily by a person who has lost the function of the cerebral cortex.

The swallowing reflex is a rigidly ordered sequence of events that results in the propulsion of food from the mouth to the stomach through the esophagus. Although swallowing is initiated as a voluntary activity, it becomes involuntary as food or fluid reaches the pharynx. Sensory impulses for the reflex begin at tactile receptors in the pharynx and esophagus and are integrated with the motor components of the response in an area of the reticular formation of the medulla and lower pons called the swallowing center. The motor impulses for the oral and pharyngeal phases of swallowing are carried in the trigeminal (V), glossopharyngeal (IX), vagus (X), and hypoglossal (XII) cranial nerves, and impulses for the esophageal phase are carried by the vagus nerve. Diseases that disrupt these brain centers or their cranial nerves disrupt the coordination of swallowing and predispose an individual to food and fluid lodging in the trachea and bronchi, leading to risk of asphyxiation or aspiration pneumonia.

Swallowing consists of three phases: an oral, or voluntary phase; a pharyngeal phase; and an esophageal phase. During the *oral phase*, the bolus is collected at the back of the mouth so the tongue can lift the food upward until it touches the posterior wall of the pharynx. At this point, the *pharyngeal phase* of swallowing is initiated. The soft palate is pulled upward, the palatopharyngeal folds are pulled together so that food does not enter the nasopharynx, the vocal cords are pulled together, and the epiglottis is moved so that it covers the larynx. Respiration is inhibited, and the bolus is moved backward into the esophagus by constrictive movements of the pharynx. Although the striated muscles of the pharynx are involved in the second stage of swallowing, it is an involuntary stage.

The third phase of swallowing is the *esophageal stage*. As food enters the esophagus and stretches its walls, local and central nervous system reflexes that initiate peristalsis are triggered. There are two types of peristalsis: primary and secondary. Primary peristalsis is controlled by the swallowing center in the brain stem and begins when food enters the esophagus. Secondary peristalsis is partially mediated by smooth muscle fibers in the esophagus and occurs when primary peristalsis is inadequate to move food through the esophagus. Peristalsis begins at the site of distention and moves downward. Before the peristaltic wave reaches the stomach, the lower esophageal sphincter relaxes to allow the bolus of food to enter the stomach. The pressure in the lower esophageal sphincter normally is greater than that in the stomach, an important factor in preventing the reflux of gastric contents.

Gastric Motility

The stomach serves as a reservoir for ingested solids and liquids. Motility of the stomach results in the churning and grinding of solid foods and regulates the emptying of the gastric contents, or chyme, into the duodenum. Peristaltic mixing and churning contractions begin in a pacemaker area in the middle of the stomach and move toward the antrum (see Fig. 26-2). They occur at a frequency of three to five contractions per minute, each with a duration of 2 to 20 seconds. As the peristaltic wave approaches the antrum, it speeds up, and the entire terminal 5 to 10 cm of the antrum contracts, occluding the pyloric opening. Contraction of the antrum reverses the movement of the chyme, returning the larger particles to the body of the stomach for further churning and kneading. Because the pylorus is contracted during antral contraction, the gastric contents are emptied into the duodenum between contractions.

Although the pylorus does not contain a true anatomic sphincter, it does function as a physiologic sphincter to prevent the backflow of gastric contents and allow them to flow into the duodenum at a rate commensurate with the ability of the duodenum to accept them. This is important because the regurgitation of bile salts and duodenal contents can damage the mucosal surface of the antrum and lead to gastric ulcers. Likewise, the duodenal mucosa can be damaged by the rapid influx of highly acid gastric contents.

Like other parts of the gastrointestinal tract, the stomach is richly innervated by the enteric nervous system and its connections with the sympathetic and parasympathetic nervous systems. Axons from the intramural plexuses innervate the smooth muscles and glands of the stomach. Parasympathetic innervation is provided by the vagus nerve and sympathetic innervation by the celiac ganglia. The emptying of the stomach is regulated by hormonal and neural mechanisms. The hormones cholecystokinin and gastric inhibitory peptide, which are thought to control gastric emptying, are released in response to the pH and the osmolar and fatty acid composition of the chyme. Local and central circuitry are involved in the neural control of gastric emptying. Afferent receptor fibers synapse with the neurons in the intramural plexus or trigger intrinsic reflexes by means of vagal or sympathetic pathways that participate in extrinsic reflexes.

Disorders of gastric motility can occur when the rate is too slow or too fast (see Chapter 27). A rate that is too slow leads to gastric retention. It can be caused by obstruction or gastric atony. Gastric atony can occur as a complication of visceral neuropathies in diabetes mellitus. Surgical procedures that disrupt vagal activity also can result in gastric atony. Abnormally fast emptying occurs in the dumping syndrome, which is a consequence of certain types of gastric operations. This condition is characterized by the rapid dumping of highly acidic and hyperosmotic gastric secretions into the duodenum and jejunum.

Small Intestinal Motility

The small intestine is the major site for the digestion and absorption of food; its movements are mixing and propulsive. Regular peristaltic movements begin in the duodenum near the entry sites of the common duct and the main hepatic duct. A series of local pacemakers maintains the frequency of intestinal contraction. The peristaltic movements (approximately 12 per minute in the jejunum) become less frequent as they move further from the pylorus, becoming approximately 9 per minute in the ileum.

The peristaltic contractions produce segmentation waves and propulsive movements of the small intestine. With segmentation waves, slow contractions of circular muscle occlude the lumen and drive the contents forward and backward. Most of the contractions that produce segmentation waves are local events involving only 1 to 4 cm at a time. They function mainly to mix the chyme with the digestive enzymes from the pancreas and to ensure adequate exposure of all parts of the chyme to the mucosal surface of the intestine, where absorption takes place. The frequency of segmenting activity increases after a meal, presumably stimulated by receptors in the stomach and intestine.

Propulsive movements occur with synchronized activity in a section 10 to 20 cm long. They are accomplished by contraction of the proximal portion of the intestine with the sequential relaxation of its distal, or anal, portion. After material has been propelled to the ileocecal junction by peristaltic movement, stretching of the distal ileum produces a local reflex that relaxes the sphincter and allows fluid to squirt into the cecum.

Motility disturbances of the small bowel are common, and auscultation of the abdomen can be used to assess bowel activity. Inflammatory changes increase motility. In many instances, it is not certain whether changes in motility occur because of inflammation or occur secondary to toxins and unabsorbed materials. Delayed passage of materials in the small intestine also can be a problem. Transient interruption of intestinal motility often occurs after gastrointestinal surgery. Intubation with suction often is required to remove the accumulating intestinal contents and gases until activity is resumed.

Colonic Motility

The storage function of the colon dictates that movements in this section of the gut are different from those in the small intestine. Movements in the colon are of two types. First are the segmental mixing movements, called *haustrations*, so named because they occur within sacculations called *haustra*. These movements produce a local digging-type action, which ensures that all portions of the fecal mass are exposed to the intestinal surface. Second are the propulsive mass movements, in which a large segment of the colon (≥ 20 cm) contracts as a unit, moving the fecal contents forward as a unit. Mass movements last approximately 30 seconds, followed by a 2- to 3-minute period of relaxation, after which another contraction occurs. A series of mass movements lasts only for 10 to 30 minutes and may occur only several times a day. Defecation normally is initiated by the mass movements.

Defecation

Defecation is controlled by the action of two sphincters, the internal and external anal sphincters. The internal sphincter is a several-centimeters long circular thickening of smooth muscle that lies inside the anus. The external sphincter, which is composed of striated voluntary muscle, surrounds the internal sphincter. Defecation is controlled by defecation reflexes. One of these reflexes is the intrinsic myenteric reflex mediated by the local enteric nervous system. It is initiated by distention of the rectal wall, with initiation of reflex peristaltic waves that spread through the descending colon, sigmoid colon, and rectum. A second defecation reflex, the parasympathetic reflex, is integrated at the level of the sacral cord. When the nerve endings in the rectum are stimulated, signals are transmitted first to the sacral cord and then reflexly back to the descending colon, sigmoid colon, rectum, and anus by way of the pelvic nerves (Fig. 26-7). These impulses greatly increase peristaltic movements as well as relax the internal sphincter.

To prevent involuntary defecation from occurring, the external anal sphincter, which is supplied by nerve fibers in the pudendal nerve, is under the conscious control of the cortex. As afferent impulses arrive at the sacral cord, signaling the presence of a distended rectum, messages are transmitted to the cortex. If defecation is inappropriate, the cortex initiates impulses that constrict the external sphincter and inhibit efferent parasympathetic activity. Normally, the afferent impulses in this reflex loop fatigue easily, and the urge to defecate soon ceases. At a more convenient time, contraction of the abdominal muscles compresses the contents in the large bowel, reinitiating afferent impulses to the cord.

In summary, motility of the gastrointestinal tract propels food products and fluids along its length from mouth to anus. Although the activity of gastrointestinal smooth muscle is selfpropagating and can continue without input from the nervous system, its rate and strength of contractions are requlated by a network of intramural neurons that receive input from the ANS and local receptors that monitor wall stretch and the chemical composition of luminal contents. Parasympathetic innervation occurs by means of the vagus nerve and nerve fibers from sacral segments of the spinal cord; it increases gastrointestinal motility. Sympathetic activity occurs by way of thoracolumbar output from the spinal cord, its paravertebral ganglia, and celiac, superior mesenteric, and inferior mesenteric ganglia. Sympathetic stimulation enhances sphincter function and reduces motility by inhibiting the activity of intramural plexus neurons.

HORMONAL AND SECRETORY FUNCTION

Each day, approximately 7000 mL of fluid is secreted into the gastrointestinal tract (Table 26-1). Approximately 50 to 200 mL of this fluid leaves the body in the stool; the remainder is reabsorbed in the small and large intestines. These secretions are mainly water and have sodium and potassium concentrations similar to those of extracellular fluid. Because water and electrolytes for digestive tract secretions are derived from the extracellular fluid compartment, excessive secretion or impaired absorption can lead to extracellular fluid deficit.

The secretory activity of the gut is influenced by local, humoral, and neural influences. Neural control of gastrointestinal secretory activity is mediated through the ANS. Secretory activity, like motility, is increased with parasympathetic stimulation and inhibited with sympathetic activity. Many of the local influences, including pH, osmolality, and chyme, consistently act as stimuli for neural and humoral mechanisms.

Gastrointestinal Hormones

The gastrointestinal tract is the largest endocrine organ in the body. It produces hormones that pass from the portal circulation into the general circulation and then back to the digestive tract, where they exert their actions. Among the hormones produced by the gastrointestinal tract are gastrin, secretin, and cholecystokinin. These hormones influence motility and the secretion of electrolytes, enzymes, and other hormones. The gastrointestinal tract hormones and their functions are summarized in Table 26-2.

The primary function of *gastrin* is the stimulation of gastric acid secretion. Gastrin also has a trophic, or growth-producing, effect on the mucosa of the small intestine, colon, and oxyntic (acid-secreting) gland area of the stomach. Removal of the tissue that produces gastrin results in atrophy of these structures. This atrophy can be reversed by the administration of exogenous gastrin.

Secretin is secreted by S cells in the mucosa of the duodenum and jejunum in an inactive form called *prosecretin*. When an acid chyme with a pH of less than 4.5 to 5.0 enters the intestine, secretin is activated and absorbed into the blood. Secretin causes the pancreas to secrete large quantities of fluid with a high bicarbonate concentration and low chloride concentration.

TABLE 26-1	Secretions of		
the Gastrointestinal Tract			
Secretions Amount Daily (mL)			
Salivary	1200		
Gastric	2000		
Pancreatic	1200		
Biliary	700		
Intestinal	2000		
Total	7100		

TABLE 26-2	Major Gastrointestinal Hormones and Their Actions		
Hormone	Site of Secretion	Stimulus for Secretion	Action
Cholecystokinin	Duodenum, jejunum	Products of protein digestion and long chain fatty acids	Stimulates contraction of the gallbladder; stimulates secretion of pancreatic enzymes; slows gastric emptying
Gastrin	Antrum of the stomach, duodenum	Vagal stimulation; epinephrine; neutral amino acids; calcium-containing fluids such as milk; and alcohol. Secretion is inhibited by acid contents in the an- trum of the stomach (below pH 2.5)	Stimulates secretion of gastric acid and pep- sinogen; increases gastric blood flow; stimu- lates gastric smooth muscle contraction; stimulates growth of gastric, small intestine, and colon mucosa
Secretin	Duodenum	Acid pH or chyme entering duodenum (below pH 3.0)	Stimulates secretion of bicarbonate-containing solution by pancreas and liver

The primary function of *cholecystokinin* is stimulation of pancreatic enzyme secretion. It potentiates the action of secretin, increasing the pancreatic bicarbonate response to low circulating levels of secretin. In addition to its effects on the pancreas, cholecystokinin also stimulates biliary secretion of fluid and bicarbonate and it regulates gallbladder contraction and gastric emptying.

Two other hormones that contribute to gastrointestinal function are gastric inhibitory peptide and motilin. *Gastric inhibitory peptide*, which is released from the intestinal mucosa in response to increased concentration of glucose and fats, inhibits gastric acid secretion, gastric motility, and gastric emptying. *Motilin*, which stimulates intestinal motility and contributes to the control of the interdigestive actions of the intestinal neurons, is released from the upper small intestine.

Gastrointestinal Secretions

Salivary Secretions

Saliva is secreted by the salivary glands. The salivary glands consist of the parotid, submaxillary, sublingual, and buccal glands. Saliva has three functions. The first is protection and lubrication. Saliva is rich in mucus, which protects the oral mucosa and coats the food as it passes through the mouth, pharynx, and esophagus. The sublingual and buccal glands produce only mucus-type secretions. The second function of saliva is its protective antimicrobial action. The saliva cleans the mouth and contains the enzyme lysozyme, which has an antibacterial action. Third, saliva contains ptyalin and amylase, which initiate the digestion of dietary starches. Secretions from the salivary glands are primarily regulated by the ANS. Parasympathetic stimulation increases flow, and sympathetic stimulation decreases flow. The dry mouth that accompanies anxiety attests to the effects of sympathetic activity on salivary secretions.

Mumps, or parotitis, is an infection of the parotid glands. Although most of us associate mumps with the contagious viral form of the disease, inflammation of the parotid glands can occur in the seriously ill person who does not receive adequate oral hygiene and who is unable to take fluids orally. Potassium iodide increases the secretory activity of the salivary glands, including the parotid glands. In a small percentage of persons, parotid swelling may occur in the course of treatment with this drug.

Gastric Secretions

In addition to mucus-secreting cells that line the entire surface of the stomach, the stomach mucosa has two types of glands: oxyntic (or gastric) glands and pyloric glands. The *oxyntic glands* are located in the proximal 80% (body and fundus) of the stomach. They secrete hydrochloric acid, pepsinogen, intrinsic factor, and mucus. The *pyloric glands* are located in the distal 20%, or antrum, of the stomach. The pyloric glands secrete mainly mucus, some pepsinogen, and the hormone gastrin.

The oxyntic gland area of the stomach is composed of glands and pits (Fig. 26-8). The surface area and gastric pits are lined with mucus-producing epithelial cells. The bases of the gastric pits contain the parietal (or oxyntic) cells, which secrete hydrochloric acid and intrinsic factor, and the chief (peptic) cells, which secrete large quantities of pepsinogen. There are approximately 1 billion parietal cells in the stomach; together they produce and secrete approximately 20 mEq of hydrochloric acid in several hundred milliliters of gastric juice each hour. Gastric intrinsic factor, which is produced by the parietal cells, is necessary for the absorption of vitamin B₁₂. The pepsinogen that is secreted by the chief cells is rapidly converted to pepsin when exposed to the low pH of the gastric juices.

One of the important characteristics of the gastric mucosa is resistance to the highly acid secretions that it produces. When the gastric mucosa is damaged by aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), ethyl alcohol, or bile salts, this resistance is disrupted, and hydrogen ions move into the mucosal cells. As the hydrogen ions accumulate in the mucosal cells, intracellular pH decreases, enzymatic reactions become impaired, and cellular structures are disrupted. The result is local ischemia and tissue necrosis. The mucosal surface is further protected by prostaglandins.

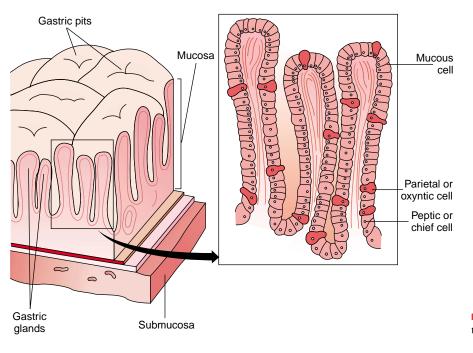

Parasympathetic stimulation (through the vagus nerve) and gastrin increase gastric secretions. Histamine increases gastric acid secretions. Gastric acid secretion and its relation to peptic ulcer are discussed in Chapter 27.

Intestinal Secretions

The small intestine secretes digestive juices and receives secretions from the liver and pancreas (see Chapter 28). An extensive array of mucus-producing glands, called *Brunner's glands*,

Dr Murtadha Alshareifi e-Library

468 Unit Seven: Alterations in the Gastrointestinal System

■ **FIGURE 26-8** ■ Gastric pit from body of the stomach.

are concentrated at the site where the contents from the stomach and secretions from the liver and pancreas enter the duodenum. These glands secrete large amounts of alkaline mucus that protect the duodenum from the acid content in the gastric chyme and from the action of the digestive enzymes. The activity of Brunner's glands is strongly influenced by ANS activity. For example, sympathetic stimulation causes a marked decrease in mucus production, leaving this area more susceptible to irritation.

In addition to mucus, the intestinal mucosa produces two other types of secretions. The first is a serous fluid (pH 6.5 to 7.5) secreted by specialized cells (*i.e.*, crypts of Lieberkühn) in the intestinal mucosal layer. This fluid, which is produced at the rate of 2000 mL/day, acts as a vehicle for absorption. The second type of secretion consists of surface enzymes that aid absorption. These enzymes are the peptidases, or enzymes that separate amino acids, and the disaccharidases, or enzymes that split sugars.

The large intestine usually secretes only mucus. ANS activity strongly influences mucus production in the bowel, as in other parts of the digestive tract. During intense parasympathetic stimulation, mucus secretion may increase to the point that the stool contains large amounts of obvious mucus. Although the bowel normally does not secrete water or electrolytes, these substances are lost in large quantities when the bowel becomes irritated or inflamed.

In summary, the secretions of the gastrointestinal tract include saliva, gastric juices, bile, and pancreatic and intestinal secretions. Each day, more than 7000 mL of fluid is secreted into the digestive tract; all but 50 to 200 mL of this fluid is reabsorbed. Water, derived from the extracellular fluid compartment, is the major component of gastrointestinal tract secretions. Neural, humoral, and local mechanisms contribute to the control of these secretions. The parasympathetic nervous system increases secretion, and sympathetic activity exerts an inhibitory effect. In addition to secreting fluids containing digestive enzymes, the gastrointestinal tract produces and secretes hormones, such as gastrin, secretin, and cholecystokinin, that contribute to the control of gastrointestinal function.

DIGESTION AND ABSORPTION

Digestion and absorption occur mainly in the small intestine. The stomach is a poor absorptive structure, and only a few lipid-soluble substances, including alcohol, are absorbed from the stomach.

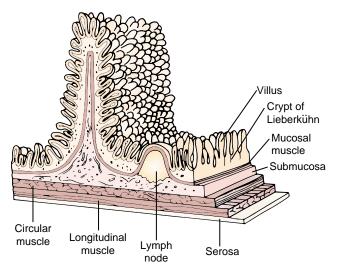

Digestion is the process of dismantling foods into their constituent parts. Digestion requires hydrolysis, enzyme cleavage, and fat emulsification. Hydrolysis is breakdown of a compound that involves a chemical reaction with water. The importance of hydrolysis to digestion is evidenced by the amount of water (7 to 8 L) that is secreted into the gastrointestinal tract daily. The intestinal mucosa is impermeable to most large molecules. Most proteins, fats, and carbohydrates must be broken down into smaller particles before they can be absorbed. Although some digestion of carbohydrates and proteins begins in the stomach, digestion takes place mainly in the small intestine. The breakdown of fats to free fatty acids and monoglycerides takes place entirely in the small intestine. The liver, with its production of bile, and the pancreas, which supplies a number of digestive enzymes, play important roles in digestion.

Absorption is the process of moving nutrients and other materials from the external environment of the gastrointestinal tract into the internal environment. Absorption is accomplished by active transport and diffusion. The absorptive function of the large intestine focuses mainly on water reabsorption. A number of substances require a specific carrier or transport system. For example, vitamin B_{12} is not absorbed in the absence of intrinsic factor, which is secreted by the parietal cells of the stomach. Transport of amino acids and glucose occurs mainly in the presence of sodium. Water is absorbed passively along an osmotic gradient.

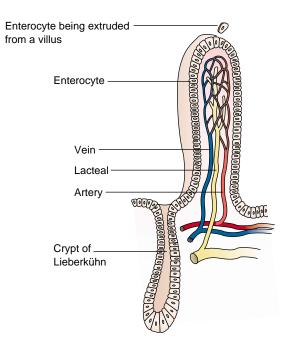

The distinguishing characteristic of the small intestine is its large surface area, which in the adult is estimated to be approximately 250 m². Anatomic features that contribute to this enlarged surface area are the circular folds that extend into the lumen of the intestine and the villi, which are finger-like projections of mucous membrane, numbering as many as 25,000, that line the entire small intestine (Fig. 26-9). Each villus is equipped with an arrangement of blood vessels for the absorption of fluid and dissolved material into the portal blood and a central lacteal for absorption into the lymph (Fig. 26-10). Fats rely largely on the lymphatics for absorption.

Each villus is covered with cells called *enterocytes* that contribute to the absorptive and digestive functions of the small bowel, and goblet cells that provide mucus. The crypts of Lieberkühn are glandular structures that open into the spaces between the villi. The enterocytes have a life span of approximately 4 to 5 days; their replacement cells differentiate from progenitor cells located in the area of the crypts. The maturing enterocytes migrate up the villus and eventually are extruded from the tip.

The enterocytes secrete enzymes that aid in the digestion of carbohydrates and proteins. These enzymes are called *brush border enzymes* because they adhere to the border of the villus structures. In this way they have access to the carbohydrates and protein molecules as they come in contact with the absorptive surface of the intestine. This mechanism of secretion places the enzymes where they are needed and eliminates the need to produce enough enzymes to mix with the entire contents that fill the lumen of the small bowel. The digested mol-

■ FIGURE 26-10 ■ A single villus from the small intestine.

ecules diffuse through the membrane or are actively transported across the mucosal surface to enter the blood or, in the case of fatty acids, the lacteal. These molecules are then transported through the portal vein or lymphatics into the systemic circulation.

Carbohydrates

Carbohydrates must be broken down into monosaccharides, or single sugars, before they can be absorbed from the small intestine. The average daily intake of carbohydrate in the American diet is approximately 350 to 400 g. Starch makes up approximately 50% of this total, sucrose (*i.e.*, table sugar) approximately 30%, lactose (*i.e.*, milk sugar) approximately 6%, and maltose approximately 1.5%.

Digestion of starch begins in the mouth with the action of amylase. Pancreatic secretions also contain an amylase. Amylase breaks down starch into several disaccharides, including maltose, isomaltose, and α -dextrins. The brush border enzymes convert the disaccharides into monosaccharides that can be absorbed (Table 26-3). Sucrose yields glucose and fructose, lactose is converted to glucose and galactose, and maltose is converted to two glucose molecules. When the disaccharides are not broken down to monosaccharides, they cannot be absorbed but remain as osmotically active particles in the contents of the digestive system, causing diarrhea. Persons who are deficient in lactase, the enzyme that breaks down lactose, experience diarrhea when they drink milk or eat dairy products.

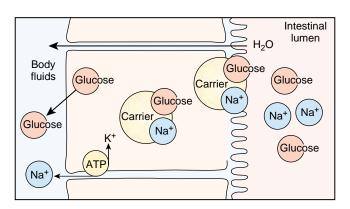

Fructose is transported across the intestinal mucosa by facilitated diffusion, which does not require energy expenditure. In this case, fructose moves along a concentration gradient. Glucose and galactose are transported by way of a sodiumdependent carrier system that uses adenosine triphosphate and the Na⁺/K⁺-ATPase pump as an energy source (Fig. 26-11).

TABLE 26-3	TABLE 26-3 Enzymes Used in Digestion of Carbohydrates			
Dietary Carbol	nydrates	Enzyme	Monosaccharides Produced	
Lactose		Lactase	Glucose and galactose	
Sucrose		Sucrase	Fructose and glucose	
Starch		Amylase	Maltose, maltotriase, and α -dextrins	
Maltose and m	naltotriose	Maltase	Glucose and glucose	
α-Dextrins		α -Dextrimase	Glucose and glucose	

Water absorption from the intestine is linked to absorption of osmotically active particles, such as glucose and sodium. It follows that an important consideration in facilitating the transport of water across the intestine (and decreasing diarrhea) after temporary disruption in bowel function is to include sodium and glucose in the fluids that are taken.

Fats

The average adult eats approximately 60 to 100 g of fat daily, principally as triglycerides containing long-chain fatty acids. These triglycerides are broken down by pancreatic lipase. Bile salts act as a carrier system for the fatty acids and fat-soluble vitamins A, D, E, and K by forming micelles, which transport these substances to the surface of intestinal villi, where they are absorbed by the lacteal. The major site of fat absorption is the upper jejunum. Medium-chain triglycerides, with 6 to 10 carbon atoms in their structures, are absorbed better than longer-chain fatty acids because they are more completely broken down by pancreatic lipase and they form micelles more easily. Because they are easily absorbed, medium-chain triglycerides often are used in the treatment of persons with malabsorption syndrome. The absorption of vitamins A, D, E, and K, which are fat-soluble vitamins, requires bile salts.

■ FIGURE 26-11 ■ The hypothetical sodium-dependent transport system for glucose. Both sodium and glucose must attach to the transport carrier before either can be transported into the cell. The concentration of glucose builds up in the intestinal cell until a diffusion gradient develops, causing glucose to move into the body fluids. Sodium is transported out of the cell by the energydependent Na⁺/K⁺-ATPase pump. This creates the gradient needed to operate the transport system. Water is passively absorbed along a concentration gradient generated by the absorption of solutes. Fat that is not absorbed in the intestine is excreted in the stool. *Steatorrhea* is the term used to describe fatty stools. It usually indicates that there is 20 g or more of fat in a 24-hour stool sample. Normally, a chemical test is done on a 72-hour stool collection, during which time the diet is restricted to 80 to 100 g of fat per day.

Proteins

Proteins from the diet must be broken into amino acids to be absorbed. Protein digestion begins in the stomach with the action of pepsin. Pepsinogen, the enzyme precursor of pepsin, is secreted by the chief cells in response to a meal and acid pH. Acid in the stomach is required for the conversion of pepsinogen to pepsin. Pepsin is inactivated when it enters the intestine by the alkaline pH.

Proteins are broken down further by pancreatic enzymes, such as trypsin, chymotrypsin, carboxypeptidase, and elastase. As with pepsin, the pancreatic enzymes are secreted as precursor molecules. Trypsinogen, which lacks enzymatic activity, is activated by an enzyme located on the brush border cells of the duodenal enterocytes. Activated trypsin activates additional trypsinogen molecules and other pancreatic precursor proteolytic enzymes. The amino acids are liberated intramurally or on the surface of the villi by brush border enzymes that degrade proteins into peptides that are one, two, or three amino acids long. Similar to glucose, many amino acids are transported across the mucosal membrane in a sodium-linked process that uses the Na⁺/K⁺- ATPase pump as an energy source.

In summary, the digestion and absorption of foodstuffs take place in the small intestine. Digestion is the process of dismantling foods into their constituent parts. Digestion requires hydrolysis, enzyme cleavage, and fat emulsification. Proteins, fats, carbohydrates, and other components of the diet are broken down into molecules that can be transported from the intestinal lumen into the body fluids. Absorption is the process of moving nutrients and other materials from the external environment of the gastrointestinal tract into the internal environment. Brush border enzymes break carbohydrates into monosaccharides that can be transported across the intestine into the bloodstream. The digestion of proteins begins in the stomach with the action of pepsin and is further facilitated in the intestine by the pancreatic enzymes, such as trypsin, chymotrypsin, carboxypeptidase, and elastase. The absorption of glucose and amino acids is facilitated by a sodium-dependent transport system. Fat in the diet is broken down by pancreatic lipase into triglycerides containing

medium- and long-chain fatty acids. Bile salts form micelles that transport these substances to the surface of intestinal villi, where they are absorbed.

ANOREXIA, NAUSEA, AND VOMITING

Anorexia, nausea, and vomiting are physiologic responses that are common to many gastrointestinal disorders. These responses are protective to the extent that they signal the presence of disease and, in the case of vomiting, remove noxious agents from the gastrointestinal tract. They also can contribute to impaired intake or loss of fluids and nutrients.

Anorexia

Anorexia represents a loss of appetite. Several factors influence appetite. One is hunger, which is stimulated by contractions of the empty stomach. Appetite or the desire for food intake is regulated by the hypothalamus and other associated centers in the brain (see Chapter 29). Smell plays an important role, as evidenced by the fact that appetite can be stimulated or suppressed by the smell of food. Loss of appetite is associated with emotional factors, such as fear, depression, frustration, and anxiety. Many drugs and disease states cause anorexia. For example, in uremia the accumulation of nitrogenous wastes in the blood contributes to the development of anorexia. Anorexia often is a forerunner of nausea, and most conditions that cause nausea and vomiting also produce anorexia.

Nausea

Nausea is an ill-defined and unpleasant subjective sensation. It is the conscious sensation resulting from stimulation of the medullary vomiting center that often precedes or accompanies vomiting. Nausea usually is preceded by anorexia, and stimuli such as foods and drugs that cause anorexia in small doses usually produce nausea when given in larger doses. A common cause of nausea is distention of the duodenum or upper small intestinal tract. Nausea frequently is accompanied by autonomic nervous system manifestations such as watery salivation and vasoconstriction with pallor, sweating, and tachycardia. Nausea may function as an early warning signal of a pathology.

Vomiting

Vomiting, or emesis, is the sudden and forceful oral expulsion of the contents of the stomach. It usually is preceded by nausea. The contents that are vomited are called vomitus. Vomiting, as a basic physiologic protective mechanism, limits the possibility of damage from ingested noxious agents by emptying the contents of the stomach and portions of the small intestine. Nausea and vomiting may represent a total-body response to drug therapy, including overdosage, cumulative effects, toxicity, and side effects.

Vomiting involves two functionally distinct medullary centers: the vomiting center and the chemoreceptor trigger zone. The act of vomiting is integrated by the vomiting center, which is located in the dorsal portion of the reticular formation of the medulla near the sensory nuclei of the vagus. The chemoreceptor trigger zone is located in a small area on the floor of the fourth ventricle, where it is exposed to both blood and cerebrospinal fluid. It is thought to mediate the emetic effects of blood-borne drugs and toxins.

The act of vomiting consists of taking a deep breath, closing the airways, and producing a strong, forceful contraction of the diaphragm and abdominal muscles along with relaxation of the gastroesophageal sphincter. Respiration ceases during the act of vomiting. Vomiting may be accompanied by dizziness, light-headedness, decrease in blood pressure, and bradycardia.

The vomiting center receives input from the gastrointestinal tract and other organs; from the cerebral cortex; from the vestibular apparatus, which is responsible for motion sickness; and from the chemoreceptor trigger zone, which is activated by many drugs and endogenous and exogenous toxins. Hypoxia exerts a direct effect on the vomiting center, producing nausea and vomiting. This direct effect probably accounts for the vomiting that occurs during periods of decreased cardiac output, shock, environmental hypoxia, and brain ischemia caused by increased intracranial pressure. Inflammation of any of the intra-abdominal organs, including the liver, gallbladder, or urinary tract, can cause vomiting because of the stimulation of the visceral afferent pathways that communicate with the vomiting center. Distention or irritation of the gastrointestinal tract also causes vomiting through the stimulation of visceral afferent neurons.

Several neurotransmitters and receptor subtypes are implicated as neuromediators in nausea and vomiting. Dopamine, serotonin, and opioid receptors are found in the gastrointestinal tract and in the vomiting and chemoreceptor trigger zone. Dopamine antagonists, such as prochlorperazine, depress vomiting caused by stimulation of the chemoreceptor trigger zone. Serotonin is believed to be involved in the nausea and emesis associated with cancer chemotherapy and radiation therapy. Serotonin antagonists (e.g., granisetron and ondansetron) are effective in treating the nausea and vomiting associated with these stimuli. Motion sickness appears to be a central nervous system (CNS) response to vestibular stimuli. Norepinephrine and acetylcholine receptors are located in the vestibular center. The acetylcholine receptors are thought to mediate the impulses responsible for exciting the vomiting center; norepinephrine receptors may have a stabilizing influence that resists motion sickness. Many of the motion sickness drugs (e.g., dimenhydrinate) have a strong CNS anticholinergic effect and act on the receptors in the vomiting center and areas related to the vestibular system.

In summary, the signs and symptoms of many gastrointestinal tract disorders are manifested by anorexia, nausea, and vomiting. Anorexia, or loss of appetite, may occur alone or may accompany nausea and vomiting. Nausea, which is an ill-defined, unpleasant sensation, signals the stimulation of the medullary vomiting center. It often precedes vomiting and frequently is accompanied by autonomic responses, such as salivation and vasoconstriction with pallor, sweating, and tachycardia. The act of vomiting, which is integrated by the vomiting center, involves the forceful oral expulsion of the gastric contents. It is a basic physiologic mechanism that rids the gastrointestinal tract of noxious agents.

REVIEW QUESTIONS

Describe the physiologic function of the digestive system in terms of transport of food, digestion, absorption of nutrients, and storage of waste products.

Approximately 7000 mL of fluid is secreted into the gastrointestinal tract, with only about 200 mL being eliminated in the stool. Explain the source, composition, function, and removal of this fluid from the gastrointestinal tract.

Describe the site of gastric acid and pepsin production and secretion in the stomach.

Describe the function of the gastric mucosal barrier.

Relate the characteristics of the small intestine to its absorptive function and explain the function of intestinal brush border enzymes in the digestion and absorption of carbohydrates, fats, and proteins.

Explain the relationship between the enteric nervous system and the autonomic nervous system in the regulation of gastrointestinal function.

Describe the innervation of the reflexive and voluntary components of defecation.

CHAPTER

Alterations in Intestinal Absorption Malabsorption Syndrome Neoplasms Adenomatous Polyps Colorectal Cancer

Gause of death in the United States, nor do they receive the same publicity as heart disease and cancer. However, according to government reports, digestive diseases rank third in the total economic burden of illness, resulting in considerable human suffering, personal expenditures for treatment, lost working hours, and a drain on the nation's economy. It has been estimated that 60 to 70 million Americans have digestive disease.¹ Even more important is the fact that proper nutrition or a change in health practices could prevent or minimize many of these disorders.

DISORDERS OF THE ESOPHAGUS

The esophagus is a tube that connects the oropharynx with the stomach. It lies posterior to the trachea and larynx and extends through the mediastinum, intersecting the diaphragm at the level of the 11th thoracic vertebra. The esophagus functions primarily as a conduit for passage of food from the pharynx to the stomach, and the structure of its wall is designed for this purpose: the smooth muscle layers provide the peristaltic movements needed to move food along its length, and the epithelial layer secretes mucus, which protects its surface and aids in lubricating food.

Dysphagia

The act of swallowing depends on the coordinated action of the tongue and pharynx. These structures are innervated by cranial nerves V, IX, X, and XII. *Dysphagia* refers to difficulty in swallowing. If swallowing is painful, it is referred to as *odynophagia*. Dysphagia can result from altered nerve function or from disorders that produce narrowing of the esophagus. Lesions of the central nervous system (CNS), such as a stroke, often involve

the cranial nerves that control swallowing. Strictures and cancer of the esophagus and strictures resulting from scarring can reduce the size of the esophageal lumen and make swallowing difficult. Scleroderma, an autoimmune disease that causes fibrous replacement of tissues in the muscularis layer of the gastrointestinal tract, is another important cause of dysphagia.² Persons with dysphagia usually report choking, coughing, or an abnormal sensation of food sticking in the back of the throat or upper chest when they swallow.

In a condition called *achalasia*, the lower esophageal sphincter fails to relax; food that has been swallowed has difficulty passing into the stomach, and the esophagus above the lower esophageal sphincter becomes enlarged. One or several meals may lodge in the esophagus and pass slowly into the stomach. There is danger of aspiration of esophageal contents into the lungs when the person lies down.

Esophageal Diverticulum

A diverticulum of the esophagus is an outpouching of the esophageal wall caused by a weakness of the muscularis layer. An esophageal diverticulum tends to retain food. Reports that the food stops before it reaches the stomach are common, as are reports of gurgling, belching, coughing, and foul-smelling breath. The trapped food may cause esophagitis and ulceration. Because the condition usually is progressive, correction of the defect requires surgical intervention.

Gastroesophageal Reflux Disease

The term *reflux* refers to backward or return movement. In the context of gastroesophageal reflux, it refers to the backward movement of gastric contents into the esophagus, a condition that causes heartburn. Often referred to as *gastroesophageal reflux disease* (GERD), it probably is the most common disorder originating in the gastrointestinal tract. Most persons experience heartburn occasionally as a result of reflux. Such symptoms usually occur soon after eating, are short lived, and seldom cause more serious problems. However, for some persons, persistent heartburn can represent reflux disease with esophagitis.

The lower esophageal sphincter regulates the flow of food from the esophagus into the stomach. Both internal and external mechanisms function in maintaining the antireflux function of the lower esophageal sphincter.^{3,4} Relaxation of the lower esophageal sphincter is a brain stem reflex that is mediated by the vagus nerve in response to a number of afferent stimuli. Transient relaxation with reflux is common after meals. Gastric distension and meals high in fat increase the frequency of relaxation. Refluxed material normally is returned to the stomach by secondary peristaltic waves in the esophagus, with swallowed saliva neutralizing and washing away the refluxed acid.

GERD is thought to be associated with a weak or incompetent lower esophageal sphincter that allows reflux to occur, the irritant effects of the refluxate, and decreased clearance of the refluxed acid from the esophagus after it has occurred.^{5,6} Delayed gastric emptying also may contribute to reflux by increasing gastric volume and pressure with greater chance for reflux. Esophageal mucosal injury is related to the destructive nature of the refluxate and the amount of time it is in contact with mucosa. Acidic gastric fluids (pH < 4.0) are particularly damaging. There is controversy regarding the importance of hiatal hernia (*i.e.*, herniation of the stomach through an enlarged hiatus in the diaphragm) in the pathogenesis of reflux disease. Small hiatal hernias are common and considered to be of no significance in asymptomatic people. However, in cases of severe erosive esophagitis where gastroesophageal reflux and large hiatal hernia coexist, the hernia may retard esophageal acid clearance and contribute to the disorder.^{3,5}

Reflux esophagitis involves mucosal injury to the esophagus, hyperemia, and inflammation. The most common symptom of gastroesophageal reflux is heartburn. It frequently is severe, occurring 30 to 60 minutes after eating. It often is made worse by bending at the waist and recumbency and usually is relieved by sitting upright. The severity of heartburn is not indicative of the extent of mucosal injury; only a small percentage of people who report heartburn have mucosal injury. Often, the heartburn occurs during the night. Antacids give prompt, although transient relief. Other symptoms include belching and chest pain. The pain usually is located in the epigastric or retrosternal area and often radiates to the throat, shoulder, or back. Because of its location, the pain may be confused with angina. The reflux of gastric contents also may produce respiratory symptoms such as wheezing, chronic cough, and hoarseness. There is considerable evidence linking gastroesophageal reflux with bronchial asthma.7 The proposed mechanisms of reflux-associated asthma and chronic cough include aspiration, laryngeal injury, and vagal-mediated bronchospasm.

Persistent gastroesophageal reflux produces a cycle of mucosal damage that predisposes to strictures and a condition called *Barrett's esophagus*. Strictures are caused by a combination of scar tissue, spasm, and edema. They produce narrowing of the esophagus and can cause dysphagia. Barrett's esophagus is characterized by a reparative process in which the squamous mucosa that normally lines the esophagus gradually is replaced by columnar epithelium resembling that in the stomach or intestines.^{5,6} It is associated with increased risk for development of esophageal cancer.

The diagnosis of gastroesophageal reflux depends on a history of reflux symptoms and selective use of diagnostic methods, including radiographic studies using a contrast medium such as barium, esophagoscopy, and ambulatory esophageal pH monitoring.⁸

The treatment of gastroesophageal reflux usually focuses on conservative measures. These measures include avoidance of positions and conditions that increase gastric reflux.⁸ Avoidance of large meals and foods that reduce lower esophageal sphincter tone (*e.g.*, caffeine, fats, chocolate), alcohol, and smoking is recommended. Sleeping with the head elevated helps to prevent reflux during the night. Weight loss usually is recommended in overweight people.

Antacids or a combination of antacids and alginic acid also are recommended for mild disease. Alginic acid produces a foam when it comes in contact with gastric acid; if reflux occurs, the foam, rather than acid, rises into the esophagus. Histamine type 2 receptor-blocking drugs, which inhibit gastric acid production, often are recommended when additional treatment is needed. Proton pump inhibitors, which block the final pathway for acid secretion, may be used for persons who continue to have daytime symptoms, recurrent strictures, or large esophageal ulcerations. Surgical treatment may be indicated in some people.

Gastroesophageal Reflux in Children

Gastroesophageal reflux is a common problem in infants. The small reservoir capacity of an infant's esophagus coupled with frequent spontaneous reductions in sphincter pressure contributes to reflux. Regurgitation of at least one episode a day occurs in as many as half of infants 0 to 3 months of age. By 6 months of age it becomes less frequent, and it abates by 2 years of age as the child assumes a more upright posture and eats solid foods.^{9,10} Although many infants have minor degrees of reflux, complications occur in 1 of every 300 to 500 children.^{9,10} The condition occurs more frequently in children with cerebral palsy, Down's syndrome, and other causes of developmental delay.

In most cases, infants with simple reflux are thriving and healthy, and symptoms resolve between 9 and 24 months of age. Pathologic reflux is classified into three categories: (1) regurgitation and malnutrition, (2) esophagitis, and (3) respiratory problems. Symptoms of esophagitis include evidence of pain when swallowing, hematemesis, anemia caused by esophageal bleeding, heartburn, irritability, and sudden or inconsolable crying. Parents often report feeding problems in their infants.9 These infants often are irritable and demonstrate early satiety. Sometimes the problems progress to actual resistance to feeding. Tilting of the head to one side and arching of the back may be noted in children with severe reflux. The head positioning is thought to represent an attempt to protect the airway or reduce the pain-associated reflux. Sometimes regurgitation is associated with dental caries and recurrent otalgia. The ear pain is thought to occur through referral from the vagus nerve in the esophagus to the ear. A variety of respiratory symptoms are caused by damage to the respiratory mucosa when gastric reflux enters the esophagus. Reflux may cause laryngospasm, apnea, and bradycardia. A relationship between reflux and acute life-threatening events or sudden infant death syndrome has been proposed. However, the association remains a matter of controversy, and the linkage may be coincidental.9,10

Rumination is the repetitive gagging, regurgitation, mouthing, and reswallowing of regurgitated material. Although the cause of the disorder is unknown, it often is associated with mental retardation or altered interaction with the environment (*e.g.*, lack of stimulation in newborn intensive care units or because of altered relationships with caregivers). As with pure reflux, rumination may produce severe esophagitis with signs of iron deficiency anemia, failure to thrive, and head tilting.¹⁰

Diagnosis of gastroesophageal reflux in infants and children often is based on parental and clinical observations. The diagnosis may be confirmed by esophageal pH probe studies or barium fluoroscopic esophagography. In severe cases, esophagoscopy may be used to demonstrate reflux and obtain a biopsy.

Various treatment methods are available for infants and children with gastroesophageal reflux. Small, frequent feedings are recommended because of the association between gastric volume and transient relaxation of the esophagus. Thickening an infant's feedings with cereal tends to decrease the volume of reflux, decrease crying and energy expenditure, and increase the calorie density of the formula.^{9,10} In infants, positioning on the left side seems to decrease reflux. In older infants and children, raising the head of the bed and keeping the child upright may help. Medications usually are not added to the treatment regimen until pathologic reflux has been documented by diagnostic testing.

Chapter 27: Alterations in Gastrointestinal Function

Cancer of the Esophagus

Carcinoma of the esophagus accounts for approximately 6% of all gastrointestinal cancers. This disease is more common in persons older than 50 years, with a male-to-female ratio of approximately 2:1.¹¹

There are two types of esophageal cancers: squamous cell and adenocarcinomas. Fewer than 50% of esophageal tumors are squamous cell cancers. These cancers are associated more commonly with dietary and environmental influences.^{11,12} Most squamous cell cancers in the United States and Europe are attributable to alcohol and tobacco use. Adenocarcinomas, which typically arise from Barrett's esophagus, account for more than 50% of esophageal cancers. The incidence of this type of cancer appears to be increasing. Adenocarcinomas typically are located in the distal esophagus and may invade the adjacent upper part of the stomach. Endoscopic surveillance in people with Barrett's esophagus may detect adenocarcinoma at an earlier stage, when it is more amenable to curative surgical resection.¹²

Dysphagia is by far the most frequent complaint of persons with esophageal cancer. It is apparent first with ingestion of bulky food, later with soft food, and finally with liquids. Unfortunately, it is a late manifestation of the disease. Weight loss, anorexia, fatigue, and pain on swallowing also may occur.

Treatment includes surgical resection, which provides a means of cure when done in early disease and palliation when done in late disease. Irradiation is used as a palliative treatment. Chemotherapy sometimes is used before surgery to decrease the size of the tumor, and it may be used along with irradiation and surgery in an effort to increase survival.¹²

The prognosis for persons with cancer of the esophagus, although poor, has improved. However, even with modern forms of therapy, the long-term survival is limited because, in many cases, the disease has already metastasized by the time the diagnosis is made.

In summary, the esophagus is a tube that connects the oropharynx with the stomach; it functions primarily as a conduit for passage of food from the pharynx to the stomach. Dysphagia refers to difficulty in swallowing; it can result from altered nerve function or from disorders that produce narrowing of the esophagus. A diverticulum of the esophagus is an outpouching of the esophageal wall caused by a weakness of the muscularis layer.

Gastrointestinal reflux refers to the backward movement of gastric contents into the esophagus, a condition that causes heartburn. Although most persons experience occasional esophageal reflux and heartburn, persistent reflux can cause esophagitis. Gastroesophageal reflux is a common problem in infants. Reflux commonly corrects itself with age, and symptoms abate in most children by 2 years of age. Although many infants have minor degrees of reflux, some infants and small children have significant reflux that interferes with feeding, causes esophagitis, and results in respiratory symptoms and other complications.

Carcinoma of the esophagus, which accounts for 6% of all cancers, is more common in persons older than 50 years, and the male-to-female ratio is approximately 2:1. There are two types of esophageal cancer: squamous cell and adenocarcinoma. Most squamous cell cancers are attributable to alcohol and tobacco use, whereas adenocarcinomas are more closely linked to esophageal reflux and Barrett's esophagus.

DISORDERS OF THE STOMACH

The stomach is a reservoir for contents entering the digestive tract. While in the stomach, food is churned and mixed with hydrochloric acid and pepsin before being released into the small intestine. Normally, the mucosal surface of the stomach provides a barrier that protects it from the hydrochloric acid and pepsin contained in gastric secretions. Disorders of the stomach include gastritis, peptic ulcer, and gastric carcinoma.

Gastric Mucosal Barrier

The stomach lining usually is impermeable to the acid it secretes, a property that allows the stomach to contain acid and pepsin without having its wall digested. Several factors contribute to the protection of the gastric mucosa, including an impermeable epithelial cell surface covering, mechanisms for the selective transport of hydrogen and bicarbonate ions, and the characteristics of gastric mucus.¹³ These mechanisms are collectively referred to as the *gastric mucosal barrier*.

KEY CONCEPTS

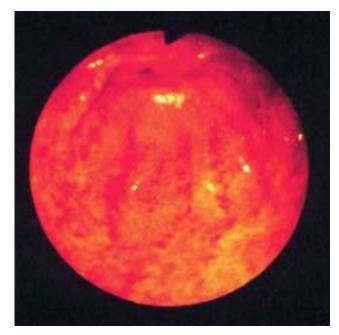

DISRUPTION OF THE GASTRIC MUCOSA AND ULCER DEVELOPMENT

- The stomach is protected by tight cellular junctions, a protective mucus layer, and prostaglandins that serve as chemical messengers to protect the stomach lining by improving blood flow, increasing bicarbonate secretion, and enhancing mucus production.
- Two of the major causes of gastric irritation and ulcer formation are aspirin or nonsteroidal antiinflammatory drugs (NSAIDs) and infection with *Helicobacter pylori*.
- Aspirin and NSAIDs exert their destructive effects by damaging epithelial cells, impairing mucus production, and inhibiting prostaglandin synthesis.
- H. pylori is an infectious agent that thrives in the acid environment of the stomach and disrupts the mucosal barrier that protects the stomach from the harmful effects of its digestive enzymes.

The gastric epithelial cells are connected by tight junctions that prevent acid penetration, and they are covered with an impermeable hydrophobic lipid layer that prevents diffusion of ionized water-soluble molecules. Aspirin, which is nonionized and lipid soluble in acid solutions, rapidly diffuses across this lipid layer, increasing mucosal permeability and damaging epithelial cells.¹⁴ Gastric irritation and occult bleeding caused by gastric irritation occur in a significant number of persons who take aspirin on a regular basis (Fig. 27-1). Alcohol, which also is lipid soluble, disrupts the mucosal barrier; when aspirin and alcohol are taken in combination, as they often are, there is increased risk of gastric irritation. Bile acids also attack the lipid components of the mucosal barrier and afford the potential for gastric irritation when there is reflux of duodenal contents into the stomach.

Normally, the secretion of hydrochloric acid by the parietal cells of the stomach is accompanied by secretion of bicarbonate ions (HCO_3^-). For every hydrogen ion (H^+) that is secreted, a HCO_3^- is produced, and as long as HCO_3^- production is equal to H^+ secretion, mucosal injury does not occur. Changes in gastric blood flow, as in shock, tend to decrease HCO_3^- production. This is particularly true in situations in which decreased blood flow is accompanied by acidosis. Aspirin and the nonsteroidal anti-inflammatory drugs (NSAIDs) also impair HCO_3^- secretion.

Prostaglandins, chemical messengers derived from cell membrane lipids, play an important role in protecting the gastrointestinal mucosa from injury. The prostaglandins probably exert their effect through improved blood flow, increased bicarbonate ion secretion, and enhanced mucus production. The fact that drugs such as aspirin and the NSAIDs inhibit prostaglandin synthesis may contribute to their ability to produce gastric irritation.¹⁴ Smoking and older age have been asso-

■ FIGURE 27-1 ■ Erosive gastritis. This endoscopic view of the stomach in a patient who was ingesting aspirin reveals acute hemorrhagic lesions. (From Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 683]. Philadelphia: Lippincott Williams & Wilkins)

Chapter 27: Alterations in Gastrointestinal Function

ciated with reduced gastric and duodenal prostaglandin concentrations; these observations may explain the predisposition to ulcer disease in smokers and older persons.¹⁵

Gastritis

Gastritis refers to inflammation of the gastric mucosa. There are many causes of gastritis, most of which can be grouped under the headings of acute or chronic gastritis.

Acute Gastritis

Acute gastritis refers to a transient inflammation of the gastric mucosa. It is most commonly associated with local irritants such as bacterial endotoxins, caffeine, alcohol, and aspirin. Depending on the severity of the disorder, the mucosal response may vary from moderate edema and hyperemia to hemorrhagic erosion of the gastric mucosa.

The complaints of persons with acute gastritis vary. Persons with aspirin-related gastritis can be totally unaware of the condition or may report only heartburn or sour stomach. Gastritis associated with excessive alcohol consumption is a different situation; it often causes transient gastric distress, which may lead to vomiting and, in more severe situations, to bleeding and hematemesis. Gastritis caused by the toxins of infectious organisms, such as the staphylococcal enterotoxins, usually has an abrupt and violent onset, with gastric distress and vomiting ensuing approximately 5 hours after the ingestion of a contaminated food source. Acute gastritis usually is a self-limiting disorder; complete regeneration and healing usually occur within several days.

Chronic Gastritis

Chronic gastritis is a separate entity from acute gastritis. It is characterized by the absence of grossly visible erosions and the presence of chronic inflammatory changes leading eventually to atrophy of the glandular epithelium of the stomach. The changes may become dysplastic and possibly transform into carcinoma. Factors such as chronic alcohol abuse, cigarette smoking, and chronic use of NSAIDs may contribute to the development of the disease.

There are four major types of chronic gastritis: (1) autoimmune gastritis, (2) multifocal atrophic gastritis, (3) *Helicobacter pylori* gastritis, and (4) chemical gastropathy.¹⁶ Autoimmune gastritis is the least common form of chronic gastritis. Most persons with the disorder have circulating antibodies to parietal cells and intrinsic factor, so this form of chronic gastritis is considered to be of autoimmune origin. Autoimmune destruction of the parietal cells leads to hypochlorhydria or achlorhydria, a high intragastric pH, and hypergastrinemia. Pernicious anemia is a megaloblastic anemia that is caused by malabsorption of vitamin B₁₂ caused by a deficiency of intrinsic factor (see Chapter 13). This type of chronic gastritis frequently is associated with other autoimmune disorders, such as Hashimoto's thyroiditis and Addison's disease.

Multifocal atrophic gastritis is a disorder of unknown etiology. It is more common than autoimmune gastritis and is seen more frequently in whites than in other races. It is particularly common in Asia, Scandinavia, and parts of Europe and Latin America. As with autoimmune gastritis, it is associated with reduced gastric acid secretion, but achlorhydria and pernicious anemia are less common.

Chronic autoimmune gastritis and multifocal atrophic gastritis cause few symptoms related directly to gastric changes. Persons with autoimmune chronic gastritis may have signs of pernicious anemia. More important is the development of peptic ulcer and increased risk of peptic ulcer and gastric carcinoma. Approximately 2% to 4% of persons with atrophic gastritis eventually experience gastric carcinoma.¹¹

H. pylori gastritis is the most common type of chronic nonerosive gastritis in the United States. H. pylori are small, curved, gram-negative rods that can colonize the mucus-secreting epithelial cells of the stomach^{16,17} (Fig. 27-2). H. pylori have multiple flagella, which allow them to move through the mucous layer of the stomach, and they secrete urease, which enables them to produce sufficient ammonia to buffer the acidity of their immediate environment. Because the organism adheres only to the mucus-secreting cells of the stomach, it does not usually colonize other parts of the gastrointestinal tract. H. pylori produce an enzyme that degrades mucin and has the capacity to interfere with the local protection of the gastric mucosa against acid. It also may produce toxins that directly damage the mucosa and produce ulceration in other ways. Chronic infection with *H. pylori* can lead to gastric atrophy and intestinal metaplasia. H. pylori also can cause peptic ulcer (to be discussed) and has been linked to the development of gastric adenocarcinoma.

Chemical gastropathy is a chronic gastric injury resulting from reflux of alkaline duodenal contents, pancreatic secretions, and bile into the stomach. It is most commonly seen in persons who have had gastroduodenostomy or gastrojejunostomy surgery. A milder form may occur in persons with gastric ulcer,

■ FIGURE 27-2 ■ Infective gastritis. *H. pylori* appears on silver staining as small, curved rods on the surface of the gastric mucosa. (From Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 687]. Philadelphia: Lippincott Williams & Wilkins)

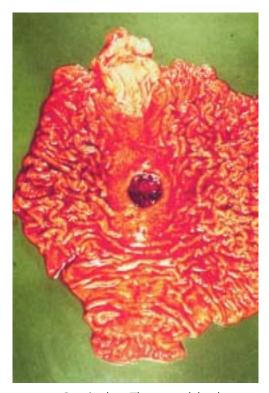

gallbladder disease, or various motility disorders of the distal stomach.

Ulcer Disease

Peptic Ulcer

Peptic ulcer is a term used to describe a group of ulcerative disorders that occur in areas of the upper gastrointestinal tract (*e.g.*, stomach and duodenum) that are exposed to acid-pepsin secretions. Peptic ulcer disease, with its remissions and exacerbations, represents a chronic health problem. Approximately 10% of the population has or will experience peptic ulcer.⁶ Duodenal ulcers occur five times more commonly than do gastric ulcers. Ulcers in the duodenum occur at any age and frequently are seen in early adulthood. Gastric ulcers tend to affect the older age group, with a peak incidence between 55 and 70 years of age. Both types of ulcers affect men three to four times more frequently than women.

A peptic ulcer can affect one or all layers of the stomach or duodenum (Fig. 27-3). The ulcer may penetrate only the mucosal surface, or it may extend into the smooth muscle layers. Occasionally, an ulcer penetrates the outer wall of the stomach or duodenum. Spontaneous remissions and exacerbations are common. Healing of the muscularis layer involves replacement with scar tissue; although the mucosal layers that cover the scarred muscle layer regenerate, the regeneration often is less than perfect, which contributes to repeated episodes of ulceration.

■ FIGURE 27-3 ■ Gastric ulcer. The stomach has been opened to reveal a sharply demarcated, deep peptic ulcer on the lesser curvature. (From Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 693]. Philadelphia: Lippincott Williams & Wilkins)

Since the early 1980s, there has been a radical shift in thinking regarding the cause of peptic ulcer. No longer is peptic ulcer thought to result from a genetic predisposition, stress, or dietary indiscretions. Most cases of peptic ulcer are caused by H. pylori infection.¹⁸ The second most common cause of peptic ulcer is NSAID and aspirin use.18 It has been reported that virtually all persons with duodenal ulcer and 70% of persons with gastric ulcer have H. pylori infection.11 Aspirin and NSAIDs account for 10% to 20% of gastric ulcers and 2% to 5% of duodenal ulcers. Aspirin appears to be the most ulcerogenic of the NSAIDs. Ulcer development in NSAID users is dose dependent, but some risk occurs even with aspirin doses of 325 mg/day.⁶ The pathogenesis of NSAID-induced ulcers is thought to involve mucosal injury and inhibition of prostaglandin synthesis. In contrast to peptic ulcer from other causes, NSAIDinduced gastric injury often is without symptoms, and lifethreatening complications can occur without warning.

The clinical manifestations of uncomplicated peptic ulcer focus on discomfort and pain. The pain, which is described as burning, gnawing, or cramplike, usually is rhythmic and frequently occurs when the stomach is empty—between meals and at 1 or 2 o'clock in the morning. The pain usually is located over a small area near the midline in the epigastrium near the xiphoid and may radiate below the costal margins, into the back, or rarely, to the right shoulder. The pain is usually relieved by food or antacids.

The complications of peptic ulcer include hemorrhage, obstruction, and perforation. Hemorrhage is caused by bleeding from granulation tissue or from erosion of an ulcer into an artery or vein. It occurs in as many as 10% to 20% of persons with peptic ulcer.⁶ Bleeding may be sudden, severe, and without warning, or it may be insidious, producing only occult blood in the stool. As many as 20% of persons with bleeding ulcers have no antecedent symptoms of pain; this is particularly true in persons receiving NSAIDs. Acute hemorrhage is evidenced by the sudden onset of weakness, dizziness, thirst, cold, moist skin, the desire to defecate, and the passage of loose, tarry, or even red stools and emesis of coffee-ground vomitus. Signs of circulatory shock develop, depending on the amount of blood lost.

Obstruction is caused by edema, spasm, or contraction of scar tissue and interference with the free passage of gastric contents through the pylorus or adjacent areas. There is a feeling of epigastric fullness and heaviness after meals. With severe obstruction, there is vomiting of undigested food.

Perforation occurs when an ulcer erodes through all the layers of the stomach or duodenum wall. Perforation develops in approximately 5% of persons with peptic ulcers, usually from ulcers on the anterior wall of the stomach or duodenum.⁶ With perforation, gastrointestinal contents enter the peritoneum and cause peritonitis, or penetrate adjacent structures such as the pancreas. Radiation of the pain into the back, severe night distress, and inadequate pain relief with the eating of foods or taking of antacids in persons with a long history of peptic ulcer may signify perforation.

Diagnosis and Treatment. Diagnostic procedures for peptic ulcer include history taking with an emphasis on aspirin and NSAID use, laboratory tests, radiologic imaging, and endoscopic examination. Laboratory findings of hypochromic anemia and occult blood in the stools indicate bleeding. X-ray

studies with a contrast medium such as barium are used to detect the presence of an ulcer crater and to exclude gastric carcinoma. Endoscopy (*i.e.*, gastroscopy and duodenoscopy) can be used to visualize the ulcer area and obtain biopsy specimens to test for *H. pylori* and exclude malignant disease.

The treatment of peptic ulcer has changed dramatically during the past several years and now aims to eradicate the cause and effect a permanent cure for the disease. Pharmacologic treatment focuses on eradicating *H. pylori* with appropriate antibiotics when present, relieving ulcer symptoms, and healing the ulcer crater. Acid-neutralizing, acid-inhibiting drugs (histamine₂-receptor antagonists and proton pump blockers), and mucosal protective agents are used to relieve symptoms and promote healing of the ulcer crater. Aspirin and NSAID use should be avoided when possible.

The current surgical management of peptic ulcer disease is largely limited to treatment of complications. When surgery is needed, it usually is performed using minimally invasive methods. With bleeding ulcers, hemostasis often can be achieved by endoscopic methods, and endoscopic balloon dilation often is effective in relieving outflow obstruction.

Zollinger-Ellison Syndrome

The Zollinger-Ellison syndrome is a rare condition caused by a gastrin-secreting tumor (gastrinoma). In persons with this disorder, gastric acid secretion reaches such levels that ulceration becomes inevitable.¹⁹ The tumors may be single or multiple; although most tumors are located in the pancreas, a few develop in the submucosa of the stomach or duodenum. More than two thirds of gastrinomas are malignant, and one third have already metastasized at the time of diagnosis.¹¹ The increased gastric secretions cause symptoms related to peptic ulcer. Diarrhea may result from hypersecretion or from the inactivation of intestinal lipase and impaired fat digestion that occurs with a decrease in intestinal pH.

Stress Ulcers

A stress ulcer, sometimes called Curling's ulcer, refers to gastrointestinal ulcerations that develop in relation to major physiologic stress. Persons at high risk for the development of stress ulcers include those with large surface-area burns, trauma, sepsis, acute respiratory distress syndrome, severe liver failure, and major surgical procedures. These lesions occur most often in the fundus of the stomach and proximal duodenum and are thought to result from ischemia, tissue acidosis, and bile salts entering the stomach in critically ill persons with decreased gastrointestinal tract motility.²⁰ Another form of stress ulcer, called Cushing ulcer, consists of gastric, duodenal, and esophageal ulcers arising in persons with intracranial injury, operations, or tumors. They are thought to be caused by hypersecretion of gastric acid resulting from stimulation of vagal nuclei by increased intracranial pressure. These ulcers are associated with a high incidence of perforation.¹¹

Stress ulcers develop in approximately 5% to 10% of persons admitted to hospital intensive care units.¹¹ They usually are manifested by painless upper gastrointestinal tract bleeding. Monitoring and maintaining the gastric pH at 3.5 or higher helps to prevent the development of stress ulcers. H₂-receptor antagonists, proton pump inhibitors, and mucosal protective agents are used in the prevention and treatment of stress ulcers.

Cancer of the Stomach

Stomach cancer is the seventh most frequent cause of cancer mortality in the United States. In 2003, it is estimated that approximately 22,400 Americans will receive a diagnosis of stomach cancer and 12,100 will die of the disease.²¹ The disease is much more common in other countries and regions, principally Japan, central Europe, the Scandinavian countries, South and Central America, republics of the former Soviet Union, China, and Korea. It is the major cause of cancer death worldwide.

Among the factors that increase the risk of gastric cancer are a genetic predisposition, carcinogenic factors in the diet (*e.g.*, *N*-nitroso compounds and benzopyrene found in smoked and preserved foods), autoimmune gastritis, and gastric adenomas or polyps. The incidence of stomach cancer in the United States has decreased fourfold since 1930, presumably because of improved storage of food with decreased consumption of salted, smoked, and preserved foods.^{11,21} Infection with *H. pylori* appears to serve as a cofactor in some types of gastric carcinomas.¹¹

Between 50% and 60% of gastric cancers occur in the pyloric region or adjacent to the antrum. Compared with a benign ulcer, which has smooth margins and is concentrically shaped, gastric cancers tend to be larger, are irregularly shaped, and have irregular margins.

Unfortunately, stomach cancers often are asymptomatic until late in their course. Symptoms, when they do occur, usually are vague and include indigestion, anorexia, weight loss, vague epigastric pain, vomiting, and an abdominal mass.

Diagnosis of gastric cancer is accomplished by means of a variety of techniques, including barium x-ray studies, endoscopic studies with biopsy, and cytologic studies (*e.g.*, Papanicolaou smear) of gastric secretions. Cytologic studies can prove particularly useful as routine screening tests for persons with atrophic gastritis or gastric polyps. Computed tomography (CT) and endoscopic ultrasonography often are used to delineate the spread of a diagnosed stomach cancer.

Surgery in the form of radical subtotal gastrectomy usually is the treatment of choice.²¹ Irradiation and chemotherapy have not proved particularly useful as primary treatment modalities in stomach cancer. These methods usually are used for palliative purposes or to control metastatic spread of the disease.

In summary, disorders of the stomach include gastritis, peptic ulcer, and cancer of the stomach. Gastritis refers to inflammation of the gastric mucosa. Acute gastritis refers to a transient inflammation of the gastric mucosa; it is associated most commonly with local irritants such as bacterial endotoxins, caffeine, alcohol, and aspirin. Chronic gastritis is characterized by the absence of grossly visible erosions and the presence of chronic inflammatory changes leading eventually to atrophy of the glandular epithelium of the stomach. Chronic gastritis increases the risk of stomach cancer.

Peptic ulcer is a term used to describe a group of ulcerative disorders that occur in areas of the upper gastrointestinal tract that are exposed to acid-pepsin secretions, most commonly the duodenum and stomach. There are two main causes of peptic ulcer: *H. pylori* infection and aspirin or NSAID use. The treatment of peptic ulcer focuses on eradication of *H. pylori*, avoidance of gastric irritation from NSAIDs, and conventional pharmacologic treatment directed at symptom relief and ulcer healing.

The Zollinger-Ellison syndrome is a rare condition caused by a gastrin-secreting tumor, in which gastric acid secretion reaches such levels that ulceration becomes inevitable. Stress ulcers occur in relation to major physiologic stresses such as burns and trauma and are thought to result from ischemia, tissue acidosis, and bile salts entering the stomach in critically ill persons with decreased gastrointestinal tract motility. Another form of stress ulcer, resulting from hypersecretion of gastric acid caused by stimulation of vagal nuclei by increased intracranial pressure, may develop in persons with intracranial injury, operations, or tumors.

Although the incidence of cancer of the stomach has declined during the past 50 years, it remains the seventh leading cause of death in the United States. Because there are few early symptoms with this form of cancer, the disease often is far advanced at the time of diagnosis.

DISORDERS OF THE SMALL AND LARGE INTESTINES

There are many similarities in conditions that disrupt the integrity and function of the small and large intestine. The walls of the small and large intestines consist of five layers (see Chapter 26, Fig. 26-3): an outer serosal layer; a muscularis layer, which is divided into a layer of circular and a layer of longitudinal muscle fibers; a submucosal layer; and an inner mucosal layer, which lines the lumen of the intestine. Among the conditions that cause altered intestinal function are irritable bowel disease, inflammatory bowel disease, diverticulitis, appendicitis, alterations in bowel motility (*i.e.*, diarrhea, constipation, and bowel obstruction), malabsorption syndrome, and cancer of the colon and rectum.

Irritable Bowel Syndrome

The term *irritable bowel syndrome* is used to describe a functional gastrointestinal disorder characterized by a variable combination of chronic and recurrent intestinal symptoms not explained by structural or biochemical abnormalities. There is evidence to suggest that 10% to 20% of people in Western countries have the disorder, although most do not seek medical attention.^{22,23}

The condition is characterized by persistent or recurrent symptoms of abdominal pain, altered bowel function, and varying complaints of flatulence, bloatedness, nausea and anorexia, and anxiety or depression. A hallmark of irritable bowel syndrome is abdominal pain that is relieved by defecation and associated with a change in consistency or frequency of stools.

Irritable bowel syndrome is believed to result from dysregulation of intestinal motor and sensory functions modulated by the CNS.²³ Persons with irritable bowel syndrome tend to experience increased motility and abnormal intestinal contractions in response to psychological and physiologic stress. The role that psychological factors play in the disease is uncertain. Although changes in intestinal activity are normal responses to stress, these responses appear to be exaggerated in persons with irritable bowel syndrome. Women tend to be affected more often than men. Menarche often is associated with onset of the disorder. Women frequently notice an exacerbation of symptoms during the premenstrual period, suggesting a hormonal component.

Diagnosis of irritable bowel syndrome is based on continuous or recurrent symptoms of at least 3 months' duration consisting of abdominal pain or discomfort relieved by defecation, a change in the frequency or consistency of stool, and the presence of three or more varying patterns of altered defecation that are present at least 25% of the time.²⁴ These patterns of defecation include altered stool frequency, altered stool form (*i.e.*, hard or loose, watery stool), altered stool passage (*i.e.*, straining, urgency, or feeling of incomplete evacuation), passage of mucus, and bloating or feeling of abdominal discomfort. A history of lactose intolerance should be considered because intolerance to lactose and other sugars may be a precipitating factor in some persons.

The treatment of irritable bowel syndrome focuses on methods of stress management, particularly those related to symptom production. Reassurance is important. Usually, no special diet is indicated, although adequate fiber intake usually is recommended. Avoidance of offending dietary substances such as fatty and gas-producing foods, alcohol, and caffeinecontaining beverages may be beneficial. Various pharmacologic agents, including antispasmodic and anticholinergic drugs, have been used with varying success in treatment of the disorder.

Inflammatory Bowel Disease

The term *inflammatory bowel disease* is used to designate two related inflammatory intestinal disorders: Crohn's disease and ulcerative colitis.^{25,26} The prevalence of these diseases ranges from 300,000 to 500,000. Although the two diseases differ sufficiently to be distinguishable, they have many features in common. Both diseases produce inflammation of the bowel, both lack confirming evidence of a proven causative agent, both have a pattern of familial occurrence, and both can be accompanied by systemic manifestations.¹⁶ The distinguishing characteristics of Crohn's disease and ulcerative colitis are summarized in Table 27-1.

The etiology of Crohn's disease and ulcerative colitis is largely unknown, but several theories have been proposed regarding their causation. The diseases appear to have a familial occurrence, suggesting a hereditary predisposition.¹¹ It is thought that genetic factors predispose to an autoimmune reaction, possibly triggered by a relatively innocuous environmental agent such as a dietary antigen or microbial agent. It also is thought that the diseases may have an infectious origin, such as Chlamydia, atypical bacteria, and mycobacteria.¹¹ Another theory is one of defective immunoregulation, in which the mucosal branch of the immune system is stimulated and then fails to down-regulate. Although psychogenic factors may contribute to the severity and onset of both conditions, it seems unlikely that they are the primary cause.

The clinical manifestations of both Crohn's disease and ulcerative colitis are ultimately the result of activation of inflammatory cells with elaboration of inflammatory mediators that

and Ulcerative Colitis			
Characteristic	Crohn's Disease	Ulcerative Colitis	
Types of inflammation	Granulomatous	Ulcerative and exudative	
Level of involvement	Primarily submucosal	Primarily mucosal	
Extent of involvement	Skip lesions	Continuous	
Areas of involvement	Primarily ileum, secondarily colon	Primarily rectum and left colon	
Diarrhea	Common	Common	
Rectal bleeding	Rare	Common	
Fistulas	Common	Rare	
Strictures	Common	Rare	
Perianal abscesses	Common	Rare	
Development of cancer	Uncommon	Relatively common

and Ulcerativ		0		

cause nonspecific tissue damage. Both diseases are characterized by remissions and exacerbations of diarrhea, fecal urgency, and weight loss. Acute complications such as intestinal obstruction may develop during periods of fulminant disease.

A number of systemic manifestations have been identified in persons with Crohn's disease and ulcerative colitis. These include axial arthritis affecting the spine and sacroiliac joints and oligoarticular arthritis affecting the large joints of the arms and legs; inflammatory conditions of the eye, usually uveitis; skin lesions, especially erythema nodosum; stomatitis; and autoimmune anemia, hypercoagulability of blood, and sclerosing cholangitis. Occasionally, these systemic manifestations may herald the recurrence of intestinal disease. In children, growth retardation may occur, particularly if the symptoms are prolonged and nutrient intake has been poor.

Crohn's Disease

Crohn's disease is a recurrent, granulomatous type of inflammatory response that can affect any area of the gastrointestinal tract from the mouth to the anus. In nearly 40% of persons with disease, the lesions are restricted to the small intestine; in 30%, only the large bowel is affected; and in the remaining 30%, the large bowel and small bowel are affected.¹¹ It is a slowly progressive, relentless, and often disabling disease. Despite the substantial increase in the prevalence of Crohn's disease in the early 1980s, the distribution of affected sites has not changed substantially. The disease usually strikes adolescents and young adults and is most common among persons of European origin, with considerably higher frequency among Ashkenazi Jews.¹⁶

A characteristic feature of Crohn's disease is the sharply demarcated, granulomatous lesions that are surrounded by normal-appearing mucosal tissue. When the lesions are multiple, they often are referred to as skip lesions because they are interspersed between what appear to be normal segments of the bowel. All the layers of the bowel are involved, with the submucosal layer affected to the greatest extent. The surface of the inflamed bowel usually has a characteristic "cobblestone" appearance resulting from the fissures and crevices that develop and that are surrounded by areas of submucosal edema (Fig. 27-4). There usually is a relative sparing of the smooth muscle layers of the bowel, with marked inflammatory and fibrotic changes of the submucosal layer. The bowel wall, after

a time, often becomes thickened and inflexible; its appearance has been likened to a lead pipe or rubber hose. The adjacent mesentery may become inflamed, and the regional lymph nodes and channels may become enlarged.

The clinical course of Crohn's disease is variable; often, there are periods of exacerbations and remissions, with symptoms being related to the location of the lesions. The principal symptoms include intermittent diarrhea, colicky pain (usually in the lower right quadrant), weight loss, fluid and electrolyte disorders, malaise, and low-grade fever. Because Crohn's disease affects the submucosal layer to a greater extent than the mucosal layer, there is less bloody diarrhea than with ulcerative colitis. Ulceration of the perianal skin is common, largely because of the severity of the diarrhea. The absorptive surface of the intestine may be disrupted; nutritional deficiencies may occur, related to the specific segment of the intestine that is involved. When Crohn's disease occurs in childhood, one of its major manifestations may be retardation of growth and physical development.16

Complications of Crohn's disease include fistula formation, perforation, abdominal abscess formation, and intestinal obstruction (Fig. 27-4). Fistulas are tubelike passages that form connections between different sites in the gastrointestinal tract.

■ FIGURE 27-4 ■ Crohn's disease. The mucosal surface of the colon displays a "cobblestone" appearance owing to the presence of linear ulcerations and edema and inflammation of the intervening tissue. (From Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 728]. Philadelphia: Lippincott Williams & Wilkins)

They also may develop between other sites, including the bladder, vagina, urethra, and skin. Fistulas between segments of the gastrointestinal tract may lead to malabsorption, syndromes of bacterial overgrowth, and diarrhea. They also can become infected and cause abscess formation.

Diagnosis and Treatment. The diagnosis of Crohn's disease requires a thorough history and physical examination. Sigmoidoscopy is used for direct visualization of the affected areas and to obtain biopsies. Measures are taken to exclude infectious agents as the cause of the disorder. This usually is accomplished by the use of stool cultures and examination of fresh stool specimens for ova and parasites. In persons suspected of having Crohn's disease, radiologic contrast studies provide a means for determining the extent of involvement of the small bowel and establishing the presence and nature of fistulas. CT scans may be used to detect an inflammatory mass or abscess.

Treatment methods focus on terminating the inflammatory response and promoting healing, maintaining adequate nutrition, and preventing and treating complications. Nutritional deficiencies are common in Crohn's disease because of diarrhea, steatorrhea (fatty stools), and other malabsorption problems. A nutritious diet that is high in calories, vitamins, and proteins is recommended. Elemental diets, which are nutritionally balanced but residue free and bulk free, may be given during the acute phase of the illness. These diets are largely absorbed in the jejunum and allow the inflamed bowel to rest. Total parenteral nutrition (*i.e.*, parenteral hyperalimentation), which is administered intravenously, may be needed when food cannot be absorbed from the intestine.

Several medications have been successful in suppressing the inflammatory reaction, including the corticosteroids, sulfasalazine, and metronidazole. Sulfasalazine is a topically active agent that has a variety of anti-inflammatory effects. Metronidazole is an antibiotic used to treat bacterial overgrowth in the small intestine. Immunosuppressive drugs such as azathioprine and its active derivative, 6-mercaptopurine, also may be used. Infliximab, a monoclonal antibody that targets tumor necrosis factor- α (TNF- α), a mediator of the inflammatory response, may be used for treatment of moderate to severe Crohn's disease that does not respond to standard therapies.²⁷ Surgical resection of damaged bowel, drainage of abscesses, or repair of fistula tracts may be necessary.

Ulcerative Colitis

Ulcerative colitis is a nonspecific inflammatory condition of the colon. The disease begins most often between 20 and 25 years of age, but the condition may affect both younger and older persons.¹¹ Unlike Crohn's disease, which can affect various sites in the gastrointestinal tract, ulcerative colitis is confined to the rectum and colon. The disease usually begins in the rectum and spreads proximally, affecting primarily the mucosal layer, although it can extend into the submucosal layer. The length of proximal extension varies. It may involve the rectum alone, the rectum and sigmoid colon, or the entire colon. The inflammatory process tends to be confluent and continuous, instead of skipping areas, as it does in Crohn's disease.

Characteristic of the disease are the lesions that form in the crypts of Lieberkühn in the base of the mucosal layer (see

Chapter 26, Fig. 26-10). The inflammatory process leads to the formation of pinpoint mucosal hemorrhages, which in time suppurate and develop into crypt abscesses. These inflammatory lesions may become necrotic and ulcerate. Although the ulcerations usually are superficial, they often extend, causing large denuded areas (Fig. 27-5). As a result of the inflammatory process, the mucosal layer often develops tonguelike projections that resemble polyps and thus are called *pseudopolyps*. The bowel wall thickens in response to repeated episodes of colitis.

Diarrhea, which is the characteristic manifestation of ulcerative colitis, varies according to the severity of the disease. There may be as many as 30 to 40 bowel movements a day. Because ulcerative colitis affects the mucosal layer of the bowel, the stools typically contain blood and mucus. Nocturnal diarrhea usually occurs when daytime symptoms are severe. There may be mild abdominal cramping and fecal incontinence. Anorexia, weakness, and fatigability are common.

Ulcerative colitis usually follows a course of remissions and exacerbations. The severity of the disease varies from mild to fulminating. Accordingly, the disease has been divided into three types: mild chronic, chronic intermittent, and acute fulminating. The most common form of the disease is the mild chronic, in which bleeding and diarrhea are mild and systemic signs are minimal or absent. This form of the disease usually can be managed conservatively. The chronic intermittent form continues after the initial attack. Compared with the milder form, more of the colon surface usually is involved with the chronic intermittent form, and there are more systemic signs and complications. In approximately 15% of affected persons, the disease assumes a more fulminant course, involves the entire colon, and manifests with severe, bloody diarrhea, fever, and acute abdominal pain. These persons are at risk for development of toxic megacolon, which is characterized by dilatation of the colon and signs of systemic toxicity. It results from extension of the inflammatory response, with involvement of neural and vascular components of the bowel. Contributing factors include the use of laxatives, narcotics, and

■ FIGURE 27-5 ■ Ulcerative colitis. Prominent erythema and ulceration of the colon begin in the ascending colon and are most severe in the rectosigmoid area. (From Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 731]. Philadelphia: Lippincott Williams & Wilkins)

anticholinergic drugs and the presence of hypokalemia. Cancer of the colon is one of the feared complications of ulcerative colitis.

Diagnosis and Treatment. Diagnosis of ulcerative colitis is based on history and physical examination. The diagnosis usually is confirmed by proctosigmoidoscopy.

Treatment depends on the extent of the disease and severity of symptoms. It includes measures to control the acute manifestations of the disease and prevent recurrence. Some people with mild to moderate symptoms are able to control their symptoms simply by avoiding caffeine, lactose (milk), highly spiced foods, and gas-forming foods. Fiber supplements may be used to decrease diarrhea and rectal symptoms.

The medications used in treatment of ulcerative colitis are similar to those used in the treatment of Crohn's disease. The corticosteroids are used selectively to lessen the acute inflammatory response. Many of these medications can be administered rectally by suppository or enema. Immunosuppressant drugs, such as cyclosporine, may be used to treat persons with severe colitis.

Surgical treatment (*i.e.*, removal of the rectum and entire colon) with the creation of an ileostomy or ileoanal anastomosis may be required for those persons with ulcerative colitis who do not experience a response to conservative methods of treatment.

Infectious Colitis

Two forms of pathogens have emerged as important causes of infectious colitis: *Clostridium difficile* and *Escherichia coli* sero-type O157:H7.

Clostridium Difficile Colitis

C. difficile, which is part of normal flora in 2% to 10% of humans, is a gram-positive spore-forming bacillus that has been implicated as the offending organism in colitis associated with antibiotic therapy.²⁸ The spores are resistant to the acid environment of the stomach and convert to vegetative forms in the colon. Treatment with broad-spectrum antibiotics predisposes to disruption of the normal bacterial flora of the colon, leading to colonization by *C. difficile*. Almost any antibiotic with activity against the gram-negative bacteria of the normal intestinal flora are the most common agents.²⁸ After antibiotic therapy has made the bowel susceptible to infection, colonization by *C. difficile* occurs by the oral-fecal route. *C. difficile* infection usually is acquired in the hospital, where the organism is commonly encountered.

C. difficile, which is not invasive, produces its effects through the release of toxins that cause mucosal damage and inflammation. The infection commonly manifests with diarrhea that is mild to moderate and sometimes is accompanied by lower abdominal cramping. Symptoms usually begin during or shortly after antibiotic therapy has been initiated, although they can be delayed for weeks. In most cases, systemic manifestations are absent, and the symptoms subside after the antibiotic has been discontinued. In the more severe cases, mucosal damage results in the development a pseudomembranous colitis. It is a life-threatening form of the disease characterized by an adherent inflammatory membrane overlying the areas of mucosal injury. Persons with the disease are acutely ill, with lethargy, fever, tachycardia, abdominal pain and distention, and dehydration. The smooth muscle tone of the colon may be lost, resulting in toxic dilatation of the colon. Prompt therapy is needed to prevent perforation of the bowel.

Diagnostic findings include a history of antibiotic use and laboratory tests that confirm the presence of *C. difficile* toxins in the stool. Treatment includes the immediate discontinuation of antibiotic therapy. Specific treatment aimed at eradicating *C. difficile* is used when symptoms are severe or persistent.^{28,29}

Escherichia Coli O157:H7 Infection

E. coli O157:H7 is a strain of *E. coli* found in feces and contaminated milk of healthy dairy and beef cattle, but it also has been found in pork, poultry, and lamb. Infection usually is by food-borne transmission, often by ingesting undercooked hamburger. The organism also can be transferred to nonmeat products such as fruits and vegetables. Personto-person transmission may occur, particularly in nursing homes, day care settings, and hospitals. The very young and the very old are particularly at risk for the infection and its complications.

The infection may cause no symptoms or cause a variety of manifestations, including acute, nonbloody diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura. The infection often presents with abdominal cramping and watery diarrhea and subsequently may progress to bloody diarrhea. The diarrhea commonly lasts 3 to 7 days or longer, with 10 to 12 diarrheal episodes per day. Fever occurs in up to one third of the cases.

An important aspect of the disease is the production of toxins and the ability to produce toxemia. The two complications of the infection, hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura, reflect the effects of toxins. Hemolytic-uremic syndrome is characterized by hemolytic anemia, thrombocytopenia, and renal failure. It occurs predominantly in infants and young children and is the most common cause of acute renal failure in children.³⁰ It has a mortality rate of 5% to 10%, and one third of the survivors are left with permanent disability. Thrombotic thrombocytopenic purpura is manifested by thrombocytopenia, renal failure, fever, and neurologic manifestations. It often is regarded as the severe end of the disease that leads to hemolytic-uremic syndrome plus neurologic problems.

No specific therapy is available for *E. coli* O157:H7 infection. Treatment is largely symptomatic and directed toward treating the effects of complications. Antibiotics have not proved useful and may even be harmful, extending the duration of bloody diarrhea.

Because of the seriousness of the infection and its complications, education of the public about techniques for decreasing primary transmission of the infection from animal sources is important. Undercooked meats and unpasteurized milk are sources of transmission. The FDA recommends a minimal internal temperature of 155°F for cooked hamburger. Food handlers and consumers should be aware of the proper methods for handling uncooked meat to prevent crosscontamination of other foods. Particular attention should be paid to hygiene in day care centers and nursing homes, where the spread of infection to the very young and very old may result in severe complications.³⁰

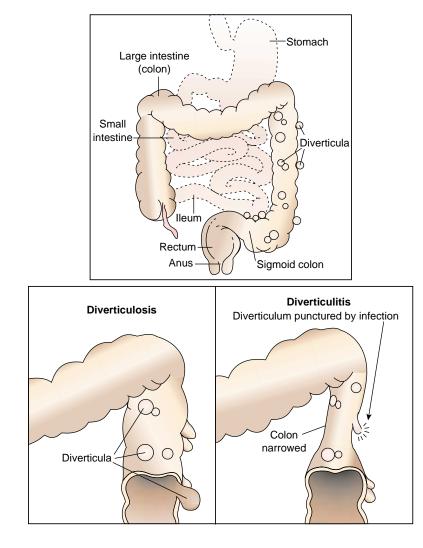

Diverticular Disease

Diverticulosis is a condition in which the mucosal layer of the colon herniates through the muscularis layer.³¹ Often, there are multiple diverticula, and most occur in the sigmoid colon (Fig. 27-6). Diverticular disease is common in Western society, affecting approximately 5% to 10% of the population older than 45 years and almost 80% of those older than 85 years.³¹ Although the disorder is prevalent in the developed countries of the world, it is almost nonexistent in many African nations and underdeveloped countries. This suggests that dietary factors (*e.g.*, lack of fiber content), a decrease in physical activity, and poor bowel habits (*e.g.*, neglecting the urge to defecate), along with the effects of aging, contribute to the development of the disease.

Diverticula, in which the mucosal and submucosal layers herniate through the muscle layers of the colon, are located primarily in the sigmoid colon but can affect any area of the colon. They vary in number from a few to several hundred. The diverticula, which measure up to 1 cm in greatest dimension, are attached to the intestinal lumen by necks of varying size. Hardened feces may be present in the diverticula without causing symptoms.

Most persons with diverticular disease remain asymptomatic. The disease often is found when x-ray studies are done for other purposes. When symptoms do occur, they often are attributed to irritable bowel syndrome or other causes. Illdefined lower abdominal discomfort, a change in bowel habits (*e.g.*, diarrhea, constipation), bloating, and flatulence are common.

Diverticulitis is a complication of diverticulosis in which there is inflammation and gross or microscopic perforation of the diverticulum. One of the most common complaints of diverticulitis is pain in the lower left quadrant, accompanied by nausea and vomiting, tenderness in the lower left quadrant, a slight fever, and an elevated white blood cell count. These symptoms usually last for several days, unless complications occur, and usually are caused by localized inflammation of the diverticula with perforation and development of a small, localized abscess. Complications include perforation with peritonitis, hemorrhage, and bowel obstruction. Fistulas can form, usually involving the bladder (*i.e.*, vesicosigmoid fistula) but sometimes involving the skin, perianal area, or small bowel. Pneumaturia (*i.e.*, air in the urine) is a sign of vesicosigmoid fistula.

■ FIGURE 27-6 ■ (Top) Location of diverticula in the sigmoid colon. (Bottom left) Diverticulosis. (Bottom right) Diverticulitis. (National Digestive Diseases Information Clearinghouse. [1989]. *Clearinghouse fact sheet: Diverticulosis and diverticulitis*. NIH publication 90-1163. Washington, DC: US Department of Health and Human Services)

The diagnosis of diverticular disease is based on history and presenting clinical manifestations. The disease may be confirmed by barium enema x-ray studies (except when acute diverticulitis is suspected), CT scans, and ultrasonographic studies. The treatment goals for diverticular disease focus on prevention of symptoms and complications. This includes increasing the bulk in the diet and bowel retraining so that the person has at least one bowel movement each day. Acute diverticulitis is treated by withholding solid food and administering a broad-spectrum antibiotic. Surgical treatment is reserved for complications.

Appendicitis

Acute appendicitis is extremely common. It is seen most frequently in the 5- to 30-year-old age group, but it can occur at any age. The appendix becomes inflamed, swollen, and gangrenous, and it eventually perforates if not treated. Although the cause of appendicitis is unknown, it is thought to be related to intraluminal obstruction with a fecalith (*i.e.*, hard piece of stool) or to twisting.

Appendicitis usually has an abrupt onset, with pain referred to the epigastric or periumbilical area. This pain is caused by stretching of the appendix during the early inflammatory process. At approximately the same time that the pain appears, there are one or two episodes of nausea. Initially, the pain is vague, but over a period of 2 to 12 hours, it gradually increases and may become colicky. When the inflammatory process has extended to involve the serosal layer of the appendix and the peritoneum, the pain becomes localized to the lower right quadrant. There usually is an elevation in temperature and a white blood cell count greater than 10,000/mm³, with 75% or more polymorphonuclear cells. Palpation of the abdomen usually reveals a deep tenderness in the lower right quadrant, which is confined to a small area approximately the size of the fingertip. It usually is located at approximately the site of the inflamed appendix. Rebound tenderness, which is pain that occurs when pressure is applied to the area and then released, and spasm of the overlying abdominal muscles are common.

Treatment consists of surgical removal of the appendix. Complications include peritonitis, localized periappendiceal abscess formation, and septicemia.

Alterations in Intestinal Motility

The movement of contents through the gastrointestinal tract is controlled by neurons located in the submucosal and myenteric plexuses of the gut (see Chapter 26). The axons from the cell bodies in the myenteric plexus innervate the circular and longitudinal smooth muscle layers of the gut. These neurons receive impulses from local receptors located in the mucosal and muscle layers of the gut and extrinsic input from the parasympathetic and sympathetic nervous systems. As a general rule, the parasympathetic nervous system tends to increase the motility of the bowel, whereas sympathetic stimulation tends to slow its activity.

The colon has sphincters at both ends: the ileocecal sphincter, which separates it from the small intestine, and the anal sphincter, which prevents the movement of feces to the outside of the body. The colon acts as a reservoir for fecal material. Normally, approximately 400 mL of water, 55 mEq of sodium, 30 mEq of chloride, and 15 mEq of bicarbonate are absorbed

KEY CONCEPTS

DISORDERS OF GASTROINTESTINAL MOTILITY

- The enteric nervous system that is incorporated into the wall of the gut controls the basic movement of the gastrointestinal tract, with input from the autonomic nervous system.
- Local irritation and the composition and constituents of gastrointestinal contents influence motility through the submucosal afferent neurons of the enteric nervous system. Gastrointestinal wall distention, chemical irritants, osmotic gradients, and bacterial toxins exert many of their effects on gastrointestinal motility through these afferent pathways.
- Autonomic influences generated by factors such as medications, trauma, and emotional experiences interact with the enteric nervous system to alter gastrointestinal motility.

each day in the colon. At the same time, approximately 5 mEq of potassium is secreted into the lumen of the colon. The amount of water and electrolytes that remains in the stool reflects the absorption or secretion that occurs in the colon. The average adult ingesting a typical American diet evacuates approximately 200 to 300 g of stool each day.

Diarrhea

The usual definition of *diarrhea* is excessively frequent passage of stools. Diarrhea can be acute or chronic. Diarrhea is considered to be chronic when the symptoms persist for 3 weeks in children or adults and 4 weeks in infants. Acute diarrhea affects 500 million children throughout the world and is the leading cause of death of children younger than 4 years of age.³² Although diarrheal disease in the United States is less prevalent than it is in other countries, it places a burden on the health care system. Approximately 220,000 children are hospitalized each year for gastroenteritis.³³

The complaint of diarrhea is a general one and can be related to a number of pathologic and nonpathologic factors. It can be caused by infectious organisms, food intolerance, drugs, or intestinal disease. Acute diarrheas that last less than 4 days are predominantly caused by infectious agents and follow a self-limited course.³⁴ Chronic diarrheas are those that persist for longer than 3 to 4 weeks. They often are caused by conditions such as inflammatory bowel disease, irritable bowel syndrome, malabsorption syndrome, endocrine disorders (hyperthyroidism, diabetic autonomic neuropathy), or radiation colitis.

Diarrhea commonly is divided into two types, large volume and small volume, based on the characteristics of the diarrheal stool. Large-volume diarrhea results from an increase in the water content of the stool, and small-volume diarrhea results from an increase in the propulsive activity of the bowel. Some of the common causes of small- and large-volume diarrhea are summarized in Chart 27-1. Often, diarrhea is a combination of these two types.

CHART 27-1 Causes of Largeand Small-Volume Diarrhea

Large-Volume Diarrhea

Fecal impaction Small-Volume Diarrhea Inflammatory bowel disease Crohn's disease Ulcerative colitis Infectious disease Shigellosis

Large-Volume Diarrhea. Large-volume diarrhea can be classified as secretory or osmotic, according to the cause of the increased water content in the feces. Water is pulled into the colon along an osmotic gradient (*i.e.*, osmotic diarrhea) or is secreted into the bowel by the mucosal cells (*i.e.*, secretory diarrhea). The large-volume form of diarrhea usually is a painless, watery type without blood or pus in the stools.

In osmotic diarrhea, water is pulled into the bowel by the hyperosmotic nature of its contents. It occurs when osmotically active particles are not absorbed. In persons with lactase deficiency, the lactose in milk cannot be broken down and absorbed. Magnesium salts, which are contained in milk of magnesia and many antacids, are poorly absorbed and cause diarrhea when taken in sufficient quantities. Another cause of osmotic diarrhea is decreased transit time, which interferes with absorption. Osmotic diarrhea usually disappears with fasting.

Secretory diarrhea occurs when the secretory processes of the bowel are increased. Most acute infectious diarrheas are of this type. Enteric organisms cause diarrhea by several ways. Some are noninvasive but secrete toxins that stimulate fluid secretion (e.g., pathogenic E. coli or Vibrio cholerae). Others (e.g., Staphylococcus aureus, Bacillus cereus, Clostridium perfringens) invade and destroy intestinal epithelial cells, thereby altering fluid transport so that secretory activity continues while absorption activity is halted.35 Diarrhea with vomiting and fever suggests food poisoning, often caused by staphylococcal enterotoxin. Secretory diarrhea also occurs when excess bile acids remain in the intestinal contents as they enter the colon. This often happens with disease processes of the ileum because bile salts are absorbed there. It also may occur with bacterial overgrowth in the small bowel, which interferes with bile absorption.

Small-Volume Diarrhea. Small-volume diarrhea commonly is associated with acute or chronic inflammation or intrinsic disease of the colon, such as ulcerative colitis or Crohn's disease. Small-volume diarrhea usually is evidenced by frequency and urgency and colicky abdominal pain. It commonly is accompanied by tenesmus (*i.e.*, painful straining at stool), fecal soiling of clothing, and awakening during the night with the urge to defecate.

Diagnosis and Treatment. The diagnosis of diarrhea is based on complaints of frequent stools and a history of accompanying factors such as concurrent illnesses, medication use, and exposure to potential intestinal pathogens. Disorders such as inflammatory bowel disease should be considered. If the onset of diarrhea is related to travel outside the United States, the possibility of traveler's diarrhea must be considered.

Although most acute forms of diarrhea are self-limited and require no treatment, diarrhea can be particularly serious in infants and small children, persons with other illnesses, the elderly, and even previously healthy persons if it continues for any length of time. Thus, the replacement of fluids and electrolytes is considered to be a primary therapeutic goal in the treatment of diarrhea. Oral electrolyte replacement solutions can be given in situations of uncomplicated diarrhea that can be treated at home. Evidence suggests that feeding should be continued during diarrheal illness, particularly in children.^{33,36} It is recommended that children who require rehydration therapy because of diarrhea be fed an age-appropriate diet. Starch and simple proteins are thought to provide cotransport molecules with little osmotic activity, increasing fluid and electrolyte uptake by intestinal cells. When oral rehydration is not feasible or adequate, intravenous fluid replacement may be needed.

Drugs used in the treatment of diarrhea include diphenoxylate and loperamide, which are opium-like drugs. These drugs decrease gastrointestinal motility and stimulate water and electrolyte absorption. Adsorbents, such as kaolin and pectin, adsorb irritants and toxins from the bowel. These ingredients are included in many over-the-counter antidiarrheal preparations. Bismuth subsalicylate can be used to reduce the frequency of unformed stools and increase stool consistency, particularly in cases of traveler's diarrhea. The drug is thought to inhibit intestinal secretion caused by enterotoxic *E. coli* and cholera toxins. Diarrheal medications should not be used in persons with bloody diarrhea, high fever, or signs of toxicity for fear of worsening the disease. Antibiotics are reserved for persons with identified enteric pathogens.

Constipation

Constipation can be defined as the infrequent passage of stools. The difficulty with this definition arises from the many individual variations of function that are normal. What is considered normal for one person (*e.g.*, two or three bowel movements per week) may be considered evidence of constipation by another. The problem increases with age; there is a sharp rise in health care visits for constipation after 65 years of age.

Constipation can occur as a primary problem or as a problem associated with another disease condition. Some common causes of constipation are failure to respond to the urge to defecate, inadequate fiber in the diet, inadequate fluid intake, weakness of the abdominal muscles, inactivity and bed rest, pregnancy, and hemorrhoids. Diseases associated with chronic

Chapter 27: Alterations in Gastrointestinal Function

487

constipation include neurologic diseases such as spinal cord injury, Parkinson's disease, and multiple sclerosis; endocrine disorders such as hypothyroidism; and obstructive lesions in the gastrointestinal tract. Drugs such as narcotics, anticholinergic agents, calcium channel blockers, diuretics, calcium (antacids and supplements), iron supplements, and aluminum antacids tend to cause constipation. Elderly people with long-standing constipation may experience dilation of the rectum, colon, or both. This condition allows large amounts of stool to accumulate with little or no sensation. Constipation, in the context of a change in bowel habits, may be a sign of colorectal cancer.

Diagnosis of constipation usually is based on a history of infrequent stools, straining with defection, the passing of hard and lumpy stools, or the sense of incomplete evacuation with defection.³⁷ Constipation as a sign of another disease condition should be excluded. The treatment of constipation usually is directed toward relieving the cause. Adequate fluid intake and bulk in the diet should be encouraged. Moderate exercise is essential, and persons on bed rest benefit from passive and active exercises. Laxatives and enemas should be used judiciously. They should not be used on a regular basis to treat simple constipation because they interfere with the defecation reflex and enemas may damage the rectal mucosa.

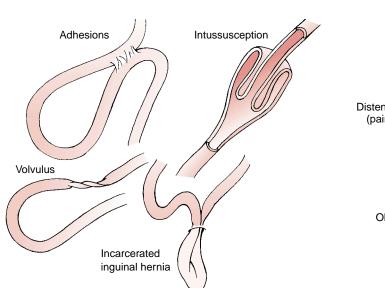

Intestinal Obstruction

Intestinal obstruction designates an impairment of movement of intestinal contents in the usual oral to anal direction. The causes can be categorized as mechanical or paralytic obstruction. Strangulation with necrosis of the bowel may occur and lead to perforation, peritonitis, and sepsis. This is a serious complication and may increase the mortality rate associated with intestinal obstruction to approximately 25% if surgery is delayed.⁶

Mechanical obstruction can result from a number of conditions, intrinsic or extrinsic, that encroach on the patency of the bowel lumen (Fig. 27-7). Major inciting causes include external hernia (*i.e.*, inguinal, femoral, or umbilical) and postoperative adhesions. Less common causes are strictures, tumor, foreign bodies, intussusception, and volvulus. Intussusception involves the telescoping of bowel into the adjacent segment. It is the most common cause of intestinal obstruction in children younger than 2 years.³⁸ The most common form is intussusception of the terminal ileum into the right colon, but other areas of the bowel may be involved. In most cases, the cause of the disorder is unknown. The condition can also occur in adults when an intraluminal mass or tumor acts as a traction force and pulls the segment along as it telescopes into the distal segment. Volvulus refers to a complete twisting of the bowel on an axis formed by its mesentery (see Fig. 27-7). Mechanical bowel obstruction may be a simple obstruction, in which there is no alteration in blood flow, or a strangulated obstruction, in which there is impairment of blood flow and necrosis of bowel tissue.

Paralytic, or adynamic, obstruction results from neurogenic or muscular impairment of peristalsis. Paralytic ileus is seen most commonly after abdominal surgery. It also accompanies inflammatory conditions of the abdomen, intestinal ischemia, pelvic fractures, and back injuries. It occurs early in the course of peritonitis and can result from chemical irritation caused by bile, bacterial toxins, electrolyte imbalances as in hypokalemia, and vascular insufficiency.

The major effects of both types of intestinal obstruction are abdominal distention and loss of fluids and electrolytes (Fig. 27-8). Gases and fluids accumulate in the area; if untreated, the distention resulting from bowel obstruction tends to perpetuate itself by causing atony of the bowel and further distention. Distention is further aggravated by the accumulation of gases. Approximately 70% of these gases are derived from swallowed air. As the process continues, the distention moves proximally (*i.e.*, toward the mouth), involving additional segments of bowel. Either form of obstruction eventually

■ FIGURE 27-7 ■ Causes of mechanical bowel obstruction.

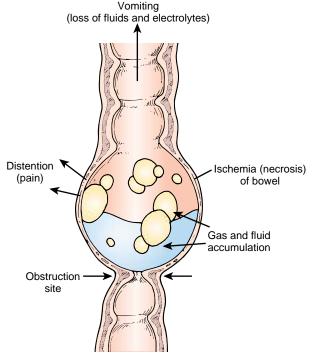

FIGURE 27-8 Pathophysiology of intestinal obstruction.

may lead to strangulation (*i.e.*, interruption of blood flow), gangrenous changes, and ultimately, perforation of the bowel. The increased pressure in the intestine tends to compromise mucosal blood flow, leading to necrosis and movement of blood into the luminal fluids. This promotes rapid growth of bacteria in the obstructed bowel. Anaerobes grow rapidly in this favorable environment and produce a lethal endotoxin.

The manifestations of intestinal obstruction depend on the degree of obstruction and its duration. With acute obstruction, the onset usually is sudden and dramatic. With chronic conditions, the onset often is more gradual. The cardinal symptoms of intestinal obstruction are pain, absolute constipation, abdominal distention, and vomiting. With mechanical obstruction, the pain is severe and colicky, in contrast with the continuous pain and silent abdomen of paralytic ileus. There also is borborygmus (i.e., rumbling sounds made by propulsion of gas in the intestine); audible, high-pitched peristalsis; and peristaltic rushes. Visible peristalsis may appear along the course of the distended intestine. Extreme restlessness and conscious awareness of intestinal movements are experienced along with weakness, perspiration, and anxiety. Should strangulation occur, the symptoms change. The character of the pain shifts from the intermittent colicky pain caused by the hyperperistaltic movements of the intestine to a severe and steady type of pain. Vomiting and fluid and electrolyte disorders occur with both types of obstruction.

Diagnosis of intestinal obstruction usually is based on history and physical findings. Abdominal x-ray studies reveal a gas-filled bowel.

Treatment depends on the cause and type of obstruction. Most cases of adynamic obstruction respond to decompression of the bowel through nasogastric suction and correction of fluid and electrolyte imbalances. Strangulation and complete bowel obstruction require surgical intervention.

Peritonitis

Peritonitis is an inflammatory response of the serous membrane that lines the abdominal cavity and covers the visceral organs. It can be caused by bacterial invasion or chemical irritation. Most commonly, enteric bacteria enter the peritoneum because of a defect in the wall of one of the abdominal organs. The most common causes of peritonitis are perforated peptic ulcer, ruptured appendix, perforated diverticulum, gangrenous bowel, pelvic inflammatory disease, and gangrenous gallbladder. Other causes are abdominal trauma and wounds. Generalized peritonitis, although no longer the overwhelming problem it once was, is still a leading cause of death after abdominal surgery.

The peritoneum has several characteristics that increase its vulnerability to or protect it from the effects of peritonitis. One weakness of the peritoneal cavity is that it is a large, unbroken space that favors the dissemination of contaminants. For the same reason, it has a large surface that permits rapid absorption of bacterial toxins into the blood. The peritoneum is particularly well adapted for producing an inflammatory response as a means of controlling infection. For example, it tends to exude a thick, sticky, and fibrinous substance that adheres to other structures, such as the mesentery and omentum, and that seals off the perforated viscus and aids in localizing the process. Localization is enhanced by sympathetic stimulation that limits intestinal motility. Although the diminished or absent peristalsis that occurs tends to give rise to associated problems, it does inhibit the movement of contaminants throughout the peritoneal cavity.

One of the most important manifestations of peritonitis is the translocation of extracellular fluid into the peritoneal cavity (through weeping or serous fluid from the inflamed peritoneum) and into the bowel as a result of bowel obstruction. Nausea and vomiting cause further losses of fluid. The fluid loss may encourage development of hypovolemia and shock. The onset of peritonitis may be acute, as with a ruptured appendix, or it may have a more gradual onset, as occurs in pelvic inflammatory disease. Pain and tenderness are common symptoms. The pain usually is more intense over the inflamed area. The person with peritonitis usually lies still because any movement aggravates the pain. Breathing often is shallow to prevent movement of the abdominal muscles. The abdomen usually is rigid and sometimes described as boardlike because of reflex muscle guarding. Vomiting is common. Fever, an elevated white blood cell count, tachycardia, and hypotension are common. Hiccups may develop because of irritation of the phrenic nerve. Paralytic ileus occurs shortly after the onset of widespread peritonitis and is accompanied by abdominal distention. Peritonitis that progresses and is untreated leads to toxemia and shock.

Treatment measures for peritonitis are directed toward preventing the extension of the inflammatory response, correcting the fluid and electrolyte imbalances that develop, and minimizing the effects of paralytic ileus and abdominal distention. Surgical intervention may be needed to remove an acutely inflamed appendix or close the opening in a perforated peptic ulcer. Oral fluids are forbidden. Nasogastric suction, which entails the insertion of a tube placed through the nose into the stomach or intestine, is used to decompress the bowel and relieve the abdominal distention. Fluid and electrolyte replacement is essential. These fluids are prescribed on the basis of frequent blood chemistry determinations. Antibiotics are given to combat infection. Narcotics often are needed for pain relief.

Alterations in Intestinal Absorption

Malabsorption is the failure to transport dietary constituents, such as fats, carbohydrates, proteins, vitamins, and minerals, from the lumen of the intestine to the extracellular fluid compartment for transport to the various parts of the body. It can selectively affect a single component, such as vitamin B_{12} or lactose, or its effects can extend to all the substances absorbed in a specific segment of the intestine. When one segment of the intestine is affected, another may compensate. For example, the ileum may compensate for malabsorption in the proximal small intestine by absorbing substantial amounts of fats, carbohydrates, and amino acids. Similarly, the colon, which normally absorbs water, sodium, chloride, and bicarbonate, can compensate for small intestine malabsorption by absorbing additional end-products of bacterial carbohydrate metabolism.

The conditions that impair one or more steps involved in digestion and absorption of nutrients can be divided into three broad categories: intraluminal maldigestion, mucosal malabsorption, and lymphatic obstruction. Intraluminal maldigestion involves a defect in processing of nutrients in the intestinal lumen. The most common causes are pancreatic insuf-

ficiency, hepatobiliary disease, and intraluminal bacterial growth. Mucosal malabsorption is caused by mucosal lesions that impair uptake and transport of available intraluminal nutrients across the mucosal surface of the intestine. They include disorders such as celiac disease, and Crohn's disease. Lymphatic obstruction interferes with the transport of the products of fat digestion to the systemic circulation after they have been absorbed by the intestinal mucosa. The process can be interrupted by congenital defects, neoplasms, trauma, and selected infectious diseases.

Malabsorption Syndrome

The term syndrome implies a common constellation of symptoms arising from multiple causes. Persons with conditions that diffusely affect the small intestine and reduce its absorptive functions share certain common features referred to as *mal*absorption syndrome. Among the causes of malabsorption syndrome are celiac sprue, Crohn's disease, and resection of large segments of the small bowel.

Celiac sprue is a relatively rare chronic disease in which there is a characteristic mucosal lesion of the small intestine and impaired nutrient absorption, which improves when gluten is removed from the diet.^{6,11} There is convincing evidence that the disorder is caused by an immunologic response to the gliadin fraction of gluten. The condition results in loss of absorptive villi from the small intestine. When the resulting lesions are extensive, they may impair absorption of virtually all nutrients. In approximately one third of the cases, symptoms begin in childhood. The effects of celiac sprue usually are reversed after removal of all wheat, rye, barley, and oat gluten from the diet. Corn and rice products are not toxic and can be used as substitutes.

Persons with intestinal malabsorption usually have symptoms directly referable to the gastrointestinal tract that include diarrhea, steatorrhea (fatty stools), flatulence, bloating, abdominal pain, and cramps. Weakness, muscle wasting, weight loss, and abdominal distention often are present. Weight loss often occurs despite normal or excessive caloric intake. In a person consuming a diet containing 80 to 100 g of fat each day, excretion of 7 to 9 g of fat indicates steatorrhea.

Along with loss of fat in the stools, there is failure to absorb the fat-soluble vitamins. This can lead to easy bruising and bleeding (*i.e.*, vitamin K deficiency), bone pain, a predisposition to the development of fractures and tetany (*i.e.*, vitamin D and calcium deficiency), macrocytic anemia, and glossitis (*i.e.*, folic acid deficiency). Neuropathy, atrophy of the skin, and peripheral edema may be present. Table 27-2 describes the signs and symptoms of impaired absorption of dietary constituents.

Neoplasms

Epithelial cell tumors of the intestines are a major cause of morbidity and mortality worldwide. Although the small intestine accounts for approximately 75% of the length of the gastrointestinal tract, its tumors account for only 3% to 6% of gastrointestinal tumors.11

Adenomatous Polyps

By far the most common types of neoplasms of the intestine are adenomatous polyps. A gastrointestinal polyp can be described as a mass that protrudes into the lumen of gut.^{11,16} Polyps can be subdivided according to their attachment to the bowel wall (sessile [raised mucosal nodules] or pedunculated [attached by a stalk]); their histopathologic appearance (hyperplastic or adenomatous); and their neoplastic potential (benign or malignant).16

Adenomatous polyps (adenomas) are benign neoplasms that arise from the mucosal epithelium of the intestine (Fig. 27-9). They are composed of neoplastic cells that have proliferated in excess of those needed to replace the cells that normally are shed from the mucosal surface. The pathogenesis of adenoma formation involves neoplastic alteration in the replication of the crypt epithelial cells in the crypts of Lieberkühn. There may be diminished apoptosis (see Chapter 2), persistence of cell replication, and failure of cell maturation and differentiation of the cells that migrate to the surface of the crypts.¹⁶ Normally, DNA synthesis ceases as the cells reach the upper two thirds of the crypts, after which they mature, migrate to the surface, and become senescent. They then become apoptotic and are shed from the surface.¹⁶ Adenomas arise from a disruption in this sequence, such that the epithelial cells retain their proliferative ability throughout the entire length of the crypt. Alterations in cell differentiation can lead to dysplasia and progression to the development of invasive carcinoma.

Most cases of colorectal cancer begin as benign adenomatous colonic polyps (Fig. 27-10). The frequency of polyps increases with age, and the prevalence of adenomatous polyps, which is approximately 20% to 30% before 40 years of age, rises to 40% to 50% after age 60 years.¹¹ Men and women are equally affected. The peak incidence of adenomatous polyps precedes by some years the peak for colorectal cancer. Programs that provide careful follow-up for persons with adenomatous polyps and removal of all suspect lesions have substantially reduced the incidence of colorectal cancer.11

Colorectal Cancer

Colorectal cancer is the second leading cause of cancer death in the United States. In 2003, there will be an estimated 105,500 new cases of colorectal cancer and 57,100 deaths associated with the disease.²¹ The death rate for colorectal cancer has been steadily declining since the early 1980s. This may attributable to a decreased number of cases, because more of the cases are found earlier, and because treatments have improved.

The cause of cancer of the colon and rectum is largely unknown. Its incidence increases with age, as evidenced by the fact that approximately 80% of persons who have this form of cancer are older than 50 years.11 The incidence of colorectal cancer is increased among persons with a family history of cancer, persons with Crohn's disease or ulcerative colitis, and those with familial adenomatous polyposis of the colon. Diet also is thought to play a role. Attention has focused on dietary fat intake, refined sugar intake, fiber intake, and the adequacy of such protective micronutrients as vitamins A, C, and E in the diet. Reports indicate that aspirin may protect against colorectal cancer.^{40,41} Although the mechanism of aspirin's action is unknown, it may be related to its effect on the synthesis of prostaglandins, one or more of which may be involved in signal systems that influence cell proliferation or tumor growth.

Usually, cancer of the colon and rectum is present for a long time before it produces symptoms. Bleeding is a highly significant early symptom, and it usually is the one that causes persons to seek medical care. Other symptoms include a change in

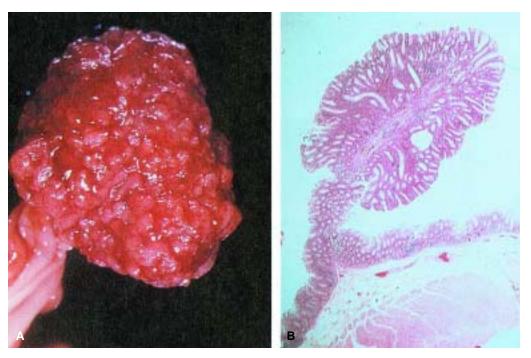

TABLE 27-2 Sites of and Requirements for Absorption of Dietary Constituents and Manifestations of Malabsorption

Dietary Constituent	Site of Absorption	Requirements	Manifestations
Water and electrolytes	Mainly small bowel	Osmotic gradient	Diarrhea
			Dehydration
			Cramps

Iron	Duodenum and jejunum	Normal pH (hydrochloric acid secretion)	Iron-deficiency anemia
			Glossitis

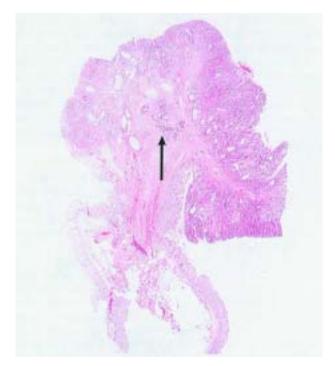

bowel habits, diarrhea or constipation, and sometimes a sense of urgency or incomplete emptying of the bowel. Pain usually is a late symptom.

The prognosis for persons with colorectal cancer depends largely on the extent of bowel involvement and on the presence of metastasis at the time of diagnosis. Colorectal cancer commonly is divided into four categories according to the Dukes classification or its variants.^{15,20} A stage A tumor is limited to invasion of the mucosal and submucosal layers of the colon and is associated with a 5-year survival rate of almost 100%.¹¹ A stage B tumor involves the entire wall of the colon, but without lymph node involvement, and is associated with a 5-year survival rate of 43% to 67%.¹¹ With a stage C tumor, there is invasion of the serosal layer and involvement of the regional lymph nodes. The 5-year survival rate is approximately 23%.¹¹ Stage D colorectal cancers involve far-advanced metastasis and have a much poorer prognosis.

Screening, Diagnosis, and Treatment. Among the methods used for the detection of colorectal cancers are stool occult blood tests and digital rectal examination, usually done during routine physical examinations; x-ray studies using barium (*e.g.*, barium enema); and flexible sigmoidoscopy and colonoscopy. Digital rectal examinations are most helpful in detecting neoplasms of the rectum. Rectal examination should be considered a routine part of a good physical examination. The American Cancer Society recommends that all asymptomatic men and women older than 40 years should have a digital rectal examination, and that those older than 50 years should have

■ FIGURE 27-9 ■ Tubular adenoma of the colon. (A) A pedunculated tubular adenoma. (B) A low-power photomicrograph of a tubular adenoma shows closely packed epithelial tubules. ■ FIGURE 27-10 ■ Adenocarcinoma arising from a pedunculated adenomatous polyp. A low-grade micrograph shows irregular neoplastic glands (*arrow*) invading the stalk. (From Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 738]. Philadelphia: Lippincott Williams & Wilkins)

an annual stool test for occult blood and a flexible sigmoidoscopy examination every 5 years and colonoscopy every 10 years or double contrast barium enema every 5 years, as recommended by their physician.³⁹

Carcinoembryonic antigen (CEA) can be used as a marker for colorectal cancer. However, blood levels are of little screening or diagnostic value because they become elevated only after the tumor has reached considerable size. Moreover, CEA is produced by other types of cancers and noncancerous conditions, such as alcoholic cirrhosis, pancreatitis, and ulcerative colitis. This marker is of greatest value for monitoring tumor recurrence in persons after resection of the primary tumor.^{11,39}

The only recognized treatment for cancer of the colon and rectum is surgical removal. Preoperative radiation therapy may be used and has in some cases demonstrated increased 5-year survival rates. Postoperative adjuvant chemotherapy may be used. Radiation therapy and chemotherapy are used as palliative treatment methods.

In summary, disorders of the small and large intestines include irritable bowel syndrome, inflammatory bowel disease, diverticular disease, disorders of motility (*i.e.*, diarrhea, constipation, infectious colitis, and intestinal obstruction), peritonitis alterations in intestinal absorption, and colorectal cancer.

Irritable bowel syndrome is a functional disorder characterized by a variable combination of chronic and recurrent intestinal symptoms not explained by structural or biochemical

492 Unit Seven: Alterations in the Gastrointestinal System

abnormalities. The term *inflammatory bowel disease* is used to designate two inflammatory conditions: Crohn's disease, which affects the small and large bowel, and ulcerative colitis, which affects the colon and rectum. Both are chronic diseases characterized by remissions and exacerbations of diarrhea, weight loss, fluid and electrolyte disorders, and systemic signs of inflammation.

Infectious forms of colitis include those caused by *C. difficile*, which is associated with antibiotic therapy, and *E. coli* O157:H7, which is found in undercooked hamburger and unpasteurized milk. Diverticular disease includes diverticulosis, which is a condition in which the mucosal layer of the colon herniates through the muscularis layer, and diverticulitis, in which there is inflammation and gross or microscopic perforation of the diverticulum.

Diarrhea and constipation represent disorders of intestinal motility. Diarrhea, characterized by excessively frequent passage of stools, can be divided into large-volume diarrhea, characterized by an increased water content in the feces, and small-volume diarrhea, associated with intrinsic bowel disease and frequent passage of small stools. Constipation can be defined as the infrequent passage of stools; it commonly is caused by failure to respond to the urge to defecate, inadequate fiber or fluid intake, weakness of the abdominal muscles, inactivity and bed rest, pregnancy, hemorrhoids, and gastrointestinal disease. Intestinal obstruction designates an impairment of movement of intestinal contents in a cephalocaudal direction as the result of mechanical or paralytic mechanisms. Peritonitis is an inflammatory response of the serous membrane that lines the abdominal cavity and covers the visceral organs. It can be caused by bacterial invasion or chemical irritation resulting from perforation of the viscera or abdominal organs.

Malabsorption results from the impaired absorption of nutrients and other dietary constituents from the intestine. It can involve a single dietary constituent, such as vitamin B_{12} , or extend to involve all of the substances absorbed in a particular part of the small intestine. Malabsorption can result from disease of the small bowel and disorders that impair digestion and in some cases obstruct the lymph flow by which fats are transported to the general circulation.

Colorectal cancer, the second most common fatal cancer, is seen most commonly in persons older than 50 years. Most, if not all, cancers of the colon and rectum arise in pre-existing adenomatous polyps. Programs that provide careful follow-up for persons with adenomatous polyps and removal of all suspect lesions have substantially reduced the incidence of colorectal cancer.

REVIEW QUESTIONS

Relate the pathophysiology of gastroesophageal reflux to measures used in diagnosis and treatment of the disorder in adults and children.

State the reason for the poor prognosis associated with esophageal cancer.

Describe the factors that contribute to the gastric mucosal barrier.

Characterize the proposed role of *Helicobacter pylori* in the development of chronic gastritis and peptic ulcer and cite methods for diagnosing the infection.

Describe the predisposing factors in the development of peptic ulcer and cite the three complications of peptic ulcer.

State the diagnostic criteria for irritable bowel syndrome.

Compare the characteristics of Crohn's disease and ulcerative colitis.

Compare the causes and manifestations of small-volume diarrhea and large-volume diarrhea.

Differentiate between mechanical and paralytic intestinal obstruction in terms of cause and manifestations.

List conditions that cause malabsorption by impaired intraluminal malabsorption, mucosal malabsorption, and lymphatic obstruction.

List the risk factors associated with colorectal cancer and cite the screening methods for detection.

he liver, the gallbladder, and the exocrine pancreas are classified as accessory organs of the gastrointestinal tract. In addition to producing digestive secretions, the liver and the pancreas have other important functions. For example, the endocrine pancreas supplies the insulin and glucagon needed in cell metabolism, whereas the liver synthesizes glucose, plasma proteins, and blood clotting factors and is responsible for the degradation and elimination of drugs and hormones, among other functions. This chapter focuses on functions and disorders of the liver, the biliary tract and gallbladder, and the exocrine pancreas.

THE LIVER AND HEPATOBILIARY SYSTEM

The liver is the largest visceral organ in the body, weighing approximately 1.3 kg (3 lb) in the adult (Fig. 28-1). It lies below and on the right side of the diaphragm. Except for the portion that is in the epigastric area, the liver is contained within the rib cage and in healthy persons cannot normally be palpated. The liver is surrounded by a tough fibroelastic capsule called *Glisson's capsule*.

The liver is unique among the abdominal organs in having a dual blood supply—the hepatic artery and the portal vein. Approximately 300 mL of blood per minute enters the liver through the hepatic artery; another 1050 mL/minute enters by way of the valveless portal vein, which carries blood from the stomach, the small and the large intestines, the pancreas, and the spleen¹ (Fig. 28-2). Although the blood from the portal vein is incompletely saturated with oxygen, it supplies approximately 60% to 70% of the oxygen needs of the liver. The venous outflow from the liver is carried by the valveless hepatic veins, which empty into the inferior vena cava just below the level of the diaphragm. The pressure difference between the hepatic vein and the portal vein normally is such that the liver stores approximately 450 mL of blood.1 This blood can be shifted back into the general circulation during periods of hypovolemia and shock. In congestive heart failure, in which the pressure in the vena cava increases, blood backs up and accumulates in the liver.

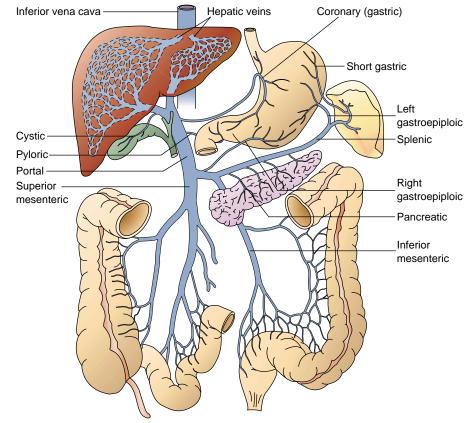

The *lobules* are the functional units of the liver. Each lobule is a cylindrical structure that measures approximately 0.8 to

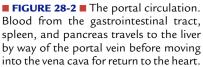

■ FIGURE 28-1 ■ The liver and biliary system, including the gallbladder and bile ducts.

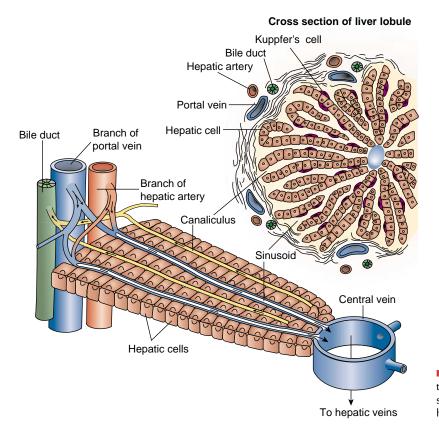

2 mm in diameter and several millimeters long. There are approximately 50,000 to 100,000 lobules in the liver.¹ Each lobule is organized around a central vein that empties into the hepatic veins and from there into the vena cava. The terminal bile ducts and small branches of the portal vein and hepatic

artery are located at the periphery of the lobule. Plates of hepatic cells radiate centrifugally from the central vein like spokes on a wheel (Fig. 28-3). These hepatic plates are separated by wide, thin-walled channels, called *sinusoids*, that extend from the periphery of the lobule to its central vein. The sinusoids are

496 Unit Seven: Alterations in the Gastrointestinal System

■ FIGURE 28-3 ■ A section of liver lobule showing the location of the hepatic veins, hepatic cells, liver sinusoids, and branches of the portal vein and hepatic artery.

supplied by blood from the portal vein and hepatic artery. Because the plates of hepatic cells are no more than two layers thick, every cell is exposed to the blood that travels through the sinusoids. Thus, the hepatic cells can remove substances from the blood or can release substances into the blood as it moves through the sinusoids.

The venous sinusoids are lined with two types of cells: endothelial cells and Kupffer's cells. *Kupffer's cells* are phagocytic cells that are capable of removing old and defective blood cells, bacteria, and other foreign material from the portal blood as it flows through the sinusoid. This phagocytic action removes the enteric bacilli and other harmful substances that filter into the blood from the intestine.

The lobules also are supplied by small tubular channels, called bile canaliculi, that lie between the cell membranes of adjacent hepatocytes. The bile produced by the hepatocytes flows into the canaliculi and then to the periphery of the lobules, which drain into progressively larger ducts, until it reaches the right and left hepatic ducts. The intrahepatic and extrahepatic bile ducts often are collectively referred to as the *hepatobiliary* tree. These ducts unite to form the common duct (see Fig. 28-1). The common duct, which is approximately 10 to 15 cm long, descends and passes behind the pancreas and enters the descending duodenum. The pancreatic duct joins the common duct at a short dilated tube called the hepatopancreatic ampulla (ampulla of Vater), which empties into the duodenum through the duodenal papilla. Muscle tissue at the junction of the papilla, called the sphincter of the bile duct, regulates the flow of bile into the duodenum. When this sphincter is closed, bile moves back into the common duct and gallbladder.

Metabolic Functions of the Liver

The liver is one of the most versatile and active organs in the body. It produces bile; metabolizes hormones and drugs; synthesizes proteins, glucose, and clotting factors; stores vitamins and minerals; changes ammonia produced by deamination of amino acids to urea; and converts fatty acids to ketones. In its capacity for metabolizing drugs and hormones, the liver serves as an excretory organ. In this respect, the bile, which carries the end-products of substances metabolized by the liver, is much like the urine, which carries the body wastes filtered by the kidneys.

Carbohydrate, Protein, and Lipid Metabolism

The liver plays an essential role in carbohydrate, fat, and proteins metabolism. It degrades excess nutrients and converts them into substances essential to the body. It builds carbohydrates from proteins, converts sugars to fats that can be stored, and interchanges chemical groups on amino acids so that they can be used for a number of purposes.

Carbohydrate Metabolism. The liver is especially important in maintaining glucose homeostasis. It stores excess glucose as glycogen and releases it into the circulation when blood glucose levels fall. The liver converts galactose and fructose to glucose and it synthesizes glucose from amino acids, glycerol, and lactic acid as a means of maintaining blood glucose during periods of fasting or increased need. The liver also converts excess carbohydrates to triglycerides for storage in adipose tissue. **Protein Synthesis and Conversion of Ammonia to Urea.** Even though the muscle contains the greatest amount of protein, the liver has the greatest rate of protein synthesis per gram of tissue. It produces the proteins for its own cellular needs and secretory proteins that are released into the circulation. The most important of these secretory proteins is albumin. Albumin contributes significantly to the plasma colloidal osmotic pressure (see Chapter 6) and to the binding and transport of numerous substances, including some hormones, fatty acids, bilirubin, and other anions. The liver also produces other important proteins, such as fibrinogen and the blood clotting factors.

Proteins are made up of amino acids. Protein synthesis and degradation involves two major reactions: transamination and deamination. In transamination, the amino group (NH₂) from an amino acid is transferred to α -ketoglutaric acid (a Krebs cycle keto acid) to form glutamic acid. The transferring amino acid becomes a keto acid and α -ketoglutaric acid becomes an amino acid (glutamic acid). The reaction is fully reversible. The process of transamination is catalyzed by aminotransferases, enzymes that are found in high amounts in the liver. Oxidative *deamination* involves the removal of an amino group from an amino acid. This occurs mainly by transamination, in which the amino group of glutamic acid is removed as ammonia, and α -ketoglutaric is regenerated. Because ammonia is very toxic to body tissues, particularly neurons, it is converted to urea in the liver and then excreted by the kidneys.² The goal of amino acid degradation is to produce molecules that can be used to produce energy or be converted to glucose.

Pathways of Lipid Metabolism. Although most body cells can metabolize fat, certain aspects of lipid metabolism occur mainly in the liver. These include the oxidation of fatty acids to supply energy for other body functions; the synthesis of large quantities of cholesterol, phospholipids, and most lipoproteins; and

KEY CONCEPTS

DISEASES OF THE LIVER

- Diseases of the liver can affect the hepatocytes or the biliary drainage system.
- Disorders of hepatocyte function impair the metabolic and synthetic functions of the liver, causing disorders in carbohydrate, protein, and fat metabolism; metabolism and removal of drugs, hormones, toxins, ammonia, and bilirubin from the blood; and the interconversion of amino acids and synthesis of proteins. Elevations in serum aminotransferase levels signal the presence of hepatocyte damage.
- Disorders of the biliary drainage system obstruct the flow of bile and interfere with the elimination of bile salts and bilirubin, producing cholestatic liver damage because of the backup of bile into the lobules of the liver. Elevations in bilirubin and alkaline phosphatase signal the presence of cholestatic liver damage.

the formation of triglycerides from carbohydrates and proteins. To derive energy from neutral fats (triglycerides), the fat must first be split into glycerol and fatty acids, and then the fatty acids split into acetyl-coenzyme A (acetyl-CoA). Acetyl-CoA can be used by the liver to produce adenosine triphosphate (ATP) or it can be converted to acetoacetic acid and released into the bloodstream and transported to other tissues, where it is used for energy. The acetyl-CoA units from fat metabolism also are used to synthesize cholesterol and bile acids. Cholesterol has several fates in the liver. It can be esterified and stored; it can be exported bound to lipoproteins; or it can be converted to bile acids.

Drug and Hormone Metabolism

By virtue of its many enzyme systems that are involved in biochemical transformations and modifications, the liver has an important role in the metabolism of many drugs and chemical substances. The liver is particularly important in terms of metabolizing lipid-soluble substances that cannot be directly excreted by the kidneys. Two major types of reactions are involved in the hepatic detoxification and metabolism of drugs and other chemicals: phase 1 reactions, which involve chemical modification or inactivation of a substance, and phase 2 reactions, which involve conversion of lipid-soluble substances to water-soluble derivatives.^{3,4} Often, the two types of reactions are linked. Many phase 1 reactants are not soluble and must therefore undergo a subsequent phase 2 reaction to be eliminated. These reactions, which are called biotransformations, are important considerations in drug therapy. Because the liver is central to metabolic disposition of virtually all drugs and foreign substances, drug-induced liver toxicity is a potential complication of many medications.

In addition to its role in metabolism of drugs and chemicals, the liver also is responsible for hormone inactivation or modification. Insulin and glucagon are inactivated by proteolysis or deamination. Thyroxine and triiodothyronine are metabolized by reactions involving deiodination. Steroid hormones such as the glucocorticoids are first inactivated by a phase 1 reaction and then converted to a more water-soluble product by a phase 2 reaction.

Bile Production and Cholestasis

The secretion of bile, approximately 600 to 1200 mL daily, is one of the many functions of the liver.¹ Bile functions in the digestion and absorption of fats and fat-soluble vitamins from the intestine, and it serves as a vehicle for excretion of bilirubin, excess cholesterol, and metabolic end-products that cannot be eliminated in the urine.

Bile contains water, electrolytes, bile salts, bilirubin, cholesterol, and certain products of organic metabolism. Of these, only the bile salts, which are formed from cholesterol, are important in digestion. Bile salts aid in emulsifying dietary fats, and they are necessary for the formation of the micelles that transport fatty acids and fat-soluble vitamins to the surface of the intestinal mucosa for absorption. Approximately 94% of bile salts that enter the intestine are reabsorbed into the portal circulation by an active transport process that takes place in the distal ileum. From the portal circulation, the bile salts pass into the liver, where they are recycled. Normally, bile salts travel this entire circuit approximately 18 times before being expelled in the feces.¹ This system for recirculation of bile is called the *enterohepatic circulation*.

Cholestasis

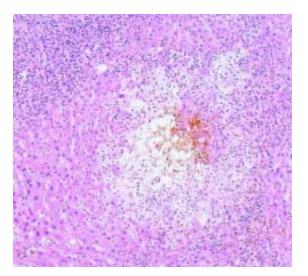

Cholestasis represents a decrease in bile flow through the intrahepatic canaliculi and a reduction in secretion of water, bilirubin, and bile acids by the hepatocytes. As a result, the materials normally transferred to the bile, including bilirubin, cholesterol, and bile acids, accumulate in the blood.^{5,6} The condition may be caused by intrinsic liver disease, in which case it is referred to as *intrahepatic cholestasis*, or by obstruction of the larger bile ducts located outside the liver, a condition known as *extrahepatic cholestasis*.

Common to all types of obstructive and hepatocellular cholestasis is the accumulation of bile pigment within the bile canaliculi and hepatocytes. Prolonged obstructive cholestasis leads not only to fatty changes in the hepatocytes but to destruction of the supporting connective tissue, giving rise to bile lakes filled with cellular debris and pigment (Fig. 28-4).⁵ Unrelieved obstruction leads to portal tract fibrosis and ultimately to end-stage biliary cirrhosis.

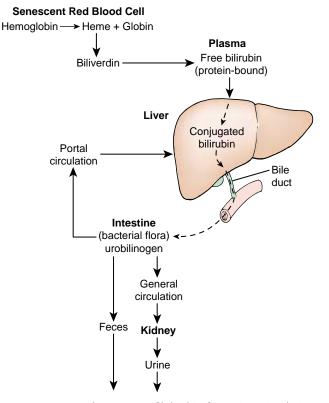

Pruritus is the most common presenting symptom in persons with cholestasis, probably related to an elevation in plasma bile acids. Skin xanthomas (focal accumulations of cholesterol) may occur, the result of hyperlipidemia and impaired excretion of cholesterol. A characteristic laboratory finding is an elevated serum alkaline phosphatase level. Alkaline phosphatase is present in the membranes between liver cells and the bile duct and is released by disorders affecting the bile duct. Other manifestations of reduced bile flow relate to intestinal absorption, including nutritional deficiencies of the fat-soluble vitamins A, D, and K.

Bilirubin Elimination

Bilirubin is the substance that gives bile its color. It is formed during the breakdown of senescent red blood cells. In the process of degradation, the heme portion of the hemoglobin mol-

■ FIGURE 28-4 ■ Bile infarct (bile lake). A photomicrograph of the liver in a patient with extrahepatic biliary obstruction shows an area of necrosis and the accumulation of extravasated bile (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 768]. Philadelphia: Lippincott Williams & Wilkins)

■ FIGURE 28-5 ■ The process of bilirubin formation, circulation, and elimination.

ecule is oxidized to form biliverdin, which is then converted to free bilirubin (Fig. 28-5). Free bilirubin, which is insoluble in plasma, is transported in the blood attached to plasma albumin. Even when it is bound to albumin, this bilirubin is still called free bilirubin. As it passes through the liver, free bilirubin is released from the albumin carrier molecule and moved into the hepatocytes. Inside the hepatocytes, free bilirubin is converted to conjugated bilirubin, making it soluble in bile. Conjugated bilirubin is secreted as a constituent of bile, and in this form it passes through the bile ducts into the small intestine. In the intestine, approximately one half of the bilirubin is converted into a highly soluble substance called *urobilinogen* by the intestinal flora. Urobilinogen is either absorbed into the portal circulation or excreted in the feces. Most of the urobilinogen that is absorbed is returned to the liver to be re-excreted into the bile. A small amount of urobilinogen, approximately 5%, is absorbed into the general circulation and then excreted by the kidneys.

Usually, only a small amount of bilirubin (0.1 to 1.2 mg/dL) is found in the blood. Laboratory measurements of bilirubin usually measure the free and the conjugated bilirubin as well as the total bilirubin. These are reported as the direct (conjugated) bilirubin and the indirect (unconjugated or free) bilirubin.

Jaundice. Jaundice (*i.e.*, icterus), which results from an abnormally high accumulation of bilirubin in the blood, is a yellowish discoloration to the skin and deep tissues. Jaundice becomes evident when the serum bilirubin levels rise above 2.0 to 2.5 mg/dL.^{5,6} Because normal skin has a yellow cast, the early signs of jaundice often are difficult to detect, especially in per-

Chapter 28: Alterations in Hepatobiliary Function 49

■ FIGURE 28-6 ■ Jaundice. A patient with hepatic failure displays a yellow sclera. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 762]. Philadelphia: Lippincott Williams & Wilkins)

sons with dark skin. Bilirubin has a special affinity for elastic tissue. The sclera of the eye, which contains considerable elastic fibers, usually is one of the first structures in which jaundice can be detected (Fig 28-6).

The four major causes of jaundice are excessive destruction of red blood cells, impaired uptake of bilirubin by the liver cells, decreased conjugation of bilirubin, and obstruction of bile flow in the canaliculi of the hepatic lobules or in the intrahepatic or extrahepatic bile ducts. From an anatomic standpoint, jaundice can be categorized as prehepatic, intrahepatic, and posthepatic. Chart 28-1 lists the common causes of prehepatic, hepatic, and posthepatic jaundice.

CHART 28-1 Causes of Jaundice

Prehepatic (Excessive Red Blood Cell Destruction)

Hemolytic blood transfusion reaction Hereditary disorders of the red blood cell Sickle cell anemia Thalassemia Spherocytosis Acquired hemolytic disorders Hemolytic disease of the newborn

Autoimmune hemolytic anemias

Intrahepatic

Decreased bilirubin uptake by the liver Decreased conjugation of bilirubin Hepatocellular liver damage Hepatitis Cirrhosis Cancer of the liver Drug-induced cholestasis

Posthepatic (Obstruction of Bile Flow)

Structural disorders of the bile duct Cholelithiasis Congenital atresia of the extrahepatic bile ducts Bile duct obstruction caused by tumors The major cause of prehepatic jaundice is excessive hemolysis of red blood cells. Hemolytic jaundice occurs when red blood cells are destroyed at a rate in excess of the liver's ability to remove the bilirubin from the blood. It may follow a hemolytic blood transfusion reaction or may occur in diseases such as hereditary spherocytosis, in which the red cell membranes are defective, or in hemolytic disease of the newborn (see Chapter 13). Neonatal hyperbilirubinemia results in an increased production of bilirubin in newborn infants and their limited ability to excrete it.⁷ Premature infants are at particular risk because their red cells have a shorter life span and higher turnover rate. In prehepatic jaundice, there is mild jaundice, the unconjugated bilirubin is elevated, the stools are of normal color, and there is no bilirubin in the urine.

Intrahepatic or hepatocellular jaundice is caused by disorders that directly affect the ability of the liver to remove bilirubin from the blood or conjugate it so it can be eliminated in the bile. Liver diseases such as hepatitis and cirrhosis are the most common causes of intrahepatic jaundice. Intrahepatic jaundice usually interferes with all phases of bilirubin metabolism—uptake, conjugation, and excretion. Both conjugated and unconjugated bilirubin are elevated and the urine often is dark because of the presence of bilirubin.

Posthepatic or obstructive jaundice, also called *cholestatic jaundice*, occurs when bile flow is obstructed between the liver and the intestine. Among the causes of posthepatic jaundice are strictures of the bile duct, gallstones, and tumors of the bile duct or the pancreas. Conjugated bilirubin levels usually are elevated; the stools are clay colored because of the lack of bilirubin in the bile; the urine is dark; the levels of serum alkaline phosphatase are markedly elevated; and the aminotransferase levels are slightly increased. Blood levels of bile acids often are elevated in obstructive jaundice. As the bile acids accumulate in the blood, pruritus develops. A history of pruritus preceding jaundice is common in obstructive jaundice.

Tests of Hepatobiliary Function

The history and physical examination, in most instances, provide clues about liver function. Diagnostic tests help to evaluate liver function and the extent of liver damage. Laboratory tests commonly are used to assess liver function and confirm the diagnosis of liver disease.

Liver function tests, including serum levels of liver enzymes, are used to assess injury to liver cells, the liver's ability to synthesize proteins, and the excretory functions of the liver.^{8,9} Elevated serum enzyme tests usually indicate liver injury earlier than do other indicators of liver function. The key enzymes are alanine aminotransferase (ALT) and aspartate aminotransferase (AST), which are present in liver cells. ALT is liver specific, whereas AST is derived from organs other than the liver. In most cases of liver damage, there are parallel increases in ALT and AST. The most dramatic rise is seen in cases of acute hepatocellular injury, such as occurs with viral hepatitis, hypoxic or ischemic injury, and acute toxic injury.

The liver's synthetic capacity is reflected in measures of serum protein levels and prothrombin time (*i.e.*, synthesis of coagulation factors). Hypoalbuminemia caused by depressed synthesis may complicate severe liver disease. Deficiencies of coagulation factor V and vitamin K-dependent factors (II, VII, IX, and X) may occur.

500 Unit Seven: Alterations in the Gastrointestinal System

Serum bilirubin, γ -glutamyltransferase (GGT), and alkaline phosphatase measure hepatic excretory function. Alkaline phosphatase is present in the membranes of cells that line the bile duct and is released by disorders affecting the bile duct.⁸ GGT is thought to function in the transport of amino acids and peptides into liver cells; it is a sensitive indicator of hepatobiliary disease. Measurement of GGT may be helpful in diagnosing alcohol abuse.⁹

Ultrasonography and computed tomography (CT) scanning provide information about the size, structure, and composition of the liver. Magnetic resonance imaging (MRI) has proved to be useful in some disorders. Selective angiography of the celiac, superior mesenteric, or hepatic artery may be used to visualize the hepatic or portal circulation. A liver biopsy affords a means of examining liver tissue without surgery.

In summary, the hepatobiliary system consists of the liver, gallbladder, and bile ducts. The liver is the largest and, in functions, one of the most versatile organs in the body. It is located between the gastrointestinal tract and the systemic circulation; venous blood from the intestine flows through the liver before it is returned to the heart. In this way, nutrients can be removed for processing and storage, and bacteria and other foreign matter can be removed by Kupffer's cells before the blood is returned to the systemic circulation.

The liver synthesizes fats, glucose, and plasma proteins. Other important functions of the liver include the deamination of amino acids, conversion of ammonia to urea, and the interconversion of amino acids and other compounds that are important to the metabolic processes of the body. The liver produces approximately 600 to 1200 mL of bile daily. Bile contains bile salts that are essential for digestion of fats and absorption of fat-soluble vitamins, and it serves as an excretory vehicle for bilirubin, cholesterol, and certain products of organic metabolism. Cholestasis represents a decrease in bile flow through the intrahepatic bile ducts. It results in destructive liver changes and an accumulation of bile components in the blood. The liver also removes, conjugates, and secretes bilirubin into the bile. Jaundice occurs when bilirubin accumulates in the blood. It can occur because of excessive red blood cell destruction, failure of the liver to remove and conjugate the bilirubin, or obstructed biliary flow.

Liver function tests, including serum aminotransferase levels, are used to assess injury to liver cells. Serum bilirubin, GGT, and alkaline phosphatase measure hepatic excretory function. Ultrasonography, CT scans, and MRI are used to evaluate liver structures. Angiography may be used to visualize the hepatic or portal circulation, and a liver biopsy may be used to obtain tissue specimens for microscopic examination.

DISORDERS OF THE LIVER

The liver is subject to many of the same pathologic conditions that affect other body organs: infection, inflammation, and immune responses; metabolic disorders; and neoplasms. This section focuses on alterations in liver function caused by viral and autoimmune hepatitis; intrahepatic biliary tract disorders; alcohol-induced liver disease; cirrhosis, portal hypertension, and liver failure; and cancer of the liver.

Hepatitis

Hepatitis refers to inflammation of the liver. It can be caused by reactions to chemical agents, drugs, and toxins; disorders such as autoimmune diseases and infectious mononucleosis that cause secondary hepatitis; and by hepatotropic viruses that primarily affect liver cells or hepatocytes.

Acute Viral Hepatitis

The known hepatotropic viruses include hepatitis A virus (HAV), hepatitis B virus (HBV), the hepatitis B-associated delta virus (HDV), hepatitis C virus (HCV), and hepatitis E virus (HEV). Although all of these viruses cause acute hepatitis, they differ in the mode of transmission and incubation period; mechanism, degree, and chronicity of liver damage; and ability to evolve to a carrier state.

There are two mechanisms of liver injury in viral hepatitis: direct cellular injury and immune responses against viral antigens in infected hepatocytes. The immune-mediated mechanisms of injury have been most closely studied in HBV. It is thought that the extent of inflammation and necrosis depends on the person's immune response. Accordingly, a prompt immune response during the acute phase of the infection would be expected to cause cell injury but at the same time eliminate the virus. Thus, people who respond with fewer symptoms and a marginal immune response are less likely to eliminate the virus, and hepatocytes expressing the viral antigens persist, leading to the chronic or carrier state. Fulminant hepatitis would be explained in terms of an accelerated immune response with severe liver necrosis.

The clinical course of viral hepatitis involves a number of syndromes, including asymptomatic infection with only sero-logic evidence of disease; acute symptomatic hepatitis; the carrier state without clinically apparent disease or with chronic hepatitis; chronic hepatitis with or without progression to cirrhosis; or fulminating disease (>1% to 3%) with rapid onset of liver failure. Not all hepatotropic viruses provoke each of the clinical syndromes.

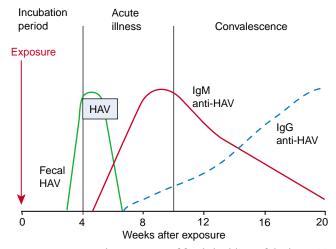

The manifestations of acute hepatitis can be divided into three phases: the prodromal or preicterus period, the icterus period, and the convalescent period. The *prodromal period* is marked by nonspecific symptoms, which vary from abrupt to insidious. There are usually complaints of malaise, easy fatigability, nausea, and loss of appetite. Weight loss, low-grade fever, headaches, muscle aches and pains, vomiting, and diarrhea are less constant symptoms. In some persons, the nonspecific symptoms are more severe with higher fever, chills, and headache, sometimes accompanied by right upper quadrant abdominal pain and liver enlargement and tenderness. Serum levels of AST and ALT show variable increases during the preicterus phase and precede a rise in serum bilirubin that accompanies the onset of the icterus or jaundice phase of infection. The icterus or jaundice phase, if it occurs, usually follows the prodromal phase by 5 to 10 days. Jaundice is less likely to occur with HCV infection. The symptoms may become worse with the onset of jaundice, followed by progressive clinical improvement. Severe pruritus and liver tenderness are common during the icterus period. The *convalescent phase* is characterized by an increased sense of well-being, return of appetite, and disappearance of jaundice. The acute illness usually subsides gradually during a 2- to 3-week period, with complete clinical recovery by approximately 9 weeks in hepatitis A and 16 weeks in uncomplicated hepatitis B.

Infection with HBV and HCV can produce a *carrier state*, in which the person does not have symptoms but harbors the virus and can transmit the disease. Evidence also indicates a carrier state for HDV infection. There is no carrier state for HAV infection. There are two types of carriers: healthy carriers who have few or no ill effects, and those with chronic disease who may or may not have symptoms. Factors that increase the risk of becoming a carrier are age at time of infection and immune status. Persons at high risk for becoming carriers are infants of HBV-infected mothers, persons with impaired immunity, those who have received multiple transfusions or blood products, those who are on hemodialysis, and drug addicts.

Hepatitis A. Hepatitis A, formerly called *infectious hepatitis*, is caused by the small, unenveloped, RNA-containing HAV. It usually is a benign, self-limited disease, although in rare cases it can cause acute fulminant hepatitis and liver failure, leading to death. The onset of symptoms usually is abrupt and includes fever, malaise, nausea, anorexia, abdominal discomfort, dark urine, and jaundice. The likelihood of having symptoms is related to age.¹⁰ Children younger than 6 years often are asymptomatic. The illness in older children and adults usually is symptomatic, and jaundice occurs in approximately 90% of cases. Symptoms usually last approximately 2 months but can last longer. HAV does not cause chronic hepatitis or induce a carrier state.

Hepatitis A has a brief incubation period (15 to 45 days) and usually is transmitted by the fecal-oral route.^{5,6,11} The virus replicates in the liver, is excreted in the bile, and shed in the stool. The fecal shedding of HAV occurs as much as 2 weeks before the development of symptoms and ends as the immunoglobulin M (IgM) levels rise.⁵ The disease often occurs sporadically or in epidemics. Drinking contaminated milk or water and eating shellfish from infected waters are fairly common routes of transmission. At special risk are persons traveling abroad who have not previously been exposed to the virus. Because young children are asymptomatic, they play an important role in the spread of the disease. Institutions housing large numbers of persons (usually children) sometimes are stricken with an epidemic of hepatitis A. Oral behavior and lack of toilet training promote viral infection among children attending preschool day care centers, who then carry the virus home to older siblings and parents. Hepatitis A usually is not transmitted by transfusion of blood or plasma derivatives, presumably because its short period of viremia usually coincides with clinical illness, so that the disease is apparent and blood donations are not accepted.

Antibodies to HAV (anti-HAV) appear early in the disease and tend to persist in the serum (Fig. 28-7). The IgM antibodies (see Chapter 8) usually appear during the first week of symptomatic disease and begin to decline in a few months. Their presence coincides with a decline in fecal shedding of the virus. Peak levels of IgG antibodies occur after 1 month of illness and may persist for years; they provide long-term protective immunity against reinfection. The presence of IgM anti-

■ FIGURE 28-7 ■ The sequence of fecal shedding of the hepatitis A virus (HAV), HAV viremia, and HAV antibody (IgM and IgG anti-HAV) changes in hepatitis A.

HAV is indicative of acute hepatitis A, whereas IgG anti-HAV merely documents past exposure.

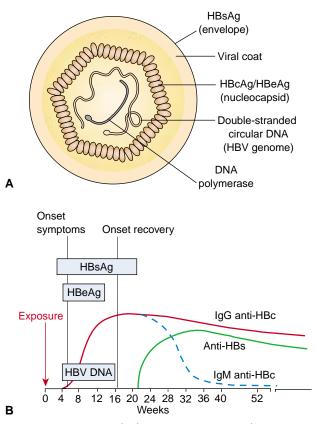

Two commercially prepared hepatitis A vaccines are available; vaccination is recommended for persons at risk for HAV exposure. It is recommended for international travelers to regions where sanitation is poor and endemic HAV infections are high, children living in communities with high rates of HAV infection, homosexually active men, and users of illicit drugs.¹⁰ A public health benefit also may be derived from vaccinating persons with increased potential for transmitting the disease (*e.g.*, food handlers). An immune globulin is available for persons with known HAV exposure who have not been immunized.

Hepatitis B. The Centers for Disease Control (CDC) estimates that there are 200,000 to 300,000 new cases of hepatitis B each year and 1 to 1.25 million chronic carriers in the United States.¹² The CDC also estimates that each year in the United States there are 4000 to 5000 deaths associated with hepatitis B-related cirrhosis and hepatocellular carcinoma. These figures are dwarfed by a much higher frequency of hepatitis B on a global scale. For example, the infection is endemic in regions of Africa and Southeast Asia.

Hepatitis B is caused by a double-stranded DNA virus (HBV).^{5,6,13,14} The complete virion, also called a *Dane particle*, consists of an outer envelope and an inner core that contains HBV DNA and DNA polymerase (Fig. 28-8). Hepatitis B has a longer incubation period and represents a more serious health problem than does hepatitis A. It can produce acute hepatitis, chronic hepatitis, progression of chronic hepatitis to cirrhosis, fulminant hepatitis with massive hepatic necrosis, and the carrier state. It also participates in the development of hepatitis D (delta hepatitis).

The HBV usually is transmitted through inoculation with infected blood or serum. However, the viral antigen can be found in most body secretions and can be spread by oral or sexual contact. In the United States, most persons with hepatitis B acquire the infection as adults or adolescents. The disease is highly prevalent among injecting drug users, persons with multiple sex

502 Unit Seven: Alterations in the Gastrointestinal System

■ FIGURE 28-8 ■ (A) The hepatitis B virus. (B) The sequence of hepatitis B virus (HBV) viral antigens (HBsAg, HBeAg), HBV DNA, and HBV antibody (IgM, IgG, anti-HBc, and anti-HBs) changes in acute resolving hepatitis B.

partners, and men who have sex with men.¹⁵ Health care workers are at risk because of blood exposure and accidental needle injuries. Although the virus can be spread through transfusion or administration of blood products, routine screening methods have appreciably reduced transmission through this route. The risk that infants born to infected mothers will have hepatitis B ranges from 10% to 85%, depending on the mother's HBV core antigen (HBeAg) status. Infants who become infected have a 90% risk of becoming chronic carriers, and as many as 25% will die of chronic liver disease as adults.¹²

Three well-defined antigens are associated with the virus: two nucleocapsid "core" antigens, HBcAg and HBeAg, and a third, HbsAg, surface antigen (see Fig. 28-8). These HBV antigens evoke specific antibodies: anti-HBs, anti-HBc, and anti-HBe. These antigens and their antibodies serve as serologic markers for following the course of the disease.

The *HBsAg* is the viral antigen measured most routinely in blood. It is produced in abundance by infected liver cells and released into the serum. HBsAg is the earliest serologic marker to appear; it appears before the onset of symptoms and is an indicator of acute or chronic infection. The HBsAg level begins to decline after the onset of the illness and usually is undetectable in 3 to 6 months. Persistence beyond 6 months indicates continued viral replication, infectivity, and the risk of chronic hepatitis. *Anti-HBs*, a specific antibody to HBsAg, occurs in most individuals after clearance of HBsAg and after successful immunization for hepatitis B. There often is a delay in appearance of anti-HBs after clearance of HBsAg. During this period of serologic gap, called the *window period*, infectivity has been demonstrated. Development of anti-HBs signals recovery from HBV infection, noninfectivity, and protection from future HBV infection.

The *HBeAg* is thought to be a cleavage product of the viral core antigen; it may be found in the serum and is an active marker for the disease and shedding of complete virions into the bloodstream. It appears during the incubation period, shortly after the appearance of HBsAg, and is found only in the presence of HBsAg. HBeAg usually disappears before HBsAg. The antibody to HBeAg, *anti-HBe*, begins to appear in the serum at about the time that HBeAg disappears, and its appearance signals the onset of resolution of the acute illness. The clinical usefulness of the antigen and its antibody lies in their predictive value as markers for infectivity.

The *HBcAg* does not circulate in the blood; therefore, it is not a useful marker for the disease. Although the antigen is not found in the blood, its antibodies (anti-HBc) are the first to be detected. They appear toward the end of the incubation period and persist during the acute illness and for several months to years after that. The initial HBcAg antibody is IgM; it serves as a marker for recent infection and is followed in 6 to 18 months by IgG antibodies. These antibodies are not protective and are detectable in the presence of chronic disease.

The presence of viral DNA (HBV DNA) in the serum is the most certain indicator of hepatitis B infection. It is transiently present during the presymptomatic period and for a brief time during the acute illness. The presence of DNA polymerase, the enzyme used in viral replication, usually is transient but may persist for years in persons who are chronic carriers and is an indication of continued infectivity.

Hepatitis B vaccine provides long-term protection against HBV infection.¹⁶ Vaccination is recommended for all children ages 0 to 18 years as a means of preventing HBV transmission.¹⁵ The vaccine also is recommended for all persons who are at high risk for exposure to the virus. All pregnant women should be tested for HBsAg during an early prenatal visit, and infants born to HBsAg-positive mothers should receive appropriate doses of hepatitis immune globulin and hepatitis B vaccine.¹²

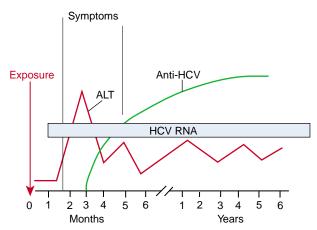

Hepatitis **C**. Hepatitis C is caused by a single-stranded RNA virus (HCV) that is distantly related to the viruses that cause yellow fever and dengue fever. There are at least six genotypes of the hepatitis C virus and multiple subtypes of the virus.¹⁷ It is likely that the wide diversity of genotypes contributes to the pathogenicity of the virus, allowing it to escape the actions of host immune mechanisms and antiviral medications, and to the difficulties in developing a preventative vaccine.^{18,19}

Hepatitis C is the most common cause of chronic hepatitis, cirrhosis, and hepatocellular cancer in the world.^{17,18} An estimated 2.7 million people in the United States have active HCV infection.¹⁷ Most of these people are chronically infected and unaware of their infection because they are not clinically ill. Infected persons serve as a source of infection to others and are at risk for chronic liver disease during the first two or more decades after initial infection.

Before 1990, the main route of transmission was through contaminated blood transfusions or blood products. With implementation of HCV testing in blood banks, the risk of HCV infection from blood transfusion is less than 1 in 103,000.¹⁴ Currently, injecting drug use is thought to be the single most important risk factor for HCV infection. There also is concern that transmission of small amounts of blood during tattooing, acupuncture, and body piercing may facilitate the transmission of HCV.19 The incidence of sexual and vertical transmission from mother to child is uncertain. Occupational exposure through incidents such as unintentional needle sticks can result in infection. However, the prevalence of HCV among health care, emergency medical, and public safety workers who are exposed to blood in the workplace is reported to be no greater than in the general public.^{17,18} Sporadic cases of hepatitis C of unknown source account for approximately 40% of cases.

The incubation period for HCV infection ranges from 15 to 150 days (average, 50 days). Clinical symptoms with acute hepatitis C tend to be milder than those seen in persons with other types of viral hepatitis. Children and adults who acquire the infection usually are asymptomatic, or have a nonspecific clinical disease characterized by fatigue, malaise, anorexia, and weight loss. Jaundice is uncommon, and only 25% to 30% of symptomatic adults have jaundice.²⁰ Unlike hepatitis A and B viral infections, fulminant hepatic failure is rare, and only a few cases have been reported. The most alarming aspects of HCV infection are its high rate of persistence and ability to induce chronic hepatitis and cirrhosis. HCV also increases the risk for development of hepatocellular cancer.

Both antibody and viral tests are available for detecting the presence of hepatitis C infection (Fig 28-9). Antibody testing has the advantage of being readily available and having a relatively low cost. False-negative results can occur in immunocompromised people and early in the course of the disease before antibodies develop. Direct measurement of HCV in the serum remains the most accurate test for infection. The viral tests are highly sensitive and specific but more costly than antibody tests. With newer antibody testing methods, infection often can be detected as early as 6 to 8 weeks after exposure, and as early as 1 to 2 weeks with viral tests that use the polymerase chain reaction (PCR) testing methods. Unlike hepatitis A and B, antibodies to HCV are not protective, but they serve as markers for the disease. At present, there is no vaccine that protects against HCV infection.

■ FIGURE 28-9 ■ The sequence of serologic changes in chronic hepatitis C with persistence of hepatitis C virus (HCV) RNA and exacerbations and remissions of clinical symptoms designated by changes in serum alanine aminotransferase (ALT) levels.

Hepatitis D. Also called the hepatitis delta virus, HDV is a defective RNA virus that can cause acute or chronic hepatitis. Infection depends on concomitant infection with hepatitis B, specifically the presence of HBsAg. Acute hepatitis D occurs in two forms: coinfection that occurs simultaneously with acute hepatitis B, and as a super-infection in which hepatitis D is imposed on chronic hepatitis B or hepatitis B carrier state.²¹ The HDV often increases the severity of HBV infection. It can convert mild HBV infection into severe, fulminating hepatitis, cause acute hepatitis in asymptomatic carriers, or increase the tendency for progression to chronic hepatitis and cirrhosis.

The routes of transmission of HDV are similar to those for HBV. In the United States, infection is restricted largely to persons at high risk for HBV infection, particularly injecting drug users and persons receiving clotting factor concentrates. The greatest risk is in HBV carriers; these persons should be informed about the dangers of HDV superinfection. Hepatitis D is diagnosed by detection of antibody to HDV (anti-HDV) in the serum or HDV RNA in the serum. There is no specific treatment for hepatitis D. Because the infection is linked to hepatitis B, prevention of hepatitis D should begin with prevention of hepatitis B through vaccination.

Hepatitis E. The hepatitis E virus is an unenveloped, singlestranded RNA virus. It is transmitted by the fecal-oral route and causes manifestations of acute hepatitis that are similar to hepatitis A. It does not cause chronic hepatitis or the carrier state. Its distinguishing feature is the high mortality rate (approximately 20%) among pregnant women attributable to the development of fulminant hepatitis. The infection occurs primarily in developing areas, such as India, other Southeast Asian countries, parts of Africa, and Mexico. The only reported cases in the United States have been in persons who have recently been in an endemic area.

Chronic Hepatitis

Chronic hepatitis is defined as inflammatory reaction of the liver of more than 3 to 6 months' duration. It is characterized by persistently elevated serum aminotransferase levels and characteristic histologic findings on liver biopsy. The causes of chronic hepatitis include HBV, HCV, HDV, autoimmune hepatitis, and hepatitis associated with certain medications.²²

Chronic Viral Hepatitis. Chronic viral hepatitis is the principal cause of chronic liver disease, cirrhosis, and hepatocellular cancer in the world and now ranks as the chief reason for liver transplantation in adults.²³

The clinical features of chronic viral hepatitis are highly variable and not predictive of outcome. The most common symptoms are fatigue, malaise, loss of appetite, and occasional bouts of jaundice. Elevation of serum aminotransferase levels depends on the degree of disease activity.

Chronic hepatitis B accounts for 5% to 10% of chronic liver disease and cirrhosis in the United States.²³ Hepatitis B is less likely than hepatitis C to progress to chronic infection. Chronic hepatitis B is characterized by the persistence of HBV DNA and usually by HBeAg in the serum, indicating active viral replication. Many persons are asymptomatic at the time of diagnosis, and elevated serum aminotransferase levels are the first sign of infection. Chronic hepatitis D depends on concurrent infection with HBV.

Chronic hepatitis C accounts for most cases of chronic viral hepatitis. HCV infection becomes chronic in 75% to 80% of cases.¹⁸ Chronic HCV infection often smolders during a period of years, silently destroying liver cells. Most persons with chronic hepatitis C are asymptomatic, and diagnosis usually follows a finding of elevated serum aminotransferase levels, a tender liver, or complaints of fatigue or nonspecific weakness. Because the course of acute hepatitis C often is mild, many persons do not recall the events of the acute infection.

There are no simple and effective treatment methods for chronic viral hepatitis.^{23,24} Persons with chronic hepatitis B who have evidence of active viral replication may be treated with a course of recombinant interferon α -2b. The antiviral drug lamivudine may be used as a substitute for interferon α .²³ Liver transplantation is a treatment option for end-stage liver disease caused by viral hepatitis. Liver transplantation has been more successful in persons with hepatitis C than in those with hepatitis B. Although the graft often is reinfected, the disease seems to progress more slowly.

Autoimmune Hepatitis. Chronic autoimmune hepatitis is a chronic inflammatory liver disease of unknown origin, but it is associated with circulating autoantibodies and high serum gamma globulin levels. Autoimmune hepatitis accounts for only approximately 10% of chronic hepatitis cases in the United States, a decrease from previously reported rates that probably reflects not a true change in incidence but better methods of detecting viral pathogens. The pathogenesis of the disorder is one of a genetically predisposed person exposed to an environmental agent that triggers an autoimmune response directed at liver cell antigens.²⁵ The resulting immune response produces a necrotizing inflammatory response that eventually leads to destruction of liver cells and development of cirrhosis. The factors surrounding the genetic predisposition and the triggering events that lead to the autoimmune response are unclear. Autoimmune hepatitis is mainly a disease of young women, although it can occur at any age and in men or women.

Clinical manifestations of the disorder cover a spectrum that extends from no apparent symptoms to the signs accompanying liver failure. In asymptomatic cases, the disorder may be discovered when abnormal serum enzyme levels are discovered during performance of routine screening tests.

The differential diagnosis includes measures to exclude other causes of liver disease, including hepatitis B and C. A characteristic laboratory finding is that of a marked elevation in serum gamma globulins. A biopsy is used to confirm the diagnosis. Corticosteroid drugs and immunosuppressant drugs are the treatment of choice for this type of hepatitis. Liver transplantation may be the only treatment for end-stage disease.

Intrahepatic Biliary Disorders

Intrahepatic biliary diseases disrupt the flow of bile through the liver, causing cholestasis and biliary cirrhosis. Among the causes of intrahepatic biliary disease are primary biliary cirrhosis, primary sclerosing cholangitis, and secondary biliary cirrhosis.

Primary Biliary Cirrhosis

Primary biliary cirrhosis involves inflammation and scarring of small intrahepatic bile ducts, portal inflammation, and progressive scarring of liver tissue.²⁶ The disease is seen most com-

monly in women 30 to 65 years of age and accounts for 2% to 5% of cases of cirrhosis. Familial occurrences of the disease are found between parents and children and among siblings. Abnormalities of cell-mediated and humoral immunity suggest an autoimmune mechanism. Antimitochondrial antibodies are found in 98% of persons with the disease, but their role in the pathogenesis of the disease is unclear.^{26,27} As many as 84% of persons with primary biliary cirrhosis have at least one other autoimmune disorder, such as scleroderma, Hashimoto's thyroiditis, rheumatoid arthritis, or the sicca complex of dry eyes and mouth (Sjögren's syndrome).

The disorder is characterized by an insidious onset and progressive scarring and destruction of liver tissue. The liver becomes enlarged and takes on a green hue because of the accumulated bile. The earliest symptoms are unexplained pruritus or itching, weight loss, and fatigue, followed by dark urine and pale stools. Jaundice is a late manifestation of the disorder, as are other signs of liver failure. Serum alkaline phosphatase levels are elevated in persons with primary biliary cirrhosis.

Treatment is largely symptomatic. Liver transplantation remains the only treatment for advanced disease.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis is a chronic cholestatic disease of unknown origin that causes destruction and fibrosis of intrahepatic and extrahepatic bile ducts.²⁸ Bile flow is obstructed (*i.e.*, cholestasis), and the bile retention destroys hepatic structures. The disease commonly is associated with inflammatory bowel disease, occurs more often in men than women, and is seen most commonly in the third to fifth decades of life. Primary sclerosing cholangitis, although much less common than alcoholic cirrhosis, is the fourth leading indication for liver transplantation in adults in the United States.²⁸

Most persons with the disorder are initially asymptomatic, with the disorder being detected during routine liver function tests that reveal elevated levels of serum alkaline phosphatase or GGT. Alternatively, some persons may present with progressive fatigue, jaundice, and pruritus. The later stages of the disease are characterized by cirrhosis, portal hypertension, and liver failure. Ten-year survival rates range from 50% to 75%.²⁸ Other than measures aimed at symptom relief, the only treatment is liver transplantation.

Secondary Biliary Cirrhosis

Secondary biliary cirrhosis results from prolonged obstruction of the extrabiliary tree. The most common cause is cholelithiasis. Other causes of secondary biliary cirrhosis are malignant neoplasms of the biliary tree or head of the pancreas and strictures of the common duct caused by previous surgical procedures. Extrahepatic biliary cirrhosis may benefit from surgical procedures designed to relieve the obstruction.

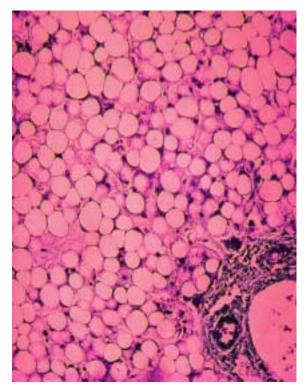

Alcohol-Induced Liver Disease

The spectrum of alcoholic liver disease includes fatty liver disease, alcoholic hepatitis, and cirrhosis. Alcoholic cirrhosis causes 200,000 deaths annually and is the fifth leading cause of death in the United States.⁵ Most deaths associated with alcoholic cirrhosis are attributable to liver failure, bleeding esophageal varices, or kidney failure. It has been estimated that there are 10 million alcoholics in the United States. However, only approximately 10% to 15% of alcoholics have cirrhosis, suggesting that other conditions such as genetic and environmental factors contribute to its occurrence.

Although the mechanism by which alcohol exerts its toxic effects on liver structures is somewhat uncertain, the changes that develop can be divided into three stages: fatty changes, alcoholic hepatitis, and cirrhosis.^{5,6} Alcoholic cirrhosis is the end result of repeated bouts of drinking-related liver injury and designates the onset of end-stage alcoholic liver disease.

Fatty liver is characterized by the accumulation of fat in hepatocytes, a condition called steatosis (Fig. 28-10). The liver becomes yellow and enlarged because of excessive fat accumulation. The pathogenesis of fatty liver is not completely understood and can depend on the amount of alcohol consumed, dietary fat content, body stores of fat, hormonal status, and other factors. There is evidence that ingestion of large amounts of alcohol can cause fatty liver changes even with an adequate diet. For example, young, nonalcoholic volunteers had fatty liver changes after 2 days of consuming 18 to 24 oz of alcohol, even though adequate carbohydrates, fats, and proteins were included in the diet.29 The fatty changes that occur with ingestion of alcohol usually do not produce symptoms and are reversible after the alcohol intake has been discontinued.

Alcoholic hepatitis is the intermediate stage between fatty changes and cirrhosis. It often is seen after an abrupt increase in alcohol intake and is common in "spree" drinkers. Alcoholic hepatitis is characterized by inflammation and necrosis of liver

■ FIGURE 28-10 ■ Alcoholic fatty liver. A photomicrograph shows the cytoplasm of almost all the hepatocytes to be distended by fat, which displaces the nucleus to the periphery. Note the absence of inflammation and fibrosis. (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 791]. Philadelphia: Lippincott Williams & Wilkins)

cells. This stage usually is characterized by hepatic tenderness, pain, anorexia, nausea, fever, jaundice, ascites, and liver failure, but some individuals may be asymptomatic. The condition is always serious and sometimes fatal. The immediate prognosis correlates with the severity of liver cell injury. In some cases, the disease progresses rapidly to liver failure and death. The mortality rate in the acute stage ranges from 10% to 30%.6 In persons who survive and continue to drink, the acute phase often is followed by persistent alcoholic hepatitis, with progression to cirrhosis in a matter of 1 to 2 years.⁶

Cirrhosis, Portal Hypertension, and Liver Failure

Cirrhosis

Cirrhosis represents the end stage of chronic liver disease in which the normal architecture of the liver is replaced by fibrous septa that encompass regenerative nodules of hepatic tissue.^{5,6} The gross appearance of the liver in early alcoholic cirrhosis is one of fine, uniform nodules on its surface. The condition has traditionally been called micronodular or Laennec cirrhosis. Although the initial nodules that develop are similar in size to the lobules in normal liver tissue, they lack all the landmarks of normal lobular architecture in terms of portal tracts and central venules. With more advanced cirrhosis, regenerative processes cause the nodules to become larger and more irregular in size and shape. The nodules may compress the hepatic veins and bile ducts, producing portal hypertension, extrahepatic portosystemic shunts, and cholestasis.

Although cirrhosis usually is associated with alcoholism, it can develop in the course of other disorders, including viral hepatitis, toxic reactions to drugs and chemicals, and biliary obstruction. Cirrhosis also accompanies metabolic disorders that cause the deposition of minerals in the liver. Two of these disorders are hemochromatosis (*i.e.*, iron deposition) and Wilson's disease (*i.e.*, copper deposition).

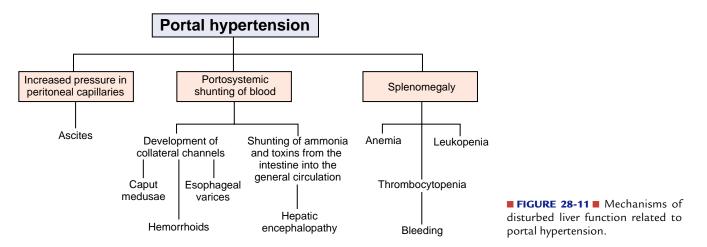

The manifestations of cirrhosis are variable, ranging from asymptomatic hepatomegaly to hepatic failure. Often there are no symptoms until the disease is far advanced. The most common signs and symptoms of cirrhosis are weight loss (sometimes masked by ascites), weakness, and anorexia. Diarrhea frequently is present, although some persons may report constipation. Hepatomegaly and jaundice also are common signs of cirrhosis. There may be abdominal pain because of liver enlargement or stretching of Glisson's capsule.

The late manifestations of cirrhosis are related to portal hypertension and liver failure (Fig. 28-11, Fig. 28-12). Splenomegaly, ascites, and portosystemic shunts (i.e., esophageal varices, anorectal varices, and caput medusae) result from portal hypertension. Other complications include bleeding caused by decreased clotting factors; thrombocytopenia caused by splenomegaly; gynecomastia, a feminizing pattern of pubic hair distribution, and testicular atrophy in men because of altered testosterone and estrogen metabolism; spider angiomas and palmar erythema; and encephalopathy with asterixis and neurologic signs.

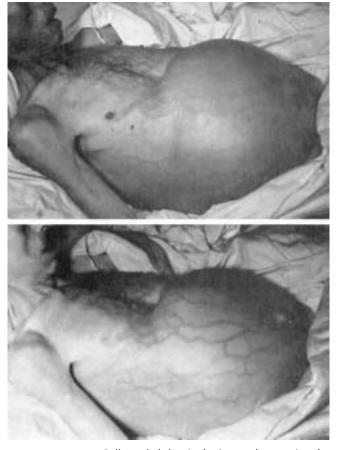

Portal Hypertension

Portal hypertension is characterized by increased resistance to flow in the portal venous system and sustained portal vein pressure above 12 mm Hg (normal, 5–10 mm Hg).^{6,30} Normally,

venous blood returning to the heart from the abdominal organs collects in the portal vein and travels through the liver before entering the vena cava. Portal hypertension can be caused by a variety of conditions that increase resistance to hepatic blood flow, including prehepatic, posthepatic, and intrahepatic

■ FIGURE 28-12 ■ Collateral abdominal veins on the anterior abdominal wall in a patient with alcoholic liver disease as recorded by black and white photography (top) and infrared photography (bottom). (Schiff L. [1982]. *Diseases of the liver*. Philadelphia: J.B. Lippincott)

obstructions (with *hepatic* referring to the liver lobules, rather than the entire liver).⁶

Prehepatic causes of portal hypertension include portal vein thrombosis and external compression caused by cancer or enlarged lymph nodes that produce obstruction of the portal vein before it enters the liver. *Posthepatic* obstruction refers to any obstruction to blood flow through the hepatic veins beyond the liver lobules, either within or distal to the liver. It is caused by conditions such as thrombosis of the hepatic veins, venoocclusive disease, and severe right-sided heart failure that impede the outflow of venous blood from the liver. *Intrahepatic* causes of portal hypertension include conditions that cause obstruction of blood flow within the liver. In alcoholic cirrhosis, which is the major cause of portal hypertension, bands of fibrous tissue and fibrous nodules distort the architecture of the liver and increase the resistance to portal blood flow, which leads to portal hypertension.

Complications of portal hypertension arise from the increased pressure and dilatation of the venous channels behind the obstruction. In addition, collateral channels open that connect the portal circulation with the systemic circulation. The major complications of the increased portal vein pressure and the opening of collateral channels are ascites, splenomegaly,

KEY CONCEPTS PORTAL HYPERTENSION

- Venous blood from the gastrointestinal tract empties into the portal vein and travels through the liver before moving into the general venous circulation.
- Obstruction of blood flow and development of portal hypertension produces an increase in the hydrostatic pressure within the peritoneal capillaries, contributing to the development of ascites, splenic engorgement with sequestration and destruction of blood cells and platelets, and shunting of blood to collateral venous channels causing varicosities of the hemorrhoidal and esophageal veins.

Chapter 28: Alterations in Hepatobiliary Function

507

and the formation of portosystemic shunts with bleeding from esophageal varices (Fig. 28-11).

Ascites. Ascites occurs when the amount of fluid in the peritoneal cavity is increased and is a late-stage manifestation of cirrhosis and portal hypertension.³¹ It is not uncommon for persons with advanced cirrhosis to present with an accumulation of 15 L or more of ascitic fluid. Those who gain this much fluid often experience abdominal discomfort, dyspnea, and insomnia.

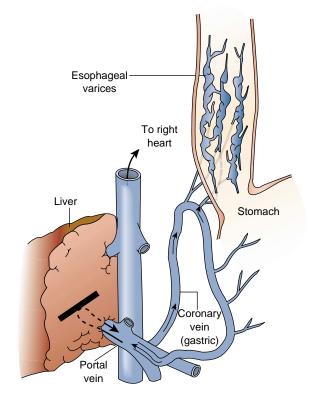

Although the mechanisms responsible for the development of ascites are not completely understood, several factors seem to contribute to fluid accumulation, including an increase in capillary pressure caused by portal hypertension and obstruction of venous flow through the liver, salt and water retention by the kidney, and decreased colloidal osmotic pressure caused by impaired synthesis of albumin by the liver (see Chapter 6).

Treatment of ascites usually focuses on dietary restriction of sodium and administration of diuretics. Water intake also may need to be restricted. Because of the many limitations in sodium restriction, the use of diuretics has become the mainstay of treatment for ascites. Oral potassium supplements often are given to prevent hypokalemia. The upright position is associated with the activation of the renin-angiotensin-aldosterone system; therefore, bed rest may be recommended for persons with a large amount of ascites.³² Large-volume paracentesis (removal of 5 L or more of ascitic fluid) may be done in persons with massive ascites and pulmonary compromise.

Splenomegaly. The spleen enlarges progressively in portal hypertension because of shunting of blood into the splenic vein. The enlarged spleen often gives rise to sequestering of significant numbers of blood elements and development of a syndrome known as hypersplenism. Hypersplenism is characterized by a decrease in the life span and a subsequent decrease in all the formed elements of the blood, leading to anemia, thrombocytopenia, and leukopenia. The person with thrombocytopenia is subject to purpura, easy bruising, hematuria, and abnormal menstrual bleeding, and is vulnerable to bleeding from the esophagus and other segments of the gastrointestinal tract.

Portosystemic Shunts. With the gradual obstruction of venous blood flow in the liver, the pressure in the portal vein increases, and large collateral channels develop between the portal and systemic veins that supply the lower rectum and esophagus and the umbilical veins of the falciform ligament that attaches to the anterior wall of the abdomen. The collaterals between the inferior and internal iliac veins may give rise to hemorrhoids. In some persons, the fetal umbilical vein is not totally obliterated; it forms a channel on the anterior abdominal wall (Fig. 28-12). Dilated veins around the umbilicus are called *caput medusae*. Portopulmonary shunts also may develop and cause blood to bypass the pulmonary capillaries, interfering with blood oxygenation and producing cyanosis.

Clinically, the most important collateral channels are those connecting the portal and coronary veins that lead to reversal of flow and formation of thin-walled varicosities in the submucosa of the esophagus (Fig. 28-13). These thin-walled esophageal varices are subject to rupture, producing massive and sometimes fatal hemorrhage. Impaired hepatic synthesis of co-

■ FIGURE 28-13 ■ Obstruction of blood flow in the portal circulation, with portal hypertension and diversion of blood flow to other venous channels, including the gastric and esophageal veins.

agulation factors and decreased platelet levels (i.e., thrombocytopenia) caused by splenomegaly may further complicate the control of esophageal bleeding. Esophageal varices develop in approximately 65% of persons with advanced cirrhosis and cause massive hemorrhage and death in approximately half of them.5

Treatment of portal hypertension and esophageal varices is directed at prevention of initial hemorrhage, management of acute hemorrhage, and prevention of recurrent variceal hemorrhage. Mechanical compression of the bleeding vessel may be accomplished through the use of an esophageal balloon, designed to compress the bleeding vessel. Prevention of recurrent hemorrhage focuses on lowering portal venous pressure and diverting blood flow away from the easily ruptured collateral channels. Pharmacologic therapy is used to lower portal venous pressure and prevent initial hemorrhage. β -Adrenergic-blocking drugs (e.g., propranolol) commonly are used for this purpose. Endoscopic sclerotherapy and band ligation is used to prevent rebleeding. Portosystemic shunt procedures involve the creation of an opening between the portal vein and a systemic vein as a means of bypassing the liver. The transjugular intrahepatic portosystemic shunt (TIPS) procedure involves the placement of an expandable metal stent between a branch of the hepatic and portal vein inserted via the internal jugular vein.

Liver Failure

The most severe clinical consequence of liver disease is hepatic failure. It may result from sudden and massive hepatic destruction, as in fulminant hepatitis, or it may be the result of progressive damage to the liver, such as occurs in alcoholic cirrhosis. Whatever the cause, 80% to 90% of hepatic functional capacity must be lost before hepatic failure occurs.⁵ In many cases, the progressive decompensating aspects of the disease are hastened by intercurrent conditions, such as gastrointestinal bleeding, systemic infection, electrolyte disturbances, or superimposed diseases such as heart failure.

The manifestations of liver failure reflect the various synthesis, storage, metabolic, and excretory functions of the liver, (Fig. 28-14). *Fetor hepaticus* refers to a characteristic musty, sweetish odor of the breath in the patient with advanced liver failure, resulting from the metabolic by-products of the intestinal bacteria.

Hematologic Disorders. Liver failure can cause anemia, thrombocytopenia, coagulation defects, and leukopenia. Anemia may be caused by blood loss, excessive red blood cell destruction, and impaired formation of red blood cells. A folic acid deficiency may lead to severe megaloblastic anemia. Changes in the lipid composition of the red cell membrane increase hemolysis. Because factors V, VII, IX, and X, prothrombin, and fibrinogen are synthesized by the liver, their decline in liver disease contributes to bleeding disorders. Malabsorption of the fat-soluble vitamin K contributes further to the impaired synthesis of these clotting factors.

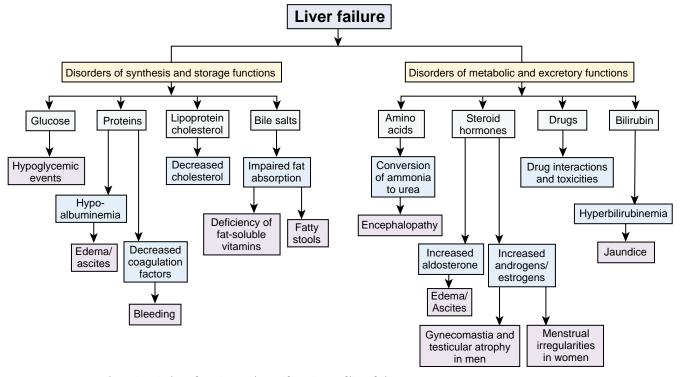

Endocrine Disorders. The liver metabolizes the steroid hormones. Endocrine disorders, particularly disturbances in gonadal function, are common accompaniments of cirrhosis and liver failure. Women may have menstrual irregularities (usually amenorrhea), loss of libido, and sterility. In men, testosterone

levels usually fall, the testes atrophy, and loss of libido, impotence, and gynecomastia occur. A decrease in aldosterone metabolism may contribute to salt and water retention by the kidney, along with a lowering of serum potassium resulting from increased elimination of potassium.

Skin Disorders. Liver failure brings on numerous skin disorders. These lesions, called variously *vascular spiders, telangiectases, spider angiomas,* and *spider nevi*, are seen most often in the upper half of the body. They consist of a central pulsating arteriole from which smaller vessels radiate. Palmar erythema is redness of the palms, probably caused by increased blood flow from higher cardiac output. Clubbing of the fingers may be seen in persons with cirrhosis. Jaundice usually is a late manifestation of liver failure.

Hepatorenal Syndrome. The hepatorenal syndrome refers to a functional state of renal failure sometimes seen during the terminal stages of liver failure with ascites. It is characterized by progressive azotemia, increased serum creatinine levels, and oliguria. Although the basic cause is unknown, a decrease in renal blood flow is believed to play a part. Ultimately, when renal failure is superimposed on liver failure, azotemia and elevated levels of blood ammonia occur; this condition is thought to contribute to hepatic encephalopathy and coma.

Hepatic Encephalopathy. Hepatic encephalopathy refers to the totality of central nervous system manifestations of liver failure. It is characterized by neural disturbances ranging from a lack of mental alertness to confusion, coma, and convulsions. A very early sign of hepatic encephalopathy is a flapping tremor

■ FIGURE 28-14 ■ Alterations in liver function and manifestations of liver failure.

Although the cause of hepatic encephalopathy is unknown, the accumulation of neurotoxins, which appear in the blood because the liver has lost its detoxifying capacity, is believed to be a factor. Hepatic encephalopathy develops in approximately 10% of persons with portosystemic shunts. One of the suspected neurotoxins is ammonia. A particularly important function of the liver is the conversion of ammonia, a by-product of protein and amino acid metabolism, to urea. The ammonium ion is produced in abundance in the intestinal tract, particularly in the colon, by the bacterial degradation of luminal proteins and amino acids. Normally, these ammonium ions diffuse into the portal blood and are transported to the liver, where they are converted to urea before entering the general circulation. When the blood from the intestine bypasses the liver or the liver is unable to convert ammonia to urea, ammonia moves directly into the general circulation and then into the cerebral circulation. Hepatic encephalopathy may become worse after a large protein meal or gastrointestinal tract bleeding.

Treatment. The treatment of liver failure is directed toward eliminating alcohol intake when the condition is caused by alcoholic cirrhosis; preventing infections; providing sufficient carbohydrates and calories to prevent protein breakdown; correcting fluid and electrolyte imbalances, particularly hypokalemia; and decreasing ammonia production in the gastrointestinal tract by controlling protein intake. In many cases, liver transplantation remains the only effective treatment.

Cancer of the Liver

Primary liver tumors are relatively rare in the United States, accounting for approximately 0.5% to 2% of all cancers.³ The American Cancer Society estimates that more than 17,300 new cases of primary liver and intrahepatic cancer will be diagnosed during 2003, and more than 14,400 people will die of the disease during the same period.³³ In contrast to many other cancers, the number of people who have liver cancer and die of it is increasing. Liver cancer is approximately 10 times more common in developing countries in Southeast Asia and Africa. In many of these countries, it is the most common type of cancer.

There are two major types of primary liver cancer: hepatocellular carcinoma, which arises from the liver cells (Fig. 28-15), and cholangiocarcinoma, which is a primary cancer of bile duct cells.⁵ Hepatocellular cancer is one of the few cancers for which an underlying etiology can be identified in most cases and is unique because it usually occurs in a background of chronic liver disease.³⁴ Among the factors identified as etiologic agents in hepatocellular cancer are chronic viral hepatitis (HBV, HCV, HDV), cirrhosis, long-term exposure to aflatoxin, and drinking water contaminated with arsenic. With HBV and HCV, both of which become integrated into the host DNA, repeated cycles of cell death and regeneration afford the potential for develop-

■ FIGURE 28-15 ■ Hepatocellular carcinoma. Cross-section of a cirrhotic liver showing a poorly circumscribed, nodular area ofyellow, partially hemorrhagic carcinoma. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 826]. Philadelphia: Lippincott Williams & Wilkins)

ment of cancer-producing mutations. Aflatoxins, produced by food spoilage molds in certain areas endemic for hepatocellular carcinoma, are particularly potent carcinogenic agents.⁵ These carcinogenic agents are activated by hepatocytes and their products incorporated into the host DNA with the potential for producing cancer-producing mutations.

The manifestations of hepatocellular cancer often are insidious in onset and masked by those related to cirrhosis or chronic hepatitis. The initial symptoms include weakness, anorexia, weight loss, fatigue, bloating, a sensation of abdominal fullness, and a dull, aching abdominal pain. Ascites, which often obscures weight loss, is common. Jaundice, if present, usually is mild. There may be a rapid increase in liver size and worsening of ascites in persons with pre-existing cirrhosis. Usually, the liver is enlarged when these symptoms appear, and there is a low fever without apparent cause. Serum α -fetoprotein, a serum protein present during fetal life, normally is barely detectable in the serum after the age of 2 years, but it is present in 60% to 75% of cases of hepatocellular carcinoma.⁵

Cholangiocarcinoma occurs much less frequently than hepatocellular carcinoma. The etiology, clinical features, and prognosis vary considerably with the part of the biliary tree that is the site of origin. Cholangiocarcinoma is not associated with the same risk factors as hepatocellular carcinoma. Instead, most of the risk factors revolve around longstanding inflammation and injury of the bile duct epithelium. Cholangiocarcinoma often presents with pain, weight loss, anorexia, and abdominal swelling or awareness of a mass in the right hypochondrium. Tumors affecting the central or distal bile ducts may present with jaundice.

Primary cancers of the liver usually are far advanced at the time of diagnosis; the 5-year survival rate is approximately 1%, and most patients die within 6 months. The treatment of choice is subtotal hepatectomy, if conditions permit. Chemo-therapy and radiation therapy are largely palliative. Although

liver transplantation may be an option for people with wellcompensated cirrhosis and small tumors, it often is impractical because of the shortage of donor organs.

Metastatic tumors of the liver are much more common than primary tumors. Common sources include colorectal cancer and spread from the breast, lung, or urogenital cancers. In addition, tumors of neuroendocrine origin spread to the liver. It often is difficult to distinguish primary from metastatic tumors with the use of CT scans, MRI, or ultrasonography. Usually the diagnosis is confirmed by biopsy.

In summary, the liver is subject to most of the disease processes that affect other body structures, such as vascular disorders, inflammation, metabolic diseases, toxic injury, and neoplasms.

Hepatitis is characterized by inflammation of the liver. Acute viral hepatitis is caused by hepatitis viruses A, B, C, D, and E. Although all these viruses cause acute hepatitis, they differ in terms of mode of transmission, incubation period, mechanism, degree and chronicity of liver damage, and the ability to evolve to a carrier state. HBV, HCV, and HDV have the potential for progression to the carrier state, chronic hepatitis, and hepatocellular carcinoma.

Intrahepatic biliary diseases disrupt the flow of bile through the liver, causing cholestasis and biliary cirrhosis. Among the causes of intrahepatic biliary diseases are primary biliary cirrhosis, primary sclerosing cholangitis, and secondary biliary cirrhosis.

Because alcohol competes for use of intracellular cofactors normally needed by the liver for other metabolic processes, it tends to disrupt the metabolic functions of the liver. The spectrum of alcoholic liver disease includes fatty liver disease, alcoholic hepatitis, and cirrhosis.

Cirrhosis represents the end stage of chronic liver disease in which much of the functional liver tissue has been replaced by fibrous tissue. The fibrous tissue replaces normally functioning liver tissue and forms constrictive bands that disrupt flow in the vascular channels and biliary duct systems of the liver. The disruption of vascular channels predisposes to portal hypertension and its complications, loss of liver cells, and eventual liver failure. Portal hypertension is characterized by increased resistance to flow and increased pressure in the portal venous system; the pathologic consequences of the disorder include ascites, the formation of collateral bypass channels (e.g., esophageal varices) from the portosystemic circulation, and splenomegaly. Liver failure represents the end stage of a number of liver diseases and occurs when less than 10% of liver tissue is functional. The manifestations of liver failure reflect the various functions of the liver, including hematologic disorders, disruption of endocrine function, skin disorders, hepatorenal syndrome, and hepatic encephalopathy.

Cancers of the liver include metastatic and primary neoplasms. Primary hepatic neoplasms are rare, accounting for less than 2% of cancers, and those involving the hepatocytes or liver cells are commonly associated with underlying diseases of the liver such as cirrhosis and chronic hepatitis. Liver cancer usually is far advanced at the time of diagnosis; the 5-year survival rate is approximately 1%.

DISORDERS OF THE GALLBLADDER AND EXTRAHEPATIC BILE DUCTS

The so-called hepatobiliary system consists of the gallbladder, the left and right hepatic ducts, which come together to form the common hepatic duct, the cystic duct, which extends to the gallbladder, and the common bile duct, which is formed by the union of the common hepatic duct and the cystic duct (see Fig. 28-16). The common bile duct descends posterior to the first part of the duodenum, where it comes in contact with the main pancreatic duct. These ducts unite to form the hepatopancreatic ampulla (ampulla of Vater). The circular muscle around the distal end of the bile duct is thickened to form the sphincter of the bile duct (Fig. 28-16).

The gallbladder is a distensible, pear-shaped, muscular sac located on the ventral surface of the liver. It has a outer serous peritoneal layer, a middle smooth muscle layer, and an inner mucosal layer that is continuous with the linings of the bile duct. The function of the gallbladder is to store and concentrate bile. Bile contains bile salts, cholesterol, bilirubin, lecithin, fatty acids, water, and the electrolytes normally found in the plasma. The cholesterol found in bile has no known function; it is assumed to be a by-product of bile salt formation, and its presence is linked to the excretory function of bile. Normally insoluble in water, cholesterol is rendered soluble by the action of bile salts and lecithin, which combine with it to form micelles. In the gallbladder, water and electrolytes are absorbed from the liver bile, causing the bile to become more concentrated. Because neither lecithin nor bile salts are absorbed in the gallbladder, their concentration increases along with that of cholesterol; in this way, the solubility of cholesterol is maintained.

Entrance of food into the intestine causes the gallbladder to contract and the sphincter of the bile duct to relax, such that bile stored in the gallbladder moves into the duodenum. The stimulus for gallbladder contraction is primarily hormonal. Products of food digestion, particularly lipids, stimulate the release of a gastrointestinal hormone called cholecystokinin from the mucosa of the duodenum. Cholecystokinin provides a strong stimulus for gallbladder contraction. The role of other gastrointestinal hormones in bile release is less clearly understood.

Cholelithiasis and Cholecystitis

Two common disorders of the gallbladder system are cholelithiasis (*i.e.*, gallstones) and inflammation of the gallbladder (cholecystitis) or common bile duct (cholangitis). At least 10% of adults have gallstones. Approximately twice as many women as men have gallstones, and there is an increased prevalence with age—after 60 years of age, 10% to 15% among men and 20% to 40% among women.³⁵

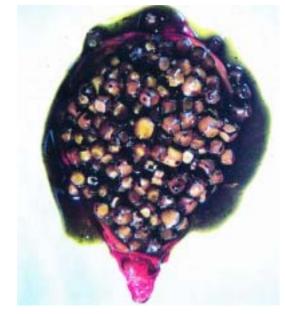

Cholelithiasis

Gallstones are caused by precipitation of substances contained in bile, mainly cholesterol and bilirubin. The bile of which gallstones are formed usually is supersaturated with cholesterol or bilirubin. Approximately 75% of gallstones are composed primarily of cholesterol; the other 25% are black or brown pigment stones consisting of calcium salts with bilirubin.³⁵ Many

FIGURE 28-16 (A) Extrahepatic bile passages, gallbladder, and pancreatic ducts. (B) Entry of bile duct and pancreatic duct into the hepatopancreatic ampulla, which opens into the duodenum.

stones have a mixed composition. Figure 28-17 shows a gallbladder with numerous cholesterol gallstones.

Three factors contribute to the formation of gallstones: (1) abnormalities in the composition of bile, (2) stasis of bile, and (3) inflammation of the gallbladder. The formation of cholesterol stones is associated with obesity and occurs more frequently in women, especially women who have had multiple pregnancies or who are taking oral contraceptives. All of these factors cause the liver to excrete more cholesterol into the bile. Estrogen reduces the synthesis of bile acid in women. Drugs that lower serum cholesterol levels, such as clofibrate, also cause increased cholesterol excretion into the bile. Malabsorption disorders stemming from ileal disease or intestinal bypass surgery interfere with intestinal reabsorption of bile salts, which are needed to maintain cholesterol solubility. Gallbladder sludge (thickened gallbladder mucoprotein with tiny trapped cholesterol crystals) causes stasis of bile flow and is thought to be a precursor of gallstones. Sludge frequently occurs with pregnancy, starvation, and rapid weight loss.³⁵ Inflammation of the gallbladder alters the absorptive characteristics of the mucosal layer, allowing excessive absorption of water and bile salts. Cholesterol gallstones are extremely common among Native Americans, which suggests that a genetic component may have a role in gallstone formation. Pigment

■ FIGURE 28-17 ■ Cholesterol gallstones. The gallbladder has been opened to reveal numerous yellow cholesterol gallstones (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 791]. Philadelphia: Lippincott Williams & Wilkins)

stones containing bilirubin are seen in persons with hemolytic disease (*e.g.*, sickle cell disease) and hepatic cirrhosis.

Many persons with gallstones have no symptoms. Gallstones cause symptoms when they obstruct bile flow. Small stones (*e.g.*, <8 mm in diameter) pass into the common duct, producing symptoms of indigestion and biliary colic. Larger stones are more likely to obstruct flow and cause jaundice. The pain of biliary colic usually is abrupt in onset and increases steadily in intensity until it reaches a climax in 30 to 60 minutes. It is usually located in the upper right quadrant or epigastric area and is often referred to the back, above the waist or to the right shoulder and scapula region. The pain usually persists for 2 to 8 hours and is followed by soreness in the upper right quadrant.

Acute and Chronic Cholecystitis

The term *cholecystitis* refers to inflammation of the gallbladder. Both acute and chronic cholecystitis are associated with cholelithiasis. Acute cholecystitis may be superimposed on chronic cholecystitis.

Acute cholecystitis almost always is associated with complete or partial obstruction. It is believed that the inflammation is caused by chemical irritation from the concentrated bile, along with mucosal swelling and ischemia resulting from venous congestion and lymphatic stasis. The gallbladder usually is markedly distended. Bacterial infections may arise secondary to the ischemia and chemical irritation. The bacteria reach the injured gallbladder through the blood, lymphatics, or bile ducts or from adjacent organs. Among the common pathogens are staphylococci and enterococci. The wall of the gallbladder is most vulnerable to the effects of ischemia, as a result of which mucosal necrosis and sloughing occur. The process may lead to gangrenous changes and perforation of the gallbladder.

The signs and symptoms of acute cholecystitis vary with the severity of obstruction and inflammation. Pain, initially similar to that of biliary colic, is characteristic of acute cholecystitis. It often is precipitated by a fatty meal and may initiate with complaints of indigestion. However, it does not subside spontaneously and responds poorly or only temporarily to potent analgesics. When the inflammation progresses to involve the peritoneum, the pain becomes more pronounced in the right upper quadrant. The right subcostal region is tender, and the muscles that surround the area spasm. Approximately 75% of patients have vomiting, and approximately 25% have jaundice.²² Fever and an abnormally high white blood cell count attest to inflammation. Total serum bilirubin, aminotransferase, and alkaline phosphatase levels usually are elevated.

Chronic cholecystitis results from repeated episodes of acute cholecystitis or chronic irritation of the gallbladder by stones. It is characterized by varying degrees of chronic inflammation. Gallstones almost always are present. Cholelithiasis with chronic cholecystitis may be associated with acute exacerbations of gallbladder inflammation, common duct stones, pancreatitis, and rarely, carcinoma of the gallbladder.

The manifestations of chronic cholecystitis are more vague than those of acute cholecystitis. There may be intolerance to fatty foods, belching, and other indications of discomfort. Often, there are episodes of colicky pain with obstruction of biliary flow caused by gallstones. The gallbladder, which in chronic cholecystitis usually contains stones, may be enlarged, shrunken, or of normal size. *Diagnosis and Treatment.* The most commonly used methods for diagnosis of gallbladder disease include ultrasonography and nuclear scanning (cholescintigraphy).³⁵ Ultrasonography is widely used in diagnosing gallbladder disease. It can detect stones as small as 1 to 2 cm, and its overall accuracy in detecting gallbladder disease is high. In addition to stones, ultrasonography can detect wall thickening, which indicates inflammation. Cholescintigraphy, also called a *gallbladder scan*, relies on the ability of the liver to extract a rapidly injected radionuclide, technetium-99m, bound to one of several iminodiacetic acids, that is excreted into the bile ducts. The gallbladder scan is highly accurate in detecting acute cholecystitis.

Gallbladder disease usually is treated by removing the gallbladder or by dissolving the stones or fragmenting them. Laparoscopic cholecystectomy has largely become the treatment of choice for symptomatic gallbladder disease.

Choledocholithiasis and Cholangitis

Choledocholithiasis refers to stones in the common duct and cholangitis to inflammation of the common duct. Common duct stones usually originate in the gallbladder but can form spontaneously in the common duct. The stones frequently are clinically silent unless there is obstruction.

The manifestations of choledocholithiasis are similar to those of gallstones and acute cholecystitis. There is a history of acute biliary colic and right upper abdominal pain, with chills, fever, and jaundice associated with episodes of abdominal pain. Bilirubinuria and an elevated serum bilirubin are present if the common duct is obstructed.

Complications include acute suppurative cholangitis accompanied by pus in the common duct. It is characterized by the presence of an altered sensorium, lethargy, and septic shock.²² Acute suppurative cholangitis represents an endoscopic or surgical emergency. Common duct stones also can obstruct the outflow of the pancreatic duct, causing a secondary pancreatitis.

Diagnostic measures include the use of ultrasonography, CT scans, and radionuclide to detect dilatation of the bile ducts and impaired blood flow. Endoscopic ultrasonography and magnetic resonance cholangiography may be used for detecting common duct stones. Both percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP) provide a direct means for determining the cause, location, and extent of obstruction. PTC involves the injection of dye directly into the biliary tree. It requires the insertion of a thin, flexible needle through a small incision in the skin with advancement into the biliary tree. ERCP involves the passage of an endoscope into the duodenum and the passage of a catheter into the hepatopancreatic ampulla. ERCP can be used to enlarge the opening of the bile duct sphincter so that a lodged stone can pass into the intestine or an instrument may be inserted into the common duct to remove the stone.

Common duct stones in persons with cholelithiasis usually are treated by stone extraction followed by laparoscopic cholecystectomy. Antibiotic therapy, with an agent that penetrates the bile, is used to treat the infection. Emergency decompression of the common duct, usually by ERCP, may be necessary for persons who are septic or fail to experience improvement with antibiotic treatment.

Cancer of the Gallbladder

Cancer of the gallbladder is found in approximately 2% of persons operated on for biliary tract disease. The onset of symptoms usually is insidious, and they resemble those of cholecystitis; the diagnosis often is made unexpectedly at the time of gallbladder surgery. Because of their ability to produce chronic irritation of the gallbladder mucosa, it is believed that gallstones play a role in the development of gallbladder cancer. The 5-year survival rate is only approximately 3%.5

In summary, the biliary tract serves as a passageway for the delivery of bile from the liver to the intestine. This tract consists of the bile ducts and gallbladder. The most common causes of biliary tract disease are cholelithiasis and cholecystitis. Three factors contribute to the development of cholelithiasis: abnormalities in the composition of bile, stasis of bile, and inflammation of the gallbladder. Cholelithiasis predisposes to obstruction of bile flow, causing biliary colic and acute or chronic cholecystitis. Cancer of the gallbladder, which has a poor 5-year survival rate, occurs in 2% of persons with biliary tract disease.

DISORDERS OF THE EXOCRINE PANCREAS

The pancreas lies transversely in the posterior part of the upper abdomen. The head of the pancreas is at the right of the abdomen; it rests against the curve of the duodenum in the area of the hepatopancreatic ampulla and its entrance into the duodenum (Fig. 28-1). The body of the pancreas lies beneath the stomach. The tail touches the spleen. The pancreas is virtually hidden because of its posterior position; unlike many other organs, it cannot be palpated. Because of the position of the pancreas and its large functional reserve, symptoms from conditions such as cancer of the pancreas do not usually appear until the disorder is far advanced.

The pancreas is both an endocrine and exocrine organ. Its function as an endocrine organ is discussed in Chapter 31. The exocrine pancreas is made up of lobules that consist of acinar cells, which secrete digestive enzymes into a system of microscopic ducts. These ducts empty into the main pancreatic duct, which extends from left to right through the substance of the pancreas. The main pancreatic duct and the bile duct unite to form the hepatopancreatic ampulla, which empties into the duodenum. The sphincter of the pancreatic duct controls the flow of pancreatic secretion into duodenum (Fig. 28-16).

The pancreatic secretions contain proteolytic enzymes that break down dietary proteins, including trypsin, chymotrypsin, carboxypolypeptidase, ribonuclease, and deoxyribonuclease. The pancreas also secretes pancreatic amylase, which breaks down starch, and lipases, which hydrolyze neutral fats into glycerol and fatty acids. The pancreatic enzymes are secreted in the inactive form and become activated in the intestine. This is important because the enzymes would digest the tissue of the pancreas itself if they were secreted in the active form. The acinar cells secrete a trypsin inhibitor, which prevents trypsin activation. Because trypsin activates other proteolytic enzymes, the trypsin inhibitor prevents subsequent activation of those other enzymes. The smaller pancreatic ducts are lined with epithelial cells that secrete water and bicarbonate and thereby modify the fluid and electrolyte composition of the pancreatic secretions. Two types of pancreatic disease are discussed in this chapter: acute and chronic pancreatitis and cancer of the pancreas.

Acute Pancreatitis

Acute pancreatitis represents an inflammation of the pancreas that ranges from a mild self-limited disease, consisting of inflammation and interstitial edema, to an acute hemorrhagic pancreatitis that is associated with massive necrosis of tissue.³⁶ Acute hemorrhagic pancreatitis is a severe, life-threatening disorder associated with the escape of activated pancreatic enzymes into the pancreas and surrounding tissues. These enzymes cause fat necrosis, or autodigestion, of the pancreas and produce fatty deposits in the abdominal cavity with hemorrhage from the necrotic vessels.

Although a number of factors are associated with the development of acute pancreatitis, most cases result from gallstones (stones in the common duct) or alcohol abuse.^{37,38} In the case of biliary tract obstruction caused by gallstones, pancreatic duct obstruction or biliary reflux is believed to activate the enzymes in the pancreatic duct system. The precise mechanisms whereby alcohol exerts its action are largely unknown. Alcohol is known to be a potent stimulator of pancreatic secretions, and it also is known to cause constriction of the sphincter of the pancreatic duct. Acute pancreatitis also is associated with hyperlipidemia, hyperparathyroidism, infections (particularly viral), abdominal and surgical trauma, and drugs such as steroids and thiazide diuretics.

The onset of acute pancreatitis usually is abrupt and dramatic, and it may follow a heavy meal or an alcoholic binge. The most common initial symptom is severe epigastric and abdominal pain that radiates to the back. The pain is aggravated when the person is lying supine; it is less severe when the person is sitting and leaning forward. Abdominal distention accompanied by hypoactive bowel sounds is common. An important disturbance related to acute necrotizing pancreatitis is the loss of a large volume of fluid into the retroperitoneal and peripancreatic spaces and the abdominal cavity. Tachycardia, hypotension, cool and clammy skin, and fever often are evident. Signs of hypocalcemia may develop, probably as a result of the precipitation of serum calcium in the areas of fat necrosis. Mild jaundice may appear after the first 24 hours because of biliary obstruction. Complications include acute respiratory distress syndrome and acute tubular necrosis. Hypocalcemia occurs in approximately 25% of patients.

Total serum amylase is the test used most frequently in the diagnosis of acute pancreatitis. Serum amylase levels increase within the first 24 hours after onset of symptoms and remain elevated for 48 to 72 hours. The serum lipase level also increases during the first 24 to 48 hours and remains elevated for 5 to 14 days. Urinary clearance of amylase is increased. Because the serum amylase level may be increased as a result of other serious illnesses, the urinary level of amylase is often measured. The white blood cell count may be increased, and blood glucose and serum bilirubin levels may be elevated. Plain radiographs of the abdomen may be used for detecting gallstones

or abdominal complications. CT scans and dynamic contrastenhanced CT of the pancreas are used to detect necrosis and fluid accumulation.

The treatment consists of measures directed at pain relief, "putting the pancreas to rest," and restoration of lost plasma volume. Antibiotic prophylaxis is used to prevent infection of necrotic pancreatic tissue. Oral foods and fluids are withheld, and gastric suction is instituted to treat distention of the bowel and prevent further stimulation of the secretion of pancreatic enzymes. Intravenous fluids and electrolytes are administered to replace those lost from the circulation and to combat hypotension and shock. Intravenous colloid solutions are given to replace the fluid that has become sequestered in the abdomen and retroperitoneal space.

Persons who survive acute necrotizing pancreatitis are at risk for development of pancreatic abscesses and pseudocysts. A pseudocyst is a collection of degraded blood, debris, and necrotic pancreatic tissue enclosed in a layer of connective tissue (Fig. 28-18). The pseudocyst most often is connected to a pancreatic duct, so that it continues to increase in mass. The symptoms depend on its location; for example, jaundice may occur when a cyst develops near the head of the pancreas, close to the common duct. Pseudocysts may become secondarily infected and form an abscess. Pseudocysts may resolve or, if they persist, may require surgical intervention.

Chronic Pancreatitis

Chronic pancreatitis is characterized by progressive destruction of the pancreas. It can be divided into two types: chronic calcifying pancreatitis and chronic obstructive pancreatitis.³⁸ In chronic calcifying pancreatitis, calcified protein plugs (*i.e.*, calculi) form in the pancreatic ducts. This form is seen most often in alcoholics. Alcohol damages pancreatic cells directly and also increases the concentration of proteins in the pancreatic secretions, which eventually leads to formation of protein plugs.³⁹ Other causes of chronic pancreatitis are cystic fibrosis and chronic obstructive pancreatitis caused by stenosis of the sphincter of the pancreatic duct. In obstructive pancreatitis, lesions are more prominent in the head of the pancreas. The disease usually is caused by cholelithiasis and sometimes is relieved by removal of the stones.

Chronic pancreatitis is manifested in episodes that are similar, albeit of lesser severity, to those of acute pancreatitis. Patients have persistent, recurring episodes of epigastric and

■ FIGURE 28-18 ■ Pancreatic pseudocyst. A cystic cavity arises from the head of the pancreas. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 847]. Philadelphia: Lippincott Williams & Wilkins)

upper left quadrant pain; the attacks often are precipitated by alcohol abuse or overeating. Anorexia, nausea, vomiting, constipation, and flatulence are common. Eventually the disease progresses to the extent that endocrine and exocrine pancreatic functions become deficient. At this point, signs of diabetes mellitus and the malabsorption syndrome (*e.g.*, weight loss, fatty stools [steatorrhea]) become apparent.³⁸

Treatment consists of measures to treat coexisting biliary tract disease. A low-fat diet usually is prescribed. The signs of malabsorption may be treated with pancreatic enzymes. When diabetes is present, it is treated with insulin. Alcohol is forbidden because it frequently precipitates attacks. Because of the frequent episodes of pain, narcotic addiction is a potential problem in persons with chronic pancreatitis. Surgical intervention sometimes is needed to relieve the pain and usually focuses on relieving any obstruction that may be present. In advanced cases, a subtotal or total pancreatectomy may be necessary.²²

Cancer of the Pancreas

Pancreatic cancer is now the fourth leading cause of cancer death in the United States, with more than 28,000 deaths attributed to the neoplasm each year.⁴⁰ Considered to be one of the most deadly malignancies, pancreatic cancer is associated with a mortality:incidence ratio of approximately 0.99. The risk of pancreatic cancer increases after the age of 50 years, with most cases occurring between the ages of 60 and 80 years. The incidence and mortality rates for both male and female African Americans are higher than those for whites.

The cause of pancreatic cancer is unknown. Smoking appears to be a major risk factor.^{41,42} The incidence of pancreatic cancer is twice as high among smokers than nonsmokers. The second most important factor appears to be diet. There appears to be an association of pancreatic cancer with an increasing total calorie intake and a high intake of fat, meat, salt, dehydrated foods, fried foods, refined sugars, soy beans, and nitrosamines. Data from animal studies indicate that nitrosamines and tobacco smoke are carcinogenic in the pancreas. A protective effect has been ascribed to a diet containing dietary fiber, vitamin C, fresh fruits and vegetables, and no preservatives. Diabetes and chronic pancreatitis also are associated with pancreatic cancer, although neither the nature nor the sequence of the possible cause-and-effect relation has been established.^{41,42} Genetic alterations appear to play a role. There appears to be an association between pancreatic cancer and certain genetic disorders, including nonpolyposis colon cancer, familial breast cancer with the BRCA2 gene mutation (see Chapter 5), ataxia-telangiectasia syndrome, familial atypical multiple molemelanoma syndrome, and hereditary pancreatitis.⁴¹

Cancer of the pancreas usually has an insidious onset. Pain, jaundice, and weight loss constitute the classic presentation of the disease. The most common pain is a dull epigastric pain often accompanied by back pain, often worse in the supine position, and relieved by sitting forward. Duodenal obstruction with nausea and vomiting is a late sign.

Because of the proximity of the pancreas to the common duct and the hepatopancreatic ampulla, cancer of the head of the pancreas tends to obstruct bile flow; this causes distention of the gallbladder and jaundice. Jaundice frequently is the presenting symptom of a person with cancer of the head of the pancreas, and it usually is accompanied by complaints of pain and pruritus. Cancer of the body of the pancreas usually impinges on the celiac ganglion, causing pain. The pain usually worsens with ingestion of food or with assumption of the supine position. Cancer of the tail of the pancreas usually has metastasized before symptoms appear.

Ultrasonography and CT scanning are the most frequently used diagnostic methods to confirm the disease. Percutaneous fine-needle aspiration cytology of the pancreas has been one of the major advances in the diagnosis of pancreatic cancer. Endoscopic retrograde cholangiopancreatography may be used for evaluation of persons with suspected pancreatic cancer and obstructive jaundice.

Most cancers of the pancreas have metastasized by the time of diagnosis. Surgical resection of the tumor is done when the tumor is localized or as a palliative measure. Radiation therapy may be useful when the disease is not resectable but appears to be localized. The use of irradiation and chemotherapy for pancreatic cancer continues to be investigated. Pain control is one of the most important aspects in the management of persons with end-stage pancreatic cancer.

In summary, the pancreas is an endocrine and exocrine organ. The exocrine pancreas produces digestive enzymes that are secreted in an inactive form and transported to the small intestine through the main pancreatic duct, which usually empties into the ampulla of Vater and then into the duodenum through the sphincter of Oddi. Acute and chronic types of pancreatitis are associated with biliary reflux and chronic alcoholism. Acute pancreatitis is a dramatic and lifethreatening disorder in which there is autodigestion of pancreatic tissue. Chronic pancreatitis causes progressive destruction of the endocrine and exocrine pancreas. It is characterized by episodes of pain and epigastric distress that are similar to but less severe than those that occur with acute pancreatitis. Cancer of the pancreas is the fourth leading cause of death in the United States. It usually is far advanced at the time of diagnosis, and the 5-year survival rate is less than 3%.

REVIEW QUESTIONS

Characterize the function of the liver in terms of bilirubin elimination and describe the pathogenesis of unconjugated and conjugated hyperbilirubinemia.

Relate the mechanism of bile formation and elimination to the development of cholestasis.

Compare hepatitis A, B, C, D, and E in terms of source of infection, incubation period, acute disease manifestations, development of chronic disease, and the carrier state.

Define the term *chronic hepatitis* and compare the pathogenesis of chronic autoimmune and chronic viral hepatitis.

Explain the metabolism of alcohol by the liver and state the metabolic mechanisms that can be used to explain liver injury.

Describe the pathogenesis of intrahepatic biliary tract disease.

Characterize the liver changes that occur with cirrhosis.

Describe the physiologic basis for portal hypertension and relate it to the development of ascites, esophageal varices, and splenomegaly.

Relate the functions of the liver to the manifestations of liver failure.

Relate the function of the gallbladder to the development of gallstones.

Describe the clinical manifestations of acute and chronic cholecystitis.

Characterize the effects of choledocholithiasis and cholangitis on bile flow and the potential for hepatic and pancreatic complications.

Compare the causes and manifestations of acute and chronic pancreatitis.

State the reason for the poor prognosis in pancreatic cancer.

CHAPTER

Nutritional status describes the condition of the body related to the availability and use of nutrients. Nutrients provide the energy and materials necessary for performing the activities of daily living; for maintaining healthy skin, muscles, and other body tissues; for replacing and healing tissues; and for the effective functioning of all body systems, including the immune and respiratory systems. Nutrients are derived from the digestive tract through the ingestion of foods. Once inside the body, nutrients are used for energy or as the building blocks for tissue growth and repair. When excess nutrients are available, they frequently are stored for future use. If the required nutrients are unavailable, the body adapts by conserving and using its nutrient stores.

REGULATION OF FOOD INTAKE AND ENERGY METABOLISM

Energy is measured in heat units called *calories*. A calorie, spelled with a small c and also called a *gram calorie*, is the amount of heat or energy required to raise the temperature of 1 g of water by 1°C. A *kilocalorie* (kcal), or *large calorie*, is the amount of energy needed to raise the temperature of 1 kg of water by 1°C. Because a calorie is so small, kilocalories often are used in nutritional and physiologic studies.

Metabolism is the organized process through which nutrients such as carbohydrates, fats, and proteins are broken down, transformed, or otherwise converted into cellular energy. The oxidation of proteins provides 4 kcal/g; fats, 9 kcal/g; carbohydrates, 4 kcal/g; and alcohol, 7 kcal/g.

The process of metabolism is unique in that it enables the continual release of energy, and it couples this energy with physiologic functioning. For example, the energy used for muscle contraction is derived largely from energy sources that are stored in muscle cells and then released as the muscle contracts. Because most of our energy sources come from the nutrients in the food that is eaten, the ability to store energy and control its release is important. Normally, energy utilization is balanced with energy expenditure. When a person is overfed and intake of food consistently exceeds energy expenditure, the excess energy is stored as fat, and the person becomes overweight. Conversely, when food intake is less than energy expenditure, fat stores and other body tissues are broken down, and the person loses weight.

Energy Storage

Adipose Tissue

More than 90% of body energy is stored in the adipose tissues of the body. *Adipocytes*, or fat cells, occur singly or in small groups in loose connective tissue. In many parts of the body, they cushion body organs such as the kidneys. In addition to

KEY CONCEPTS

ENERGY METABOLISM

- Energy is required for all the body's activities. Food is the source of the body's energy, which is measured in kilocalories (kcal).
- Fats, which are a concentrated water-free energy source, contain 9 kcal/g. They are stored in fat cells as triglycerides, which are the main storage sites for energy.
- Carbohydrates are hydrated fuels, which supply 4 kcal/g. They are stored in limited quantities as glycogen and can be converted to fatty acids and stored in fat cells as triglycerides.
- Amino acids, which supply 4 kcal/g, are used in building body proteins. Amino acids in excess of those needed for protein synthesis are converted to fatty acids, ketones, or glucose and are stored or used as metabolic fuel.

isolated groups of fat cells, entire regions of fat tissue are committed to fat storage. Collectively, fat cells constitute a large body organ that is metabolically active in the uptake, synthesis, storage, and mobilization of lipids, which are the main source of fuel storage for the body. Some tissues, such as liver cells, are able to store small amounts of lipids, but when these lipids accumulate, they begin to interfere with cell function. Adipose tissue not only serves as a storage site for body fuels, it provides insulation for the body, fills body crevices, and protects body organs.

Studies of adipocytes in the laboratory have shown that fully differentiated cells do not divide. However, such cells have a long life span, and anyone born with large numbers of adipocytes runs the risk of becoming obese. Some immature adipocytes capable of division are present in postnatal life; these cells respond to estrogen stimulation and are the potential source of additional fat cells during postnatal life.¹ Fat deposition results from proliferation of these existing immature adipocytes and can occur as a consequence of excessive caloric intake when a woman is breast-feeding or during estrogen stimulation around the time of puberty. An increase in fat cells also may occur during late adolescence and in middle-aged persons who already are overweight.

There are two types of adipose tissue: white fat and brown fat. White fat, which despite its name is cream colored or yellow, is the prevalent form of adipose tissue in postnatal life. It constitutes 10% to 20% of body weight in adult males and 15% to 25% in adult females. At body temperature, the lipid content of fat cells exists as an oil. It consists of triglycerides, which are three molecules of fatty acids esterified to a glycerol molecule. Triglycerides, which contain no water, have the highest caloric content of all nutrients and are an efficient form of energy storage. Fat cells synthesize triglycerides, the major fat storage form, from dietary fats and carbohydrates. Insulin is required for transport of glucose into fat cells. When calorie intake is restricted for any reason, fat cell triglycerides are broken down, and the resultant fatty acids and glycerol are released as energy sources.

Brown fat differs from white fat in terms of its thermogenic capacity or ability to produce heat. Brown fat, the site of diet-induced thermogenesis and nonshivering thermogenesis, is found primarily in early neonatal life in humans and in animals that hibernate. In humans, brown fat decreases with age but is still detectable in the sixth decade. This small amount of brown fat has a minimal effect on energy expenditure.

Nutritional Needs

Recommended Dietary Allowances and Dietary Reference Intakes

The *Recommended Daily Allowances* (RDAs) define the average daily intakes that meet the nutrient needs of almost all healthy persons in a specific age and sex group.² The RDAs, which are periodically updated, have been published since 1941 by the National Academy of Sciences. The RDA is used in advising persons about the level of nutrient intake they need to decrease the risk of chronic disease.

The Dietary Reference Intake (DRI) includes a set of at least four nutrient-based reference values, each of which has specific uses: the RDA, the Adequate Intake, the Estimated Average Requirement, and the Tolerable Upper Intake Level.³ The United States RDA (USRDA) was established for the purpose of labeling foods. It takes the highest recommended daily intake of each nutrient for children older than 4 years of age and for adults (excluding those pregnant or lactating); therefore, the USRDA sometimes provides a margin of nutritional safety higher than the RDA.

The Adequate Intake (AI) is set when there is not enough scientific evidence to estimate an average requirement. An *Estimated Average Requirement* is the intake that meets the estimated nutrient need of half of the persons in a specific group. The *Tolerable Upper Intake Level* is the maximum intake that is judged unlikely to pose a health risk in almost all healthy persons in a specific group. The DRIs are regularly reviewed and updated by the Food and Nutrition Board of the Institute of Medicine and the National Academy of Science.

Proteins, fats, carbohydrates, vitamins, and minerals each have their own function in providing the body with what it needs to maintain life and health. Recommended allowances have not been established for every nutrient; some are given as a safe and adequate intake, but others, such as carbohydrates and fats, are expressed as a percentage of the calorie intake.

Calories

Energy requirements are greater during growth periods. Infants require approximately 115 kcal/kg at birth, 105 kcal/kg at 1 year, and 80 kcal/kg of body weight between 1 to 10 years of age. During adolescence, boys require 45 kcal/kg of body weight and girls require 38 kcal/kg of body weight. During pregnancy, a woman needs an extra 300 kcal/day above her usual requirement, and during the first 3 months of breastfeeding, she requires an additional 500 kcal.² Table 29-1 can be used to predict the caloric requirements of healthy adults.

TABLE 29-1Caloric RequirementsBased on Body Weight andActivity Level						
	Sedentary	Moderate	Active			
Overweight	20–25 kcal/kg	30 kcal/kg	35 kcal/kg			
Normal	30 kcal/kg	35 kcal/kg	40 kcal/kg			
Underweight	30 kcal/kg	40 kcal/kg	45–50 kcal/kg			

(Adapted from Goodhart R.S., Shils M.E. [1980]. Modern nutrition in health and disease [6th ed.]. Philadelphia: Lea and Febiger)

Proteins, Fats, and Carbohydrates

Proteins are required for growth and maintenance of body tissues, formation of enzymes and antibodies, fluid and electrolyte balance, and nutrient transport. Proteins are composed of amino acids, nine of which are essential to the body. These are leucine, isoleucine, methionine, phenylalanine, threonine, tryptophan, valine, lysine, and histidine. The foods that provide these essential amino acids in adequate amounts are milk, eggs, meat, fish, and poultry. Dried peas and beans, nuts, seeds, and grains contain all the essential amino acids but in less than adequate proportions. The proteins in these foods need to be combined with each other or with complete proteins to meet the amino acid requirements for protein synthesis.

Unlike carbohydrates and fats, which are composed of hydrogen, carbon, and oxygen, proteins contain 16% nitrogen; therefore, nitrogen excretion is an indicator of protein intake. If the amount of nitrogen taken in by way of protein is equivalent to the nitrogen excreted, the person is said to be in nitrogen balance. A person is in positive nitrogen balance when the nitrogen consumed by way of protein is greater than the amount excreted. This occurs during growth, pregnancy, or healing after surgery or injury. A negative nitrogen balance often occurs with fever, illness, infection, trauma, or burns, when more nitrogen is excreted than is consumed. It represents a state of tissue breakdown.

Dietary fats are composed primarily of triglycerides (*i.e.*, a mixture of fatty acids and glycerol). The fatty acids are saturated (*i.e.*, no double bonds), monounsaturated (*i.e.*, one double bond), or polyunsaturated (*i.e.*, two or more double bonds). The saturated fatty acids elevate blood cholesterol, whereas the monounsaturated and polyunsaturated fats lower blood cholesterol. Saturated fats usually are from animal sources and remain solid at room temperature. With the exception of coconut and palm oils (which are saturated), unsaturated fats are found in plant oils and usually are liquid at room temperature.

Dietary fats provide energy, serve as carriers for the fatsoluble vitamins, are precursors of prostaglandins, and are a source of fatty acids. The polyunsaturated fatty acid linoleic acid is the only fatty acid that is required. A deficiency of linoleic acid results in dermatitis. The daily requirement is 5 g or 1% to 2% of the total daily calories. Because vegetable oils are rich sources of linoleic acid, this level can be met by including two teaspoons of oil.

Other than the requirement for linoleic acid, there is no specific requirement for dietary fat, provided there is adequate nutrition available for energy. Fat is the most concentrated source of energy. It is recommended that 30% or less of the calories in the diet should come from fats.

Cholesterol is the major constituent of cell membranes and is synthesized by the body. Cholesterol metabolism and transport are discussed in Chapter 15. The daily dietary recommendation for cholesterol is less than 300 mg.

Dietary carbohydrates are composed of simple sugars, complex carbohydrates, and undigested carbohydrates (*i.e.*, fiber). Within the body, carbohydrate is transformed into glucose, a six-carbon molecule. Excess glucose is stored as glycogen or converted to triglycerides for storage in fat cells. Because of their vitamin, mineral, and fiber content, it is recommended that the bulk of the carbohydrate content in the diet be in the complex form, rather than as simple sugars that contain few nutrients. Sucrose (*i.e.*, table sugar) is implicated in the development of dental caries.

There is no specific dietary requirement for carbohydrates. All of the energy requirements can be met by dietary fats and proteins. Although some tissues, such as the nervous system, require glucose as an energy source, this need can be met through the conversion of amino acids and the glycerol part of the triglyceride molecule to glucose. A carbohydrate-deficient diet usually results in the loss of tissue proteins and the development of ketosis. Because protein and fat metabolism increases the production of osmotically active metabolic wastes that must be eliminated through the kidneys, there is a danger of dehydration and electrolyte imbalances. The amount of carbohydrate needed to prevent tissue wasting and ketosis is 50 to 100 g/day. In practice, most of the daily energy requirement should be from carbohydrate. This is because protein is an expensive source of calories and because it is recommended that no more than 30% of the calories in the diet be derived from fat. The current recommendation is that the diet should provide 50% to 60% of the calories as carbohydrates.

Vitamins and Minerals

Vitamins are a group of organic compounds that act as catalysts in various chemical reactions. A compound cannot be classified as a vitamin unless it is shown that a deficiency of it causes disease. Contrary to popular belief, vitamins do not provide energy directly. As catalysts, they are part of the enzyme systems required for the release of energy from protein, fat, and carbohydrates. Vitamins also are necessary for the formation of red blood cells, hormones, genetic materials, and the nervous system. They are essential for normal growth and development.

There are two types of vitamins: fat soluble and water soluble. The four fat-soluble vitamins are vitamins A, D, E, and K. The nine required water-soluble vitamins are thiamine, ribo-flavin, niacin, pyridoxine (Vitamin B_6), pantothenic acid, vitamin B_{12} , folic acid, biotin, and vitamin C. Because the water-soluble vitamins are excreted in the urine, it is less likely that they may become toxic to the body, but the fat-soluble vitamins are stored in the body, and they may reach toxic levels.

Minerals serve many functions. They are involved in acidbase balance and in the maintenance of osmotic pressure in body compartments. Minerals are components of vitamins, hormones, and enzymes. They maintain normal hemoglobin levels, play a role in nervous system function, and are involved in muscle contraction and skeletal development and maintenance. Minerals that are present in relatively large amounts in the body are called *macrominerals*. These include calcium, phosphorus, sodium, chloride, potassium, magnesium, and sulfur. The remainder are classified as *trace minerals*; they include iron, manganese, copper, iodine, zinc, cobalt, fluorine, and selenium.

Regulation of Food Intake and Energy Storage

Stability of the weight and body composition over time requires that energy intake matches energy utilization. Environmental, cultural, genetic, and psychological factors all influence food intake and energy expenditure. However, powerful physiological control systems also regulate hunger and food intake.¹

Hunger, Appetite, and Food Intake

The sensation of *hunger* is associated with several sensory perceptions, such as the rhythmic contractions of the stomach and that "empty feeling" in the stomach that stimulates a person to seek food. A person's *appetite* is the desire for a particular type of food. It is useful in helping the person determine the type of food that is eaten. Satiety is the feeling of fullness or decreased desire for food.

The hypothalamus contains centers for hunger and satiety (Fig 29-1). It receives neural input from the gastrointestinal tract that provides information about stomach filling, chemical signals from the blood about the nutrients in food, and input from the cerebral cortex regarding the smell, sight, and taste of the food. Centers in the hypothalamus also control the secretion of several hormones (*e.g.*, thyroid and adrenocortical hormones) that regulate energy balance and metabolism.

The control of food intake can be divided into short-term regulation, which is concerned with the amount of food that is consumed at a meal or snack, and intermediate and long-term regulation, which is concerned with the maintenance of energy stores over time.¹

The short-term regulation of food intake provides a person with the feeling of satiety and turns off the desire for eating when adequate food has been consumed. It requires rapid feedback mechanisms that signal the adequacy of food intake be-

fore digestion has taken place and nutrients have been absorbed into the blood. These mechanisms include receptors that monitor filling of the gastrointestinal tract, gastrointestinal tract hormones, and oral receptors that monitor food intake. Stretch receptors in the gastrointestinal tract monitor gastrointestinal filling and send inhibitory impulses by way of the vagus nerve to the feeding center to suppress the desire for food. The gastrointestinal hormone cholecystokinin, which is released in response to fat in the duodenum, has a strong suppressant effect on the feeding center. The presence of food in the stomach increases the release of insulin and glucagon, both of which suppress the neurogenic feeding signals from the brain.¹ The act of tasting, chewing, and swallowing also appears to suppress the feeling of hunger.

The intermediate and long-term regulation of food intake is determined by the amount of nutrients that are in the blood and in storage sites. It has long been known that a decrease in blood glucose causes hunger. In contrast, an increase in breakdown products of lipids such as ketoacids produces a decrease in appetite. The ketogenic weight-loss diet relies on the appetite suppressant effects of ketones in the blood. Recent evidence suggests that the hypothalamus also senses the amount of energy that is stored in fat cells through a hormone called *leptin*. Increased amounts of leptin are released from the adipocytes when fat stores are increased. The stimulation of leptin receptors in the hypothalamus produces a decrease in appetite and food intake as well as an increase in metabolic rate and energy consumption. It also produces a decrease in insulin release from the beta cells, which decreases energy storage in fat cells.

Assessment of Energy Stores and Nutritional Status

Anthropometric measurements provide a means for assessing body composition, particularly fat stores and skeletal muscle mass. This is done by measuring height, weight, body circumferences, and thickness of various skinfolds. These measurements commonly are used to determine growth patterns in children and appropriateness of current weight in adults.

Body weight is the most frequently used method of assessing nutritional status; it should be used in combination with measurements of body height to establish whether a person is underweight or overweight.

Relative weight is the actual weight divided by the desirable weight and multiplied by 100. A relative weight greater than 120% is indicative of obesity. Recent changes in weight are probably a better indication of undernutrition than a low relative weight. An unintentional loss of 10% of body weight or more within the past 6 months usually is considered predictive of a poor clinical outcome, especially if weight loss is continuing.⁴ The body mass index (BMI) uses height and weight to determine healthy weight (Table 29-2). It is calculated by dividing the weight in kilograms by the height in meters squared (BMI = weight [kg]/height [m²]). A BMI between 18.5 and 25 has the lowest statistical health risk.⁵ A BMI of 25 to 29.9 is considered overweight; a BMI of 30 or greater as obese; and a BMI greater than 40 as very or morbidly obese.⁶

Body weight reflects both lean body mass and adipose tissue and cannot be used as a method for describing body composition or the percentage of fat tissue present. Statistically, the best percentage of body fat for men is between 12% and

TABLE 29-2 Classification of Overweight and Obesity by BMI, Waist Circumference, and Associated Disease Risk*						
			Disease Risk* Relative to Normal Weight and Waist Circumference			
	BMI (kg/m²)	Obesity Class	Men ≤102 cm (≤40 in) Women ≤88 cm (≤35 in)	Men >102 cm (>40 in) Women >88 cm (>35 in)		
Underweight	<18.5		_	_		
Normal [†]	18.5–24.9		_	_		
Overweight	25.0-29.9		Increased	High		
Obesity	30.0-34.9		High	Very high

adults. National Institutes of Health. [On-line.] Available: http://nhlbi.nih.gov/guidelines/ob_gdlns.htm.

20%, and for women, it is between 20% and 30%.⁷ During physical training, body fat usually decreases and lean body mass increases.

Among the methods used to estimate body fat are skinfold thickness, body circumferences, bioelectrical impedance, computed tomography (CT), and magnetic resonance imaging (MRI). The measurement of *body circumferences*, most commonly waist and hip, provides an objective measurement of body fat and supplies the information needed to calculate the waist circumference to hip circumference. The measurement of body circumference has received attention because of an interest in excess visceral or intra-abdominal fat. The waist circumference is commonly used for this purpose.⁶

Bioelectrical impedance involves the use of electrodes attached to the wrist and ankles to send a harmless current through the body. The flow of the current is affected by the amount of water in the body. Because fat-free tissue contains virtually all the water and current-conducting electrolytes, measurements of the resistance (*i.e.*, impedance) can be used to estimate the percentage of body fat present.⁸

Computed tomography and *MRI* can be used to provide quantitative pictures from which the thickness of fat can be determined. CT scans also can be used to provide quantitative estimates of regional fat and give a ratio of intra-abdominal to extra-abdominal fat. Because these methods are costly, they usually are reserved for research studies.

Various laboratory tests can aid in evaluating nutritional status. Some of the most commonly performed tests are serum albumin to assess the protein status, total lymphocyte count and delayed hypersensitivity reaction to assess cellular immunity, and creatinine-height index to assess skeletal muscle protein.

In summary, nutritional status describes the condition of the body related to the availability and use of nutrients. Metabolism is the organized process whereby nutrients such as carbohydrates, fats, and proteins are broken down, transformed, or otherwise converted to cellular energy. Glucose, fats, and amino acids from proteins serve as fuel sources for cellular metabolism. These fuel sources are ingested during meals and stored for future use. Glucose is stored as glycogen or converted to triglycerides in fat cells for storage. Fats are stored in adipose tissue as triglycerides. Amino acids are the building blocks of proteins, and most of the stored amino acids are contained in body proteins and as fuel sources for cellular metabolism. Energy is measured in heat units called *kilocalories*. The RDA is the recommended daily allowance needed to meet the known nutritional needs of healthy persons.

Nutritional status reflects the continued daily intake of nutrients over time and the deposition and use of these nutrients in the body. When a person is consistently overfed, the excess energy is stored as fat, and the person gains weight. When energy expenditure exceeds food intake, body fat and other tissues are broken down, and the person loses weight. The nutritional status of a person can be assessed by evaluation of dietary intake, anthropometric measurements, health assessment, and laboratory tests. Anthropometric measurements are used for assessing body composition; they include height and weight measurements and measurements to determine the composition of the body in relation to lean body mass and fat tissue (*e.g.*, skinfold thickness, body circumferences, bioelectrical impedance, and CT scans).

OVERNUTRITION AND OBESITY

Obesity is defined as a condition characterized by excess body fat. Clinically, obesity and overweight have been defined in terms of the BMI. Historically, various world organizations have used different BMI cutoff points to define obesity. In 1997, the World Health Organization defined the various classifications of overweight (BMI \ge 25) and obesity (BMI \ge 30). This classification system was subsequently adopted by the National Institutes of Health.⁶ The use of a BMI cutoff of 25 as a measure of overweight raised some concern that the BMI in some men might be attributable to muscle, rather than fat, weight. However, it has been shown that a BMI cutoff of 25 can sensitively detect most overweight people and does not erroneously detect overlean people.⁹

Overweight and obesity have become national health problems, increasing the risk of hypertension, hyperlipidemia, type 2 diabetes, coronary heart disease, and other health problems. Fifty-five percent of the U.S. population is estimated to be overweight (BMI \ge 25). Obesity is particularly prevalent among some minority groups, lower income groups, and people with less education. The prevalence of obesity (BMI \ge 30) in the United States has increased from 12.0% in 1991 to 17.9% in 1998.¹⁰

Causes of Obesity

The excess body fat of obesity often significantly impairs health. This excess body fat is generated when the calories consumed exceed those expended through exercise and activity.¹¹ The physiologic mechanisms that lead to this imbalance are poorly understood. They probably exist in different combinations among obese persons.

Although factors that lead to the development of obesity are not understood, they are thought to involve the interaction of the person's genotype with environmental influences such as social, behavioral, and cultural factors.¹² Obesity is known to run in families, suggesting a hereditary component. The question that surrounds this observation is whether the disorder arises because of genetic endowment or environmental influences. Studies of twin and adopted children have provided evidence that heredity contributes to the disorder.¹³ It is now believed that the heritability of the BMI is approximately 33%.¹⁴

Although genetic factors may explain some of the individual variations in terms of excess weight, environmental influences also must be taken into account. These influences include family dietary patterns, decreased level of activity because of labor-saving devices and time spent using the computer, re-

KEY CONCEPTS

OBESITY

- Obesity results from an imbalance between energy intake and energy consumption. Because fat is the main storage form of energy, obesity represents an excess of body fat.
- Overweight and obesity are determined by measurements of body mass index (BMI; weight [kg]/height [m²]) and waist circumference. A BMI of 25 to 29.9 is considered overweight; a BMI of 30 or greater, obese; and a BMI greater than 40, very or morbidly obese.
- Waist circumference is used to determine the distribution of body fat. Central, or abdominal, obesity is an independent predictor of morbidity and mortality associated with obesity.

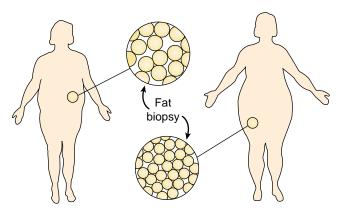

liance on the automobile for transportation, easy access to food, energy density of food, and large food portions. The obese may be greatly influenced by the availability of food, the flavor of food, time of day, and other cues. The composition of the diet also may be a causal factor, and the percentage of dietary fat independent of total calorie intake may play a part in the development of obesity. Psychological factors include using food as a reward, comfort, or means of getting attention. Eating may be a way to cope with tension, anxiety, and mental fatigue. Some persons may overeat and use obesity as a means of avoiding emotionally threatening situations.

Types of Obesity

Two types of obesity based on distribution of fat have been described: upper body and lower body obesity. *Upper body obesity* is also referred to as *central, abdominal,* or *male* obesity. Lower body obesity is known as *peripheral, gluteal-femoral,* or *female* obesity. The obesity type is determined by dividing the waist by the hip circumference. A waist-hip ratio greater than 1.0 in men and 0.8 in women indicates upper body obesity (Fig. 29-2).¹⁵ Research suggests that fat distribution may be a more important factor for morbidity and mortality than overweight or obesity.

The presence of excess fat in the abdomen out of proportion to total body fat is an independent predictor of risk factors and mortality. Waist circumference is positively correlated with abdominal fat content. Waist circumference 35 inches or greater in women and 40 inches or greater in men has been associated with increased health risk⁶ (see Table 29-2). Central obesity can be further differentiated into intra-abdominal, or visceral, fat and subcutaneous fat by the use of CT or MRI scans. However, intra-abdominal fat usually is synonymous with central fat distribution. One of the characteristics of intra-abdominal fat is that fatty acids released from the viscera go directly to the liver before entering the systemic circulation, having a potentially greater impact on hepatic function. Higher levels of circulating free fatty acids in obese persons, particularly those with upper body obesity, are thought to be associated with many of the adverse effects of obesity.11

In general, men have more intra-abdominal fat and women more subcutaneous fat. As men age, the proportion of intra-

■ FIGURE 29-2 ■ Distribution of body fat and size of fat cells in persons with upper and lower body obesity. (Courtesy of Ahmed Kissebah, M.D., Ph.D., Medical College of Wisconsin, Milwaukee)

abdominal fat to subcutaneous fat increases. After menopause, women tend to acquire more central fat distribution. Increasing weight gain, alcohol, and low levels of activity are associated with upper body obesity. These changes place persons with upper body obesity at greater risk for ischemic heart disease, stroke, and death independent of total body fat. They also tend to exhibit hypertension, elevated levels of triglycerides and decreased levels of high-density lipoproteins, hyperinsulinemia and diabetes mellitus, breast and endometrial cancer, gallbladder disease, menstrual irregularities, and infertility. Visceral fat also is associated with abnormalities of metabolic and sex hormone levels.15

Weight reduction causes a loss of intra-abdominal fat and has resulted in improvements in metabolic and hormonal abnormalities.¹⁶ In terms of weight reduction, some studies have shown that persons with upper body obesity are easier to treat than those with lower body obesity. Other studies have shown no difference in terms of success with weight reduction programs between the two types of obesity.

Weight cycling (the losing and gaining of weight) has been found to have little or no effect on metabolic variables, central obesity, or cardiovascular risk factors or future amount of weight loss.¹⁷ More research is needed to determine its effect on dietary preference for fat, psychological adjustment, disordered eating, and mortality.

Health Risks Associated With Obesity

Obese persons are more likely to have high blood pressure, hyperlipidemia, cardiovascular disease, glucose intolerance, insulin resistance, type 2 diabetes, stroke, gallbladder disease, infertility, and cancer of the endometrium, prostate, colon, and in postmenopausal women, the breast.6 The increased weight associated with obesity stresses the bones and joints, increasing the likelihood of arthritis. Other conditions associated with obesity include sleep apnea and pulmonary dysfunction, nonalcoholic steatohepatitis, carpal tunnel syndrome, venous insufficiency and deep vein thrombosis, and poor wound healing.⁶ Because some drugs are lipophilic and exhibit increased distribution in fat tissue, the administration of these drugs, including some anesthetic agents, can be more dangerous in obese persons. If surgery is required, the obese person tends to heal more slowly than a nonobese person of the same age.

Massive obesity, because of its close association with so many health problems, can be regarded as a disease in its own right.18 It is the second leading cause of preventable death. In men who have never smoked, the risk of death increases from 1.06 at a BMI of 24.5 to 1.67 at a BMI higher than 26.19

Prevention and Treatment

It has been theorized that obesity is preventable because the effect of hereditary factors is no more than moderate. A more active lifestyle together with a low-fat diet (<30% of calories) is seen as the strategy for prevention. The target audience should be young children, adolescents, and young adults.²⁰ Tools needed to achieve this goal include promotion of regular lowfat meals, avoidance of snacking, substitution of water for calorie-containing beverages, reduction of time spent in sedentary activities, such as television viewing, and an increase in activity. Other high-risk periods are from 25 to 35 years, at menopause,²⁰ and the year after successful weight loss.

The goals for weight loss are, at a minimum, prevention of further weight gain, reduction of current weight, and maintenance of a lowered body weight indefinitely. An algorithm has been designed for use in treating overweight and obesity. The initial goal in treatment is to lower body weight by 10% from baseline during a 6-month period. This degree of weight loss requires a calorie reduction of 300 to 500 kcal/day in individuals with a BMI of 27 to 35. For those persons with a BMI greater than 35, the calorie intake needs to be reduced by 500 to 1000 kcal/day. After 6 months, the person should be given strategies for maintaining the new weight. The person who is unable to achieve significant weight loss should be enrolled in a weight management program to prevent further weight gain.

There are many ways to treat obesity. It is currently recommended that treatment should focus on lifestyle modification through a combination of a low-calorie diet, increased physical activity, and behavior therapy.⁶

Dietary therapy should be individually prescribed based on the person's overweight status and risk profile. The diet should be a personalized plan that is 300 to 1000 kcal/day less than the current dietary intake. If the patient's risk status warrants it, the diet also should be decreased in saturated fat and contain 30% or less of total calories from fat. Reduction of dietary fat without a calorie deficit will not result in weight loss.

Physical activity is important in the prevention of weight gain. In addition, it reduces cardiovascular and diabetes risk beyond that achieved by weight loss alone. Although physical activity is an important part of weight loss therapy, it does not lead to a significant weight loss. Exercise should be started slowly, with the duration and intensity increased independent of each other. The goal should be 30 minutes or more of moderate-intensity activity on most days of the week. The activity can be performed at one time or intermittently over the day.

Techniques for changing behavior include self-monitoring of eating habits and physical activity, stress management, stimulus control, problem solving, contingency management, cognitive restructuring, and social support.

Pharmacotherapy and surgery are available as an adjunct to lifestyle changes in individuals who meet specific criteria.²¹ Pharmacotherapy is usually considered only after combined diet, exercise, and behavioral therapy has been in effect for a minimum of 6 months. Weight loss surgery is limited to persons with a BMI greater than 40; those with a BMI greater than 35 who have comorbid conditions and in whom efforts at medical therapy have failed; and those who have complications of extreme obesity.

Ē Childhood Obesity

Obesity is the most prevalent nutritional disorder affecting the pediatric population in the United States. The findings from the third National Health and Nutrition Examination Survey (NHANES III), conducted between 1988 and 1994, showed that 14% of children and 12% of adolescents were overweight.²² The definition for overweight for the NHANES III study was a BMI at or above the sex- and age-specific 95th percentile. Another definition of overweight in children is a weight for height greater than 120% of ideal when controlled for age and sex.23 Children who are 120% of weight expected for their height are overweight, but they are only considered to have excess fat when the triceps skinfold thickness is greater than the 85th percentile. This distinction is important in preventing misdiagnosis of obesity and creating anxiety for the parents and the child.

The major concern of childhood obesity is that obese children will grow up to become obese adults. Health care providers are beginning to see hypertension, dyslipidemia, and type 2 diabetes in obese children and adolescents.²⁴ In addition, there is a growing concern that childhood and adolescent obesity may be associated with negative psychosocial consequences, such as low self-esteem and discrimination by adults and peers.²⁵

Childhood obesity is determined by a combination of hereditary and environmental factors. It is associated with obese parents, higher socioeconomic status, increased parental education, small family size, and sedentary lifestyle.²⁶ Children with overweight parents are at highest risk; the risk for those with two overweight parents is much higher than for children in families in which neither parent is obese. One of the trends leading to childhood obesity is the increase in inactivity. Increasing perceptions that neighborhoods are unsafe has resulted in less time spent outside playing and walking and more time spent indoors engaging in sedentary activities, such as television viewing. Television viewing is associated with consumption of calorie-dense snacks and decreased indoor activity. Obese children also may have a deficit in recognizing hunger sensations, stemming perhaps from parents who use food as gratification.

Because adolescent obesity is predictive of adult obesity, treatment of childhood obesity is desirable. Weight loss without adverse health effects and maintenance of that loss are the goals. Each child should be assessed and treated individually. In young children who have mild to moderate weight problems, weight maintenance or a reduced rate of weight gain is sufficient. Studies indicate that physical activity in combination with diet therapy is more effective than diet therapy alone.

When weight loss is required, a loss of 1 pound per month is reasonable together with permanent changes in food consumption and activity. However, the focus should be on normalizing food intake, particularly fat intake, and increasing physical activity. If weight gain can be slowed or maintained during growth, lean body mass increases, and some of the abnormal metabolic effects of obesity may be reversed. Family members need to be involved so they can learn to provide appropriate support and assist the child in taking responsibility for his or her own actions. Highly restrictive diets should be limited to the rare child or adolescent who has morbid complications. They should not be used for children or adolescents with renal, liver, or cardiac disease. These diets should contain a minimum of 2 g protein/kg body weight.²² There should be close monitoring for sustained nitrogen losses, cardiac dysrhythmias, and cholelithiasis. Commercial diets are not recommended.

In summary, obesity is defined as excess body fat resulting from the consumption of calories in excess of those expended for exercise and activities. Heredity, socioeconomic, cultural, and environmental factors, psychological influences, and activity levels have been implicated as causative factors in the development of obesity. The health risks associated with obesity include hypertension and cardiovascular disease, hyperlipidemia, insulin resistance and type 2 diabetes mellitus, menstrual irregularities and infertility, cancer of the endometrium, breast, prostate, and colon, and gallbladder disease. There are two types of obesity—upper body and lower body obesity. Upper body obesity is associated with a higher incidence of complications. The treatment of obesity focuses on nutritionally adequate weight-loss diets, behavior modification, exercise, social support, and in situations of marked obesity, surgical methods. Obesity is the most prevalent nutritional disorder affecting the pediatric population in the United States.

UNDERNUTRITION

Undernutrition ranges from the selective deficiency of a single nutrient to starvation in which there is deprivation of all ingested nutrients. Undernutrition can result from eating disorders; lack of food availability; or health problems that impair food intake and decrease its absorption and use. Weight loss and malnutrition are common during illness, recovery from trauma, and hospitalization.

The prevalence of malnutrition in children is substantial. Globally, nearly 195 million children younger than 5 years of age are undernourished.²⁷ Malnutrition is most obvious in developing countries of the world, where the condition takes severe forms. Even in developed nations, malnutrition remains a problem. In 1992, it was estimated that 12 million American children consumed diets that were significantly below the recommended allowances of the National Academy of Sciences.²⁷

Protein and Calorie Malnutrition

Malnutrition and starvation are conditions in which a person does not receive or is unable to use an adequate amount of calories and nutrients for body function. Among the many causes of starvation, some are willful, such as the person with anorexia nervosa who does not consume enough food to maintain weight and health, and some are medical, such as persons with Crohn's disease who are unable to absorb their food. Most cases of food deprivation result in semistarvation with protein and calorie malnutrition.

Protein-calorie malnutrition, also referred to as *marasmus*, is characterized by loss of muscle and fat stores. Marasmus is characterized by progressive wasting from inadequate food intake that is equally deficient in calories and protein. The person appears emaciated, with sparse, dry, and dull hair and depressed heart rate, blood pressure, and body temperature. The female experiences anovulation and amenorrhea, and the male experiences decreased testicular function. The child with marasmus has a wasted appearance, with stunted growth and loss of subcutaneous fat, but with relatively normal skin, hair, liver function, and affect.

Kwashiorkor is caused by protein deficiency. The term *kwashiorkor* comes from the African word meaning "the disease suffered by the displaced child," because the condition devel-

ops soon after a child is displaced from the breast after the arrival of a new infant and placed on a starchy gruel feeding. The child with kwashiorkor is characterized by edema, desquamating skin, discolored hair, enlarged abdomen, anorexia, and extreme apathy. The serum albumin level is less that 3.0 g/dL, and there is pitting edema of the extremities. There is less weight loss and wasting of skeletal muscles than in marasmus. Other manifestations include skin lesions, easily pluckable hair, enlarged liver and distended abdomen, cold extremities, and decreased cardiac output and tachycardia.

Marasmus-kwashiorkor is an advanced protein-calorie deficit together with increased protein requirement or loss. This results in a rapid decrease in anthropometric measurements with obvious edema and wasting and loss of organ mass.

Malnutrition and Wasting in Illness

Malnutrition and wasting are common in persons with trauma, sepsis, and serious illnesses such as cancer and acquired immunodeficiency syndrome. Approximately half of all persons with cancer experience tissue wasting in which the tumor induces metabolic changes, leading to a loss of adipose tissue and muscle mass.²⁸ In healthy adults, body protein homeostasis is maintained by a cycle in which the net loss of protein in the postabsorptive state is matched by a net postprandial gain of protein.²⁹ In persons with severe injury or illness, net protein breakdown is accelerated and protein rebuilding disrupted. Consequently, these persons may lose up to 20% of body protein, much of which originates in skeletal muscle.²⁹ Protein mass is lost from the liver, gastrointestinal tract, kidneys, and heart. As protein is lost from the liver, hepatic synthesis of serum proteins decreases and decreased levels of serum proteins are observed. There is a decrease in immune cells and those needed for wound healing. The lungs are affected primarily by weakness and atrophy of the respiratory muscles. The gastrointestinal tract undergoes mucosal atrophy with loss of villi in the small intestine, resulting in malabsorption. The loss of protein from cardiac muscle leads to a decrease in myocardial contractility and cardiac output.

In hospitalized patients, malnutrition increases morbidity and mortality rates, incidence of complications, and length of stay. Malnutrition may present at the time of admission or develop during hospitalization. The hospitalized patient often finds eating a healthful diet difficult and commonly has restrictions on food and water intake in preparation for tests and surgery. Pain, medications, special diets, and stress can decrease appetite. Even when the patient is well enough to eat, being alone in a room where unpleasant treatments may be given is not conducive to eating. Although hospitalized patients may appear to need fewer calories because they are on bed rest, their actual need for caloric intake may be higher because of other energy expenditures. For example, more calories are expended during fever, when the metabolic rate is increased. There also may be an increased need for protein to support tissue repair after trauma or surgery.

Treatment

The treatment of severe protein-calorie malnutrition involves the use of measures to correct fluid and electrolyte abnormalities and replenish proteins, calories, and micronutrients.³⁰ Treatment is started with modest quantities of proteins and calories based on the person's actual weight. Concurrent administration of vitamins and minerals is needed. Either the enteral or parenteral route can be used. The treatment should be undertaken slowly to avoid complications. The administration of water and sodium with carbohydrates can overload a heart that has been weakened by malnutrition and result in congestive failure. Enteral feedings can result in malabsorptive symptoms caused by abnormalities in the gastrointestinal tract. Refeeding edema is benign dependent edema that results from renal sodium reabsorption and poor skin and blood vessel integrity. It is treated by elevation of the dependent area and modest sodium restrictions. Diuretics are ineffective and may aggravate electrolyte deficiencies.

Eating Disorders

Eating disorders affect an estimated 5 million Americans each year.³¹These illnesses, which include anorexia nervosa, bulimia nervosa, and binge-eating disorder and their variants, incorporate serious disturbances in eating, such as restriction of intake and binging, with an excessive concern over body shape or body weight. Eating disorders typically occur in adolescent girls and young women, although 5% to 15% of cases of anorexia nervosa and 40% of cases of binge-eating disorder occur in boys and men.³¹ The mortality rate associated with anorexia nervosa, 0.56% per year, is more than 12 times the mortality rate among young women in the general population.³¹

Eating disorders are more prevalent in industrialized societies and occur in all socioeconomic and major ethnic groups. A combination of genetic, neurochemical, developmental, and sociocultural factors is thought to contribute to the development of the disorders. The American Psychiatric Society's

KEY CONCEPTS

- Eating disorders are serious disturbances in eating, such as willful restriction of intake and binge eating, as well as excessive concern over body weight and shape.
- Anorexia nervosa is characterized by a refusal to maintain a minimally normal body weight (*e.g.*, at least 85% of minimal expected weight); an excessive concern over gaining weight and how the body is perceived in terms of size and shape; and amenorrhea (in girls and women after menarche).
- Bulimia nervosa is characterized by recurrent binge eating; inappropriate compensatory behaviors, such as self-induced vomiting, fasting, or excessive exercise that follow the binge-eating episode; and extreme concern over body shape and weight.
- Binge eating consists of consuming unusually large quantities of food during a discrete period (*e.g.*, within any 2-hour period) along with a lack of control over the binge-eating episode.

Diagnostic and Statistical Manual of Mental Disorders, Text Revision (DSM-IV-TR) has established criteria for the diagnosis of anorexia nervosa and bulimia nervosa.32 Although these criteria allow clinicians to make a diagnosis in persons with a specific eating disorder, the symptoms often occur along a continuum between those of anorexia nervosa and bulimia nervosa. Preoccupation with weight and excessive self-evaluation of weight and shape are common to both disorders, and persons with eating disorders may demonstrate a mixture of both disorders.³² The female athlete triad, which includes disordered eating, amenorrhea, and osteoporosis, does not meet the strict DSM-IV-TR criteria for anorexia nervosa or bulimia nervosa but shares many of the characteristics and therapeutic concerns of the two disorders (see Chapter 43). Persons with eating disorders may require concomitant evaluation for psychiatric illness because eating disorders often are accompanied by mood, anxiety, and personality disorders. Suicidal behavior may accompany anorexia nervosa and bulimia nervosa and should be excluded.31

Anorexia Nervosa

Anorexia nervosa was first described in the scientific literature more than 100 years ago by Sir William Gull.33 The DSM-IV-TR diagnostic criteria for anorexia nervosa are (1) a refusal to maintain a minimally normal body weight for age and height (e.g., $\leq 85\%$ of minimal expected weight or BMI ≥ 17.5); (2) an intense fear of gaining weight or becoming fat; (3) a disturbance in the way one's body size, weight, or shape is perceived; and (4) amenorrhea (in girls and women after menarche).³² Anorexia nervosa is more prevalent among young women than men. The disorder typically begins in teenage girls who are obese or perceive themselves as being obese. An interest in weight reduction becomes an obsession, with severely restricted caloric intake and frequently with excessive physical exercise. The term *anorexia*, meaning "loss of appetite," is a misnomer because hunger is felt but in this case is denied.

Many organ systems are affected by the malnutrition that occurs in persons with anorexia nervosa. The severity of the abnormalities tends to be related to the degree of malnutrition and is reversed by refeeding. The most frequently occurring complication of anorexia is amenorrhea and loss of secondary sex characteristics with decreased levels of estrogen, which can eventually lead to osteoporosis. Bone loss can occur in young women after as short a period of illness as 6 months.³¹ Symptomatic compression fractures and kyphosis have been reported. Constipation, cold intolerance and failure to shiver in cold, bradycardia, hypotension, decreased heart size, electrocardiographic changes, blood and electrolyte abnormalities, and skin with lanugo (*i.e.*, increased amounts of fine hair) are common. Unexpected sudden deaths have been reported; the risk appears to increase as weight drops to less than 35% to 40% of ideal weight. It is believed that these deaths are caused by myocardial degeneration and heart failure, rather than dysrhythmias.

The most exasperating aspect of the treatment of anorexia is the inability of the person with anorexia to recognize there is a problem. Because anorexia is a form of starvation, it can lead to death if left untreated. A multidisciplinary approach appears to be the most effective method of treating persons with the disorder.^{34,35} The goals of treatment are eating and weight gain, resolution of issues with the family, healing of pain from the past, and efforts to work on psychological, relationship, and emotional issues.

Bulimia Nervosa and Binge Eating

Bulimia nervosa and binge eating are eating disorders that encompass an array of distinctive behaviors, feelings, and thoughts. Binge eating is characterized by the consumption of an unusually large quantity of food during a discrete time along with lack of control over the binge-eating episode. Bulimia nervosa is a condition of recurrent binge eating that is accompanied by purging, excessive exercise, or fasting.

Bulimia Nervosa. Bulimia nervosa is 10 times more common in women than men; it usually begins between 13 and 20 years of age, and affects as many as 3% of young women.³⁶ The DSM-IV-TR criteria for bulimia nervosa are (1) recurrent binge eating (at least two times per week for 3 months); (2) inappropriate compensatory behaviors, such as self-induced vomiting, abuse of laxatives or diuretics, fasting, or excessive exercise that follow the binge-eating episode; (3) self-evaluation that is unduly influenced by body shape and weight; and (4) a determination that the eating disorder does not occur exclusively during episodes of anorexia nervosa.³² The diagnostic criteria for bulimia nervosa now include subtypes to distinguish patients who compensate by purging (e.g., vomiting or abuse of laxatives or diuretics) and those who use nonpurging behaviors (e.g., fasting or excessive exercise). The disorder may be associated with other psychiatric disorders, such as substance abuse.31,36

The complications of bulimia nervosa include those resulting from overeating, self-induced vomiting, and cathartic and diuretic abuse. Among the complications of self-induced vomiting are dental disorders, parotitis, and fluid and electrolyte disorders. Dental abnormalities, such as sensitive teeth, increased dental caries, and periodontal disease, occur with frequent vomiting because the high acid content of the vomitus causes tooth enamel to dissolve. Esophagitis, dysphagia, and esophageal stricture are common. With frequent vomiting, there often is reflux of gastric contents into the lower esophagus because of relaxation of the lower esophageal sphincter. Vomiting may lead to aspiration pneumonia, especially in intoxicated or debilitated persons. Potassium, chloride, and hydrogen are lost in the vomitus, and frequent vomiting predisposes to metabolic alkalosis with hypokalemia (see Chapter 6). An unexplained physical response to vomiting is the development of benign, painless parotid gland enlargement.

The weights of persons with bulimia nervosa may fluctuate, although not to the dangerously low levels seen in anorexia nervosa. Their thoughts and feelings range from fear of not being able to stop eating to a concern about gaining too much weight. They also experience feelings of sadness, anger, guilt, shame, and low self-esteem.

Treatment strategies include psychological and pharmacologic treatments. Unlike persons with anorexia nervosa, persons with bulimia nervosa or binge eating are upset by the behaviors practiced and the thoughts and feelings experienced, and they are more willing to accept help. Pharmacotherapeutic agents include the tricyclic antidepressants (*e.g.*, desipramine, imipramine), the selective serotonin reuptake inhibitors (*e.g.*, fluoxetine), and other antidepressant medications.³⁶

Binge Eating. Binge eating is characterized by recurrent episodes of binge eating at least 2 days per week for 6 months and at least three of the following: (1) eating rapidly; (2) eating until becoming uncomfortably full; (3) eating large amounts when not hungry; (4) eating alone because of embarrassment; and (5) disgust, depression, or guilt because of eating episodes.^{31,34,36}

The primary goal of therapy for binge-eating disorders is to establish a regular, healthful eating pattern. Persons with binge-eating disorders who have been successfully treated for their eating disorder have reported that making meal plans, eating a balanced diet at three regular meals a day, avoiding high-sugar foods and other binge foods, recording food intake and binge-eating episodes, exercising regularly, finding alternative activities, and avoiding alcohol and drugs are helpful in maintaining their more healthful eating behaviors after treatment.

In summary, undernutrition can range from a selective deficiency of a single nutrient to starvation in which there is deprivation of all ingested nutrients. Malnutrition and starvation are among the most widespread causes of morbidity and mortality in the world. Malnutrition is common during illness, recovery from trauma, and hospitalization. The effects of malnutrition and starvation on body function are widespread. They include loss of muscle mass, impaired wound healing, impaired immunologic function, decreased appetite, loss of calcium and phosphate from bone, anovulation and amenorrhea in women, and decreased testicular function in men.

Anorexia nervosa, bulimia nervosa, and binge eating are eating disorders that result in malnutrition. In anorexia nervosa, distorted attitudes about eating lead to serious weight loss and malnutrition. Bulimia nervosa is characterized by secretive episodes or binges of eating large quantities of easily consumed, high-caloric foods, followed by compensatory behaviors such as fasting, self-induced vomiting, or abuse of laxatives or diuretics. Binge-eating disorder is characterized by eating large quantities of food but is not accompanied by purging and other inappropriate compensatory behaviors seen in persons with bulimia nervosa.

REVIEW QUESTIONS

Define *calorie* and state the number of calories derived from the oxidation of 1 g of protein, fat, or carbohydrate.

State the purpose of the Recommended Dietary Allowance of calories, proteins, fats, carbohydrates, vitamins, and minerals.

State the factors used in determining body mass index and explain its use in evaluating body weight in terms of undernutrition and overnutrition.

Define and discuss the causes of obesity and health risks associated with obesity.

Explain the effect of malnutrition on muscle mass, respiratory function, acid-base balance, wound healing, immune function,

bone mineralization, the menstrual cycle, and testicular function.

Compare the eating disorders and complications associated with anorexia nervosa and the binge-purge syndrome.

he endocrine system is involved in all of the integrative aspects of life, including growth, sex differentiation, metabolism, and adaptation to an ever-changing environment. This chapter focuses on general aspects of endocrine function, organization of the endocrine system, hormone receptors and hormone actions, and regulation of hormone levels.

THE ENDOCRINE SYSTEM

The endocrine system uses chemical substances called hormones as a means of regulating and integrating body functions. The endocrine system participates in the regulation of digestion, use, and storage of nutrients; growth and development; electrolyte and water metabolism; and reproductive functions. Although the endocrine system once was thought to consist solely of discrete endocrine glands, it is now known that a number of other tissues release chemical messengers that modulate body processes. The functions of the endocrine system are closely linked with those of the nervous system and the immune system. For example, neurotransmitters such as epinephrine can act as neurotransmitters or as hormones. The functions of the immune system also are closely linked with those of the endocrine system. The immune system responds to foreign agents by means of chemical messengers (cytokines, e.g., interleukins, interferons) and complex receptor mechanisms (see Chapter 8). The immune system also is extensively regulated by hormones such as the adrenal corticosteroid hormones.

Hormones

Hormones generally are thought of as chemical messengers that are transported in body fluids. They are highly specialized organic molecules produced by endocrine organs that exert their action on specific target cells. Hormones do not initiate reactions; they are modulators of systemic and cellular responses. Most hormones are present in body fluids at all times but in greater or lesser amounts, depending on the needs of the body.

A characteristic of hormones is that a single hormone can exert various effects in different tissues or, conversely, a single function can be regulated by several hormones. For example, estradiol, which is produced by the ovary, can act on the ovarian follicles to promote their maturation, on the uterus to stimulate its growth and maintain the cyclic changes in the uterine mucosa, on the mammary gland to stimulate ductal growth, on the hypothalamic-pituitary system to regulate the secretion of gonadotropins and prolactin, and on general metabolic processes to affect adipose tissue distribution. Lipolysis, which is the release of free fatty acids from adipose tissue, is an example of a single function that is regulated by several hormones, including the catecholamines, glucagon, and secretin. Table 30-1 lists the major functions and sources of body hormones.

Paracrine and Autocrine Actions

In the past, hormones were described as chemical substances that were released into the bloodstream and transported to distant target sites, where they exerted their action (Fig. 30-1). Although many hormones travel by this mechanism, some hormones and hormone-like substances never enter the bloodstream but instead act locally in the vicinity in which they are released. When they act locally on cells other than those that produced the hormone, the action is called *paracrine*. The action of sex steroids on the ovary is a paracrine action. Hormones also can exert an *autocrine* action on the cells from which they were produced. For example, the release of insulin from

KEY CONCEPTS

HORMONES

- Hormones function as chemical messengers, moving through the blood to distant target sites of action, or acting more locally as paracrine or autocrine messengers that incite more local effects.
- Most hormones are present in body fluids at all times but in greater or lesser amounts, depending on the needs of the body.
- Hormones exert their actions by interacting with high-affinity receptors, which in turn are linked to one or more effector systems in the cell. Some hormone receptors are located on the surface of the cell and act through second messenger mechanisms, and others are located in the cell, where they modulate the synthesis of enzymes, transport proteins, or structural proteins.

pancreatic beta cells can inhibit its release from the same cells. *Juxtacrine* refers to a mechanism whereby a cytokine that is embedded in, bound to, or associated with the plasma membrane of one cell interacts with a specific receptor in a juxtaposed cell.

Eicosanoids and Retinoids

A group of compounds that have a hormone-like action are the eicosanoids, which are derived from polyunsaturated fatty acids in the cell membrane. Among these, *arachidonic acid* is the most important and abundant precursor of the various eicosanoids. The most important of the eicosanoids are the prostaglandins, leukotrienes, and thromboxanes. These fatty acid derivatives are produced by most body cells, are rapidly cleared from the circulation, and are thought to act mainly by paracrine and autocrine mechanisms. Eicosanoid synthesis often is stimulated in response to hormones, and they serve as mediators of hormone action. Retinoids (*e.g.*, retinoic acid) also are derived from fatty acids and have an important role in regulating nuclear receptor action.

Structural Classification

Hormones have diverse structures, ranging from single amino acids to complex proteins and lipids. Hormones usually are divided into four categories according to their structures: (1) amines and amino acids; (2) peptides, polypeptides, glycoproteins, and proteins; (3) steroids; and (4) fatty acid derivatives (Table 30-2). The first category, the amines, includes norepinephrine and epinephrine, which are derived from a single amino acid (*i.e.*, tyrosine), and the thyroid hormones, which are derived from two iodinated tyrosine amino acid residues. The second category, the peptides, polypeptides, glycoproteins, and proteins, can be as small as thyrotropinreleasing hormone (TRH), which contains three amino acids, and as large and complex as growth hormone (GH) and follicle-stimulating hormone (FSH), which have approximately 200 amino acids. Glycoproteins are large peptide hormones associated with a carbohydrate (e.g., FSH). The third category comprises the steroid hormones, which are derivatives of cholesterol. The fourth category, the fatty acid derivatives, includes the eicosanoids and retinoids.

Synthesis and Transport

The mechanisms for hormone synthesis vary with hormone structure. Protein and peptide hormones are synthesized and stored in granules or vesicles in the cytoplasm of the cell until secretion is required. The lipid-soluble steroid hormones are released as they are synthesized.

Protein and peptide hormones are synthesized in the rough endoplasmic reticulum in a manner similar to the synthesis of other proteins (see Chapter 1). The appropriate amino acid sequence is dictated by messenger RNAs from the nucleus. Usually, synthesis involves the production of a precursor hormone, which is modified by the addition of peptides or sugar units. These precursor hormones often contain extra peptide units that ensure proper folding of the molecule and insertion of essential linkages. If extra amino acids are present, as in insulin, the precursor hormone is called a prohormone. After synthesis and sequestration in the endoplasmic reticulum, the protein and peptide hormones move into the Golgi complex, where they are packaged in granules or vesicles. It is in the Golgi complex that prohormones are converted into hormones.

TABLE 30-1	0-1 Major Action and Source of Selected Hormones		
Source	Hormone	Major Action	
Hypothalamus	Releasing and inhibiting hormones Corticotropin-releasing hormone (CRH) Thyrotropin-releasing hormone (TRH) Growth hormone-releasing hormone (GHRH)	Controls the release of pituitary hormones	
Antonion pituiton (Gonadotropin-releasing hormone (GnRH)	Ctimulates growth of home and muscle promotes protein arm	
Anterior pituitary	Growth hormone (GH) Adrenocorticotropic hormone (ACTH) Thyroid-stimulating hormone (TSH) Follicle-stimulating hormone (FSH)	Stimulates growth of bone and muscle, promotes protein syn- thesis and fat metabolism, decreases carbohydrate metabolism Stimulates synthesis and secretion of adrenal cortical hormones Stimulates synthesis and secretion of thyroid hormone Female: stimulates growth of ovarian follicle, ovulation Male: stimulates sperm production	
	Luteinizing hormone (LH)	Female: stimulates development of corpus luteum, release of oocyte, production of estrogen and progesterone Male: stimulates secretion of testosterone, development of inter- stitial tissue of testes	
Posterior pituitary	Antidiuretic hormone (ADH) Oxytocin	Increases water reabsorption by kidney Stimulates contraction of pregnant uterus, milk ejection from breasts after childbirth	
Adrenal cortex	Mineralocorticosteroids, mainly aldosterone Glucocorticoids, mainly cortisol	Increases sodium absorption, potassium loss by kidney Affects metabolism of all nutrients; regulates blood glucose levels, affects growth, has anti-inflammatory action, and decreases effects of stress	
	Adrenal androgens, mainly dehydroepiandros- terone (DHEA) and androstenedione	Have minimal intrinsic androgenic activity; they are converted to testosterone and dihydrotestosterone in the periphery	
Adrenal medulla	Epinephrine Norepinephrine	Serve as neurotransmitters for the sympathetic nervous system	
Thyroid (follicular cells)	Thyroid hormones: triiodothyronine (T ₃), thyroxine (T ₄)	Increase the metabolic rate; increase protein and bone turnover; increase responsiveness to catecholamines; necessary for fetal and infant growth and development	
Thyroid C cells	Calcitonin	Lowers blood calcium and phosphate levels	
Parathyroid glands	Parathyroid hormone	Regulates serum calcium	
Pancreatic islet cells	Insulin	Lowers blood glucose by facilitating glucose transport across cell membranes of muscle, liver, and adipose tissue	
	Glucagon	Increases blood glucose concentration by stimulation of glycogenolysis and glyconeogenesis	
	Somatostatin	Delays intestinal absorption of glucose	
Kidney	1,25-Dihydroxyvitamin D	Stimulates calcium absorption from the intestine	
Ovaries	Estrogen	Affects development of female sex organs and secondary sex characteristics	
	Progesterone	Influences menstrual cycle; stimulates growth of uterine wall; maintains pregnancy	
Testes	Androgens, mainly testosterone	Affect development of male sex organs and secondary sex characteristics; aid in sperm production	

Steroid hormones are synthesized in the smooth endoplasmic reticulum, and steroid-secreting cells can be identified by their large amounts of smooth endoplasmic reticulum. Certain steroids serve as precursors for the production of other hormones. For example, in the adrenal cortex, progesterone and other steroid intermediates are enzymatically converted into aldosterone, cortisol, or androgens (see Chapter 31).

Hormones that are released into the bloodstream circulate as either free, unbound molecules or as hormones attached to transport carriers (Fig. 30-2). Peptide hormones and protein hormones usually circulate unbound in the blood. Steroid hormones and thyroid hormone are carried by specific carrier proteins synthesized in the liver. The extent of carrier binding influences the rate at which hormones leave the blood and enter the cells. The half-life of a hormone—the time it takes for the body to reduce the concentration of the hormone by one half—is positively correlated with its percentage of protein binding. Thyroxine, which is more than 99% protein bound, has a half-life of 6 days. Aldosterone, which is only 15% bound, has a half-life of only 25 minutes. Drugs that compete with a hormone for binding with transport carrier molecules increase hormone action by increasing the availability of the active unbound hormone. For example, aspirin competes with thyroid hormone for binding to transport proteins; when the

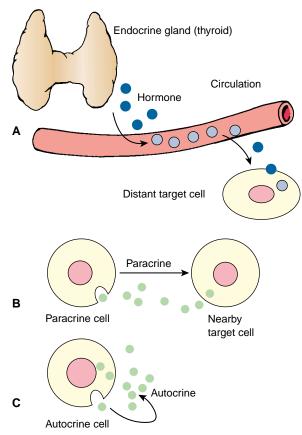

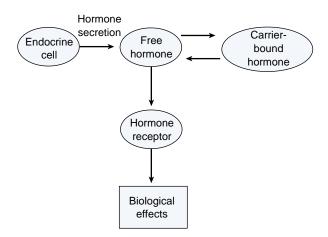

FIGURE 30-1 Examples of endocrine (A), paracrine (B), and autocrine (C) secretions.

drug is administered to persons with excessive levels of circulating thyroid hormone, such as during thyroid crisis, serious effects may occur.

Metabolism and Elimination

Metabolism of hormones and their precursors can generate more or less active products or it can degrade them to inactive forms. In some cases, hormones are eliminated in the intact

■ FIGURE 30-2 ■ Relationship of free and carrier-bound hormone.

form. Hormones secreted by endocrine cells must be inactivated continuously to prevent their accumulation. Intracellular and extracellular mechanisms participate in the termination of hormone function. Some hormones are enzymatically inactivated at receptor sites where they exert their action. The catecholamines, which have a very short half-life, are degraded by catechol-O-methyl transferase (COMT) and monoamine oxidase (MAO). Because of their short half-life, their production is measured by some of their metabolites. In general, peptide hormones also have a short life span in the circulation. Their major mechanism of degradation is through binding to cell surface receptors, with subsequent uptake and degradation by enzymes in the cell membrane or inside the cell. Peptide hormones have a short life span and are inactivated by enzymes that split peptide bonds. Steroid hormones are bound to protein carriers for transport and are inactive in the bound state. Their activity depends on the availability of transport carriers. Unbound adrenal and gonadal steroid hormones are conjugated in the liver, which renders them inactive, and then excreted in the bile or urine. Thyroid hormones also are transported by carrier molecules. The free hormone is rendered inactive by the removal of amino acids (*i.e.*, deamination) in the tissues, and the hormone is conjugated in the liver and eliminated in the bile.

TABLE 30-2 Classes of Hormones Based on Structure				
Amines and Amin	o Acids	Peptides, Polypeptides, and Proteins	Steroids	Fatty Acid Compounds
Dopamine Epinephrine Norepinephrine Thyroid hormone		Corticotropin-releasing hormone (CRH) Growth hormone–releasing hormone (GHRH) Thyrotropin-releasing hormone (TRH) Adrenocorticotropic hormone (ACTH) Follicle-stimulating hormone (FSH) Luteinizing hormone (LH) Thyroid-stimulating hormone (TSH) Growth hormone (GH) Antidiuretic hormone (ADH) Oxytocin Insulin Glucagon Somatostatin Calcitonin Parathyroid hormone	Aldosterone Glucocorticoids Estrogens Testosterone Progesterone Androstenedione 1,25-Dihydroxyvitamin D Dihydrotestosterone (DHT) Dehydroepiandrosterone (DHEA)	Eicosanoids Retinoids

Mechanisms of Action

Hormones produce their effects through interaction with highaffinity receptors, which in turn are linked to one or more effector systems within the cell. These mechanisms involve many of the cell's metabolic activities, ranging from ion transport at the cell surface to stimulation of nuclear transcription of complex molecules. The rate at which hormones react depends on their mechanism of action. The neurotransmitters, which control the opening of ion channels, have a reaction time of milliseconds. Thyroid hormone, which functions in the control of cell metabolism and synthesis of intracellular signaling molecules, requires days for its full effect to occur.

Receptors. Hormones exert their action by binding to highaffinity receptors located either on the surface or inside the target cells. The function of these receptors is to recognize a specific hormone and translate the hormonal signal into a cellular response. The structure of these receptors varies in a manner that allows target cells to respond to one hormone and not to others. For example, receptors in the thyroid are specific for thyroid-stimulating hormone, and receptors on the gonads respond to the gonadotropic hormones.

The response of a target cell to a hormone varies with the *number* of receptors present and with the *affinity* of these receptors for hormone binding. A variety of factors influence the number of receptors that are present on target cells and their affinity for hormone binding.

There are approximately 2000 to 100,000 hormone receptor molecules per cell. The number of hormone receptors on a cell may be altered for any of several reasons. Antibodies may destroy or block the receptor proteins. Increased or decreased hormone levels often induce changes in the activity of the genes that regulator receptor synthesis. For example, decreased hormone levels often produce an increase in receptor numbers by means of a process called *up-regulation*; this increases the sensitivity of the body to existing hormone levels. Likewise, sustained levels of excess hormone often bring about a decrease in receptor numbers by down-regulation, producing a decrease in hormone sensitivity. In some instances, the reverse effect occurs, and an increase in hormone levels appears to recruit its own receptors, thereby increasing the sensitivity of the cell to the hormone. The process of up-regulation and down-regulation of receptors is regulated largely by inducing or repressing the transcription of receptor genes.

The affinity of receptors for binding hormones also is affected by a number of conditions. For example, the pH of the body fluids plays an important role in the affinity of insulin receptors. In ketoacidosis, a lower pH reduces insulin binding.

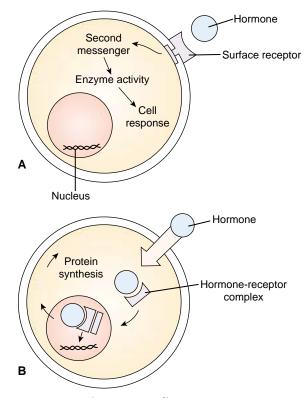

Some hormone receptors are located on the surface of the cell and act through second messenger mechanisms, and others are located within the cell, where they modulate the synthesis of enzymes, transport proteins, or structural proteins. The receptors for thyroid hormones, which are found in the nucleus, are thought to be directly associated with controlling the activity of genes located on one or more of the chromosomes. Chart 30-1 lists hormones that act through the two types of receptors.

Surface Receptors. Because of their low solubility in the lipid layer of cell membranes, peptide hormones and catecholamines cannot readily cross the cell membrane. Instead, these hormones interact with surface receptors in a manner that in-

CHART 30-1 Hormone–Receptor Interactions					
Surface (Second Messenger) Receptors					
Glucagon Insulin Epinephrine Parathyroid hormone Thyroid-stimulating hormone (TSH) Adrenocorticotropic hormone (ACTH) Follicle-stimulating hormone (FSH) Luteinizing hormone (LH) Antidiuretic hormone (ADH) Secretin					
Intracellular Interactions					
Estrogens Testosterone Progesterone Adrenal cortical hormones Thyroid hormones					

cites the generation of an intracellular signal or message. The intracellular signal system is termed the *second messenger*, and the hormone is considered to be the first messenger (Fig. 30-3). For example, the first messenger glucagon binds to surface receptors on liver cells to incite glycogen breakdown by way of the second messenger system.

The most widely distributed second messenger is cyclic adenosine monophosphate (cAMP). cAMP is formed from

■ FIGURE 30-3 ■ The two types of hormone-receptor interactions: the surface receptor (A) and the intracellular receptor (B).

534 Unit Eight: Alterations in the Endocrine System

cellular adenosine triphosphate (ATP) by the enzyme adenylate cyclase, a membrane-bound enzyme that is located on the inner aspect of the cell membrane. Adenylate cyclase is functionally coupled to various cell surface receptors by the regulatory actions of G proteins (see Chapter 1 and Fig. 1-12). A second messenger similar to cAMP is cyclic GMP, derived from guanine triphosphate (GTP). As a result of binding to specific cell receptors, many peptide hormones incite a series of enzymatic reactions that produce an almost immediate increase in cAMP. Some hormones act to decrease cAMP levels and have an opposite effect.

In some cells, the binding of hormones or neurotransmitters to surface receptors acts directly, rather than through a second messenger, to open ion channels in the cell membrane. The influx of ions serves as an intracellular signal to convey the hormonal message to the cell interior. In many instances, the activation of hormone receptors results in the opening of calcium channels. The increasing cytoplasmic concentration of calcium may result in direct activation of calcium-dependent enzymes or calcium-calmodulin complexes with their attendant effects.

Intracellular Receptors. A second type of receptor mechanism is involved in mediating the action of hormones such as the steroid and thyroid hormones (see Fig. 30-3). These hormones are lipid soluble and pass freely through the cell membrane. They then attach to intracellular receptors and form a hormone-

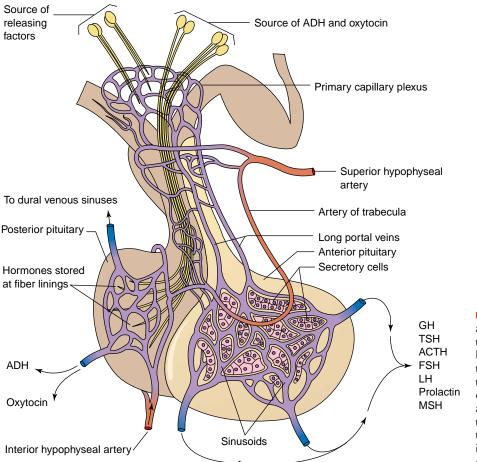

receptor complex that travels to the cell nucleus. The hormonemessenger complex then activates or suppresses intracellular mechanisms such as gene activity, with subsequent production or inhibition of messenger RNA and protein synthesis.

Control of Hormone Levels

Hormone secretion varies widely during a 24-hour period. Some hormones, such as growth hormone (GH) and adrenocorticotropic hormone (ACTH), have diurnal fluctuations that vary with the sleep-wake cycle. Others, such as the female sex hormones, are secreted in a complicated cyclic manner. The levels of hormones such as insulin and antidiuretic hormone (ADH) are regulated by feedback mechanisms that monitor substances such as glucose (insulin) and water (ADH) in the body. The levels of many of the hormones are regulated by feedback mechanisms that involve the hypothalamic-pituitary-target cell system.

Hypothalamic-Pituitary Regulation

The hypothalamus and pituitary (*i.e.*, hypophysis) form a unit that exerts control over many functions of several endocrine glands as well as a wide range of other physiologic functions. These two structures are connected by blood flow in the hypophyseal portal system, which begins in the hypothalamus and drains into the anterior pituitary gland, and by the nerve axons that connect the supraoptic and paraventricular nuclei of the hypothalamus with the posterior pituitary gland (Fig. 30-4).

■ FIGURE 30-4 ■ The hypothalamus and the anterior and posterior pituitary. The hypothalamic releasing or inhibiting hormones are transported to the anterior pituitary by way of the portal vessels. ADH and oxytocin are produced by nerve cells in the supraoptic and paraventricular nuclei of the hypothalamus and then transported through the nerve axon to the posterior pituitary, where they are released into the circulation. The pituitary is enclosed in the bony sella turcica ("Turkish saddle") and is bridged by the diaphragma sellae. Embryologically, the anterior pituitary gland developed from glandular tissue and the posterior pituitary developed from neural tissue.

Hypothalamic Hormones. The synthesis and release of anterior pituitary hormones are largely regulated by the action of releasing or inhibiting hormones from the hypothalamus, which is the coordinating center of the brain for endocrine, behavioral, and autonomic nervous system function. It is at the level of the hypothalamus that emotion, pain, body temperature, and other neural input are communicated to the endocrine system (Fig. 30-5). The posterior pituitary hormones, ADH and oxytocin, are synthesized in the cell bodies of neurons in the hypothalamus that have axons that travel to the posterior pituitary. The release and function of ADH are discussed in Chapter 31.

The hypothalamic hormones that regulate the secretion of anterior pituitary hormones include GH-releasing hormone (GHRH), somatostatin, dopamine, thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH), and gonadotropin-releasing hormone (GnRH). With the exception of GH and prolactin, most of the pituitary hormones are regulated by hypothalamic stimulatory hormones. GH secretion is stimulated by GHRH; thyroid-stimulating hormone (TSH) by TRH; ACTH by CRH; and luteinizing hormone (LH) and FSH

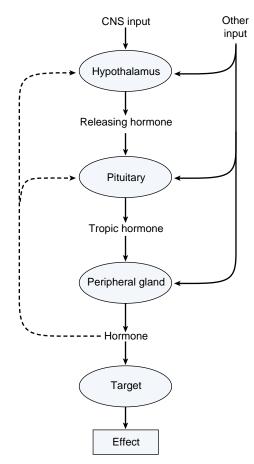

FIGURE 30-5 Hypothalamic-pituitary control of hormone levels. The dashed line represents feedback control.

by GnRH. Somatostatin functions as an inhibitory hormone for GH and TSH. Prolactin secretion is inhibited by dopamine; thus, persons receiving antipsychotic drugs that block dopamine often have increased prolactin levels.

The activity of the hypothalamus is regulated by both hormonally mediated signals (e.g., negative feedback signals) and by neuronal input from a number of sources. Neuronal signals are mediated by neurotransmitters such as acetylcholine, dopamine, norepinephrine, serotonin, γ -aminobutyric acid, and opioids. Cytokines that are involved in immune and inflammatory responses, such as the interleukins, also are involved in the regulation of hypothalamic function. This is particularly true of the hormones involved in the hypothalamic-pituitaryadrenal axis. Thus, the hypothalamus can be viewed as a bridge by which signals from multiple systems are relayed to the pituitary gland.

Pituitary Hormones. The pituitary gland has been called the master gland because its hormones control the functions of many target glands and cells. Hormones produced by the anterior pituitary control body growth and metabolism (GH), function of the thyroid gland (TSH), glucocorticoid hormone levels (ACTH), function of the gonads (FSH and LH), and breast growth and milk production (prolactin). Melanocyte-stimulating hormone, which is involved in the control of pigmentation of the skin, is produced by the pars intermedia of the pituitary gland. The functions of many of these hormones are discussed in other parts of this book (e.g., thyroid hormone, GH, and the corticosteroids in Chapter 31, the sex hormones in Chapters 33 and 34, and ADH from the posterior pituitary in Chapter 6).

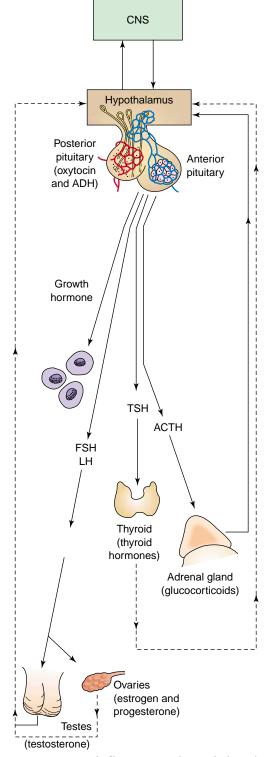

Feedback Regulation

The level of many of the hormones in the body is regulated by negative feedback mechanisms. The function of this type of system is similar to that of the thermostat in a heating system. In the endocrine system, sensors detect a change in the hormone level and adjust hormone secretion so that body levels are maintained within an appropriate range. When the sensors detect a decrease in hormone levels, they initiate changes that cause an increase in hormone production; when hormone levels rise above the set point of the system, the sensors cause hormone production and release to decrease. For example, an increase in thyroid hormone is detected by sensors in the hypothalamus or anterior pituitary gland, and this causes a reduction in the secretion of TSH, with a subsequent decrease in the output of thyroid hormone from the thyroid gland. The feedback loops for the hypothalamic-pituitary feedback mechanisms are illustrated in Figures 30-5 and 30-6.

Exogenous forms of hormones (given as drug preparations) can influence the normal feedback control of hormone production and release. One of the most common examples of this influence occurs with the administration of the corticosteroid hormones, which causes suppression of the hypothalamicpituitary-target cell system that regulates the production of these hormones.

Although the levels of most hormones are regulated by negative feedback mechanisms, a small number are under positive feedback control, in which increasing levels of a hormone cause another gland to release a hormone that is stimulating to the first. However, there must be a mechanism for shutting off the release of the first hormone, or its production would

■ FIGURE 30-6 ■ Control of hormone production by hypothalamicpituitary-target cell feedback mechanism. Hormone levels from the target glands regulate the release of hormones from the anterior pituitary by means of a negative feedback system. The *dashed line* represents feedback control.

continue unabated. An example of such a system is that of the female ovarian hormone estradiol. Increased estradiol production during the follicular stage of the menstrual cycle causes increased gonadotropin (FSH) production by the anterior pituitary gland. This stimulates further increases in estradiol levels until the demise of the follicle, which is the source of estradiol, results in a decrease in gonadotropin levels.

In addition to positive and negative feedback mechanisms that monitor changes in hormone levels, some hormones are regulated by the level of the substance they regulate. For example, insulin levels normally are regulated in response to blood glucose levels and those of aldosterone in response to body levels of sodium and potassium. Other factors such as stress, environmental temperature, and nutritional status can alter feedback regulation of hormone levels.

Diagnostic Tests

Several techniques are available for assessing endocrine function and hormone levels. One technique measures the effect of a hormone on body function. For example, measurement of blood glucose reflects insulin levels and is an indirect method of assessing insulin availability. Another method is to measure hormone levels.

Blood Tests

Hormones circulating in the plasma were first detected by bioassays using the intact animal or a portion of tissue from the animal. At one time, female rats or male frogs were used to test women's urine for the presence of human chorionic gonadotropin, which is produced by the placenta during pregnancy. Unfortunately, most bioassays lack the precision, sensitivity, and specificity to measure low concentrations of hormones in plasma, and they are inconvenient to perform.

Blood hormone levels provide information about hormone levels at a specific time. For example, blood insulin levels can be measured along with blood glucose after administration of a challenge dose of glucose to measure the time course of change in blood insulin levels.

Real progress in measuring plasma hormone levels came more than 40 years ago with the use of competitive binding and the development of radioimmunoassay (RIA) methods. This method uses a radiolabeled form of the hormone and a hormone antibody that has been prepared by injecting an appropriate animal with a purified form of the hormone. The unlabeled hormone in the sample being tested competes with the radiolabeled hormone for attachment to the binding sites of the antibody. Measurement of the radiolabeled hormoneantibody complex then provides a means of arriving at a measure of the hormone level in the sample. Because hormone binding is competitive, the amount of radiolabeled hormoneantibody complex that is formed decreases as the amount of unlabeled hormone in the sample is increased. Newer techniques of RIA have been introduced, including the immunoradiometric assay (IRMA). IRMA uses two antibodies instead of one. These two antibodies are directed against two different parts of the molecule, so IRMA assays are more specific. RIA has several disadvantages, including limited shelf-life of the radiolabeled hormone and the cost for the disposal of radioactive waste.

Nonradiolabeled methods have been developed in which the antigen of the hormone being measured is linked to an enzyme-activated label (*e.g.*, fluorescent label, chemiluminescent label) or latex particles that can be agglutinated with an antigen and measured. The enzyme-linked immunosorbent assays (ELISA) use antibody-coated plates and an enzyme-labeled reporter antibody. Binding of the hormone to the enzymelabeled reporter antibody produces a colored reaction that can be measured using a spectrophotometer.

Urine Tests

Measurements of urinary hormone or hormone metabolite excretion often are done on a 24-hour urine sample and provide a better measure of hormone levels during that period than hormones measured in an isolated blood sample. The advantages of a urine test include the relative ease of obtaining urine samples and the fact that blood sampling is not required. The disadvantage is that reliably timed urine collections often are difficult to obtain. For example, a person may be unable to urinate at specific timed intervals, and urine samples may be accidentally discarded or inaccurately preserved. Because many urine tests involve the measure of a hormone metabolite. rather than the hormone itself, drugs or disease states that alter hormone metabolism may interfere with the test result. Some urinary hormone metabolite measurements include hormones from more than one source and are of little value in measuring hormone secretion from a specific source. For example, urinary 17-ketosteroids are a measure of both adrenal and gonadal androgens.

Stimulation and Suppression Tests

Stimulation tests are used when hypofunction of an endocrine organ is suspected. A tropic or stimulating hormone can be administered to test the capacity of an endocrine organ to increase hormone production. The capacity of the target gland to respond is measured by an increase in the appropriate hormone. For example, the function of the hypothalamic-pituitarythyroid system can be evaluated through stimulation tests using TRH and measuring TSH response. Failure to effect an increase in TSH after a TRH stimulation test suggests inadequate production of TSH by the pituitary.

Suppression tests are used to determine if negative feedback control mechanisms are intact. For example, a glucocorticoid hormone can be administered to persons suspected of having hypercortisolism to assess the capacity to inhibit CRH.

Genetic Tests

Deoxyribonucleic acid (DNA) analysis is being increasingly used for the identification of affected family members in a kindred harboring a known mutation (*e.g.*, looking for the RET protooncogene in certain multiple endocrine neoplasia syndromes).

Imaging

Imaging studies are gaining increasing importance in the diagnosis and follow-up of endocrine diseases. Magnetic resonance imaging (MRI) and computed tomography scans are especially useful for imaging endocrine glands and endocrine tumors. Nuclear scanning also is widely used for assessing thyroid, parathyroid, and adrenal disorders. Ultrasound scanning is recommended for managing thyroid nodules. Positron emission tomography scanning is being used more widely for parathyroid detection after failed parathyroid surgery for hyperparathyroidism.

In summary, the endocrine system acts as a communication system that uses chemical messengers, or hormones, for the transmission of information from cell to cell and from organ to organ. Hormones act by binding to receptors that are specific for the different types of hormones. Many of the endocrine glands are under the regulatory control of other parts of the endocrine system. The hypothalamus and the pituitary gland form a complex integrative network that joins the nervous system and the endocrine system; this central network controls the output from many of the other glands in the body.

Endocrine function can be assessed directly by measuring hormone levels or indirectly by assessing the effects that a hormone has on the body (*e.g.*, assessment of insulin function through blood glucose). Imaging techniques are increasingly used to visualize endocrine structures, and genetic techniques are used to determine the presence of genes that contribute to the development of endocrine disorders.

REVIEW QUESTIONS

Characterize a hormone.

- State a difference between the synthesis of protein hormones and that of steroid hormones.
- Describe mechanisms of hormone transport and inactivation.

State the function of a hormone receptor, and state the difference between cell surface hormone receptors and intracellular hormone receptors.

Describe the role of the hypothalamus in regulating pituitary control of endocrine function.

- **State** the major difference between positive and negative feedback control mechanisms.
- Describe methods used in the diagnosis of endocrine disorders.

he endocrine system affects all aspects of body function, including growth and development, energy metabolism, muscle and adipose tissue distribution, sexual development, fluid and electrolyte balance, and inflammation and immune responses. This chapter focuses on disorders of pituitary function, growth and growth hormone levels, thyroid function, and adrenocortical function.

GENERAL ASPECTS OF ALTERED ENDOCRINE FUNCTION

Hypofunction and Hyperfunction

Disturbances of endocrine function usually can be divided into two categories: hypofunction and hyperfunction. Hypofunction of an endocrine gland can occur for a variety of reasons. Congenital defects can result in the absence or impaired development of the gland or the absence of an enzyme needed for hormone synthesis. The gland may be destroyed by a disruption in blood flow, infection, inflammation, autoimmune responses, or neoplastic growth. There may be a decline in function with aging, or the gland may atrophy as the result of drug therapy or for unknown reasons. Some endocrine-deficient states are associated with receptor defects: hormone receptors may be absent, the receptor binding of hormones may be defective, or the cellular response to the hormone may be impaired. It is suspected that in some cases a gland may produce a biologically inactive hormone or that an active hormone may be destroyed by circulating antibodies before it can exert its action.

Hyperfunction usually is associated with excessive hormone production. This can result from excessive stimulation and hyperplasia of the endocrine gland or from a hormoneproducing tumor of the gland. An ectopic tumor can produce hormones; for example, certain bronchogenic tumors produce hormones such as antidiuretic hormone (ADH) and adrenocorticotropic hormone (ACTH).

Primary, Secondary, and Tertiary Disorders

Endocrine disorders in general can be divided into primary, secondary, and tertiary groups. *Primary defects* in endocrine function originate in the target gland responsible for producing the hormone. In *secondary disorders* of endocrine function, the target gland is essentially normal, but its function is altered by defective levels of stimulating hormones or releasing factors from the pituitary system. For example, adrenalectomy produces a primary deficiency of adrenal corticosteroid hormones. Removal or destruction of the pituitary gland eliminates ACTH stimulation of the adrenal cortex and brings about a secondary deficiency. A *tertiary disorder* results from hypothalamic dysfunction (as may occur with craniopharyngiomas or cerebral irradiation); thus, both the pituitary and target organ are understimulated.

In summary, endocrine disorders are the result of hypofunction or hyperfunction of an endocrine gland. They can occur as a primary defect in hormone production by a target gland or as a secondary or tertiary disorder resulting from a defect in the hypothalamic-pituitary system that controls a target gland's function.

PITUITARY AND GROWTH HORMONE DISORDERS

The anterior lobe of the pituitary gland produces ACTH, thyroid stimulating hormone (TSH), growth hormone (GH), the gonadotrophic hormones (follicle stimulating hormone [FSH] and luteinizing hormone [LH]), and prolactin (see Chapter 30, Fig. 30-4). Four of these, ACTH, TSH, LH, and FSH control the secretion of hormones from other endocrine glands. ACTH controls the release of cortisol from the adrenal gland and TSH the secretion of thyroid hormone from the thyroid gland; LH regulates sex hormones, and FSH regulates fertility.

Hypopituitarism

Hypopituitarism, which is characterized by a decreased secretion of pituitary hormones, is a condition that affects many of the other endocrine systems. Typically, 70% to 90% of the anterior pituitary must be destroyed before hypopituitarism becomes clinically evident.¹ The cause may be congenital or result from a variety of acquired abnormalities (Chart 31-1). The manifestations of hypopituitarism usually occur gradually, but it can present as an acute and life-threatening condition. Patients usually report being chronically unfit, with weakness, fatigue, loss of appetite, impairment of sexual function, and

CHART 31-1 Causes of Hypopituitarism

- Tumors and mass lesions—pituitary adenomas, cysts, metastatic cancer, and other lesions
- Pituitary surgery or radiation
- Infiltrative lesions and infections—hemochromatosis, lymphocytic hypophysitis
- Pituitary infarction—infarction of the pituitary gland after substantial blood loss during childbirth (Sheehan's syndrome)
- Pituitary apoplexy—sudden hemorrhage into the pituitary gland
- Genetic diseases—rare congenital defects of one or more pituitary hormones
- Empty sella syndrome—an enlarged sella turcica that is not entirely filled with pituitary tissue
- Hypothalamic disorders—tumors and mass lesions (*e.g.*, craniopharyngiomas and metastatic malignancies), hypothalamic radiation, infiltrative lesions (*e.g.*, sarcoidosis), trauma, infections

cold intolerance. However, ACTH deficiency (secondary adrenal failure) is the most serious endocrine deficiency, leading to weakness, nausea, anorexia, fever, and postural hypotension. Hypopituitarism is associated with increased morbidity and mortality.

Anterior pituitary hormone loss tends to follow a typical sequence, especially with progressive loss of pituitary reserve caused by tumors or previous pituitary radiation therapy (which may take 10 to 20 years to produce hypopituitarism). Usually GH secretion is lost first, then LH and FSH, followed by TSH deficiency. ACTH is usually the last to become deficient.

Treatment of hypopituitarism includes treating any identified underlying cause. Hormone deficiencies are treated with replacement of the target gland hormone. Cortisol replacement is started when ACTH deficiency is present; thyroid replacement when TSH deficiency is detected; and sex hormone replacement when LH and FSH are deficient. GH replacement is being used increasingly to treat GH deficiency.

Growth and Growth Hormone Disorders

Several hormones are essential for normal body growth and maturation, including growth hormone (GH), insulin, thyroid hormone, and androgens. In addition to its actions on carbohydrate and fat metabolism, insulin plays an essential role in growth processes. Children with diabetes, particularly those with poor control, often fail to grow normally even though GH levels are normal. When levels of thyroid hormone are lower than normal, bone growth and epiphyseal closure are delayed. Androgens such as testosterone and dihydrotestosterone exert anabolic growth effects through their actions on protein synthesis. Glucocorticoids at excessive levels inhibit growth, apparently because of their antagonistic effect on GH secretion.

Growth Hormone

Growth hormone, also called *somatotropin*, is a 191-aminoacid polypeptide hormone synthesized and secreted by special cells in the anterior pituitary called *somatotropes*. For many

540 Unit Eight: Alterations in the Endocrine System

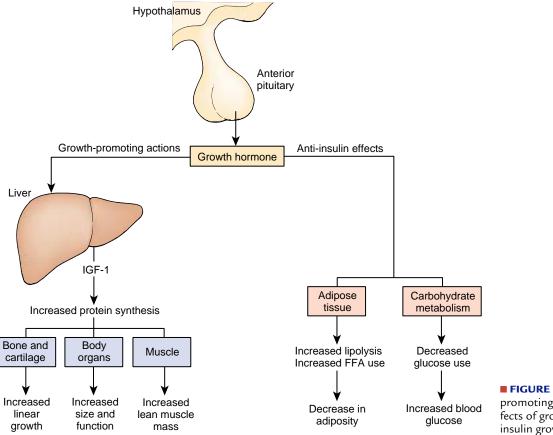

years, it was thought that GH was produced primarily during periods of growth. However, this has proved to be incorrect because the rate of GH production in adults is almost as great as in children. GH is necessary for growth and contributes to the regulation of metabolic functions (Fig. 31-1).^{2,3} All aspects of cartilage growth are stimulated by GH; one of the most striking effects of GH is on linear bone growth, resulting from its action on the epiphyseal growth plates of long bones. The width of bone increases because of enhanced periosteal growth; visceral and endocrine organs, skeletal and cardiac muscle, skin, and connective tissue all undergo increased growth in response to GH. In many instances, the increased growth of visceral and endocrine organs is accompanied by enhanced functional capacity. For example, increased growth of cardiac muscle is accompanied by an increase in cardiac output.

In addition to its effects on growth, GH facilitates the rate of protein synthesis by all of the cells of the body; it enhances fatty acid mobilization and increases the use of fatty acids for fuel; and it maintains or increases blood glucose levels by decreasing the use of glucose for fuel. GH has an initial effect of increasing insulin levels. However, the predominant effect of prolonged GH excess is to increase glucose levels despite an insulin increase. This is because GH induces a resistance to insulin in the peripheral tissues, inhibiting the uptake of glucose by muscle and adipose tissues.

Many of the effects of GH depend on a family of peptides called *insulin-like growth factors* (IGF), also called *somatomedins*, which are produced mainly by the liver. GH cannot directly produce bone growth; instead, it acts indirectly by causing the liver to produce IGF. These peptides act on cartilage and bone to promote their growth. At least four IGFs have been identified; of these, IGF-1 appears to be the more important in terms of growth, and it is the one that usually is measured in laboratory tests. The IGFs have been sequenced and have structures that are similar to that of proinsulin. This undoubtedly explains the insulin-like activity of the IGFs and the weak action of insulin on growth. IGF levels are themselves influenced by a family of at least six binding factors called *IGF-binding proteins* (IGFBPs).

GH is carried unbound in the plasma and has a half-life of approximately 20 to 50 minutes. The secretion of GH is regulated by two hypothalamic hormones: GH-releasing hormone (GHRH), which increases GH release, and somatostatin, which inhibits GH release. A third hormone, the recently identified ghrelin, also may be important. These hypothalamic influences (*i.e.*, GHRH and somatostatin) are tightly regulated by neural, metabolic, and hormonal factors. The secretion of GH fluctuates during a 24-hour period, with peak levels occurring 1 to 4 hours after onset of sleep (*i.e.*, during sleep stages 3 and 4). The nocturnal sleep bursts, which account for 70% of daily GH secretion, are greater in children than in adults.⁴

GH secretion is stimulated by hypoglycemia, fasting, starvation, increased blood levels of amino acids (particularly arginine), and stress conditions such as trauma, excitement, emotional stress, and heavy exercise. GH is inhibited by increased glucose levels, free fatty acid release, cortisol, and obesity. Impairment of secretion, leading to growth retardation, is not uncommon in children with severe emotional deprivation.

■ FIGURE 31-1 ■ Growthpromoting and anti-insulin effects of growth hormone. IGF-1, insulin growth factor 1.

KEY CONCEPTS

GROWTH HORMONE

Growth hormone (GH), which is produced by somatotropes in the anterior pituitary, is necessary for linear bone growth in children. It also stimulates cells to increase in size and divide more rapidly; it enhances amino acid transport across cell membranes and increases protein synthesis; and it increases the rate at which cells use fatty acids and decreases the rate at which they use carbohydrates.

The effects of GH on cartilage growth require insulin-like growth factors (IGFs), also called somatomedins, which are produced mainly by the liver.

In children, GH deficiency interferes with linear bone growth, resulting in short stature or dwarfism. In a rare condition called Laron-type dwarfism, GH levels are normal or elevated, but there is a hereditary defect in IGF production.

GH excess in children results in increased linear bone growth, or gigantism. In adults, GH excess results in overgrowth of the cartilaginous parts of the skeleton, enlargement of the heart and other organs of the body, and metabolic disturbances resulting in altered fat metabolism and impaired glucose tolerance.

Short Stature and Growth Hormone Deficiency in Children

Short stature is a condition in which the attained height is well below the fifth percentile or linear growth is below normal for age and gender. Short stature, or growth retardation, has a variety of causes, including chromosomal abnormalities such as Turner's syndrome (see Chapter 4), GH deficiency, hypothyroidism, and panhypopituitarism. Other conditions known to cause short stature include protein-calorie malnutrition, chronic diseases such as renal failure and poorly controlled diabetes mellitus, malabsorption syndromes, and certain therapies such as corticosteroid administration. Emotional disturbances can lead to functional endocrine disorders, causing psychosocial dwarfism. The causes of short stature are summarized in Chart 31-2.

Accurate measurement of height is an extremely important part of the physical examination of children. Completion of the developmental history and growth charts is essential. Growth curves and growth velocity studies also are needed. Diagnosis of short stature is not made on a single measurement but is based on actual height and on velocity of growth and parental height. The diagnostic procedures for short stature include tests to exclude nonendocrine causes. Extensive hormonal testing procedures are initiated in cases where an endocrine cause is suspected. Usually, tests to determine GH and IGF-1 levels are done. Radiologic films are used to assess bone age, which most

CHART 31-2 Causes of Short Stature

Variants of Normal

Chronic Illness and Malnutrition

Chronic organic or systemic disease (e.g., asthma, especially when treated with glucocorticoids; heart or renal disease) Nutritional deprivation Malabsorption syndrome

Functional Endocrine Disorders (Psychosocial Dwarfism)

Chromosomal Disorders (e.g., Turner's Syndrome)

Skeletal Abnormalities (e.g., achondroplasia)

often is delayed. Lateral skull x-rays may be used to evaluate the size and shape of the sella turcica (*i.e.*, depression in the sphenoid bone that contains the pituitary gland) and determine if a pituitary tumor exists. Magnetic resonance imaging (MRI) or computed axial tomography (CT) scans of the hypothalamicpituitary area may be done if a pituitary lesion is suspected. After the cause of short stature has been determined, treatment can be initiated.

Genetic and Constitutional Short Stature. Two forms of short stature, genetic short stature and constitutional short stature, are not disease states but variations from population norms.⁵ Genetically short children tend to be well proportioned and to have a height close to the midparental height of their parents. The midparental height for boys can be calculated by adding 13 cm (5 inches) to the height of the mother, adding the father's height, and dividing the total by two. For girls, 13 cm (5 inches) is subtracted from the father's height, the result is added to the mother's height, and the total is divided by two. Ninety-five percent of normal children are within 8.5 cm of the midparental height.

Constitutional short stature is a term used to describe children (particularly boys) who have moderately short stature, thin

542 Unit Eight: Alterations in the Endocrine System

build, delayed skeletal and sexual maturation, and absence of other causes of decreased growth. *Catch-up growth* is a term used to describe an abnormally high growth rate that occurs as a child approaches normal height for age. It occurs after the initiation of therapy for GH deficiency and hypothyroidism and the correction of chronic diseases.

Psychosocial Dwarfism. Psychosocial dwarfism involves a functional hypopituitarism and is seen in some emotionally deprived children. These children usually present with poor growth, potbelly, and poor eating and drinking habits.^{5,6} Typically, there is a history of disturbed family relationships in which the child has been severely neglected or disciplined. Often, the neglect is confined to one child in the family. GH function usually returns to normal after the child is removed from the constraining environment. The prognosis depends on improvement in behavior and catch-up growth. Family therapy usually is indicated, and foster care may be necessary.

Growth Hormone Deficiency in Children. There are seseveral forms of GH deficiency that present in childhood. Children with idiopathic GH deficiency lack the hypothalamic GHRH but have adequate somatotropes, whereas children with pituitary tumors or agenesis of the pituitary lack somatotropes. The term *panhypopituitarism* refers to conditions that cause a deficiency of all of the anterior pituitary hormones. In a rare condition called *Laron-type dwarfism*, GH levels are normal or elevated, but there is a hereditary defect in IGF production that can be treated directly with IGF-1 replacement.⁷

Congenital GH deficiency is associated with normal birth length, followed by a decrease in growth rate that can be identified by careful measurement during the first year and that becomes obvious by 1 to 2 years of age. Persons with classic GH deficiency have normal intelligence, short stature, obesity with immature facial features, and some delay in skeletal maturation (Fig. 31-2). Puberty often is delayed, and males with the disorder have microphallus (abnormally small penis), especially if the condition is accompanied by gonadotropinreleasing hormone (GnRH) deficiency. In the neonate, GH deficiency can lead to hypoglycemia and seizures; if adrenocorticotropic hormone (ACTH) deficiency also is present, the hypoglycemia often is more severe. Acquired GH deficiency develops in later childhood; it may be caused by a hypothalamicpituitary tumor, particularly if it is accompanied by other pituitary hormone deficiencies.

When short stature is due to a GH deficiency, GH replacement therapy is the treatment of choice. GH is species specific, and only human GH (hGH) is effective in humans. Human GH, which is synthesized by recombinant DNA techniques, is now available in adequate supply. It is administered subcutaneously in multiple weekly doses during the period of active growth, and its use can be continued into adulthood.

Children with short stature due to Turner's syndrome and chronic renal insufficiency also are treated with hGH.⁸ hGH therapy may be considered for children with short stature but without GH deficiency. Several studies suggest that short-term treatment with GH increases the rate of growth in these children. Although the effect of GH on adult height is not great, it can result in improved psychological well-being. There are concerns about misuse of the drug to produce additional growth in children with normal GH function who are of near-

normal height. Guidelines for use of the hormone continue to be established.

Growth Hormone Deficiency in Adults

There are two categories of GH deficiency in adults: (1) GH deficiency that was present in childhood, and (2) GH deficiency that developed during adulthood, mainly as the result of hypopituitarism resulting from a pituitary tumor or its treatment. GH levels also can decline with aging, and there has been interest in the effects of declining GH levels in the elderly (described as the *somatopause*).

Several studies have shown that cardiovascular mortality is increased in GH-deficient adults.⁹ Increased arterial intimamedia thickness and a higher prevalence of atherosclerotic plaques and endothelial dysfunction have been reported in both childhood and adult GH deficiency. The GH deficiency syndrome is associated with a cluster of cardiovascular risk factors, including central adiposity (increased waist-hip ratio), increased visceral fat, insulin resistance, and dyslipidemia. These features also are associated with the *metabolic syndrome* (syndrome X; see Chapter 32). In addition to these so-called traditional cardiovascular risk factors, nontraditional cardiovascular risk factors (*e.g.*, C-reactive protein and interleukin-6, which are markers of the inflammatory pathway) also are elevated.

The diagnosis of GH deficiency in adults is made by finding subnormal serum GH responses to two stimulation tests that measure GH reserve. Measurements of the serum IGF-1 or basal GH do not distinguish reliably between normal and subnormal GH secretion in adults. Insulin-induced hypoglycemia is the gold standard test for GH reserve. The L-dopa test probably is the next best test. Other stimulation tests involve the use of arginine or arginine plus GHRH, clonidine (an α -adrenergic agonist), glucagon, or GHRH.

GH replacement obviously is important in the growing child; however, the role in adults (especially for the somato-

pause) is being assessed. Adults with documented GH deficiency may be treated with hGH. In the United States, persons with GH deficiency acquired as an adult must meet at least two criteria for therapy: a poor GH response to at least two standard stimuli, and hypopituitarism caused by pituitary or hypothalamic damage.⁸

Tall Stature and Growth Hormone Excess in Children

Tall Stature. Just as there are children who are short for their age and sex, there also are children who are tall for their age and sex. Normal variants of tall stature include genetic tall stature and constitutional tall stature. Children with exceptionally tall parents tend to be taller than children with shorter parents. The term *constitutional tall stature* is used to describe a child who is taller than his or her peers and is growing at a velocity that is within the normal range for bone age.^{5,10} Other causes of tall stature are genetic or chromosomal disorders, such as Marfan's syndrome or XYY syndrome (see Chapter 4). Endocrine causes of tall stature include sexual precocity because of early onset of estrogen and androgen secretion and excessive GH.

Exceptionally tall children (*i.e.*, genetic tall stature and constitutional tall stature) can be treated with sex hormones estrogens in girls and testosterone in boys—to effect early epiphyseal closure. Such treatment is undertaken only after full consideration of the risks involved. To be effective, such treatment must be instituted 3 to 4 years before expected epiphyseal fusion.

Gigantism. Growth hormone excess occurring before puberty and the fusion of the epiphyses of the long bones results in gigantism (Fig. 31-3). Excessive secretion of GH by somatotrope adenomas causes gigantism in the prepubertal child. It occurs when the epiphyses are not fused and high levels of IGF stimulate excessive skeletal growth. Fortunately, the condition is rare because of early recognition and treatment of the adenoma.

Growth Hormone Excess in Adults

When GH excess occurs in adulthood or after the epiphyses of the long bones have fused, the condition is referred to as *acromegaly*.¹¹ Acromegaly results from excess levels of GH that stimulate the hepatic secretion of IGF-1, which causes most of the clinical manifestations of acromegaly. The annual incidence of acromegaly is 3 to 4 cases per 1 million people, with a mean age at the time of diagnosis of 40 to 45 years.

The most common cause of acromegaly is a somatotrope adenoma. Approximately 75% of persons with acromegaly have large expansive tumors that erode the sella turcica and impinge on adjacent cranial structures, and most of the remainder have small tumors contained within the pituitary gland. Other causes of acromegaly (<5%) are excess secretion of GHRH by hypothalamic tumors, ectopic GHRH secretion by nonendocrine tumors such as carcinoid tumors or small cell lung cancers, and ectopic secretion of GH by nonendocrine tumors.

The disorder usually has an insidious onset, and symptoms often are present for a considerable period before a diagnosis is made. When the production of excessive GH occurs after the epiphyses of the long bones have closed, as in the adult, the person cannot grow taller, but the soft tissues continue to grow. Enlargement of the small bones of the hands and feet and of the membranous bones of the face and skull results in a pro-

nounced enlargement of the hands and feet, a broad and bulbous nose, a protruding lower jaw, and a slanting forehead. The teeth become splayed, causing a disturbed bite and difficulty in chewing. The cartilaginous structures in the larynx and respiratory tract also become enlarged, resulting in a deepening of the voice and tendency to develop bronchitis. Vertebral changes often lead to kyphosis, or hunchback. Bone overgrowth often leads to arthralgias and degenerative arthritis of the spine, hips, and knees. Virtually every organ of the body is increased in size. Enlargement of the heart and accelerated atherosclerosis may lead to an early death.

The metabolic effects of excess levels of GH include alterations in fat and carbohydrate metabolism. GH causes increased release of free fatty acids from adipose tissue, leading to increased concentration of free fatty acids in body fluids. In addition, GH enhances the formation of ketones and the utilization of free fatty acids for energy in preference to use of carbohydrates and proteins. GH exerts multiple effects on carbohydrate metabolism, including decreased glucose uptake by tissues such as skeletal muscle and adipose tissue, increased glucose production by the liver, and increased insulin secretion. Each of these changes results in GH-induced insulin resistance (see Chapter 32). This leads to glucose intolerance, which stimulates the beta cells of the pancreas to produce additional insulin. Long-term elevation of GH results in overstimulation of the beta cells, causing them literally to "burn out." Impaired glucose tolerance occurs in as many as 50% to 70% of persons with acromegaly; overt diabetes mellitus subsequently can result.

The pituitary gland is located in the pituitary fossa of the sphenoid bone (i.e., sella turcica), which lies directly below the optic nerve. Enlargement of the pituitary gland eventually causes erosion of the surrounding bone, and because of its location, this can lead to headaches, visual field defects resulting from compression of the optic nerve, and palsies of cranial nerves III, IV, and VI. Compression of other pituitary structures can cause secondary hypothyroidism, hypogonadism, and adrenal insufficiency. Other manifestations include excessive sweating with an unpleasant odor, oily skin, heat intolerance, moderate weight gain, muscle weakness and fatigue, menstrual irregularities, and decreased libido. Hypertension is relatively common. Paresthesias may develop because of nerve entrapment and compression caused by excess soft tissue and accumulation of subcutaneous fluid (especially carpal tunnel syndrome). Acromegaly also is associated with an increased risk of colonic polyps and colorectal cancer. The mortality rate of patients with acromegaly is two to three times the expected rate, mostly from cardiovascular diseases and cancer. The cardiovascular disease results from the combination of cardiomyopathy, hypertension, insulin resistance and hyperinsulinemia, and hyperlipidemia.

Acromegaly often develops insidiously, and only a small number of persons seek medical care because of changes in appearance. The diagnosis of acromegaly is facilitated by the typical features of the disorder—enlargement of the hands and feet and coarsening of facial features. Laboratory tests to detect elevated levels of GH not suppressed by a glucose load are used to confirm the diagnosis. CT and MRI scans can detect and localize the pituitary lesions. Because most of the effects of GH are mediated by IGF-1, IGF-1 levels may provide information about disease activity.

The treatment goals for acromegaly focus on the correction of metabolic abnormalities and include normalization of the GH response to an oral glucose load; normalization of IGF-1 levels to age- and gender-matched control levels; removal or reduction of the tumor mass; relieving the central pressure effects; improvement of adverse clinical features; and normalization of the mortality rate.¹² Pituitary tumors can be removed surgically using the transsphenoidal approach or, if that is not possible, a transfrontal craniotomy. Radiation therapy may be used, but remission (reduction in GH levels) may not occur for several years after therapy. Radiation therapy also significantly increases the risk of hypopituitarism, hypothyroidism, hypoadrenalism, and hypogonadism.⁵

Medications used for the treatment of acromegaly include the somatostatin analogs, which produce feedback inhibition of GH. Sustained-release preparations, which effectively inhibit GH secretion for 30 days after a single intramuscular injection, are now available.⁴

Isosexual Precocious Puberty

Sexual development is considered precocious and warrants investigation when it occurs before 8 years of age for girls and before 9 years of age for boys. Precocious sexual development may be idiopathic or may be caused by gonadal, adrenal, or hypothalamic tumors. True isosexual precocious puberty is caused by early activation of the hypothalamic-pituitary-gonadal axis. The gonadotropin-mediated increase in size and activity of the gonads leads to increasing sex hormone production with early development of sexual characteristics and fertility.^{13,14} Benign and malignant tumors of the central nervous system (CNS) can cause precocious puberty. These tumors are thought to remove the inhibitory influences normally exerted on the hypothalamus during childhood. Gonadotropin-independent causes of precocious puberty include functioning ovarian tumors and feminizing adrenal tumors in girls and congenital adrenal hyperplasia and Leydig cell tumors in boys.¹³

Diagnosis of precocious puberty is based on physical findings of early thelarche (*i.e.*, beginning of breast development), adrenarche (*i.e.*, beginning of augmented adrenal androgen production), and menarche (*i.e.*, beginning of menstrual function) in girls. The most common sign in boys is early genital enlargement. Radiologic findings may indicate advanced bone age. Persons with precocious puberty usually are tall for their age as children but short as adults because of the early closure of the epiphyses. CT or MRI should be used to exclude intracranial lesions.

Depending on the cause of precocious puberty, the treatment may involve surgery, medication, or no treatment. The treatment of choice for gonadotropin-dependent precocious puberty is administration of a long-acting GnRH agonist. Constant levels of the hormone cause a decrease in pituitary responsiveness to GnRH, leading to decreased secretion of gonadotropic hormones and sex steroids. Parents often need education, support, and anticipatory guidance in dealing with their feelings and the child's physical needs and in relating to a child who appears older than his or her years.

In summary, hypopituitarism, which is characterized by a decreased secretion of pituitary hormones, is a condition that affects many of the other endocrine systems. Depending on the extent of the disorder, it can result in decreased levels of GH, thyroid hormones, adrenal corticosteroid hormones, and testosterone in the male and of estrogens and progesterone in the female.

A number of hormones are essential for normal body growth and maturation, including GH, insulin, thyroid hormone, and androgens. GH exerts its growth effects through a group of IGFs. GH also exerts an effect on metabolism and is produced in the adult and in the child. Its metabolic effects include a decrease in peripheral use of carbohydrates and an increased mobilization and use of fatty acids.

In children, alterations in growth include short stature, tall stature, and isosexual precocious puberty. Short stature is a condition in which the attained height is well below the fifth percentile or the linear growth velocity is below normal for a child's age or gender. Short stature can occur as a variant of normal growth (*i.e.*, genetic short stature or constitutional short stature) or as the result of endocrine disorders, chronic illness, malnutrition, emotional disturbances, or chromosomal disorders. Short stature resulting from GH deficiency can be treated with human GH preparations. In adults, GH deficiency represents a deficiency carried over from childhood or one that develops during adulthood as the result of a pituitary tumor or its treatment. GH levels also can decline with aging,

and there has been interest in the effects of declining GH levels in the elderly (described as the *somatopause*).

Tall stature refers to the condition in which children are tall for their age and gender. It can occur as a variant of normal growth (*i.e.*, genetic tall stature or constitutional tall stature) or as the result of a chromosomal abnormality or GH excess. GH excess in adults results in acromegaly, which involves proliferation of bone, cartilage, and soft tissue along with the metabolic effects of excessive hormone levels.

Isosexual precocious puberty defines a condition of early activation of the hypothalamic-pituitary-gonadal axis (*i.e.*, before 8 years of age in girls and 9 years of age in boys), resulting in the development of appropriate sexual characteristics and fertility. It causes tall stature during childhood but results in short stature in adulthood because of the early closure of the epiphyses.

THYROID DISORDERS

Control of Thyroid Function

The thyroid gland is a shield-shaped structure located immediately below the larynx in the anterior middle portion of the neck. It is composed of a large number of tiny, saclike structures called *follicles* (Fig. 31-4). These are the functional units of the thyroid. Each follicle is formed by a single layer of epithelial (follicular) cells and is filled with a secretory substance called *colloid*, which consists largely of a glycoprotein-iodine complex called *thyroglobulin*.

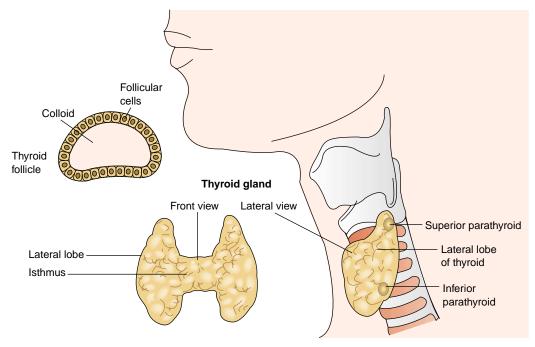

The thyroglobulin that fills the thyroid follicles is a large glycoprotein molecule that contains 140 tyrosine amino acids. In the process of thyroid synthesis, iodine is attached to these tyrosines. Both thyroglobulin and iodide are secreted into the colloid of the follicle by the follicular cells.

The thyroid is remarkably efficient in its use of iodide. A daily absorption of 100 to 200 μ g of dietary iodide is sufficient to form normal quantities of thyroid hormone. In the process of removing it from the blood and storing it for future use, iodide is pumped into the follicular cells against a concentration gradient. As a result, the concentration of iodide in the normal thyroid gland is approximately 30 times that in the blood.²

Once inside the follicle, most of the iodide is oxidized by the enzyme peroxidase in a reaction that facilitates combination with a tyrosine molecule to form monoiodotyrosine and then diiodotyrosine (Fig. 31-5). Two diiodotyrosine residues are coupled to form thyroxine (T_4), or a monoiodotyrosine and a diiodotyrosine are coupled to form triiodothyronine (T_3). Only T_4 (93%) and T_3 (7%) are released into the circulation.² There is evidence that T_3 is the active form of the hormone and that T_4 is converted to T_3 before it can act physiologically.

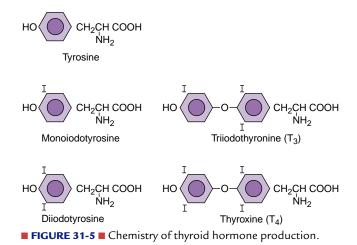

Thyroid hormones are bound to thyroid-binding globulin and other plasma proteins for transport in the blood. Only the free hormone enters cells and regulates the pituitary feedback mechanism. Protein-bound thyroid hormone forms a large reservoir that is slowly drawn on as free thyroid hormone is needed. There are three major thyroid-binding proteins: thyroid hormone-binding globulin (TBG), thyroxine-binding prealbumin (TBPA), and albumin. More than 99% of T₄ and T₃ is carried in the bound form. TBG carries approximately 70% of T₄ and T₃; TBPA binds approximately 10% of circulating T₄ and lesser amounts of T₃; and albumin binds approximately 15% of circulating T₄ and T₃.

A number of disease conditions and pharmacologic agents can decrease the amount of binding protein in the plasma or influence the binding of hormone. Congenital TBG deficiency

■ FIGURE 31-4 ■ The thyroid gland and the follicular structure.

546 Unit Eight: Alterations in the Endocrine System

is an X-linked trait that occurs in 1 of every 2500 live births. Corticosteroid medications and systemic disease conditions such as protein malnutrition, nephrotic syndrome, and cirrhosis decrease TBG concentrations. Medications such as phenytoin, salicylates, and diazepam may bind to TBG, displacing T_4 and T_3 , effectively producing a low TBG state.

The secretion of thyroid hormone is regulated by the hypothalamic-pituitary-thyroid feedback system (Fig. 31-6). In this system, thyrotropin-releasing hormone (TRH), which is produced by the hypothalamus, controls the release of thyroidstimulating hormone (TSH) from the anterior pituitary gland. TSH, in turn, increases the overall activity of the thyroid gland by promoting the release of thyroid hormone into the bloodstream and increasing T_4 and T_3 synthesis. The effect of TSH on the release of thyroid hormones occurs within approximately 30 minutes, but the other effects require days or weeks.

Increased levels of thyroid hormone act in the feedback inhibition of TRH or TSH. High levels of iodide (e.g., from

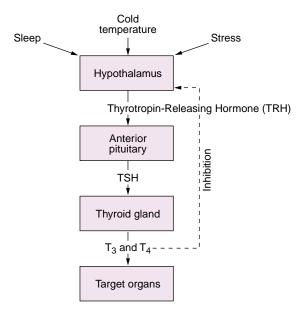

FIGURE 31-6 The hypothalamic-pituitary-thyroid feedback system, which regulates the body levels of thyroid hormone.

iodide-containing cough syrup or kelp tablets) also cause a temporary decrease in thyroid activity that lasts for several weeks, probably through a direct inhibition of TSH on the thyroid. Cold exposure is one of the strongest stimuli for increased thyroid hormone production and probably is mediated through TRH from the hypothalamus. Various emotional reactions also can affect the output of TRH and TSH and therefore indirectly affect secretion of thyroid hormones.

Actions of Thyroid Hormone

All the major organs in the body are affected by altered levels of thyroid hormone. Thyroid hormone has two major functions: it increases metabolism and protein synthesis, and it is necessary for growth and development in children, including mental development and attainment of sexual maturity.

Metabolic Rate. Thyroid hormone increases the metabolism of all body tissues except the retina, spleen, testes, and lungs. The basal metabolic rate can increase by 60% to 100% above normal when large amounts of T_4 are present.² As a result of this higher metabolism, the rate of glucose, fat, and protein use increases. Lipids are mobilized from adipose tissue, and the catabolism of cholesterol by the liver is increased. Blood levels of cholesterol are decreased in hyperthyroidism and increased in hypothyroidism. Muscle proteins are broken down and used as fuel, probably accounting for some of the muscle fatigue that occurs with hyperthyroidism. The absorption of glucose from the gastrointestinal tract is increased. Because vitamins are essential parts of metabolic enzymes and coenzymes, an increase in the metabolic rate "speeds up" the use of vitamins and tends to cause vitamin deficiency.

Cardiovascular Function. Cardiovascular and respiratory functions are strongly affected by thyroid function. With an increase in metabolism, there is an increase in oxygen consumption and production of metabolic end-products, with an accompanying increase in vasodilatation. Blood flow to the skin, in particular, is augmented as a means of dissipating the body heat that results from the higher metabolism. Blood volume, cardiac output, and ventilation all are increased as a means of maintain-

KEY CONCEPTS

THYROID HORMONE

- Thyroid hormone increases the metabolism and protein synthesis in nearly all of the tissues of the body.
- Hypothyroidism produces a decrease in metabolic rate, an accumulation of a hydrophilic mucopolysaccharide substance (myxedema) in the connective tissues throughout the body, and an elevation in serum cholesterol.
- Hyperthyroidism has an effect opposite that of hypothyroidism. It produces an increase in metabolic rate and oxygen consumption, increased use of metabolic fuels, and increased sympathetic nervous ystem responsiveness.

ing blood flow and oxygen delivery to body tissues. Heart rate and cardiac contractility are enhanced as a means of maintaining the needed cardiac output. However, blood pressure is likely to change little because the increase in vasodilatation tends to offset the increase in cardiac output.

Gastrointestinal Function. Thyroid hormone enhances gastrointestinal function, causing an increase in motility and production of gastrointestinal secretions that often results in diarrhea. An increase in appetite and food intake accompanies the higher metabolic rate that occurs with increased thyroid hormone levels. At the same time, weight loss occurs because of the increased use of calories.

Neuromuscular Effects. Thyroid hormone has marked effects on neural control of muscle function and tone. Slight elevations in hormone levels cause skeletal muscles to react more vigorously, and a drop in hormone levels causes muscles to react more sluggishly. In the hyperthyroid state, a fine muscle tremor is present. The cause of this tremor is unknown, but it may represent an increased sensitivity of the neural synapses in the spinal cord that control muscle tone.

In the infant, thyroid hormone is necessary for normal brain development. The hormone enhances cerebration; in the hyperthyroid state, it causes extreme nervousness, anxiety, and difficulty in sleeping.

Evidence suggests a strong interaction between thyroid hormone and the sympathetic nervous system. Many of the signs and symptoms of hyperthyroidism suggest overactivity of the sympathetic division of the autonomic nervous system, such as tachycardia, palpitations, and sweating. Tremor, restlessness, anxiety, and diarrhea also may reflect autonomic nervous system imbalances. Drugs that block sympathetic activity have proved to be valuable adjuncts in the treatment of hyperthyroidism because of their ability to relieve some of these undesirable symptoms.

Tests of Thyroid Function

The diagnosis of thyroid disorders is based on tests of $T_{3_{4}}$ $T_{4_{4}}$ and TSH levels, radioiodine uptake studies, thyroid scans, ultrasound, and CT or MRI scans.¹⁵ Measures of T₃, T₄, and TSH have been made available through immunoassay methods. The free T_4 test measures the unbound portion of T_4 that is free to enter cells to produce its effects. Ultrasensitive TSH measurements are used to diagnose hyperthyroidism and hypothyroidism, as well differentiate between primary and secondary thyroid disorders. T₃, T₄, and free T₄ levels are low in primary hypothyroidism, and the TSH level (via negative feedback) is elevated.

The radioiodine (123I) uptake test measures the ability of the thyroid gland to remove and concentrate iodine from the blood. Thyroid scans (i.e., 123I, 99mTc-pertechnetate) can be used to detect thyroid nodules and determine the functional activity of the thyroid gland. Ultrasonography can be used to differentiate cystic from solid thyroid lesions, and CT and MRI scans are used to demonstrate tracheal compression or impingement on other neighboring structures.

Alterations in Thyroid Function

An alteration in thyroid function can represent a hypofunctional or a hyperfunctional state. The manifestations of these two altered states are summarized in Table 31-1. Disorders of the thyroid may be caused by a congenital defect in thyroid development, or they may develop later in life, with a gradual or sudden onset.

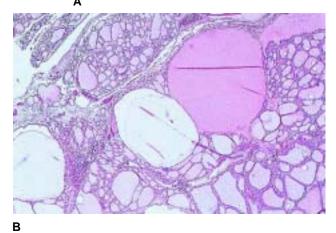

Goiter is an increase in the size of the thyroid gland. It can occur in hypothyroid, euthyroid, and hyperthyroid states.

TABLE 31-1 Manifestations of Hypothyroid and Hyperthyroid States				
Level of Organization	Hypothyroidism	Hyperthyroidism		
Basal metabolic rate	Decreased	Increased		
Sensitivity to catecholamines	Decreased	Increased		
General features	Myxedematous features Deep voice Impaired growth (child)	Exophthalmos Lid lag Decreased blinking		
Blood cholesterol levels	Increased	Decreased		
General behavior	Mental retardation (infant) Mental and physical sluggishness Somnolence	Restlessness, irritability, anxiety Hyperkinesis Wakefulness		
Cardiovascular function	Decreased cardiac output Bradycardia	Increased cardiac output Tachycardia and palpitations		
Gastrointestinal function	Constipation Decreased appetite	Diarrhea Increased appetite		
Respiratory function	Hypoventilation	Dyspnea		
Muscle tone and reflexes	Decreased	Increased, with tremor and fibrillatory twitching		
Temperature tolerance	Cold intolerance	Heat intolerance		
Skin and hair	Decreased sweating Coarse and dry skin and hair	Increased sweating Thin and silky skin and hair		
Weight	Gain	Loss		

Goiters may be diffuse, involving the entire gland without evidence of nodularity, or they may contain nodules. Diffuse goiters usually become nodular. Goiters may be toxic, producing signs of extreme hyperthyroidism, or thyrotoxicosis, or they may be nontoxic. Diffuse nontoxic and multinodular goiters are the result of compensatory hypertrophy and hyperplasia of follicular epithelium from some derangement that impairs thyroid hormone output (Fig. 31-7).

The degree of thyroid enlargement usually is proportional to the extent and duration of thyroid deficiency. Multinodular goiters produce the largest thyroid enlargements and often are associated with thyrotoxicosis. When sufficiently enlarged, they

■ FIGURE 31-7 ■ (A) Middle-aged woman with a nontoxic (nodular) goiter that has enlarged to produce a conspicuous neck mass. (B) Microscopic view of one of the macroscopic nodules shows marked variation in size of the follicles. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1164]. Philadelphia: Lippincott Williams & Wilkins) may compress the esophagus and trachea, causing difficulty in swallowing, a choking sensation, and inspiratory stridor. Such lesions also may compress the superior vena cava, producing distention of the veins of the neck and upper extremities, edema of the eyelids and conjunctiva, and syncope with coughing.

Hypothyroidism

Hypothyroidism can occur as a congenital or an acquired defect. Congenital hypothyroidism develops prenatally and is present at birth. Acquired hypothyroidism develops later in life because of primary disease of the thyroid gland or secondary to disorders of hypothalamic or pituitary origin.

Congenital Hypothyroidism

Congenital hypothyroidism is a common cause of preventable mental retardation. It affects approximately 1 of 4000 infants.¹⁶ Hypothyroidism in the infant may result from a congenital lack of the thyroid gland, abnormal biosynthesis of thyroid hormone, or deficient TSH secretion. With congenital lack of the thyroid gland, the infant usually appears normal and functions normally at birth because of the transplacental passage of moderate amounts of maternal T₄. The manifestations of untreated congenital hypothyroidism are referred to as *cretinism*. However, the term does not apply to the normally developing infant in whom replacement thyroid hormone therapy was instituted shortly after birth.

Thyroid hormone is essential for normal brain development and growth, almost half of which occurs during the first 6 months of life. If untreated, congenital hypothyroidism causes mental retardation and impairs growth. Fortunately, neonatal screening tests have been instituted to detect congenital hypothyroidism during early infancy. Screening usually is done in the hospital nursery. In this test, a drop of blood is taken from the infant's heel and analyzed for T_4 and TSH.

Transient congenital hypothyroidism has been recognized more frequently since the introduction of neonatal screening. It is characterized by high TSH levels and low thyroid hormone levels. The fetal and infant thyroids are sensitive to iodine excess. Iodine crosses the placenta and mammary glands and is readily absorbed by infant skin. Transient hypothyroidism may be caused by maternal or infant exposure to substances such as topical iodine-containing disinfectants (*e.g.*, iodine-containing douches or nursery disinfectants). Antithyroid drugs such as propylthiouracil, methimazole, and carbimazole also cross the placenta and block fetal thyroid function.

Congenital hypothyroidism is treated by hormone replacement. Evidence indicates that it is important to normalize T_4 levels as rapidly as possible (in the first 6 weeks of life) because a delay is accompanied by poorer psychomotor and mental development. Dosage levels are adjusted as the child grows. Infants with transient hypothyroidism usually can have the replacement therapy withdrawn at 6 to 12 months. When early and adequate treatment regimens are followed, the risk of mental retardation in infants detected by screening programs essentially is nonexistent.

Acquired Hypothyroidism and Myxedema

Acquired hypothyroidism in older children and adults represents a decrease in thyroid function resulting from destruction or dysfunction of the thyroid gland (*i.e.*, primary hypothyroidism) or impaired hypothalamic or pituitary function (*i.e.*, secondary hypothyroidism).

Primary hypothyroidism is much more common than secondary hypothyroidism. It may result from thyroidectomy (*i.e.*, surgical removal) or ablation of the gland with radiation. Certain goitrogenic agents, such as lithium carbonate (i.e., used in the treatment of manic-depressive states) and the antithyroid drugs propylthiouracil and methimazole in continuous dosage can block hormone synthesis and produce hypothyroidism with goiter. Iodine-containing drugs (e.g., kelp tablets, iodide-containing cough syrups, radiographic contrast media) also can block thyroid hormone production, particularly in persons with autoimmune thyroid disease. Amiodarone (an antiarrhythmic drug), which contains 75 mg of iodine per 200-mg tablet, is being increasingly implicated in causing thyroid problems. Iodine deficiency, which can cause goiter and hypothyroidism, is rare in the United States because of the widespread use of iodized salt and other iodide sources.

Hashimoto's thyroiditis is an autoimmune disorder in which the thyroid gland may be totally destroyed by an immunologic process.¹ It is the major cause of goiter and hypothyroidism in children and adolescents.¹⁶ Hashimoto's thyroiditis is predominantly a disease of women, with a female-to-male ratio of 10:1 to 20:1.¹ The course of the disease varies. At the onset, only a goiter may be present. In time, hypothyroidism usually becomes evident. Although the disorder usually causes hypothyroidism, a hyperthyroid state may develop midcourse in the disease. The transient hyperthyroid state is caused by leakage of preformed thyroid hormone from damaged cells of the gland.

Clinical Manifestations. The clinical manifestations of hypothyroidism can range from mild nonspecific complaints associated with subclinical hypothyroidism to those associated with overt hypothyroidism.¹⁷ The manifestations of the overt hypothyroidism are related largely to two factors: the hypometabolic state resulting from thyroid hormone deficiency, and myxedematous involvement of body tissues.

The hypometabolic state is characterized by a gradual onset of weakness and fatigue, a tendency to gain weight despite a loss of appetite, and cold intolerance. As the condition progresses, the skin becomes dry and rough and acquires a pale yellowish cast, which primarily results from carotene deposition, and the hair becomes coarse and brittle. There can be loss of the lateral one third of the eyebrows. Gastrointestinal motility is decreased, producing constipation, flatulence, and abdominal distention. Nervous system involvement is manifested in mental dullness, lethargy, and impaired memory.

Myxedema represents the presence of a nonpitting mucous type of edema caused by an accumulation of a hydrophilic mucopolysaccharide substance in the connective tissues throughout the body. As a result of myxedematous fluid accumulation, the face takes on a characteristic puffy look, especially around the eyes, the tongue becomes enlarged, and the voice hoarse and husky (Fig. 31-8). Mucopolysaccharide deposits in the heart can cause generalized cardiac dilatation, bradycardia, and other signs of altered cardiac function. The signs and symptoms of hypothyroidism are summarized in Table 31-1.

Diagnosis and Treatment. Diagnosis of hypothyroidism is based on history and physical examination and laboratory mea-

surement of TSH and free T_4 levels. The condition is treated with replacement therapy using synthetic preparations of T_3 or T_4 . Most people are treated with T_4 . Serum TSH levels are used to estimate the adequacy of T_4 replacement therapy.

Myxedematous Coma. Myxedematous coma is a lifethreatening, end-stage expression of hypothyroidism. It is characterized by coma, hypothermia, cardiovascular collapse, hypoventilation, and severe metabolic disorders that include hyponatremia, hypoglycemia, and lactic acidosis.¹⁸ It occurs most often in elderly women who have chronic hypothyroidism from a spectrum of causes. It occurs more frequently in the winter months, which suggests that cold exposure may be a precipitating factor. The severely hypothyroid person is unable to metabolize sedatives, analgesics, and anesthetic drugs, and buildup of these agents may precipitate coma.

Treatment includes aggressive management of precipitating factors; supportive therapy such as management of cardiorespiratory status, hyponatremia, and hypoglycemia; and thyroid replacement therapy. Prevention is preferable to treatment and entails special attention to high-risk populations, such as women with a history of Hashimoto's thyroiditis. These persons should be informed about the signs and symptoms of severe hypothyroidism and the need for early medical treatment.

Hyperthyroidism

Hyperthyroidism, or thyrotoxicosis, results from excessive delivery of thyroid hormone to the peripheral tissues. The most common cause of hyperthyroidism is Graves' disease, which is accompanied by ophthalmopathy (exophthalmos, *i.e.*, bulging of the eyeballs) and goiter. Other causes of hyperthyroidism are multinodular goiter, adenoma of the thyroid, and occasionally, ingestion of excessive thyroid hormone. Thyroid crisis, or storm, is an acutely exaggerated manifestation of the hyperthyroid state.

Many of the manifestations of hyperthyroidism are related to the increase in oxygen consumption and use of metabolic fuels associated with the hypermetabolic state, as well as to the increase in sympathetic nervous system activity. With the hypermetabolic state, there are frequent complaints of nervousness, irritability, and fatigability. Weight loss is common, despite a large appetite. Other manifestations include tachycardia, palpitations, shortness of breath, excessive sweating, muscle cramps, and heat intolerance. The person appears restless and has a fine muscle tremor. Even in persons without exophthalmos, there is an abnormal retraction of the eyelids and infrequent blinking such that they appear to be staring. The hair and skin usually are thin and have a silky appearance. The signs and symptoms of hyperthyroidism are summarized in Table 31-1.

The treatment of hyperthyroidism is directed toward reducing the level of thyroid hormone. This can be accomplished with eradication of the thyroid gland with radioactive iodine, through surgical removal of part or all of the gland, or the use of drugs that decrease thyroid function and thereby the effect of thyroid hormone on the peripheral tissues. Destruction of thyroid tissue with radioactive iodine is used more frequently than surgery. The β -adrenergic–blocking drug propranolol may be used to block the effects of the hyperthyroid state on sympathetic nervous system function. It is given in conjunction with other antithyroid drugs such as propylthiouracil and methimazole. These drugs prevent the thyroid gland from converting iodine to its organic (hormonal) form and block the conversion of T₄ to T₃ in the tissues.

Graves' Disease

Graves' disease is a state of hyperthyroidism, goiter, and ophthalmopathy (or, less commonly, dermopathy).^{19,20} The onset usually is between the ages of 20 and 40 years, and women are five times more likely to experience the disease than men. Graves' disease is an autoimmune disorder characterized by abnormal stimulation of the thyroid gland by thyroid-stimulating antibodies (thyroid-stimulating immunoglobulins [TSI]) that act through the normal TSH receptors. It may be associated with other autoimmune disorders, such as myasthenia gravis and pernicious anemia. The disease is associated with human leukocyte antigen (HLA)-DR3 and HLA-B8, and a familial tendency is evident.

The exophthalmos, which occurs in as many as one third of persons with Graves' disease, is thought to result from thyroidstimulating antibodies sensitized to interact with antigens found in fibroblasts in orbital tissue behind the eyeball and in the extraocular muscles that move the eyeball.^{21,22} The ophthalmopathy of Graves' disease can cause severe eye problems, including paralysis of the extraocular muscles; involvement of the optic nerve, with some visual loss; and corneal ulceration because the lids do not close over the protruding eyeball. The exophthalmos usually tends to stabilize after treatment of the hyperthyroidism. Unfortunately, not all of the ocular changes are reversible with treatment. Smoking tends to aggravate the condition. Figure 31-9 depicts a woman with Graves' disease.

■ FIGURE 31-9 ■ Graves' disease. A young woman with hyperthyroidism presented with a mass in the neck and exophthalmos. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1167]. Philadelphia: Lippincott Williams & Wilkins)

Thyroid Storm

Thyroid storm, or crisis, is an extreme and life-threatening form of thyrotoxicosis, rarely seen today because of improved diagnosis and treatment methods. When it does occur, it is seen most often in undiagnosed cases or in persons with hyperthyroidism who have not been adequately treated. It often is precipitated by stress such as an infection (usually respiratory), diabetic ketoacidosis, physical or emotional trauma, or manipulation of a hyperactive thyroid gland during thyroidectomy. Thyroid storm is manifested by a very high fever, extreme cardiovascular effects (*i.e.*, tachycardia, congestive failure, and angina), and severe CNS effects (*i.e.*, agitation, restlessness, and delirium). Thyroid storm requires rapid diagnosis and implementation of treatment.

In summary, thyroid hormones play a role in the metabolic process of almost all body cells and are necessary for normal physical and mental growth in the infant and young child. Alterations in thyroid function can manifest as a hypothyroid or a hyperthyroid state. Hypothyroidism can occur as a congenital or an acquired defect. Congenital hypothyroidism leads to mental retardation and impaired physical growth unless treatment is initiated during the first months of life. Acquired hypothyroidism leads to a decrease in metabolic rate and an accumulation of a mucopolysaccharide substance in the intercellular spaces; this substance attracts water and causes a mucous type of edema called myxedema. Hyperthyroidism causes an increase in metabolic rate and alterations in body function similar to those produced by enhanced sympathetic nervous system activity. Graves' disease, which is caused by thyroid-stimulating antibodies, is characterized by hyperthyroidism, goiter, and ophthalmopathy.

PARATHYROID HORMONE DISORDERS

Parathyroid hormone (PTH), a major regulator of serum calcium and phosphate, is secreted by the parathyroid glands. There are four parathyroid glands located on the dorsal surface of the thyroid gland.¹ The dominant regulator of PTH is a decrease in serum calcium concentration. A unique calcium receptor within the parathyroid cell membrane responds rapidly to changes in serum calcium levels. The response to a decrease in serum calcium is prompt, occurring within seconds. Phosphate does not exert a direct effect on PTH secretion. Instead, it acts indirectly by complexing with calcium and decreasing serum calcium concentration.

The secretion, synthesis, and action of PTH are also influenced by magnesium. Magnesium serves as a cofactor in the generation of cellular energy and is important in the function of second messenger systems. Magnesium's effects on the synthesis and release of PTH are thought to be mediated through these mechanisms.²³ Because of its function in regulating PTH release, severe and prolonged hypomagnesemia can markedly inhibit PTH levels.

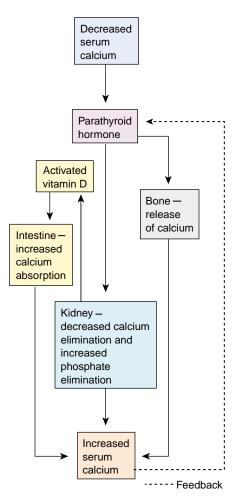

The main function of PTH is to maintain the calcium concentration of the extracellular fluids. It performs this function by promoting the release of calcium from bone, increasing the activation of vitamin D as a means of enhancing intestinal absorption of calcium, and stimulating calcium conservation by the kidney while increasing phosphate excretion (Fig. 31-10).

Parathyroid hormone acts on bone to accelerate the mobilization and transfer of calcium to the extracellular fluid. The skeletal response to PTH is a two-step process. There is an immediate response in which calcium that is present in bone fluid is released into the extracellular fluid and a second more slowly developing response in which completely mineralized bone is resorbed resulting in the release of both calcium and phosphate The actions of PTH in terms of bone resorption require normal levels of both vitamin D and magnesium.

The activation of vitamin D by the kidney is enhanced by the presence of PTH; it is through the activation of vitamin D that PTH increases intestinal absorption of calcium and phosphate. PTH acts directly on the kidney to increase tubular reabsorption of calcium and magnesium while increasing phosphate elimination. The accompanying increase in phosphate elimination ensures that calcium released from bone does not produce hyperphosphatemia and increase the risk of soft tissue deposition of calcium/phosphate crystals.

Hypoparathyroidism

Hypoparathyroidism reflects deficient PTH secretion resulting in hypocalcemia. PTH deficiency may be caused by a congenital absence of all of the parathyroid glands, such as occurs in DiGeorge syndrome.²⁴ An acquired deficiency of PTH may occur after neck surgery, particularly if the surgery involves removal of a parathyroid adenoma, thyroidectomy, or bilateral neck resection for cancer. Hypoparathyroidism may also have an autoimmune origin. Antiparathyroid antibodies have been detected in some persons with hypoparathyroidism, particularly those with multiple endocrine disorders. Other causes of hypoparathyroidism include heavy metal damage, such as occurs with Wilson's disease, metastatic tumors, and infection.

■ FIGURE 31-10 ■ Regulation of serum calcium concentration by parathyroid hormone.

Functional impairment of parathyroid function occurs with magnesium deficiency. Correction of the hypomagnesemia results in rapid disappearance of the condition.

Manifestations of acute hypoparathyroidism that result from a decrease in serum calcium include tetany with muscle cramps, carpopedal spasm, and convulsions (see discussion of hypocalcemia in Chapter 6). Paresthesias, such as tingling of the circumoral area and in the hands and feet, are almost always present. There may be prolongation of the QT interval caused by low calcium levels, resistance to digitalis, hypotension, and refractory heart failure. Symptoms of chronic deficiency include lethargy, anxiety state, and personality changes. There may be blurring of vision caused by cataracts, which develop during an extended period of time. Extrapyramidal signs, such as those seen with Parkinson's disease, may occur because of calcification of the basal ganglia. Successful treatment of the hypocalcemia may improve the disorder and is sometimes associated with decreases in basal ganglia calcification on x-ray. Teeth may be defective if the disorder occurs during childhood.

Diagnosis of hypoparathyroidism is based on low serum calcium levels, high serum phosphate levels, and low serum PTH levels. Serum magnesium levels are usually measured to exclude hypomagnesemia as a cause of the disorder. Acute hypoparathyroid tetany is treated with intravenous calcium gluconate followed by oral administration of calcium salts and vitamin D. Magnesium supplementation is used when the disorder is caused by magnesium deficiency. Persons with chronic hypoparathyroidism are treated with oral calcium and vitamin D. Serum calcium levels are monitored at regular intervals (at least every 3 months) as a means of maintaining serum calcium within a slightly low but asymptomatic range. Maintaining serum calcium within this range helps to prevent hypercalciuria and kidney damage.

Pseudohypoparathyroidism is a rare familial disorder characterized by target tissue resistance to PTH. It is characterized by hypocalcemia, increased parathyroid function, and a variety of congenital defects in the growth and development of the skeleton, including short stature and short metacarpal and metatarsal bones. There are variants in the disorders, with some persons having the pseudohypoparathyroidism with the congenital defects and others having the congenital defects with normal calcium and phosphate levels. The manifestations of the disorder are primarily attributable to hypocalcemia. Treatment is similar to that for hypoparathyroidism.

Hyperparathyroidism

Hyperparathyroidism is caused by hypersecretion of parathyroid hormone. Hyperparathyroidism can manifest as a primary disorder caused by hyperplasia, an adenoma, or carcinoma of the parathyroid glands or as a secondary disorder seen in persons with renal failure.²⁵

Primary hyperparathyroidism is seen more commonly after age 50 years and is more common in women than men. Primary hyperparathyroidism causes hypercalcemia and an increase in calcium in the urine filtrate, resulting in hypercalcuria and the potential for development of kidney stones. Chronic bone resorption may produce diffuse demineralization, pathologic fractures, and cystic bone lesions. Signs and symptoms of the disorder are related to skeletal abnormalities, exposure of the kidney to high calcium levels, and elevated serum calcium levels (see hypercalcemia). Diagnostic procedures include serum calcium and parathyroid hormone levels. Imaging studies of the parathyroid area may be used to identify a parathyroid adenoma.

Secondary hyperparathyroidism involves hyperplasia of the parathyroid glands and occurs primarily in persons with renal failure (see Chapter 24).²⁵ In early renal failure, an increase in PTH results from decreased serum calcium and activated vitamin D levels. As the disease progresses, there is a decrease in vitamin D and calcium receptors, making the parathyroid glands more resistant to vitamin D and calcium. At this point, elevated phosphate levels induce hyperplasia of the parathyroid glands independent of calcium and activated vitamin D.

The bone disease seen in persons with secondary hyperparathyroidism caused by renal failure is known as renal osteodystrophy. Treatment includes resolving the hypercalcemia with large fluid intake. Persons with mild disease are advised to keep active and drink adequate fluids. They also are advised to avoid calcium-containing antacids, vitamin D, and thiazide diuretics, which increase reabsorption of calcium by the kidney. Bisphosphonates (*e.g.*, pamidronate and alendronate), which are potent inhibitors of bone resorption, may be used temporarily to treat the hypercalcemia of hyperparathyroidism. Parathyroidectomy may be indicated in persons with symptomatic hyperthyroidism, kidney stones, or bone disease.

DISORDERS OF ADRENAL CORTICAL FUNCTION

Control of Adrenal Cortical Function

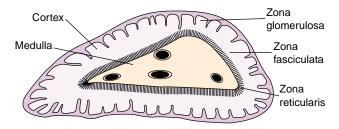

The adrenal glands are small, bilateral structures that weigh approximately 5 g each and lie retroperitoneally at the apex of each kidney (Fig. 31-11). The medulla or inner portion of the gland secretes epinephrine and norepinephrine and is part of the sympathetic nervous system. The cortex forms the bulk of the adrenal gland and is responsible for secreting three types of hormones: the glucocorticoids, the mineralocorticoids, and the adrenal sex hormones. Because the sympathetic nervous system also secretes epinephrine and norepinephrine, adrenal medullary function is not essential for life, but adrenal cortical function is.

Biosynthesis, Transport, and Metabolism

More than 30 hormones are produced by the adrenal cortex. Of these hormones, aldosterone is the principal mineralocorticoid, cortisol (hydrocortisone) is the major glucocorticoid, and androgens are the chief sex hormones.¹ All of the adrenal cortical hormones have a similar structure in that all are steroids and are synthesized from acetate and cholesterol. Each of the steps involved in the synthesis of the various hormones requires a specific enzyme (Fig. 40-11). The secretion of the glucocorticoids and the adrenal androgens is controlled by the ACTH secreted by the anterior pituitary gland.

Cortisol and the adrenal androgens are secreted in an unbound state and bind to plasma proteins for transport in the circulatory system. Cortisol binds largely to corticosteroidbinding globulin and to a lesser extent to albumin. Aldosterone circulates mostly bound to albumin. It has been suggested that the pool of protein-bound hormones may extend the duration of their action by delaying metabolic clearance.

The main site for metabolism of the adrenal cortical hormones is the liver, where they undergo a number of metabolic conversions before being conjugated and made water soluble. They are then eliminated in either urine or bile.

■ FIGURE 31-11 ■ The adrenal gland, showing the medulla and the three layers of the cortex. The zona glomerulosa is the outer layer of the cortex and is primarily responsible for mineralocorticoid production. The middle layer, the zona fasciculata, and the inner layer, the zona reticularis, produce the glucocorticoids and the adrenal sex hormones.

KEY CONCEPTS

ADRENAL CORTICAL HORMONES

- The adrenal cortex produces three types of steroid hormones: the mineralocorticoids (principally aldosterone), which function in sodium, potassium, and water balance; the glucocorticoids (principally cortisol), which aid in regulating the metabolic functions of the body and in controlling the inflammatory response, and are essential for survival in stress situations; and the adrenal sex hormones (principally androgens), which serve mainly as a source of androgens for women.
- The manifestations of adrenal cortical insufficiency are related mainly to mineralocorticoid deficiency and glucocorticoid deficiency.
- The manifestations of adrenal cortical excess are related to mineralocorticoid excess, glucocorticoid excess with derangements in glucose metabolism and impaired ability to respond to stress because of inhibition of inflammatory and immune responses, and signs of increased androgen levels, such as hirsutism in women.

Adrenal Sex Hormones

The adrenal sex hormones are synthesized primarily by the zona reticularis and the zona fasciculata of the cortex (see Fig. 31-12). These sex hormones probably exert little effect on normal sexual function. However, there is evidence that the adrenal sex hormones (the most important of which is dehydroepiandrosterone) contribute to the pubertal growth of body hair, particularly pubic and axillary hair in women. They also may play a role in the steroid hormone economy of the pregnant woman and the fetal-placental unit.

Mineralocorticoids

The mineralocorticoids play an essential role in regulating potassium and sodium levels and water balance. They are produced in the zona glomerulosa, the outer layer of cells of the adrenal cortex. Aldosterone secretion is regulated by the reninangiotensin mechanism and by blood levels of potassium. Increased levels of aldosterone promote sodium retention by the distal tubules of the kidney while increasing urinary losses of potassium. The influence of aldosterone on fluid and electrolyte balance is discussed in Chapter 6, and its effect on blood pressure is discussed in Chapter 16.

Glucocorticoids

The glucocorticoid hormones, mainly cortisol, are synthesized in the zona fasciculata and the zona reticularis of the adrenal gland. The blood levels of these hormones are regulated by negative feedback mechanisms of the hypothalamic-pituitaryadrenal (HPA) system (Fig. 31-13). The hypothalamus releases corticotropin-releasing hormone, which is important in controlling the release of ACTH from the pituitary.¹ Cortisol levels increase as ACTH levels rise and decrease as ACTH levels fall. There is considerable diurnal variation in ACTH levels, which reach their peak in the early morning (around 6 to 8 AM) and decline as the day progresses (Fig. 31-14). This appears to be attributable to rhythmic activity in the CNS, which causes bursts of corticotropin-releasing hormone (CRH) secretion and, in turn, ACTH secretion. This diurnal pattern is reversed in people who work during the night and sleep during the day. The rhythm also may be changed by physical and psychological stresses, endogenous depression, manic-depressive psychosis, and liver disease or other conditions that affect cortisol metabolism. One of the earliest signs of Cushing's syndrome, a disorder of cortisol excess, is the loss of diurnal variation in CRH and ACTH secretion.

The glucocorticoids perform a necessary function in response to stress and are essential for survival. When produced as part of the stress response, these hormones aid in regulating the metabolic functions of the body and in controlling the inflammatory response. The actions of cortisol are summarized in Table 31-2.

Metabolic Effects. Cortisol stimulates glucose production by the liver, promotes protein breakdown, and causes mobilization of fatty acids. As body proteins are broken down, amino acids are mobilized and transported to the liver, where they are used in the production of glucose (*i.e.*, gluconeogenesis). Mobilization of fatty acids converts cell metabolism from the use of glucose for energy to the use of fatty acids. As glucose production by the liver increases and peripheral glucose use decreases, a moderate resistance to insulin develops. In persons with diabetes and those who are diabetes prone, this has the effect of raising the blood glucose level.

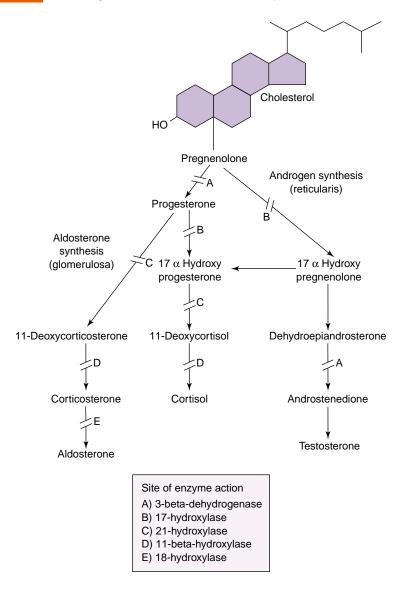

Psychological Effects. The glucocorticoid hormones appear to be involved directly or indirectly in emotional behavior. Receptors for these hormones have been identified in brain tissue, which suggests that they play a role in the regulation of behavior. Persons treated with adrenal cortical hormones have been known to display behavior ranging from mildly aberrant to psychotic.

Immunologic and Inflammatory Effects. Cortisol influences multiple aspects of immunologic function and inflammatory responsiveness. It blocks inflammation at an early stage by decreasing capillary permeability and stabilizing the lysosomal membranes so that inflammatory mediators are not released. Cortisol suppresses the immune response by reducing humoral and cell-mediated immunity. With this lessened inflammatory response comes a reduction in fever. During the healing phase, cortisol suppresses fibroblast activity and thereby lessens scar formation. Cortisol also inhibits prostaglandin synthesis, which may account in large part for its antiinflammatory actions. Large quantities of cortisol are required for an effective anti-inflammatory action. This is achieved by the administration of pharmacologic, rather than physiologic, doses of synthetic cortisol.

Suppression of Adrenal Function

A highly significant aspect of long-term therapy with pharmacologic preparations of the adrenal cortical hormones is adrenal insufficiency on withdrawal of the drugs. The deficiency

554 Unit Eight: Alterations in the Endocrine System

results from suppression of the HPA system. Chronic suppression causes atrophy of the adrenal gland, and the abrupt withdrawal of drugs can cause acute adrenal insufficiency. Recovery to a state of normal adrenal function may be prolonged, requiring 12 months or more.

Tests of Adrenal Function

Several diagnostic tests can be used to evaluate adrenal cortical function and the HPA system. Blood levels of cortisol, aldosterone, and ACTH can be measured using immunoassay methods. A 24-hour urine specimen measures the excretion of 17-ketosteroids, 17-ketogenic steroids, and 17-hydroxycorticosteroids. These metabolic end-products of the adrenal hormones and the male androgens provide information about alterations in the biosynthesis of the adrenal cortical hormones. The 24-hour urinary free cortisol is an excellent screening test for Cushing's syndrome.

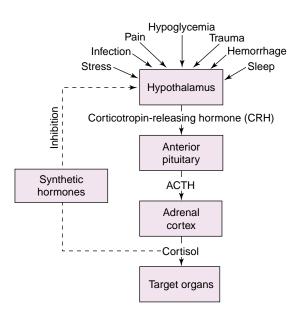

Suppression and stimulation tests afford a means of assessing the state of the HPA feedback system. For example, a test dose of ACTH can be given to assess the response of the adrenal

■ FIGURE 31-12 ■ Predominant biosynthetic pathways of the adrenal cortex. Critical enzymes in the biosynthetic process include 11-beta-hydroxylase and 21-hydroxylase. A deficiency in one of these enzymes blocks the synthesis of hormones dependent on that enzyme and routes the precursors into alternative pathways.

cortex to stimulation. Similarly, administration of dexamethasone, a synthetic glucocorticoid drug, provides a means of measuring negative feedback suppression of ACTH. Adrenal tumors and ectopic ACTH-producing tumors usually are unresponsive to ACTH suppression by dexamethasone. CRH tests can be used to diagnose a pituitary ACTH-secreting tumor (*i.e.*, Cushing's disease), especially when combined with inferior petrosal venous sampling (this allows the blood drainage of the pituitary to be sampled directly). Metyrapone (Metopirone) blocks the final step in cortisol synthesis, resulting in the production of 11-dehydroxycortisol, which does not inhibit ACTH. This test measures the ability of the pituitary to release ACTH. The gold standard test for assessing the HPA axis is the insulin hypoglycemic stress test.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH), or the adrenogenital syndrome, describes a congenital disorder caused by an autosomal recessive trait in which a deficiency exists in any of the

■ FIGURE 31-13 ■ The hypothalamic-pituitary-adrenal (HPA) feedback system that regulates glucocorticoid (cortisol) levels. Cortisol release is regulated by ACTH. Stress exerts its effects on cortisol release through the HPA system and the corticotropin-releasing hormone (CRH), which controls the release of ACTH from the anterior pituitary gland. Increased cortisol levels incite a negative feedback inhibition of ACTH release. Pharmacologic doses of synthetic steroids inhibit ACTH release by way of the hypothalamic CRH.

enzymes necessary for the synthesis of cortisol.^{26,27} A common characteristic of all types of CAH is a defect in the synthesis of cortisol that results in increased levels of ACTH and adrenal hyperplasia. The increased levels of ACTH overstimulate the pathways for production of adrenal androgens. Mineralocorticoids may be produced in excessive or insufficient amounts, depending on the precise enzyme deficiency. Infants of both genders are affected. The condition is seldom diagnosed in males at birth unless they have enlarged genitalia or lose salt

and manifest adrenal crisis. In female infants, an increase in androgens is responsible for creating the virilization syndrome of ambiguous genitalia, with an enlarged clitoris, fused labia, and urogenital sinus (Fig. 31-15). In male and female children, other secondary sex characteristics are normal, and fertility is unaffected if appropriate therapy is instituted.

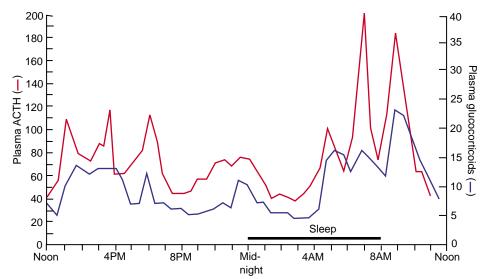

The two most common enzyme deficiencies are 21hydroxylase (accounting for >90% of cases) and 11- β hydroxylase deficiency. The clinical manifestations of both deficiencies are largely determined by the functional properties of the steroid intermediates and the completeness of the block in the cortisol pathway.

A spectrum of 21-hydroxylase deficiency states exists, ranging from simple virilizing CAH to a complete salt-losing enzyme deficiency. Simple virilizing CAH impairs the synthesis of cortisol, and steroid synthesis is shunted to androgen production. Persons with these deficiencies usually produce sufficient aldosterone or aldosterone intermediates to prevent signs and symptoms of mineralocorticoid deficiency. The salt-losing form is accompanied by deficient production of aldosterone and its intermediates. This results in fluid and electrolyte disorders after the fifth day of life, including hyponatremia, hyperkalemia, vomiting, dehydration, and shock.

The 11- β -hydroxylase deficiency is rare and manifests a spectrum of severity. Affected persons have excessive androgen production and impaired conversion of 11-deoxycorticosterone to corticosterone. The overproduction of 11-deoxycorticosterone, which has mineralocorticoid activity, is responsible for the hypertension that accompanies this deficiency. Diagnosis of adrenogenital syndrome depends on the precise biochemical evaluation of metabolites in the cortisol pathway and on clinical signs and symptoms.

Medical treatment of adrenogenital syndrome includes oral or parenteral cortisol replacement. Fludrocortisone acetate, a mineralocorticoid, also may be given to children who are salt losers. Depending on the degree of virilization, reconstructive surgery during the first 2 years of life is indicated to reduce the size of the clitoris, separate the labia, and exteriorize the vagina. Surgery has provided excellent results and does not impair sexual function.

■ FIGURE 31-14 ■ Pulsatile changes in the concentration of adrenocorticotropic hormone (ACTH) and glucocorticoids over a 24-hour period. The amplitude of the pulses of ACTH and glucocorticoids is lower in the evening hours and then increases greatly during the early morning hours. This is due to the diurnal oscillation of the hypothalamic-pituitary axis. (Modified from Krieger D.T. [1979]. Rhythms of CRF, ACTH and corticosteroids. In Krieger D.T. [Ed.], *Endocrine rhythms* [pp. 123–142]. New York: Raven)

556 Unit Eight: Alterations in the Endocrine System

TABLE 31-2 Actions of Cortisol		
Major Influence	Effect on Body	
Glucose metabolism	Stimulates gluconeogenesis Decreases glucose use by the tissues	
Protein metabolism	Increases breakdown of proteins Increases plasma protein levels	
Fat metabolism	Increases mobilization of fatty acids Increases use of fatty acids	
Anti-inflammatory action (pharmacologic levels)	Stabilizes lysosomal membranes of the inflammatory cells, preventing the release of inflammatory mediators Decreases capillary permeability to prevent inflammatory edema Depresses phagocytosis by white blood cells to reduce the release of inflammatory mediators Suppresses the immune response Causes atrophy of lymphoid tissue Decreases eosinophils Decreases antibody formation Decreases the development of cell-mediated immunity Reduces fever Inhibits fibroblast activity	
Psychic effect Permissive effect	May contribute to emotional instability Facilitates the response of the tissues to humoral and neural influences, such as that of the catecholamines, during trauma and extreme stress	

Adrenal Cortical Insufficiency

There are two forms of adrenal insufficiency: primary and secondary. Primary adrenal insufficiency, or Addison's disease, is caused by destruction of the adrenal gland. Secondary adrenal insufficiency results from a disorder of the HPA system.

Primary Adrenal Cortical Insufficiency

In 1855, Thomas Addison, an English physician, provided the first detailed clinical description of primary adrenal insufficiency, now called *Addison's disease*. The use of this term is reserved for primary adrenal insufficiency in which adrenal cortical hormones are deficient and ACTH levels are elevated because of lack of feedback inhibition.²⁸⁻³⁰

■ FIGURE 31-15 ■ A female infant with congenital adrenal hyperplasia demonstrating virilization of the genitalia with hypertrophy of the clitoris and partial fusion of labioscrotal folds. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1186]. Philadelphia: Lippincott Williams & Wilkins)

Addison's disease is a relatively rare disorder in which all the layers of the adrenal cortex are destroyed. Autoimmune destruction is the most common cause of Addison's disease in the United States. Before 1950, tuberculosis was the major cause of Addison's disease in the United States, and it continues to be a major cause of the disease in countries where it is more prevalent. Rare causes include metastatic carcinoma, fungal infection (particularly histoplasmosis), cytomegalovirus infection, amyloid disease, and hemochromatosis. Bilateral adrenal hemorrhage may occur in persons taking anticoagulants, during open heart surgery, and during birth or major trauma. Adrenal insufficiency can be caused by acquired immunodeficiency syndrome (AIDS), in which the adrenal gland is destroyed by a variety of opportunistic infectious agents.

Addison's disease, like type 1 diabetes mellitus, is a chronic metabolic disorder that requires lifetime hormone replacement therapy. The adrenal cortex has a large reserve capacity, and the manifestations of adrenal insufficiency usually do not become apparent until approximately 90% of the gland has been destroyed. These manifestations are related primarily to mineralocorticoid deficiency, glucocorticoid deficiency, and hyperpigmentation resulting from elevated ACTH levels. Although lack of the adrenal androgens (*i.e.*, DHEAS) exerts few effects in men because the testes produce these hormones, women have sparse axillary and public hair.³¹

Mineralocorticoid deficiency causes increased urinary losses of sodium, chloride, and water, along with decreased excretion of potassium. The result is hyponatremia, loss of extracellular fluid, decreased cardiac output, and hyperkalemia. There may be an abnormal appetite for salt. Orthostatic hypotension is common. Dehydration, weakness, and fatigue are common early symptoms. If loss of sodium and water is extreme, cardiovascular collapse and shock ensue. Because of a lack of glucocorticoids, the person with Addison's disease has poor tolerance to stress. This deficiency causes hypoglycemia, lethargy, weakness, fever, and gastrointestinal symptoms, such as anorexia, nausea, vomiting, and weight loss.

Hyperpigmentation results from elevated levels of ACTH. The skin looks bronzed or suntanned in exposed and unexposed areas, and the normal creases and pressure points tend to become especially dark. The gums and oral mucous membranes may become bluish-black. The amino acid sequence of ACTH is strikingly similar to that of melanocyte-stimulating hormone; hyperpigmentation occurs in more than 90% of persons with Addison's disease and is helpful in distinguishing the primary and secondary forms of adrenal insufficiency.

The daily regulation of the chronic phase of Addison's disease usually is accomplished with oral replacement therapy, with higher doses being given during periods of stress. The pharmacologic agent that is used should have both glucocorticoid and mineralocorticoid activity. Mineralocorticoids are needed only in primary adrenal insufficiency. Hydrocortisone usually is the drug of choice. In mild cases, hydrocortisone alone may be adequate. Fludrocortisone (a mineralocorticoid) is used for persons who do not obtain a sufficient salt-retaining effect from hydrocortisone. DHEAS replacement also may be helpful in the female patient.

Because persons with the disorder are likely to have episodes of hyponatremia and hypoglycemia, they need to have a regular schedule for meals and exercise. Persons with Addison's disease also have limited ability to respond to infections, trauma, and other stresses. Such situations require immediate medical attention and treatment. All persons with Addison's disease should be advised to wear a medical alert bracelet or medal.

Secondary Adrenal Cortical Insufficiency

Secondary adrenal insufficiency can occur as the result of hypopituitarism or because the pituitary gland has been surgically removed. Tertiary adrenal insufficiency results from a hypothalamic defect. However, a far more common cause than either of these is the rapid withdrawal of glucocorticoids that have been administered therapeutically. These drugs suppress the HPA system, with resulting adrenal cortical atrophy and loss of cortisol production. This suppression continues long after drug therapy has been discontinued and can be critical during periods of stress or when surgery is performed.

Acute Adrenal Crisis

Acute adrenal crisis is a life-threatening situation. If Addison's disease is the underlying problem, exposure to even a minor illness or stress can precipitate nausea, vomiting, muscular weakness, hypotension, dehydration, and vascular collapse. The onset of adrenal crisis may be sudden, or it may progress during a period of several days. The symptoms may occur suddenly in children with salt-losing forms of the adrenogenital syndrome. Massive bilateral adrenal hemorrhage causes an acute fulminating form of adrenal insufficiency. Hemorrhage can be caused by meningococcal septicemia (*i.e.*, Waterhouse-Friderichsen syndrome), adrenal trauma, anticoagulant therapy, adrenal vein thrombosis, or adrenal metastases.

Acute adrenal insufficiency is treated with intravenous fluids and corticosteroid replacement therapy. Corticosteroid replacement is accomplished through the intravenous administration of either dexamethasone or hydrocortisone.

Glucocorticoid Hormone Excess (Cushing's Syndrome)

The term *Cushing's syndrome* refers to the manifestations of hypercortisolism from any cause. Three important forms of Cushing's syndrome result from excess glucocorticoid production by the body. One is a pituitary form, which results from excessive production of ACTH by a tumor of the pituitary gland. This form of the disease was the one originally described by Cushing; therefore, it is called *Cushing's disease*.^{32,33} The second form is the adrenal form, caused by a benign or malignant adrenal tumor. The third form is ectopic Cushing's, caused by a nonpituitary ACTH-secreting tumor.³⁴ Certain extrapituitary malignant tumors such as small cell carcinoma of the lung may secrete ACTH or rarely CRH and produce Cushing's syndrome. Cushing's syndrome also can result from long-term therapy with one of the potent pharmacologic preparations of glucocorticoids; this form is called *iatrogenic Cushing's syndrome*.

The major manifestations of Cushing's syndrome represent an exaggeration of the many actions of cortisol (see Table 31-2). Altered fat metabolism causes a peculiar deposition of fat characterized by a protruding abdomen; subclavicular fat pads or "buffalo hump" on the back; and a round, plethoric "moon face" (Fig. 31-16). There is muscle weakness, and the extremities are thin because of protein breakdown and muscle wasting. In advanced cases, the skin over the forearms and legs becomes thin, having the appearance of parchment. Purple striae, or stretch marks, from stretching of the catabolically weakened skin and subcutaneous tissues are distributed over the breast, thighs, and abdomen. Osteoporosis may develop because of destruction of bone proteins and alterations in calcium metabolism, resulting in back pain, compression fractures of the vertebrae, and rib fractures. As calcium is mobilized from bone, renal calculi may develop.

Derangements in glucose metabolism are found in approximately 75% of patients, with clinically overt diabetes mellitus occurring in approximately 20%. The glucocorticoids possess mineralocorticoid properties; this causes hypokalemia as a result of excessive potassium excretion and hypertension resulting

■ FIGURE 31-16 ■ Cushing's syndrome. A woman who suffered from a pituitary adenoma that produced ACTH exhibits a moon face, buffalo hump, increased facial hair, and thinning of the scalp hair. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1193]. Philadelphia: Lippincott Williams & Wilkins)

from sodium retention. Inflammatory and immune responses are inhibited, resulting in increased susceptibility to infection. Cortisol increases gastric acid secretion, which may provoke gastric ulceration and bleeding. An accompanying increase in androgen levels causes hirsutism, mild acne, and menstrual irregularities in women. Excess levels of the glucocorticoids may give rise to extreme emotional lability, ranging from mild euphoria and absence of normal fatigue to grossly psychotic behavior.

Diagnosis of Cushing's syndrome depends on the finding of cortisol hypersecretion. The determination of 24-hour excretion of cortisol in urine provides a reliable and practical index of cortisol secretions. One of the prominent features of Cushing's syndrome is loss of the diurnal pattern of cortisol secretion. Cortisol determinations often are made on three blood samples: one taken in the morning, one in late afternoon or early evening, and a third drawn the following morning after a midnight dose of dexamethasone. Measurement of the plasma levels of ACTH, measurement of 24-hour urinary 17-ketosteroids, 17-ketogenic steroids, and 17-hydroxycorticosteroids, and suppression or stimulation tests of the HPA system often are made. MRI or CT scans afford a means for locating adrenal or pituitary tumors.

Untreated, Cushing's syndrome produces serious morbidity and even death. The choice of surgery, irradiation, or pharmacologic treatment is determined largely by the cause of the hypercortisolism. The goal of treatment for Cushing's syndrome is to remove or correct the source of hypercortisolism without causing any permanent pituitary or adrenal damage. Transsphenoidal removal of a pituitary adenoma or a hemihypophysectomy is the preferred method of treatment for Cushing's disease. This allows removal of only the tumor, rather than the entire pituitary gland. After successful removal, the person must receive cortisol replacement therapy for 6 to 12 months or until adrenal function returns. Patients also may receive pituitary radiation therapy, but the full effects of treatment may not be realized for 3 to 12 months. Unilateral or bilateral adrenalectomy may be done in the case of adrenal adenoma. When possible, ectopic ACTH-producing tumors are removed. Pharmacologic agents that block steroid synthesis (i.e., etomidate, mitotane, ketoconazole, metyrapone, and aminoglutethimide) may be used to treat persons with ectopic tumors that cannot be resected. Many of these patients also require Pneumocystis carinii pneumonia prophylaxis because of the profound immunosuppression caused by the excessive glucocorticoid.

In summary, the adrenal cortex produces three types of hormones: mineralocorticoids, glucocorticoids, and adrenal sex hormones. The mineralocorticoids along with the reninangiotensin mechanism contribute to the control of body levels of sodium and potassium. The glucocorticoids have antiinflammatory actions and aid in regulating glucose, protein, and fat metabolism during periods of stress. These hormones are under the control of the HPA system. The adrenal sex hormones exert little effect on daily control of body function, but they probably contribute to the development of body hair in women. The adrenogenital syndrome describes a genetic defect in the cortisol pathway resulting from a deficiency of one of the enzymes needed for its synthesis. Depending on the enzyme involved, the disorder causes virilization of female infants and, in some instances, fluid and electrolyte disturbances because of impaired mineralocorticoid synthesis.

Chronic adrenal insufficiency (Addison's disease) can be caused by destruction of the adrenal gland or by dysfunction of the HPA system. Adrenal insufficiency requires replacement therapy with cortical hormones. Acute adrenal insufficiency is a life-threatening situation. Cushing's syndrome refers to the manifestations of excessive cortisol levels. This syndrome may be a result of pharmacologic doses of cortisol, a pituitary or adrenal tumor, or an ectopic tumor that produces ACTH. The clinical manifestations of Cushing's syndrome reflect the very high level of cortisol that is present.

REVIEW QUESTIONS

Use thyroid hormone as an example for describing the etiology of primary, secondary, and tertiary hypothyroidism.

Differentiate genetic short stature from constitutional short stature.

State the mechanisms of short stature in hypothyroidism, poorly controlled diabetes mellitus, treatment with adrenal glucocorticosteroid hormones, malnutrition, and psychosocial dwarfism.

List three causes of tall stature.

Relate the functions of growth hormone to the manifestations of acromegaly.

Explain why children with isosexual precocious puberty are tall-statured children but short-statured adults.

Diagram the hypothalamic-pituitary-thyroid feedback system.

Relate the functions of thyroid hormone to hypothyroidism and hyperthyroidism.

Explain how a defect in a single step of corticosteroid hormone synthesis produces the manifestations of the adrenogenital syndrome.

Relate the functions of the adrenal cortical hormones to Addison's disease (*i.e.*, adrenal insufficiency) and Cushing's syndrome (*i.e.*, cortisol excess).

he male genitourinary system is subject to structural defects, inflammation, and neoplasms, all of which can affect urine elimination, sexual function, and fertility. This chapter focuses on spermatogenesis and hormonal control of male reproductive function; neural control of sexual function and erectile dysfunction; disorders of the penis, scrotum, testes, and prostate; disorders of the male reproductive system in children; and changes in function as a result of the aging process.

PHYSIOLOGIC BASIS OF MALE REPRODUCTIVE FUNCTION

The male genitourinary system is composed of the paired gonads, or testes, genital ducts, accessory organs, and penis (Fig. 33-1). The dual function of the testes is to produce male sex androgens (*i.e.*, male sex hormones), mainly testosterone, and spermatozoa (*i.e.*, male germ cells). The internal accessory organs produce the fluid constituents of semen, and the ductile system aids in the storage and transport of spermatozoa. The penis functions in urine elimination and sexual function.

582 Unit Nine: Alterations in the Male and Female Reproductive Systems

■ FIGURE 33-1 ■ The structures of the male reproductive system, including the testes, the scrotum, and the excretory ducts.

Spermatogenesis

Spermatogenesis refers to the generation of spermatozoa or sperm. It begins at an average age of 13 years and continues throughout the reproductive years of a man's life. Spermatogenesis occurs in the seminiferous tubules of the testes (Fig. 33-2). Internally, the testes are composed of several hundred compartments or lobules. Each lobule contains one or more coiled seminiferous tubules. The outer layer of the seminiferous tubules is made up of connective tissue and smooth muscle; the inner lining is composed of Sertoli's cells, which are embedded with sperm in

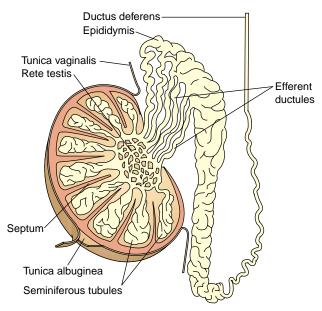

KEY CONCEPTS

MALE REPRODUCTIVE SYSTEM

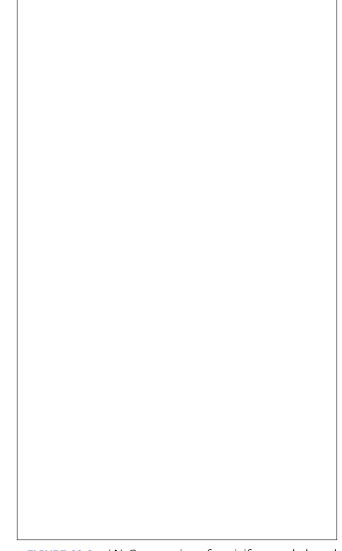

- The male genitourinary system functions in both urine elimination and reproduction.
- The testes function in both production of male germ cells (spermatogenesis) and secretion of the male sex hormone, testosterone.
- The ductile system (epididymides, vas deferens, and ejaculatory ducts) transports and stores sperm and assists in their maturation, and the accessory glands (seminal vesicles, prostate gland, and bulbourethral glands) prepare the sperm for ejaculation.
- Sperm production requires temperatures that are 2° to 3°C below body temperature. The position of the testes in the scrotum and the unique blood flow-cooling mechanisms provide this environment.
- The urethra, which is enclosed in the penis, is the terminal portion of the male genitourinary system.
 Because it conveys both urine and semen, it serves both urinary and reproductive functions.

various stages of development (Fig. 33-3). Sertoli's cells secrete a special fluid that contains nutrients to bathe and nourish the immature germ cells; they provide digestive enzymes that play a role in spermiation (*i.e.*, converting the spermatocytes to sperm); and they are thought to play a role in shaping the head and tail of the sperm. Sertoli's cells also secrete several hormones, including the principal feminizing sex hormone, estradiol, which seems to be required in the male for spermatogenesis, and inhibin, which controls the function of Sertoli's cells through feedback inhibition of follicle-stimulating hormone (FSH) from the anterior pituitary gland.

After the spermatozoa are formed in the seminiferous tubules, they travel through the efferent tubules to the epididymis, which is the final site for sperm maturation. Because the spermatozoa are not motile at this stage of development,

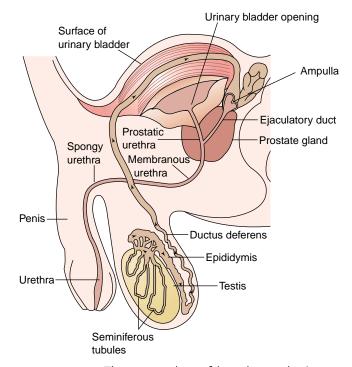

■ FIGURE 33-2 ■ The parts of the testes and epididymis.

■ FIGURE 33-3 ■ (A) Cross-section of seminiferous tubule and (B) stages of development of spermatozoa.

peristaltic movements of the ductal walls of the epididymis aid in their movement.¹ The spermatozoa continue their migration through the ductus deferens, also called the *vas deferens*. The ampulla of the vas deferens serves as a storage reservoir for sperm. Sperm are stored in the ampulla until they are released through the penis during ejaculation (Fig. 33-4). Spermatozoa can be stored in the genital ducts for as long as 42 days and still maintain their fertility. Surgical disconnection of the vas deferens in the scrotal area (*i.e.*, vasectomy) serves as an effective method of male contraception. Because sperm are stored in the ampulla, men can remain fertile for 4 to 5 weeks after performance of a vasectomy.

The seminal vesicles, the prostate gland, and the bulbourethral glands form the accessory reproductive structures of the male genitourinary system. The spermatozoa plus the secretions from the genital ducts and accessory organs make up

■ FIGURE 33-4 ■ The excretory ducts of the male reproductive system and the path that sperm follows as it leaves the testis and travels to the urethra.

the semen (from the Latin word meaning seed). The seminal vesicles consist of two highly tortuous tubes that secrete fluid for the semen. Each of the paired seminal vesicles is lined with secretory epithelium containing an abundance of fructose, prostaglandins, and several other proteins. The fructose secreted by the seminal vesicles provides the energy for sperm motility. The prostaglandins are thought to assist in fertilization by making the cervical mucus more receptive to sperm and by causing reverse peristaltic contractions in the uterus and fallopian tubes to move the sperm toward the ovaries. Each seminal vesicle joins its corresponding vas deferens to form the ejaculatory duct, which enters the posterior part of the prostate and continues through until it ends in the prostatic portion of the urethra. During the emission phase of coitus, each vesicle empties fluid into the ejaculatory duct, adding bulk to the semen. Approximately 70% of the ejaculate originates in the seminal vesicles.

Hormonal Control of Male Reproductive Function

The male sex hormones are called *androgens*. The testes secrete several male sex hormones, including *testosterone*, *dihydrotes*-*tosterone*, and *androstenedione*.² Testosterone, which is the most abundant of these hormones, is considered the main testicular hormone. The adrenal cortex also produces androgens, although in much smaller quantities (<5% of the total male androgens) than those produced in the testes. The testes also secrete small quantities of estradiol and estrone.

Testosterone is produced and secreted by the interstitial Leydig's cells in the testes. It is metabolized in the liver and excreted by the kidneys. In the bloodstream, testosterone exists in a free (unbound) or a bound form. The bound form is attached to plasma proteins, including albumin and the sex hormonebinding protein produced by the liver. Only approximately 2% of circulating testosterone is unbound and therefore able to enter the cell and exert its metabolic effects. Much of the testosterone that becomes fixed to the tissues is converted to dihydrotestosterone, especially in certain target tissues such as the prostate gland. Some of the actions of testosterone depend on this conversion, whereas others do not. Testosterone also can be aromatized or converted to estradiol in the peripheral tissues.

Testosterone exerts a variety of biologic effects in the male (Chart 33-1). In the male embryo, testosterone is essential for the appropriate differentiation of the internal and external genitalia, and it is necessary for descent of the testes in the fetus. Testosterone is essential to the development of primary and secondary male sex characteristics during puberty and for the maintenance of these characteristics during adult life. It causes growth of pubic, chest, and facial hair; it produces changes in the larynx that result in the male bass voice; and it increases the thickness of the skin and the activity of the sebaceous glands, predisposing to acne.

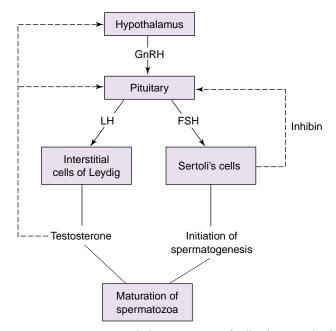

All or almost all of the actions of testosterone and other androgens result from increased protein synthesis in target tissues. Androgens function as anabolic agents in males and females to promote metabolism and musculoskeletal growth. Testosterone and the androgens have a great effect on the development of increasing musculature during puberty, with boys averaging approximately 50% more of an increase in muscle mass than do girls.

Action of the Hypothalamic and Anterior Pituitary Hormones

The hypothalamus and the anterior pituitary gland play an essential role in promoting spermatogenic activity in the testes and maintaining the endocrine function of the testes by means of the gonadotropic hormones. The synthesis and release of the gonadotropic hormones from the pituitary gland are regulated by gonadotropin-releasing hormone (GnRH), which is synthesized by the hypothalamus and secreted into the hypothalamohypophysial portal circulation (Fig. 33-5).

CHART 33-1 Main Actions of Testosterone

- Promotes spermatogenesis (in FSH-primed tubules) and maturation of sperm

■ **FIGURE 33-5** ■ Hypothalamic-pituitary feedback control of spermatogenesis and testosterone levels in the male. The *dashed line* represents negative feedback.

Two gonadotropic hormones are secreted by the pituitary gland: FSH and luteinizing hormone (LH). In the male, LH also is called interstitial cell-stimulating hormone. The production of testosterone by the interstitial cells of Leydig is regulated by LH. FSH binds selectively to Sertoli's cells surrounding the seminiferous tubules, where it functions in the initiation of spermatogenesis. Under the influence of FSH, Sertoli's cells produce and rogen-binding protein, plasminogen activator, and inhibin. Androgen-binding protein binds testosterone and serves as a carrier of testosterone in Sertoli's cells and as a storage site for testosterone. Although FSH is necessary for the initiation of spermatogenesis, full maturation of the spermatozoa requires testosterone. Androgen-binding protein also serves as a carrier of testosterone from the testes to the epididymis. Plasminogen activator, which converts plasminogen to plasmin, functions in the final detachment of mature spermatozoa from Sertoli's cells.

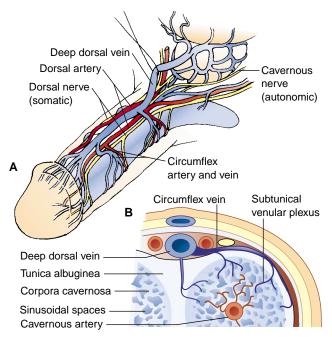

Circulating levels of the gonadotropic hormones are regulated in a negative feedback manner by testosterone. High levels of testosterone suppress LH secretion through a direct action on the pituitary and an inhibitory effect on the hypothalamus. FSH is thought to be inhibited by a substance called *inhibin*, produced by Sertoli's cells. Inhibin suppresses FSH release from the pituitary gland. The pituitary gonadotropic hormones and Sertoli's cells in the testes form a classic negative feedback loop in which FSH stimulates inhibin and inhibin suppresses FSH. Unlike the cyclic hormonal pattern in the female, in the male, FSH, LH, and testosterone secretion and spermatogenesis occur at relatively unchanging rates during adulthood.

Neural Control of Sexual Function

The penis is the male external genital organ through which the urethra passes. It functions both as a sexual organ and as an organ of urine elimination. Anatomically, the external penis consists of a shaft that ends in a tip called the *glans* (Fig. 33-1). The loose skin of the penis shaft folds to cover the glans, forming the prepuce, or foreskin. The glans of the penis contains many sensory nerves, making this the most sensitive portion of the penile shaft. The cylindrical body or shaft of the penis is composed of three masses of erectile tissue held together by fibrous strands and covered with a thin layer of skin (Fig. 33-6). The two lateral masses of tissue are called the *corpora cavernosa*. The third, ventral mass is called the *corpus spongiosum*. The corpora cavernosa and corpus spongiosum are cavernous sinuses that normally are relatively empty but become engorged with blood during penile erection.

The physiology of the male sex act involves a complex interaction between autonomic-mediated spinal cord reflexes, higher neural centers, and the vascular system. It involves erection, emission, ejaculation, and detumescence. Erection involves increased inflow of blood into the corpora cavernosa and penile rigidity. Ejaculation represents the expulsion of the sperm from the urethra. Detumescence, or penile relaxation, results from outflow of blood from the corpora cavernosa.

Erection is a neurovascular process involving the autonomic nervous system, neurotransmitters and endothelial relaxing factors, the vascular smooth muscle of the arteries and veins supplying the penile tissue, and the trabecular smooth muscle of the sinusoids of the corpora cavernosa (Fig. 33-6). The penis is innervated by both the autonomic and somatic nervous systems. In the pelvis, the sympathetic and parasympathetic components of the autonomic nervous system merge to form what are called the *cavernous nerves*.³ Erection is under the control of the parasympathetic nervous system, and ejaculation and detumescence (penile relaxation) are under the control of the sympathetic nervous system. Somatic innervation, which occurs through the pudendal nerve, is responsible for penile sensation and contraction and relaxation of the

■ FIGURE 33-6 ■ Anatomy and mechanism of penile erection. (A) Innervation and arterial and venous blood supply to penis. (B) Cross-section of the sinusoidal system of the corpora cavernosa.

KEY CONCEPTS

DISORDERS OF PENILE ERECTION

- Erection is a neurovascular process involving the autonomic nervous system, the somatic nervous system by way of the pudendal nerve, the vascular system, and the sinusoidal spaces of the corpora cavernosa.
- Parasympathetic innervation through the pelvic nerves initiates relaxation of the trabecular smooth muscle of the corpora cavernosa through the action of nitric oxide, the inflow of arterial blood, and cessation of venous outflow.
- Erectile failure can result from disorders in one or a combination of the neural, vascular, or chemical mediator aspects of the erectile process.

extracorporeal striated muscles (bulbocavernous and ischio-cavernous).³

Penile erection is the first effect of male sexual stimulation, whether psychological or physical. It involves increased inflow of blood into the corpora cavernosa due to relaxation of the trabecular smooth muscle that surrounds the sinusoidal spaces and compression of the veins controlling outflow of blood from the venous plexus. Erection is mediated by parasympathetic impulses that pass from the sacral segments of the spinal cord through the pelvic nerves to the penis. Parasympathetic stimulation results in release of nitric oxide, a nonadrenergic-noncholinergic neurotransmitter, which causes relaxation of trabecular smooth muscle of the corpora cavernosa. This relaxation permits inflow of blood into the sinuses of the cavernosa at pressures approaching those of the arterial system. Because the erectile tissues of the cavernosa are surrounded by a nonelastic fibrous covering, high pressure in the sinusoids causes ballooning of the erectile tissue to such an extent that the penis becomes hard and elongated. At the same time, contraction of the somatic-innervated ischiocavernous muscles forcefully compresses the blood-filled corpora cavernosa, producing a further increase in intercavernous pressures. During this phase of erection, inflow and outflow of blood cease.

Parasympathetic innervation must be intact and nitric oxide synthesis must be active for erection to occur. Nitric oxide activates guanyl cyclase, an enzyme that increases the concentration of cyclic guanosine monophosphate (cGMP), which in turn causes smooth muscle relaxation. Other smooth muscle relaxants (*e.g.*, prostaglandin E_1 analogs and α -adrenergic antagonists), if present in high enough concentrations, can independently cause sufficient cavernosal relaxation to result in erection.³ Many of the drugs that have been developed to treat erectile dysfunction act at the levels of these mediators.

Detumescence or penile relaxation is largely a sympathetic nervous system response. It can result from a cessation of neurotransmitter release, the breakdown of second messengers such as cGMP, or sympathetic discharge during ejaculation. Contraction of the trabecular smooth muscle opens the venous channels so that the trapped blood can be expelled and penile flaccidity return.

Erectile Dysfunction

"Erectile dysfunction is defined as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse."⁴ It has been estimated that the disorder affects 20 to 30 million men in the United States.⁵ Erectile dysfunction is commonly classified as psychogenic, organic, or mixed psychogenic or organic.^{5,6} The latter is the most common.

Psychogenic causes of erectile dysfunction include performance anxiety, a strained relationship with a sexual partner, depression, and overt psychotic disorders such as schizophrenia. Depression is a common cause of erectile dysfunction.⁵

Organic causes span a wide range of pathologies. They include neurogenic, hormonal, vascular, drug-induced, and cavernous impairment etiologies. Neurogenic disorders such as Parkinson's disease, stroke, and cerebral trauma often contribute to erectile dysfunction by decreasing libido or preventing the initiation of erection. In spinal cord injury, the extent of neural impairment depends on the level, location, and extent of the lesion. Somatosensory involvement of the genitalia is essential to the reflex mechanisms involved in erection; this becomes important with aging and conditions such as diabetes that impair peripheral nerve function.

Hormonal causes of erectile dysfunction include a decrease in androgen levels. Androgen levels may be decreased because of aging. Hypoprolactinemia from any cause interferes with both reproduction and erectile function. This is because prolactin acts centrally to inhibit dopaminergic activity, which is a stimulus for release of the hypothalamic GnRH that controls the release of pituitary gonadotropic hormones.

Common risk factors for generalized penile arterial insufficiency include hypertension, hyperlipidemia, cigarette smoking, diabetes mellitus, and pelvic irradiation.⁵ In hypertension, erectile function is impaired not so much by the increased blood pressure as by the associated stenotic arterial lesions. Focal stenosis of the common penile artery most often occurs in men who sustained blunt pelvic or perineal trauma (*e.g.*, from bicycling accidents). Failure of the veins to close completely during an erection (veno-occlusive dysfunction) may occur in men with large venous channels that drain the corpora cavernosa. Other disorders that impair venous occlusion are degenerative changes involving the tunica albuginea, as in Peyronie's disease. Poor relaxation of the trabecular smooth muscle may accompany anxiety with excessive adrenergic tone.

Many drugs are reported to cause erectile dysfunction, including antidepressant, antipsychotic, and antihypertensive medications. Cigarette smoking can induce vasoconstriction and penile venous leakage because of its effects on cavernous smooth muscle.⁵ Alcohol in small amounts may increase libido and improve erection; however, in large amounts it can cause central sedation, decreased libido, and transient erectile dysfunction.

Aging is known to increase the risk of erectile dysfunction.⁷ Many of the pathologic processes that contribute to erectile dysfunction are more common in older men, including diabetes, hyperlipidemia, vascular disease, and the long-term effects of cigarette smoking. Age-related declines in testosterone also may play a role. Psychosocial problems such as depression, esteem issues, partner relationships, history of substance abuse, and anxiety and fear of performance failure also may contribute to erectile dysfunction in older men.

A diagnosis of erectile dysfunction requires careful history (medical, sexual, and psychosocial), physical examination, and laboratory tests aimed at determining what other tests are needed to rule out organic causes of the disorder.⁶ Because many medications, including prescribed, over-the-counter, and illicit drugs, can cause erectile dysfunction, a careful drug history is indicated.

Treatment methods include psychosexual counseling, androgen replacement therapy, oral and intracavernous drug therapy, vacuum constriction devices, and surgical treatment (prosthesis and vascular surgery).⁶ Among the commonly prescribed drugs are sildenafil, yohimbine, alprostadil, and phentolamine. Sildenafil (Viagra) is a selective inhibitor of phosphodiesterase type 5, the enzyme that inactivates cGMP. Yohimbine, an α_2 -adrenergic receptor antagonist, acts at the adrenergic receptors in brain centers associated with libido and penile erection. Both sildenafil and yohimbine are taken orally. Alprostadil, a prostaglandin E analog, acts by producing relaxation of cavernous smooth muscle. It is either injected directly into the cavernosa or placed in the urethra as a minisuppository. Phentolamine, an α_2 -adrenergic receptor antagonist, also is administered by intracavernous injection.

In summary, spermatogenesis occurs in the Sertoli's cells of the seminiferous tubules of the testes. After formation in seminiferous tubules, the spermatozoa travel through the efferent tubules to the epididymis, then to the ductus deferens, and on to the ampulla, where they are stored until released through the penis during ejaculation. The male accessory organs consist of the seminal vesicles, prostate gland, and bulbourethral glands. Secretions from the genital ducts and accessory organs combine with the spermatozoa to form the semen.

The function of the male reproductive system is under the negative feedback control of the hypothalamus and the anterior pituitary gonadotropic hormones FSH and LH. Spermatogenesis is initiated by FSH, and the production of testosterone is regulated by LH. Testosterone, the major male sex hormone, is produced by the interstitial Leydig's cells in the testes. In addition to its role in the differentiation of the internal and external genitalia in the male embryo, testosterone is essential for the development of secondary male characteristics during puberty, the maintenance of these characteristics during adult life, and spermatozoa maturation.

The male sex act involves erection, emission, ejaculation, and detumescence. The physiology of these functions involves a complex interaction between autonomic-mediated spinal cord reflexes, higher neural centers, and the vascular system. Erection is mediated by the parasympathetic nervous system and emission and ejaculation by the sympathetic nervous system. Erectile dysfunction is defined as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse. It can be due to psychogenic factors, organic disorders, or mixed psychogenic and organic conditions.

DISORDERS OF THE PENIS, THE SCROTUM AND TESTES, AND THE PROSTATE

Disorders of the Penis

Disorders of the penis include congenital defects (discussed in Disorders in Childhood), acute and chronic inflammatory conditions, Peyronie's disease, priapism, and neoplasms.

Inflammation and Infection

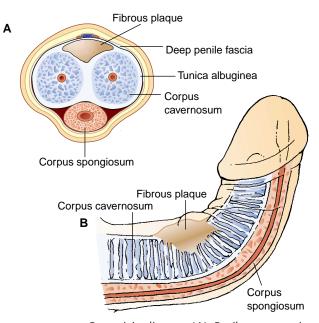

Balantitis and Balanoposthitis. Balanitis is an acute or chronic inflammation of the glans penis. Balanoposthitis refers to inflammation of the glans and prepuce. It usually is encountered in males with phimosis (a tight foreskin) or a large, redundant prepuce that interferes with cleanliness and predisposes to bacterial growth in the accumulated secretions and smegma (*i.e.*, debris from the desquamated epithelia). If left untreated, the condition may cause ulcerations of the mucosal surface of the glans; these ulcerations may lead to inflammatory scarring of the phimosis and further aggravate the condition.

Acute superficial balanoposthitis is characterized by erythema of the glans and prepuce. An exudate in the form of malodorous discharge may be present. Extension of the erythema and edema may result in phimosis. The condition may result from infection, trauma, or irritation. Infective balanoposthitis may be caused by a wide variety of organisms. Chlamydiae and mycoplasmas have been identified as causative organisms in this disease. The inflammatory reaction is nonspecific, and correct identification of the specific agent requires bacterial smears and cultures.

Balanitis xerotica obliterans is a chronic white, patchy lesion that originates on the glans and usually progresses to involve the meatus. It is clinically and histologically similar to the lichen sclerosus that is seen in females. It commonly is observed in middle-aged diabetic men. Treatment measures include topical or intralesional injections of corticosteroids.⁸

Peyronie's Disease

Peyronie's disease involves a localized and progressive fibrosis of unknown origin that affects the tunica albuginea (*i.e.*, the tough, fibrous sheath that surrounds the corpora cavernosa) of the penis. It is named after Francois de la Peyronie, who wrote in 1743, describing a patient who had "rosary beads of scar tissue to cause upward curvature of the penis during erection."9 The disorder is characterized initially by an inflammatory process that results in dense fibrous plaque formation. The plaque usually is on the dorsal midline of the shaft, causing upward bowing of the shaft during erection (Fig. 33-7). Some men may develop scarring on both the dorsal and ventral aspects of the shaft, causing the penis to be straight but shortened or have a lateral bend.9 The fibrous tissue prevents lengthening of the involved area during erection, making intercourse difficult and painful. The disease usually occurs in middle-aged or elderly men. Although the cause of the disorder is unknown, the dense microscopic plaques are consistent with findings of severe vasculitis. As many as 47% of men with Peyronie's disease have another condition associated with fascial tissue fibrosis, such as Dupuytren's contracture (fibrosis of the palmar fascia).9

■ FIGURE 33-7 ■ Peyronie's disease. (A) Penile cross-section showing plaque between the corpora. (B) Penile curvature.

The manifestations of Peyronie's disease include painful erection, bent erection, and the presence of a hard mass at the site of fibrosis. Approximately two thirds of men report pain as a symptom. The pain is thought to be generated by inflammation of the adjacent fascial tissue and usually disappears as the inflammation resolves.¹⁰ During the first year or so after formation of the plaque, while the scar tissue is undergoing the process of remodeling, penile distortion may increase, remain static, or resolve and disappear completely.⁹ In some cases, the scar tissue may progress to calcification and formation of bone-like tissue.

Diagnosis is based on history and physical examination. Doppler ultrasonography may be used to assess causation of the disorder. Although surgical intervention can be used to correct the disorder, it often is delayed, because in many cases the disorder is self-limiting.¹⁰ Less invasive treatments include the administration of oral agents with antioxidant properties (*e.g.*, vitamin D, potassium aminobenzoate, and colchicine).

Priapism

Priapism is an involuntary, prolonged, abnormal and painful erection that is not associated with sexual excitement. Priapism is a true urologic emergency because the prolonged erection can result in ischemia and fibrosis of the erectile tissue with significant risk of subsequent impotence. Priapism can occur at any age, in the newborn as well as other age groups. Sickle cell disease or neoplasms are the most common cause in boys between 5 and 10 years of age.

Priapism is due to impaired blood flow in the corpora cavernosa of the penis. Two mechanisms for priapism have been proposed: low-flow (ischemic) priapism, in which there is stasis of blood flow in the corpora cavernosa with a resultant failure of detumescence, and high-flow (nonischemic) priapism, which involves persistent arterial flow into the corpora cavernosa.¹¹ In high-flow priapism, there is no hypoxia of local tissue, the penis is less rigid, the pain is less than in stasis priapism, and permanent corporal fibrosis and cellular damage are rare.¹¹

Priapism is classified as primary (idiopathic) or secondary to a disease or drug effect. Primary priapism is the result of conditions such as trauma, infection, and neoplasms. Secondary causes include hematologic conditions such as leukemia, sickle cell disease, and thrombocytopenia; neurologic conditions such as stroke, spinal cord injury, and other central nervous system lesions; and renal failure. Between 6% and 12% of males with sickle cell disorders are affected by priapism.¹¹ The relative deoxygenation and stasis of cavernosal blood during erection is thought to increase sickling. Various medications, such as antihypertensive drugs, anticoagulant drugs, antidepressant drugs, alcohol, and marijuana, can contribute to the development of priapism. Androstenedione, sold as an over-the-counter drug to enhance muscle building and athletic performance, has been implicated in the disorder.¹² Currently, intracavernous injection therapy for erectile dysfunction is one of the more common causes of priapism.

The diagnosis of priapism usually is based on clinical findings. Doppler studies of penile blood flow, penile ultrasonography, and computed tomography (CT) scans may be used to determine intrapelvic pathology.

Initial treatment measures include analgesics, sedation, and hydration. Urinary retention may necessitate catheterization. Local measures include application of ice packs and irrigation of the corpus cavernosum with plain or heparinized saline, or instillation of α -adrenergic drugs. If less aggressive treatment does not produce detumescence, a temporary surgical shunt may be established between the corpus cavernosum and the corpus spongiosum.

The prognosis for whether fibrosis or erectile failure will occur is determined by the severity and duration of blood stasis. In high-flow priapism, the damaging effects of decreased oxygen tension and intracavernal blood pressure are less pronounced than in stasis priapism. Normal erectile potency can be restored even after a long duration of high-flow priapism. In contrast, persistent stasis priapism is known to result in impaired erectile function and tissue fibrosis unless resolved within 24 to 48 hours of onset.¹¹

Cancer of the Penis

Squamous cell cancer of the penis is most common in men between 45 and 60 years of age. In the United States, it accounts for less than 1% of male genital tumors; however, in other countries, it accounts for 10% to 20% of male cancers.^{13,14} When it is diagnosed early, penile cancer is highly curable. The greatest hindrance to early diagnosis is a delay in seeking medical attention.

The cause of penile cancer is unknown. Several risk factors have been suggested, including poor hygiene, human papillomavirus (HPV) infections, ultraviolet radiation exposure, and immunodeficiency states. There is an association between penile cancer and poor genital hygiene and phimosis. One theory postulates that smegma accumulation under the phimotic foreskin may produce chronic inflammation, leading to carcinoma. The HPVs have been implicated in the genesis of several genital cancers, including cancer of the penis.¹³ Ultraviolet radiation also is thought to have a carcinogenic effect on the penis. Males who were treated for psoriasis with ultraviolet A or B therapies (*i.e.*, PUVA or PUVB) have had a reported increased incidence of genital squamous cell carcinomas.¹³ Because of this observation, it is suggested that men should shield their genital area when using tanning salons. Immunodeficiency states also may play a role in the pathogenesis of penile cancer. Approximately 18% of men with acquired immunodeficiency syndrome (AIDS)-related Kaposi's sarcoma have lesions of the penis or genitalia.¹³

Dermatologic lesions with precancerous potential include balanitis xerotica obliterans (discussed earlier) and giant condylomata acuminata.¹⁴ Giant condylomata acuminata are cauliflower-like lesions arising from the prepuce or glans that result from HPV infection.

Approximately 95% of penile cancers are squamous cell carcinoma.¹³ It is thought to progress from an in situ lesion to an invasive carcinoma. Bowen's disease and erythroplasia of Queyrat are penile lesions with histologic features of carcinoma in situ.¹⁴ Bowen's disease appears as a solitary, thickened, gray-white, opaque plaque with shallow ulceration and crusting. It commonly involves the skin of the shaft of the penis and the scrotum. Erythroplasia of Queyrat involves the mucosal surface of the glans or prepuce. It is characterized by single or multiple shiny red, sometimes velvety, plaques.¹⁴ These lesions require careful follow-up because of their potential to progress to invasive carcinoma.

Invasive carcinoma of the penis begins as a small lump or ulcer. If phimosis is present, there may be painful swelling, purulent drainage, or difficulty urinating. Palpable lymph nodes may be present in the inguinal region. Diagnosis usually is based on physical examination and biopsy results. CT scans, penile ultrasound studies, and magnetic resonance imaging (MRI) may be used in the diagnostic workup.

Treatment options vary according to stage, size, location, and invasiveness of the tumor. Carcinoma in situ may be treated conservatively with fluorouracil cream application or laser treatment.¹⁴ Surgery remains the mainstay of treatment for invasive carcinoma. Partial or total penectomy is indicated for invasive lesions.

Disorders of the Scrotum and Testes

The testes, or male gonads, are two egg-shaped structures located outside the abdominal cavity in the scrotum. Embryologically, the testes develop in the abdominal cavity and then descend through the inguinal canal into a pouch of peritoneum (which becomes the tunica vaginalis) in the scrotum during the seventh to ninth months of fetal life. As they descend, the testes pull their arteries, veins, lymphatics, nerves, and conducting excretory ducts with them. These structures are encased by the cremaster muscle and layers of fascia that constitute the spermatic cord (Fig. 33-8A). The descent of the testes is thought to be mediated by testosterone, which is active during this stage of development.

After descent of the testes, the inguinal canal closes almost completely. Failure of this canal to close predisposes to the development of an inguinal hernia later in life (Fig. 33-8B). An inguinal hernia or "rupture" is a protrusion of the parietal peritoneum and part of the intestine through an abnormal opening from the abdominal cavity. A loop of small bowel may become incarcerated in an inguinal hernia (strangulated hernia), in which case the lumen may become obstructed, and the vascular supply compromised (see Chapter 27).

The testes and epididymis are completely surrounded by the tunica vaginalis, a serous pouch derived from the peritoneum during fetal descent of the testes into the scrotum. The tunica vaginalis has an outer parietal layer and a deeper visceral layer that adheres to the dense fibrous covering of the testes, the tunica albuginea. The tunica albuginea protects the testes and gives them their ovoid shape. A space exists between these two layers that typically contains a few milliliters of clear fluid. The cremaster muscles, which are bands of skeletal muscle arising from the internal oblique muscles of the trunk, elevate the testes. The testes receive their arterial blood supply from the long testicular arteries, which branch from the aortic artery. The spermatic veins, which drain the testes, arise from a venous network called the pampiniform plexus that surrounds the spermatic artery. The testes are innervated by fibers from both divisions of the autonomic nervous system. Associated sensory nerves transmit pain impulses, resulting in excruciating pain, especially when the testes are hit forcibly.

The scrotum, which houses the testes, is made up of a thin outer layer of skin that forms rugae, or folds, and is continuous with the perineum and outer skin of the groin. Under the outer skin lies a thin layer of fascia and smooth muscle (*i.e.*, dartos muscle). This layer contains a septum that separates the two testes. The dartos muscle responds to changes in temperature. When it is cold, the muscle contracts, bringing the testes closer to the body, and the scrotum becomes shorter and heavily wrinkled. When it is warmer, the muscle relaxes, allowing the scrotum to fall away from the body.

The location of the testes in the scrotum is important for sperm production, which is optimal at 2°C to 3°C below body temperature. Two systems maintain the temperature of the testes at a level consistent with sperm production. One is the pampiniform plexus of spermatic veins that surround the spermatic artery. This plexus absorbs heat from the arterial blood, cooling it as it enters the testes. The other is the cremaster muscles, which respond to decreases in testicular temperature by moving the testes closer to the body. Prolonged exposure to elevated temperatures, as a result of prolonged fever or the dysfunction of thermoregulatory mechanisms, can impair spermatogenesis. Some tight-fitting undergarments hold the testes against the body and are thought to contribute to a decrease in sperm counts and infertility by interfering with the thermoregulatory function of the scrotum. Cryptorchidism, the failure of the testes to descend into the scrotum, also exposes the testes to the higher temperature of the body.

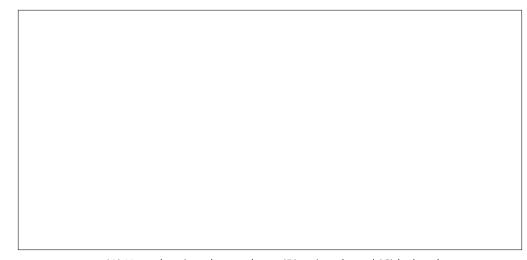

Disorders of the Testicular Tunica

Hydrocele. A hydrocele forms when excess fluid collects between the layers of the tunica vaginalis (Fig. 33-9). It may be unilateral or bilateral and can develop as a primary congenital defect or as a secondary condition. Acute hydrocele may develop after local injury, epididymitis or orchitis, gonorrhea, lymph obstruction, or germ cell testicular tumor, or as a side effect of radiation therapy. Chronic hydrocele is more common. Fluid collects about the testis, and the mass grows gradually. Its cause is unknown, and it usually develops in men older than 40 years.

Most cases of hydrocele in male infants and children are due to a patent processus vaginalis, which is continuous with the peritoneal cavity. In many cases they are associated with an indirect inguinal hernia.¹⁵ Most hydroceles of infancy close spontaneously; therefore, they are not usually repaired before the age of 1 year. Hydroceles that persist beyond 2 years of age may require surgical treatment.

Hydroceles are palpated as cystic masses that may attain massive proportions. If there is enough fluid, the mass may be mistaken for a solid tumor. Transillumination of the scrotum (*i.e.*, shining a light through the scrotum for the purposes of visualizing its internal structures) or ultrasonography can help to determine whether the mass is solid or cystic and whether the testicle is normal.¹⁶ A dense hydrocele that does not illuminate should be differentiated from a testicular tumor. If a hydrocele develops in a young man without apparent cause, careful evaluation is needed to exclude cancer or infection.

In an adult male, a hydrocele is a relatively benign condition. The condition often is asymptomatic, and no treatment is necessary. When symptoms do occur, the feeling may be that of heaviness in the scrotum or pain in the lower back. In cases of secondary hydrocele, the primary condition is treated. If the hydrocele is painful or cosmetically undesirable, surgical correction is indicated. Surgical repair may be done inguinally or transcrotally.

■ FIGURE 33-9 ■ (A) Normal testis and appendages, (B) varicocele, and (C) hydrocele.

Hematocele. A hematocele is an accumulation of blood in the tunica vaginalis, which causes the scrotal skin to become dark red or purple. It may develop as a result of an abdominal surgical procedure, scrotal trauma, a bleeding disorder, or a testicular tumor.

Spermatocele. A spermatocele is a painless, sperm-containing cyst that forms at the end of the epididymis. It is located above and posterior to the testis, is attached to the epididymis, and is separate from the testes. Spermatoceles may be solitary or multiple and usually are less than 1 cm in diameter. They are freely movable and should transilluminate. Spermatoceles rarely cause problems, but a large one may become painful and require excision.

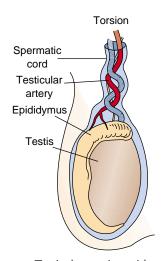

Varicocele. A varicocele is characterized by varicosities of the pampiniform plexus, a network of veins supplying the testes (Fig. 33-9). The left side is more commonly affected because the left internal spermatic vein inserts into the left renal vein at a right angle, whereas the right spermatic vein usually enters the inferior vena cava. Incompetent valves are more common in the left internal spermatic veins, causing a reflux of blood back into the veins of the pampiniform plexus. The force of gravity resulting from the upright position also contributes to venous dilatation. If the condition persists, there may be damage to the elastic fibers and hypertrophy of the vein walls, as occurs in formation of varicose veins in the leg. Sperm concentration and motility are decreased in 65% to 75% of men with varicocele because of changes in testicular temperature resulting from altered blood flow.¹⁶

Varicoceles rarely are found before puberty, and the incidence is highest in men between 15 and 35 years of age. Symptoms of varicocele include an abnormal feeling of heaviness in the left scrotum, although many varicoceles are asymptomatic. Usually, the varicocele is readily diagnosed on physical examination with the patient in the standing and recumbent positions. Typically, the varicocele disappears in the lying position because of venous decompression into the renal vein. Scrotal palpation of a varicocele has been compared to feeling a "bag of worms." Treatment options include surgical ligation or sclerosis using a percutaneous transvenous catheter under fluoroscopic guidance. It has been shown that 40% of men with abnormalities in their semen and a varicocele show some degree of improvement in fertility after obliteration of the dilated veins.¹⁶ Aside from improving fertility, other reasons for surgery include the relief of the sensation of "heaviness" and cosmetic improvement.

Testicular Torsion

Testicular torsion is a twisting of the spermatic cord that suspends the testis (Fig. 33-10). It is the most common acute scrotal disorder in the pediatric and young adult population. Testicular torsion can be divided into two distinct clinical entities, depending on the level of spermatic cord involvement: extravaginal and intravaginal torsion.¹⁷

Extravaginal torsion, which occurs almost exclusively in neonates, is the less common form of testicular torsion. It occurs

■ FIGURE 33-10 ■ Testicular torsion with twisting of the spermatic cord that suspends the testis and the spermatic vessels that supply the testis with blood.

when the testicle and the fascial tunicae that surround it rotate around the spermatic cord at a level well above the tunica vaginalis. Intravaginal torsion is considerably more common than extravaginal torsion. It occurs when the testis rotates on the long axis in the tunica vaginalis. In most cases, congenital abnormalities of the tunica vaginalis or spermatic cord exist.¹⁷ The tunica vaginalis normally surrounds the testes and epididymis, allowing the testicle to rotate freely in the tunica. Although anomalies of suspension vary, the epididymal attachment may be loose enough to permit torsion between the testis and the epididymis. More commonly, the testis rotates about the distal spermatic cord. Because this abnormality is developmental, bilateral anomalies are common.

Intravaginal torsion occurs most frequently between the ages of 8 and 18 years and rarely is seen after 30 years of age. Males usually present in severe distress within hours of onset and often have nausea, vomiting, and tachycardia. The affected testis is large and tender, with pain radiating to the inguinal area. Extensive cremaster muscle contraction causes a thickening of the spermatic cord.

Testicular torsion must be differentiated from epididymitis, orchitis, and trauma to the testis. On physical examination, the testicle often is high in the scrotum and in an abnormal orientation. These changes are due to the twisting and shortening of the spermatic cord. The degree of scrotal swelling and redness depends on the duration of symptoms. The testes are firm and tender. The cremasteric reflex, normally elicited by stroking the medial aspect of the thigh and observing testicular retraction, frequently is absent.¹⁷ Color Doppler ultrasonography is increasingly used in the evaluation of suspected testicular torsion.17

Intravaginal testicular torsion is a true surgical emergency, and early recognition and treatment are necessary if the testicle is to be saved. Treatment includes surgical detorsion (repositioning and fixation) and orchiectomy. Orchiectomy is carried out when the testis is deemed nonviable after surgical detorsion. Testicular salvage rates are directly related to the duration of torsion. Because the opposite testicle usually is affected by the same abnormal attachments, prophylactic fixation of that testis often is performed.

Inflammation and Infection

Epididymitis. Epididymitis is an inflammation of the epididymis. There are two major types of epididymitis: sexually transmitted infections associated with urethritis and primary nonsexually transmitted infections associated with urinary tract infections and prostatitis. Most cases of epididymitis are caused by bacterial pathogens.

In primary nonsexual infections, the pressure associated with voiding or physical strain may force pathogen-containing urine from the urethra or prostate up the ejaculatory duct and through the vas deferens and into the epididymis. Infections also may reach the epididymis through the lymphatics of the spermatic cord. In rare cases, organisms from other foci of infection reach the epididymis through the bloodstream. In children, the disorder usually is associated with congenital urinary tract abnormalities and infection with gram-negative rods.

Sexually transmitted acute epididymitis occurs mainly in young men without underlying genitourinary disease and is most commonly caused by Chlamydia trachomatis and Neisseria gonorrhoeae (singly or in combination). In men older than 35 years, epididymitis often is associated with pathogens such as Escherichia coli, Pseudomonas, and gram-positive cocci.

Epididymitis is characterized by unilateral pain and swelling, accompanied by erythema and edema of the overlying scrotal skin that develops during a period of 24 to 48 hours. Initially, the swelling and induration are limited to the epididymis. However, the distinction between the testis and epididymis becomes less evident as the inflammation progresses, and the testis and epididymis become one mass. There may be tenderness over the groin (spermatic cord) or in the lower abdomen. Fever and reports of dysuria occur in approximately one half of cases. Whether urethral discharge is present depends on the organism causing the infection; it usually accompanies gonorrheal infections, is common in chlamydial infections, and is less common in infections caused by gram-negative organisms.

Laboratory findings usually reveal an elevated white blood cell count. Urinalysis and urine culture are important in the diagnosis of epididymitis, with bacteriuria and pyuria suggestive of the disorder. Treatment during the acute phase (which usually lasts for 3 to 4 days) includes bed rest, scrotal elevation and support, and antibiotics.¹⁸ Bed rest with scrotal support improves lymphatic drainage. The choice of antibiotics is determined by age, physical findings, urinalysis, Gram's stain results, cultures, and sexual history. Oral analgesics and antipyretics usually are indicated. Sexual activity or physical strain may exacerbate the infection and worsen the symptoms and should be avoided.

Orchitis. Orchitis is an infection of the testes. It can be precipitated by a primary infection in the genitourinary tract, or the infection can be spread to testes through the bloodstream or the lymphatics. Epididymitis with subsequent infection of the testis is commonly related to genitourinary tract infections (cystitis, urethritis, genitoprostatitis) that travel to the epididymis and testis through the vas deferens or the lymphatics of the spermatic cord.

Orchitis can develop as a complication of a systemic infection, such as parotitis (i.e., mumps), scarlet fever, or pneumonia. Probably the best known of these complications is orchitis caused by the mumps virus. Mumps orchitis does not occur in prepubertal boys. However, approximately 20% to 35% of adolescent boys and young men with mumps develop this form of orchitis.¹⁸ The onset of mumps orchitis is sudden; it usually occurs approximately 3 to 4 days after the onset of the parotitis and is characterized by fever, painful enlargement of the testes, and small hemorrhages into the tunica albuginea. Unlike epididymitis, the urinary symptoms are absent. The symptoms usually run their course in 7 to 10 days. The residual effects seen after the acute phase include hyalinization of the seminiferous tubules and atrophy of the testes. Spermatogenesis is irreversibly impaired in approximately 30% of testes damaged by mumps orchitis.¹⁸ If both testes are involved, permanent sterility results, but and rogenic hormone function usually is maintained.

Cancer of the Scrotum and Testes

Tumors can develop in the scrotum or the testes. Benign scrotal tumors are common and often do not require treatment. Carcinoma of the scrotum is rare and usually is associated with exposure to carcinogenic agents. Almost all solid tumors of the testes are malignant.

Scrotal Cancer. Cancer of the scrotum was the first cancer directly linked to a specific occupation when, in the 1800s, it was associated with chimney sweeps.¹⁹ Studies have linked this cancer to exposure to tar, soot, and oils. Most squamous cell cancers of the scrotum are linked to poor hygiene and chronic inflammation. Exposure to ultraviolet A radiation (*e.g.*, PUVA) or HPV also has been associated with the disease. The mean age of presentation with the disease is 60 years, often preceded by 20 to 30 years of chronic irritation.

In the early stages, cancer of the scrotum may appear as a small tumor or wartlike growth that eventually ulcerates. The thin scrotal wall lacks the tissue reactivity needed to block the malignant process; more than one half of the cases seen involve metastasis to the lymph nodes. Because this tumor does not respond well to chemotherapy or irradiation, the treatment includes wide local excision of the tumor with inguinal and femoral node dissection.²⁰

Testicular Cancer. Testicular cancer accounts for 1% of all male cancers and 3% of male urogenital cancers. Although relatively rare, it is the most common cause of cancer in the 15- to 34-year-old age group.^{20,21} In the past, testicular cancer was a leading cause of death among males entering their most productive years. However, since the late 1970s, advances in therapy have transformed an almost invariably fatal disease into one that is highly curable. With appropriate treatment, the prognosis for men with testicular cancer is excellent. The 5-year survival rate for patients with early disease exceeds 95%. Even patients with more advanced disease have excellent chances for long-term survival.

Although the cause of testicular cancer is unknown, several predisposing influences may be important: cryptorchidism, genetic factors, and disorders of testicular development.²² The strongest association has been with cryptorchid or undescended testes. The higher the location of the undescended testis, the greater the risk.²² Genetic predisposition also appears to be important. Family clustering of the disorder has been described, although a well-defined pattern of inheritance has not been established. Men with disorders of testicular development, including those with Klinefelter's syndrome and testicular feminization, have a higher risk of germ cell tumors.

Approximately 95% of malignant tumors arising in the testis are germ cell tumors.^{21,23} Germ cell tumors can be classified as seminomas and nonseminomas based on their origin in primordial germ cells and their ability to differentiate in vivo. Because these tumors derive from germ cells in the testis, they are multipotential (able to differentiate into different tissue types) and often secrete polypeptide hormones or enzymes representing earlier stages of development (see Chapter 5). *Seminomas* are the most common type of testicular tumors. They account for approximately 50% of germ cell tumors and occur most frequently during the fourth decade of life.²¹ Seminomas are thought to arise from the seminiferous epithelium of the testes and are the type of germ cell tumor most likely to produce a uniform population of cells.

The nonseminoma tumors include embryonal carcinoma, teratoma, choriocarcinoma, and yolk cell carcinoma derivatives. Nonseminoma tumors usually contain more than one cell type and are less differentiated than seminomas. Embryonal carcinomas are the least differentiated of the tumors, with totipotential capacity to differentiate into other nonseminomatous cell types. They occur most commonly in the 20- to 30-year-old age group. Choriocarcinoma is a rare and highly malignant form of testicular cancer that is identical to tumors that arise in placental tissue. Yolk sac tumors mimic the embryonic yolk sac histologically. They are the most common type of testicular tumors in infants and children to 3 years of age, and in this age group are associated with a very good prognosis.²² Teratomas are composed of somatic cell types from two or more germ-line layers (ectoderm, mesoderm, or endoderm). They constitute less than 2% to 3% of germ cell tumors and can occur at any age from infancy to old age. They usually behave as benign tumors in children; in adults, they often contain minute foci of cancer cells.

Often the first sign of testicular cancer is a slight enlargement of the testicle that may be accompanied by some degree of discomfort. This may be an ache in the abdomen or groin or a sensation of dragging or heaviness in the scrotum. Frank pain may be experienced in the later stages, when the tumor is growing rapidly and hemorrhaging occurs. Testicular cancer can spread when the tumor may be barely palpable. Signs of metastatic spread include swelling of the lower extremities, back pain, cough, hemoptysis, or dizziness. Gynecomastia (breast enlargement) may result from human chorionic gonadotropin (hCG)-producing tumors.

Early diagnosis of testicular cancer is important because a delay in seeking medical attention often results in presentation with a later stage of the disease and decreased treatment effectiveness. Recognition of the importance of prompt diagnosis and treatment has resulted in the development of a procedure for testicular self-examination and an emphasis on public education programs about this type of cancer. The American Cancer Society strongly advocates that every young adult male examine his testes at least once each month as a means of early detection of testicular cancer.

The diagnosis of testicular cancer requires a thorough urologic history and physical examination. A painless testicular mass may be cancer. The examination for masses should include palpation of the testes and surrounding structures, transillumination of the scrotum, and abdominal palpation. Testicular ultrasonography can be used to differentiate testicular masses. CT scans and MRI are used in assessing metastatic spread.

Tumor markers, which measure protein antigens produced by malignant cells, provide information about the existence of a small or undetected tumor and the type of tumor present. Three tumor markers are useful in evaluating the tumor response: α -fetoprotein, a glycoprotein that normally is present in fetal serum in large amounts; hCG, a hormone that normally is produced by the placenta in pregnant women; and lactate dehydrogenase (LDH), a cellular enzyme normally found in muscle, liver, kidney, and brain. The reappearance in the adult of these protein markers suggests activity normally present in the embryo.

The basic treatment of all testicular cancers includes orchiectomy, which is done at the time of diagnostic exploration. Dependent on the histologic characteristics of the tumor and the clinical stage of the disease, radiation or chemotherapy may used after orchiectomy. Rigorous follow-up in all men with testicular cancer is necessary to detect recurrence, which most often occurs within the first year.²³

Disorders of the Prostate

The prostate is a fibromuscular and glandular organ lying just inferior to the bladder. The prostate gland secretes a thin, milky, alkaline fluid containing citric acid, calcium, acid phosphate, a clotting enzyme, and a profibrinolysin. During ejaculation, the capsule of the prostate contracts, and the added fluid increases the bulk of the semen. Both vaginal secretions and the fluid from the vas deferens are strongly acidic. Because sperm mobilization occurs at a pH of 6.0 to 6.5, the alkaline nature of the prostatic secretions is essential for successful fertilization of the ovum. The bulbourethral glands (Fig. 33-1) lie on either side of the membranous urethra and secrete an alkaline mucus, which further aids in neutralizing acids from the urine that remain in the urethra.

The prostate gland, which forms a fibrous capsule that surrounds the urethra where it joins the bladder, also functions in the elimination of urine. The segment of urethra that travels through the prostate gland is called the *prostatic urethra*. The prostatic urethra is lined by a thin layer of smooth muscle that is continuous with the bladder wall. This smooth muscle represents the true involuntary sphincter of the male posterior urethra. Because the prostate surrounds the urethra, enlargement of the gland can produce urinary obstruction.

The prostate gland is made up of many secretory glands arranged in three concentric areas surrounding the prostatic urethra, into which they open. The component glands of the prostate include the (1) small mucosal glands associated with the urethral mucosa, (2) the intermediate submucosal glands that lie peripheral to the mucosal glands, and (3) the large main prostatic glands that are situated toward the outside of the gland. It is the overgrowth of the mucosal glands that causes benign prostatic hyperplasia in older men.

Prostatitis

Prostatitis refers to a variety of inflammatory disorders of the prostate gland, some of which are bacterial and some are not. It may occur spontaneously, as a result of catheterization or instrumentation, or secondary to other diseases of the male genitourinary system. As an outcome of 1995 and 1998 consensus conferences, the National Institutes of Health has established a classification system with four categories of prostatitis syndromes: asymptomatic inflammatory prostatitis, acute bacterial prostatitis, chronic bacterial prostatitis, and chronic prostatitis/ pelvic pain syndrome.²⁴ Men with asymptomatic inflammatory prostatitis have no subjective symptoms and are detected incidentally on biopsy or examination of prostatic fluid.

Acute Bacterial Prostatitis. Acute bacterial prostatitis often is considered a subtype of urinary tract infection. The most likely etiology of acute bacterial prostatitis is an ascending urethral infection or reflux of infected urine into the prostatic ducts. The most common organism is E. coli. Other frequently found species include Pseudomonas, Klebsiella, and Proteus. Less frequently, the infection is caused by Staphylococcus aureus, Streptococcus faecalis, Chlamydia, or anaerobes such as Bacteroides species.^{25,26}

The manifestations of acute bacterial prostatitis include fever and chills, malaise, myalgia, arthralgia, frequent and urgent urination, dysuria, and urethral discharge. Dull, aching pain often is present in the perineum, rectum, or sacrococcygeal region. The urine may be cloudy and malodorous because of urinary tract infection. Rectal examination reveals a swollen, tender, warm prostate with scattered soft areas. Prostatic massage produces a thick discharge with white blood cells that grows large numbers of pathogens on culture.

Acute prostatitis usually responds to appropriate antimicrobial therapy chosen in accordance with the sensitivity of the causative agents in the urethral discharge. Depending on the urine culture results, antibiotic therapy usually is continued for at least 4 weeks. Because acute prostatitis often is associated with anatomic abnormalities, a thorough urologic examination usually is performed after treatment is completed.

A persistent fever indicates the need for further investigation for an additional site of infection or a prostatic abscess. CT scans and transrectal ultrasonography of the prostate are useful in the diagnosis of prostatic abscesses. Prostatic abscesses, which are relatively uncommon since the advent of effective antibiotic therapy, are found more commonly in males with diabetes mellitus. Because prostatic abscesses usually are associated with bacteremia, prompt drainage by transperitoneal or transurethral incision followed by appropriate antimicrobial therapy usually is indicated.²⁵

Chronic Bacterial Prostatitis. In contrast to acute bacterial prostatitis, chronic bacterial prostatitis is a subtle disorder that is difficult to treat. Men with the disorder typically have recurrent urinary tract infections with persistence of the same strain of pathogenic bacteria in prostatic fluid and urine. Organisms responsible for chronic bacterial prostatitis usually are the gram-negative enterobacteria (E. coli, Proteus, or Klebsiella) or *Pseudomonas*. Occasionally, a gram-positive organism such as S. faecalis is the causative organism. Infected prostatic calculi may develop and contribute to the chronic infection.

The symptoms of chronic prostatitis are variable and include frequent and urgent urination, dysuria, perineal discomfort, and low back pain. Occasionally, myalgia and arthralgia accompany the other symptoms. Secondary epididymitis sometimes is associated with the disorder. Many men develop relapsing lower or upper urinary tract infections because of recurrent invasion of the bladder by the prostatic bacteria. Bacteria may exist in the prostate gland even when the prostatic fluid is sterile.

The most accurate method of establishing a diagnosis is by urine cultures. Even after an accurate diagnosis has been established, treatment of chronic prostatitis often is difficult and frustrating. Unlike their action in the acutely inflamed prostate, antibacterial drugs penetrate poorly into the chronically inflamed prostate. Long-term therapy (3 to 4 months) with an appropriate low-dose oral antimicrobial agent often is used to treat the infection. Transurethral prostatectomy may be indicated when the infection is not cured or adequately controlled by medical therapy, particularly when prostate stones are present.

Chronic Prostatitis/Chronic Pelvic Pain Syndrome. Chronic prostatitis/pelvic pain syndrome is both the most common and least understood of the prostatitis syndromes.²⁷ The category is divided into two types, inflammatory and noninflammatory, based on the presence of leukocytes in the prostatic fluid. The inflammatory type was previously referred to as nonbacterial prostatitis, and the noninflammatory type as prostatodynia.

Men with nonbacterial prostatitis have inflammation of the prostate with an elevated leukocyte count, inflammatory cells

594 Unit Nine: Alterations in the Male and Female Reproductive Systems

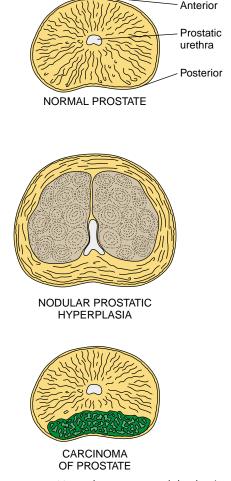

in their prostatic secretions, but no evidence of bacteria. The cause of the disorder is unknown, and efforts to prove the presence of unusual pathogens (*e.g.*, mycoplasmas, chlamydiae, trichomonads, viruses) have been largely unsuccessful. It also is thought that nonbacterial prostatitis may be an autoimmune disorder. Manifestations of *inflammatory prostatitis* include pain along the penis, testicles, and scrotum; painful ejaculation; low back pain; rectal pain along the inner thighs; urinary symptoms; decreased libido; and impotence.

Men with noninflammatory prostatitis have symptoms resembling those of nonbacterial prostatitis but have negative urine culture results and no evidence of prostatic inflammation (*i.e.*, normal leukocyte count). The cause of noninflammatory prostatitis is unknown, but because of the absence of inflammation, the search for the cause of symptoms has been directed toward extraprostatic sources. In some cases, there is an apparent functional obstruction of the bladder neck near the external urethral sphincter; during voiding, this results in higher than normal pressures in the prostatic urethra that cause intraprostatic urine reflux and chemical irritation of the prostate by urine. In other cases, there is an apparent myalgia (*i.e.*, muscle pain) associated with prolonged tension of the pelvic floor muscles. Emotional stress also may play a role.

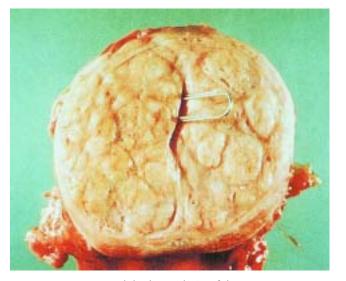

Treatment methods for chronic prostatitis/pelvic pain syndrome are highly variable. Antibiotic therapy is used when an occult infection is suspected. Sitz baths and nonsteroidal antiinflammatory agents may provide some symptom relief. In men with irritative urination symptoms, anticholinergic agents or α -adrenergic-blocking agents may be beneficial.

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is an age-related, nonmalignant enlargement of the prostate gland (Fig. 33-11). It is characterized by the formation of large, nodular lesions in

■ FIGURE 33-12 ■ Normal prostate, nodular benign prostatic hypertrophy, and cancer of the prostate. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 954]. Philadelphia: Lippincott Williams & Wilkins.) (Artist: Dimitri Karetnikov)

■ FIGURE 33-11 ■ Nodular hyperplasia of the prostate. Cut surface of a prostate enlarged by nodular hyperplasia shows numerous, well-circumscribed nodules of prostatic tissue. The prostatic urethra (*paper clip*) has been compressed to a narrow slit. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 955]. Philadelphia: Lippincott Williams & Wilkins)

the periurethral region of the prostate, rather than the peripheral zones, which commonly are affected by prostate cancer (Fig. 33-12). BPH is one of the most common diseases of aging men. It has been reported that 25% of men older than 55 years of age and 50% of men older than 75 years of age experience symptoms of BPH.²⁸

The exact cause of the BPH is unknown. Potential risk factors include age, family history, race, ethnicity, and hormonal factors. The incidence of BPH increases with advancing age, is highest in African Americans, and is lowest in native Japanese. Men with a family history of BPH are reported to have had larger prostates than those of control subjects, and higher rates of BPH were found in monozygotic twins than in dizygotic twins.²⁸

Both androgens (testosterone) and estrogens appear to contribute to the development of BPH. Dihydrotestosterone (DHT), the biologically active metabolite of testosterone, is thought to be the ultimate mediator of prostatic hyperplasia, with estrogen serving to sensitize the prostatic tissue to the growth-producing effects of DHT. Free plasma testosterone enters prostatic cells, where at least 90% is converted into DHT by

KEY CONCEPTS

HYPERPLASIA AND CANCER OF THE PROSTATE

- The prostate gland surrounds the urethra, and periurethral enlargement will cause manifestations of urinary obstruction.
- Benign prostatic hyperplasia is an age-related enlargement of the prostate gland with formation of large, discrete lesions in the periurethral region of the prostate. These lesions compress the urethra and produce symptoms of dysuria or difficulty urinating.
- Prostatic cancer begins in the peripheral zones of the prostate gland and usually is asymptomatic until the disease is far advanced and the tumor has eroded the outer prostatic capsule and spread to adjacent pelvic tissues or metastasized.

the action of 5α -reductase. The discovery that DHT is the active factor in BPH is the rationale for use of 5α -reductase inhibitors in the treatment of the disorder. Although the exact source of estrogen is uncertain, small amounts of estrogen are produced in the male. It has been postulated that a relative increase in estrogen levels that occurs with aging may facilitate the action of androgens in the prostate despite a decline in the testicular output of testosterone.

The anatomic location of the prostate at the bladder neck contributes to the pathophysiology and symptomatology of BPH. There are two prostatic components to the obstructive properties of BPH and the development of lower urinary tract symptoms: dynamic and static.28,29 The static component of BPH is related to an increase in prostatic size and gives rise to symptoms such as a weak urinary stream, postvoid dribbling, frequency of urination, and nocturia. The dynamic component of BPH is related to prostatic smooth muscle tone. The α_1 adrenergic receptors are the main receptors for the smooth muscle component of the prostate. The recognition of the role of α_1 -adrenergic receptor on neuromuscular function in the prostate is the basis for use of α_1 -adrenergic-receptor blockers in treating BPH. A third component, detrusor instability and impaired bladder contractility, may contribute to the symptoms of BPH independent of the outlet obstruction created by an enlarged prostate (see Chapter 25).^{29,30} It has been suggested that some of the symptoms of BPH might be related to a decompensating or aging bladder, rather than being primarily related to outflow obstruction. An example is the involuntary contraction that results in urgency and an attempt to void that occurs because of small bladder volume.29

Clinical Course. The clinical significance of BPH resides in its tendency to compress the urethra and cause partial or complete obstruction of urinary outflow. As the obstruction increases, acute retention may occur with overdistention of the bladder. The residual urine in the bladder causes increased frequency of urination and a constant desire to empty the bladder, which be-

comes worse at night. With marked bladder distention, overflow incontinence may occur with the slightest increase in intra-abdominal pressure. The resulting obstruction to urinary flow can give rise to urinary tract infection, destructive changes of the bladder wall, hydroureter, and hydronephrosis. Hypertrophy and changes in bladder wall structure develop in stages. Initially, the hypertrophied fibers form trabeculations and then herniations, or sacculations; finally, diverticula develop as the herniations extend through the bladder wall (Chapter 25, Fig. 25-4). Because urine seldom is completely emptied from them, these diverticula are readily infected. Back pressure on the ureters and collecting system of the kidneys promotes hydroureter, hydronephrosis, and eventual renal failure.

It is now thought that the single most important factor in the evaluation and treatment of BPH is the man's own experiences related to the disorder. The American Urological Society Symptom Index consists of seven questions about symptoms regarding incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia.^{31,32} Each question is rated with a score of 0 (mild) to 7 (severe). A maximum score of 35 indicates severe symptoms. Total scores below 7 are considered mild; those between 8 and 20, moderate; and scores over 20, severe. A final question relates to quality of life related to urinary problems.

Diagnosis of BPH is based on history, physical examination, digital rectal examination, urinalysis, blood tests for serum creatinine and prostate-specific antigen (PSA), and urine flow rate. Blood and urine analyses are used as adjuncts to determine BPH complications. Urinalysis is done to detect bacteria, white blood cells, or microscopic hematuria in the presence of infection and inflammation. The serum creatinine test is used as an estimate of the glomerular filtration rate and kidney function. The PSA test is used to screen for prostatic cancer. These evaluation measures, along with the symptom index, are used to describe the extent of obstruction, determine if other diagnostic tests are needed, and establish the need for treatment.

Transabdominal or transrectal diagnostic ultrasonography can be used to evaluate the kidneys, ureters, and bladder. Abdominal radiographs may be used to reveal the size of the gland. Urethrocystoscopy is indicated in men with a history of hematuria, stricture disease, urethral injury, or prior lower urinary tract surgery. It is used to evaluate the length and diameter of the urethra, the size and configuration of the prostate, and bladder capacity. It also detects the presence of trabeculations, bladder stones, and small bladder cancers. CT scans, MRI studies, and radionuclide scans are reserved for rare instances of tumor detection.

Treatment of BPH is determined by the degree of symptoms that the condition produces and complications due to obstruction. When a man develops mild symptoms related to BPH, a "watch and wait" stance often is taken. The condition does not always run a predictable course; it may remain stable or even improve. Until the 1980s, surgery was the mainstay of treatment to alleviate urinary obstruction due to BPH. Currently, there is an emphasis on less invasive methods of treatment, including use of pharmacologic agents. However, when more severe signs of obstruction develop, surgical treatment (*e.g.*, transurethral resection of the prostate [TURP]) usually is indicated to provide comfort and avoid serious renal damage. For men who have heart or lung disease or a condition that precludes major surgery, a stent may be used to widen and maintain the patency of the urethra.

Pharmacologic management includes the use of 5α -reductase inhibitors and α_1 -adrenergic–blocking drugs.^{28,29} The 5α reductase inhibitors such as finasteride reduce prostate size by blocking the effect of androgens on the prostate. The presence of α -adrenergic receptors in prostatic smooth muscle has prompted the use of α_1 -adrenergic–blocking drugs to relieve prostatic obstruction and increase urine flow.

Cancer of the Prostate

Prostatic cancer is the most common male cancer in the United States and is second to lung cancer as a cause of cancer-related death in men. The American Cancer Society estimates that during 2002, approximately 189,000 men in the United States received a diagnosis of prostate cancer, and 32,200 men died of the disorder.³³ The increase in diagnosed cases is thought to reflect earlier diagnosis because of the widespread use of PSA testing since the early 1990s.³⁴ The incidence of prostate cancer varies markedly from country to country and varies among races in the same country.³³ African-American men have the highest reported incidence for prostate cancer at all ages, and Asians and Native American men have the lowest rate. Prostate cancer also is a disease of aging. The incidence increases rapidly after 50 years of age; more than 80% of all prostate cancers are diagnosed in men older than 65 years of age.³³

The precise cause of prostatic cancer is unclear. As with other cancers, it appears that the development of prostate cancer is a multistep process involving genes that control cell differentiation and growth (see Chapter 5). Several risk factors, such as age, race, heredity, and environmental influences, are suspected of playing a role.^{35,36} Male hormone levels also may play a role. There is insufficient evidence linking socioeconomic status, infectious agents, smoking, vasectomy, sexual behavior, or BPH to the pathogenesis of prostate cancer.

The incidence of prostate cancer appears to be higher in relatives of men with prostate cancer. Diet may also play a role. It has been suggested that a diet high in fats may alter the production of sex hormones and increase the risk of prostate cancer. Supporting the role of dietary fats as a risk factor for prostate cancer has been the observation that the diet of Japanese men, who have a low rate of prostate cancer, is much lower in fat content than that of U.S. men, who have a much higher incidence.

In terms of hormonal influence, androgens are believed to play a role in the pathogenesis of prostate cancer.³⁵ Evidence favoring a hormonal influence includes the presence of steroid receptors in the prostate, the requirement of sex hormones for normal growth and development of the prostate, and the fact that prostate cancer almost never develops in men who have been castrated. The response of prostatic cancer to estrogen administration or androgen deprivation further supports a correlation between the disease and testosterone levels.

Prostatic adenocarcinomas, which account for 98% of all primary prostatic cancers, are commonly multicentric and located in the peripheral zones of the prostate³⁶ (see Fig. 33-12). The high frequency of invasion of the prostatic capsule by adenocarcinoma relates to its subcapsular location. Invasion of the urinary bladder is less common and occurs later in the clinical course. Metastasis to the lung reflects lymphatic spread through the thoracic duct and dissemination from the prostatic venous plexus to the inferior vena cava. Bony metastases, particularly to the vertebral column, ribs, and pelvis, produce pain that often presents as a first sign of the disease.

Most men with early-stage prostate cancer are asymptomatic. The presence of symptoms often suggests locally advanced or metastatic disease. Depending on the size and location of prostatic cancer at the time of diagnosis, there may be changes associated with the voiding pattern similar to those found in BPH. These include urgency, frequency, nocturia, hesitancy, dysuria, hematuria, or blood in the ejaculate. On physical examination, the prostate is nodular and fixed. Bone metastasis often is characterized by low back pain. Pathologic fractures can occur at the site of metastasis. Men with metastatic disease may experience weight loss, anemia, or shortness of breath.

Screening. Because early cancers of the prostate usually are asymptomatic, screening tests are important. The screening tests currently available are digital rectal examination, PSA testing, and transrectal ultrasonography. PSA is a glycoprotein secreted into the cytoplasm of benign and malignant prostatic cells that is not found in other normal tissues or tumors. However, a positive PSA test indicates only the possible presence of prostate cancer. It also can be positive in cases of BPH and prostatitis. The American Cancer Society and the American Urological Association recommend that men 50 years of age or older should undergo annual measurement of PSA and rectal examination for early detection of prostate cancer.³³ Men at high risk for prostate cancer, such as blacks and those with a strong family history, should undergo annual screening beginning at 45 years of age.³³

Diagnosis. The diagnosis of prostate cancer is based on history and physical examination and confirmed through biopsy methods. Transrectal ultrasonography, a continuously improving method of imaging, is used to guide a biopsy needle and document the exact location of the biopsied tissue. It also is used for providing staging information.²⁸ Newly developed small probes for transrectal MRI have been shown to be effective in detecting the presence of cancer in the prostate. Radiologic examination of the bones of the skull, ribs, spine, and pelvis can be used to reveal metastases, although radionuclide bone scans are more sensitive. Excretory urograms are used to delineate changes due to urinary tract obstruction and renal involvement.

Cancer of the prostate, like other forms of cancer, is graded and staged (see Chapter 5). Prostatic adenocarcinoma commonly is classified using the Gleason grading system.^{35,36} Welldifferentiated tumors are assigned a grade of 1, and poorly differentiated tumors a grade of 5. Two tumor markers, PSA and serum acid phosphatase, are important in the staging and management of prostatic cancer. In untreated cases, the level of PSA correlates with the volume and stage of disease.³⁷ A rising PSA after treatment is consistent with progressive disease, whether it is locally recurring or metastatic. Measurement of PSA is used to detect recurrence after total prostatectomy. Because the prostate is the source of PSA, levels of the antigen should drop to zero after surgery; a rising PSA indicates recurring disease. Serum acid phosphatase is less sensitive than PSA and is used less frequently. However, it is more predictive of metastatic disease and may be used for that purpose.

Treatment. Cancer of the prostate is treated by surgery, radiation therapy, and hormonal manipulations.^{28,38,39} Chemotherapy has shown limited effectiveness in the treatment of prostate cancer. Treatment decisions are based on tumor grade and stage and on the age and health of the man. Expectant therapy (watching and waiting) may be used if the tumor is not producing symptoms, is expected to grow slowly, and is small and contained in one area of the prostate. This approach is particularly suited for men who are elderly or have other health problems. Most men with an anticipated survival greater than 10 years are considered for surgical or radiation therapy.³⁹ Radical prostatectomy involves complete removal of the seminal vesicles, prostate, and ampullae of the vas deferens. Radiation therapy can be delivered by a variety of techniques, including external beam radiation therapy and transperineal implantation of radioisotopes.

Metastatic disease often is treated with androgen deprivation therapy. Androgen deprivation may be induced at several levels along the pituitary-gonadal axis using a variety of methods or agents. Orchiectomy or estrogen therapy often is effective in reducing symptoms and extending survival. The GnRH analogs (*e.g.*, leuprolide, buserelin, nafarelin) block luteinizing hormone release from the pituitary and reduce testosterone levels without orchiectomy or estrogen therapy. When given continuously and in therapeutic doses, these drugs desensitize GnRH receptors in the pituitary, thereby preventing the release of luteinizing hormone. The antiandrogens block the uptake and actions of androgens in the target tissues. Complete androgen blockade can be achieved by combining an antiandrogen with a GnRH agent or orchiectomy.

In summary, disorders of the penis include balanitis, an acute or chronic inflammation of the glans penis, and balanoposthitis, an inflammation of the glans and prepuce. Peyronie's disease is characterized by the growth of a band of fibrous tissue on top of the penile shaft. Priapism is prolonged, painful, and nonsexual erection that can lead to thrombosis with ischemia and necrosis of penile tissue. Cancer of the penis accounts for less than 1% of male genital cancers in the United States. Although the tumor is slow growing and highly curable when diagnosed early, the greatest hindrance to successful treatment is a delay in seeking medical attention.

Disorders of the scrotum and testes include hydrocele, hematocele, spermatocele, varicocele, and testicular torsion. Inflammatory conditions can involve the scrotal sac, epididymis, or testes. Tumors can arise in the scrotum or the testes. Scrotal cancers usually are associated with exposure to petroleum products such as tar, pitch, and soot. Testicular cancers account for 1% of all male cancers and 3% of cancers of the male genitourinary system. With current treatment methods, a large percentage of men with these tumors can be cured. Testicular self-examination is recommended as a means of early detection of this form of cancer.

The prostate is a firm, glandular structure that surrounds the urethra. Inflammation of the prostate occurs as an acute or a chronic process. Chronic prostatitis probably is the most common cause of relapsing urinary tract infections in men. BPH is a common disorder in men older than 50 years. Because the prostate encircles the urethra, BPH exerts its effect through obstruction of urinary outflow from the bladder. Advances in the treatment of BPH include laser surgery, balloon dilatation, prostatic stents, and pharmacologic treatment.

Prostatic cancer is the most common male cancer in the United States and is second to lung cancer as a cause of cancer-related death in men. A recent increase in diagnosed cases is thought to reflect earlier diagnosis because of widespread use of PSA testing. Most prostate cancers are asymptomatic and are incidentally discovered on rectal examination. Cancer of the prostate, like other forms of cancer, is graded according to the histologic characteristics of the tumor and staged clinically using the TNM system. Treatment, which is based on the extent of the disease, includes surgery, radiation therapy, and hormonal manipulation.

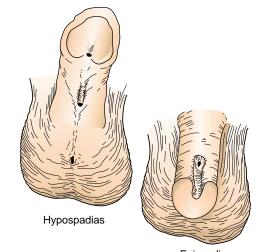

DISORDERS IN CHILDHOOD AND AGING CHANGES

Disorders of Childhood

Disorders of the male reproductive system that present in childhood include hypospadias, epispadias, phimosis and paraphimosis, and cryptorchidism.

Hypospadias and Epispadias

Hypospadias and epispadias are congenital disorders of the penis resulting from embryologic defects in the development of the urethral groove and penile urethra (Fig. 33-13). In hypospadias, which affects approximately 1 in 300 male infants, the termination of the urethra is on the ventral surface of the penis.^{34,40} The testes are undescended in 10% of boys born with hypospadias and chordee (*i.e.*, ventral bowing of the penis), and inguinal hernia also may accompany the disorder. In the newborn with severe hypospadias and cryptorchidism (undescended testes), the differential diagnosis should consider ambiguous genitalia and masculinization

Epispadias

FIGURE 33-13 Hypospadias and epispadias.

that is seen in females with congenital adrenal hyperplasia (see Chapter 31). Because many chromosomal aberrations result in ambiguity of the external genitalia, chromosomal studies often are recommended for male infants with hypospadias and cryptorchidism.³⁴

Surgery is the treatment of choice for hypospadias.³⁴ Circumcision is avoided because the foreskin is used for surgical repair. Factors that influence the timing of surgical repair include anesthetic risk, penile size, and the psychological effects of the surgery on the child. In mild cases, the surgery is done for cosmetic reasons only. In more severe cases, surgical repair becomes essential for normal sexual functioning and to prevent the psychological effects of having malformed genitalia. When indicated, surgical repair is usually done between the ages of 6 to 12 months.

Epispadias, in which the opening of the urethra is on the dorsal surface of the penis, is a less common defect. Although epispadias may occur as a separate entity, it often is associated with exstrophy of the bladder, a condition in which the abdominal wall fails to cover the bladder. The treatment depends on the extent of the developmental defect.

Phimosis and Paraphimosis

Phimosis refers to a tightening of the prepuce or penile foreskin that prevents its retraction over the glans. Embryologically, the foreskin begins to develop during the eighth week of gestation as a fold of skin at the distal edge of the penis that eventually grows forward over the base of the glans.⁴⁰ By the 16th week of gestation, the prepuce and the glans are adherent. Only a small percentage of newborns have a fully retractable foreskin. With growth, a space develops between the glans and foreskin, and by 3 years of age, approximately 90% of male children have retractable foreskins.

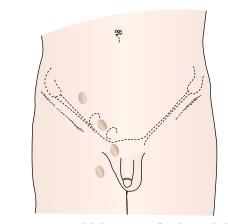

Because the foreskin of many boys cannot be fully retracted in early childhood, it is important that the area be cleaned thoroughly. There is no need to retract the foreskin forcibly because this could lead to infection, scarring, or paraphimosis. As the child grows, the foreskin becomes retractable, and the glans and foreskin should be cleaned routinely. If symptomatic phimosis occurs after childhood, it can cause difficulty with voiding or sexual activity. Circumcision is then the treatment of choice.

In a related condition called *paraphimosis*, the foreskin is so tight and constricted that it cannot cover the glans. A tight foreskin can constrict the blood supply to the glans and lead to ischemia and necrosis. Many cases of paraphimosis result from the foreskin being retracted for an extended period, as in the case of catheterized uncircumcised males.

Cryptorchidism

Cryptorchidism, or undescended testes, occurs when one or both of the testicles fail to move down into the scrotal sac. The condition is bilateral in 10% to 20% of cases. The testes develop intra-abdominally in the fetus and usually descend into the scrotum through the inguinal canal during the seventh to ninth months of gestation.⁴⁰ The undescended testes may remain in the lower abdomen or at a point of descent in the inguinal canal (Fig. 33-14).

The incidence of cryptorchidism is directly related to birth weight and gestational age; infants who are born prematurely

■ FIGURE 33-14 ■ Possible locations of undescended testicles.

or are small for gestational age have the highest incidence of the disorder. Up to one third of premature infants and 3% to 5% of full-term infants are born with undescended testicles.^{35,41} The cause of cryptorchidism in full-term infants is poorly understood. Most cases are idiopathic, but some may result from genetic or hormonal factors.²⁹

The major manifestation of cryptorchidism is the absence of one or more of the testes in the scrotum. The testis either is not palpable or can be felt external to the inguinal ring. Spontaneous descent often occurs during the first 3 months of life, and by 6 months of age the incidence decreases to 0.8%.^{34,41} Spontaneous descent rarely occurs after 6 months of age.

In children with cryptorchidism, histologic abnormalities of the testes reflect intrinsic defects in the testicle or adverse effects of the extrascrotal environment. The undescended testicle is normal at birth, but pathologic changes can be demonstrated at 6 to 12 months.³⁴ There is a delay in germ cell development, changes in the spermatic tubules, and reduced number of Leydig cells. These changes are progressive if the testes remain undescended. When the disorder is unilateral, it also may produce morphologic changes in the contralateral descended testis.

The consequences of cryptorchidism include infertility, malignancy, and the possible psychological effects of an empty scrotum. Indirect inguinal hernias usually accompany the undescended testes but rarely are symptomatic. Recognition of the condition and early treatment are important steps in preventing adverse consequences. The risk of malignancy in the undescended testis is four to six times higher than in the general population.^{34,41} The increased risk of testicular cancer is not significantly affected by orchiopexy, hormonal therapy, or late spontaneous descent after the age of 2 years. However, orchiopexy does allow for earlier detection of a testicular malignancy by positioning the testis in a more easily palpable location.

As a group, males with unilateral or bilateral cryptorchidism usually have decreased sperm counts, poorer-quality sperm, and lower fertility rates than do men whose testicles descend normally. The likelihood of decreased fertility increases when the condition is bilateral. Unlike the risk of testicular cancer, there seems to be some advantage to early orchiopexy for protection of fertility.^{34,41}

Diagnosis is based on careful examination of the genitalia in male infants. Undescended testes due to cryptorchidism should be differentiated from retractable testes that retract into the inguinal canal in response to an exaggerated cremaster muscle reflex. Retractable testes usually are palpable at birth but become nonpalpable later. They can be brought down with careful palpation in a warm room. Retractable testes usually assume a scrotal position during puberty. They have none of the complications associated with undescended testicles due to cryptorchidism.³⁴

Improved techniques for testicular localization include ultrasonography (*i.e.*, visualization of the testes by recording the pulses of ultrasonic waves directed into the tissues), gonadal venography and arteriography (*i.e.*, radiography of the veins and arteries of the testes after the injection of a contrast medium), and laparoscopy (*i.e.*, examination of the interior of the abdomen using a visualization instrument).

The treatment goals for the child with cryptorchidism include measures to enhance future fertility potential, placement of the gonad in a favorable place for cancer detection, and improved cosmetic appearance. Regardless of the type of treatment used, it should be carried out between 6 months and 2 years of age.34,41 Treatment modalities for children with unilateral or bilateral cryptorchidism include initial hormone therapy with hCG or luteinizing hormone-releasing hormone (LHRH), a hypothalamic hormone that stimulates production of the gonadotropic hormones by the anterior pituitary gland. For children who do no respond to hormonal treatment, surgical placement and fixation of the testes in the scrotum (*i.e.*, orchiopexy) have proved effective. Approximately 95% of infants who have orchiopexy for a unilateral undescended testis will be fertile, compared with a 30% to 50% fertility rate in uncorrected males.41

Treatment of males with undescended testis should include lifelong follow-up, considering the sequelae of testicular cancer and infertility. Parents need to be aware of the potential issues of infertility and increased risk of testicular cancer. On reaching puberty, boys should be instructed in the necessity of testicular self-examination.

Aging Changes

Like other body systems, the male reproductive system undergoes degenerative changes as a result of the aging process; it becomes less efficient with age. The declining physiologic efficiency of male reproductive function occurs gradually and involves the endocrine, circulatory, and neuromuscular systems.⁴² Compared with the marked physiologic change in aging females, the changes in the aging male are more gradual and less drastic. Gonadal and reproductive failure usually are not related directly to age because a man remains fertile into advanced age; 80- and 90-year-old men have been known to father children.

As the male ages, his reproductive system becomes measurably different in structure and function from that of the younger male. Male sex hormone levels, particularly of testosterone, decrease with age, with the decline starting later on average than in women. The term *andropause* has been used to describe an illdefined collection of symptoms in aging men, typically those older than 50 years, who may have a low androgen level.⁴³

The sex hormones play a part in the structure and function of the reproductive system and other body systems from conception to old age; they affect protein synthesis, salt and water balance, bone growth, and cardiovascular function. Decreasing levels of testosterone affect sexual energy, muscle strength, and the genital tissues. The testes become smaller and lose their firmness. The seminiferous tubules, which produce spermatozoa, thicken and begin a degenerative process that finally inhibits sperm production, resulting in a decrease of viable spermatozoa. The prostate gland enlarges, and its contractions become weaker. The force of ejaculation decreases because of a reduction in the volume and viscosity of the seminal fluid. The seminal vesicle changes little from childhood to puberty. The pubertal increases in the fluid capacity of the gland remain throughout adulthood and decline after the age of 60 years. After age 60 years, the walls of the seminal vesicles thin, the epithelium decreases, and the muscle layer is replaced by connective tissue. Age-related changes in the penis consist of fibrotic changes in the trabeculae in the corpus spongiosum, with progressive sclerotic changes in arteries and veins. Sclerotic changes also follow in the corpora cavernosa, with the condition becoming generalized in 55- to 60-year-old men.

Erectile dysfunction in the elderly male often is directly related to the general physical condition of the person. Diseases that accompany aging can have direct bearing on male reproductive function. Various cardiovascular, respiratory, hormonal, neurologic, and hematologic disorders can be responsible for secondary impotence. For example, vascular disease affects male potency because it may impair blood flow to the pudendal arteries or their tributaries, resulting in loss of blood volume with subsequent poor distention of the vascular spaces of erectile tissue. Other diseases affecting potency include hypertension, diabetes, cardiac disease, and malignancies of the reproductive organs. In addition, certain medications can have an effect on sexual function.

Testosterone and other synthetic androgens may be used in older males with low androgen levels to improve muscle strength and vigor. Preliminary studies of androgen replacement in aging males with low androgen levels show an increase in lean body mass and a decrease in bone turnover. Before testosterone replacement therapy is initiated, all men should be screened for prostate cancer. Testosterone is available as an injectable form that is administered every 2 to 3 weeks or as a transdermal patch or gel. Side effects of replacement therapy may include acne, gynecomastia, and reduced HDL levels. It also may contribute to a worsening of sleep apnea in men who are troubled by this problem.

In summary, childhood disorders of the male reproductive system include congenital disorders in which the urethral opening is located on the ventral surface of the penis (hypospadias) or on the dorsal surface (epispadias). Phimosis is the condition in which the opening of the foreskin is too tight to permit retraction over the glans. Disorders of the scrotum and testes include cryptorchidism or undescended testicles. Early diagnosis and treatment is important because of the risk of malignancy and infertility. Like other body systems, the male reproductive system undergoes changes as a result of the aging process. The changes occur gradually and involve parallel changes in endocrine, circulatory, and neuromuscular function. Testosterone levels decrease, the size and firmness of the testes decrease, sperm production declines, and the prostate gland enlarges. There usually is a decrease in frequency of intercourse, intensity of sensation, speed of attaining erection, and force of ejaculation.

REVIEW QUESTIONS

Describe the structure and function of the male reproductive system and hormones and relate to the process of spermatogenesis.

Relate the development and descent of testes to the pathogenesis of inguinal hernia and cryptorchidism.

Compare the pathophysiology of cancer of the penis, scrotum, and testes.

Compare the cause, appearance, and significance of hydrocele, hematocele, spermatocele, and varicocele.

State the difference between extravaginal and intravaginal testicular torsion.

Compare the pathology and symptoms of acute bacterial prostatitis, chronic bacterial prostatitis, and chronic prostatitis/pelvic pain syndrome.

Describe the urologic manifestations and treatment of benign prostatic hyperplasia.

List the methods used in the diagnosis and treatment of prostatic cancer.

Describe the autonomic nervous system control of erection, emission, and ejaculation and relate to the pathogenesis of erectile dysfunction and priapism.

State the difference between hypospadias and epispadias.

Describe changes in the male reproductive system that occur with aging.

he male genitourinary system is subject to structural defects, inflammation, and neoplasms, all of which can affect urine elimination, sexual function, and fertility. This chapter focuses on spermatogenesis and hormonal control of male reproductive function; neural control of sexual function and erectile dysfunction; disorders of the penis, scrotum, testes, and prostate; disorders of the male reproductive system in children; and changes in function as a result of the aging process.

PHYSIOLOGIC BASIS OF MALE REPRODUCTIVE FUNCTION

The male genitourinary system is composed of the paired gonads, or testes, genital ducts, accessory organs, and penis (Fig. 33-1). The dual function of the testes is to produce male sex androgens (*i.e.*, male sex hormones), mainly testosterone, and spermatozoa (*i.e.*, male germ cells). The internal accessory organs produce the fluid constituents of semen, and the ductile system aids in the storage and transport of spermatozoa. The penis functions in urine elimination and sexual function.

■ FIGURE 33-1 ■ The structures of the male reproductive system, including the testes, the scrotum, and the excretory ducts.

Spermatogenesis

Spermatogenesis refers to the generation of spermatozoa or sperm. It begins at an average age of 13 years and continues throughout the reproductive years of a man's life. Spermatogenesis occurs in the seminiferous tubules of the testes (Fig. 33-2). Internally, the testes are composed of several hundred compartments or lobules. Each lobule contains one or more coiled seminiferous tubules. The outer layer of the seminiferous tubules is made up of connective tissue and smooth muscle; the inner lining is composed of Sertoli's cells, which are embedded with sperm in

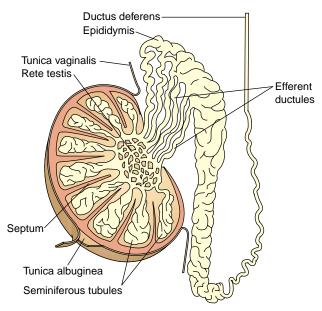

KEY CONCEPTS

MALE REPRODUCTIVE SYSTEM

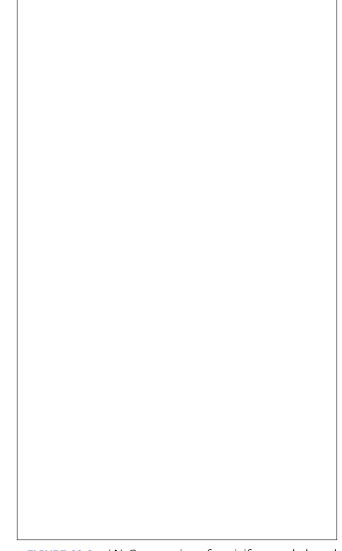

- The male genitourinary system functions in both urine elimination and reproduction.
- The testes function in both production of male germ cells (spermatogenesis) and secretion of the male sex hormone, testosterone.
- The ductile system (epididymides, vas deferens, and ejaculatory ducts) transports and stores sperm and assists in their maturation, and the accessory glands (seminal vesicles, prostate gland, and bulbourethral glands) prepare the sperm for ejaculation.
- Sperm production requires temperatures that are 2° to 3°C below body temperature. The position of the testes in the scrotum and the unique blood flow-cooling mechanisms provide this environment.
- The urethra, which is enclosed in the penis, is the terminal portion of the male genitourinary system. Because it conveys both urine and semen, it serves both urinary and reproductive functions.

various stages of development (Fig. 33-3). Sertoli's cells secrete a special fluid that contains nutrients to bathe and nourish the immature germ cells; they provide digestive enzymes that play a role in spermiation (*i.e.*, converting the spermatocytes to sperm); and they are thought to play a role in shaping the head and tail of the sperm. Sertoli's cells also secrete several hormones, including the principal feminizing sex hormone, estradiol, which seems to be required in the male for spermatogenesis, and inhibin, which controls the function of Sertoli's cells through feedback inhibition of follicle-stimulating hormone (FSH) from the anterior pituitary gland.

After the spermatozoa are formed in the seminiferous tubules, they travel through the efferent tubules to the epididymis, which is the final site for sperm maturation. Because the spermatozoa are not motile at this stage of development,

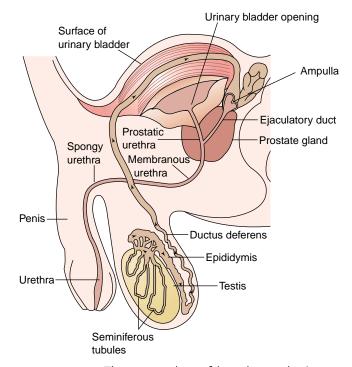

■ FIGURE 33-2 ■ The parts of the testes and epididymis.

■ FIGURE 33-3 ■ (A) Cross-section of seminiferous tubule and (B) stages of development of spermatozoa.

peristaltic movements of the ductal walls of the epididymis aid in their movement.¹ The spermatozoa continue their migration through the ductus deferens, also called the *vas deferens*. The ampulla of the vas deferens serves as a storage reservoir for sperm. Sperm are stored in the ampulla until they are released through the penis during ejaculation (Fig. 33-4). Spermatozoa can be stored in the genital ducts for as long as 42 days and still maintain their fertility. Surgical disconnection of the vas deferens in the scrotal area (*i.e.*, vasectomy) serves as an effective method of male contraception. Because sperm are stored in the ampulla, men can remain fertile for 4 to 5 weeks after performance of a vasectomy.

The seminal vesicles, the prostate gland, and the bulbourethral glands form the accessory reproductive structures of the male genitourinary system. The spermatozoa plus the secretions from the genital ducts and accessory organs make up

■ FIGURE 33-4 ■ The excretory ducts of the male reproductive system and the path that sperm follows as it leaves the testis and travels to the urethra.

the semen (from the Latin word meaning seed). The seminal vesicles consist of two highly tortuous tubes that secrete fluid for the semen. Each of the paired seminal vesicles is lined with secretory epithelium containing an abundance of fructose, prostaglandins, and several other proteins. The fructose secreted by the seminal vesicles provides the energy for sperm motility. The prostaglandins are thought to assist in fertilization by making the cervical mucus more receptive to sperm and by causing reverse peristaltic contractions in the uterus and fallopian tubes to move the sperm toward the ovaries. Each seminal vesicle joins its corresponding vas deferens to form the ejaculatory duct, which enters the posterior part of the prostate and continues through until it ends in the prostatic portion of the urethra. During the emission phase of coitus, each vesicle empties fluid into the ejaculatory duct, adding bulk to the semen. Approximately 70% of the ejaculate originates in the seminal vesicles.

Hormonal Control of Male Reproductive Function

The male sex hormones are called *androgens*. The testes secrete several male sex hormones, including *testosterone*, *dihydrotes*-*tosterone*, and *androstenedione*.² Testosterone, which is the most abundant of these hormones, is considered the main testicular hormone. The adrenal cortex also produces androgens, although in much smaller quantities (<5% of the total male androgens) than those produced in the testes. The testes also secrete small quantities of estradiol and estrone.

Testosterone is produced and secreted by the interstitial Leydig's cells in the testes. It is metabolized in the liver and excreted by the kidneys. In the bloodstream, testosterone exists in a free (unbound) or a bound form. The bound form is attached to plasma proteins, including albumin and the sex hormonebinding protein produced by the liver. Only approximately 2% of circulating testosterone is unbound and therefore able to enter the cell and exert its metabolic effects. Much of the testosterone that becomes fixed to the tissues is converted to dihydrotestosterone, especially in certain target tissues such as the prostate gland. Some of the actions of testosterone depend on this conversion, whereas others do not. Testosterone also can be aromatized or converted to estradiol in the peripheral tissues.

Testosterone exerts a variety of biologic effects in the male (Chart 33-1). In the male embryo, testosterone is essential for the appropriate differentiation of the internal and external genitalia, and it is necessary for descent of the testes in the fetus. Testosterone is essential to the development of primary and secondary male sex characteristics during puberty and for the maintenance of these characteristics during adult life. It causes growth of pubic, chest, and facial hair; it produces changes in the larynx that result in the male bass voice; and it increases the thickness of the skin and the activity of the sebaceous glands, predisposing to acne.

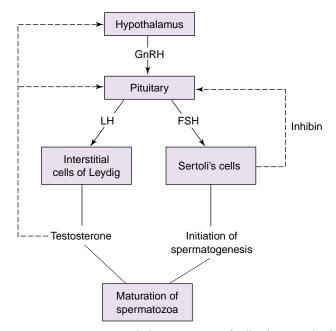

All or almost all of the actions of testosterone and other androgens result from increased protein synthesis in target tissues. Androgens function as anabolic agents in males and females to promote metabolism and musculoskeletal growth. Testosterone and the androgens have a great effect on the development of increasing musculature during puberty, with boys averaging approximately 50% more of an increase in muscle mass than do girls.

Action of the Hypothalamic and Anterior Pituitary Hormones

The hypothalamus and the anterior pituitary gland play an essential role in promoting spermatogenic activity in the testes and maintaining the endocrine function of the testes by means of the gonadotropic hormones. The synthesis and release of the gonadotropic hormones from the pituitary gland are regulated by gonadotropin-releasing hormone (GnRH), which is synthesized by the hypothalamus and secreted into the hypothalamohypophysial portal circulation (Fig. 33-5).

CHART 33-1 Main Actions of Testosterone

■ **FIGURE 33-5** ■ Hypothalamic-pituitary feedback control of spermatogenesis and testosterone levels in the male. The *dashed line* represents negative feedback.

Two gonadotropic hormones are secreted by the pituitary gland: FSH and luteinizing hormone (LH). In the male, LH also is called interstitial cell-stimulating hormone. The production of testosterone by the interstitial cells of Leydig is regulated by LH. FSH binds selectively to Sertoli's cells surrounding the seminiferous tubules, where it functions in the initiation of spermatogenesis. Under the influence of FSH, Sertoli's cells produce and rogen-binding protein, plasminogen activator, and inhibin. Androgen-binding protein binds testosterone and serves as a carrier of testosterone in Sertoli's cells and as a storage site for testosterone. Although FSH is necessary for the initiation of spermatogenesis, full maturation of the spermatozoa requires testosterone. Androgen-binding protein also serves as a carrier of testosterone from the testes to the epididymis. Plasminogen activator, which converts plasminogen to plasmin, functions in the final detachment of mature spermatozoa from Sertoli's cells.

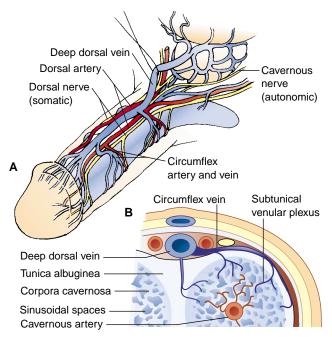

Circulating levels of the gonadotropic hormones are regulated in a negative feedback manner by testosterone. High levels of testosterone suppress LH secretion through a direct action on the pituitary and an inhibitory effect on the hypothalamus. FSH is thought to be inhibited by a substance called *inhibin*, produced by Sertoli's cells. Inhibin suppresses FSH release from the pituitary gland. The pituitary gonadotropic hormones and Sertoli's cells in the testes form a classic negative feedback loop in which FSH stimulates inhibin and inhibin suppresses FSH. Unlike the cyclic hormonal pattern in the female, in the male, FSH, LH, and testosterone secretion and spermatogenesis occur at relatively unchanging rates during adulthood.

Neural Control of Sexual Function

The penis is the male external genital organ through which the urethra passes. It functions both as a sexual organ and as an organ of urine elimination. Anatomically, the external penis consists of a shaft that ends in a tip called the *glans* (Fig. 33-1). The loose skin of the penis shaft folds to cover the glans, forming the prepuce, or foreskin. The glans of the penis contains many sensory nerves, making this the most sensitive portion of the penile shaft. The cylindrical body or shaft of the penis is composed of three masses of erectile tissue held together by fibrous strands and covered with a thin layer of skin (Fig. 33-6). The two lateral masses of tissue are called the *corpora cavernosa*. The third, ventral mass is called the *corpus spongiosum*. The corpora cavernosa and corpus spongiosum are cavernous sinuses that normally are relatively empty but become engorged with blood during penile erection.

The physiology of the male sex act involves a complex interaction between autonomic-mediated spinal cord reflexes, higher neural centers, and the vascular system. It involves erection, emission, ejaculation, and detumescence. Erection involves increased inflow of blood into the corpora cavernosa and penile rigidity. Ejaculation represents the expulsion of the sperm from the urethra. Detumescence, or penile relaxation, results from outflow of blood from the corpora cavernosa.

Erection is a neurovascular process involving the autonomic nervous system, neurotransmitters and endothelial relaxing factors, the vascular smooth muscle of the arteries and veins supplying the penile tissue, and the trabecular smooth muscle of the sinusoids of the corpora cavernosa (Fig. 33-6). The penis is innervated by both the autonomic and somatic nervous systems. In the pelvis, the sympathetic and parasympathetic components of the autonomic nervous system merge to form what are called the *cavernous nerves*.³ Erection is under the control of the parasympathetic nervous system, and ejaculation and detumescence (penile relaxation) are under the control of the sympathetic nervous system. Somatic innervation, which occurs through the pudendal nerve, is responsible for penile sensation and contraction and relaxation of the

■ FIGURE 33-6 ■ Anatomy and mechanism of penile erection. (A) Innervation and arterial and venous blood supply to penis. (B) Cross-section of the sinusoidal system of the corpora cavernosa.

KEY CONCEPTS

DISORDERS OF PENILE ERECTION

- Erection is a neurovascular process involving the autonomic nervous system, the somatic nervous system by way of the pudendal nerve, the vascular system, and the sinusoidal spaces of the corpora cavernosa.
- Parasympathetic innervation through the pelvic nerves initiates relaxation of the trabecular smooth muscle of the corpora cavernosa through the action of nitric oxide, the inflow of arterial blood, and cessation of venous outflow.
- Erectile failure can result from disorders in one or a combination of the neural, vascular, or chemical mediator aspects of the erectile process.

extracorporeal striated muscles (bulbocavernous and ischio-cavernous).³

Penile erection is the first effect of male sexual stimulation, whether psychological or physical. It involves increased inflow of blood into the corpora cavernosa due to relaxation of the trabecular smooth muscle that surrounds the sinusoidal spaces and compression of the veins controlling outflow of blood from the venous plexus. Erection is mediated by parasympathetic impulses that pass from the sacral segments of the spinal cord through the pelvic nerves to the penis. Parasympathetic stimulation results in release of nitric oxide, a nonadrenergic-noncholinergic neurotransmitter, which causes relaxation of trabecular smooth muscle of the corpora cavernosa. This relaxation permits inflow of blood into the sinuses of the cavernosa at pressures approaching those of the arterial system. Because the erectile tissues of the cavernosa are surrounded by a nonelastic fibrous covering, high pressure in the sinusoids causes ballooning of the erectile tissue to such an extent that the penis becomes hard and elongated. At the same time, contraction of the somatic-innervated ischiocavernous muscles forcefully compresses the blood-filled corpora cavernosa, producing a further increase in intercavernous pressures. During this phase of erection, inflow and outflow of blood cease.

Parasympathetic innervation must be intact and nitric oxide synthesis must be active for erection to occur. Nitric oxide activates guanyl cyclase, an enzyme that increases the concentration of cyclic guanosine monophosphate (cGMP), which in turn causes smooth muscle relaxation. Other smooth muscle relaxants (*e.g.*, prostaglandin E_1 analogs and α -adrenergic antagonists), if present in high enough concentrations, can independently cause sufficient cavernosal relaxation to result in erection.³ Many of the drugs that have been developed to treat erectile dysfunction act at the levels of these mediators.

Detumescence or penile relaxation is largely a sympathetic nervous system response. It can result from a cessation of neurotransmitter release, the breakdown of second messengers such as cGMP, or sympathetic discharge during ejaculation. Contraction of the trabecular smooth muscle opens the venous channels so that the trapped blood can be expelled and penile flaccidity return.

Erectile Dysfunction

"Erectile dysfunction is defined as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse."⁴ It has been estimated that the disorder affects 20 to 30 million men in the United States.⁵ Erectile dysfunction is commonly classified as psychogenic, organic, or mixed psychogenic or organic.^{5,6} The latter is the most common.

Psychogenic causes of erectile dysfunction include performance anxiety, a strained relationship with a sexual partner, depression, and overt psychotic disorders such as schizophrenia. Depression is a common cause of erectile dysfunction.⁵

Organic causes span a wide range of pathologies. They include neurogenic, hormonal, vascular, drug-induced, and cavernous impairment etiologies. Neurogenic disorders such as Parkinson's disease, stroke, and cerebral trauma often contribute to erectile dysfunction by decreasing libido or preventing the initiation of erection. In spinal cord injury, the extent of neural impairment depends on the level, location, and extent of the lesion. Somatosensory involvement of the genitalia is essential to the reflex mechanisms involved in erection; this becomes important with aging and conditions such as diabetes that impair peripheral nerve function.

Hormonal causes of erectile dysfunction include a decrease in androgen levels. Androgen levels may be decreased because of aging. Hypoprolactinemia from any cause interferes with both reproduction and erectile function. This is because prolactin acts centrally to inhibit dopaminergic activity, which is a stimulus for release of the hypothalamic GnRH that controls the release of pituitary gonadotropic hormones.

Common risk factors for generalized penile arterial insufficiency include hypertension, hyperlipidemia, cigarette smoking, diabetes mellitus, and pelvic irradiation.⁵ In hypertension, erectile function is impaired not so much by the increased blood pressure as by the associated stenotic arterial lesions. Focal stenosis of the common penile artery most often occurs in men who sustained blunt pelvic or perineal trauma (*e.g.*, from bicycling accidents). Failure of the veins to close completely during an erection (veno-occlusive dysfunction) may occur in men with large venous channels that drain the corpora cavernosa. Other disorders that impair venous occlusion are degenerative changes involving the tunica albuginea, as in Peyronie's disease. Poor relaxation of the trabecular smooth muscle may accompany anxiety with excessive adrenergic tone.

Many drugs are reported to cause erectile dysfunction, including antidepressant, antipsychotic, and antihypertensive medications. Cigarette smoking can induce vasoconstriction and penile venous leakage because of its effects on cavernous smooth muscle.⁵ Alcohol in small amounts may increase libido and improve erection; however, in large amounts it can cause central sedation, decreased libido, and transient erectile dysfunction.

Aging is known to increase the risk of erectile dysfunction.⁷ Many of the pathologic processes that contribute to erectile dysfunction are more common in older men, including diabetes, hyperlipidemia, vascular disease, and the long-term effects of cigarette smoking. Age-related declines in testosterone also may play a role. Psychosocial problems such as depression, esteem issues, partner relationships, history of substance abuse, and anxiety and fear of performance failure also may contribute to erectile dysfunction in older men.

A diagnosis of erectile dysfunction requires careful history (medical, sexual, and psychosocial), physical examination, and laboratory tests aimed at determining what other tests are needed to rule out organic causes of the disorder.⁶ Because many medications, including prescribed, over-the-counter, and illicit drugs, can cause erectile dysfunction, a careful drug history is indicated.

Treatment methods include psychosexual counseling, androgen replacement therapy, oral and intracavernous drug therapy, vacuum constriction devices, and surgical treatment (prosthesis and vascular surgery).⁶ Among the commonly prescribed drugs are sildenafil, yohimbine, alprostadil, and phentolamine. Sildenafil (Viagra) is a selective inhibitor of phosphodiesterase type 5, the enzyme that inactivates cGMP. Yohimbine, an α_2 -adrenergic receptor antagonist, acts at the adrenergic receptors in brain centers associated with libido and penile erection. Both sildenafil and yohimbine are taken orally. Alprostadil, a prostaglandin E analog, acts by producing relaxation of cavernous smooth muscle. It is either injected directly into the cavernosa or placed in the urethra as a minisuppository. Phentolamine, an α_2 -adrenergic receptor antagonist, also is administered by intracavernous injection.

In summary, spermatogenesis occurs in the Sertoli's cells of the seminiferous tubules of the testes. After formation in seminiferous tubules, the spermatozoa travel through the efferent tubules to the epididymis, then to the ductus deferens, and on to the ampulla, where they are stored until released through the penis during ejaculation. The male accessory organs consist of the seminal vesicles, prostate gland, and bulbourethral glands. Secretions from the genital ducts and accessory organs combine with the spermatozoa to form the semen.

The function of the male reproductive system is under the negative feedback control of the hypothalamus and the anterior pituitary gonadotropic hormones FSH and LH. Spermatogenesis is initiated by FSH, and the production of testosterone is regulated by LH. Testosterone, the major male sex hormone, is produced by the interstitial Leydig's cells in the testes. In addition to its role in the differentiation of the internal and external genitalia in the male embryo, testosterone is essential for the development of secondary male characteristics during puberty, the maintenance of these characteristics during adult life, and spermatozoa maturation.

The male sex act involves erection, emission, ejaculation, and detumescence. The physiology of these functions involves a complex interaction between autonomic-mediated spinal cord reflexes, higher neural centers, and the vascular system. Erection is mediated by the parasympathetic nervous system and emission and ejaculation by the sympathetic nervous system. Erectile dysfunction is defined as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse. It can be due to psychogenic factors, organic disorders, or mixed psychogenic and organic conditions.

DISORDERS OF THE PENIS, THE SCROTUM AND TESTES, AND THE PROSTATE

Disorders of the Penis

Disorders of the penis include congenital defects (discussed in Disorders in Childhood), acute and chronic inflammatory conditions, Peyronie's disease, priapism, and neoplasms.

Inflammation and Infection

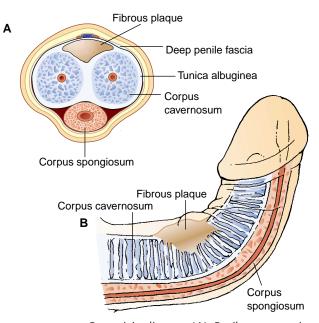

Balantitis and Balanoposthitis. Balanitis is an acute or chronic inflammation of the glans penis. Balanoposthitis refers to inflammation of the glans and prepuce. It usually is encountered in males with phimosis (a tight foreskin) or a large, redundant prepuce that interferes with cleanliness and predisposes to bacterial growth in the accumulated secretions and smegma (*i.e.*, debris from the desquamated epithelia). If left untreated, the condition may cause ulcerations of the mucosal surface of the glans; these ulcerations may lead to inflammatory scarring of the phimosis and further aggravate the condition.

Acute superficial balanoposthitis is characterized by erythema of the glans and prepuce. An exudate in the form of malodorous discharge may be present. Extension of the erythema and edema may result in phimosis. The condition may result from infection, trauma, or irritation. Infective balanoposthitis may be caused by a wide variety of organisms. Chlamydiae and mycoplasmas have been identified as causative organisms in this disease. The inflammatory reaction is nonspecific, and correct identification of the specific agent requires bacterial smears and cultures.

Balanitis xerotica obliterans is a chronic white, patchy lesion that originates on the glans and usually progresses to involve the meatus. It is clinically and histologically similar to the lichen sclerosus that is seen in females. It commonly is observed in middle-aged diabetic men. Treatment measures include topical or intralesional injections of corticosteroids.⁸

Peyronie's Disease

Peyronie's disease involves a localized and progressive fibrosis of unknown origin that affects the tunica albuginea (*i.e.*, the tough, fibrous sheath that surrounds the corpora cavernosa) of the penis. It is named after Francois de la Peyronie, who wrote in 1743, describing a patient who had "rosary beads of scar tissue to cause upward curvature of the penis during erection."9 The disorder is characterized initially by an inflammatory process that results in dense fibrous plaque formation. The plaque usually is on the dorsal midline of the shaft, causing upward bowing of the shaft during erection (Fig. 33-7). Some men may develop scarring on both the dorsal and ventral aspects of the shaft, causing the penis to be straight but shortened or have a lateral bend.9 The fibrous tissue prevents lengthening of the involved area during erection, making intercourse difficult and painful. The disease usually occurs in middle-aged or elderly men. Although the cause of the disorder is unknown, the dense microscopic plaques are consistent with findings of severe vasculitis. As many as 47% of men with Peyronie's disease have another condition associated with fascial tissue fibrosis, such as Dupuytren's contracture (fibrosis of the palmar fascia).9

■ FIGURE 33-7 ■ Peyronie's disease. (A) Penile cross-section showing plaque between the corpora. (B) Penile curvature.

The manifestations of Peyronie's disease include painful erection, bent erection, and the presence of a hard mass at the site of fibrosis. Approximately two thirds of men report pain as a symptom. The pain is thought to be generated by inflammation of the adjacent fascial tissue and usually disappears as the inflammation resolves.¹⁰ During the first year or so after formation of the plaque, while the scar tissue is undergoing the process of remodeling, penile distortion may increase, remain static, or resolve and disappear completely.⁹ In some cases, the scar tissue may progress to calcification and formation of bone-like tissue.

Diagnosis is based on history and physical examination. Doppler ultrasonography may be used to assess causation of the disorder. Although surgical intervention can be used to correct the disorder, it often is delayed, because in many cases the disorder is self-limiting.¹⁰ Less invasive treatments include the administration of oral agents with antioxidant properties (*e.g.*, vitamin D, potassium aminobenzoate, and colchicine).

Priapism

Priapism is an involuntary, prolonged, abnormal and painful erection that is not associated with sexual excitement. Priapism is a true urologic emergency because the prolonged erection can result in ischemia and fibrosis of the erectile tissue with significant risk of subsequent impotence. Priapism can occur at any age, in the newborn as well as other age groups. Sickle cell disease or neoplasms are the most common cause in boys between 5 and 10 years of age.

Priapism is due to impaired blood flow in the corpora cavernosa of the penis. Two mechanisms for priapism have been proposed: low-flow (ischemic) priapism, in which there is stasis of blood flow in the corpora cavernosa with a resultant failure of detumescence, and high-flow (nonischemic) priapism, which involves persistent arterial flow into the corpora cavernosa.¹¹ In high-flow priapism, there is no hypoxia of local tissue, the penis is less rigid, the pain is less than in stasis priapism, and permanent corporal fibrosis and cellular damage are rare.¹¹

Priapism is classified as primary (idiopathic) or secondary to a disease or drug effect. Primary priapism is the result of conditions such as trauma, infection, and neoplasms. Secondary causes include hematologic conditions such as leukemia, sickle cell disease, and thrombocytopenia; neurologic conditions such as stroke, spinal cord injury, and other central nervous system lesions; and renal failure. Between 6% and 12% of males with sickle cell disorders are affected by priapism.¹¹ The relative deoxygenation and stasis of cavernosal blood during erection is thought to increase sickling. Various medications, such as antihypertensive drugs, anticoagulant drugs, antidepressant drugs, alcohol, and marijuana, can contribute to the development of priapism. Androstenedione, sold as an over-the-counter drug to enhance muscle building and athletic performance, has been implicated in the disorder.¹² Currently, intracavernous injection therapy for erectile dysfunction is one of the more common causes of priapism.

The diagnosis of priapism usually is based on clinical findings. Doppler studies of penile blood flow, penile ultrasonography, and computed tomography (CT) scans may be used to determine intrapelvic pathology.

Initial treatment measures include analgesics, sedation, and hydration. Urinary retention may necessitate catheterization. Local measures include application of ice packs and irrigation of the corpus cavernosum with plain or heparinized saline, or instillation of α -adrenergic drugs. If less aggressive treatment does not produce detumescence, a temporary surgical shunt may be established between the corpus cavernosum and the corpus spongiosum.

The prognosis for whether fibrosis or erectile failure will occur is determined by the severity and duration of blood stasis. In high-flow priapism, the damaging effects of decreased oxygen tension and intracavernal blood pressure are less pronounced than in stasis priapism. Normal erectile potency can be restored even after a long duration of high-flow priapism. In contrast, persistent stasis priapism is known to result in impaired erectile function and tissue fibrosis unless resolved within 24 to 48 hours of onset.¹¹

Cancer of the Penis

Squamous cell cancer of the penis is most common in men between 45 and 60 years of age. In the United States, it accounts for less than 1% of male genital tumors; however, in other countries, it accounts for 10% to 20% of male cancers.^{13,14} When it is diagnosed early, penile cancer is highly curable. The greatest hindrance to early diagnosis is a delay in seeking medical attention.

The cause of penile cancer is unknown. Several risk factors have been suggested, including poor hygiene, human papillomavirus (HPV) infections, ultraviolet radiation exposure, and immunodeficiency states. There is an association between penile cancer and poor genital hygiene and phimosis. One theory postulates that smegma accumulation under the phimotic foreskin may produce chronic inflammation, leading to carcinoma. The HPVs have been implicated in the genesis of several genital cancers, including cancer of the penis.¹³ Ultraviolet radiation also is thought to have a carcinogenic effect on the penis. Males who were treated for psoriasis with ultraviolet A or B therapies (*i.e.*, PUVA or PUVB) have had a reported increased incidence of genital squamous cell carcinomas.¹³ Because of this observation, it is suggested that men should shield their genital area when using tanning salons. Immunodeficiency states also may play a role in the pathogenesis of penile cancer. Approximately 18% of men with acquired immunodeficiency syndrome (AIDS)-related Kaposi's sarcoma have lesions of the penis or genitalia.¹³

Dermatologic lesions with precancerous potential include balanitis xerotica obliterans (discussed earlier) and giant condylomata acuminata.¹⁴ Giant condylomata acuminata are cauliflower-like lesions arising from the prepuce or glans that result from HPV infection.

Approximately 95% of penile cancers are squamous cell carcinoma.¹³ It is thought to progress from an in situ lesion to an invasive carcinoma. Bowen's disease and erythroplasia of Queyrat are penile lesions with histologic features of carcinoma in situ.¹⁴ Bowen's disease appears as a solitary, thickened, gray-white, opaque plaque with shallow ulceration and crusting. It commonly involves the skin of the shaft of the penis and the scrotum. Erythroplasia of Queyrat involves the mucosal surface of the glans or prepuce. It is characterized by single or multiple shiny red, sometimes velvety, plaques.¹⁴ These lesions require careful follow-up because of their potential to progress to invasive carcinoma.

Invasive carcinoma of the penis begins as a small lump or ulcer. If phimosis is present, there may be painful swelling, purulent drainage, or difficulty urinating. Palpable lymph nodes may be present in the inguinal region. Diagnosis usually is based on physical examination and biopsy results. CT scans, penile ultrasound studies, and magnetic resonance imaging (MRI) may be used in the diagnostic workup.

Treatment options vary according to stage, size, location, and invasiveness of the tumor. Carcinoma in situ may be treated conservatively with fluorouracil cream application or laser treatment.¹⁴ Surgery remains the mainstay of treatment for invasive carcinoma. Partial or total penectomy is indicated for invasive lesions.

Disorders of the Scrotum and Testes

The testes, or male gonads, are two egg-shaped structures located outside the abdominal cavity in the scrotum. Embryologically, the testes develop in the abdominal cavity and then descend through the inguinal canal into a pouch of peritoneum (which becomes the tunica vaginalis) in the scrotum during the seventh to ninth months of fetal life. As they descend, the testes pull their arteries, veins, lymphatics, nerves, and conducting excretory ducts with them. These structures are encased by the cremaster muscle and layers of fascia that constitute the spermatic cord (Fig. 33-8A). The descent of the testes is thought to be mediated by testosterone, which is active during this stage of development.

After descent of the testes, the inguinal canal closes almost completely. Failure of this canal to close predisposes to the development of an inguinal hernia later in life (Fig. 33-8B). An inguinal hernia or "rupture" is a protrusion of the parietal peritoneum and part of the intestine through an abnormal opening from the abdominal cavity. A loop of small bowel may become incarcerated in an inguinal hernia (strangulated hernia), in which case the lumen may become obstructed, and the vascular supply compromised (see Chapter 27).

The testes and epididymis are completely surrounded by the tunica vaginalis, a serous pouch derived from the peritoneum during fetal descent of the testes into the scrotum. The tunica vaginalis has an outer parietal layer and a deeper visceral layer that adheres to the dense fibrous covering of the testes, the tunica albuginea. The tunica albuginea protects the testes and gives them their ovoid shape. A space exists between these two layers that typically contains a few milliliters of clear fluid. The cremaster muscles, which are bands of skeletal muscle arising from the internal oblique muscles of the trunk, elevate the testes. The testes receive their arterial blood supply from the long testicular arteries, which branch from the aortic artery. The spermatic veins, which drain the testes, arise from a venous network called the pampiniform plexus that surrounds the spermatic artery. The testes are innervated by fibers from both divisions of the autonomic nervous system. Associated sensory nerves transmit pain impulses, resulting in excruciating pain, especially when the testes are hit forcibly.

The scrotum, which houses the testes, is made up of a thin outer layer of skin that forms rugae, or folds, and is continuous with the perineum and outer skin of the groin. Under the outer skin lies a thin layer of fascia and smooth muscle (*i.e.*, dartos muscle). This layer contains a septum that separates the two testes. The dartos muscle responds to changes in temperature. When it is cold, the muscle contracts, bringing the testes closer to the body, and the scrotum becomes shorter and heavily wrinkled. When it is warmer, the muscle relaxes, allowing the scrotum to fall away from the body.

The location of the testes in the scrotum is important for sperm production, which is optimal at 2°C to 3°C below body temperature. Two systems maintain the temperature of the testes at a level consistent with sperm production. One is the pampiniform plexus of spermatic veins that surround the spermatic artery. This plexus absorbs heat from the arterial blood, cooling it as it enters the testes. The other is the cremaster muscles, which respond to decreases in testicular temperature by moving the testes closer to the body. Prolonged exposure to elevated temperatures, as a result of prolonged fever or the dysfunction of thermoregulatory mechanisms, can impair spermatogenesis. Some tight-fitting undergarments hold the testes against the body and are thought to contribute to a decrease in sperm counts and infertility by interfering with the thermoregulatory function of the scrotum. Cryptorchidism, the failure of the testes to descend into the scrotum, also exposes the testes to the higher temperature of the body.

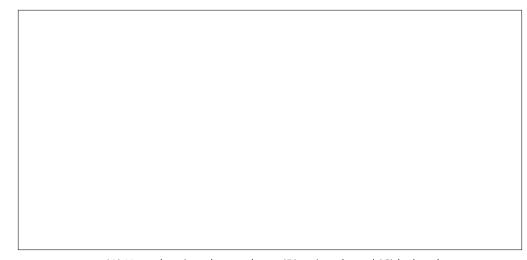

Disorders of the Testicular Tunica

Hydrocele. A hydrocele forms when excess fluid collects between the layers of the tunica vaginalis (Fig. 33-9). It may be unilateral or bilateral and can develop as a primary congenital defect or as a secondary condition. Acute hydrocele may develop after local injury, epididymitis or orchitis, gonorrhea, lymph obstruction, or germ cell testicular tumor, or as a side effect of radiation therapy. Chronic hydrocele is more common. Fluid collects about the testis, and the mass grows gradually. Its cause is unknown, and it usually develops in men older than 40 years.

Most cases of hydrocele in male infants and children are due to a patent processus vaginalis, which is continuous with the peritoneal cavity. In many cases they are associated with an indirect inguinal hernia.¹⁵ Most hydroceles of infancy close spontaneously; therefore, they are not usually repaired before the age of 1 year. Hydroceles that persist beyond 2 years of age may require surgical treatment.

Hydroceles are palpated as cystic masses that may attain massive proportions. If there is enough fluid, the mass may be mistaken for a solid tumor. Transillumination of the scrotum (*i.e.*, shining a light through the scrotum for the purposes of visualizing its internal structures) or ultrasonography can help to determine whether the mass is solid or cystic and whether the testicle is normal.¹⁶ A dense hydrocele that does not illuminate should be differentiated from a testicular tumor. If a hydrocele develops in a young man without apparent cause, careful evaluation is needed to exclude cancer or infection.

In an adult male, a hydrocele is a relatively benign condition. The condition often is asymptomatic, and no treatment is necessary. When symptoms do occur, the feeling may be that of heaviness in the scrotum or pain in the lower back. In cases of secondary hydrocele, the primary condition is treated. If the hydrocele is painful or cosmetically undesirable, surgical correction is indicated. Surgical repair may be done inguinally or transcrotally.

■ FIGURE 33-9 ■ (A) Normal testis and appendages, (B) varicocele, and (C) hydrocele.

Hematocele. A hematocele is an accumulation of blood in the tunica vaginalis, which causes the scrotal skin to become dark red or purple. It may develop as a result of an abdominal surgical procedure, scrotal trauma, a bleeding disorder, or a testicular tumor.

Spermatocele. A spermatocele is a painless, sperm-containing cyst that forms at the end of the epididymis. It is located above and posterior to the testis, is attached to the epididymis, and is separate from the testes. Spermatoceles may be solitary or multiple and usually are less than 1 cm in diameter. They are freely movable and should transilluminate. Spermatoceles rarely cause problems, but a large one may become painful and require excision.

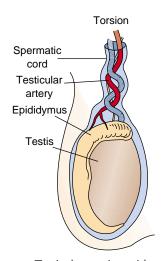

Varicocele. A varicocele is characterized by varicosities of the pampiniform plexus, a network of veins supplying the testes (Fig. 33-9). The left side is more commonly affected because the left internal spermatic vein inserts into the left renal vein at a right angle, whereas the right spermatic vein usually enters the inferior vena cava. Incompetent valves are more common in the left internal spermatic veins, causing a reflux of blood back into the veins of the pampiniform plexus. The force of gravity resulting from the upright position also contributes to venous dilatation. If the condition persists, there may be damage to the elastic fibers and hypertrophy of the vein walls, as occurs in formation of varicose veins in the leg. Sperm concentration and motility are decreased in 65% to 75% of men with varicocele because of changes in testicular temperature resulting from altered blood flow.¹⁶

Varicoceles rarely are found before puberty, and the incidence is highest in men between 15 and 35 years of age. Symptoms of varicocele include an abnormal feeling of heaviness in the left scrotum, although many varicoceles are asymptomatic. Usually, the varicocele is readily diagnosed on physical examination with the patient in the standing and recumbent positions. Typically, the varicocele disappears in the lying position because of venous decompression into the renal vein. Scrotal palpation of a varicocele has been compared to feeling a "bag of worms." Treatment options include surgical ligation or sclerosis using a percutaneous transvenous catheter under fluoroscopic guidance. It has been shown that 40% of men with abnormalities in their semen and a varicocele show some degree of improvement in fertility after obliteration of the dilated veins.¹⁶ Aside from improving fertility, other reasons for surgery include the relief of the sensation of "heaviness" and cosmetic improvement.

Testicular Torsion

Testicular torsion is a twisting of the spermatic cord that suspends the testis (Fig. 33-10). It is the most common acute scrotal disorder in the pediatric and young adult population. Testicular torsion can be divided into two distinct clinical entities, depending on the level of spermatic cord involvement: extravaginal and intravaginal torsion.¹⁷

Extravaginal torsion, which occurs almost exclusively in neonates, is the less common form of testicular torsion. It occurs

■ FIGURE 33-10 ■ Testicular torsion with twisting of the spermatic cord that suspends the testis and the spermatic vessels that supply the testis with blood.

when the testicle and the fascial tunicae that surround it rotate around the spermatic cord at a level well above the tunica vaginalis. Intravaginal torsion is considerably more common than extravaginal torsion. It occurs when the testis rotates on the long axis in the tunica vaginalis. In most cases, congenital abnormalities of the tunica vaginalis or spermatic cord exist.¹⁷ The tunica vaginalis normally surrounds the testes and epididymis, allowing the testicle to rotate freely in the tunica. Although anomalies of suspension vary, the epididymal attachment may be loose enough to permit torsion between the testis and the epididymis. More commonly, the testis rotates about the distal spermatic cord. Because this abnormality is developmental, bilateral anomalies are common.

Intravaginal torsion occurs most frequently between the ages of 8 and 18 years and rarely is seen after 30 years of age. Males usually present in severe distress within hours of onset and often have nausea, vomiting, and tachycardia. The affected testis is large and tender, with pain radiating to the inguinal area. Extensive cremaster muscle contraction causes a thickening of the spermatic cord.

Testicular torsion must be differentiated from epididymitis, orchitis, and trauma to the testis. On physical examination, the testicle often is high in the scrotum and in an abnormal orientation. These changes are due to the twisting and shortening of the spermatic cord. The degree of scrotal swelling and redness depends on the duration of symptoms. The testes are firm and tender. The cremasteric reflex, normally elicited by stroking the medial aspect of the thigh and observing testicular retraction, frequently is absent.¹⁷ Color Doppler ultrasonography is increasingly used in the evaluation of suspected testicular torsion.17

Intravaginal testicular torsion is a true surgical emergency, and early recognition and treatment are necessary if the testicle is to be saved. Treatment includes surgical detorsion (repositioning and fixation) and orchiectomy. Orchiectomy is carried out when the testis is deemed nonviable after surgical detorsion. Testicular salvage rates are directly related to the duration of torsion. Because the opposite testicle usually is affected by the same abnormal attachments, prophylactic fixation of that testis often is performed.

Inflammation and Infection

Epididymitis. Epididymitis is an inflammation of the epididymis. There are two major types of epididymitis: sexually transmitted infections associated with urethritis and primary nonsexually transmitted infections associated with urinary tract infections and prostatitis. Most cases of epididymitis are caused by bacterial pathogens.

In primary nonsexual infections, the pressure associated with voiding or physical strain may force pathogen-containing urine from the urethra or prostate up the ejaculatory duct and through the vas deferens and into the epididymis. Infections also may reach the epididymis through the lymphatics of the spermatic cord. In rare cases, organisms from other foci of infection reach the epididymis through the bloodstream. In children, the disorder usually is associated with congenital urinary tract abnormalities and infection with gram-negative rods.

Sexually transmitted acute epididymitis occurs mainly in young men without underlying genitourinary disease and is most commonly caused by Chlamydia trachomatis and Neisseria gonorrhoeae (singly or in combination). In men older than 35 years, epididymitis often is associated with pathogens such as Escherichia coli, Pseudomonas, and gram-positive cocci.

Epididymitis is characterized by unilateral pain and swelling, accompanied by erythema and edema of the overlying scrotal skin that develops during a period of 24 to 48 hours. Initially, the swelling and induration are limited to the epididymis. However, the distinction between the testis and epididymis becomes less evident as the inflammation progresses, and the testis and epididymis become one mass. There may be tenderness over the groin (spermatic cord) or in the lower abdomen. Fever and reports of dysuria occur in approximately one half of cases. Whether urethral discharge is present depends on the organism causing the infection; it usually accompanies gonorrheal infections, is common in chlamydial infections, and is less common in infections caused by gram-negative organisms.

Laboratory findings usually reveal an elevated white blood cell count. Urinalysis and urine culture are important in the diagnosis of epididymitis, with bacteriuria and pyuria suggestive of the disorder. Treatment during the acute phase (which usually lasts for 3 to 4 days) includes bed rest, scrotal elevation and support, and antibiotics.¹⁸ Bed rest with scrotal support improves lymphatic drainage. The choice of antibiotics is determined by age, physical findings, urinalysis, Gram's stain results, cultures, and sexual history. Oral analgesics and antipyretics usually are indicated. Sexual activity or physical strain may exacerbate the infection and worsen the symptoms and should be avoided.

Orchitis. Orchitis is an infection of the testes. It can be precipitated by a primary infection in the genitourinary tract, or the infection can be spread to testes through the bloodstream or the lymphatics. Epididymitis with subsequent infection of the testis is commonly related to genitourinary tract infections (cystitis, urethritis, genitoprostatitis) that travel to the epididymis and testis through the vas deferens or the lymphatics of the spermatic cord.

Orchitis can develop as a complication of a systemic infection, such as parotitis (i.e., mumps), scarlet fever, or pneumonia. Probably the best known of these complications is orchitis caused by the mumps virus. Mumps orchitis does not occur in prepubertal boys. However, approximately 20% to 35% of adolescent boys and young men with mumps develop this form of orchitis.¹⁸ The onset of mumps orchitis is sudden; it usually occurs approximately 3 to 4 days after the onset of the parotitis and is characterized by fever, painful enlargement of the testes, and small hemorrhages into the tunica albuginea. Unlike epididymitis, the urinary symptoms are absent. The symptoms usually run their course in 7 to 10 days. The residual effects seen after the acute phase include hyalinization of the seminiferous tubules and atrophy of the testes. Spermatogenesis is irreversibly impaired in approximately 30% of testes damaged by mumps orchitis.¹⁸ If both testes are involved, permanent sterility results, but and rogenic hormone function usually is maintained.

Cancer of the Scrotum and Testes

Tumors can develop in the scrotum or the testes. Benign scrotal tumors are common and often do not require treatment. Carcinoma of the scrotum is rare and usually is associated with exposure to carcinogenic agents. Almost all solid tumors of the testes are malignant.

Scrotal Cancer. Cancer of the scrotum was the first cancer directly linked to a specific occupation when, in the 1800s, it was associated with chimney sweeps.¹⁹ Studies have linked this cancer to exposure to tar, soot, and oils. Most squamous cell cancers of the scrotum are linked to poor hygiene and chronic inflammation. Exposure to ultraviolet A radiation (*e.g.*, PUVA) or HPV also has been associated with the disease. The mean age of presentation with the disease is 60 years, often preceded by 20 to 30 years of chronic irritation.

In the early stages, cancer of the scrotum may appear as a small tumor or wartlike growth that eventually ulcerates. The thin scrotal wall lacks the tissue reactivity needed to block the malignant process; more than one half of the cases seen involve metastasis to the lymph nodes. Because this tumor does not respond well to chemotherapy or irradiation, the treatment includes wide local excision of the tumor with inguinal and femoral node dissection.²⁰

Testicular Cancer. Testicular cancer accounts for 1% of all male cancers and 3% of male urogenital cancers. Although relatively rare, it is the most common cause of cancer in the 15- to 34-year-old age group.^{20,21} In the past, testicular cancer was a leading cause of death among males entering their most productive years. However, since the late 1970s, advances in therapy have transformed an almost invariably fatal disease into one that is highly curable. With appropriate treatment, the prognosis for men with testicular cancer is excellent. The 5-year survival rate for patients with early disease exceeds 95%. Even patients with more advanced disease have excellent chances for long-term survival.

Although the cause of testicular cancer is unknown, several predisposing influences may be important: cryptorchidism, genetic factors, and disorders of testicular development.²² The strongest association has been with cryptorchid or undescended testes. The higher the location of the undescended testis, the greater the risk.²² Genetic predisposition also appears to be important. Family clustering of the disorder has been described, although a well-defined pattern of inheritance has not been established. Men with disorders of testicular development, including those with Klinefelter's syndrome and testicular feminization, have a higher risk of germ cell tumors.

Approximately 95% of malignant tumors arising in the testis are germ cell tumors.^{21,23} Germ cell tumors can be classified as seminomas and nonseminomas based on their origin in primordial germ cells and their ability to differentiate in vivo. Because these tumors derive from germ cells in the testis, they are multipotential (able to differentiate into different tissue types) and often secrete polypeptide hormones or enzymes representing earlier stages of development (see Chapter 5). *Seminomas* are the most common type of testicular tumors. They account for approximately 50% of germ cell tumors and occur most frequently during the fourth decade of life.²¹ Seminomas are thought to arise from the seminiferous epithelium of the testes and are the type of germ cell tumor most likely to produce a uniform population of cells.

The nonseminoma tumors include embryonal carcinoma, teratoma, choriocarcinoma, and yolk cell carcinoma derivatives. Nonseminoma tumors usually contain more than one cell type and are less differentiated than seminomas. Embryonal carcinomas are the least differentiated of the tumors, with totipotential capacity to differentiate into other nonseminomatous cell types. They occur most commonly in the 20- to 30-year-old age group. Choriocarcinoma is a rare and highly malignant form of testicular cancer that is identical to tumors that arise in placental tissue. Yolk sac tumors mimic the embryonic yolk sac histologically. They are the most common type of testicular tumors in infants and children to 3 years of age, and in this age group are associated with a very good prognosis.²² Teratomas are composed of somatic cell types from two or more germ-line layers (ectoderm, mesoderm, or endoderm). They constitute less than 2% to 3% of germ cell tumors and can occur at any age from infancy to old age. They usually behave as benign tumors in children; in adults, they often contain minute foci of cancer cells.

Often the first sign of testicular cancer is a slight enlargement of the testicle that may be accompanied by some degree of discomfort. This may be an ache in the abdomen or groin or a sensation of dragging or heaviness in the scrotum. Frank pain may be experienced in the later stages, when the tumor is growing rapidly and hemorrhaging occurs. Testicular cancer can spread when the tumor may be barely palpable. Signs of metastatic spread include swelling of the lower extremities, back pain, cough, hemoptysis, or dizziness. Gynecomastia (breast enlargement) may result from human chorionic gonadotropin (hCG)-producing tumors.

Early diagnosis of testicular cancer is important because a delay in seeking medical attention often results in presentation with a later stage of the disease and decreased treatment effectiveness. Recognition of the importance of prompt diagnosis and treatment has resulted in the development of a procedure for testicular self-examination and an emphasis on public education programs about this type of cancer. The American Cancer Society strongly advocates that every young adult male examine his testes at least once each month as a means of early detection of testicular cancer.

The diagnosis of testicular cancer requires a thorough urologic history and physical examination. A painless testicular mass may be cancer. The examination for masses should include palpation of the testes and surrounding structures, transillumination of the scrotum, and abdominal palpation. Testicular ultrasonography can be used to differentiate testicular masses. CT scans and MRI are used in assessing metastatic spread.

Tumor markers, which measure protein antigens produced by malignant cells, provide information about the existence of a small or undetected tumor and the type of tumor present. Three tumor markers are useful in evaluating the tumor response: α -fetoprotein, a glycoprotein that normally is present in fetal serum in large amounts; hCG, a hormone that normally is produced by the placenta in pregnant women; and lactate dehydrogenase (LDH), a cellular enzyme normally found in muscle, liver, kidney, and brain. The reappearance in the adult of these protein markers suggests activity normally present in the embryo.

The basic treatment of all testicular cancers includes orchiectomy, which is done at the time of diagnostic exploration. Dependent on the histologic characteristics of the tumor and the clinical stage of the disease, radiation or chemotherapy may used after orchiectomy. Rigorous follow-up in all men with testicular cancer is necessary to detect recurrence, which most often occurs within the first year.²³

Disorders of the Prostate

The prostate is a fibromuscular and glandular organ lying just inferior to the bladder. The prostate gland secretes a thin, milky, alkaline fluid containing citric acid, calcium, acid phosphate, a clotting enzyme, and a profibrinolysin. During ejaculation, the capsule of the prostate contracts, and the added fluid increases the bulk of the semen. Both vaginal secretions and the fluid from the vas deferens are strongly acidic. Because sperm mobilization occurs at a pH of 6.0 to 6.5, the alkaline nature of the prostatic secretions is essential for successful fertilization of the ovum. The bulbourethral glands (Fig. 33-1) lie on either side of the membranous urethra and secrete an alkaline mucus, which further aids in neutralizing acids from the urine that remain in the urethra.

The prostate gland, which forms a fibrous capsule that surrounds the urethra where it joins the bladder, also functions in the elimination of urine. The segment of urethra that travels through the prostate gland is called the *prostatic urethra*. The prostatic urethra is lined by a thin layer of smooth muscle that is continuous with the bladder wall. This smooth muscle represents the true involuntary sphincter of the male posterior urethra. Because the prostate surrounds the urethra, enlargement of the gland can produce urinary obstruction.

The prostate gland is made up of many secretory glands arranged in three concentric areas surrounding the prostatic urethra, into which they open. The component glands of the prostate include the (1) small mucosal glands associated with the urethral mucosa, (2) the intermediate submucosal glands that lie peripheral to the mucosal glands, and (3) the large main prostatic glands that are situated toward the outside of the gland. It is the overgrowth of the mucosal glands that causes benign prostatic hyperplasia in older men.

Prostatitis

Prostatitis refers to a variety of inflammatory disorders of the prostate gland, some of which are bacterial and some are not. It may occur spontaneously, as a result of catheterization or instrumentation, or secondary to other diseases of the male genitourinary system. As an outcome of 1995 and 1998 consensus conferences, the National Institutes of Health has established a classification system with four categories of prostatitis syndromes: asymptomatic inflammatory prostatitis, acute bacterial prostatitis, chronic bacterial prostatitis, and chronic prostatitis/ pelvic pain syndrome.²⁴ Men with asymptomatic inflammatory prostatitis have no subjective symptoms and are detected incidentally on biopsy or examination of prostatic fluid.

Acute Bacterial Prostatitis. Acute bacterial prostatitis often is considered a subtype of urinary tract infection. The most likely etiology of acute bacterial prostatitis is an ascending urethral infection or reflux of infected urine into the prostatic ducts. The most common organism is E. coli. Other frequently found species include Pseudomonas, Klebsiella, and Proteus. Less frequently, the infection is caused by Staphylococcus aureus, Streptococcus faecalis, Chlamydia, or anaerobes such as Bacteroides species.^{25,26}

The manifestations of acute bacterial prostatitis include fever and chills, malaise, myalgia, arthralgia, frequent and urgent urination, dysuria, and urethral discharge. Dull, aching pain often is present in the perineum, rectum, or sacrococcygeal region. The urine may be cloudy and malodorous because of urinary tract infection. Rectal examination reveals a swollen, tender, warm prostate with scattered soft areas. Prostatic massage produces a thick discharge with white blood cells that grows large numbers of pathogens on culture.

Acute prostatitis usually responds to appropriate antimicrobial therapy chosen in accordance with the sensitivity of the causative agents in the urethral discharge. Depending on the urine culture results, antibiotic therapy usually is continued for at least 4 weeks. Because acute prostatitis often is associated with anatomic abnormalities, a thorough urologic examination usually is performed after treatment is completed.

A persistent fever indicates the need for further investigation for an additional site of infection or a prostatic abscess. CT scans and transrectal ultrasonography of the prostate are useful in the diagnosis of prostatic abscesses. Prostatic abscesses, which are relatively uncommon since the advent of effective antibiotic therapy, are found more commonly in males with diabetes mellitus. Because prostatic abscesses usually are associated with bacteremia, prompt drainage by transperitoneal or transurethral incision followed by appropriate antimicrobial therapy usually is indicated.²⁵

Chronic Bacterial Prostatitis. In contrast to acute bacterial prostatitis, chronic bacterial prostatitis is a subtle disorder that is difficult to treat. Men with the disorder typically have recurrent urinary tract infections with persistence of the same strain of pathogenic bacteria in prostatic fluid and urine. Organisms responsible for chronic bacterial prostatitis usually are the gram-negative enterobacteria (E. coli, Proteus, or Klebsiella) or *Pseudomonas*. Occasionally, a gram-positive organism such as S. faecalis is the causative organism. Infected prostatic calculi may develop and contribute to the chronic infection.

The symptoms of chronic prostatitis are variable and include frequent and urgent urination, dysuria, perineal discomfort, and low back pain. Occasionally, myalgia and arthralgia accompany the other symptoms. Secondary epididymitis sometimes is associated with the disorder. Many men develop relapsing lower or upper urinary tract infections because of recurrent invasion of the bladder by the prostatic bacteria. Bacteria may exist in the prostate gland even when the prostatic fluid is sterile.

The most accurate method of establishing a diagnosis is by urine cultures. Even after an accurate diagnosis has been established, treatment of chronic prostatitis often is difficult and frustrating. Unlike their action in the acutely inflamed prostate, antibacterial drugs penetrate poorly into the chronically inflamed prostate. Long-term therapy (3 to 4 months) with an appropriate low-dose oral antimicrobial agent often is used to treat the infection. Transurethral prostatectomy may be indicated when the infection is not cured or adequately controlled by medical therapy, particularly when prostate stones are present.

Chronic Prostatitis/Chronic Pelvic Pain Syndrome. Chronic prostatitis/pelvic pain syndrome is both the most common and least understood of the prostatitis syndromes.²⁷ The category is divided into two types, inflammatory and noninflammatory, based on the presence of leukocytes in the prostatic fluid. The inflammatory type was previously referred to as nonbacterial prostatitis, and the noninflammatory type as prostatodynia.

Men with nonbacterial prostatitis have inflammation of the prostate with an elevated leukocyte count, inflammatory cells

594 Unit Nine: Alterations in the Male and Female Reproductive Systems

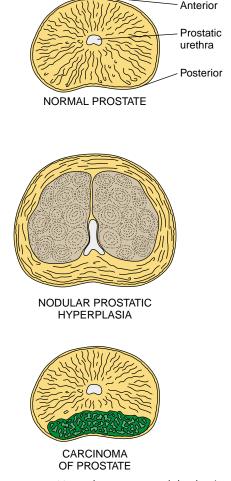

in their prostatic secretions, but no evidence of bacteria. The cause of the disorder is unknown, and efforts to prove the presence of unusual pathogens (*e.g.*, mycoplasmas, chlamydiae, trichomonads, viruses) have been largely unsuccessful. It also is thought that nonbacterial prostatitis may be an autoimmune disorder. Manifestations of *inflammatory prostatitis* include pain along the penis, testicles, and scrotum; painful ejaculation; low back pain; rectal pain along the inner thighs; urinary symptoms; decreased libido; and impotence.

Men with noninflammatory prostatitis have symptoms resembling those of nonbacterial prostatitis but have negative urine culture results and no evidence of prostatic inflammation (*i.e.*, normal leukocyte count). The cause of noninflammatory prostatitis is unknown, but because of the absence of inflammation, the search for the cause of symptoms has been directed toward extraprostatic sources. In some cases, there is an apparent functional obstruction of the bladder neck near the external urethral sphincter; during voiding, this results in higher than normal pressures in the prostatic urethra that cause intraprostatic urine reflux and chemical irritation of the prostate by urine. In other cases, there is an apparent myalgia (*i.e.*, muscle pain) associated with prolonged tension of the pelvic floor muscles. Emotional stress also may play a role.

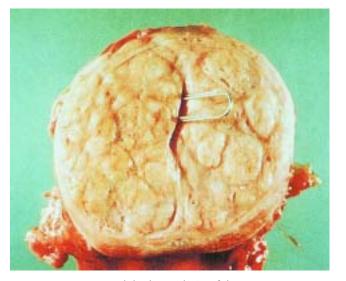

Treatment methods for chronic prostatitis/pelvic pain syndrome are highly variable. Antibiotic therapy is used when an occult infection is suspected. Sitz baths and nonsteroidal antiinflammatory agents may provide some symptom relief. In men with irritative urination symptoms, anticholinergic agents or α -adrenergic-blocking agents may be beneficial.

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is an age-related, nonmalignant enlargement of the prostate gland (Fig. 33-11). It is characterized by the formation of large, nodular lesions in

■ FIGURE 33-12 ■ Normal prostate, nodular benign prostatic hypertrophy, and cancer of the prostate. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 954]. Philadelphia: Lippincott Williams & Wilkins.) (Artist: Dimitri Karetnikov)

■ FIGURE 33-11 ■ Nodular hyperplasia of the prostate. Cut surface of a prostate enlarged by nodular hyperplasia shows numerous, well-circumscribed nodules of prostatic tissue. The prostatic urethra (*paper clip*) has been compressed to a narrow slit. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 955]. Philadelphia: Lippincott Williams & Wilkins)

the periurethral region of the prostate, rather than the peripheral zones, which commonly are affected by prostate cancer (Fig. 33-12). BPH is one of the most common diseases of aging men. It has been reported that 25% of men older than 55 years of age and 50% of men older than 75 years of age experience symptoms of BPH.²⁸

The exact cause of the BPH is unknown. Potential risk factors include age, family history, race, ethnicity, and hormonal factors. The incidence of BPH increases with advancing age, is highest in African Americans, and is lowest in native Japanese. Men with a family history of BPH are reported to have had larger prostates than those of control subjects, and higher rates of BPH were found in monozygotic twins than in dizygotic twins.²⁸

Both androgens (testosterone) and estrogens appear to contribute to the development of BPH. Dihydrotestosterone (DHT), the biologically active metabolite of testosterone, is thought to be the ultimate mediator of prostatic hyperplasia, with estrogen serving to sensitize the prostatic tissue to the growth-producing effects of DHT. Free plasma testosterone enters prostatic cells, where at least 90% is converted into DHT by

KEY CONCEPTS

HYPERPLASIA AND CANCER OF THE PROSTATE

- The prostate gland surrounds the urethra, and periurethral enlargement will cause manifestations of urinary obstruction.
- Benign prostatic hyperplasia is an age-related enlargement of the prostate gland with formation of large, discrete lesions in the periurethral region of the prostate. These lesions compress the urethra and produce symptoms of dysuria or difficulty urinating.
- Prostatic cancer begins in the peripheral zones of the prostate gland and usually is asymptomatic until the disease is far advanced and the tumor has eroded the outer prostatic capsule and spread to adjacent pelvic tissues or metastasized.

the action of 5α -reductase. The discovery that DHT is the active factor in BPH is the rationale for use of 5α -reductase inhibitors in the treatment of the disorder. Although the exact source of estrogen is uncertain, small amounts of estrogen are produced in the male. It has been postulated that a relative increase in estrogen levels that occurs with aging may facilitate the action of androgens in the prostate despite a decline in the testicular output of testosterone.

The anatomic location of the prostate at the bladder neck contributes to the pathophysiology and symptomatology of BPH. There are two prostatic components to the obstructive properties of BPH and the development of lower urinary tract symptoms: dynamic and static.28,29 The static component of BPH is related to an increase in prostatic size and gives rise to symptoms such as a weak urinary stream, postvoid dribbling, frequency of urination, and nocturia. The dynamic component of BPH is related to prostatic smooth muscle tone. The α_1 adrenergic receptors are the main receptors for the smooth muscle component of the prostate. The recognition of the role of α_1 -adrenergic receptor on neuromuscular function in the prostate is the basis for use of α_1 -adrenergic-receptor blockers in treating BPH. A third component, detrusor instability and impaired bladder contractility, may contribute to the symptoms of BPH independent of the outlet obstruction created by an enlarged prostate (see Chapter 25).^{29,30} It has been suggested that some of the symptoms of BPH might be related to a decompensating or aging bladder, rather than being primarily related to outflow obstruction. An example is the involuntary contraction that results in urgency and an attempt to void that occurs because of small bladder volume.29

Clinical Course. The clinical significance of BPH resides in its tendency to compress the urethra and cause partial or complete obstruction of urinary outflow. As the obstruction increases, acute retention may occur with overdistention of the bladder. The residual urine in the bladder causes increased frequency of urination and a constant desire to empty the bladder, which be-

comes worse at night. With marked bladder distention, overflow incontinence may occur with the slightest increase in intra-abdominal pressure. The resulting obstruction to urinary flow can give rise to urinary tract infection, destructive changes of the bladder wall, hydroureter, and hydronephrosis. Hypertrophy and changes in bladder wall structure develop in stages. Initially, the hypertrophied fibers form trabeculations and then herniations, or sacculations; finally, diverticula develop as the herniations extend through the bladder wall (Chapter 25, Fig. 25-4). Because urine seldom is completely emptied from them, these diverticula are readily infected. Back pressure on the ureters and collecting system of the kidneys promotes hydroureter, hydronephrosis, and eventual renal failure.

It is now thought that the single most important factor in the evaluation and treatment of BPH is the man's own experiences related to the disorder. The American Urological Society Symptom Index consists of seven questions about symptoms regarding incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia.^{31,32} Each question is rated with a score of 0 (mild) to 7 (severe). A maximum score of 35 indicates severe symptoms. Total scores below 7 are considered mild; those between 8 and 20, moderate; and scores over 20, severe. A final question relates to quality of life related to urinary problems.

Diagnosis of BPH is based on history, physical examination, digital rectal examination, urinalysis, blood tests for serum creatinine and prostate-specific antigen (PSA), and urine flow rate. Blood and urine analyses are used as adjuncts to determine BPH complications. Urinalysis is done to detect bacteria, white blood cells, or microscopic hematuria in the presence of infection and inflammation. The serum creatinine test is used as an estimate of the glomerular filtration rate and kidney function. The PSA test is used to screen for prostatic cancer. These evaluation measures, along with the symptom index, are used to describe the extent of obstruction, determine if other diagnostic tests are needed, and establish the need for treatment.

Transabdominal or transrectal diagnostic ultrasonography can be used to evaluate the kidneys, ureters, and bladder. Abdominal radiographs may be used to reveal the size of the gland. Urethrocystoscopy is indicated in men with a history of hematuria, stricture disease, urethral injury, or prior lower urinary tract surgery. It is used to evaluate the length and diameter of the urethra, the size and configuration of the prostate, and bladder capacity. It also detects the presence of trabeculations, bladder stones, and small bladder cancers. CT scans, MRI studies, and radionuclide scans are reserved for rare instances of tumor detection.

Treatment of BPH is determined by the degree of symptoms that the condition produces and complications due to obstruction. When a man develops mild symptoms related to BPH, a "watch and wait" stance often is taken. The condition does not always run a predictable course; it may remain stable or even improve. Until the 1980s, surgery was the mainstay of treatment to alleviate urinary obstruction due to BPH. Currently, there is an emphasis on less invasive methods of treatment, including use of pharmacologic agents. However, when more severe signs of obstruction develop, surgical treatment (*e.g.*, transurethral resection of the prostate [TURP]) usually is indicated to provide comfort and avoid serious renal damage. For men who have heart or lung disease or a condition that precludes major surgery, a stent may be used to widen and maintain the patency of the urethra.

Pharmacologic management includes the use of 5α -reductase inhibitors and α_1 -adrenergic–blocking drugs.^{28,29} The 5α reductase inhibitors such as finasteride reduce prostate size by blocking the effect of androgens on the prostate. The presence of α -adrenergic receptors in prostatic smooth muscle has prompted the use of α_1 -adrenergic–blocking drugs to relieve prostatic obstruction and increase urine flow.

Cancer of the Prostate

Prostatic cancer is the most common male cancer in the United States and is second to lung cancer as a cause of cancer-related death in men. The American Cancer Society estimates that during 2002, approximately 189,000 men in the United States received a diagnosis of prostate cancer, and 32,200 men died of the disorder.³³ The increase in diagnosed cases is thought to reflect earlier diagnosis because of the widespread use of PSA testing since the early 1990s.³⁴ The incidence of prostate cancer varies markedly from country to country and varies among races in the same country.³³ African-American men have the highest reported incidence for prostate cancer at all ages, and Asians and Native American men have the lowest rate. Prostate cancer also is a disease of aging. The incidence increases rapidly after 50 years of age; more than 80% of all prostate cancers are diagnosed in men older than 65 years of age.³³

The precise cause of prostatic cancer is unclear. As with other cancers, it appears that the development of prostate cancer is a multistep process involving genes that control cell differentiation and growth (see Chapter 5). Several risk factors, such as age, race, heredity, and environmental influences, are suspected of playing a role.^{35,36} Male hormone levels also may play a role. There is insufficient evidence linking socioeconomic status, infectious agents, smoking, vasectomy, sexual behavior, or BPH to the pathogenesis of prostate cancer.

The incidence of prostate cancer appears to be higher in relatives of men with prostate cancer. Diet may also play a role. It has been suggested that a diet high in fats may alter the production of sex hormones and increase the risk of prostate cancer. Supporting the role of dietary fats as a risk factor for prostate cancer has been the observation that the diet of Japanese men, who have a low rate of prostate cancer, is much lower in fat content than that of U.S. men, who have a much higher incidence.

In terms of hormonal influence, androgens are believed to play a role in the pathogenesis of prostate cancer.³⁵ Evidence favoring a hormonal influence includes the presence of steroid receptors in the prostate, the requirement of sex hormones for normal growth and development of the prostate, and the fact that prostate cancer almost never develops in men who have been castrated. The response of prostatic cancer to estrogen administration or androgen deprivation further supports a correlation between the disease and testosterone levels.

Prostatic adenocarcinomas, which account for 98% of all primary prostatic cancers, are commonly multicentric and located in the peripheral zones of the prostate³⁶ (see Fig. 33-12). The high frequency of invasion of the prostatic capsule by adenocarcinoma relates to its subcapsular location. Invasion of the urinary bladder is less common and occurs later in the clinical course. Metastasis to the lung reflects lymphatic spread through the thoracic duct and dissemination from the prostatic venous plexus to the inferior vena cava. Bony metastases, particularly to the vertebral column, ribs, and pelvis, produce pain that often presents as a first sign of the disease.

Most men with early-stage prostate cancer are asymptomatic. The presence of symptoms often suggests locally advanced or metastatic disease. Depending on the size and location of prostatic cancer at the time of diagnosis, there may be changes associated with the voiding pattern similar to those found in BPH. These include urgency, frequency, nocturia, hesitancy, dysuria, hematuria, or blood in the ejaculate. On physical examination, the prostate is nodular and fixed. Bone metastasis often is characterized by low back pain. Pathologic fractures can occur at the site of metastasis. Men with metastatic disease may experience weight loss, anemia, or shortness of breath.

Screening. Because early cancers of the prostate usually are asymptomatic, screening tests are important. The screening tests currently available are digital rectal examination, PSA testing, and transrectal ultrasonography. PSA is a glycoprotein secreted into the cytoplasm of benign and malignant prostatic cells that is not found in other normal tissues or tumors. However, a positive PSA test indicates only the possible presence of prostate cancer. It also can be positive in cases of BPH and prostatitis. The American Cancer Society and the American Urological Association recommend that men 50 years of age or older should undergo annual measurement of PSA and rectal examination for early detection of prostate cancer.³³ Men at high risk for prostate cancer, such as blacks and those with a strong family history, should undergo annual screening beginning at 45 years of age.³³

Diagnosis. The diagnosis of prostate cancer is based on history and physical examination and confirmed through biopsy methods. Transrectal ultrasonography, a continuously improving method of imaging, is used to guide a biopsy needle and document the exact location of the biopsied tissue. It also is used for providing staging information.²⁸ Newly developed small probes for transrectal MRI have been shown to be effective in detecting the presence of cancer in the prostate. Radiologic examination of the bones of the skull, ribs, spine, and pelvis can be used to reveal metastases, although radionuclide bone scans are more sensitive. Excretory urograms are used to delineate changes due to urinary tract obstruction and renal involvement.

Cancer of the prostate, like other forms of cancer, is graded and staged (see Chapter 5). Prostatic adenocarcinoma commonly is classified using the Gleason grading system.^{35,36} Welldifferentiated tumors are assigned a grade of 1, and poorly differentiated tumors a grade of 5. Two tumor markers, PSA and serum acid phosphatase, are important in the staging and management of prostatic cancer. In untreated cases, the level of PSA correlates with the volume and stage of disease.³⁷ A rising PSA after treatment is consistent with progressive disease, whether it is locally recurring or metastatic. Measurement of PSA is used to detect recurrence after total prostatectomy. Because the prostate is the source of PSA, levels of the antigen should drop to zero after surgery; a rising PSA indicates recurring disease. Serum acid phosphatase is less sensitive than PSA and is used less frequently. However, it is more predictive of metastatic disease and may be used for that purpose.

Treatment. Cancer of the prostate is treated by surgery, radiation therapy, and hormonal manipulations.^{28,38,39} Chemotherapy has shown limited effectiveness in the treatment of prostate cancer. Treatment decisions are based on tumor grade and stage and on the age and health of the man. Expectant therapy (watching and waiting) may be used if the tumor is not producing symptoms, is expected to grow slowly, and is small and contained in one area of the prostate. This approach is particularly suited for men who are elderly or have other health problems. Most men with an anticipated survival greater than 10 years are considered for surgical or radiation therapy.³⁹ Radical prostatectomy involves complete removal of the seminal vesicles, prostate, and ampullae of the vas deferens. Radiation therapy can be delivered by a variety of techniques, including external beam radiation therapy and transperineal implantation of radioisotopes.

Metastatic disease often is treated with androgen deprivation therapy. Androgen deprivation may be induced at several levels along the pituitary-gonadal axis using a variety of methods or agents. Orchiectomy or estrogen therapy often is effective in reducing symptoms and extending survival. The GnRH analogs (*e.g.*, leuprolide, buserelin, nafarelin) block luteinizing hormone release from the pituitary and reduce testosterone levels without orchiectomy or estrogen therapy. When given continuously and in therapeutic doses, these drugs desensitize GnRH receptors in the pituitary, thereby preventing the release of luteinizing hormone. The antiandrogens block the uptake and actions of androgens in the target tissues. Complete androgen blockade can be achieved by combining an antiandrogen with a GnRH agent or orchiectomy.

In summary, disorders of the penis include balanitis, an acute or chronic inflammation of the glans penis, and balanoposthitis, an inflammation of the glans and prepuce. Peyronie's disease is characterized by the growth of a band of fibrous tissue on top of the penile shaft. Priapism is prolonged, painful, and nonsexual erection that can lead to thrombosis with ischemia and necrosis of penile tissue. Cancer of the penis accounts for less than 1% of male genital cancers in the United States. Although the tumor is slow growing and highly curable when diagnosed early, the greatest hindrance to successful treatment is a delay in seeking medical attention.

Disorders of the scrotum and testes include hydrocele, hematocele, spermatocele, varicocele, and testicular torsion. Inflammatory conditions can involve the scrotal sac, epididymis, or testes. Tumors can arise in the scrotum or the testes. Scrotal cancers usually are associated with exposure to petroleum products such as tar, pitch, and soot. Testicular cancers account for 1% of all male cancers and 3% of cancers of the male genitourinary system. With current treatment methods, a large percentage of men with these tumors can be cured. Testicular self-examination is recommended as a means of early detection of this form of cancer.

The prostate is a firm, glandular structure that surrounds the urethra. Inflammation of the prostate occurs as an acute or a chronic process. Chronic prostatitis probably is the most common cause of relapsing urinary tract infections in men. BPH is a common disorder in men older than 50 years. Because the prostate encircles the urethra, BPH exerts its effect through obstruction of urinary outflow from the bladder. Advances in the treatment of BPH include laser surgery, balloon dilatation, prostatic stents, and pharmacologic treatment.

Prostatic cancer is the most common male cancer in the United States and is second to lung cancer as a cause of cancer-related death in men. A recent increase in diagnosed cases is thought to reflect earlier diagnosis because of widespread use of PSA testing. Most prostate cancers are asymptomatic and are incidentally discovered on rectal examination. Cancer of the prostate, like other forms of cancer, is graded according to the histologic characteristics of the tumor and staged clinically using the TNM system. Treatment, which is based on the extent of the disease, includes surgery, radiation therapy, and hormonal manipulation.

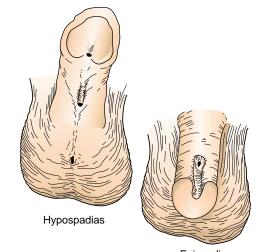

DISORDERS IN CHILDHOOD AND AGING CHANGES

Disorders of Childhood

Disorders of the male reproductive system that present in childhood include hypospadias, epispadias, phimosis and paraphimosis, and cryptorchidism.

Hypospadias and Epispadias

Hypospadias and epispadias are congenital disorders of the penis resulting from embryologic defects in the development of the urethral groove and penile urethra (Fig. 33-13). In hypospadias, which affects approximately 1 in 300 male infants, the termination of the urethra is on the ventral surface of the penis.^{34,40} The testes are undescended in 10% of boys born with hypospadias and chordee (*i.e.*, ventral bowing of the penis), and inguinal hernia also may accompany the disorder. In the newborn with severe hypospadias and cryptorchidism (undescended testes), the differential diagnosis should consider ambiguous genitalia and masculinization

Epispadias

FIGURE 33-13 Hypospadias and epispadias.

that is seen in females with congenital adrenal hyperplasia (see Chapter 31). Because many chromosomal aberrations result in ambiguity of the external genitalia, chromosomal studies often are recommended for male infants with hypospadias and cryptorchidism.³⁴

Surgery is the treatment of choice for hypospadias.³⁴ Circumcision is avoided because the foreskin is used for surgical repair. Factors that influence the timing of surgical repair include anesthetic risk, penile size, and the psychological effects of the surgery on the child. In mild cases, the surgery is done for cosmetic reasons only. In more severe cases, surgical repair becomes essential for normal sexual functioning and to prevent the psychological effects of having malformed genitalia. When indicated, surgical repair is usually done between the ages of 6 to 12 months.

Epispadias, in which the opening of the urethra is on the dorsal surface of the penis, is a less common defect. Although epispadias may occur as a separate entity, it often is associated with exstrophy of the bladder, a condition in which the abdominal wall fails to cover the bladder. The treatment depends on the extent of the developmental defect.

Phimosis and Paraphimosis

Phimosis refers to a tightening of the prepuce or penile foreskin that prevents its retraction over the glans. Embryologically, the foreskin begins to develop during the eighth week of gestation as a fold of skin at the distal edge of the penis that eventually grows forward over the base of the glans.⁴⁰ By the 16th week of gestation, the prepuce and the glans are adherent. Only a small percentage of newborns have a fully retractable foreskin. With growth, a space develops between the glans and foreskin, and by 3 years of age, approximately 90% of male children have retractable foreskins.

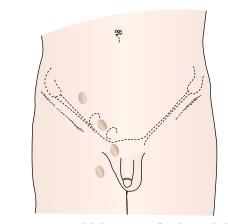

Because the foreskin of many boys cannot be fully retracted in early childhood, it is important that the area be cleaned thoroughly. There is no need to retract the foreskin forcibly because this could lead to infection, scarring, or paraphimosis. As the child grows, the foreskin becomes retractable, and the glans and foreskin should be cleaned routinely. If symptomatic phimosis occurs after childhood, it can cause difficulty with voiding or sexual activity. Circumcision is then the treatment of choice.

In a related condition called *paraphimosis*, the foreskin is so tight and constricted that it cannot cover the glans. A tight foreskin can constrict the blood supply to the glans and lead to ischemia and necrosis. Many cases of paraphimosis result from the foreskin being retracted for an extended period, as in the case of catheterized uncircumcised males.

Cryptorchidism

Cryptorchidism, or undescended testes, occurs when one or both of the testicles fail to move down into the scrotal sac. The condition is bilateral in 10% to 20% of cases. The testes develop intra-abdominally in the fetus and usually descend into the scrotum through the inguinal canal during the seventh to ninth months of gestation.⁴⁰ The undescended testes may remain in the lower abdomen or at a point of descent in the inguinal canal (Fig. 33-14).

The incidence of cryptorchidism is directly related to birth weight and gestational age; infants who are born prematurely

■ FIGURE 33-14 ■ Possible locations of undescended testicles.

or are small for gestational age have the highest incidence of the disorder. Up to one third of premature infants and 3% to 5% of full-term infants are born with undescended testicles.^{35,41} The cause of cryptorchidism in full-term infants is poorly understood. Most cases are idiopathic, but some may result from genetic or hormonal factors.²⁹

The major manifestation of cryptorchidism is the absence of one or more of the testes in the scrotum. The testis either is not palpable or can be felt external to the inguinal ring. Spontaneous descent often occurs during the first 3 months of life, and by 6 months of age the incidence decreases to 0.8%.^{34,41} Spontaneous descent rarely occurs after 6 months of age.

In children with cryptorchidism, histologic abnormalities of the testes reflect intrinsic defects in the testicle or adverse effects of the extrascrotal environment. The undescended testicle is normal at birth, but pathologic changes can be demonstrated at 6 to 12 months.³⁴ There is a delay in germ cell development, changes in the spermatic tubules, and reduced number of Leydig cells. These changes are progressive if the testes remain undescended. When the disorder is unilateral, it also may produce morphologic changes in the contralateral descended testis.

The consequences of cryptorchidism include infertility, malignancy, and the possible psychological effects of an empty scrotum. Indirect inguinal hernias usually accompany the undescended testes but rarely are symptomatic. Recognition of the condition and early treatment are important steps in preventing adverse consequences. The risk of malignancy in the undescended testis is four to six times higher than in the general population.^{34,41} The increased risk of testicular cancer is not significantly affected by orchiopexy, hormonal therapy, or late spontaneous descent after the age of 2 years. However, orchiopexy does allow for earlier detection of a testicular malignancy by positioning the testis in a more easily palpable location.

As a group, males with unilateral or bilateral cryptorchidism usually have decreased sperm counts, poorer-quality sperm, and lower fertility rates than do men whose testicles descend normally. The likelihood of decreased fertility increases when the condition is bilateral. Unlike the risk of testicular cancer, there seems to be some advantage to early orchiopexy for protection of fertility.^{34,41}

Diagnosis is based on careful examination of the genitalia in male infants. Undescended testes due to cryptorchidism should be differentiated from retractable testes that retract into the inguinal canal in response to an exaggerated cremaster muscle reflex. Retractable testes usually are palpable at birth but become nonpalpable later. They can be brought down with careful palpation in a warm room. Retractable testes usually assume a scrotal position during puberty. They have none of the complications associated with undescended testicles due to cryptorchidism.³⁴

Improved techniques for testicular localization include ultrasonography (*i.e.*, visualization of the testes by recording the pulses of ultrasonic waves directed into the tissues), gonadal venography and arteriography (*i.e.*, radiography of the veins and arteries of the testes after the injection of a contrast medium), and laparoscopy (*i.e.*, examination of the interior of the abdomen using a visualization instrument).

The treatment goals for the child with cryptorchidism include measures to enhance future fertility potential, placement of the gonad in a favorable place for cancer detection, and improved cosmetic appearance. Regardless of the type of treatment used, it should be carried out between 6 months and 2 years of age.34,41 Treatment modalities for children with unilateral or bilateral cryptorchidism include initial hormone therapy with hCG or luteinizing hormone-releasing hormone (LHRH), a hypothalamic hormone that stimulates production of the gonadotropic hormones by the anterior pituitary gland. For children who do no respond to hormonal treatment, surgical placement and fixation of the testes in the scrotum (*i.e.*, orchiopexy) have proved effective. Approximately 95% of infants who have orchiopexy for a unilateral undescended testis will be fertile, compared with a 30% to 50% fertility rate in uncorrected males.41

Treatment of males with undescended testis should include lifelong follow-up, considering the sequelae of testicular cancer and infertility. Parents need to be aware of the potential issues of infertility and increased risk of testicular cancer. On reaching puberty, boys should be instructed in the necessity of testicular self-examination.

Aging Changes

Like other body systems, the male reproductive system undergoes degenerative changes as a result of the aging process; it becomes less efficient with age. The declining physiologic efficiency of male reproductive function occurs gradually and involves the endocrine, circulatory, and neuromuscular systems.⁴² Compared with the marked physiologic change in aging females, the changes in the aging male are more gradual and less drastic. Gonadal and reproductive failure usually are not related directly to age because a man remains fertile into advanced age; 80- and 90-year-old men have been known to father children.

As the male ages, his reproductive system becomes measurably different in structure and function from that of the younger male. Male sex hormone levels, particularly of testosterone, decrease with age, with the decline starting later on average than in women. The term *andropause* has been used to describe an illdefined collection of symptoms in aging men, typically those older than 50 years, who may have a low androgen level.⁴³

The sex hormones play a part in the structure and function of the reproductive system and other body systems from conception to old age; they affect protein synthesis, salt and water balance, bone growth, and cardiovascular function. Decreasing levels of testosterone affect sexual energy, muscle strength, and the genital tissues. The testes become smaller and lose their firmness. The seminiferous tubules, which produce spermatozoa, thicken and begin a degenerative process that finally inhibits sperm production, resulting in a decrease of viable spermatozoa. The prostate gland enlarges, and its contractions become weaker. The force of ejaculation decreases because of a reduction in the volume and viscosity of the seminal fluid. The seminal vesicle changes little from childhood to puberty. The pubertal increases in the fluid capacity of the gland remain throughout adulthood and decline after the age of 60 years. After age 60 years, the walls of the seminal vesicles thin, the epithelium decreases, and the muscle layer is replaced by connective tissue. Age-related changes in the penis consist of fibrotic changes in the trabeculae in the corpus spongiosum, with progressive sclerotic changes in arteries and veins. Sclerotic changes also follow in the corpora cavernosa, with the condition becoming generalized in 55- to 60-year-old men.

Erectile dysfunction in the elderly male often is directly related to the general physical condition of the person. Diseases that accompany aging can have direct bearing on male reproductive function. Various cardiovascular, respiratory, hormonal, neurologic, and hematologic disorders can be responsible for secondary impotence. For example, vascular disease affects male potency because it may impair blood flow to the pudendal arteries or their tributaries, resulting in loss of blood volume with subsequent poor distention of the vascular spaces of erectile tissue. Other diseases affecting potency include hypertension, diabetes, cardiac disease, and malignancies of the reproductive organs. In addition, certain medications can have an effect on sexual function.

Testosterone and other synthetic androgens may be used in older males with low androgen levels to improve muscle strength and vigor. Preliminary studies of androgen replacement in aging males with low androgen levels show an increase in lean body mass and a decrease in bone turnover. Before testosterone replacement therapy is initiated, all men should be screened for prostate cancer. Testosterone is available as an injectable form that is administered every 2 to 3 weeks or as a transdermal patch or gel. Side effects of replacement therapy may include acne, gynecomastia, and reduced HDL levels. It also may contribute to a worsening of sleep apnea in men who are troubled by this problem.

In summary, childhood disorders of the male reproductive system include congenital disorders in which the urethral opening is located on the ventral surface of the penis (hypospadias) or on the dorsal surface (epispadias). Phimosis is the condition in which the opening of the foreskin is too tight to permit retraction over the glans. Disorders of the scrotum and testes include cryptorchidism or undescended testicles. Early diagnosis and treatment is important because of the risk of malignancy and infertility. Like other body systems, the male reproductive system undergoes changes as a result of the aging process. The changes occur gradually and involve parallel changes in endocrine, circulatory, and neuromuscular function. Testosterone levels decrease, the size and firmness of the testes decrease, sperm production declines, and the prostate gland enlarges. There usually is a decrease in frequency of intercourse, intensity of sensation, speed of attaining erection, and force of ejaculation.

REVIEW QUESTIONS

Describe the structure and function of the male reproductive system and hormones and relate to the process of spermatogenesis.

Relate the development and descent of testes to the pathogenesis of inguinal hernia and cryptorchidism.

Compare the pathophysiology of cancer of the penis, scrotum, and testes.

Compare the cause, appearance, and significance of hydrocele, hematocele, spermatocele, and varicocele.

State the difference between extravaginal and intravaginal testicular torsion.

Compare the pathology and symptoms of acute bacterial prostatitis, chronic bacterial prostatitis, and chronic prostatitis/pelvic pain syndrome.

Describe the urologic manifestations and treatment of benign prostatic hyperplasia.

List the methods used in the diagnosis and treatment of prostatic cancer.

Describe the autonomic nervous system control of erection, emission, and ejaculation and relate to the pathogenesis of erectile dysfunction and priapism.

State the difference between hypospadias and epispadias.

Describe changes in the male reproductive system that occur with aging.

he reproductive function of the female is far more complex than the male. Not only must the female produce germ cells, but she must also nourish the developing embryo and prepare to nurse the infant once childbirth has occurred. This chapter includes a review of the structure and function of the female reproductive system and a discussion of disorders of the internal and external female reproductive organs.

STRUCTURE AND FUNCTION OF THE FEMALE REPRODUCTIVE SYSTEM

The female genitourinary system consists of the external and internal genital organs. The external sex organs of the female are referred to as the genitalia or vulva. The internal genital organs include the vagina, uterus, uterine tubes, and ovaries. These organs are largely located within the pelvic cavity (Fig. 34-1).

External Genitalia

The external genitalia are located at the base of the pelvis in the perineal area. The external genitalia, also called the vulva, include the mons pubis, labia majora, labia minora, clitoris, and

perineal body (Fig. 34-2). Because of their location, the urethra and anus usually are considered in a discussion of the external genitalia.

The *mons pubis* is a rounded skin-covered fat pad located anterior to the symphysis pubis. Running posteriorly from the mons pubis is two elongated hair-covered fatty folds, the *labia majora*. The labia majora are analogous to the male scrotum. The labia majora enclose the *labia minora*, which are smaller than the labia majora and are composed of skin, fat, and some

KEY CONCEPTS

THE FEMALE GENITOURINARY SYSTEM

- The female reproductive system, which consists of the external and internal genitalia, has both sexual and reproductive functions.
- The external genitalia (labia majora, labia minora, clitoris, and vestibular glands) surround the openings of the urethra and vagina. Although the female urinary and genital structures are anatomically separate, their close proximity provides a means for cross-contamination and shared symptomatology.
- The internal genitalia of the female reproductive system are specialized to participate in sexual intercourse (the vagina), to produce and maintain the female egg cells (the ovaries), to transport these cells to the site of fertilization (the fallopian tubes), to provide a favorable environment for development of the offspring (the uterus), and to produce the female sex hormones (the ovaries).

erectile tissue. The *clitoris* is located below the clitoral hood, which is formed by the joining of the two labia minora. The female clitoris is an erectile organ, rich in vascular and nervous supply. Analogous to the male penis, it is a highly sensitive organ that becomes distended during sexual stimulation.

The area between the labia minora is called the *vestibule*. Located in the vestibule are the urethral and vaginal openings and Bartholin's lubricating glands. The urethra is located posterior to the clitoris and usually is closer to the vaginal opening than to the clitoris. The urethral opening is the site of *Skene's glands*, which have a lubricating function. The vaginal orifice, commonly known as the *introitus*, is the opening between the external and internal genitalia.

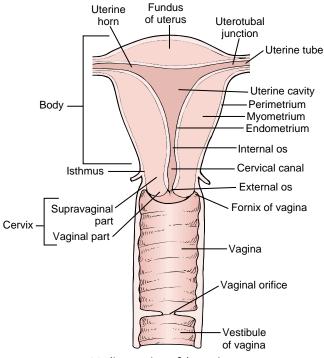

Internal Genitalia

Vagina

The vagina is a fibromuscular tube that connects the external and internal genitalia. The vagina, which is essentially free of sensory nerve fibers, is located behind the urinary bladder and urethra and anterior to the rectum (Fig. 34-3). The uterine cervix projects into the vagina at its upper end, forming recesses called *fornices*. The vagina functions as a route for discharge of menses and other secretions. It also serves as an organ of sexual fulfillment and reproduction.

Cervix, Uterus, and Uterine Tubes

Cervix. The round cervix forms the neck of the uterus. The opening, or os, of the cervix, forms a pathway between the uterus and the vagina. The vaginal opening is called the external os and the uterine opening, the *internal os*. The space between these two openings is the called the *endocervical canal*. Secretions from the columnar epithelium of the endocervix protect the uterus from infection, alter receptivity to sperm, and form a mucoid "plug" during pregnancy. The endocervical canal provides a route for menstrual discharge and entry of sperm.

■ FIGURE 34-3 ■ Median section of the vagina.

604

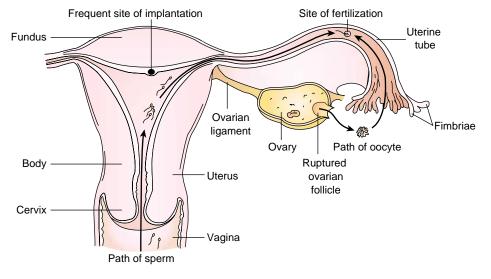

Uterus. The uterus is a thick-walled muscular organ. This pearshaped, hollow structure is located between the bladder and the rectum. The uterus can be divided into three parts: (1) the upper portion above the insertion of the fallopian tubes, called the *fundus*; (2) the central tapering portion, called the *body*; and (3) the inferior constricted part, called the *cervix* (Fig. 34-4).

The wall of the uterus is composed of three layers: the perimetrium, the myometrium, and the endometrium. The *perimetrium* is the outer serous covering that is derived from the abdominal peritoneum. This outer layer merges with the peritoneum that covers the broad ligaments. Anteriorly, the perimetrium is reflected over the bladder wall, forming the vesicouterine pouch; posteriorly, it extends to form the *cul-de-sac*, or *pouch of Douglas* (Fig. 34-3). Because of the proximity of the perimetrium to the urinary bladder, infection of this organ often causes uterine symptoms, particularly during pregnancy.

The middle muscle layer, the *myometrium*, forms the major portion of the uterine wall. It is continuous with the myometrium of the fallopian tubes and the vagina and extends into all the supporting ligaments with the exception of the broad ligaments. The inner fibers of the myometrium run in various directions, giving it an interwoven appearance. Contractions of these muscle fibers help to expel menstrual flow and the products of conception during miscarriage or childbirth.

The endometrium, or inner layer of the uterus, is continuous with the lining of the fallopian tubes and vagina. It consists of two distinct layers, or zones, that are responsive to hormonal stimulation: a basal layer and a functional layer.¹ The basal layer lies adjacent to the myometrium and is not sloughed during menstruation. The functional laver, which can be subdivided into a thin compact superficial layer and a deeper spongiosa layer, arises from the basal layer and undergoes proliferative changes and menstrual sloughing. The endometrial cycle can be divided into three phases: proliferative, secretory, and menstrual. The proliferative, or preovulatory, phase is the period during which the glands and stroma of the superficial layer grow rapidly under the influence of estrogen. The secretory, or postovulatory, phase is the period during which progesterone produces glandular dilation and active mucus secretion and the endometrium becomes highly vascular and edematous. The menstrual phase is the period during which the superficial layer degenerates and sloughs off.

Uterine Tubes. The *fallopian*, or uterine, tubes are slender cylindrical structures attached bilaterally to the uterus and supported by the upper folds of the broad ligament. The end of the fallopian tube nearest the ovary forms a funnel-like opening with fringed fingerlike projections, called *fimbriae*, that pick up the ovum following its release into the peritoneal cavity after ovulation (see Fig. 34-4). The fallopian tubes are formed of smooth muscle and lined with a ciliated, mucus-producing epithelial layer. The beating of the cilia, along with contractile movements of the smooth muscle, propels the nonmobile ovum toward the uterus. Besides providing a passageway for

■ FIGURE 34-4 ■ Schematic drawing of female reproductive organs, showing the path of the oocyte as it moves from the ovary into the fallopian (uterine) tube; the path of sperm is also shown, as is the usual site of fertilization.

ova and sperm, the fallopian tubes provide for drainage of tubal secretions into the uterus.

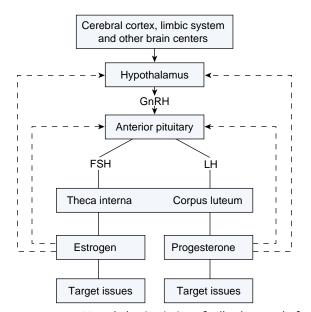

Ovaries

In the adult, the ovaries are flat, almond-shaped structures that are $4 \times 2.5 \times 1.5$ cm in dimension.² They are located on either side of the uterus below the ends of the two fallopian tubes. The ovaries are attached to the posterior surface of the broad ligament and to the uterus by the ovarian ligament (see Fig. 34-4). They are covered with a thin layer of surface epithelium that is continuous with the lining of the peritoneum. The integrity of this covering is periodically broken at the time of ovulation.

The tissues of the adult ovary can be conveniently divided into four compartments, or units: (1) the stroma, or supporting tissue; (2) the interstitial cells; (3) the follicles; and (4) the corpus luteum. The *stroma* is the connective tissue substance of the ovary in which the follicles are distributed. The *interstitial cells* are estrogen-secreting cells that resemble the Leydig's cells, or interstitial cells, of the testes. The *follicles* contain the female germ cells or ovum. The *corpus luteum* (*yellow body*) develops after expulsion of the ovum from the follicle.

Ovarian Hormones

The ovaries produce estrogens, progesterone, and androgens.³ Ovarian hormones are secreted in a cyclic pattern as a result of the interaction between the hypothalamic gonadotrophic releasing hormone (GnRH) and the pituitary gonadotropic hormones, follicle stimulating hormone (FSH), and luteinizing hormone (LH). The secretion of LH and FSH is stimulated by GnRH from the hypothalamus (Fig. 34-5). In addition to LH and FSH, the anterior pituitary secretes a third hormone called *prolactin*. The primary function of prolactin is the stimulation of lactation in the postpartum period. During pregnancy, prolactin and other hormones such as estrogen, progesterone, in-

■ **FIGURE 34-5** ■ Hypothalamic-pituitary feedback control of estrogen and progesterone levels in the female. The *dashed line* represents negative feedback.

sulin, and cortisol contribute to breast development in preparation for lactation.

Estrogens. Estrogens are a family of structurally related female sex hormones synthesized and secreted by cells in the ovaries and, in small amounts, by cells in the adrenal cortex. Androgens can be converted to estrogens peripherally, especially in fat tissue. Three estrogens occur naturally in humans: estrone, estradiol, and estriol. Of these, estradiol is the most biologically potent and the most abundantly secreted product of the ovary. Estrogens are secreted throughout the menstrual cycle. Two peaks occur: one before ovulation and the other in the middle of the luteal phase. Estrogens are transported in the blood bound to specific plasma globulins, inactivated and conjugated in the liver, and then excreted in the bile.

Estrogens are necessary for the normal female physical maturation. In concert with other hormones, estrogens provide for the reproductive processes of ovulation, implantation of the products of conception, pregnancy, parturition, and lactation by stimulating the development and maintaining the growth of the accessory organs. The estrogens stimulate the intrauterine development of the vagina, uterus, and uterine tubes in the embryo. They also stimulate the stromal development and ductal growth of the breasts at puberty, are responsible for the accelerated pubertal skeletal growth phase and for closure of the epiphyses of the long bones, contribute to the growth of axillary and pubic hair, and alter the distribution of body fat to produce the typical female body contours.

Estrogens have a number of important extragenital metabolic effects. They are responsible for maintaining the normal structure of skin and blood vessels in women. Estrogens decrease the rate of bone resorption by antagonizing the effects of calcitonin on bone; for this reason, osteoporosis is a common problem in estrogen-deficient postmenopausal women (see Chapter 43). In the liver, estrogens increase the synthesis of transport proteins for thyroxine, estrogen, testosterone, and other hormones. Estrogens also affect the composition of the plasma lipoproteins. They produce an increase in highdensity lipoproteins (HDLs), a slight reduction in low-density lipoproteins (LDLs), and a reduction in cholesterol levels (see Chapter 15). Estrogens also increase plasma triglyceride levels, and they enhance the coagulability of blood by effecting increased circulating levels of plasminogen and factors II, VII, IX, and X.

The estrogens cause moderate retention of sodium and water. Most women retain sodium and water and gain weight just before menstruation. This occurs because the estrogens facilitate the movement of intravascular fluids into the extracellular spaces, producing edema and increased sodium and water retention by the kidneys because of the decreased plasma volume. The actions of estrogens are summarized in Table 34-1.

Progesterone. Although the word *progesterone* refers to a substance that maintains pregnancy, progesterone is secreted as part of the normal menstrual cycle. The corpus luteum of the ovary secretes large amounts of progesterone after ovulation, and the adrenal cortex secretes small amounts. The hormone circulates in the blood attached to a specific plasma protein. It is metabolized in the liver and conjugated for excretion in the bile.

The local effects of progesterone on reproductive organs include the glandular development of the lobular and alveolar

606 Unit Nine: Alterations in the Male and Female Reproductive Systems

TABLE 34-1 Actions of Estrogens				
General Function	Specific Actions			
Growth and development				
Reproductive organs	Stimulate development of vagina, uterus, and fallopian tubes in utero and of secondary sex characteristics during puberty			
Skeleton	Accelerate growth of long bones and closure of epiphyses at puberty			
Reproductive processes				
Ovulation	Promote growth of ovarian follicles			
Fertilization	Alter the cervical secretions to favor survival and transport of sperm Promote motility of sperm within the fallopian tubes by decreasing mucus viscosity			
Implantation	Promote development of endometrial lining in the event of pregnancy			
Vagina	Proliferate and cornify vaginal mucosa			
Cervix	Increase mucus consistency			
Breasts	Stimulate stromal development and ductal growth			
General metabolic effects				
Bone resorption	Decrease rate of bone resorption			
Plasma proteins	Increase production of thyroid and other binding globulins			
Lipoproteins	Increase high-density and slightly decrease low-density lipoproteins			

tissue of the breasts and the cyclic glandular development of the endometrium. Progesterone also can compete with aldosterone at the level of the renal tubule, causing a decrease in sodium reabsorption, with a resultant increase in secretion of aldosterone by the adrenal cortex (as occurs in pregnancy). Although the mechanism is uncertain, progesterone increases basal body temperature and is responsible for the increase in body temperature that occurs with ovulation. Smooth muscle relaxation under the influence of progesterone plays an important role in maintaining pregnancy by decreasing uterine contractions and is responsible for many of the common discomforts of pregnancy, such as edema, nausea, constipation, flatulence, and headaches. The increased progesterone present during pregnancy and the luteal phase of the menstrual cycle enhances the ventilatory response to carbon dioxide, leading to a measurable change in arterial and alveolar carbon dioxide (PCO₂) levels.

Androgens. The normal female also produces androgens. Approximately 25% of these androgens are secreted from the ovaries, 25% from the adrenal cortex, and 50% from ovarian or adrenal precursors. In the female, androgens contribute to normal hair growth at puberty and may have other important metabolic effects.

Ovarian Follicle Development and Ovulation

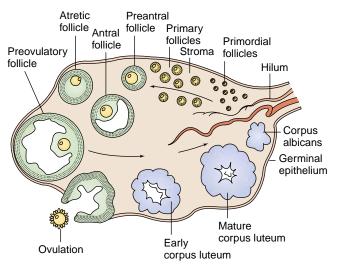

Unlike the male gonads, which produce sperm throughout a man's reproductive life, the female gonads contain a fixed number of ova at birth that diminishes throughout a woman's life. The process of oogenesis begins during the sixth week of fetal life and proceeds to the development of the primary oocytes, which become surrounded by a single layer of granulosa cells. The primary oocytes with their surrounding granulosa cells are referred to as *primordial follicles*. These primitive germ cells provide the 1 to 2 million oocytes that are present in the ovaries at birth. Throughout childhood, the granulosa cells provide nourishment for the ovum and secrete an in-

hibiting factor that keeps the ovum suspended in a primordial state.³ After puberty, when FSH and LH from the anterior pituitary begin to be secreted in sufficient amounts, the entire ovaries, together with some of the follicles within them, begin to grow.

Ovarian Cycle. The monthly series of events associated with the maturation of the ovum is called the ovarian cycle. It consists of two phases: the follicular phase and the luteal phase. The follicular phase, typically days 1 to 14, is the period of follicle growth. The luteal phase, days 14 to 28, is the period of corpus luteum activity. The typical ovarian cycle repeats at intervals of 28 days, with ovulation occurring midcycle. However, cycles as long as 40 days and as short as 21 days are not uncommon.

Follicles at all stages of development can be found in both ovaries, except in menopausal women (Fig. 34-6). Most follicles exist as primary follicles, each of which consists of a round oocyte surrounded by a single layer of flattened, epitheliumderived granulosa cells and a basement membrane. The primary follicles constitute an inactive pool of follicles from which all the ovulating follicles develop.

Under the influence of FSH and LH stimulation, 6 to 12 primary follicles develop into secondary follicles once every ovulatory cycle. During the development of the secondary follicle, the primary oocyte increases in size, and the surrounding granulosa cells proliferate to form a multilayered wall around it. In addition, cells from the surrounding ovarian interstitium align themselves to form a cellular wall called the *theca*. The cells of the theca become differentiated into two layers: an inner theca interna, which lies adjacent to the follicular cells, and an outer theca externa. The cells in the theca interna take on epithelioid characteristics similar to those of the granulosa cells and develop the ability to secrete additional sex hormones (estrogen and progesterone). The theca externa develops into a highly vascular connective tissue capsule that becomes the capsule for the developing follicle.

■ FIGURE 34-6 ■ Schematic diagram of an ovary, showing the sequence of events in the origin, growth, and rupture of an ovarian follicle and the formation and retrogression of a corpus luteum. The atretic follicles are those that show signs of degeneration and death.

As the follicle enlarges, a single large cavity, or *antrum*, is formed, and a portion of the granulosa cells and the oocytes are displaced to one side of the follicle by the fluid that accumulates. The secondary oocyte remains surrounded by a crown of granulosa cells, the *corona radiata*. As the granulosa cells continue to divide and the follicle grows, the thecal and granulosa cells cooperate to secrete a follicular fluid that contains a high concentration of estrogen. Selection of a dominant follicle occurs with the conversion to an estrogen microenvironment. The dominant follicle accumulates a greater mass of granulosa cells, and the theca becomes richly vascular, giving the follicle a hyperemic appearance. The lesser follicles, although continuing to produce some estrogen, atrophy or become atretic.

High levels of estrogen also exert a negative feedback effect on FSH, inhibiting further follicular development and causing an increase in LH levels. This represents the follicular stage of the menstrual cycle. As estrogen suppresses FSH, the actions of LH predominate, and the mature follicle bursts; the oocyte, along with the corona radiata, is ejected from the follicle. The ovum normally is then picked up and transported through the fallopian tube toward the uterus.

After ovulation, the follicle collapses, and the luteal stage of the menstrual cycle begins. The granulosa cells are invaded by blood vessels and yellow lipochrome-bearing cells from the theca layer. A rapid accumulation of blood and fluid forms a mass called the corpus luteum. Leakage of this blood onto the peritoneal surface that surrounds the ovary is thought to contribute to the *mittelschmerz* ("middle [or intermenstrual] pain") of ovulation. During the luteal stage, progesterone is secreted from the corpus luteum. If fertilization does not take place, the corpus luteum atrophies and is replaced by white scar tissue called the *corpus albicans*; the hormonal support of the endometrium is withdrawn, and menstruation occurs. In the event of fertilization, the corpus luteum remains functional for 3 months and provides hormonal support for pregnancy until the placenta is fully functional.

In summary, the genitourinary system as a whole serves sexual and reproductive functions throughout a woman's life. The female reproductive system consists of external and internal genitalia. The internal genitalia consist of the vagina, uterus, uterine tubes, and paired ovaries. The uterus is a thickwalled, muscular organ. The wall of the uterus is composed of three layers: the outer perimetrium; the myometrium or muscle layer, which is continuous with the myometrium of the fallopian tubes and the vagina; and the inner lining or endometrium, which is continuous with the lining of the fallopian tubes and vagina.

The gonads, or ovaries, which are internal in the female (unlike the testes in the male), have the dual function of storing the female germ cells, or ova, and producing the female sex hormones. Through the regulation and release of sex hormones, the ovaries influence the development of secondary sexual characteristics, regulation of menstrual cycles, maintenance of pregnancy, and advent of menopause.

DISORDERS OF THE FEMALE REPRODUCTIVE ORGANS

Disorders of the female genitourinary system have widespread effects on physical and psychological function, affecting sexuality and reproductive function. The reproductive organs are located close to other pelvic structures, particularly those of the urinary system, and disorders of the reproductive system may affect urinary function. This section of the chapter focuses on infections and benign and malignant disorders of the external and internal genitalia.

Disorders of the External Genitalia

Bartholin Gland Cyst and Abscess

A Bartholin gland cyst is a fluid-filled sac that results from the occlusion of the duct system of the gland. When the cyst becomes infected, the contents become purulent; if the infection goes untreated, an abscess can result. Most commonly cyst and abscess formation follows a bacterial, chlamydial, or gonococcal infection. Cysts can attain the size of an orange and frequently recur. Abscesses can be extremely tender and painful. Treatment of symptomatic cysts consists of the administration of appropriate antibiotics, local application of moist heat, and incision and drainage.

Non-neoplastic Epithelial Disorders

The term non-neoplastic epithelial disorders refers to nonmalignant atrophic and hyperplastic changes of the vulvar skin and mucosa. The condition, commonly referred to as leukoplakia, presents as white lesions of the vulva. Itching is the most common symptom, and dyspareunia (painful intercourse) is common.⁴

There are two forms of non-neoplastic epithelial lesions: lichen sclerosus and lichen simplex chronicus. Lichen sclerosus patches are hypopigmented, parchment-thin, and atrophic. Such lesions occur in all age groups but are most common in postmenopausal women. They may also occur on other areas of the skin. Although slowly progressive in its development, lichen sclerosus is not premalignant. Lichen simple chronicus *lesions* are thick, gray-white plaques. The thickened epithelium displays a marked increase in superficial keratin, which imparts a white appearance to the vulva. Because squamous carcinoma may also appear as white plaques, biopsy is required to distinguish benign from malignant lesions.

Vulvodynia

Vulvodynia is a syndrome of unexplained vulvar pain, also referred to as *vulvar pain syndrome* or *burning vulva syndrome*. It is characterized by burning, stinging, irritation, and rawness. Several forms or subsets of vulvodynia have been identified. It may occur as localized tenderness near the vaginal opening at the onset of intercourse or tampon insertion (*i.e.*, insertional vulvodynia), as a sensitivity to tight-fitting pants, bicycling, or prolonged sitting (*vulvar vestibulitis*), or as episodic flares that occur only before menses or after coitus (*cyclic vulvodynia*). Symptoms that are in general noncyclic and pruritic and develop progressively during the perimenopausal or postmenopausal years are characteristic of *vulvar dermatoses*.

Vulvar dysesthesia, also known as idiopathic or essential vulvodynia, involves severe, constant, widespread burning that interferes with daily activities.⁵ Although the cause is unknown, the quality of pain with vulvar dysesthesia resembles reflex sympathetic dystrophy (see Chapter 39). One of the proposed causes is pudendal neuralgia or pain along the pudendal nerve.

Possible causes for other forms of vulvodynia include candidal hypersensitivity related to chronic recurrent yeast infections; chemical irritation or drug effects, especially prolonged use of topical steroid creams; and dermatoses such as lichen sclerosus. Herpes simplex virus may be related to episodic vulvodynia.

Treatment of vulvodynia is aimed at symptom relief and elimination of suspected underlying problems. Careful history taking and physical assessment are essential for differential diagnosis and treatment. Psychosocial support often is needed because this condition can cause strain in sexual, family, and work relationships. Severe forms of the disorder often need to be managed from a multidimensional, chronic pain perspective.⁵

Premalignant and Malignant Neoplasms

Carcinoma of the vulva accounts for approximately 3% of all cancers of the female genitourinary system, occurring most often in women who are 60 years of age or older.⁴ Approximately 90% of vulvar malignancies are squamous cell carcinomas; the remainder are adenocarcinomas, melanomas, and basal cell carcinomas.

Vulvar intraepithelial neoplasia (VIN), which is a precursor lesion of squamous cell carcinoma, represents a spectrum of neoplastic changes that range from minimal cellular atypia to invasive cancer. There has been a significant increase in frequency of one form of VIN among younger women (40 to 60 years of age) during the past several decades. The increase is more common in women who smoke and those with human papillomavirus (HPV) infections, particularly HPV type 16 (see Chapter 35).⁴ A second form of VIN, which is seen more often in older women, often is preceded by chronic vulvar irritation or lichen sclerosus.⁶ This form of VIN does not appear to be associated with HPV.

The initial lesion of squamous cell vulvar carcinoma may appear as an inconspicuous thickening of the skin, a small raised area or lump, or an ulceration that fails to heal. It may be single or multiple and vary in color from white to velvety red or black. The lesions may resemble eczema or dermatitis and may produce few symptoms, other than pruritus, local discomfort, and exudation. A recurrent, persistent, pruritic vulvitis may be the only complaint. The symptoms frequently are treated with various home remedies before medical treatment is sought. The lesion often becomes secondarily infected, and this causes pain and discomfort. The malignant lesion gradually spreads superficially or as a deep furrow involving all of one labial side. Because there are many lymph channels around the vulva, the cancer metastasizes freely to the regional lymph nodes. The most common extension is to the superficial inguinal, deep femoral, and external iliac lymph nodes.

Early diagnosis is important in the treatment of vulvar carcinoma. Outlook for survival diminishes with increasing tumor size and nodal involvement. Treatment is primarily wide surgical excision of the lesion for noninvasive cancer and vulvectomy with node resection for invasive cancer.

Disorders of the Vagina

The normal vaginal ecology depends on the delicate balance of hormones and bacterial flora. The vagina is lined with mucus-secreting stratified squamous epithelial cells. The epithelial cells of the vagina, like other tissues of the reproductive system, respond to changing levels of the ovarian sex hormones. Estrogen stimulates the proliferation and maturation of the vaginal mucosa; this results in a thickening of the vaginal mucosa and an increased glycogen content of the epithelial cells.

Vaginal tissue usually is moist, with a pH maintained within the bacteriostatic range of 3.8 to 4.2. Döderlein's bacilli, part of the normal vaginal flora, metabolize glycogen, and in the process produce the lactic acid that normally maintains the vaginal pH below 4.5. The vaginal ecology can be disrupted at many levels, rendering it susceptible to infection. Pregnancy and the use of oral contraceptive agents increase the amount of estrogen in the system. Diabetes or a prediabetic state may increase the glycogen content of the cells. The use of systemic antibiotics may decrease the number of lactobacilli in the vagina. Decreased estrogen stimulation after menopause causes the vaginal mucosa to become thin and dry, often resulting in dyspareunia (*i.e.*, painful intercourse), atrophic vaginitis, and occasionally in vaginal bleeding.

Vaginitis

Vaginitis is an inflammatory condition of the vagina. It is characterized by vaginal discharge and burning, itching, redness, and swelling of vaginal tissues. Pain often occurs with urination and sexual intercourse. Vaginitis may be caused by chemical irritants, foreign bodies, and infectious agents. The causes of vaginitis differ in various age groups. In premenarchal girls, most vaginal infections have nonspecific causes, such as poor hygiene, intestinal parasites, or the presence of foreign bodies. *C. albicans, Trichomonas vaginalis,* and bacterial vaginosis are the most common causes of vaginitis in the childbearing years, and some of these organisms can be transmitted sexually (see Chapter 35).^{7,8} Atrophic vaginitis, which is caused by a decrease in estrogen levels, is the most common form in postmenopausal women or after removal of the ovaries. Estrogen deficiency results in a lack of regenerative growth of the vaginal epithelium, rendering these tissues more susceptible to infection and irritation.⁷ Döderlein's bacilli disappear, and the vaginal secretions become less acidic.

Every woman has a normal vaginal discharge during the menstrual cycle, but it should not cause burning or itching or have an unpleasant odor. These symptoms suggest inflammation or infection. Because these symptoms are common to the different types of vaginitis, precise identification of the organism is essential for proper treatment. A careful history should include information about systemic disease conditions, the use of drugs such as antibiotics that foster the growth of yeast, dietary habits, stress, and other factors that alter the resistance of vaginal tissue to infections. A physical examination usually is done to evaluate the nature of the discharge and its effects on the genital structures. Treatment is directed at the cause of the disorder.

Cancer of the Vagina

Primary cancers of the vagina are extremely rare. They account for approximately 3% of all cancers of the female reproductive system. Approximately 85% to 90% of primary vaginal cancers are squamous cell carcinomas.⁹ Adenocarcinoma of the vagina is a rare tumor that is seen almost exclusively in women exposed in utero to diethylstilbestrol (DES). DES is a nonsteroidal synthetic estrogen that was commonly prescribed between 1940 and 1971 to prevent miscarriage. Fortunately, less than 0.14% of women exposed to DES actually develop adenocarcinoma.⁴ Vaginal cancers may also result from local extension of cervical cancer, from local irritation such as occurs with prolonged use of a pessary, or from exposure to sexually transmitted herpesvirus or HPV.

Like vulvar carcinoma, carcinoma of the vagina is largely a disease of older women. Approximately half are women 60 years of age or older at the time of diagnosis. The most common symptom of vaginal carcinoma is abnormal bleeding. Twenty percent of women are asymptomatic, with the cancer being discovered during a routine pelvic examination. The anatomic proximity of the vagina to other pelvic structures (*e.g.*, urethra, bladder, rectum) permits early spread to these areas. Pelvic pain, dysuria, constipation, and vaginal discharge can be associated symptoms.

Vaginal cancer is often detected by vaginal cytology (Papanicolaou's test [Pap smear]) or examination of the vagina during a pelvic exam. It is recommended that women who have been exposed to DES have an initial colposcopic examination to identify areas of abnormal vaginal epithelium, followed by yearly Pap smears. It is also important for women who have had a hysterectomy to continue to have vaginal Pap smears every 3 to 5 years for early detection of vaginal cancer. Diagnosis of vaginal cancer requires biopsy of suspect lesions or areas.

Treatment of vaginal cancer must take into consideration the type of cancer; the size, location, and spread of the lesion; and the woman's age. Local excision, laser vaporization, or a loop electrode excision procedure (LEEP) can be considered with stage 0 squamous cell cancer. Radical surgery (a total hysterectomy, pelvic lymph node dissection, partial vaginectomy) and radiation therapy are both curative with more advanced cancers.

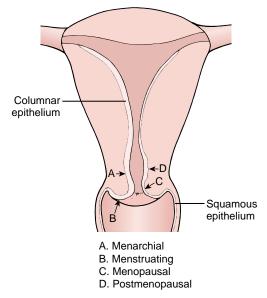

Disorders of the Uterine Cervix

The cervix is composed of two distinct types of tissue. The exocervix, or visible portion, is covered with stratified squamous epithelium, which also lines the vagina. The endocervical canal is lined with columnar epithelium (see Chapter 1). The junction of these two tissue types (*i.e.*, squamocolumnar junction) appears at various locations on the cervix at different points in a woman's life (Fig. 34-7). During periods of high estrogen production, particularly fetal existence, menarche, and the first pregnancy, the cervix everts or turns outward, exposing the columnar epithelium to the vaginal environment. The combination of estrogen and low vaginal pH leads to a gradual transformation from columnar to squamous epithelium-a process called metaplasia (see Chapter 2). The dynamic area of change where metaplasia occurs is called the transformation zone. The transformation zone is a critical area for the development of cervical cancer. During metaplasia, the newly developed squamous epithelial cells are vulnerable to the development of dysplastic changes.

The process of transformation is increased by trauma and infections occurring during the reproductive years.⁴ As the squamous epithelium expands and obliterates the surface columnar papillae, it covers and obstructs crypt openings, with trapping of mucus in the deeper crypts (glands) to form retention cysts, called *nabothian cysts*. These are benign cysts that require no treatment unless they become so numerous that they cause cervical enlargement. The nabothian cyst farthest away from the external cervical os indicates the outer aspect of the transformation zone.

Cervicitis and Cervical Polyps

Cervicitis is an acute or chronic inflammation of the cervix. Acute cervicitis may result from the direct infection of the cervix or may be secondary to a vaginal or uterine infection. It

■ FIGURE 34-7 ■ Location of squamocolumnar junction (transformation zone) in menarchial, menstruating, menopausal, and postmenopausal women.

may be caused by a variety of infective agents, including *C. albicans, T. vaginalis, Neisseria gonorrhoeae, Gardnerella vaginalis, Chlamydia trachomatis, Ureaplasma urealyticum,* and herpes simplex virus. Chronic cervicitis represents a low-grade inflammatory process. It is common in parous women and may be a sequela to minute lacerations that occur during childbirth, instrumentation, or other trauma. The organisms usually are of a nonspecific type, often staphylococcal, streptococcal, or coliform bacteria.

With acute cervicitis, the cervix becomes reddened and edematous. Irritation from the infection results in copious mucopurulent drainage and leukorrhea. The symptoms of chronic cervicitis are less well defined: the cervix may be ulcerated or normal in appearance; it may contain nabothian cysts; the cervical os may be distorted by old lacerations or everted to expose areas of columnar epithelium; and a mucopurulent drainage may be present.

Untreated cervicitis may extend to include the development of pelvic cellulitis, low back pain, painful intercourse, cervical stenosis, dysmenorrhea, and further infection of the uterus or fallopian tubes. Depending on the causative agent, acute cervicitis is treated with appropriate antibiotic therapy. Diagnosis of chronic cervicitis is based on vaginal examination, colposcopy, cytologic (Pap) smears, and occasionally on biopsy to exclude malignant changes. The treatment usually involves cryosurgery or cauterization, which causes the tissues to slough and leads to eradication of the infection.

Polyps are the most common lesions of the cervix. They can be found in women of all ages, but their incidence is higher during the reproductive years. Polyps are soft, velvety red lesions; they usually are pedunculated and often are found protruding through the cervical os. They usually develop as a result of inflammatory hyperplasia of the endocervical mucosa. Polyps typically are asymptomatic but may have associated postcoital bleeding. Most are benign, but they should be removed and examined by a pathologist to exclude malignant change.

Cancer of the Cervix

Cervical cancer is readily detected and, if detected early, is the most easily cured of all the cancers of the female reproductive system. Cervical cancer was the most common cause of cancer deaths in women in the United States in the 1930s.¹¹ However, with the introduction of the Papanicolaou (Pap) smear, early detection and treatment of preinvasive disease became possible. Incidence and mortality rates for cervical cancer in the United States declined dramatically during the remainder of the 20th century. In 2001, there were an estimated 12,900 new cases and 4,400 deaths of cervical cancer.¹¹ By comparison, there were four times as many new cases of cervical carcinoma

in situ (*i.e.*, precancerous lesion) diagnosed, indicating that a large number of potentially invasive cancers are cured by early detection and effective treatment. However, worldwide the incidence of and mortality associated with cervical cancer are second only to breast cancer, and in parts of the developing world, cervical cancer is the major cause of death in women of reproductive age.¹¹

Carcinoma of the cervix is often considered a sexually transmitted disease. A preponderance of evidence suggests a causal link between HPV infection and uterine cancer. Certain strains of HPV have been identified in invasive carcinoma of the cervix, whereas others are associated more often with dysplasia or carcinoma in situ. The strongest link is with HPV types 16, 18, 31, and 33 (see Chapter 35).^{2,7} Because these viruses are spread by sexual contact, their association with cervical cancer provides a tempting hypothesis to explain the relation between sexual practices and cervical cancer. Other factors such as smoking, nutrition, and coexisting sexual partners may play a contributing role in determining whether a woman with HPV infection develops cervical cancer. The recent development of an HPV type 16 vaccine offers hope for the future prevention of cervical cancer.¹²

Precursor Lesions. One of the most important advances in the early diagnosis and treatment of cancer of the cervix was made possible by the observation that this cancer arises from precursor lesions, which begin with the development of atypical (i.e., dysplasia) cervical cells. Atypical cells differ from normal cervical squamous epithelium. There are changes in the nuclear and cytoplasmic parts of the cell and more variation in cell size and shape (*i.e.*, dysplasia). These atypical cells gradually progress to carcinoma in situ, which is localized to the epithelial layer, to invasive cancer of the cervix. Carcinoma in situ is localized to the epithelial layer, whereas invasive cancer of the cervix spreads to deeper layers. A system of grading devised to describe the dysplastic changes of cancer precursors uses the term cervical intraepithelial neoplasia (CIN).^{2,7} The CIN system uses the thickness of the epithelial layer involvement as a means of grading the dysplastic changes (see Table 34-2).

The Pap Smear. There are no specific signs or symptoms of cervical dysplasia or cancer in situ. A presumptive diagnosis is made by Pap smear studies of an asymptomatic population with no visible cervical changes. The purpose of the Pap smear (see Chapter 5) is to detect the presence of abnormal cells on the surface of the cervix or in the endocervix. This test detects precancerous and cancerous lesions. Although the American Cancer Society has suggested that the Pap smear need not be done annually if there have been three negative tests in successions.

TABLE 34-2	Cervical Intraepithelial Neoplasia Grading System		
Grade		Extent of Involvement	Differentiation of Lesion
CIN I (mild dyspla CIN II (moderate o CIN III (severe dys carcinoma in sit	dysplasia) plasia or	Initial one third of epithelial layer Initial two thirds of epithelial layer Full-thickness involvement	Well differentiated Less well differentiated Undifferentiated

(Data from Rubin E., Farber J.L. [1999]. Pathology [3rd ed., pp. 982–983]. Philadelphia: Lippincott Williams & Wilkins)

sion, many clinicians maintain that performing an annual test is the safest course to follow. If the woman has risk factors, such as previous HPV infection, DES exposure in utero, or a strong family history of cervical cancer, more frequent Pap smears may be recommended.

It has been estimated that approximately 15% to 25% of women with intraepithelial lesions have normal Pap smear results.¹¹ New techniques of specimen collection, slide preparation and processing, and computer-assisted evaluation of Pap smears are being evaluated and offer the hope of improved accuracy in the diagnosis of precancerous cervical changes.

Squamous Cell Cervical Carcinoma. The majority of cervical cancers are squamous cell carcinomas. Cancers of the cervix have a long latent period; untreated dysplasia or CIN gradually progresses to carcinoma in situ, which may remain static for 7 to 10 years before it becomes invasive. After the preinvasive period, growth may be rapid, and survival rates decline significantly, depending on the extent of disease at the time of diagnosis.¹³

Diagnosis of cervical cancer requires pathologic confirmation. Although the Pap smear has been shown to be a costeffective cancer prevention method, it remains a screening method, not a diagnostic method. Pap smear results demonstrating squamous intraepithelial lesions often require further evaluation by colposcopy. This is a vaginal examination that is done using a colposcope, an instrument that affords a well-lit and magnified stereoscopic view of the cervix. A biopsy sample may be obtained from suspect areas and examined microscopically. A diagnostic cone biopsy, which involves the removal of a cone-shaped wedge of cervix, may be indicated when a lesion is partly or completely beyond colposcopic view.

KEY CONCEPTS

GYNECOLOGIC CANCERS

- Certain types of sexually transmitted human papillomaviruses are risk factors for cervical intraepithelial neoplasia, which can be a precursor lesion of invasive carcinoma.
- Endometrial cancers, which are seen most frequently in women 55 to 65 years of age, are strongly associated with conditions that produce excessive estrogen stimulation and endometrial hyperplasia.
- Ovarian cancer is the second most common female cancer and the most lethal because there are few early signs and no good screening tests. The most significant risk factors for ovarian cancers are the length of time that a woman's ovarian cycles are not suppressed by pregnancy, lactation, or oral contraceptive use, and family history.
- Breast cancer is the most common cancer in women and the second most common cause of cancer death in women. Risk factors include age, family history, and hormonal influences.

Early treatment of cervical cancer involves removal of the lesion by one of various techniques. Biopsy or local cautery may be therapeutic in and of itself. Electrocautery, cryosurgery, or carbon dioxide laser therapy may be used to treat moderate to severe dysplasia that is limited to the exocervix. Invasive cancer is treated with radiation therapy, surgery, or both. External beam irradiation and intracavitary cesium irradiation (*i.e.*, insertion of a closed metal cylinder containing cesium) can be used in the treatment of cervical cancer. Surgery can include extended hysterectomy (*i.e.*, removal of the uterus, fallopian tubes, ovaries, and upper portion of the vagina) without pelvic lymph node dissection, radical hysterectomy with pelvic lymph node dissection, or pelvic exenteration (*i.e.*, removal of all pelvic organs, including the bladder, rectum, vulva, and vagina).

Disorders of the Uterus

Infectious Disorders of the Uterus and Pelvic Structures

The uterus and pelvic structures are subject to infections by a number of agents, including *N. gonorrhoeae* and *C. trachomatis,* as well as endogenous microorganisms such as anaerobes, *Haemophilus influenzae*, enteric gram-negative rods, and *Streptococci.* Tuberculosis salpingitis is rare in the United States but more common in developing countries.

Endometritis. Inflammation or infection of the endometrium is an ill-defined entity that produces variable symptoms. Endometritis can occur as a postpartum or postabortal infection, with gonococcal or chlamydial salpingitis, or after instrumentation or surgery, or can be associated with an intrauterine device.¹² Abnormal vaginal bleeding, mild to severe uterine tenderness, fever, malaise, and foul-smelling discharge have been associated with endometritis, but the clinical picture is variable. Treatment involves oral or intravenous antibiotic therapy, depending on the severity of the condition.

Pelvic Inflammatory Disease. Pelvic inflammatory disease (PID) is an inflammation of the upper reproductive tract that involves the uterus (endometritis), fallopian tubes (salpingitis), or ovaries (oophoritis). Most women with acute salpingitis have *N. gonorrhoeae* or *C. trachomatis* identified in the reproductive tract. PID is a polymicrobial infection, and the cause varies by geographic location and population.

The organisms ascend through the endocervical canal to the endometrial cavity and then to the tubes and ovaries. The endocervical canal is slightly dilated during menstruation, allowing bacteria to gain entrance to the uterus and other pelvic structures. After entering the upper reproductive tract, the organisms multiply rapidly in the favorable environment of the sloughing endometrium and ascend to the fallopian tube. Factors that predispose women to the development of PID include an age of 16 to 24 years, unmarried status, nulliparity, history of multiple sexual partners, and previous history of PID.

The symptoms of PID include lower abdominal pain, which may start just after a menstrual period; purulent cervical discharge; pelvic tenderness; and an exquisitely painful cervix. Fever (>101°F), increased erythrocyte sedimentation rate, and an elevated white blood cell count (>10,000 cells/mL)

commonly are seen, even though the woman may not appear acutely ill.¹³

Diagnosis is based on the presence of lower abdominal pain and pelvic or cervical tenderness. A newer test involves measurement of C-reactive protein in the blood. Elevated C-reactive protein levels equate with inflammation.¹³ Endocervical cultures may be done to document the presence of *N. gonorrhoeae* or *C. trachomatis.* Transvaginal ultrasonography or imaging techniques may be used. Laparoscopy is often used to confirm a diagnosis of PID.

Treatment is aimed at preventing complications, which can include pelvic adhesions, infertility, ectopic pregnancy, chronic abdominal pain, and tubo-ovarian abscesses. It may involve hospitalization with intravenous administration of antibiotics. If the condition is diagnosed early, outpatient antibiotic therapy may be sufficient.

Endometriosis

Endometriosis is the condition in which functional endometrial tissue is found in ectopic sites outside the uterus. The site may be the ovaries, broad ligaments, pouch of Douglas (cul-de-sac), pelvis, vagina, vulva, perineum, or intestines (Fig. 34-8). Rarely, endometrial implants have been found in the nostrils, umbilicus, lungs, and limbs.

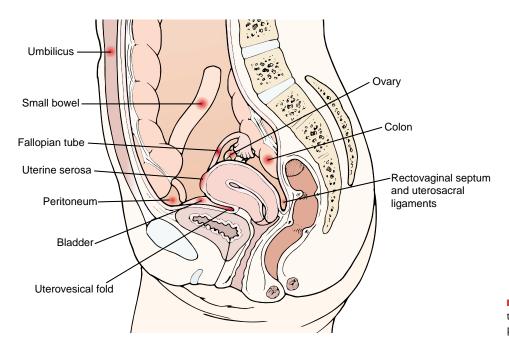

The cause of endometriosis is unknown. There appears to have been an increase in its incidence in the developed Western countries during the past four to five decades. Approximately 10% to 15% of premenopausal women have some degree of endometriosis. The incidence may be higher in women with infertility (25% to 40%)¹⁴ or women younger than 20 years of age with chronic pelvic pain (45% to 70%).¹⁵ It is more common in women who have postponed childbearing. Risk factors for endometriosis may include early menarche; regular periods with shorter cycles (<27 days), longer duration (>7 days), or heavier flow; increased menstrual pain; and other first-degree relatives with the condition.

Several theories attempt to account for endometriosis. One theory suggests that menstrual blood containing fragments of endometrium is forced upward through the fallopian tubes into the peritoneal cavity. Retrograde menstruation is not an uncommon phenomenon, and it is unknown why endometrial cells implant and grow in some women but not in others. Another proposal is that dormant, immature cellular elements from embryonic development persist into adult life and develop into ectopic endometrial tissue. Another theory suggests that the endometrial tissue may metastasize through the lymphatics or vascular system. Altered cellular immunity and genetic components also have been studied as contributing factors to the development of endometriosis.¹⁴

The gross pathologic changes that occur in endometriosis differ with location and duration. In the ovary, the endometrial tissue may form cysts (*i.e.*, endometriomas filled with old blood that resembles chocolate syrup [chocolate cysts]). Rupture of these cysts can cause peritonitis and adhesions. Elsewhere in the pelvis, the tissue may take the form of small hemorrhagic lesions, some of which may be surrounded by scar tissue. These ectopic implants respond to hormonal stimulation in the same way normal endometrium does, becoming proliferative, then secretory, and finally undergoing menstrual breakdown. Bleeding into the surrounding structures can cause pain and the development of significant pelvic adhesions. Ex-

Endometriosis may be difficult to diagnose because its symptoms mimic those of other pelvic disorders, and the severity of the symptoms does not always reflect the extent of the disease. The classic triad of dysmenorrhea, dyspareunia, and infertility strongly suggests endometriosis. Accurate diagnosis can be accomplished only through laparoscopy. This minimally invasive surgery allows direct visualization of pelvic organs to determine the presence and extent of endometrial lesions.

Treatment goals for endometriosis are pain management or restoration of fertility. Treatment modalities fall into three cat-

■ FIGURE 34-8 ■ Common locations of endometriosis within the pelvis and abdomen.

egories: pain relief, endometrial suppression, and surgery. In young women, who have no fertility concerns, simple observation and antiprostaglandin analgesics (*i.e.*, nonsteroidal anti-inflammatory drugs [NSAIDs]) may be sufficient treatment. The use of hormones to induce physiologic amenorrhea is based on the observation that pregnancy affords temporary relief by inducing atrophy of the endometrial tissue.

Surgery is the most definitive therapy for many women with endometriosis. With the advent of lasers, in-depth treatment of endometriosis or pelvic adhesions can be accomplished by means of laparoscopy.¹⁶ Radical treatment involves total hysterectomy and bilateral salpingo-oophorectomy (*i.e.*, removal of the fallopian tubes and ovaries) when the symptoms are unbearable or the woman's childbearing is completed.

Treatment offers relief but not cure. Recurrence of endometriosis is not uncommon, regardless of the treatment (except for radical surgery). Pregnancy may delay, but does not preclude, recurrence.

Adenomyosis

Adenomyosis is the condition in which endometrial glands and stroma are found within the myometrium, interspersed between the smooth muscle fibers.⁴ It is thought that events associated with repeated pregnancies, deliveries, and uterine involution may cause the endometrium to be displaced throughout the myometrium. In contrast to endometriosis, which usually is a problem of young, infertile women, adenomyosis typically is found in multiparous women in their late fourth or fifth decade. Up to 70% of these women have a retrospective history of painful, heavy periods.¹⁷

The diagnosis of adenomyosis often occurs as an incidental finding in a uterus removed for symptoms indicative of myoma or hyperplasia. Adenomyosis resolves with menopause. Conservative therapy using oral contraceptives or gonadotropinreleasing hormone (GnRH) agonists is the first choice for treatment. Hysterectomy (with preservation of the ovaries in premenopausal women) is considered when this approach fails.¹⁷

Endometrial Cancer

Endometrial cancer is the most common invasive cancer of the female reproductive tract. It accounts for 7% of all invasive cancers in women, excluding skin cancers.² There is now an estimated 34,000 new diagnoses of endometrial cancer a year, compared with 13,000 new invasive cervical cancers.²

Endometrial cancer occurs more frequently in older women (peak ages of 55 to 65 years) and is uncommon in women younger than 40 years of age. A major risk factor for endometrial cancer is prolonged estrogenic stimulation with excessive growth (*i.e.*, hyperplasia) of the endometrium. Obesity, anovulatory cycles, conditions that alter estrogen metabolism, estrogen-secreting neoplasms, and unopposed estrogen therapy all increase the risk of endometrial cancer.^{20,21} Estrogens are synthesized in body fats from adrenal and ovarian androgen precursors; endometrial hyperplasia and endometrial cancer appear to be related to obesity. The degree of risk correlates with body weight, with the risk increasing 10-fold for women who are more than 50 pounds overweight.7 Ovulatory dysfunction that causes infertility at any age or occurs with declining ovarian function in perimenopausal women also can result in unopposed estrogen and increase the risk of endometrial cancer. Diabetes mellitus, hypertension, and polycystic ovary syndrome are conditions that alter estrogen metabolism and elevate estrogen levels.

Endometrial cancer risk also is increased in women with estrogen-secreting granulosa cell tumors and in those receiving unopposed estrogen therapy. It is the presence of progesterone in the second half of the normal menstrual cycle that matures the endometrium and the withdrawal of progesterone that ultimately results in endometrial sloughing. Long-term unopposed estrogen exposure without periodic addition of progesterone allows for continued endometrial growth and the development of hyperplasia, with or without the presence of atypical cells. A sharp increase in endometrial cancer was seen during the 1970s among middle-aged women who had received unopposed estrogen therapy (i.e., estrogen therapy without progesterone) for menopausal symptoms. It was later determined that it was not the estrogen exposure that increased the risk of cancer, but administration of estrogen without administration of progesterone. Tamoxifen, a drug that blocks estrogen receptor sites and is used in the treatment of breast cancer, exerts a weak estrogenic effect on the endometrium and represents another exogenous risk factor for endometrial cancer.

A small subset of women in whom endometrial cancer develops do not exhibit increased estrogen levels or pre-existing hyperplasia. These women usually acquire the disease at an older age. These tumors arise from clones of cancer-initiated mutant cells and are more poorly differentiated. This type of endometrial cancer usually is associated with a poorer prognosis than is the endometrial cancer that is associated with prolonged estrogen stimulation and endometrial hyperplasia.²¹

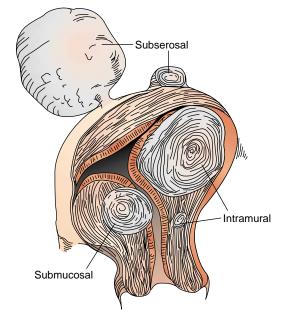

The major symptom of endometrial hyperplasia or overt endometrial cancer is abnormal, painless bleeding. In menstruating women, this takes the form of bleeding between periods or excessive, prolonged menstrual flow. In postmenopausal women, any bleeding is abnormal and warrants investigation. Abnormal bleeding is an early warning sign of the disease, and because endometrial cancer tends to be slow growing in its early stages, the chances of cure are good if prompt medical care is sought. Later signs of uterine cancer may include cramping, pelvic discomfort, postcoital bleeding, lower abdominal pressure, and enlarged lymph nodes.

Although the Pap smear can identify a small percentage of endometrial cancers, it is not a good screening test for the tumor. Endometrial biopsy is far more accurate. Dilatation and curettage (D & C), which consists of dilating the cervix and scraping the uterine cavity, is the definitive procedure for diagnosis because it provides a more thorough evaluation. Transvaginal ultrasonography may be used to determine the endometrial thickness as an indicator of hypertrophy and possible neoplastic change.

The prognosis for endometrial cancer depends on the clinical stage of the disease when it is discovered and its histologic grade and type. Surgery and radiation therapy are the most successful methods of treatment for endometrial cancer. With early diagnosis and treatment, the 5-year survival rate is approximately 90%. This decreases to 20% for more advanced stages of the disease.²

Leiomyomas

Leiomyomas are benign neoplasms of smooth muscle origin. They also are known as *myomas* and sometimes are called *fibroids*. These are the most common form of pelvic tumor and are believed to occur in one of every four or five women older than 35 years of age. They are seen more often and their rate of growth is more rapid in black women than in white women. Leiomyomas usually develop in the corpus of the uterus; they may be submucosal, subserosal, or intramural (Fig. 34-9). Intramural fibroids are embedded in the myometrium. They are the most common type of fibroid and present as a symmetric enlargement of the nonpregnant uterus. Subserosal tumors are located beneath the perimetrium of the uterus. These tumors are recognized as irregular projections on the uterine surface; they may become pedunculated, displacing or impinging on other genitourinary structures and causing hydroureter or bladder problems. Submucosal fibroids displace endometrial tissue and are more likely to cause bleeding, necrosis, and infection than either of the other types.

В

■ FIGURE 34-9 (A) Submucosal, intramural, and subserosal leiomyomas. (A redrawn from Green T.H. [1977]. *Gynecology: Essentials of clinical practice* [3rd ed.]. Boston: Little, Brown.) (B) A bisected uterus displays a prominent, sharply circumscribed, fleshy tumor. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 999]. Philadelphia: Lippincott Williams & Wilkins)

Leiomyomas are asymptomatic approximately half of the time and may be discovered during a routine pelvic examination, or they may cause menorrhagia (excessive menstrual bleeding), anemia, urinary frequency, rectal pressure/constipation, abdominal distention, and infrequently pain. Their rate of growth is variable, but they may increase in size during pregnancy or with exogenous estrogen stimulation (*i.e.*, oral contraceptives or menopausal estrogen replacement therapy). Interference with pregnancy is rare unless the tumor is submucosal and interferes with implantation or obstructs the cervical outlet. These tumors may outgrow their blood supply, become infarcted, and undergo degenerative changes.

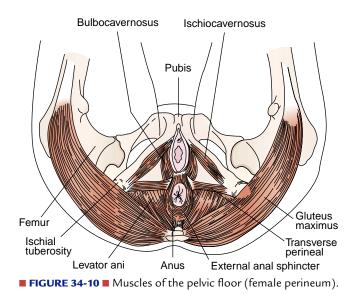

Most leiomyomas regress with menopause, but if bleeding, pressure on the bladder, pain, or other problems persist, hysterectomy may be required. Myomectomy (removal of just the tumors) can be done to preserve the uterus for future childbearing. Cesarean section may be recommended if the uterine cavity is entered during myomectomy. Hypothalamic GnRH may be used to suppress leiomyoma growth before surgery. Uterine artery embolization is a nonsurgical therapy for management of heavy bleeding.²²

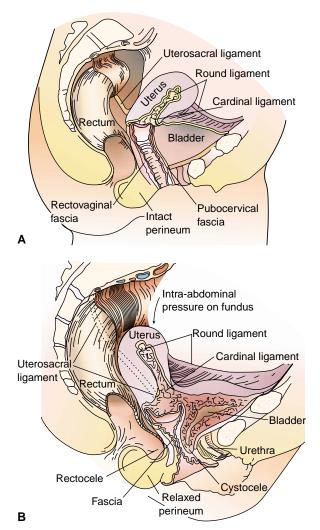

Disorders of Pelvic Support and Uterine Position

The muscular floor of the pelvis is a strong, slinglike structure that supports the uterus, vagina, urinary bladder, and rectum (Fig. 34-10). In the female anatomy, nature is faced with the problems of supporting the pelvic viscera against the force of gravity and increases in intra-abdominal pressure associated with coughing, sneezing, defecation, and laughing while at the same time allowing for urination, defecation, and normal reproductive tract function, especially the delivery of an infant.

Disorders of Pelvic Support

The uterus and the pelvic structures are maintained in proper position by the uterosacral ligaments, round ligaments, broad ligament, and cardinal ligaments. The two cardinal ligaments maintain the cervix in its normal position. The uterosacral ligaments normally hold the uterus in a forward position

■ FIGURE 34-11 ■ (A) Normal support of the uterus and vagina. (B) Relaxation of pelvic support structures with descent of the uterus as well as formation of cystocele and rectocele. (Rock J.A., Thompson J.D. [1992]. *Te Linde's operative gynecology* [7th ed.]. Philadelphia: J.B. Lippincott)

(Fig. 34-11 A). The broad ligament suspends the uterus, fallopian tubes, and ovaries in the pelvis.

Three supporting structures are provided for the abdominal pelvic diaphragm. The bony pelvis provides support and protection for parts of the digestive tract and genitourinary structures, and the peritoneum holds the pelvic viscera in place. However, the main support for the viscera is the pelvic diaphragm, made up of muscles and connective tissue that stretch across the bones of the pelvic outlet. The openings that must exist for the urethra, rectum, and vagina cause an inherent weakness in the pelvic diaphragm. Congenital or acquired weakness of the pelvic diaphragm results in widening of these openings, particularly the vagina, with the possible herniation of pelvic viscera through the pelvic floor (*i.e.*, prolapse).

Relaxation of the pelvic outlet usually comes about because of overstretching of the perineal supporting tissues during pregnancy and childbirth. Although the tissues are stretched only during these times, there may be no difficulty until later in life, such as the fifth or sixth decade, when further loss of elasticity and muscle tone occurs. Even in a woman who has not borne children, the combination of aging and postmenopausal changes may give rise to problems related to relaxation of the pelvic support structures. It also may result from pelvic tumors and neurologic conditions, such as spina bifida and diabetic neuropathy, that interrupt the innervation of pelvic muscles. The three most common conditions associated with this relaxation are cystocele, rectocele, and uterine prolapse. These may occur separately or together.

Cystocele is a herniation of the bladder into the vagina (Fig. 34-11 B). It occurs when the normal muscle support for the bladder is weakened, and the bladder sags below the uterus. The vaginal wall stretches and bulges downward because of the force of gravity and the pressure from coughing, lifting, or straining at stool. The bladder herniates through the anterior vaginal wall, and a cystocele forms. The symptoms include an annoying bearing-down sensation, difficulty in emptying the bladder, frequency and urgency of urination, and cystitis. Stress incontinence may occur at times of increased abdominal pressure, such as during squatting, straining, coughing, sneezing, laughing, or lifting.

Rectocele is the herniation of the rectum into the vagina (Fig 34-11 A). It occurs when the posterior vaginal wall and underlying rectum bulge forward, ultimately protruding through the introitus as the pelvic floor and perineal muscles are weakened. The symptoms include discomfort because of the protrusion of the rectum and difficulty in defecation. Digital pressure (*i.e.*, splinting) on the bulging posterior wall of the vagina may become necessary for defecation.

Uterine prolapse is the bulging of the uterus into the vagina that occurs when the primary supportive ligaments (*i.e.*, cardinal ligaments) are stretched. Prolapse is ranked as first, second, or third degree, depending on how far the uterus protrudes through the introitus. First-degree prolapse shows some descent, but the cervix has not reached the introitus. In seconddegree prolapse, the cervix or part of the uterus has passed through the introitus. The entire uterus protrudes through the vaginal opening in third-degree prolapse (*i.e.*, procidentia). Prolapse often is accompanied by perineal relaxation, cystocele, or rectocele. The symptoms associated with uterine prolapse result from irritation of the exposed mucous membranes of the cervix and vagina and the discomfort of the protruding mass.

Most of the disorders of pelvic relaxation require surgical correction. These are elective surgeries and usually are deferred until after the childbearing years. The symptoms associated with the disorders often are not severe enough to warrant surgical correction. In other cases, the stress of surgery is contraindicated because of other physical disorders; this is particularly true of older women, in whom many of these disorders occur. Kegel exercises, which strengthen the pubococcygeus muscle, may be helpful in cases of mild cystocele or rectocele or after surgical repair to help maintain the improved function (see Chapter 25). In women with uterine prolapse, a pessary may be inserted to hold the uterus in place and may stave off surgical intervention in women who want to have children or in older women for whom the surgery may pose a significant health risk.

Variations in Uterine Position

Variations in the position of the uterus are common. Some variations are innocuous; others, which may be the result of weakness and relaxation of the perineum, give rise to various problems that compromise the structural integrity of the pelvic floor, particularly after childbirth.

The uterus usually is flexed approximately 45 degrees anteriorly, with the cervix positioned posteriorly and downward in the anteverted position. When the woman is standing, the angle of the uterus is such that it lies practically horizontal, resting lightly on the bladder. Asymptomatic, normal variations in the axis of the uterus in relation to the cervix (i.e., flexion) and physiologic displacements that arise after pregnancy or with pathology of the cul-de-sac include anteflexion, retroflexion, and retroversion (Fig. 34-12). An anteflexed uterus is flexed forward on itself. Retroflexion is flexion backward at the isthmus. Retroversion describes the condition in which the uterus inclines posteriorly while the cervix remains tilted forward. Simple retroversion is the most common variation. It usually is a congenital condition caused by a short anterior vaginal wall and relaxed uterosacral ligaments. Retroversion also can follow certain diseases, such as endometriosis and PID, which produce fibrous tissue adherence with retraction of the fundus posteriorly. Large leiomyomas can also cause the uterus to move into a posterior position. Symptoms of retroversion include dyspareunia with deep penetration and low back pain with menses.

Disorders of the Ovaries

Disorders of the ovaries frequently cause menstrual and fertility problems. Benign conditions of the ovaries can present as primary lesions of the ovarian structures or as secondary disorders related to hypothalamic, pituitary, or adrenal dysfunction.

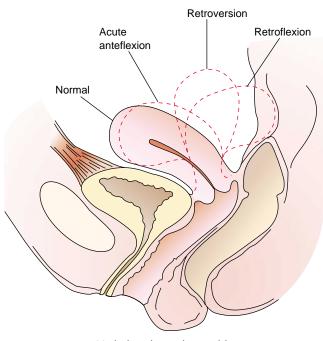

Ovarian Cysts

Cysts are the most common form of ovarian tumor.⁷ Many are benign. A follicular cyst is one that results from occlusion of the duct of the follicle. Each month, several follicles begin to de-

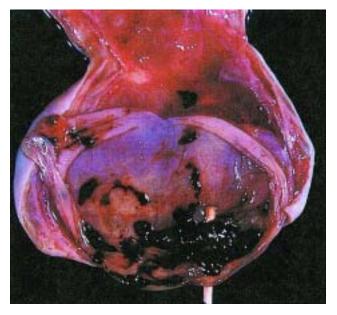

velop and are blighted at various stages of development. These follicles form cavities that fill with fluid, producing a cyst. The dominant follicle normally ruptures to release the egg (*i.e.*, ovulation) but occasionally persists and continues growing. Likewise, a luteal cyst is a persistent cystic enlargement of the corpus luteum that is formed after ovulation and does not regress in the absence of pregnancy. Functional cysts are asymptomatic unless there is substantial enlargement or bleeding into the cyst. This can cause considerable discomfort or a dull, aching sensation on the affected side. The cyst may become twisted or may rupture into the intra-abdominal cavity (Fig. 34-13). However, usually these regress spontaneously.

Polycystic Ovary Syndrome. Ovarian dysfunction associated with infrequent or absent menses in obese, infertile women was first reported in the 1930s by Stein and Leventhal, for whom the syndrome was originally named. Polycystic ovary syndrome (PCOS) is characterized by numerous cystic follicles or follicular cysts. Once thought to be relatively rare, it appears that this clinical entity is one of the most common endocrine disorders among women during the reproductive years. PCOS is characterized by varying degrees of hirsutism, acne, obesity, and anovulation and infertility, and often is associated with hyperinsulinemia or insulin resistance (see Chapter 31).^{7,23} Chronic anovulation can increase a woman's risk of endometrial cancer, cardiovascular disease, and hyperinsulinemia leading to diabetes mellitus.⁷

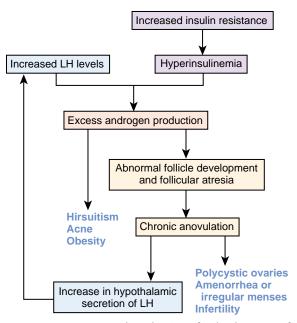

This syndrome has been the subject of considerable research. Chronic anovulation, causing amenorrhea or irregular menses, is now thought to be the underlying cause of the bilaterally enlarged "polycystic" ovaries (Fig. 34-14). Thus, the appearance of the ovary is a sign of the disorder, not the disease itself.²⁴ The precise etiology of this condition is still being de-

■ FIGURE 34-12 ■ Variations in uterine position.

■ FIGURE 34-13 ■ Follicle cyst of the ovary. The rupture of this thin-walled follicular cyst led to intra-abdominal hemorrhage. The cyst has been opened and rupture site indicated by the dowel stick. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1002]. Philadelphia: Lippincott Williams & Wilkins)

■ FIGURE 34-14 ■ Proposed mechanisms for development of the polycystic ovary syndrome.

bated. A possible genetic basis has been suggested with an autosomal dominant mode of inheritance and premature balding as the phenotype in males.²⁴

Most women with PCOS have elevated luteinizing hormone (LH) levels with normal estrogen and follicle-stimulating hormone (FSH) production. Elevated levels of testosterone, dehydroepiandrosterone sulfate (DHAS), or androstenedione are not uncommon, and occasionally hyperprolactinemia or hypothyroidism is present. Persistent anovulation results in an estrogen environment that alters the hypothalamic release of GnRH and with a resultant increase in LH secretion and suppression of FSH secretion by the pituitary. This altered LH: FSH ratio often is used as a diagnostic criterion for this condition, but it is not universally present. Although the presence of some FSH allows for new follicular development, full maturation is not attained, and ovulation does not occur. The elevated LH level also results in increased androgen production, which in turn prevents normal follicular development and contributes to the vicious cycle of anovulation.24 The association between insulin resistance and increased androgen levels is complex. Evidence suggests that the hyperinsulinemia may lead to the excess androgen production. Lowering insulin levels by weight loss or treatment with several of the oral antidiabetic drugs (thiazolidinediones or metformin) may reduce testosterone levels and restore ovulatory cycles in many women with the disorder.25,26

The diagnosis can be suspected from the clinical picture. Confirmation with ultrasonography or laparoscopic visualization of the ovaries is not required. When fertility is desired, the condition usually is treated by the administration of the hypothalamic-pituitary–stimulating drug clomiphene citrate or injectable gonadotropins to induce ovulation. These drugs must be used carefully because they can induce extreme enlargement of the ovaries. An insulin-sensitizing drug may be used before or concurrent with ovulation-inducing medications.²⁶ Weight loss also may be beneficial in restoring normal ovulation when obesity is present. When medication is ineffective, laser surgery to puncture the multiple follicles may restore normal ovulatory function, although adhesion formation is a potential problem. If fertility is not desired, oral contraceptives or cyclic progesterone can induce regular menses and prevent the development of endometrial hyperplasia caused by unopposed estrogen.

Benign and Functioning Ovarian Tumors

Benign ovarian tumors can be composed of epithelial tissue, endometriosis tissue, fibrocytes and collagen fibers, or primordial germ cells. Benign epithelial tumors are almost always serous or mucinous.^{2,7} They generally occur in women between the ages of 20 and 60 years and are often large, growing 15 to 30 cm in diameter. They are often cystic, thus the term cystadenomas. However, some of the cystadenomas are considered to have low malignant potential. Endometriomas are the "chocolate cysts" that develop secondary to ovarian endometriosis (see the endometriosis section earlier in this chapter). Ovarian fibromas are connective tissue tumors composed of fibrocytes and collagen. They range in size from 6 to 20 cm. Cystic teratomas, or dermoid cysts, are derived from primordial germ cells and are composed of various combinations of well-differentiated ectodermal, mesodermal, and endodermal elements. Not uncommonly, they contain sebaceous material, hair, or teeth.

Benign ovarian tumors are usually asymptomatic unless their size is sufficient to cause abdominal enlargement. Treatment for all ovarian tumors is surgical excision. Ovarian tissue that is not affected by the tumor can be left intact if frozensection analysis does not reveal malignancy. When ovarian tumors are very large, as is frequently the case with serous or mucinous cystadenomas, the entire ovary must be removed.

The three types of functioning ovarian tumors are estrogen secreting, androgen secreting, and mixed estrogen-androgen secreting. These tumors may be benign or cancerous. One such tumor, the granulosa cell tumor, is associated with excess estrogen production. When it develops during the reproductive period, the persistent and uncontrolled production of estrogen interferes with the normal menstrual cycle, causing irregular and excessive bleeding, endometrial hyperplasia, or amenorrhea and fertility problems. When it develops after menopause, it causes postmenopausal bleeding, stimulation of the glandular tissues of the breast, and other signs of renewed estrogen production. Androgen-secreting tumors inhibit ovulation and estrogen production. They tend to cause hirsutism and development of masculine characteristics, such as baldness, acne, oily skin, breast atrophy, and deepening of the voice. The treatment of functioning ovarian tumors is surgical removal.

Ovarian Cancer

Ovarian cancer is the second most common female genitourinary cancer and the most lethal. In 2000, 23,100 new cases of ovarian cancer were reported in the United States, two thirds of which were in advanced stages of the disease. Of these women, it is estimated that 14,000 will die of the disease, accounting for 53% of all deaths caused by gynecological cancers.²⁷ The incidence of ovarian cancer increases with age, being greatest between 65 and 84 years of age. Ovarian cancer is difficult to diagnose, and as many as 75% of women have metastatic disease before the time of discovery. The most significant risk factor for ovarian cancer appears to be ovulatory age—the length of time during a woman's life when her ovarian cycle is not suppressed by pregnancy, lactation, or oral contraceptive use. The incidence of ovarian cancer is much lower in countries where women bear numerous children than in the United States. Family history also is a significant risk factor for ovarian cancer. Women with two or more first- or second-degree relatives who have had *site-specific ovarian cancer* have as much as a 50% risk for development of the disease. A high-fat Western diet and use of powders containing talc in the genital area are other factors that have been linked to the development of ovarian cancer.

Cancer of the ovary is complex because of the diversity of tissue types that originate in the ovary. As a result of this diversity, there are several types of ovarian cancers. Malignant neoplasms of the ovary can be divided into three categories: epithelial tumors, germ cell tumors, and gonadal stromal tumors. Epithelial tumors account for approximately 90% of cases. These different cancers display various degrees of virulence, depending on the type of tumor and degree of differentiation involved. A well-differentiated cancer of the ovary may have produced symptoms for many months and still be found operable at the time of surgery. A poorly differentiated tumor may have been clinically evident for only a few days but found to be widespread and inoperable. Often no correlation exists between the duration of symptoms and the extent of the disease.

Most cancers of the ovary produce no symptoms or the symptoms are so vague that the woman seldom seeks medical care until the disease is far advanced. These vague discomforts include abdominal distress, flatulence, and bloating, especially after ingesting food. These gastrointestinal manifestations may precede other symptoms by months. It is not fully understood why the initial symptoms of ovarian cancer are manifested as gastrointestinal disturbances. It is thought that biochemical changes in the peritoneal fluids may irritate the bowel or that pain originating in the ovary may be referred to the abdomen and be interpreted as a gastrointestinal disturbance. Clinically evident ascites (*i.e.*, fluid in the peritoneal cavity) is seen in approximately one fourth of women with malignant ovarian tumors and is associated with a worse prognosis.

At present, there are no good screening tests or other early methods of detection for ovarian cancer. The serum tumor marker CA-125 is a cell surface antigen that can be used in monitoring therapy and recurrences when preoperative levels have been elevated. Because it lacks sensitivity and specificity, CA-125 has limited value as a single screening test. Transvaginal ultrasonography (TVS) can be used to evaluate ovarian masses for malignant potential. However, cost has prohibited its use as a universal screening tool. The National Institutes of Health Consensus Panel convened in 1995 recommended against widespread screening of women for ovarian cancer.²⁸ CA-125 with TVS is suggested only for women who are part of a family with hereditary ovarian cancer syndrome (*i.e.*, two or more affected first-degree relatives).

When ovarian cancer is suspected, surgical evaluation is required for diagnosis, complete and accurate staging, and cytoreduction and debulking procedures to reduce the size of the tumor. Recommendations regarding treatment beyond surgery and prognosis depend on the stage of the disease. In summary, the external genitalia are affected by disorders that affect skin on other parts of the body. Bartholin's cysts are the result of occluded ducts in Bartholin's glands. They often are painful and can become infected. Vulvar dystrophies are characterized by thinning and hyperplastic thickening of vulvar tissues. Vulvodynia is a chronic vulvar pain syndrome with several classifications and variable treatment results. Cancer of the vulva, which accounts for 4% of all female genitourinary cancers, is associated with HPV infections.

The normal vaginal ecology depends on the delicate balance of hormones and bacterial flora. Vaginitis or inflammation of the vagina is characterized by vaginal discharge and burning, itching, redness, and swelling of vaginal tissues. It may be caused by chemical irritants, foreign bodies, and infectious agents. Primary cancers of the vagina are uncommon, accounting for 3% of all cancers of the female reproductive system. Daughters of women treated with DES to prevent miscarriage are at increased risk for the development of adenocarcinoma of the vagina.

Disorders of the cervix and uterus include inflammatory conditions (*i.e.*, cervicitis and endometritis), cancer (*i.e.*, cervical and endometrial cancer), endometriosis, and leiomyomas. Acute cervicitis, which may be caused by a number of agents, may result from the direct infection of the cervix or may be secondary to a vaginal or uterine infection. Chronic cervicitis represents a low-grade inflammatory process resulting from trauma or nonspecific infectious agents. Cervical cancer arises from precursor lesions that can be detected on a Pap smear, and if detected early, is the most easily cured of all the cancers of the female reproductive system.

PID is an inflammation of the upper reproductive tract that involves the uterus (endometritis), fallopian tubes (salpingitis), or ovaries (oophoritis). It is most commonly caused by *N. gonorrhoeae* or *C. trachomatis*. Endometriosis is the condition in which functional endometrial tissue is found in ectopic sites outside the uterus. It causes dysmenorrhea, dyspareunia, and infertility.

Adenomyosis is the condition in which endometrial glands and stroma are found in the myometrium interspersed between the smooth muscle fibers. Leiomyomas are benign uterine wall neoplasms of smooth muscle origin. They can develop in the corpus of the uterus and can be submucosal, subserosal, or intramural. Submucosal fibroids displace endometrial tissue and are more likely to cause bleeding, necrosis, and infection than either of the other types. Endometrial cancer is the most common cancer found in the female pelvis; it occurs more than twice as often as cervical cancer. Prolonged estrogen stimulation with hyperplasia of the endometrium has been identified as a major risk factor for endometrial cancer.

Alterations in pelvic support frequently occur because of weaknesses and relaxation of the pelvic floor and perineum. Cystocele and rectocele involve herniation of the bladder or rectum into the vagina. Uterine prolapse occurs when the uterus bulges into the vagina. Pelvic relaxation disorders typically result from overstretching of the perineal supporting muscles during pregnancy and childbirth. The loss of elasticity in these structures that is a normal accompaniment of aging contributes to these problems. Variations in uterine position are common; they include anteflexion, in which the uterus is flexed forward on itself; retroflexion, in which the uterus is flexed backward at the isthmus; and retroversion, in which the uterus inclines posteriorly while the cervix remains tilted forward.

Disorders of the ovaries include benign cysts, functioning ovarian tumors, and cancer of the ovary; they usually are asymptomatic unless there is substantial enlargement or bleeding into the cyst, or the cyst becomes twisted or ruptures. Polycystic ovary syndrome is characterized by numerous cystic follicles or follicular cysts; it causes various degrees of hirsutism, obesity, and infertility. Benign ovarian tumors consist of endometriomas, which are chocolate cysts that develop secondarily to ovarian endometriosis; ovarian fibromas, which are connective tissue tumors composed of fibrocytes and collagen; and cystic teratomas or dermoid cysts, which are derived from primordial germ cells and are composed of various combinations of well-differentiated ectodermal, mesodermal, and endodermal elements. Functioning ovarian tumors are of three types: estrogen secreting, androgen secreting, and mixed estrogen-androgen secreting, and may be benign or cancerous. Cancer of the ovary is the second most common female genitourinary cancer and the most lethal. It can be divided into three categories: epithelial tumors, germ cell tumors, and gonadal stromal tumors. There are no effective screening methods for ovarian cancer, and often the disease is well advanced at the time of diagnosis.

MENSTRUAL DISORDERS

Between menarche (i.e., first menstrual bleeding) and menopause (*i.e.*, last menstrual bleeding), the female reproductive system undergoes cyclic changes called the *menstrual cycle*. This includes the maturation and release of oocytes from the ovary during ovulation and periodic vaginal bleeding resulting from the shedding of the endometrial lining. It is not necessary for a woman to ovulate to menstruate; anovulatory cycles do occur. The menstrual cycle produces changes in the breasts, uterus, skin, ovaries, and perhaps other unidentified tissues. The maintenance of the cycle affects biologic and sociologic aspects of a woman's life, including fertility, reproduction, sexuality, and femaleness.

The hormonal control of the menstrual cycle is complex. For example, the biosynthesis of estrogens that occurs in adipose tissue may be a significant source of the hormone. There is evidence that a certain minimum body weight (48 kg) and fat content (16% to 24%) are necessary for menarche to occur and for the menstrual cycle to be maintained. This is supported by the observation of amenorrhea in women with anorexia nervosa, chronic disease, and malnutrition and in those who are longdistance runners. In women with anorexia nervosa, gonadotropin and estradiol secretion, including LH release and responsiveness to the GnRH, can revert to prepubertal levels. With resumption of weight gain and attainment of sufficient body mass, the normal hormonal pattern usually is reinstated. Obesity or significant weight gain also is associated with oligomenorrhea or amenorrhea and infertility, although the mechanism is not well understood.

In addition to their effects on the growth of uterine muscle, estrogens play an important role in the development of the endometrial lining. During anovulatory cycles, continued exposure to estrogens for prolonged periods leads to abnormal hyperplasia of the endometrium and abnormal bleeding patterns. When estrogen production is poorly coordinated during the normal menstrual period, inappropriate bleeding and shedding of the endometrium also can occur.

Dysfunctional Menstrual Cycles

Normal menstrual function results from interactions among the central nervous system, hypothalamus, anterior pituitary, ovaries, and associated target tissues. Although each part of the system is essential to normal function, the ovaries are primarily responsible for controlling the cyclic changes and the length of the menstrual cycle. In most women in the middle reproductive years, menstrual bleeding occurs every 25 to 35 days, with a median length of 28 days.

Dysfunctional Bleeding

Although unexplained uterine bleeding can occur for many reasons, such as pregnancy, abortion, bleeding dyscrasias, and neoplasms, the most frequent cause in the nonpregnant female is what is commonly called *dysfunctional menstrual cycles* or *bleeding*. Dysfunctional cycles may take the form of amenorrhea (absence of menstruation), hypomenorrhea (scanty menstruation), oligomenorrhea (infrequent menstruation, periods more than 35 days apart), menorrhagia (excessive menstruation), or metrorrhagia (bleeding between periods). Menometrorrhagia is heavy bleeding during and between menstrual periods.

Dysfunctional menstrual cycles are related to alterations in the hormones that support normal cyclic endometrial changes. Estrogen deprivation causes retrogression of a previously builtup endometrium and bleeding. Such bleeding often is irregular

KEY CONCEPTS

DYSFUNCTIONAL MENSTRUAL CYCLES

- The pattern of menstrual bleeding tends to be fairly consistent in most healthy women with regard to frequency, duration, and amount of flow.
- Dysfunctional bleeding in postpubertal women can take the form of absent or scanty periods, infrequent periods, excessive and irregular periods, excessive bleeding during periods, and bleeding between periods.
- When the basic pattern of bleeding is changed, it is most often due to a lack of ovulation and disturbances in the pattern of hormone secretion.
- When the basic pattern is undisturbed and there are superimposed episodes of bleeding or spotting, the etiology is more likely to be related to organic lesions or hematologic disorders.

in amount and duration, with the flow varying with the time and degree of estrogen stimulation and with the degree of estrogen withdrawal. A lack of progesterone can cause abnormal menstrual bleeding; in its absence, estrogen induces development of a much thicker endometrial layer with a richer blood supply. The absence of progesterone results from the failure of any of the developing ovarian follicles to mature to the point of ovulation, with the subsequent formation of the corpus luteum and production and secretion of progesterone.

Periodic bleeding episodes alternating with amenorrhea are caused by variations in the number of functioning ovarian follicles present. If sufficient follicles are present and active and if new follicles assume functional capacity, high levels of estrogen develop, causing the endometrium to proliferate for weeks or even months. In time, estrogen withdrawal and bleeding develop. This can occur for two reasons: an absolute estrogen deficiency may develop when several follicles simultaneously degenerate, or a relative deficiency may develop as the needs of the enlarged endometrial tissue mass exceed the capabilities of the existing follicles, even though estrogen levels remain constant. Estrogen and progesterone deficiency are associated with the absence of ovulation, thus the term *anovulatory bleeding*. Because the vasoconstriction and myometrial contractions that normally accompany menstruation are caused by progesterone, anovulatory bleeding seldom is accompanied by cramps, and the flow frequently is heavy. Anovulatory cycles are common among adolescents during the first several years after menarche, when ovarian function is becoming established, and among perimenopausal women, whose ovarian function is beginning to decline.

Dysfunctional menstrual cycles can originate as a primary disorder of the ovaries or as a secondary defect in ovarian function related to hypothalamic-pituitary stimulation. The latter can be initiated by emotional stress, marked variation in weight (*i.e.*, sudden gain or loss), or nonspecific endocrine or metabolic disturbances. Organic causes of irregular menstrual bleeding include endometrial polyps, submucosal myoma (*i.e.*, fibroid), blood dyscrasia, infection, endometrial cancer, polycystic ovarian disease, and pregnancy.

The treatment of dysfunctional bleeding depends on what is identified as the probable cause. The minimum evaluation should include a detailed history with emphasis on bleeding pattern and a physical examination. Endocrine studies (FSH:LH ratio, prolactin, testosterone, DHAS), β -hCG pregnancy test, endometrial biopsy, D & C with or without hysteroscopy, and progesterone withdrawal tests may be needed for diagnosis. If organic problems are excluded and alterations in hormone levels are the primary cause, treatment may include the use of oral contraceptives, cyclic progesterone therapy, or long-acting progesterone injections.

Amenorrhea

There are two types of amenorrhea: primary and secondary. Primary amenorrhea is the failure to menstruate by 16 years of age, or by 14 years of age if failure to menstruate is accompanied by absence of secondary sex characteristics. Secondary amenorrhea is the cessation of menses for at least 6 months in a woman who has established normal menstrual cycles. Primary amenorrhea usually is caused by gonadal dysgenesis, congenital müllerian agenesis, testicular feminization, or a hypothalamic-pituitary-ovarian axis disorder. Causes of secondary amenorrhea include ovarian, pituitary, or hypothalamic dysfunction and destruction of the endometrial cavity by chronic infections such as tuberculosis or destruction of the endometrium by curettage (surgical scraping). Another cause is anorexia nervosa or participation in athletic activities to the extent that there is an alteration in the critical body fatmuscle ratio needed for menses to occur.²⁹

Diagnostic evaluation of amenorrhea resembles that for dysfunctional uterine bleeding, with the possible addition of a computed tomographic scan to exclude a pituitary tumor. Treatment is based on correcting the underlying cause and inducing menstruation with cyclic progesterone or combined estrogen-progesterone regimens.

Dysmenorrhea

Dysmenorrhea is pain or discomfort with menstruation. Although not usually a serious medical problem, it causes some degree of monthly disability for a significant number of women. There are two forms of dysmenorrhea: primary and secondary. Primary dysmenorrhea is menstrual pain that is not associated with a physical abnormality or pathology.³⁰ It usually occurs with ovulatory menstruation beginning 6 months to 2 years after menarche. Symptoms may begin 1 to 2 days before menses, peak on the first day of flow, and subside within several hours to several days. Severe dysmenorrhea may be associated with systemic symptoms such as headache, nausea, vomiting, diarrhea, fatigue, irritability, dizziness, and syncope. The pain typically is described as dull, lower abdominal aching or cramping, spasmodic or colicky in nature, often radiating to the lower back, labia majora, or upper thighs.

Secondary dysmenorrhea is menstrual pain caused by specific organic conditions, such as endometriosis, uterine fibroids, adenomyosis, pelvic adhesions, or PID. Laparoscopy often is required for diagnosis of secondary dysmenorrhea if medication for primary dysmenorrhea is ineffective.

Treatment for primary dysmenorrhea is directed at symptom control. Although analgesic agents such as aspirin and acetaminophen may relieve minor uterine cramping or low back pain, prostaglandin synthetase inhibitors, such as ibuprofen, naproxen, mefenamic acid, and indomethacin, are more specific for dysmenorrhea. Ovulation suppression and symptomatic relief of dysmenorrhea can be instituted simultaneously with the use of oral contraceptives. Relief of secondary dysmenorrhea depends on identifying the cause of the problem. Medical or surgical intervention may be needed to eliminate the problem.

Premenstrual Syndrome

The *premenstrual syndrome* (PMS) is a distinct clinical entity characterized by a cluster of physical and psychological symptoms limited to 3 to 14 days preceding menstruation and relieved by onset of the menses. The incidence of PMS seems to increase with age. It is less common in women in their teens and 20s, and most of the women seeking help for the problem are in their mid-30s.³¹

Although the causes of PMS are poorly documented, they probably are multifactorial. Like dysmenorrhea, it is only recently that PMS has been recognized as a bona fide disorder, rather than merely a psychosomatic illness.

The physical symptoms of PMS include painful and swollen breasts, bloating, abdominal pain, headache, and backache. Psychologically, there may be depression, anxiety, irritability, and behavioral changes. In some cases, there are puzzling alterations in motor function, such as clumsiness and altered handwriting. Women with PMS may report one or several symptoms, with symptoms varying from woman to woman and from month to month in the same patient. Signs and symptoms associated with this disorder are summarized in Table 34-3. PMS can significantly affect a woman's ability to perform at normal levels. She may lose time from or function ineffectively at work. Family responsibilities and relationships may suffer. More crimes are committed by females during the premenstrual phase of the cycle, and more lives are lost to suicide during this period. The term premenstrual dysphoric disorder is a psychiatric diagnosis that has been developed to distinguish women whose symptoms are severe enough to interfere significantly with activities of daily living or in whom the symptoms are not relieved with the onset of menstruation, as is usually the case with PMS.31,32

Diagnosis focuses on identification of the symptom clusters by means of prospective charting for at least 3 months. A complete history and physical examination are necessary to exclude other physical causes of the symptoms. Depending on the symptom pattern, blood studies, including thyroid hormones and glucose tests, may be done. Psychosocial evaluation is helpful to exclude emotional illness that is merely exacerbated premenstrually.

Treatment of PMS is directed toward an integrated program of regular exercise, avoidance of caffeine, and a diet emphasizing complex carbohydrates. Foods high in simple sugars and alcohol should be avoided. Drug therapy should be used cautiously until well-controlled studies establish criteria for use and effective treatment results.

Menopause and Aging Changes

Menopause is the cessation of menstrual cycles. Like menarche, it is more of a process than a single event. Most women stop menstruating between 48 and 55 years of age. Perimenopause (the years immediately surrounding menopause) precedes menopause by approximately 4 years and is characterized by menstrual irregularity and other menopausal symptoms. Climacteric is a more encompassing term that refers to the entire transition to the nonreproductive period of life. Premature

ovarian failure describes the approximately 1% of women who experience menopause before the age of 40 years. A woman who has not menstruated for a full year or has an FSH level greater than 30 mIU/mL is considered menopausal.33

Menopause results from the gradual cessation of ovarian function and the resultant diminished levels of estrogen. Although estrogens derived from the adrenal cortex continue to circulate in a woman's body, they are insufficient to maintain the secondary sexual characteristics in the same manner as ovarian estrogens. As a result, breast tissue, body hair, skin elasticity, and subcutaneous fat decrease; the ovaries and uterus diminish in size; and the cervix and vagina become pale and friable. Problems that can arise as a result of this urogenital atrophy include vaginal dryness, urinary stress incontinence, urgency, nocturia, vaginitis, and urinary tract infection. The woman may find intercourse painful and traumatic, although some type of vaginal lubrication may be helpful.

Systemically a woman may experience significant vasomotor instability secondary to the decrease in estrogens and the relative increase in other hormones, including FSH, LH, GnRH, dehydroepiandrosterone, and androstenedione, epinephrine, corticotropin, β -endorphin, growth hormone, and calcitonin gene-related peptide. This instability may give rise to "hot flashes," palpitations, dizziness, and headaches as the blood vessels dilate. Despite the association with these biochemical changes, the underlying cause of hot flashes is unknown.³⁴ Tremendous variation exists in the onset, frequency, severity, and length of time that women experience hot flashes. When they occur at night and are accompanied by significant perspiration, they are referred to as *night sweats*. Insomnia as well as frequent awakening because of vasomotor symptoms can lead to sleep deprivation. A woman may experience irritability, anxiety, and depression as a result of these uncontrollable and unpredictable events.

Consequences of long-term estrogen deprivation include osteoporosis, due to an imbalance in bone remodeling (*i.e.*, bone resorption occurs at a faster rate than bone formation), and an increased risk for cardiovascular disease (atherosclerosis is accelerated), which is the leading cause of death for women after menopause.

Hormone replacement therapy (HRT) has recently come under scrutiny. Topical hormone preparations are available to treat symptoms related to vaginal atrophy. Selective estrogen receptor modulators (SERMs) may be used in place of estrogen to prevent osteoporosis.

TABLE 34-3	Symptoms of Premenstrual Syndrome (PMS) by System
Body System	Symptoms
Cerebral	Irritability, anxiety, nervousness, fatigue, and exhaustion; increased physical and mental activity; lability; crying spells; depressions; inability to concentrate
Gastrointestinal	Craving for sweets or salts, lower abdominal pain, bloating, nausea, vomiting, diarrhea, constipation
Vascular	Headache, edema, weakness, or fainting
Reproductive	Swelling and tenderness of the breasts, pelvic congestion, ovarian pain, altered libido
Neuromuscular	Trembling of the extremities, changes in coordination, clumsiness, backache, leg aches
General	Weight gain, insomnia, dizziness, acne

In summary, between the menarche and menopause, the female reproductive system undergoes cyclic changes called the *menstrual cycle*. The normal menstrual function results from complex interactions among the hypothalamus, which produces GnRH; the anterior pituitary gland, which synthesizes and releases FSH, LH, and prolactin; the ovaries, which synthesize and release estrogens, progesterone, and androgens; and associated target tissues, such as the endometrium and the vaginal mucosa. Although each component of the system is essential for normal functioning, the ovarian hormones are largely responsible for controlling the cyclic changes and length of the menstrual cycle.

Menstrual disorders include dysfunctional menstrual cycles, dysmenorrhea, and PMS. Dysfunctional menstrual cycles produce amenorrhea, oligomenorrhea, metrorrhagia, or menorrhagia. Dysmenorrhea is characterized by pain or discomfort during menses. It can occur as a primary or secondary disorder. Primary dysmenorrhea is not associated with other disorders and begins soon after menarche. Secondary dysmenorrhea is caused by a specific organic condition, such as endometriosis or pelvic adhesions. It occurs in women with previously painless menses. PMS represents a cluster of physical and psychological symptoms that precede menstruation by 1 to 2 weeks.

Menopause is the cessation of ovarian function and menstrual cycles. It is accompanied by a decline in secondary sexual characteristics, vasomotor instability, and long-term consequences, including osteoporosis and increased rate of heart disease.

DISORDERS OF THE BREAST

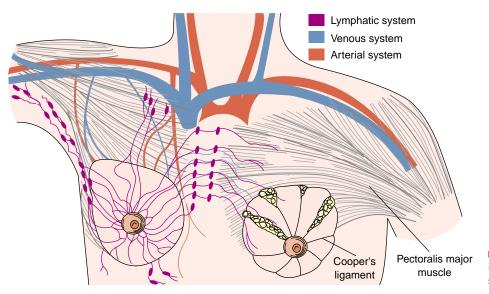

Although anatomically separate, the breasts are functionally related to the female genitourinary system in that they respond to the cyclic changes in sex hormones and produce milk for infant nourishment. Most breast diseases may be described as benign or cancerous. Benign breast conditions are nonprogressive; however, some forms of benign disease increase the risk of malignant disease.

Breast Structures

The breasts, or mammary tissues, are located between the third and seventh ribs of the anterior chest wall and are supported by the pectoral muscles and superficial fascia. They are specialized glandular structures that have an abundant shared nervous, vascular, and lymphatic supply (Fig. 34-15). Structurally the breast consists of fat, fibrous connective tissue, and glandular tissue. The superficial fibrous connective tissue is attached to the skin, a fact that is important in the visual observation of skin movement over the breast during breast self-examination. The breast mass is supported by the fascia of the pectoralis major and minor muscles and by the fibrous connective tissue of the breast. Fibrous tissue ligaments, called Cooper's ligaments, extend from the outer boundaries of the breast to the nipple area in a radial manner, like the spokes on a wheel. These ligaments further support the breast and form septa that divide the breast into 15 to 25 lobes. Each lobe consists of grapelike clusters, alveoli or glands, which are interconnected by ducts. Estrogen stimulates the growth of the ductile system, while progesterone stimulates the growth and development of the ductile and alveolar secretory epithelium.

The alveoli are lined with secretory cells capable of producing milk or fluid under the proper hormonal conditions (Fig. 34-16). The route of descent of milk and other breast secretions is from alveoli to duct, to intralobar duct, to lactiferous duct and reservoir, to nipple. Breast milk is produced secondary to complex hormonal changes associated with pregnancy. The breasts respond to the cyclic changes in the menstrual cycle with fullness and discomfort.

The nipple is made up of epithelial, glandular, erectile, and nervous tissue. Areolar tissue surrounds the nipple and is recognized as the darker, smooth skin between the nipple and the breast. The small bumps or projections on the areolar surface known as *Montgomery's tubercles* are sebaceous glands that keep the nipple area soft and elastic. At the time of puberty and during pregnancy, increased levels of estrogen and progesterone

■ FIGURE 34-15 ■ The breasts, showing the shared vascular and lymphatic supply as well as the pectoral muscles.

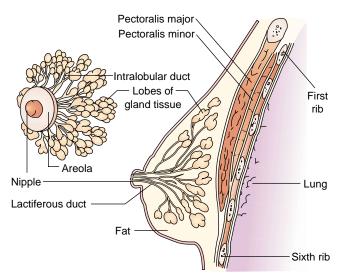

FIGURE 34-16 The breast, showing the glandular tissue and ducts of the mammary glands.

cause the areola and nipple to become darker and more prominent and Montgomery's glands to become more active. The erectile tissue of the nipple is responsive to psychological and tactile stimuli, which contributes to the sexual function of the breasts.

Mastitis

Mastitis is inflammation of the breast. It most frequently occurs during lactation but may also result from other conditions. In the lactating woman, inflammation results from an ascending infection that travels from the nipple to the ductile structures. The most common organisms isolated are *Staphylococcus* and *Streptococcus*.⁷ The offending organisms originate from the suckling infant's nasopharynx or the mother's hands. During the early weeks of nursing, the breast is particularly vulnerable to bacterial invasion because of minor cracks and fissures that occur with vigorous suckling. Infection and inflammation cause obstruction of the ductile system. The breast area becomes hard, inflamed, and tender if not treated early. Without treatment, the area becomes walled off and may abscess, requiring incision and drainage. It is advisable for the mother to continue breastfeeding during antibiotic therapy to prevent this.

Mastitis is not confined to the postpartum period; it can occur as a result of hormonal fluctuations, tumors, trauma, or skin infection. Cyclic inflammation of the breast occurs most frequently in adolescents, who commonly have fluctuating hormone levels. Tumors may cause mastitis secondary to skin involvement or lymphatic obstruction. Local trauma or infection may develop into mastitis because of ductal blockage of trapped blood, cellular debris, or the extension of superficial inflammation. The treatment for mastitis symptoms may include application of heat or cold, excision, aspiration, mild analgesics, antibiotics, and a supportive brassiere or breast binder.

Ductile Disorders

Ductal ectasia manifests in older women as a spontaneous, intermittent, usually unilateral, grayish-green nipple discharge. Palpation of the breast increases the discharge. Ectasia occurs during or after menopause and is symptomatically associated with burning, itching, pain, and a pulling sensation of the nipple and areola. The disease results in inflammation of the ducts and subsequent thickening. The treatment requires removal of the involved ductal mass.

Intraductal papillomas are benign epithelial tissue tumors that range in size from 2 mm to 5 cm. Papillomas usually manifest with a bloody nipple discharge. The tumor may be palpated in the areolar area. The papilloma is probed through the nipple, and the involved duct is removed.

Fibrocystic Disease

The term *fibrocystic breast disease* is the most common lesion of the breast. It is most common in women 30 to 50 years of age and is rare in postmenopausal women not receiving hormone replacement.³⁵ Fibrocystic disease usually presents as nodular (*i.e.*, "shotty"), granular breast masses that are more prominent and painful during the luteal or progesterone-dominant portion of the menstrual cycle. Discomfort ranges from heaviness to exquisite tenderness, depending on the degree of vascular engorgement and cystic distention.

Fibrocystic disease encompasses a wide variety of lesions and breast changes. Microscopically, fibrocystic disease refers to a constellation of morphologic changes manifested by (1) cystic dilation of terminal ducts, (2) relative increase in fibrous tissue, and (3) variable proliferation of terminal duct epithelial elements.⁷ Autopsy studies have demonstrated some degree of fibrocystic change in 60% to 80% of adult women in the United States.⁷ Symptomatic fibrocystic disease, in which large, clinically detectable cysts are present, is much less common, occurring in approximately 10% of the adult women between 35 and 50 years of age.⁷ Although fibrocystic disease often has been thought to increase the risk of breast cancer, only certain variants in which proliferation of the epithelial components is demonstrated represent a true risk.

Diagnosis of fibrocystic disease is made by physical examination, mammography, ultrasound, and biopsy (*i.e.*, aspiration or tissue sample). Ultrasound is useful in differentiating a cystic from a solid mass. Because a mass caused by fibrocystic disease may be indistinguishable from carcinoma on the basis of clinical findings, suspicious lesions should undergo biopsy. Fineneedle aspiration may be used, but if a suspect mass that was nonmalignant on cytologic examination does not resolve during the course of several months, it should be removed surgically.

Treatment for fibrocystic breast disease usually is symptomatic. Aspirin, mild analgesics, and local application of heat or cold may be recommended. Women should be encouraged to wear a good supporting brassiere and advised to avoid foods that contain xanthines (*e.g.*, coffee, cola, chocolate, and tea) in their daily diets, particularly premenstrually. Aspiration of a discrete mass indicative of a cyst may be used to relieve pain and confirm the cystic nature of the lesion. Danazol, a synthetic androgen, may be used for treatment of severe pain.

Breast Cancer

Cancer of the breast is the most common female cancer. One in eight women in the United States will have breast cancer in her lifetime. In 2000, breast cancer affected 182,800 American women and killed almost 40,800 women.³⁶ Although the breast cancer mortality rate has shown a slight decline, it is second only to lung cancer as a cause of cancer-related deaths in women. Incidence rates for carcinoma in situ have increased dramatically since the mid-1970s because of recommendations regarding mammography screening. The decline in the breast cancer mortality rate since 1989 is attributable to this earlier diagnosis as well as improvements in cancer treatments.³⁷

Risk factors for breast cancer include sex, increasing age, personal or family history of breast cancer (i.e., at highest risk are those with multiple affected first-order relatives), history of benign breast disease (*i.e.*, primary "atypical" hyperplasia), and hormonal influences that promote breast maturation and may increase the chance of cell mutation (i.e., early menarche, late menopause, and no term pregnancies or first child after 30 years of age).³⁸ Most women with breast cancer have no identifiable risk factors.

Approximately 8% of all breast cancers are hereditary.³⁸ Two breast cancer susceptibility genes-BRCA1 on chromosome 17 and BRCA2 on chromosome 13-may account for most inherited forms of breast cancer (see Chapter 5). Known carriers of these genes should begin monthly breast self-examination (BSE) at 18 years of age and begin having annual mammograms at 25 years of age.39

Breast cancer may involve the lobular or ductile structures. Invasive, or infiltrating, ductile carcinoma is the most common form of breast cancer. Invasive lobular carcinoma is the second most common form of breast cancer. It may occur alone or mixed with ductile carcinoma. Paget's disease accounts for 1% of all breast cancers. The disease presents as an eczematoid lesion of the nipple and areola. Paget's disease usually is associated with an infiltrating, intraductal carcinoma. Ductile carcinoma in situ (including Paget's disease) has increased in the past several decades from less than 5% of all carcinomas before mammography screening to 15% to 20% in well screened populations. The lesion consists of a malignant population of cells that lack the capacity to invade the basement membrane and metastasize. However, they can spread throughout the ductile system involving an entire sector of the breast.²

Detection

Cancer of the breast may manifest clinically as a mass, a puckering, nipple retraction, or unusual discharge. Many cancers are found by women themselves through BSE-sometimes when only a thickening or subtle change in breast contour is noticed. The variety of symptoms and potential for self-discovery underscore the need for regular, systematic self-examination. BSE should be done routinely by women older than 20 years of age. As an adjunct to BSE, women should have a clinical examination by a trained health professional at least every 3 years between 20 and 40 years of age, and annually after 40 years of age.

Mammography is the only effective screening technique for the early detection of clinically inapparent lesions. A generally slow-growing form of cancer, breast cancer may have been present for 2 to 9 years before it reaches 1 cm, the smallest mass normally detected by palpation. Mammography can disclose lesions as small as 1 mm and the clustering of calcifications that may warrant biopsy to exclude cancer. The American Cancer Society recommends annual evaluation for women after 40 years of age. The most comprehensive approach to screening is a combination of BSE, clinical evaluation by a health professional, and mammography.

Diagnosis and Classification

Procedures used in the diagnosis of breast cancer include physical examination, mammography, ultrasonography, percutaneous needle aspiration, stereotactic needle biopsy (i.e., core biopsy), and excisional biopsy. Figure 34-17 illustrates the appearance of breast cancer on mammography. Breast cancer often manifests as a solitary, painless, firm, fixed lesion with poorly defined borders. It can be found anywhere in the breast but is most common in the upper outer quadrant. Because of the variability in presentation, any suspect change in breast tissue warrants further investigation. The diagnostic use of mammography enables additional definition of the clinically suspect area (e.g., appearance, character, calcification). Placement of a wire marker under radiographic guidance can ensure accurate surgical biopsy of nonpalpable suspect areas. Ultrasonography is useful as a diagnostic adjunct to differentiate cystic from solid tissue in women with nonspecific thickening.

Fine-needle aspiration is a simple in-office procedure that can be performed repeatedly in multiple sites and with minimal discomfort. It can be used to identify the presence of malignant cells, but it cannot differentiate in situ from infiltrating cancers. Stereotactic needle biopsy is an outpatient procedure done with the guidance of a mammography machine. After the lesion is localized radiologically, a large-bore needle is mechanically thrust quickly into the area, removing a core of tissue. Excisional biopsy to remove the entire lump provides the only definitive diagnosis of breast cancer and often is therapeutic without additional surgery.

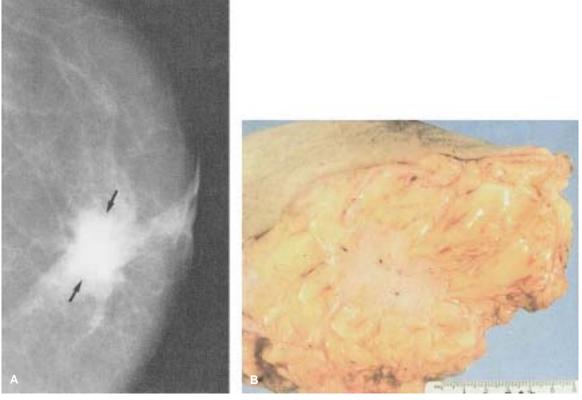

Tumors are classified histologically according to tissue characteristics and staged clinically according to tumor size, nodal involvement, and presence of metastasis. It is recommended that estrogen and progesterone receptor analysis be performed on surgical specimens. Information about the presence or absence of estrogen and progesterone receptors can be used in predicting tumor responsiveness to hormonal manipulation. High levels of both receptors improve the prognosis and increase the likelihood of remission.

Treatment

The treatment methods for breast cancer include surgery, chemotherapy, radiation therapy, and hormonal manipulation.⁴⁰ Radical mastectomy (*i.e.*, removal of the entire breast, underlying muscles, and all axillary nodes) rarely is used today as a primary surgical therapy unless breast cancer is advanced at the time of diagnosis. Modified surgical techniques (*i.e.*, mastectomy plus axillary dissection or lumpectomy for breast conservation) accompanied by chemotherapy or radiation therapy have achieved outcomes comparable with those obtained with radical surgical methods and constitute the preferred treatment methods.

The prognosis and need for adjuvant systemic therapy is related more to the extent of nodal involvement than to the extent of breast involvement. A newer technique for evaluating lymph node involvement is sentinel lymph node biopsy. A radioactive substance or dye is injected into the region of the tumor. In theory, the dye is carried to the first (sentinel) node to receive lymph from the tumor. This would therefore be the node most likely to contain cancer cells if the cancer has spread. If the sentinel node biopsy is positive, more nodes are removed. If it is negative, further lymph node evaluation may not be needed. It is not always possible to identify the sentinel node.41

624

■ FIGURE 34-17 ■ Carcinoma of the breast. (A) Mammogram. An irregularly shaped, dense mass (*arrows*) is seen in this otherwise fatty breast. (B) Mastectomy specimen. The irregular white, firm mass in the center is surrounded by fatty tissue. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1042]. Philadelphia: Lippincott Williams & Wilkins)

Adjuvant systemic therapy refers to the administration of chemotherapy or hormonal therapy to women without detectable metastatic disease. The goal of this therapy depends on nodal involvement, menopausal status, and hormone receptor status. Tamoxifen is a nonsteroidal antiestrogen that binds to estrogen receptors and blocks the effects of estrogens on the growth of malignant cells in the breast. Studies have shown decreased cancer recurrence, decreased mortality rates, and increased 5-year survival rates in women with estrogen receptorpositive tissue samples who have been treated with the drug. Autologous bone marrow transplantation and peripheral stem cell transplantation are experimental therapies that may be used for the treatment of advanced disease or in women at increased risk for recurrence.

In summary, the breasts are subject to benign and malignant disease. Mastitis is inflammation of the breast, occurring most frequently during lactation. Ductal ectasia and intraductal papilloma cause abnormal drainage from the nipple. Fibroadenoma and fibrocystic disease are characterized by abnormal masses in the breast that are benign. By far the most important disease of the breast is breast cancer, which is a significant cause of death of women. BSE and mammography afford a woman the best protection against breast cancer. They provide the means for early detection of breast cancer and, in many cases, allow early treatment and cure.

REVIEW QUESTIONS

List the actions of estrogen and progesterone and explain the interactions among the gonadotropin-releasing hormones, LH, and FSH; ovarian follicle development; and estrogen and progesterone levels.

- Compare the extragenital abnormalities associated with Bartholin cyst and abscess, vulvar dystrophy, vulvodynia, and cancer of the vulva.
- Characterize the development of cervical cancer, from the appearance of atypical cells to the development of invasive cervical cancer, and the role of the Pap smear in early detection.
- State the proposed relationship between unopposed estrogen stimulation of the endometrium and endometrial cancer.
- List the common causes and symptoms of pelvic inflammatory disease.
- State the underlying cause of ovarian cysts.
- Differentiate benign ovarian cyst from polycystic ovary syndrome.
- State the reason that ovarian cancer may be difficult to detect at an early stage.
- Describe the manifestations of cystocele, rectocele, and enterocele.
- Compare the symptoms of primary dysmenorrhea with those of secondary dysmenorrhea.

Characterize the manifestations of the premenstrual syndrome, its possible causes, and the methods of treatment.

Describe the physiology of normal menopause.

Describe changes in breast function that occur with mastitis and ductal ectasia.

Describe the manifestations of fibrocystic disease and state why it is often referred to as a "catchall" for breast irregularities.

CHAPTER

Sexually Transmitted Diseases

Infections of the External Genitalia Human Papillomavirus (Condylomata Acuminata) Genital Herpes Chancroid Lymphogranuloma Venereum Vaginal Infections Candidiasis Trichomoniasis Bacterial Vaginosis (Nonspecific Vaginitis) Vaginal-Urogenital-Systemic Infections Chlamydial Infections Gonorrhea Syphilis

he incidence and types of sexually transmitted diseases (STDs), as reported in the professional literature and public health statistics, are increasing. However, the incidence of disease is based on clinical reports, and many STDs are not reportable or not reported. The agents of transmission include bacteria, chlamydiae, viruses, fungi, protozoa, parasites, and unidentified microorganisms. Portals of entry include the mouth, genitalia, urinary meatus, rectum, and skin. All STDs are more common in persons who have more than one sexual partner, and it is not uncommon for a person to be concurrently infected with more than one type of STD.

This chapter discusses the manifestations of STDs in men and women in terms of infections of the external genitalia, vaginal infections, and infections that have systemic effects and genitourinary manifestations. Human immunodeficiency virus (HIV) infection is presented in Chapter 10.

INFECTIONS OF THE EXTERNAL GENITALIA

Some STDs primarily affect the mucocutaneous tissues of the external genitalia. These include human papillomavirus infection, genital herpes, chancroid, granuloma inguinale, and lymphogranuloma venereum (LGV).

Human Papillomavirus (Condylomata Acuminata)

Condylomata acuminata, or *genital warts*, are caused by the human papillomavirus (HPV). Although recognized for centuries, HPV-induced genital warts have become one of the fastest-growing STDs of the past decade. The Centers for Disease Control and Prevention (CDC) estimates that 20 million Americans carry the virus and that as many as 5.5 million new cases are diagnosed each year.¹ The current prevalence of HPV is difficult to determine because it is not a reportable disease in all states.

A 1998 American Medical Association consensus conference on external genital warts identified four specific types of warts: *condyloma acuminata* (cauliflower-shaped lesions that tend to appear on moist skin surfaces such as the vaginal introitus or anus); *keratotic warts* (display a thick, horny layer; develop on dry, fully keratinized skin such as the penis, scrotum, or labia majora); *papular warts* (smooth surface; typically develop on fully keratinized skin); and *flat warts* (macular, sometimes faintly raised, usually invisible to the naked eye; occur on either fully or partially keratinized skin). Biopsy may be required to differentiate warts from other hyperkeratotic or precancerous lesions.²

A relation between HPV and genital (*i.e.*, cervix, vulva, and penis) neoplasms has become increasingly apparent since the early 1980s. One hundred types of HPV have been identified, more than 30 of which affect the anogenital area. Types 6 and 11 are found in most external genital warts but usually are benign, with only a low potential for dysplasia. Persons with visible genital warts may be infected simultaneously with multiple HPV types. Other HPV types of the anogenital region (*e.g.*, types 16, 18, 31, 33, and 35) have been strongly associated with cervical neoplasia.³ HPV type 16 is present in 50%

KEY CONCEPTS

SEXUALLY TRANSMITTED DISEASE

- Sexually transmitted diseases (STDs) are spread by sexual contact and involve both male and female partners. Portals of entry include the mouth, genitalia, urinary meatus, rectum, and skin. All STDs are more common in persons who have more than one sexual partner, and it is not uncommon for a person to be concurrently infected with more than one type of STD.
- In general, STDs due to bacterial pathogens can be successfully treated and the pathogen eliminated by antimicrobial therapy. However, many of these pathogens are developing antibiotic resistance.
- STDs due to viral pathogens, such as the human papillomavirus (HPV) and genital herpes simplex virus infections (HSV-1 and HSV-2), are not eliminated by current treatment modalities and persist with risk of recurrence (HSV infections) or increased cancer risk (HPV).
- Untreated, STDs such as chlamydial infection and gonorrhea can spread to involve the internal genital organs with risk of complications and infertility.
- Intrauterine or perinatally transmitted STDs can have potentially fatal or severely debilitating effects on a fetus or an infant.

of cervical cancers and in 25% of low-grade cervical intraepithelial neoplasias⁴ (see Chapter 34). However, only a subset of women with HPV go on to develop cancer, suggesting that there may be variants of even the most virulent HPV, type 16, with differing oncogenic potential. Cofactors that may increase the risk for cancer include smoking, immunosuppression, and exposure to hormonal alteration (*e.g.*, pregnancy, oral contraceptives).⁵ The association with premalignant and malignant changes has increased the concern about diagnosis and treatment of this viral infection.

HPV infection begins with viral inoculation into a stratified squamous epithelium, where infection stimulates the replication of the squamous epithelium, producing the various HPV-proliferative lesions. The incubation period for HPVinduced genital warts ranges from 6 weeks to 8 months. Subclinical infection occurs more frequently than visible genital warts among men and women. Infection often is indirectly diagnosed on the cervix by Papanicolaou testing (Pap smear), colposcopy, or biopsy. Both spontaneous resolution and infection with new HPV types are common. Although reinfection from sexual partners has been considered as a reason for the high prevalence of this disease, it is now thought that reinfection with the same HPV type is infrequent. Instead, it is thought that HPV may be a lifelong infection.

Genital condylomas should be considered in any woman who presents with the primary complaint of vulvar pruritus or who has had an abnormal Pap smear. Microscopic examination of a wet-mount slide preparation and cultures are used to exclude associated vaginitis. Acetic acid soaks may be used before inspecting the vulva under magnification, and specimens for biopsy can be taken from questionable areas. Colposcopic examination of the cervix and vagina may be advised as a followup measure when there is an abnormal Pap smear or when HPV lesions are identified on the vulva. Evaluation and treatment of sexual partners may be suggested, although this may be difficult considering that warts often do not become clinically apparent for several years after exposure.

The recent development and controlled trial of a vaccine to protect against HPV type 16 may eventually reduce the risk of cervical cancer associated with this strain of HPV.⁴ However, currently there is no treatment to eradicate the virus once a person has become infected. Thus, treatment goals are aimed at elimination of symptomatic warts, surveillance for malignancy and premalignant changes, and education and counseling to decrease psychosocial distress.⁶ Prevention of HPV transmission through condom use has not been adequately demonstrated.

The CDC recommends several pharmacologic agents for symptomatic removal of visible genital warts, including patientapplied therapies (podofilox and imiquimod) and provideradministered therapies (podophyllin and trichloroacetic acid).³ Podophyllin, a topical cytotoxic agent, has long been used for the treatment of visible external growths. Trichloroacetic acid is a weak destructive agent that produces an initial burning in the affected area, followed in several days by a sloughing of the superficial tissue. Imiquimod cream is a new type of therapeutic agent that stimulates the body's immune system (*i.e.*, production of interferon- α and other cytokines).

Genital warts also may removed using cryotherapy, laser surgery, or electrocautery. Because it can penetrate deeper than other forms of therapy, cryotherapy (*i.e.*, freezing therapy) often is the treatment of choice for cervical HPV lesions. Laser surgery can be used to remove large or widespread lesions of the cervix, vagina, or vulva, or lesions that have failed to respond to other first-line methods of treatment. Electrosurgical treatment has become more widespread for these types of lesions because it is more readily available in outpatient settings and is much less expensive than laser.

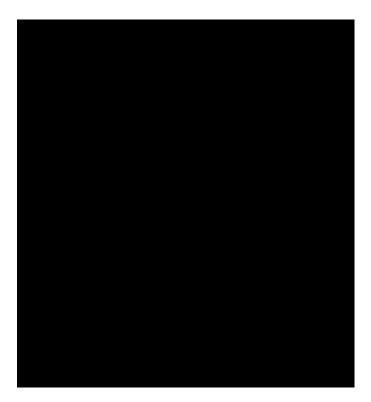

Genital Herpes

Herpesviruses are large, encapsulated viruses that have a doublestranded genome. There are nine types of herpesviruses, belonging to three groups, that cause infections in humans: (1) neurotropic α -group viruses, including herpes simplex virus type 1 (HSV-1; usually associated with cold sores) and HSV-2 (usually associated with genital herpes); (2) varicella-zoster virus (causes chickenpox and shingles); and (3) lymphotropic β -group viruses, including cytomegalovirus (causes cytomegalic inclusion disease), Epstein-Barr virus (causes infectious mononucleosis and Burkitt's lymphoma), and human herpesvirus type 8 (the apparent cause of Kaposi's sarcoma).⁷

Genital herpes is caused by the herpes simplex virus. Because herpesvirus infection is not reportable in all states, reliable data on its true incidence (estimated number of new cases every year) and prevalence (estimated number of people currently infected) are lacking. From the late 1970s to early 1990s, genital herpes prevalence increased 30%. Incidence rates have been relatively stable since 1990, with an estimated 1 million new cases occurring each year. Recent estimates in the United States indicate 50 million people (one in five adolescents or adults) are infected with genital herpes.³ Women have a greater mucosal surface area exposed in the genital area and therefore are at greater risk of acquiring the infection.

HSV-1 and HSV-2 are genetically similar, both cause a similar set of primary and recurrent infections, and both can cause genital lesions. Both viruses replicate in the skin and mucous membranes at the site of infection (oropharynx or genitalia), where they cause vesicular lesions of the epidermis and infect the neurons that innervate the area. HSV-1 and HSV-2 are neurotropic viruses, meaning that they grow in neurons and share the biologic property of latency. Latency refers to the ability to maintain disease potential in the absence of clinical signs and symptoms. In genital herpes, the virus ascends through the peripheral nerves to the sacral dorsal root ganglia (Fig. 35-1). The virus can remain dormant in the dorsal root ganglia, or it can reactivate, in which case the viral particles are transported back down the nerve root to the skin, where they multiply and cause a lesion to develop. During the dormant or latent period, the virus replicates in a different manner so that the immune system or available treatments have no effect on it. It is not known what reactivates the virus. It may be that the body's defense mechanisms are altered. Numerous studies have shown that host responses to infection influence initial development of the disease, severity of infection, development and maintenance of latency, and the frequency of HSV recurrences.

HSV is transmitted by contact with infectious lesions or secretions. HSV-1 is transmitted by oral secretions, and infections frequently occur in childhood, with most persons (50% to 90%) being infected by adulthood.⁸ HSV-1 may be spread to the genital area by autoinoculation after poor hand washing or through oral intercourse. HSV-2 usually is transmitted by sex-

ual contact but can be passed to an infant during childbirth if the virus is actively being shed from the genital tract. Most cases of HSV-2 infection are subclinical, manifesting as truly asymptomatic or symptomatic but unrecognized infections. These subclinical infections can occur in people who have never had a symptomatic outbreak or between recognized clinical recurrences. Up to 70% of genital herpes cases are spread through asymptomatic shedding by people who do not realize they have the infection.³ This "unknown" transmission of the virus to sex partners explains why this infection has reached epidemic proportions throughout the world.

The incubation period for HSV is 2 to 10 days. Genital HSV infection may manifest as a primary, nonprimary, or recurrent infection. *Primary infections* are infections that occur in a person who is seronegative for antibody to HSV-1 or HSV-2. *Initial nonprimary infections* refer to the first clinical episode in a person who is seropositive for antibodies to the opposite HSV type (usually genital herpes in someone seropositive to HSV-1). *Recurrent infections* refer to the second or subsequent outbreak caused by the same virus type. HSV-2 is responsible for more than 90% of recurrent genital herpes infections.⁶

The initial symptoms of primary genital herpes infections include tingling, itching, and pain in the genital area, followed by eruption of small pustules and vesicles. These lesions rupture on approximately the fifth day to form wet ulcers that are excruciatingly painful to touch and can be associated with dysuria, dyspareunia, and urine retention. Involvement of the cervix and urethra is seen in more than 80% of women with primary infections.⁹ In men, the infection can cause urethritis and lesions of the penis and scrotum. Rectal and perianal infections are possible with anal contact. Systemic symptoms associated with primary infections include fever, headache, malaise, muscle ache, and lymphadenopathy. Primary infections may be debilitating enough to require hospitalization, particularly in women.

Untreated primary infections typically are self-limited and last for approximately 2 to 4 weeks. The symptoms usually worsen for the first 10 to 12 days. This period is followed by a 10- to 12-day interval during which the lesions crust over and gradually heal. Nonprimary episodes of genital herpes manifest with less severe symptoms that usually are of shorter duration and have fewer systemic manifestations. Except for the greater tendency of HSV-2 to recur, the clinical manifestations of HSV-2 and genital HSV-1 are similar. Recurrent HSV infection results from reactivation of the virus stored in the dorsal root ganglia of the infected dermatomes. An outbreak may be preceded by a prodrome of itching, burning, or tingling at the site of future lesions. Because immune lymphocytes have already developed from the primary infection, recurrent episodes have fewer lesions, fewer systemic symptoms, less pain, and a shorter duration (7 to 10 days). The frequency and severity of recurrences vary from person to person. Numerous factors, including emotional stress, lack of sleep, overexertion, other infections, vigorous or prolonged coitus, and premenstrual or menstrual distress have been identified as triggering mechanisms.

Diagnosis of genital herpes is based on the symptoms, appearance of the lesions, and identification of the virus from cultures taken from the lesions. The likelihood of obtaining a positive culture decreases with each day that has elapsed after a lesion develops. The chance of obtaining a positive culture from a crusted lesion is slight, and patients suspected of having genital herpes should be instructed to have a culture within 48 hours of development of new lesions. Type specific (HSV-1 and HSV-2) serologic tests are available for determining past infection. Because almost all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibodies usually indicates anogenital infection; whereas the presence of HSV-1 antibodies does not distinguish between anogenital and orolabial infections. The CDC recommends that serologic assays for HSV-2 be available for persons who request them but does not recommend they be used for screening of the general population.³

There is no known cure for genital herpes, and the methods of treatment are largely symptomatic. The antiviral drugs acyclovir, valacyclovir, and famciclovir have become the cornerstone for management of genital herpes. By interfering with viral DNA replication, these drugs decrease the frequency of recurrences, shorten the duration of active lesions, reduce the number of new lesions formed, and decrease viral shedding with primary infections. Good hygiene is essential to prevent secondary HSV infection. Fastidious hand washing is recommended to avoid hand-to-eye spread of the infection. HSV infection of the eye is the most common cause of corneal blindness in the United States. To prevent spread of the disease, intimate contact should be avoided until lesions are completely healed.

Approximately 30% to 50% of infants born vaginally to mothers experiencing a primary HSV infection at the time of delivery will be infected, compared with only 1% of those born to women with recurrent infection.³ The risk of mortality in HSV-infected neonates ranges from 15% to 57%, and a significant number of survivors have significant sequelae.¹⁰ Active infection during labor may necessitate cesarean delivery.

Chancroid

Chancroid (*i.e.*, soft chancre) is a disease of the external genitalia and lymph nodes. The causative organism is the gramnegative bacterium *Haemophilus ducreyi*, which causes acute ulcerative lesions with profuse discharge. This disease has become uncommon in the United States, with only 143 reported cases in 1999.¹ It typically occurs in discrete outbreaks, rather than as an endemic disease in this country. It is more prevalent in Southeast Asia, the West Indies, and North Africa. A highly infectious disease, chancroid usually is transmitted by sexual intercourse or through skin and mucous membrane abrasions. Autoinoculation may lead to multiple chancres.

Lesions begin as macules, progress to pustules, and then rupture. This painful ulcer has a necrotic base and jagged edges. In contrast, the syphilitic chancre is nontender and indurated. Subsequent discharge can lead to further infection of self or others. On physical examination, lesions and regional lymphadenopathy (*i.e.*, buboes) may be found. Secondary infection may cause significant tissue destruction. Diagnosis usually is made clinically but may be confirmed through culture. Gram's stain rarely is used today because it is insensitive and nonspecific. Polymerase chain reaction (PCR) methods may soon be available commercially for definitive identification of *H. ducreyi*. The organism has shown resistance to treatment with sulfamethoxazole alone and to tetracycline. The CDC recommends treatment with azithromycin, erythromycin, ciprofloxacin, or ceftriaxone.³

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is an acute and chronic venereal disease caused by *Chlamydia trachomatis* types L1, L2, and P3. The disease, although found worldwide, has a low incidence outside the tropics. Most cases reported in the United States are in men.

The lesions of LGV can incubate for a few days to several weeks and thereafter cause small, painless papules or vesicles that may go undetected. An important characteristic of the disease is the early (1 to 4 weeks later) development of large, tender, and sometimes fluctuant inguinal lymph nodes called buboes. There may be flulike symptoms with joint pain, rash, weight loss, pneumonitis, tachycardia, splenomegaly, and proctitis. In later stages of the disease, a small percentage of affected persons develop elephantiasis of the external genitalia, caused by lymphatic obstruction or fibrous strictures of the rectum or urethra from inflammation and scarring. Urethral involvement may cause pyuria and dysuria. Cervicitis is a common manifestation of primary LGV and could extend to perimetritis or salpingitis, which are known to occur in other chlamydial infections.⁵ Anorectal structures may be compromised to the point of incontinence. Complications of LGV may be minor or extensive, involving compromise of whole systems or progression to a cancerous state.

Diagnosis usually is accomplished by means of a complement fixation test for LGV-specific *Chlamydia* antibodies. High titers for this antibody differentiate this group from other chlamydial subgroups. Treatment involves 3 weeks of doxycycline or erythromycin.³ Surgery may be required to correct sequelae such as strictures or fistulas or to drain fluctuant lymph nodes.

In summary, STDs that primarily affect the external genitalia include HPV (condyloma acuminata), genital herpes (HSV-2), chancroid, and lymphogranuloma venereum. The lesions of these infections occur on the external genitalia of male and female sexual partners. Of concern is the relation between HPV and genital neoplasms. Genital herpes is caused by a neurotropic virus (HSV-2) that ascends through the peripheral nerves to reside in the sacral dorsal root ganglia. The herpesvirus can be reactivated, producing recurrent lesions in genital structures that are supplied by the peripheral nerves of the affected ganglia. There is no permanent cure for herpes infections. Chancroid and lymphogranuloma venereum produce external genital lesions with various degrees of inguinal lymph node involvement.

VAGINAL INFECTIONS

Candidiasis, trichomoniasis, and bacterial vaginosis are vaginal infections that can be sexually transmitted. Although these infections can be transmitted sexually, the male partner usually is asymptomatic.

Candidiasis

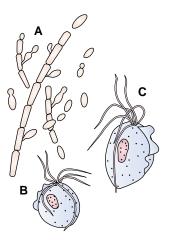

Also called *yeast infection, thrush,* and *moniliasis,* candidiasis is the second leading cause of vulvovaginitis in the United States. Approximately 75% of reproductive-age women in the United

States experience one episode in their lifetime; 40% to 45% experience two or more infections.5

The causative organism is Candida, a genus of yeastlike fungi. The species most commonly identified is Candida albicans, but other candidal species, such as Candida glabrata and Candida tropicalis, have caused symptoms. Although vulvovaginal candidiasis usually is not transmitted sexually, it is included in the CDC STD treatment guidelines because it often is diagnosed in women being evaluated for STDs.3 The possibility of sexual transmission has been recognized for many years; however, candidiasis requires a favorable environment for growth. The gastrointestinal tract also serves as a reservoir for this organism, and candidiasis can develop through autoinoculation in women who are not sexually active. Although studies have documented the presence of Candida on the penis of male partners of women with vulvovaginal candidiasis, few men develop balanoposthitis that requires treatment.

Causes for the overgrowth of C. albicans include antibiotic therapy, which suppresses the normal protective bacterial flora; high hormone levels associated with pregnancy or the use of oral contraceptives, which cause an increase in vaginal glycogen stores; and diabetes mellitus or HIV infection because they compromise the immune system. In obese persons, Candida may grow in skin folds underneath the breast tissue, the abdominal flap, and the inguinal folds. Vulvar pruritus accompanied by irritation, dysuria, dyspareunia, erythema, and an odorless, thick, cheesy vaginal discharge are the predominant symptoms of the infection. Accurate diagnosis is made by identification of budding yeast filaments (*i.e.*, hyphae) or spores on a wet-mount slide using 20% potassium hydroxide (Fig. 35-2). The pH of the discharge, which is checked with litmus paper, typically is less than 4.5. When the wet-mount technique is negative but the clinical manifestations are indicative of candidiasis, a culture may be necessary.

Antifungal agents such as clotrimazole, miconazole, butoconazole, and terconazole, in various forms, are effective in treating candidiasis. These drugs, with the exception of terconazole, are available without prescription for use by women who have had a previously confirmed diagnosis of candidiasis.

■ FIGURE 35-2 ■ Organisms that cause vaginal infections. (A) Candida albicans (blastospores and pseudohyphae). (B, C) Trichomonas vaginalis.

Oral fluconazole has been shown to be as safe and effective as the standard intravaginal regimens.³ Tepid sodium bicarbonate baths, clothing that allows adequate ventilation, and the application of cornstarch to dry the area may increase comfort during treatment. Chronic vulvovaginal candidiasis, defined as four or more mycologically confirmed episodes within 1 year, affects approximately 5% of women and is difficult to manage. Subsequent prophylaxis (maintenance therapy) often is required for the long-term management of this problem.¹¹

Trichomoniasis

An anaerobic protozoan that can be transmitted sexually, Trichomonas vaginalis is shaped like a turnip and has three or four anterior flagella (see Fig. 35-2). Trichomonads can reside in the paraurethral glands of both sexes. Males harbor the organism in the urethra and prostate and are asymptomatic. Although 10% to 25% of women are asymptomatic, trichomoniasis is a common cause of vaginitis when some imbalance allows the protozoan to proliferate. Five million cases of trichomoniasis were diagnosed in 1999.¹ This extracellular parasite feeds on the vaginal mucosa and ingests bacteria and leukocytes. The infection causes a copious, frothy, malodorous, green or yellow discharge. There commonly is erythema and edema of the affected mucosa, with occasional itching and irritation. Sometimes, small hemorrhagic areas, called strawberry spots, appear on the cervix.

Diagnosis is made microscopically by identification of the protozoan on a wet-mount slide preparation. The pH of the discharge usually is greater than 6.0. Special culture media are available for diagnosis but are costly and not needed for diagnosis.

Because the organism resides in urogenital structures other than the vagina, systemic treatment is recommended. The treatment of choice is oral metronidazole (Flagyl), a medication that is effective against anaerobic protozoans.³ Metronidazole is chemically similar to disulfiram (Antabuse), a drug used in the treatment of alcohol addiction that causes nausea, vomiting, flushing of the skin, headache, palpitations, and lowering of the blood pressure when alcohol is ingested. Alcohol should be avoided during and for 24 to 48 hours after treatment. Gastrointestinal disturbances and a metallic taste in the mouth are potential adverse effects of the drug. Metronidazole has not been proven safe for use during pregnancy and is used only after the first trimester for fear of potential teratogenic effects. Sexual partners should be treated to avoid reinfection, and abstinence is recommended until the full course of therapy is completed.

Bacterial Vaginosis (Nonspecific Vaginitis)

Bacterial vaginosis is a vaginal infection that produces a characteristic fishy- or ammonia-smelling discharge yet fails to produce an inflammatory response that is characteristic of most infections.

Bacterial vaginosis represents an upheaval in the complex vaginal bacterial flora with disappearance of the normal lactobacillus species in the vagina and an overgrowth of other organisms, including Gardnerella vaginalis and resident anaerobic vaginal bacterial.¹² It has been suggested that the presence of anaerobes, which produce ammonia or amines from amino

acids, favors the growth of *G. vaginalis* by raising vaginal pH. Because of the presence of anaerobic bacteria and the lack of an inflammatory response, the disorder has come to be called *bacterial vaginosis*.⁵

Bacterial vaginosis is the most prevalent form of vaginal infection seen by health care professionals. Its relation to sexual activity is not clear. Sexual activity is believed to be a catalyst, rather than a primary mode of transmission, and endogenous factors play a role in the development of symptoms. The predominant symptom of bacterial vaginosis is a thin, grayishwhite discharge that has a foul, fishy odor. Burning, itching, and erythema usually are absent because the bacteria has only minimal inflammatory potential. Bacterial vaginosis may be carried asymptomatically by men and women.

The diagnosis is made when at least three of the following characteristics are present: homogeneous, white, noninflammatory discharge that smoothly coats the vaginal walls; production of a fishy, amine odor when a 10% potassium hydroxide solution is dropped onto the secretions; vaginal pH greater than 4.5 (usually 5.0 to 6.0); and the appearance of characteristic "clue cells" on wet-mount microscopic studies.³ *Clue cells* are squamous epithelial cells covered with masses of coccobacilli, often with large clumps of organisms floating free from the cell. Because *G. vaginalis* can be a normal vaginal flora, cultures should not be done routinely.

The mere presence of *G. vaginalis* in an asymptomatic woman is not an indication for treatment. When indicated, treatment is aimed at eradicating the anaerobic component of bacterial vaginosis to re-establish the normal balance of the vaginal flora. The CDC recommends oral metronidazole. Alternative therapies include metronidazole vaginal gel, clindamycin vaginal cream, or oral clindamycin. Treatment of sexual partners is not recommended.³

Bacterial vaginosis is associated with adverse pregnancy outcomes across all gestational ages. It has been linked to first and second trimester fetal losses, preterm delivery, low-birth-weight infants, and maternal/neonatal infections. Oral or cream clindamycin formulations can be used for treatment during the first trimester of pregnancy; oral or vaginal metronidazole can be used after the first trimester for treatment failures.

In summary, candidiasis, trichomoniasis, and bacterial vaginosis are common vaginal infections that become symptomatic because of changes in the vaginal ecosystem. Only trichomoniasis is spread through sexual contact. Trichomoniasis is caused by an anaerobic protozoan. The infection incites the production of a copious, frothy, yellow or green, malodorous discharge. Candidiasis, also called a yeast infection, is the form of vulvovaginitis with which women are most familiar. Candida can be present without producing symptoms; usually some host factor, such as altered immune status, contributes to the development of vulvovaginitis. It often can be treated with over-the-counter medications. Bacterial vaginosis is the most common cause of vaginal discharge. It is a nonspecific type of infection that produces a characteristic fishy-smelling discharge. The infection is thought to be caused by the combined presence of G. vaginalis and anaerobic bacteria. The anaerobe raises the vaginal pH, thereby favoring the growth of G. vaginalis.

VAGINAL-UROGENITAL-SYSTEMIC INFECTIONS

Some sexually transmitted diseases (STDs) infect male and female genital and extragenital structures. Among the infections of this type are chlamydial infections, gonorrhea, and syphilis. Many of these infections also pose a risk to infants born to infected mothers. Syphilis may be spread to the infant while in utero, whereas chlamydial and gonorrheal infections can be spread to the infant during the birth process.

Chlamydial Infections

Chlamydia trachomatis is an obligate intracellular bacterial pathogen that is closely related to gram-negative bacteria. It resembles a virus in that it requires tissue culture for isolation, but like a bacteria, it has RNA and DNA and is susceptible to some antibiotics. C. trachomatis causes a wide variety of genitourinary infections, including nongonococcal urethritis in men and pelvic inflammatory disease (PID) in women. The closely related organisms Chlamydia pneumoniae and Chlamydia psittaci cause mild and severe pneumonia, respectively. C. trachomatis can be serologically subdivided into types A, B, and C, which are associated with trachoma and chronic keratoconjunctivitis; types D through K, which are associated with genital infections and their complications; and types L1, L2, and L3, which are associated with LGV. C. trachomatis can cause significant ocular disease in neonates; it is a leading cause of blindness in underdeveloped countries. In these countries, the organism is spread primarily by flies, fomites, and nonsexual personal contact. In industrial countries, the organism is spread almost exclusively by sexual contact and therefore affects primarily the genitourinary structures.

Chlamydial infection is the most prevalent STD in the United States. Although chlamydial infections are not reportable in all states, their incidence is estimated to be more than twice that of gonorrhea. According to CDC estimates, chlamydial infections occur at a rate of 3 million new cases each year, predominantly among individuals younger than 25 years.¹ Reported rates for chlamydial infections are higher in women, largely because of the increased use of screening tests, although actual occurrence rates are thought to be the same for men and women.¹³ In the United States, costs associated with managing chlamydial infections and their complications exceed \$2 billion annually.¹³ Rates are believed to be declining because of increased efforts to screen and treat this infection.

Chlamydiae exist in two forms: (1) the elementary bodies, which are the infectious particles capable of entering uninfected cells, and (2) the initiator or reticulate bodies, which multiply by binary fission to produce the inclusions identified in stained cells. The 48-hour growth cycle starts with attachment of the elementary body to the susceptible host cell, after which it is ingested by a process that resembles phagocytosis (Fig. 35-3). Once inside the cell, the elementary body is organized into the reticulate body, the metabolically active form of the organism that is capable of reproduction. The reticulate body is not infectious and cannot survive outside the body. The reticulate bodies divide in the cell for as long as 36 hours and then condense to form new elementary bodies, which are released when the infected cell bursts.

In women, chlamydial infections may cause urinary frequency, dysuria, and vaginal discharge. The most common symptom is a mucopurulent cervical discharge. The cervix itself frequently hypertrophies and becomes erythematous, edematous, and extremely friable. Seventy-five percent of women with chlamydial infection have no symptoms; therefore, most cases are undiagnosed, unreported, and untreated.¹³ This can lead to greater fallopian tube damage and increase the reservoir for further chlamydial infections. Approximately 40% of women with an untreated chlamydial infection develop PID, and 1 in 5 of these women becomes infertile. Research has identified a possible link between three specific serotypes of chlamydiae and an increased risk for cervical cancer. The mechanism by which this occurs is unclear.¹⁴

In men, chlamydial infections cause urethritis, including meatal erythema and tenderness, urethral discharge, dysuria, and urethral itching. Prostatitis and epididymitis with subsequent infertility may develop. However, approximately 50% of men are asymptomatic. The most serious complication that can develop with nongonococcal urethritis is Reiter's syndrome, a systemic condition characterized by urethritis, conjunctivitis, arthritis, and mucocutaneous lesions (see Chapter 43).

Routine screening for adolescents and young adults has been suggested by the CDC in an effort to minimize these serious sequelae of asymptomatic infection.³ Between 25% and 50% of infants born to mothers with cervical chlamydial infections develop ocular disease (*i.e.*, inclusion conjunctivitis), and 10% to 20% having chlamydial pneumonitis.

Diagnosis of chlamydial infections takes several forms. The identification of polymorphonuclear leukocytes on Gram's stain of male discharge or cervical discharge is presumptive evidence. The direct fluorescent antibody test and the enzymelinked immunosorbent assay that use antibodies against an antigen in the *Chlamydia* cell wall are rapid tests that are highly sensitive and specific. The positive predictive value of these tests is excellent among high-risk groups, but false-positive results occur more often in populations with lower risks. Amplified DNA probe assays, such as the PCR, ligase chain reaction (LCR), or transcription-mediated amplification (TMA), have demonstrated specificities of near 100%.

The CDC recommends the use of azithromycin or doxycycline as the treatment of choice for chlamydial infection; penicillin is ineffective. Erythromycin or amoxicillin is the preferred choice in pregnancy.³ Antibiotic treatment of both sexual partners simultaneously is recommended. Abstinence from sexual activity is encouraged to facilitate cure.

Gonorrhea

Gonorrhea is a reportable disease caused by the bacterium Neisseria gonorrhoeae. In 1999, there were 360,076 reported cases of gonorrhea in the United States.¹ Of these reported cases, more than 90% involved persons between 15 and 44 years of age, with the heaviest concentration among young adults (15 to 24 years of age).¹³ There are an estimated 600,000 new cases every year.³ Although the incidence of gonorrhea has declined steadily from its peak in 1975, there was an increase in occurrence between 1997 and 1998. Improved screening efforts as well as greater use of more sensitive nonculture methods of testing may have contributed to this increase. Higher rates of occurrence among homosexual men were documented in several states, leading to a concern that an increase in unsafe sexual behavior may be occurring because of the availability of highly active antiretroviral agents for treatment of HIV infection.15

The gonococcus is a pyogenic (*i.e.*, pus-forming), gramnegative diplococcus that evokes inflammatory reactions characterized by purulent exudates. Humans are the only natural host for *N. gonorrhoeae*. The organism grows best in warm, mucus-secreting epithelia. The portal of entry can be the genitourinary tract, eyes, oropharynx, anorectum, or skin.

Transmission usually is by heterosexual or homosexual intercourse. Autoinoculation of the organism to the conjunctiva is possible. Neonates born to infected mothers can acquire the infection during passage through the birth canal and are in danger of experiencing gonorrheal conjunctivitis, with resultant blindness, unless treated promptly. An amniotic infection syndrome characterized by premature rupture of the membranes, premature delivery, and increased risk of infant morbidity and mortality has been identified as an additional complication of gonococcal infections in pregnancy. Genital gonorrhea in young children should raise the possibility of sexual abuse.

The infection commonly manifests 2 to 7 days after exposure. It typically begins in the anterior urethra, accessory urethral glands, Bartholin's or Skene's glands, and the cervix. If untreated, gonorrhea spreads from its initial sites upward into the genital tract. In males, it spreads to the prostate and epididymis; in females, it commonly moves to the fallopian tubes. Pharyngitis may follow oral-genital contact. The organism also can invade the bloodstream (*i.e.*, disseminated gonococcal infection), causing serious sequelae such as bacteremic involvement of joint spaces, heart valves, meninges, and other body organs and tissues.

Persons with gonorrhea may be asymptomatic and may unwittingly spread the disease to their sexual partners. Men are more likely to be symptomatic than women. In men, the initial symptoms include urethral pain and a creamy, yellow, sometimes bloody discharge. The disorder may become chronic and affect the prostate, epididymis, and periurethral glands. Rectal infections are common in homosexual men. In women, recognizable symptoms include unusual genital or urinary discharge, dysuria, dyspareunia, pelvic pain or tenderness, unusual vaginal bleeding (including bleeding after intercourse), fever, and proctitis. Symptoms may occur or increase during or immediately after menses because the bacterium is an intracellular diplococcus that thrives in menstrual blood but cannot survive long outside the human body. There may be infections of the uterus and development of acute or chronic infection of the fallopian tubes (*i.e.*, salpingitis), with ultimate scarring and sterility.

Diagnosis is based on the history of sexual exposure and symptoms. It is confirmed by identification of the organism on Gram's stain or culture. An enzyme immunoassay for detecting gonococcal antigens (Gonozyme) is available but has several requirements that limit its usefulness. Detection by means of amplified DNA probes (PCR, LCR, TMA) is possible using urine and urethral swab specimens. The sensitivity of these probes is similar to that of culture, and they may be cost effective in high-risk populations.

Testing for other STDs, particularly syphilis and chlamydial infections, is suggested at the time of examination. Pregnant women are routinely screened at the time of their first prenatal visit; high-risk populations should have repeat cultures during the third trimester. Neonates are routinely treated with various antibacterial agents applied to the conjunctiva within 1 hour of birth to protect against undiagnosed gonorrhea and other diseases.

Penicillin-resistant strains of *N. gonorrhoeae* are prevalent worldwide, and strains with other kinds of antibiotic resistance continue to evolve and spread. The current treatment recommendation to combat tetracycline- and penicillin-resistant strains of *N. gonorrhoeae* is ceftriaxone in a single injection or cefixime, ciprofloxacin, levofloxacin, or ofloxacin in a single oral dose. All are equally effective and should be followed with azithromycin or doxycycline for chlamydiae. All sex partners 60 days prior to discovery of the infection should be con-

tacted, tested, and treated. Test of cure is not required with observed single-dose therapy. Patients are instructed to refrain from intercourse until therapy is completed and symptoms are no longer present.³

Syphilis

Syphilis is a reportable disease caused by a spirochete, Treponema pallidum. During 1999, 6657 new cases of primary and secondary syphilis were reported in the United States (2.5 per 100,000 population). This is the lowest rate ever reported, and it now appears that syphilis transmission is primarily concentrated in a few geographic areas.¹⁶ This represents a steady decline from the 50,000 cases reached in 1990 after an epidemic resurgence of this problem between 1985 and 1990. Syphilis continues to disproportionately affect minority populations. Although the 1999 rate for blacks declined by 10% from that of the previous year, it was still 30 times the rate reported in whites. The rate for Hispanics increased 20%, primarily among men. The National Plan to Eliminate Syphilis was launched in 1999 with a goal of reducing primary and secondary syphilis to fewer than 1000 cases and increasing the number of syphilisfree counties to 90% by 2005. Federal funding is available to support this effort.16

T. pallidum is spread by direct contact with an infectious, moist lesion, usually through sexual intercourse. Bacteria-laden secretions may transfer the organism during kissing or intimate contact. Skin abrasions provide another possible portal of entry. There is rapid transplacental transmission of the organism from the mother to the fetus after 16 weeks' gestation, so that active disease in the mother during pregnancy can produce congenital syphilis in the fetus. Untreated syphilis can cause prematurity, stillbirth, and congenital defects and active infection in the infant. Once treated for syphilis, a pregnant woman usually is followed up throughout pregnancy by repeat testing of serum titers.

The clinical disease is divided into three stages: primary, secondary, and tertiary. Primary syphilis is characterized by the appearance of a chancre at the site of exposure. Chancres typically appear within 3 weeks of exposure but may incubate for 1 week to 3 months. The primary chancre begins as a single, indurated, button-like papule up to several centimeters in diameter that erodes to create a clean-based ulcerated lesion on an elevated base. These lesions usually are painless and located at the site of sexual contact. Primary syphilis is readily apparent in the male, where the lesion is on the penis or scrotum. Although chancres can develop on the external genitalia in females, they are more common on the vagina or cervix, so primary syphilis may go untreated. There usually is an accompanying regional lymphadenopathy. The disease is highly contagious at this stage, but because the symptoms are mild, it frequently goes unnoticed. The chancre usually heals within 3 to 12 weeks, with or without treatment.

The timing of the second stage of syphilis varies even more than that of the first, lasting from 1 week to 6 months. The symptoms of a rash (especially on the palms and soles), fever, sore throat, stomatitis, nausea, loss of appetite, and inflamed eyes may come and go for a year but usually last for 3 to 6 months. Secondary manifestations may include alopecia and genital condylomata lata. Condylomata lata are elevated, redbrown lesions that may ulcerate and produce a foul discharge.

After the second stage, syphilis frequently enters a latent phase that may last the lifetime of the person or progress to tertiary syphilis at some point. Persons can be infective during the first 1 to 2 years of latency.

Tertiary syphilis is a delayed response of the untreated disease. It can occur as long as 20 years after the initial infection. Only approximately one third of those with untreated syphilis progress to the tertiary stage of the disease, and symptoms develop in approximately one half of these. Approximately one third undergo spontaneous cure, and the remaining one third continue to have positive serologic tests but do not have structural lesions.¹⁷ When syphilis does progress to the symptomatic tertiary stage, it commonly takes one of three forms: (1) development of localized destructive lesions called gummas, (2) development of cardiovascular lesions, or (3) development of central nervous system lesions. The syphilitic gumma is a peculiar, rubbery, necrotic lesion that is caused by noninflammatory tissue necrosis. Gummas can occur singly or multiply and vary in size from microscopic lesions to large, tumorous masses. They most commonly are found in the liver, testes, and bone. Central nervous system lesions can produce dementia, blindness, or injury to the spinal cord, with ataxia and sensory loss (*i.e.*, tabes dorsalis). Cardiovascular manifestations usually result from scarring of the medial layer of the thoracic aorta with aneurysm formation. These aneurysms produce enlargement of the aortic valve ring with aortic valve insufficiency.

T. pallidum does not produce endotoxins or exotoxins but evokes a humoral immune response that provides the basis for serologic tests. Two types of antibodies-nonspecific and specific—are produced. The nonspecific antibodies can be detected by flocculation tests such as the Venereal Disease Research Laboratory (VDRL) test or the rapid plasma reagin (RPR) test. Because these tests are nonspecific, positive results can occur with diseases other than syphilis. The tests are easy to perform, rapid, and inexpensive and frequently are used as screening tests for syphilis. Results become positive 4 to 6 weeks after infection or 1 to 3 weeks after the appearance of the primary lesion. Because these tests are quantitative, they can be used to measure the degree of disease activity or treatment effectiveness. The VDRL titer usually is high during the secondary stage of the disease and becomes less so during the tertiary stage. A falling titer during treatment suggests a favorable response. The fluorescent treponemal antibody absorption test or microhemagglutinin test is used to detect specific antibodies to T. pallidum. These qualitative tests are used to determine whether a positive result on a nonspecific test such as the VDRL is attributable to syphilis. The test results remain positive for life.

T. pallidum cannot be cultured. The diagnosis of syphilis is based on serologic tests or dark-field microscopic examination with identification of the spirochete in specimens collected from lesions. Because the disease's incubation period may delay test sensitivity, serologic tests usually are repeated after 6 weeks if the initial test results were negative.

The treatment of choice for syphilis is penicillin.³ Because of the spirochetes' long generation time, effective tissue levels of penicillin must be maintained for several weeks. Long-acting injectable forms of penicillin are used. Tetracycline or doxycycline is used for treatment in persons who are sensitive to penicillin. Pregnant patients should be desensitized and treated

with penicillin because erythromycin does not treat fetal infection. Sexual partners should be evaluated and treated prophylactically even though they may show no sign of infection. All treated individuals should be re-examined clinically and serologically at 6 and 12 months after completing therapy; more frequent monitoring (3-month intervals) is suggested for individuals with HIV infection.3

In summary, the vaginal-urogenital-systemic STDschlamydial infections, gonorrhea, and syphilis-can severely involve the genital structures and manifest as systemic infections. Gonorrheal and chlamydial infections can cause a wide variety of genitourinary complications in men and women, and both can cause ocular disease and blindness in neonates born to infected mothers. Syphilis is caused by a spirochete, T. pallidum. It can produce widespread systemic effects and is transferred to the fetus of infected mothers through the placenta.

REVIEW QUESTIONS

- Define what is meant by a sexually transmitted disease (STD) and cite the common portals of entry for STDs.
- State the significance of infection with the human papillomavirus.
- Explain the recurrent infections in genital herpes.
- Compare the signs and symptoms of infections caused by Candida albicans, Trichomonas vaginalis, and bacterial vaginosis.
- Compare the signs and symptoms of gonorrhea in the male and female.
- State the genital and nongenital complications that can occur with chlamydial infections, gonorrhea, and syphilis.

he nervous system, in coordination with the endocrine system, provides the means by which cell and tissue functions are integrated into a solitary, surviving organism. It controls skeletal muscle movement and helps to regulate cardiac and visceral smooth muscle activity. The nervous system enables the reception, integration, and perception of sensory information; it provides the substratum necessary for intelligence, anticipation, and judgment; and it facilitates adjustment to an ever-changing external environment.

NERVOUS TISSUE CELLS

The nervous system can be divided into two parts: the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain and spinal cord, which is

protected by the skull and vertebral column. The PNS is found outside these structures. Inherent in the basic design of the nervous system is the provision for the concentration of computational and control functions in the CNS. In this design, the PNS functions as an input-output system for relaying input to the CNS and for transmitting output messages that control effector organs, such as muscles and glands.

Nervous tissue contains two types of cells: neurons and supporting cells. The neurons are the functional cells of the nervous system. They exhibit membrane excitability and conductivity and secrete neurotransmitters and hormones, such as epinephrine and antidiuretic hormone. The supporting cells, such as Schwann cells in the PNS and the glial cells in the CNS, protect the nervous system and provide metabolic support for the neurons.

Neurons

The functioning cells of the nervous system are called *neurons*. Neurons have three distinct parts: the soma or cell body and its cytoplasm-filled processes, the dendrites and axons (Fig. 36-1). These processes form the functional connections, or synapses, with other nerve cells, with receptor cells, or with effector cells. Axonal processes are particularly designed for rapid communication with other neurons and the many body structures innervated by the nervous system. Afferent, or sensory, neurons transmit information from the PNS to the CNS. Efferent neurons, or motoneurons, carry information away from the CNS (Fig. 36-1). Interspersed between the afferent and efferent neurons is a network of interconnecting neurons (interneurons or internuncial neurons) that modulate and control the body's response to changes in the internal and external environments.

The cell body of a neuron contains a large, vesicular nucleus with one or more distinct nucleoli and a well-developed rough endoplasmic reticulum. A neuron's nucleus has the same DNA

KEY CONCEPTS

THE STRUCTURAL ORGANIZATION OF THE NERVOUS SYSTEM

- The nervous system is divided into two parts: the CNS, which consists of the brain and spinal cord, and the PNS, which contains the input and output neurons that lie outside the CNS.
- The neurons, which are functioning cells of the nervous system, consist of a cell body with cytoplasmfilled processes, the dendrites, and the axons, which form the functional connections with other nerve or effector cells.
- There are two types of neurons: afferent neurons or sensory neurons, which carry information to the CNS, and efferent neurons or motoneurons, which carry information from the CNS to the effector organs.

and genetic code content that is present in other cells of the body, and its nucleolus, which is composed of portions of several chromosomes, produces RNA associated with protein synthesis. The cytoplasm contains large masses of ribosomes that are prominent in most neurons. These acidic RNA masses, which are involved in protein synthesis, stain as dark Nissl bodies with basic histologic stains (see Fig. 36-1).

The dendrites (*i.e.*, "treelike") are multiple, branched extensions of the nerve cell body; they conduct information toward the cell body and are the main source of information for the neuron. The dendrites and cell body are studded with synaptic terminals that communicate with axons and dendrites of other neurons.

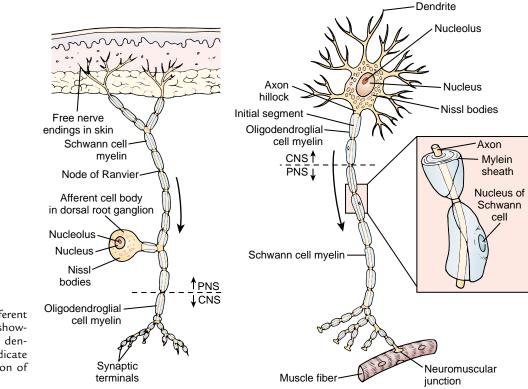

Axons are long efferent processes that project from the cell body and carry impulses away from the cell. Most neurons have only one axon; however, axons may exhibit multiple branching that results in many axonal terminals. The cytoplasm of the cell body extends to fill the dendrites and the axon. The proteins and other materials used by the axon are synthesized in the cell body and then flow down the axon through its cytoplasm.

The cell body of the neuron is equipped for a high level of metabolic activity. This is necessary because the cell body must synthesize the cytoplasmic and membrane constituents required to maintain the function of the axon and its terminals. Some of these axons extend for a distance of 1 to 1.5 m and have a volume that is 200 to 500 times greater than the cell body itself. Two axonal transport systems, one slow and one rapid, move molecules from the cell body through the cytoplasm of the axon to its terminals. Replacement proteins and nutrients slowly diffuse from the cell body, where they are synthesized, down the axon, moving at the rate of approximately 1 mm/day. Other molecules, such as some neurosecretory granules (e.g., neurotransmitters, neuromodulators, and neurohormones) or their precursors, are conveyed by a rapid, energy-dependent active transport system, moving at the rate of approximately 400 mm/day. For example, antidiuretic hormone and oxytocin, which is synthesized by neurons in the hypothalamus, is carried by rapid axonal transport to the posterior pituitary, where the hormones are released into the blood. A reverse rapid (*i.e.*, retrograde) axonal transport system moves materials, including target cell messenger molecules, from axonal terminals back to the cell body.

Supporting Cells

Supporting cells of the nervous system, the Schwann and satellite cells of the PNS and the several types of glial cells of the CNS, give the neurons protection and metabolic support. The supporting cells segregate the neurons into isolated metabolic compartments, which are required for normal neural function. Astrocytes, together with the tightly joined endothelial cells of the capillaries in the CNS, contribute to what is called the *blood-brain barrier*. This term is used to emphasize the impermeability of the nervous system to large or potentially harmful molecules.

The many-layered myelin wrappings of Schwann cells of the PNS and the oligodendroglia of the CNS produce the myelin sheaths that serve to increase the velocity of nerve impulse conduction in axons. Myelin has a high lipid content, which gives

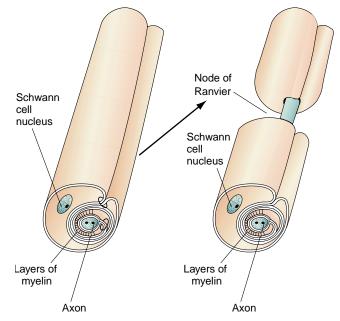

■ FIGURE 36-1 ■ (A) Afferent and (B) efferent neurons, showing the soma or cell body, dendrites, and axon. Arrows indicate the direction for conduction of action potential.

it a whitish color, and the name white matter is given to the masses of myelinated fibers of the spinal cord and brain. Besides its role in increasing conduction velocity, the myelin sheath is essential for the survival of larger neuronal processes, perhaps by the secretion of neurotrophic compounds. In some pathologic conditions, such as multiple sclerosis in the CNS and Guillain-Barré syndrome in the PNS, the myelin may degenerate or be destroyed, leaving a section of the axonal process without myelin while leaving the nearby Schwann or oligodendroglial cells intact. Unless remyelination takes place, the axon eventually dies.

Supporting Cells of the Peripheral Nervous System

Schwann cells and satellite cells are the two types of supporting cells in the PNS. Normally, the nerve cell bodies in the PNS are collected into ganglia, such as the dorsal root and autonomic ganglia. The cell bodies and processes of the peripheral nerves are separated from the connective tissue framework of the ganglion by a single layer of flattened capsular cells called *satellite cells*. Satellite cells secrete a basement membrane that protects the cell body from the diffusion of large molecules.

The processes of larger afferent and efferent neurons are surrounded by the cell membrane and cytoplasm of Schwann cells, which are close relatives of the satellite cells. During myelination, the Schwann cell wraps around the nerve process many times in a "jelly roll" fashion (Fig. 36-2). Schwann cells line up along the neuronal process, and each of these cells forms its own discrete myelin segment. The end of each myelin segment attaches to the cell membrane of the axon by means

■ FIGURE 36-2 ■ The Schwann cell forms a myelin sheath around the larger nerve fibers in the peripheral nervous system. During myelination, the Schwann cell wraps around the nerve process many times in a "jelly roll" fashion. The end of each myelin segment attaches to the cell membrane of the axon by means of intercellular junctions. Successive Schwann cells are separated by short extracellular fluid gaps called the *nodes of Ranvier*, where the myelin is missing and the voltage-gated sodium channels are concentrated.

640 Unit Ten: Alterations in the Nervous System

of intercellular junctions. Successive Schwann cells are separated by short extracellular fluid gaps called the *nodes of Ranvier*, where the myelin is missing and voltage-gated sodium channels are concentrated. The nodes of Ranvier increase nerve conduction by allowing the impulse to jump from node to node through the extracellular fluid in a process called *saltatory conduction* (from the Latin *saltare*, "to jump"). In this way, the impulse can travel more rapidly than it could if it were required to move systematically along the entire nerve process. This increased conduction velocity greatly reduces reaction time, or time between the application of a stimulus and the subsequent motor response. The short reaction time is of particular importance in peripheral nerves with long distances (sometimes 1 to 1.5 m) for conduction between the CNS and distal effector organs.

Each of the Schwann cells along a peripheral nerve is encased in a continuous tube of basement membrane, which in turn is surrounded by a multilayered sheath of loose connective tissue known as the *endoneurium* (Fig. 36-3). The endoneurial sheath, which is essential to the regeneration of injured peripheral nerves, provides a collagenous tube through which a regenerating axon can again reach its former target. The endoneurial sheath does not penetrate the CNS. The absence of the endoneurial sheath is thought to be a major factor in the limited axonal regeneration of CNS nerves compared with those of the PNS.

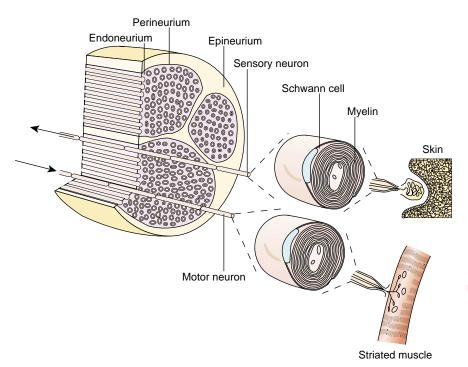

The endoneurial sheaths are bundled with blood vessels into small bundles or clusters of nerves called *fascicles*. In the nerve, the fascicles consisting of bundles of nerve fibers are surrounded by another protective covering called the *perineurium*. Usually, several fascicles are further surrounded by the heavy, protective *epineurial sheath* of the peripheral nerve. The protective layers that surround the peripheral nerve processes are continuous with the connective tissue capsule of the sensory nerve endings and the connective tissue that surrounds the effector structures, such as the skeletal muscle cell. Centrally, the connective tissue layers continue along the dorsal and ventral roots of the nerve and fuse with the meninges that surround the spinal cord and brain.

Supporting Cells of the Central Nervous System

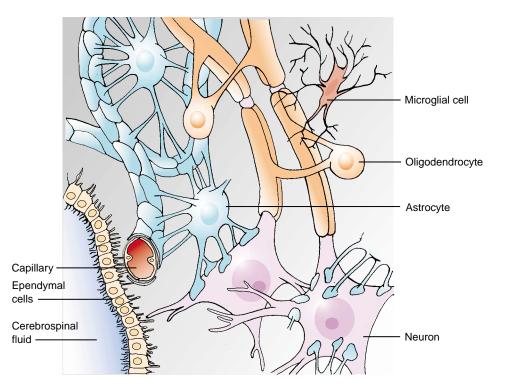

Supporting cells of the CNS consist of the oligodendroglia, astroglia, microglia, and ependymal cells (Fig. 36-4). The *oligodendroglial* cells form the myelin in the CNS. Instead of forming a myelin covering for a single axon, these cells reach out with several processes, each wrapping around and forming a multilayered myelin segment around several different axons. The coverings of axons in the CNS function in increasing the velocity of nerve conduction, similar to the peripheral myelinated fibers.

A second type of glial cell, the *astroglia*, is particularly prominent in the gray matter of the CNS. These large cells have many processes, some reaching to the surface of the capillaries, others reaching to the surface of the nerve cells, and still others filling most of the intercellular space of the CNS. The astrocytic linkage between the blood vessels and the neurons may provide a transport mechanism for the exchange of oxygen, carbon dioxide, and metabolites. The astrocytes also have an important role in sequestering cations such as calcium and potassium from the intercellular fluid. Astrocytes can fill their cytoplasm with microfibrils (*i.e.*, fibrous astrocytes), and masses of these cells form the special type of scar tissue called *gliosis* that develops in the CNS when tissue is destroyed.

A third type of glial cell, the *microglia*, is a small phagocytic cell that is available for cleaning up debris after cellular damage, infection, or cell death. The fourth type of cell, the *ependymal* cell, forms the lining of the neural tube cavity, the ventricular system. In some areas, these cells combine with a rich vascular network to form the *choroid plexus*, where production of the cerebrospinal fluid (CSF) takes place.

Metabolic Requirements of Nervous Tissue

Nervous tissue has a high rate of metabolism. Although the brain comprises only 2% of the body's weight, it receives approximately 15% of the resting cardiac output and consumes 20% of its oxygen. Despite its substantial energy requirements, the brain can neither store oxygen nor engage in anaerobic metabolism. An interruption in the blood or oxygen supply to the brain rapidly leads to clinically observable signs and symptoms. Without oxygen, brain cells continue to function for approximately 10 seconds. Unconsciousness occurs almost simultaneously with cardiac arrest, and the death of brain cells begins within 4 to 6 minutes. Interruption of blood flow also leads to the accumulation of metabolic by-products that are toxic to neural tissue.

Glucose is the major fuel source for the nervous system, but neurons have no provision for storing glucose. Ketones can provide for limited temporary energy requirements; however, these sources are rapidly depleted. Unlike muscle cells, neurons have no glycogen stores and must rely on glucose from the blood or the glycogen stores of supporting glial cells. Persons receiving insulin for diabetes may experience signs of neural dysfunction and unconsciousness (*i.e.*, insulin reaction or shock) when blood glucose drops because of insulin excess (see Chapter 32).

In summary, nervous tissue is composed of two types of cells: neurons and supporting cells. Neurons are composed of three parts: a cell body, which controls cell activity; the dendrites, which conduct information toward the cell body; and the axon, which carries impulses from the cell body. The supporting cells consist of Schwann and satellite cells of the PNS and the glial cells of the CNS. Supporting cells protect and

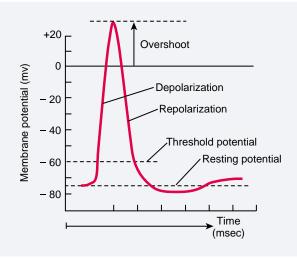

provide metabolic support for the neurons and aid in segregating them into isolated compartments, which is necessary for normal neuronal function. The Schwann cells of the PNS and the oligodendroglial cells of the CNS form the myelin sheath that allows for rapid conduction of impulses. The nervous system has a high level of metabolic activity, requiring a continuous supply of oxygen and glucose. Although the brain comprises only 2% of the body's weight, it receives approximately 15% of the resting cardiac output and consumes 20% of its oxygen.

NERVE CELL COMMUNICATION

Neurons are characterized by the ability to communicate with other neurons and body cells through pulsed electrical signals called *impulses*. An impulse, or action potential (discussed in Chapter 1), represents the movement of electrical charge along the axon membrane. This phenomenon, sometimes called *conductance*, is based on the rapid flow of charged ions through the plasma membrane. In excitable tissue, ions such as sodium, potassium, and calcium move through the membrane channels and carry the electrical charges involved in the initiation and transmission of such impulses.

Action Potentials

Nerve signals are transmitted by action potentials, which are abrupt, pulsatile changes in the membrane potential that last a few ten thousandths to a few thousandths of a second. Action potentials can be divided into three phases: the resting or polarized state, depolarization, and repolarization (Fig. 36-5).

■ **FIGURE 36-5** ■ Time course of the action potential recorded at one point of an axon with one electrode inside and one on the outside of the plasma membrane.

The *resting membrane potential* represents the undisturbed period of the action potential during which the nerve is not transmitting impulses. During this time the inside of the membrane is negatively charged with respect to the outside, and the membrane is said to be *polarized*. The resting phase of the membrane potential continues until some event causes the membrane to increase its permeability to sodium. The *threshold potential* represents the membrane potential at which neurons or other excitable tissues are stimulated to fire. When the threshold potential is reached, the gatelike structures in the ion channels open. The gates are either fully open or fully closed (all-or-none). Under ordinary circumstances, the threshold stimulus is sufficient to open large numbers of ion channels, triggering massive depolarization of the membrane (the action potential).

Depolarization is characterized by the flow of electrically charged ions and the reversal of the membrane potential. During the depolarization phase, the membrane suddenly becomes permeable to sodium ions. The rapid inflow of sodium ions produces local currents that travel through the adjacent cell membrane, causing the sodium channels in this part of the membrane to open. Thus, the impulse moves longitudinally along the nerve, moving from one part of the axon to another. Repolarization is the phase during which the polarity of the resting membrane potential is re-established. This is accomplished with closure of the sodium channels and opening of the potassium channels. The outflow of positively charged potassium ions across the cell membrane returns the membrane potential to negativity. The sodium-potassium pump gradually re-establishes the resting ionic concentrations on each side of the membrane.

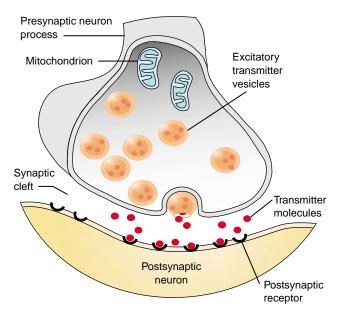

The excitability of neurons can be affected by conditions that alter the resting membrane potential, moving it either closer to or further from the threshold potential. *Hypopolarization* increases the excitability of the postsynaptic neuron by bringing the membrane potential closer to the threshold potential so that a smaller subsequent stimulus is needed to cause the neuron to fire. *Hyperpolarization* brings the membrane potential further from threshold and has the opposite effect. It has an inhibitory effect and decreases the likelihood that an action potential will be generated.

Synaptic Transmission

Neurons communicate with each other through structures known as synapses. Two types of synapses are found in the nervous system: electrical and chemical. *Electrical synapses* permit the passage of current-carrying ions through small openings called *gap junctions* that penetrate the cell junction of adjoining cells and allow current to travel in either direction. The gap junctions allow an action potential to pass directly and quickly from one neuron to another. They may link neurons having close functional relationships into circuits.

The most common type of synapse is the *chemical synapse*. Chemical synapses involve special presynaptic and postsynaptic membrane structures, separated by a synaptic cleft (Fig. 36-6). The presynaptic terminal secretes one and often several chemical transmitter molecules (i.e., neurotransmitters or neuromodulators) into the synaptic cleft. The neurotransmitters diffuse into the synaptic cleft and unite with receptors on the postsynaptic membrane. In contrast to an electrical synapse, a chemical synapse serves as a rectifier, permitting only one-way communication. One-way conduction is a particularly important characteristic of chemical synapses. Chemical synapses are divided into two types: excitatory and inhibitory. In excitatory synapses, binding of the neurotransmitter to the receptor produces depolarization of the postsynaptic membrane. Binding of the neurotransmitter to the receptor in an inhibitory synapse reduces the postsynaptic neuron's ability to generate an action potential. Most inhibitory neurotransmitters induce hyperpolarization of the postsynaptic membrane by making the membrane more permeable to potassium or chloride, or both (see Chapter 6).

Chemical synapses are the slowest component in progressive communication through a sequence of neurons, such as in

■ FIGURE 36-6 ■ A chemical synapse showing the synaptic vesicles in the presynaptic neuron, release of the transmitter, and binding of the transmitter to the receptors on the membrane surface of the postsynaptic neuron.

a spinal reflex. In contrast to the conduction of electrical action potentials, each successive event at the chemical synapse transmitter secretion, diffusion across the synaptic cleft, interaction with postsynaptic receptors, and generation of a subsequent action potential in the postsynaptic neuron—consumes time. On average, conduction across a chemical synapse requires approximately 0.3 milliseconds.

A neuron's cell body and dendrites are covered by thousands of synapses, any or many of which can be active at any moment. Because of the interaction of this rich synaptic input, each neuron resembles a little integrator, in which circuits of many neurons interact with one another. It is the complexity of these interactions and the subtle integrations involved in producing behavorial responses that gives the system its intelligence.

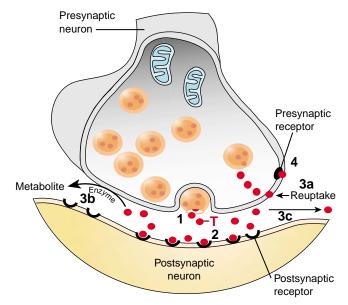

Messenger Molecules

Neurotransmitters are the chemical messenger molecules of the nervous system. The messenger molecules of the nervous system include the neurotransmitters, neurohumoral mediators such as epinephrine, neuromodulators, and neurotrophic or nerve growth factors.

Neurotransmitters are small molecules that incorporate a positively charged nitrogen atom; they include several amino acids, peptides, and monoamines. Amino acids are the building blocks of proteins and are present in body fluids. Peptides are low-molecular-weight molecules that are made up of two or more amino acids. They include substance P and the endorphins and enkephalins, which are involved in pain sensation and perception (see Chapter 39). A monoamine is an amine molecule containing one amino group (NH₂). Serotonin, dopamine, norepinephrine, and epinephrine are monoamines synthesized from amino acids. Fortunately, the blood-brain barrier protects the nervous system from circulating amino acids and other molecules with potential neurotransmitter activity.

The process of neurotransmission involves the synthesis, storage, and release of a neurotransmitter; the reaction of the neurotransmitter with a receptor; and termination of the receptor action (Fig. 36-7). Neurotransmitters are synthesized in the cytoplasm of the axon terminal. The synthesis of transmitters may require one or more enzyme-catalyzed steps (e.g., one for acetylcholine and three for norepinephrine). Neurons are limited as to the type of transmitter they can synthesize by their enzyme systems. After synthesis, the neurotransmitter molecules are stored in the axon terminal in tiny, membrane-bound sacs called synaptic vesicles. There may be thousands of vesicles in a single terminal, each containing 10,000 to 100,000 transmitter molecules. The vesicle protects the neurotransmitters from enzyme destruction in the nerve terminal. The arrival of an impulse at a nerve terminal causes the vesicles to move to the cell membrane and release their transmitter molecules into the synaptic space.

Neurotransmitters exert their actions through specific proteins, called *receptors*, embedded in the postsynaptic membrane. These receptors are tailored precisely to match the size and shape of the transmitter. In each case, the interaction between a transmitter and receptor results in a specific physiologic response. The action of a transmitter is determined by the type of receptor (excitatory or inhibitory) to which it binds. For example, acetylcholine is excitatory when it is released at a myoneural junction, and it is inhibitory when it is released at the sinoatrial node in the heart. Receptors are named according to the type of

■ FIGURE 36-7 ■ Schematic illustration of (1) neurotransmitter (T) release; (2) binding of transmitter to postsynaptic receptor; termination of transmitter action by (3a) reuptake of transmitter into the presynaptic terminal, (3b) enzymatic degradation, or (3c) diffusion away from the synapse; and (4) binding of transmitter to presynaptic receptors for feedback regulation of transmitter release.

neurotransmitter with which they interact. For example, a *cholinergic receptor* is a receptor that binds acetylcholine.

Rapid removal of a transmitter, once it has exerted its effects on the postsynaptic membrane, is necessary to maintain precise control of neural transmission. A released transmitter can undergo one of three fates: it can be broken down into inactive substances by enzymes; it can be taken back up into the presynaptic neuron in a process called *reuptake*; or it can diffuse away into the intercellular fluid until its concentration is too low to influence postsynaptic excitability. For example, acetylcholine is rapidly broken down by acetylcholinesterase into acetic acid and choline, with the choline being taken back into the presynaptic neuron for reuse in acetylcholine synthesis. The catecholamines are largely taken back into the neuron in an unchanged form for reuse. Catecholamines also can be degraded by enzymes in the synaptic space or in the nerve terminals.

Neurohumoral mediators reach their target cells through the bloodstream and produce an even slower action than do the neuromodulators. Both the nervous system and the endocrine system use chemical molecules as messengers. As more information is obtained about the chemical messengers of these systems, the distinction between them becomes less evident. Many neurons, such as those in the adrenal medulla, secrete transmitters into the bloodstream, and it has been found that other neurons possess receptor sites for hormones. Many hormones have turned out to be neurotransmitters. Vasopressin (also known as *antidiuretic hormone*), a peptide hormone released from the posterior pituitary gland, acts as a hormone in the kidney and as a neurotransmitter for nerve cells in the hypothalamus. More than a dozen of these cell-to-cell and blood-borne messengers can relay signals in the nervous system or the endocrine system.

Other classes of messenger molecules, known as *neuro-modulators*, also may be released from axon terminals. Neuro-modulator molecules react with presynaptic or postsynaptic

644 Unit Ten: Alterations in the Nervous System

receptors to alter the release of or response to neurotransmitters. Neuromodulators may act on postsynaptic receptors to produce slower and longer-lasting changes in membrane excitability. This alters the action of the faster-acting neurotransmitter molecules by enhancing or decreasing their effectiveness. By combining with autoreceptors on its own presynaptic membrane, a transmitter can act as a neuromodulator to augment or inhibit further nerve activity. In some nerves, such as the peripheral sympathetic nerves, a messenger molecule can have both transmitter and modulator functions. For example, norepinephrine can activate an α_1 -adrenergic postsynaptic receptor to produce vasoconstriction or stimulate an α_2 -adrenergic presynaptic receptor to inhibit further norepinephrine release.

Neurotrophic or *nerve growth factors* are required to maintain the long-term survival of the postsynaptic cell and are secreted by axon terminals independent of action potentials. Examples include neuron-to-neuron trophic factors in the sequential synapses of CNS sensory neurons. Trophic factors from target cells that enter the axon and are necessary for the long-term survival of presynaptic neurons also have been demonstrated. Target cell-to-neuron trophic factors probably have great significance in establishing specific neural connections during normal embryonic development.

In summary, neurons are characterized by the ability to communicate with other neurons and body cells through pulsed electrical signals called *action potentials*. The cell membranes of neurons contain ion channels that are responsible for generating action potentials. Action potentials are divided into three parts: (1) the resting membrane potential, during which the membrane is polarized but no electrical activity occurs; the (2) depolarization phase, during which sodium channels open, allowing rapid inflow of the sodium ions that generate the electrical impulse; and (3) the repolarization phase, during which the membrane is permeable to the potassium ion, allowing for the efflux of potassium ions and return to the resting membrane potential.

Synapses are structures that permit communication between neurons. Two types of synapses have been identified: electrical and chemical. Electrical synapses consist of gap junctions between adjacent cells that allow action potentials to move rapidly from one cell to another. Chemical synapses involve special presynaptic and postsynaptic structures, separated by a synaptic cleft. They rely on chemical messengers, released from the presynaptic neuron, that cross the synaptic cleft and then interact with receptors on the postsynaptic neuron.

Neurotransmitters are chemical messengers that control neural function; they selectively cause excitation or inhibition of action potentials. Three major types of neurotransmitters are known: amino acids such as glutamic acid and GABA, peptides such as the endorphins and enkephalins, and monoamines such as epinephrine and norepinephrine. Neurotransmitters interact with cell membrane receptors to produce either excitatory or inhibitory actions. Neuromodulators are chemical messengers that react with membrane receptors to produce slower and longer-acting changes in membrane permeability. Neurotrophic or growth factors, also released from presynaptic terminals, are required to maintain the long-term survival of postsynaptic neurons.

DEVELOPMENT AND ORGANIZATION OF THE NERVOUS SYSTEM

The development of the nervous system can be traced far back into evolutionary history. During its development, newer functional features and greater complexity resulted from the modification and enlargement of more primitive structures. Survival of the species depended on the rapid reaction to environmental danger, to potential food sources, or to a sexual partner.

The front, or *rostral*, end of the CNS became specialized for sensing the external environment and controlling reactions to it. In time, the ancient organization, which is largely retained in the spinal cord segments, was expanded in the forward segments of the nervous system. Of these, the most forward segments have undergone the most radical modification and have developed into the forebrain: the diencephalon and the cerebral hemispheres. The dominance of the front end of the CNS is reflected in a hierarchy of control levels: brain stem over spinal cord, and forebrain over brain stem. Throughout evolution, newer functions were added to the surface of functionally more ancient systems. As newer functions became concentrated at the rostral end of the nervous system, they also became more vulnerable to injury.

Embryonic Development

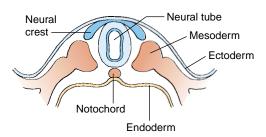

The nervous system appears very early in embryonic development (week 3). This early development is essential because it influences the development and organization of many other body systems, including the axial skeleton, skeletal muscles, and sensory organs such as the eyes and ears. During later fetal life and thereafter, the nervous system provides communication, signal processing, integrative, and memory functions. The early induction and later lifelong communication functions of the nervous system are at the center of the integrity, survival, and individuality of each person.

All body tissues and organs have developed from the three embryonic layers (*i.e.*, endoderm, ectoderm, and mesoderm) that were present during the third week of embryonic life (Fig. 36-8). The body is organized into the soma and viscera.

KEY CONCEPTS

HIERARCHY OF NERVOUS SYSTEM CONTROL

- No part of the nervous system functions independently of other parts.
- Progressively greater complexity in the responses and greater precision in their control occur at each higher level of the nervous system.
- The more rostral, recently developed parts of the neural tube gain dominance or control over lower levels.
- As newer functions became concentrated at the rostral end of the nervous system, they also became more vulnerable to injury.

■ FIGURE 36-8 ■ Transverse section of a 22-23-day-old embryo showing the ectoderm, mesoderm, endoderm, neural crest cells, notocord, and neural tube. During development, the neural tube develops into the CNS and the notocord becomes the foundation upon which the vertebral column develops. The neural crest cells become the progenitors of the neurons and supporting cells of the peripheral nervous system.

The soma, or body wall, includes all of the structures derived from the embryonic ectoderm, such as the epidermis of the skin and the CNS. The mesodermal connective tissues of the soma include the dermis of the skin, skeletal muscle, bone, and the outer lining of the body cavity (*i.e.*, parietal pleura and peritoneum). The nervous system innervates all somatic structures as well as the internal structures making up the viscera. The viscera includes the great vessels derived from the intermediate mesoderm, the urinary system, and the gonadal structures; it also includes the inner lining of the body cavities, such as the visceral pleura and peritoneum, and the mesodermal tissues that surround the endoderm-lined gut and its derivative organs (e.g., lungs, liver, pancreas).

There are both somatic and visceral nerves. The somatic nerves innervate the skeletal muscles and the smooth muscle and glands of skin and body wall. The visceral nerves supply the visceral organs of the body, transmitting information through the autonomic nerves in the PNS to control the smooth muscle and cardiac muscle as well as the glands of the visceral organs.

Segmental Organization

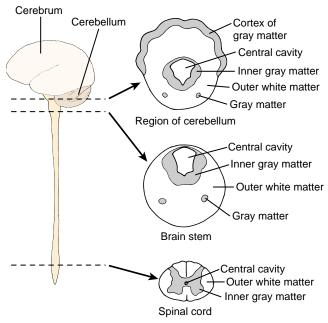

The early pattern of segmental development is presented as a framework for understanding the nervous system. Although the early muscular, skeletal, vascular, and excretory systems and the nerves that supply the somatic and visceral structures have the same segmental pattern, it is the nervous system that most clearly retains this organization in postnatal life. Developmentally, the basic organizational pattern of the body is that of a longitudinal series of segments, each repeating the same fundamental pattern. The CNS and its associated peripheral nerves consist of approximately 43 segments, 33 of which form the spinal cord and spinal nerves, and 10 of which form the brain and its cranial nerves.

The basic pattern of the CNS is that seen in the spinal cord a central cavity surrounded by inner core of gray matter and a superficial layer of white matter (Fig. 36-9). The brain retains this organization, but it also contains additional regions of gray matter that are not evident in the spinal cord. The gray matter is functionally divided into longitudinal columns of nerve cell bodies called the *cell columns*. The superficial white matter region contains the longitudinal tract systems of the CNS. The dorsal half of the gray matter is called the dorsal horn.

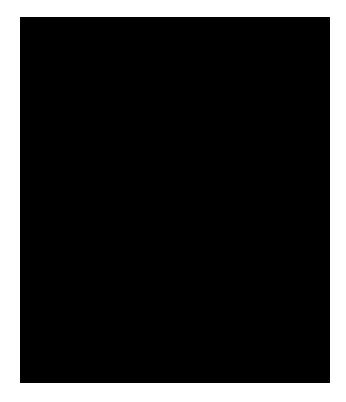

KEY CONCEPTS

THE DEVELOPMENTAL ORGANIZATION OF THE NERVOUS SYSTEM

- On cross section, the embryonic neural tube develops into a central canal surrounded by gray matter, or cellular portion (cell columns), and white matter, or tract system of the central nervous system (CNS).
- As the nervous system develops, it becomes seqmented, with a repeating pattern of afferent neuron axons forming the dorsal roots of each succeeding segmental nerve and the exiting efferent neurons forming the ventral roots of each succeeding segmental nerve.
- The nerve cells in the gray matter are arranged longitudinally in cell columns, with afferent sensory neurons located in the dorsal columns and efferent motor neurons located in the ventral columns.
- The axons of the cell column neurons project out into the white matter of the CNS, forming the longitudinal tract systems.

■ FIGURE 36-9 ■ Segmental organization of gray and white matter in the CNS (highly simplified). From top to bottom, the diagrams represent cross-sections at the levels of cerebellum, brain stem, and spinal cord. In each section, the dorsal aspect is on top. In general, white matter lies external to gray matter; however, collections of gray matter migrate externally into the white matter in the developing brain (see arrows). The cerebrum resembles the cerebellum in its external cortex of gray matter. (Marieb E.N. [1995]. Human anatomy and physiology. [3rd edition, p. 383]. Redwood City, CA. The Benjamin/Cummings Publishing Company)

The ventral portion, or *ventral horn*, contains efferent neurons that communicate by way of the ventral roots with effector cells of the body segment. Many CNS neurons develop axons that grow longitudinally as tract systems that communicate between neighboring and distal segments of the neural tube.

Each segment of the CNS is accompanied by bilateral pairs of bundled nerve fibers, or roots, a ventral pair and a dorsal pair (Fig. 36-10). The paired dorsal roots connect a pair of dorsal root ganglia and their corresponding CNS segment. The dorsal root ganglia contain many afferent nerve cell bodies, each having two axon-like processes—one that ends in a peripheral receptor and the other that enters the central neural segment. The axon-like process that enters the central neural segment communicates with a neuron called an *input association (IA) neuron*. The paired ventral roots of each segment are bundles of axons that provide efferent output to effector sites such as the muscles and glandular cells of the body segment.

Cell Columns

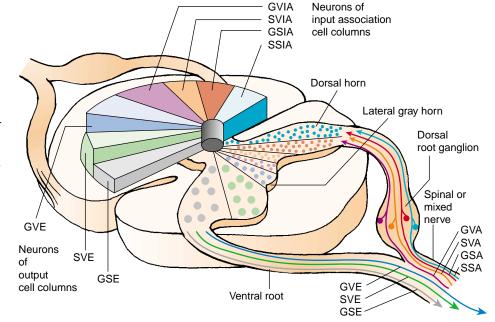

The organizational structure of the nervous system can be best explained and simplified as a pattern in which functionally specific PNS and CNS neurons are repeated as parallel cell columns running lengthwise along the nervous system. In this organizational pattern, afferent neurons, dorsal horn cells, and ventral horn cells are organized as a bilateral series of 11 cell columns.

The cell columns on each side can be further grouped according to their location in the PNS: four in the dorsal ganglia that contain sensory neurons; four in the dorsal horn containing sensory IA neurons; and three in the ventral horn that contain motoneurons (Fig. 36-11). Each column of dorsal root ganglia projects to its particular column of IA neurons in the dorsal horn. The IA neurons distribute afferent information to local reflex circuitry and to more rostral and elaborate segments of the CNS. The ventral horns contain output association (OA) neurons and lower motoneurons, which project to the effector muscles. The afferent and efferent cell columns of the PNS and CNS, their projections, and the type of information they transmit are summarized in Table 36-1.

Between the IA neurons and the OA neurons are networks of small internuncial neurons arranged in complex circuits. Internuncial neurons provide the discreteness, appropriateness, and intelligence of responses to stimuli. Most of the billions of CNS cells in the spinal cord and brain gray matter are internuncial neurons.

Dorsal Horn Cell Columns. Four columns of afferent (sensory) neurons in the dorsal root ganglia directly innervate four

■ FIGURE 36-11 ■ Cell columns of the central nervous system. The cell columns in the dorsal horn contain input association (IA) neurons for the general visceral afferent (GVA), special visceral afferent (SVA), special sensory afferent (SSA), and general somatic afferent (GSA) neurons with cell bodies in the dorsal root ganglion. The cell columns in the ventral horn contain the general visceral efferent (GVE), pharyngeal efferent (PE), and general somite efferent (GSE) neurons and their output association (OA) neurons.

Segment and Nerve	Component	Innervation	Function
1. Forebrain			
I. Olfactory	SVA	Receptors in olfactory mucosa	Reflexes, olfaction (smell)
2. II. Optic nerve		Optic nerve and retina (part of brain system, not a peripheral nerve)	
3. Midbrain			
V. Trigeminal (V ₁) ophthalmic division	SSA GSA	Muscles: upper face: forehead, upper lid Skin, subcutaneous tissue; conjunctiva; frontal/ethmoid sinuses	Facial expression, proprioceptio Somesthesia Reflexes (blink)
III. Oculomotor	GVE	Iris sphincter Ciliary muscle	Pupillary constriction Accommodation
	GSE	Extrinsic eye muscles	Eye movement, lid movement
4. Pons			
V. Trigeminal (V ₂) maxillary division	SSA	Muscles: facial expression	Proprioception Reflexes (sneeze), somesthesia
	GSA	Skin, oral mucosa, upper teeth, hard palate, maxillary sinus	
V. Trigeminal (V ₃) mandibular division	SSA GSA	Lower jaw, muscles: mastication Skin, mucosa, teeth, anterior ½ of tongue	Proprioception, jaw jerk Reflexes, somesthesia
	PE	Muscles: mastication tensor tympani tensor veli palantini	Mastication: speech Protects ear from loud sound Tenses soft palate
IV. Trochlear	GSE	Extrinsic eye muscle	Moves eye down and in
5. Caudal Pons			
VIII. Vestibular, cochlear (vestibulocochlear)	SSA	Vestibular end organs Organ of Corti	Reflexes, sense of head position Reflexes, hearing
VII. Facial nerve, intermedius	GSA	External auditory meatus	Somesthesia
portion	GVA	Nasopharynx	Gag reflex: sensation
	SVA GVE	Taste buds of anterior ⅔ of tongue Nasopharynx	Reflexes: gustation (taste) Mucous secretion, reflexes
Facial nerve	PE	Lacrimal, sublingual, submandibular glands Muscles: facial expression, stapedius	Lacrimation, salivation Facial expression
VI. Abducens	GSE	Extrinsic eye muscle	Protects ear from loud sounds Lateral eye deviation
6. Middle Medulla			
IX. Glossopharyngeal	SSA	Stylopharyngeus muscle	Proprioception
1 7 5	GSA	Posterior external ear	Somesthesia
	SVA	Taste buds of posterior ½ of tongue	Gustation (taste)
	GVA	Oral pharynx	Gag reflex: sensation
	GVE PE	Parotid gland; pharyngeal mucosa Stylopharyngeus muscle	Salivary reflex: mucous secretion Assists swallowing
	12	stylopharyngeus musee	Assists swallowing
7,8,9,10. Caudal Medulla	66A		D
X. Vagus	SSA	Muscles: pharynx, larynx	Proprioception
	GSA SVA	Posterior external ear	Somesthesia Reflexes gustation
	GVA	Taste buds, pharynx, larynx Visceral organs (esophagus to midtransverse colon, liver, pancreas, heart, lungs)	Reflexes, gustation Reflexes, sensation
	GVE	Visceral organs as above	Parasympathetic efferent
	PE	Muscles: pharynx, larynx	Swallowing, phonation, emesis
XIII. Hypoglossal	GSE	Muscles of tongue	Tongue movement, reflexes
Spinal Segments			
C1–C4 Upper Cervical XI. Spinal accessory nerve	PE	Muscles: sternocleidomastoid, trapezius	Head, shoulder movement
Spinal nerves	SSA	Muscles of neck	Proprioception, DTRs
	GSA	Neck, back of head	Somesthesia
	GSE	Neck muscles	Head, shoulder movement

TABLE 36-1 The Segmental Nerves and Their Components (Continued)

Afferent (sensory) components: SSA, special somatic afferent; GSA, general somatic afferent; SVA, special visceral afferent; GVA, general visceral afferent.

Efferent (motor) components: GVE, general visceral efferent (autonomic nervous system); PE, pharyngeal efferent; GSE, general somatic efferent; DTRs, deep tendon reflexes.

corresponding columns of SIA neurons in the dorsal horn. These columns are categorized as special and general afferents: special somatic afferent (SSA), general somatic afferent (GSA), special visceral afferent (SVA), and general visceral afferent (GVA).

The SSA fibers are concerned with internal sensory information such as joint and tendon sensation (*i.e.*, proprioception). Neurons in the special sensory IA cell columns relay their information to local reflexes concerned with posture and movement. These neurons also relay information to the cerebellum, contributing to coordination of movement, and to the forebrain, contributing to experience. Afferents innervating the vestibular system of the inner ear also belong to the special somatic afferent category.

The GSA neurons innervate the skin and other somatic structures, responding to stimuli such as those that produce pressure or pain. General sensory IA column neurons relay information to protective and other local reflex circuits and project the information to the forebrain, where it is perceived as painful, warm, cold, and the like.

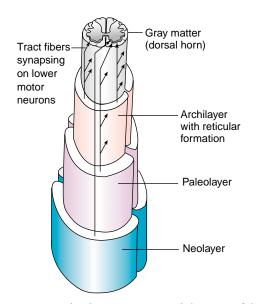

The SVAs innervate specialized gut-related receptors, such as the taste buds and receptors of the olfactory mucosa. Their central processes communicate with special visceral IA column neurons that project to reflex circuits producing salivation, chewing, swallowing, and other responses. Forebrain projection fibers from these association cells provide sensations of taste (*i.e.*, gustation) and smell (*i.e.*, olfaction).

GVA neurons innervate visceral structures such as the gastrointestinal tract, urinary bladder, and heart and great vessels; they project to the general visceral IA column, which relays information to vital reflex circuits and sends information to the forebrain regarding visceral sensations such as stomach fullness and bladder pressure.

Ventral Horn Cell Columns. The ventral horn contains three longitudinal cell columns: general visceral efferent (GVE), pharyngeal efferent (PE), and general somatic efferent (GSE) (Fig. 36-11). The efferent neurons for the OA in the ventral horn originate in brain centers (motor cortex and autonomic nervous system centers) that control skeletal muscle and visceral function. Each of these cell columns contains OA and efferent neurons. The OA neurons coordinate and integrate the function of the efferent motoneurons of its column.

GVE neurons transmit the efferent output of the autonomic nervous system and are called preganglionic neurons. These neurons are structurally and functionally divided between either the sympathetic or the parasympathetic nervous systems (discussed later in this chapter). Their axons project through the segmental ventral roots to innervate smooth and cardiac muscle and glandular cells of the body, most of which are in the viscera. In the viscera, three additional cell columns are present on each side of the body. These become the postganglionic neurons of the autonomic nervous system. In the sympathetic nervous system, the columns are represented by the paravertebral or sympathetic chain ganglia and the prevertebral series of ganglia (e.g., celiac ganglia) associated with the dorsal aorta. For the parasympathetic nervous system, these become the enteric plexus in the wall of the gut-derived organs and a series of ganglia in the head.

The PE neurons innervate the muscles of mastication, facial expression, and muscles of the pharynx and larynx. PE neurons also innervate the muscles responsible for moving the head.

■ **FIGURE 36-12** The three concentric subdivisions of the tract systems of the white matter. Migration of neurons into the archilayer converts it into the reticular formation of the white matter.

The GSE neurons supply skeletal muscles of the body and head, including those of the body, limbs, tongue, and extrinsic eye muscles. These efferent neurons transmit the commands of the CNS to peripheral effectors, the skeletal muscles. They are the "final common pathway neurons" in the sequence leading to motor activity. They often are called *lower motoneurons* (*LMNs*) because they are under the control of higher levels of the CNS, including precise control by *upper motoneurons* (*UMNs*).

Longitudinal Tracts

The gray matter of the cell columns in the CNS is surrounded by bundles of myelinated axons (*i.e.*, white matter) and unmyelinated axons that travel longitudinally along the length of the neural axis. This white matter can be divided into three layers: an inner, a middle, and an outer layer (Fig. 36-12). The inner layer contains short fibers that project for a maximum of approximately five segments before re-entering the gray matter. The middle layer projects to six or more segments. The inner and middle layer fibers have many branches, or collaterals, that enter the gray matter of intervening segments. The outer layer contains large-diameter axons that that can travel the entire length of the nervous system (Table 36-2). *Suprasegmental* is a term that refers to higher levels of the CNS, such as the brain stem and cerebrum and structures above a given CNS segment. The middle and outer layer fibers have suprasegmental projections.

The longitudinal layers are arranged in bundles, or fiber tracts, that contain axons that have the same destination, origin, and function (Fig. 36-13). These longitudinal tracts are named systematically to reflect their origin and destination; the origin is named first, and the destination is named second. For example, the spinothalamic tract originates in the spinal cord and terminates in the thalamus. The corticospinal tract originates in the cerebral cortex and ends in the spinal cord.

The Inner Layer. The inner layer of white matter contains the axons of neurons that connect neighboring segments of the nervous system. Axons of this layer permit the pool of motoneurons of several segments to work together as a functional unit. They also allow the afferent neurons of one segment to trigger reflexes that activate motor units in neighboring and in the same segments. In terms of evolution, this is the oldest of the three layers, and it is sometimes called the archilayer. It is the first of the longitudinal layers to become functional, and its circuitry may be limited to reflex types of movements, including reflex movements of the fetus (*i.e.*, quickening) that begin during the fifth month of intrauterine life.

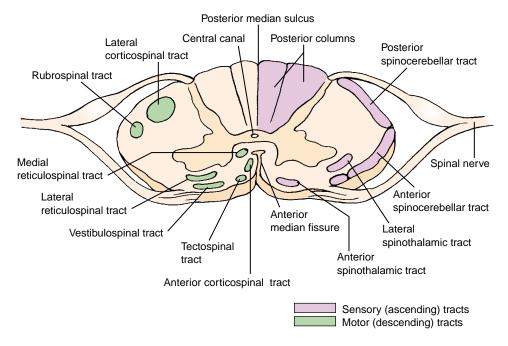

The archilayer of the white matter differs from the other two layers in one important aspect. Many neurons in the embryonic gray matter migrate out into this layer, resulting in a rich mixture of neurons and local fibers called the *reticular formation*. The circuitry of most reflexes is contained in the reticular formation. In the brain stem, the reticular formation becomes quite large and contains major portions of vital reflexes, such as those controlling respiration, cardiovascular function, swallowing, and vomiting. A functional system called the *reticular activating system* operates in the lateral portions of the reticular formation of the medulla, pons, and especially the midbrain. Information converging from all sensory modalities, including those of the somesthetic, auditory, visual, and visceral afferent nerves, bombards the neurons of this system.

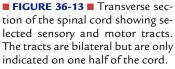

The reticular activating system has descending and ascending portions. The descending portion communicates with all spinal segmental levels through middle layer reticulospinal tracts and serves to facilitate many cord-level reflexes. For example, it speeds reaction time and stabilizes postural reflexes. The ascending portion accelerates brain activity, particularly thalamic and cortical activity. This is reflected by the appearance of awake brain-wave patterns. Sudden stimuli result in protective and attentive postures and cause increased awareness.

ast Fastest
pinothalamic tracts Corticospinal tracts

The Middle Layer. The middle layer of the white matter contains most of the major fiber tract systems required for sensation and movement. It contains the ascending spinoreticular and spinothalamic tracts. This layer consists of larger-diameter and longer suprasegmental fibers, which ascend to the brain stem and are largely functional at birth. In terms of evolutionary development, these tracts are quite old, and this layer is sometimes called the *paleolayer*. It facilitates many primitive functions, such as the auditory startle reflex, which occurs in response to loud noises. This reflex consists of turning the head and body toward the sound, dilating the pupils of the eyes, catching of the breath, and quickening of the pulse.

The Outer Layer. The outer layer of the tract systems is the newest of the three layers with respect to evolutionary development, and it is sometimes called the *neolayer*. It becomes functional approximately the second year of life, and it includes the pathways needed for bladder training. Myelination of these suprasegmental tracts, which include many pathways required for delicate and highly coordinated skills, is not complete until approximately the fifth year of life. This includes the development of tracts needed for fine manipulative skills, such as the finger-thumb coordination required for using tools and the toe movements needed for acrobatics. Neolayer tracts are the most recently evolved systems and, being more superficial on the brain and spinal cord, are the most vulnerable to injury.

Collateral Communication Pathways. Axons in the archilayer and paleolayer characteristically possess many collateral branches that move into the gray cell columns or synapse with fibers of the reticular formation as the axon passes each succeeding CNS segment. Should a major axon be destroyed at some point along its course, these collaterals provide multisynaptic alternative pathways that bypass the local damage. Damage usually is followed by slow return of function, presumably through the collateral connections.

Neolayer tracts do not possess these collaterals but instead project mainly to the target neurons with which they communicate. When neolayer tracts are damaged, the paleolayer and archilayer tracts often remain functional, and rehabilitation methods can result in effective use of the older systems. Delicacy and refinement may be lost, but basic function remains. For example, when the corticospinal system, an important neolayer system that permits the fine manipulative control required for writing, is damaged, the remaining paleolayer systems, if intact, permit the grasping and holding of objects. The hand can still be used to perform its basic function, but the individual manipulation of the fingers is permanently lost.

In summary, the nervous system can be divided into two parts: the CNS, which consists of the brain and spinal cord, and the PNS, which contains the neurons and neuronal processes that leave the CNS and innervate skeletal muscles and visceral structures of the body. The brain stem and spinal cord are subdivided into the dorsal horn, which contains neurons that receive and process incoming or afferent information, and the ventral horn, which contains efferent motoneurons that handle the final stages of output processing.

Throughout life, the organization of the nervous system retains many patterns established during early embryonic life. Each of the 43 or more body segments is connected to corresponding CNS or neural tube segments by segmental afferent and efferent neurons. Afferent or sensory neuronal processes that carry afferent or sensory information enter the CNS through the dorsal root ganglia and the dorsal roots. Afferent neurons of the dorsal root ganglia are of four types: GSA, SSA, GVA, and SVA. Each of these afferent neurons synapses with its appropriate IA neurons in the cell columns of the dorsal horn. There are three cells columns in the ventral horn. The OA neurons in these columns synapse with ventral horn motoneurons that exit the CNS in the ventral roots. GSE neurons are LMNs that innervate skeletal muscles; PE neurons innervate pharyngeal muscles; and GVE neurons innervate visceral structures. This pattern of afferent and efferent neurons, which in general is repeated in each segment of the body, forms parallel cell columns running lengthwise through the CNS and PNS.

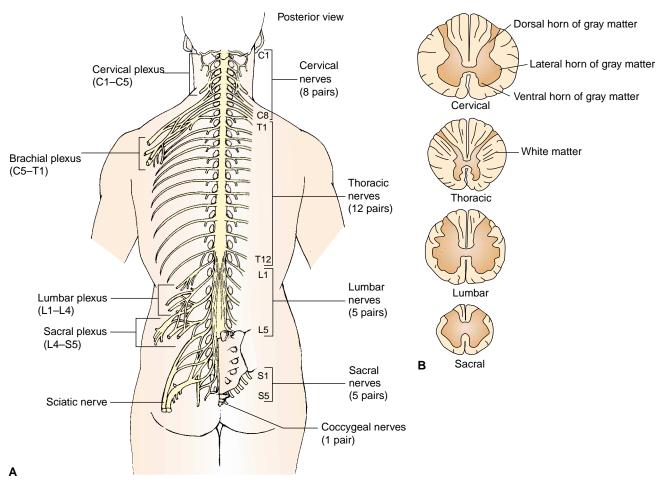

Longitudinal communication between CNS segments is provided by tracts that are arranged in three layers: an inner, middle, and outer layer. The inner layer of white matter contains the axons of neurons that connect neighboring seqments of the nervous system. It contains a mix of nerve cells and axons called the reticular formation and is the site of many important spinal cord and brain stem reflex circuits. The middle layer tracts provide the longitudinal communication between more distant segments of the nervous system; it contains most of the major fiber tract systems required for sensation and movement. The recently evolved outer or neolayer systems, which become functional during infancy and childhood, provide the means for very delicate and discriminative function. The outer position of the neolayer tracts and their lack of collateral and redundant pathways make them the most vulnerable to injury.

THE SPINAL CORD AND BRAIN

The Spinal Cord

In the adult, the spinal cord is found in the upper two thirds of the spinal canal of the vertebral column (Fig. 36-14A). It extends from the foramen magnum at the base of the skull to a cone-shaped termination, the conus medullaris, usually at the level of the first or second lumbar vertebra (L1 or L2) in the adult. The dorsal and ventral roots of the more caudal portions of the cord elongate during development and angle downward from the cord, forming what is called the *cauda equina* (from the Latin for "horse's tail"). The filum terminale, which is composed of non-neural tissues and the pia mater, continues caudally and attaches to the second sacral vertebra (S2).

The spinal cord is somewhat oval on transverse section. Internally, the gray matter has the appearance of a butterfly or the letter "H" on cross section (Fig. 36-14B). The extensions of the gray matter that form the letter "H" are called the *horns*. Those that extend posteriorly are called the *dorsal horns*, and those that extend anteriorly are called the *ventral horns*. The central portion of the cord, which connects the dorsal and ventral horns, is called the *intermediate gray matter*. The inter-

■ **FIGURE 36-14** ■ (**A**) Dorsal view of the spinal cord including portions of the major spinal nerves and some of the components of the major nerve plexuses. (**B**) Cross-sectional views of the spinal cord, showing regional variations in gray matter and increasing white matter as the cord ascends.

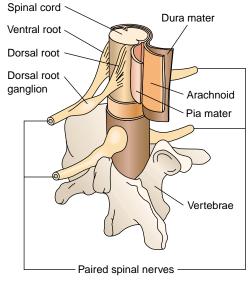

mediate gray matter surrounds the central canal. In the thoracic area, the small, slender projections that emerge from the intermediate gray matter are called the *intermediolateral columns* of the horns. These columns contain the visceral OA neurons and the efferent neurons of the sympathetic nervous system.

The gray matter is proportional to the amount of tissue innervated by a given segment of the cord (Fig. 36-14B). Larger amounts of gray matter are present in the lower lumbar and upper sacral segments, which supply the lower extremities, and in the fifth cervical segment to the first thoracic segment, which supply the upper limbs. The white matter in the spinal cord also increases progressively toward the brain because ever more ascending fibers are added and the number of descending axons is greater.

The spinal cord and the dorsal and ventral roots are covered by a connective tissue sheath, the pia mater, which also contains the blood vessels that supply the white and gray matter of the cord (Fig. 36-15). On the lateral sides of the spinal cord, extensions of the pia mater, the denticulate ligaments, attach the sides of the spinal cord to the bony walls of the spinal canal. Thus, the cord is suspended by both the denticulate ligaments and the segmental nerves. A fat- and vessel-filled epidural space intervenes between the spinal dura mater and the inner wall of the spinal canal. Each vertebral body has two pedicles that extend posteriorly and support the laterally oriented transverse processes of the neural laminae, which arch medially and fuse to continue as the spinal processes.

The spaces between the vertebral bodies are filled with fibrocartilaginous discs and stabilized with tough ligaments. A gap, the intervertebral foramen, occurs between each two succeeding pedicles, allowing for the exit of the segmental nerves and passage of blood vessels. The spinal cord lives in the protective confines of this series of concentric flexible tissue and body sheaths. Supporting structures of the spinal cord are discussed further in Chapter 37.

Early in fetal life, the spinal cord extends the entire length of the vertebral column and the spinal nerves exit through the intervertebral foramina (openings) near their level of origin. Because the vertebral column and spinal dura grow faster than

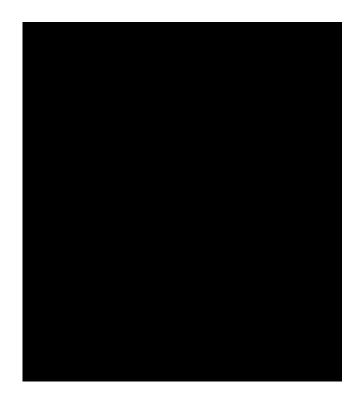

■ FIGURE 36-15 ■ Spinal cord and meninges.

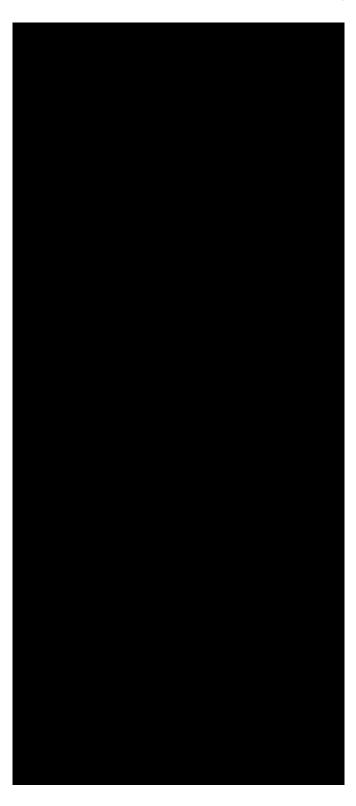

the spinal cord, a disparity develops between each succeeding cord segment and the exit of its dorsal and ventral nerve roots through the corresponding intervertebral foramina. In the newborn, the cord terminates at the level of L2 or L3. In the adult, the cord usually terminates in the inferior border of L1, and the arachnoid and its enclosed subarachnoid space, which is filled with CSF, do not close down on the filum terminale until they reach the level of S2 (Fig. 36-16). This results in the formation of a pocket of CSF, the dural cisterna spinalis, which extends from approximately L2 to S2. Because this area contains an abundant supply of CSF and the spinal cord does not extend this far, the area often is used for sampling the CSF. A procedure called a *spinal tap*, or puncture, can be done by inserting a special needle into the dural sac at L3 or L4. The spinal roots, which are covered with pia mater, are in little danger of trauma from the needle used for this purpose.

Spinal Nerves

The peripheral nerves that carry information to and from the spinal cord are called *spinal nerves*. There are 32 or more pairs of spinal nerves (*i.e.*, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 2 or more coccygeal); each pair is named for the segment of the spinal cord from which it exits. Because the first cervical spinal nerve exits the spinal cord just above the first cervical vertebra (C1), the nerve is given the number of the bony vertebra just below it. However, the numbering is changed for all lower levels. An extra cervical nerve, the C8 nerve, exits above the T1 vertebra, and each subsequent nerve is numbered for the vertebra just above its point of exit (Fig. 36-17).

Each spinal cord segment communicates with its corresponding body segment through the paired segmental spinal nerves. Each spinal nerve, accompanied by the blood vessels supplying the spinal cord, enters the spinal canal through an intervertebral foramen, where it divides into two branches, or

roots. One branch enters the dorsolateral surface of the cord (*i.e.*, dorsal root), carrying the axons of afferent neurons into the CNS. The other branch leaves the ventrolateral surface of the cord (*i.e.*, ventral root), carrying the axons of efferent neurons into the periphery. These two branches or roots fuse at the intervertebral foramen, forming the mixed spinal nerve—"mixed" because it has both afferent and efferent axons.

After emerging from the vertebral column, the spinal nerve divides into two branches or *rami* (singular, *ramus*): a small dorsal primary ramus and a larger ventral primary ramus (Fig. 36-18). The thoracic and upper lumbar spinal nerves also lead to a third branch, the ramus communicans, which contains sympathetic axons supplying the blood vessels, the genitourinary system, and the gastrointestinal system. The dorsal ramus contains sensory fibers from the skin and motor fibers to muscles of the back. The anterior primary ramus contains motor fibers that innervate the skeletal muscles of the anterior body wall and the legs and arms.

Spinal nerves do not go directly to skin and muscle fibers; instead, they form complicated nerve networks called *plexuses* (Fig. 36-14A). A plexus is a site of intermixing nerve branches. Many spinal nerves enter a plexus and connect with other spinal nerves before exiting from the plexus. Nerves emerging from a plexus form progressively smaller branches that supply the skin and muscles of the various parts of the body. The PNS contains four major plexuses: the cervical plexus, the brachial plexus, the lumbar plexus, and the sacral plexus.

The Brain

The brain is divided into three regions, the hindbrain, the midbrain, and the forebrain (Fig. 36-19A). The hindbrain includes the medulla oblongata, the pons, and its dorsal outgrowth, the cerebellum (see Chapter 38). Midbrain structures include two pairs of dorsal enlargements: the superior and inferior colliculi. The forebrain, which consists of two hemispheres and is covered by the cerebral cortex, contains central masses of gray matter, the basal ganglia (discussed in Chapter 38), and the rostral end of the neural tube, the diencephalon with its adult derivatives—the thalamus and hypothalamus.

An important concept is that the more rostral, recently developed parts of neural tube gain dominance or control over regions and functions at lower levels. They do not replace the more ancient circuitry but merely dominate it. After damage to

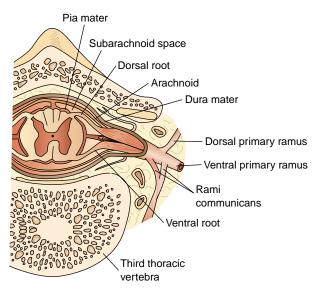

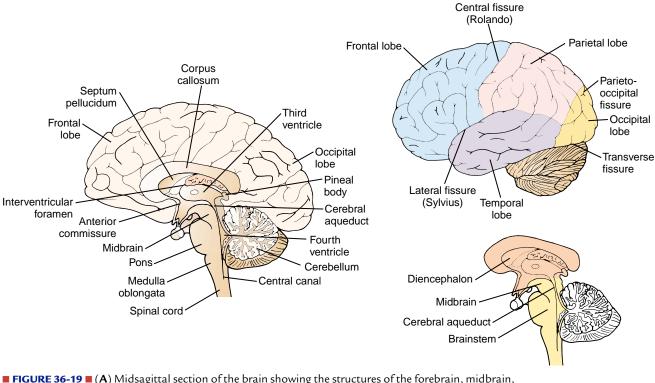

FIGURE 36-18 Cross-section of vertebral column at the level of the third thoracic vertebra, showing the meninges, the spinal cord, and the origin of a spinal nerve and its branches or rami.

■ FIGURE 36-19 ■ (A) Midsagittal section of the brain showing the structures of the forebrain, midbrain, and hindbrain. (B) Lateral view of the cerebral hemispheres. (C) Diencephalon, brain stem, and the cerebral aqueduct connecting the 3rd and 4th ventricles.

the more vulnerable parts of the forebrain, as occurs with brain death, a brain stem-controlled organism remains that is capable of breathing and may survive if the environmental temperature is regulated and nutrition and other aspects of care are provided. However, all aspects of intellectual function, experience, perception, and memory usually are permanently lost. The organization of content in this section moves from the more ancient circuitry of the hindbrain to the more dominant and recently developed structures of the forebrain.

Hindbrain

The term *brain stem* often is used to include the hindbrain, pons, and the midbrain. These regions of the neural tube have the organization of spinal cord segments, except that more of the longitudinal cell columns are present, reflecting the increased complexity of the cranial segmental nerves. In the brain stem, the structure and function of the reticular formation have been greatly expanded. In the pons and medulla, the reticular formation contains networks controlling basic breathing, eating, and locomotion functions. Higher-level integration of these functions occurs in the midbrain. The reticular formation is surrounded on the outside by the long tract systems that connect the forebrain with lower parts of the CNS.

Medulla. The *medulla oblongata* represents the caudal five segments of the brain part of the neural tube; the cranial nerve branches entering and leaving it have functions similar to the spinal segmental nerves. Although the ventral horn areas in the medulla are quite small, the dorsal horn areas are enlarged,

processing a large amount of the information pouring through the cranial nerves. Cranial nerves XII (hypoglossal), X (vagus), and (IX) glossopharyngeal have their origin in the medulla (see Table 36-1).

Pons. The pons, which develops from the fifth neural tube segment, is located between the medulla oblongata and the midbrain. Dorsally, it forms part of the anterior wall of the fourth ventricle (Fig. 36-19B).

As the name implies (pons = bridge), the pons is composed chiefly of conduction fibers. The enlarged area on the ventral surface of the pons contains the pontine nuclei, which receive information from all parts of the cerebral cortex. The axons of these neurons form a massive bundle that swings around the lateral side of the fourth ventricle to enter the cerebellum. In the pons, the reticular formation is large and contains the circuitry for masticating food and manipulating the jaws during speech. Cranial nerves VIII, VII, and VI have their origin in the pons (see Table 36-1).

Midbrain

The midbrain develops from the fourth segment of the neural tube, and its organization is similar to that of a spinal segment. The central canal is re-established as the cerebral aqueduct, connecting the fourth ventricle with the third ventricle (see Fig. 36-19B).

Two prominent bundles of nerve fibers, the *cerebral peduncles*, pass along the ventral surface of the midbrain. These fibers include the corticospinal tracts and are the main motor pathways between the forebrain and the pons. On the dorsal surface, four "little hills," the *superior* and *inferior colliculi*, are areas of cortical formation. The inferior colliculus is involved in directional turning and, to some extent, in experiencing the direction of sound sources. The superior colliculi are essential to the reflex mechanisms that control conjugate eye movements when the visual environment is surveyed. Two general somatic efferent cranial nerves, the oculomotor nerve, or cranial nerve III, and the trochlear nerve, or cranial nerve IV, exit the midbrain (see Table 36-1).

Forebrain

The most rostral part of the brain, the forebrain consists of the telencephalon, or "end brain," and the diencephalon, or "between brain." The diencephalon forms the core of the forebrain, and the telencephalon forms the cerebral hemispheres.

Diencephalon. Three of the most forward brain segments form an enlarged dorsal horn and ventral horn with a narrow, deep, enlarged central canal—the third ventricle—separating the two sides. This region is called the *diencephalon*. The dorsal horn part of the diencephalon is the thalamus and subthalamus, and the ventral horn part is the hypothalamus (Fig. 36-20). The optic nerve, or cranial nerve II, and retina are outgrowths of the diencephalon.

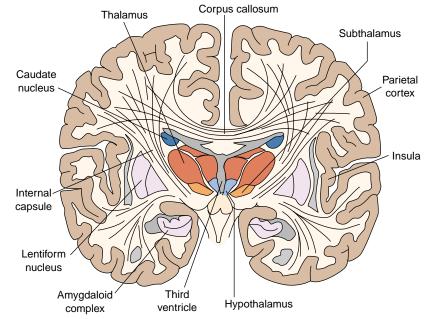

The thalamus consists of two large, egg-shaped masses, one on either side of the third ventricle. The thalamus is divided into several major parts, and each part is divided into distinct nuclei, which are the major relay stations for information going to and from the cerebral cortex. All sensory pathways have direct projections to thalamic nuclei, which convey the information to restricted areas of the sensory cortex. Coordination and integration of peripheral sensory stimuli occur in the thalamus, along with some crude interpretation of highly emotion-laden auditory experiences that not only occur but can be remembered. For example, a person can recover from a deep coma in which cerebral cortex activity is minimal and remember some of what was said at the bedside. The thalamus also plays a role in relaying critical information regarding motor activities to and from selected areas of the motor cortex. Two neuronal circuits are significant in this regard. One is the pathway from the cerebral cortex to the pons and cerebellum and then, by way of the thalamus, back to the motor cortex. The second is the feedback circuit that travels from the cortex to the basal ganglia, then to the thalamus, and from the thalamus back to the cortex. The subthalamus also contains movement control systems related to the basal ganglia.

Through its connections with the ascending reticular activating system, the thalamus processes neural influences that are basic to cortical excitatory rhythms (*i.e.*, those recorded on the electroencephalogram), to essential sleep-wakefulness cycles, and to the process of attending to stimuli. Besides their cortical connections, the thalamic nuclei have connections with each other and with neighboring nonthalamic brain structures such as the limbic system. Through their connections with the limbic system, some thalamic nuclei are involved in the relation between stimuli and the emotional responses they evoke.

The ventral horn portion of the diencephalon is the hypothalamus, which borders the third ventricle and includes a ventral extension, the neurohypophysis (*i.e.*, posterior pituitary). The hypothalamus is the area of master-level integration of homeostatic control of the body's internal environment. Maintenance of blood gas concentration, water balance, food consumption, and major aspects of endocrine and autonomic nervous system control require hypothalamic function.

The internal capsule is a broad band of projection fibers that lies between the thalamus medially and the basal ganglia laterally (see Fig. 36-20). It contains all of the fibers that connect the cerebral cortex with deeper structures, including the basal ganglia, thalamus, midbrain, pons, medulla, and spinal cord.

Cerebral Hemispheres. The two cerebral hemispheres are lateral outgrowths of the diencephalon. The cerebral hemispheres contain the lateral ventricles (*i.e.*, ventricles I and II), which are

■ FIGURE 36-20 ■ Frontal section of the brain passing through the third ventricle, showing the thalamus, subthalamus, hypothalamus, internal capsule, corpus callosum, basal ganglia (caudate nucleus, lenticular nucleus), amygdaloid complex, insula, and parietal cortex.

656 Unit Ten: Alterations in the Nervous System

connected with the third ventricle of the diencephalon by a small opening called the *interventricular foramen* (*i.e.*, foramen of Monro). Axons of the olfactory nerve, or cranial nerve I, terminate in the most ancient portion of the cerebrum—the olfactory bulb, where initial processing of olfactory information occurs. Projection axons from the olfactory bulb relay information through the olfactory tracts to the thalamus and to other parts of the cerebral cortex (*i.e.*, orbital cortex), where olfactory-related reflexes and olfactory experience occur.

The *corpus callosum* is a massive commissure, or bridge, of myelinated axons that connects the cerebral cortex of the two sides of the brain. Two smaller commissures, the anterior and posterior commissures, connect the two sides of the more specialized regions of the cerebrum and diencephalon.

The surfaces of the hemispheres are lateral (side), medial (area between the two sides of the brain), and basal (ventral). The cerebral cortex observed laterally is the recently evolved sixlayered neocortex. The surface of the hemispheres contains many ridges and grooves. A *gyrus* is the ridge between two grooves, and the groove is called a *sulcus* or *fissure*. The cerebral cortex is arbitrarily divided into lobes named after the bones that cover them: the frontal, parietal, temporal, and occipital lobes (Fig. 36-19C).

Frontal Lobe. The frontal lobe extends from the frontal pole to the central sulcus (*i.e.*, fissure) and is separated from the temporal lobe by the lateral sulcus. The frontal lobe can be subdivided rostrally into the frontal pole and laterally into the superior, middle, and inferior gyri, which continue on the undersurface over the eyes as the orbital cortex. These areas are associated with the medial thalamic nuclei, which also are related to the limbic system. In terms of function, the prefrontal cortex is thought to be involved in anticipation and prediction of consequences of behavior.

The precentral gyrus (area 4), next to the central sulcus, is the *primary motor cortex* (Fig. 36-21). This area of the cortex provides precise movement control for distal flexor muscles of the hands and feet and of the phonation apparatus required for speech. Just rostral to the precentral gyrus is a region of the frontal cortex called the *premotor* or *motor association cortex*. This region (area 8 and rostral area 6) is involved in the planning of complex learned movement patterns. The primary motor cortex and the association motor cortex are connected with lateral thalamic nuclei, through which they receive feedback information from the basal ganglia and cerebellum. On the medial surface of the hemisphere, the premotor area includes a *supplementary motor cortex* involved in the control of bilateral movement patterns requiring great dexterity.

Parietal Lobe. The parietal lobe of the cerebrum lies behind the central sulcus (*i.e.*, postcentral gyrus) and above the lateral sulcus. The strip of cortex bordering the central sulcus is called the primary somatosensory cortex (areas 3, 1, and 2) because it receives very discrete sensory information from the lateral nuclei of the thalamus. Just behind the primary sensory cortex is the somatosensory association cortex (areas 5 and 7), which is connected with the thalamic nuclei and with the primary sensory cortex. This region is necessary for perceiving the meaningfulness of integrated sensory information from various sensory systems, especially the perception of "where" the stimulus is in space and in relation to body parts. Localized lesions of this region can result in the inability to recognize the meaningfulness of an object (i.e., agnosia). With the person's eyes closed, a screwdriver can be felt and described as to shape and texture. Nevertheless, the person cannot integrate the sensory information required to identify it as a screwdriver (discussed further in Chapter 39).

Temporal Lobe. The temporal lobe lies below the lateral sulcus and merges with the parietal and occipital lobes. It includes the temporal pole and three primary gyri: the superior, middle, and inferior gyri. The primary auditory cortex (area 41) involves the part of the superior temporal gyrus that extends into the lateral sulcus (see Fig. 36-21). This area is particularly important in discrimination of sounds entering opposite ears. It receives auditory input projections by way of the inferior colliculus of the midbrain and a ventrolateral thalamic nucleus. The more exposed part of the superior temporal gyrus involves the auditory association area (area 22). The recognition of certain sound patterns and their meaning requires the function

of this area. The remaining portion of the temporal cortex is less defined functionally but apparently is important in longterm memory recall. This is particularly true with respect to perception and memory of complex sensory patterns, such as geometric figures and faces (*i.e.*, recognition of "what" or "who" the stimulus is). Irritation or stimulation can result in vivid hallucinations of long-past events.

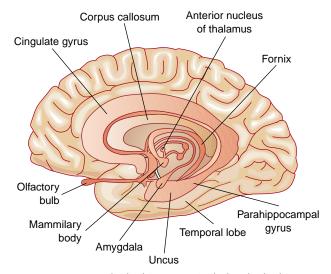

Occipital Lobe. The occipital lobe lies posterior to the temporal and parietal lobes and is only arbitrarily separated from them. The medial surface of the occipital lobe contains a deep sulcus extending from the limbic lobe to the occipital pole, the *calcarine sulcus*, which is surrounded by the primary visual cortex (area 17). Stimulation of this cortex causes the experience of bright lights (phosphenes) in the visual field. Just superior and inferior and extending onto the lateral side of the occipital pole is the *visual association cortex* (areas 18 and 19). This area is closely connected with the primary visual cortex and with complex nuclei of the thalamus. Integrity of the association cortex is required for gnostic visual function, by which the meaningfulness of visual experience, including experiences of color, motion, depth perception, pattern, form, and location in space, occurs.

The neocortical areas of the parietal lobe, between the somatosensory and the visual cortices, have a function in relating the texture, or "feel," and location of an object with its visual image. Between the auditory and visual association areas, the *parieto-occipital region* is necessary for relating the meaningfulness of a sound and image to an object or person.

Limbic System. The medial aspect of the cerebrum is organized into concentric bands of cortex, the limbic system (lim*bic* = borders), which surrounds the connection between the lateral and third ventricles. The innermost band just above and below the cut surface of the corpus callosum is folded out of sight but is an ancient, three-layered cortex ending as the hippocampus in the temporal lobe. Just outside the folded area is a band of transitional cortex, which includes the cingulate and the parahippocampal gyri (Fig. 36-22). This limbic lobe has reciprocal connections with the medial and the intralaminar nuclei of the thalamus, with the deep nuclei of the cerebrum (e.g., amygdaloid nuclei, septal nuclei), and with the hypothalamus. Overall, this region of the brain is involved in emotional experience and in the control of emotion-related behavior. Stimulation of specific areas in this system can lead to feelings of dread, high anxiety, or exquisite pleasure. It also can result in violent behaviors, including attack, defense, or explosive and emotional speech.

Meninges

Inside the skull and vertebral column, the brain and spinal cord are loosely suspended and protected by several connective tissue sheaths called the *meninges* (Fig. 36-23). The surfaces of the spinal cord, brain, and segmental nerves are covered with a delicate connective tissue layer called the *pia mater* (Latin for "delicate mother"). The surface blood vessels and those that penetrate the brain and spinal cord are encased in this protective tissue layer. A second, very delicate, nonvascular, and waterproof layer, called the *arachnoid*, encloses the entire CNS. The arachnoid layer is named for its spider web appearance. The CSF is contained in the subarachnoid space. Immediately

■ FIGURE 36-22 ■ The limbic system includes the limbic cortex (cingulated gyrus, parahippocampal gyrus, uncus) and associated subcortical structures (thalamus, hypothalamus, amygdala).

outside the arachnoid is a continuous sheath of strong connective tissue, the *dura mater* (*i.e.*, "tough mother"), which provides the major protection for the brain and spinal cord. The cranial dura often splits into two layers, with the outer layer serving as the periosteum of the inner surface of the skull.

The inner layer of the dura forms two major folds. The first, a longitudinal fold called the *falx cerebri*, separates the cerebral hemispheres and fuses with a second transverse fold, called the *tentorium cerebelli* (Fig. 36-24). The tentorium cerebelli separates the anterior and middle depression in the skull (cranial fossae), which contains the cerebral hemispheres, from the posterior fossa, found interiorly and containing the brain stem and cerebellum. A semicircular gap, or incisura, is formed at the midline to permit the midbrain to pass forward from the posterior fossa.

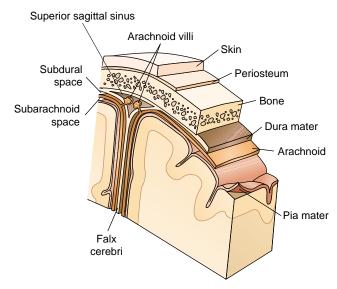

FIGURE 36-23 The cranial meninges. Arachnoid villi, shown within the superior sagittal sinus, are one site of cerebrospinal fluid absorption into the blood.

■ FIGURE 36-24 ■ Cranial dura mater. The skull is open to show the falx cerebri and the tentorium cerebelli, as well as some of the cranial venous sinuses.

Ventricular System and Cerebrospinal Fluid

The ventricular system is a series of CSF-filled cavities in the brain (Fig. 36-25). The CSF provides a supporting and protective fluid in which the brain and spinal cord float. CSF helps maintain a constant ionic environment that serves as a medium for diffusion of nutrients, electrolytes, and metabolic end-products into the extracellular fluid surrounding CNS neurons and glia. Filling the ventricles, the CSF supports the mass of the brain. Because it fills the subarachnoid space surrounding the CNS, a physical force delivered to either the skull or spine is to some extent diffused and cushioned.

The lining of the ventricles and central canal of the spinal cord is called the *ependyma*. There is a tremendous expansion of the ependyma in the roof of the lateral, third and fourth ventricles. The CSF is produced by tiny reddish masses of specialized capillaries from the pia mater, called the *choroid plexus*, that project into the ventricles. CSF is an ultrafiltrate of blood plasma, composed of 99% water with other constituents, mak-

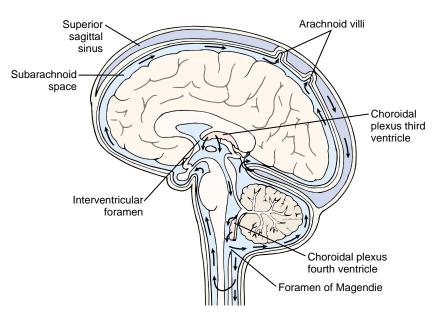

ing it close to the composition of the brain extracellular fluid. Humans secrete approximately 500 mL of CSF each day. However, only approximately 150 mL is in the ventricular system at any one time, meaning that the CSF is continuously being absorbed.

Once produced, the CSF flows freely through the ventricles. Three openings, or foramina, allow the CSF to pass into the subarachnoid space. Two of these, the foramina of Luschka, are located at the lateral corners of the fourth ventricle. The third, the medial foramen of Magendie, is in the midline at the caudal end of the fourth ventricle (see Fig. 36-25). Approximately 30% of the CSF passes down into the subarachnoid space that surrounds the spinal cord, mainly on its dorsal surface, and moves back up to the cranial cavity along its ventral surface.

Reabsorption of CSF into the vascular system occurs along the sides of the superior sagittal sinus in the anterior and middle fossa. Here, the waterproof arachnoid has protuberances, the *arachnoid villi*, that penetrate the inner dura and venous walls of the superior sagittal sinus. The arachnoid villi function as one-way valves, permitting CSF outflow into the blood but not allowing blood to pass into the arachnoid spaces.

Blood-Brain and Cerebrospinal Fluid–Brain Barriers

Maintenance of a chemically stable environment is essential to the function of the brain. In most regions of the body, extracellular fluid undergoes small fluctuations in pH and concentrations of hormones, amino acids, and potassium ions during routine daily activities such as eating and exercising. If the brain were to undergo such fluctuations, the result would be uncontrolled neural activity because some substances such as amino acids act as neurotransmitters, and ions such as potassium influence the threshold for neural firing. Two barriers, the blood-brain barrier and the CSF-brain barrier, provide the means for maintaining the stable chemical environment of the brain. Only water, carbon dioxide, and oxygen enter the brain with relative ease; the transport of other substances between the brain and the blood is slow.

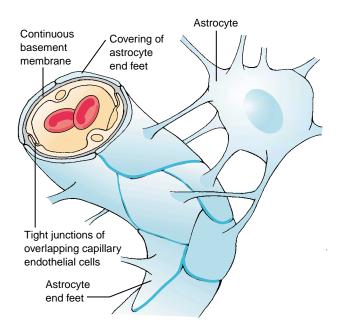

■ FIGURE 36-25 ■ The flow of cerebrospinal fluid from the time of its formation from blood in the choroid plexuses until its return to the blood in the superior sagittal sinus. Plexuses in the lateral ventricles are not illustrated.

Blood-Brain Barrier. The blood-brain barrier depends on the unique characteristics of the brain capillaries. The endothelial cells of brain capillaries are joined by continuous tight junctions. In addition, most brain capillaries are completely surrounded by a basement membrane and by the processes of supporting cells of the brain, called *astrocytes* (Fig. 36-26). The blood-brain barrier permits passage of essential substances while excluding unwanted materials. Reverse transport systems remove materials from the brain. Large molecules such as proteins and peptides are largely excluded from crossing the blood-brain barrier. Acute cerebral lesions, such as trauma and infection, increase the permeability of the blood-brain barrier and alter brain concentrations of proteins, water, and electrolytes.

The blood-brain barrier prevents many drugs from entering the brain. Most highly water-soluble compounds are excluded from the brain, especially molecules with high ionic charge, such as many of the catecholamines. In contrast, many lipidsoluble molecules cross the lipid layers of the blood-brain barrier with ease. Some drugs, such as the antibiotic chloramphenicol, are highly lipid soluble and therefore enter the brain readily. Other medications have a low solubility in lipids and enter the brain slowly or not at all. Alcohol, nicotine, and heroin are very lipid soluble and rapidly enter the brain. Some substances that enter the capillary endothelium are converted by metabolic processes to a chemical form incapable of moving into the brain.

The cerebral capillaries are much more permeable at birth than in adulthood, and the blood-brain barrier develops during the early years of life. In severely jaundiced infants, bilirubin can cross the immature blood-brain barrier, producing kernicterus and brain damage (see Chapter 15). In adults, the mature blood-brain barrier prevents bilirubin from entering the brain, and the nervous system is not affected.

■ FIGURE 36-26 ■ The three components of the blood-brain barrier: the astrocyte and astrocytic feet that encircle the capillary, the capillary basement membrane, and the tight junctions that join the overlapping capillary endothelial cells.

Cerebrospinal Fluid–Brain Barrier. The ependymal cells covering the choroid plexus are linked together by tight junctions, forming a blood-CSF barrier to diffusion of many molecules from the blood plasma of choroid plexus capillaries to the CSF. Water is transported through the choroid epithelial cells by osmosis. Oxygen and carbon dioxide move into the CSF by diffusion, resulting in partial pressures roughly equal to those of plasma. The high sodium and low potassium contents of the CSF are actively regulated and kept relatively constant. Lipids and nonpeptide hormones diffuse through the barrier rather easily, but most large molecules, such as proteins, peptides, many antibiotics, and other medications, do not normally get through. Many substances such as proteins; sodium ions; a number of micronutrients such as vitamins C, B_6 (pyridoxine), and folate are actively secreted into the CSF by the choroid epithelium. Because the resultant CSF has a relatively high sodium content, the negatively charged chloride and bicarbonate diffuse into the CSF along an ionic gradient. The choroid cells also generate bicarbonate from carbon dioxide in the blood. The generation of bicarbonate is important to the regulation of the pH of the CSF.

Mechanisms exist that facilitate the transport of other molecules such as glucose without energy expenditure. Ammonia, a toxic metabolite of neuronal activity, is converted to glutamine by astrocytes. Glutamine moves by facilitated diffusion through the choroid epithelium into the plasma. This exemplifies a major function of the CSF, that of providing a means of removal of toxic waste products from the CNS. Because the brain and spinal cord have no lymphatic channels, the CSF serves this function.

There are several specific areas of the brain where the blood-CSF barrier does not exist. One area is at the caudal end of the fourth ventricle, where specialized receptors for the carbon dioxide level of the CSF influence respiratory function. Another area consists of the walls of the third ventricle, which permit hypothalamic neurons to monitor blood glucose levels. This mechanism permits hypothalamic centers to respond to these blood glucose levels, contributing to hunger and eating behaviors.

In summary, in the adult, the spinal cord is in the upper two thirds of the spinal canal of the vertebral column. On transverse section, the spinal cord has an oval shape, and the internal gray matter has the appearance of a butterfly or letter "H." The dorsal horns contain the IA neurons and receive afferent information from dorsal root and other connecting neurons. The ventral horns contain the OA neurons and efferent LMNs that leave the cord by the ventral roots. Thirty-two pairs of spinal nerves (i.e., 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 2 or more coccygeal) are present. Each pair communicates with its corresponding body segments. The spinal nerves and the blood vessels that supply the spinal cord enter the spinal canal through an intervertebral foramen. After entering the foramen, they divide into two branches, or roots, one of which enters the dorsolateral surface of the cord (i.e., dorsal root), carrying the axons of afferent neurons into the CNS. The other root leaves the ventrolateral surface of the cord (i.e., ventral root), carrying the axons of efferent neurons into the periphery. These two roots fuse at the intervertebral foramen, forming the mixed spinal nerve.

The brain can be divided into three regions: the hindbrain, the midbrain, and the forebrain. The hindbrain, consisting of the medulla oblongata, pons, and cerebellum, contains the neuronal circuits for the eating, breathing, and locomotive functions required for survival. Cranial nerves XII, XI, X, IX, VIII, VII, VII, and V are located in the hindbrain. The midbrain contains cranial nerves III and IV.

The forebrain is the most rostral part of the brain; it consists of the diencephalon and the telencephalon. The diencephalon forms the core of the forebrain, and telencephalon forms the cerebral hemispheres. The dorsal horn part of the diencephalon contains the thalamus and subthalamus, and the ventral horn contains the hypothalamus. All sensory pathways have direct projections to the thalamic nuclei, which convey the information to restricted parts of the sensory cortex. The hypothalamus functions in the homeostatic control of the internal environment. The cerebral hemispheres are the lateral outgrowths of the diencephalon and are arbitrarily divided into lobes-the frontal, parietal, temporal, and occipital lobes. The prefrontal premotor area and primary motor cortex are located in the frontal lobe; the primary sensory cortex and somatosensory association area are in the parietal cortex; the primary auditory cortex and the auditory association area are in the temporal lobe; and the primary visual cortex and association visual cortex are in the occipital lobe. The limbic system, which is involved in emotional experience and release of emotional behaviors, is located in the medial aspect of the cerebrum.

The brain is enclosed and protected by the pia mater, arachnoid, and dura mater. The protective CSF in which the brain and spinal cord float isolates them from minor and moderate trauma. The CSF is secreted into the ventricles, circulates through the ventricular system, passes outside to surround the brain, and is reabsorbed into the venous system through the arachnoid villi. The CSF-brain barrier and the blood-brain barrier protect the brain from substances in the blood that would disrupt brain function.

THE AUTONOMIC NERVOUS SYSTEM

The ability to maintain homeostasis and perform the activities of daily living in an ever-changing physical environment is largely vested in the autonomic nervous system (ANS). The ANS functions at the subconscious level and is involved in regulating, adjusting, and coordinating vital visceral functions such as blood pressure and blood flow, body temperature, respiration, digestion, metabolism, and elimination. The ANS is strongly affected by emotional influences and is involved in many of the expressive aspects of behavior. Blushing, pallor, palpitations of the heart, clammy hands, and dry mouth are several emotional expressions that are mediated through the ANS.

As with the somatic nervous system, the ANS is represented in both the CNS and the PNS. Traditionally, the ANS has been defined as a general efferent system innervating visceral organs. The efferent outflow from the ANS has two divisions: the sympathetic nervous system and the parasympathetic nervous system. The afferent input to the ANS is pro-

KEY CONCEPTS

THE AUTONOMIC NERVOUS SYSTEM (ANS)

- The ANS functions at the subconscious level and is responsible for maintaining homeostatic functions of the body.
- The ANS has two divisions: the sympathetic and parasympathetic systems. Although the two divisions function in concert, they are generally viewed as having opposite and antagonistic actions.
- The sympathetic nervous system functions in maintaining vital functions and responding when there is a critical threat to the integrity of the individual the "fight-or-flight" response.
- The parasympathetic nervous system functions in conserving energy, resource replenishment, and maintenance of organ function during periods of minimal activity.

vided by visceral afferent neurons, usually not considered to be part of the ANS.

The functions of the sympathetic nervous system include maintaining body temperature and adjusting blood flow and blood pressure to meet the changing needs of the body that occur with activities of daily living, such as moving from the supine to the standing position. The sympathoadrenal system also can discharge as a unit when there is a critical threat to the integrity of the individual-the so-called fight-or-flight response. During a stress situation, the heart rate accelerates; the blood pressure rises; blood flow shifts from the skin and gastrointestinal tract to the skeletal muscles and brain; blood sugar increases; the bronchioles and pupils dilate; the sphincters of the stomach and intestine and the internal sphincter of the urethra constrict; and the rate of secretion of exocrine glands that are involved in digestion diminishes. Emergency situations often require vasoconstriction and shunting of blood away from the skin and into the muscles and brain, a mechanism that, should a wound occur, provides for a reduction in blood flow and preservation of vital functions needed for survival. Sympathetic function often is summarized as catabolic in that its actions predominate during periods of pronounced energy expenditure, such as when survival is threatened.

In contrast to the sympathetic nervous system, the functions of the parasympathetic nervous system are concerned with conservation of energy, resource replenishment and storage (*i.e.*, anabolism), and maintenance of organ function during periods of minimal activity. The parasympathetic nervous system slows heart rate, stimulates gastrointestinal function and related glandular secretion, promotes bowel and bladder elimination, and contracts the pupil, protecting the retina from excessive light during periods when visual function is not vital to survival. The two divisions of the ANS usually are viewed as having opposite and antagonistic actions (*i.e.*, if one activates, the other inhibits a function). Exceptions are functions, such as sweating and regulation of arteriolar blood vessel diameter, that are controlled by a single division of the ANS, in this case the sympathetic nervous system.

The sympathetic and parasympathetic nervous systems are continually active. The effect of this continual or basal (baseline) activity is referred to as tone. The tone of an effector organ or system can be increased or decreased and usually is regulated by a single division of the ANS. For example, vascular smooth muscle tone is controlled by the sympathetic nervous system. Increased sympathetic activity produces local vasoconstriction from increased vascular smooth muscle tone, and decreased activity results in vasodilatation caused by decreased tone. In structures such as the sinoatrial node and atrioventricular node of the heart, which are innervated by both divisions of the ANS, one division predominates in controlling tone. In this case, the tonically active parasympathetic nervous system exerts a constraining or braking effect on heart rate, and when parasympathetic outflow is withdrawn, similar to releasing a brake, the heart rate increases. The increase in heart rate that occurs with vagal withdrawal can be further augmented by sympathetic stimulation.

Autonomic Efferent Pathways

The outflow of both divisions of the ANS follows a two-neuron pathway. The first motoneuron, called the *preganglionic neuron*, lies in the intermediolateral cell column in the ventral horn of the spinal cord or its equivalent location in the brain stem. The second motoneuron, called the *postganglionic neuron*, synapses with a preganglionic neuron in an autonomic ganglion located in the PNS. The two divisions of the ANS differ in terms of location of preganglionic cell bodies, relative length of preganglionic fibers, general function, nature of peripheral responses, and preganglionic and postganglionic neuromediators (Table 36-3). This two-neuron outflow pathway and the interneurons in the autonomic ganglia that add further modulation to ANS function are features distinctly different from the arrangement in somatic motor innervation.

Most visceral organs are innervated by both sympathetic and parasympathetic fibers. Exceptions include structures such

as blood vessels and sweat glands that have input from only one division of the ANS. The fibers of the sympathetic nervous system are distributed to effectors throughout the body, and as a result, sympathetic actions tend to be more diffuse than those of the parasympathetic nervous system, in which there is a more localized distribution of fibers. The preganglionic fibers of the sympathetic nervous system may traverse a considerable distance and pass through several ganglia before synapsing with postganglionic neurons, and their terminals make contact with a large number of postganglionic fibers. In some ganglia, the ratio of preganglionic to postganglionic cells may be 1:20; because of this, the effects of sympathetic stimulation are diffuse. There is considerable overlap, and one ganglion cell may be supplied by several preganglionic fibers. In contrast to the sympathetic nervous system, the parasympathetic nervous system has its postganglionic neurons located very near or in the organ of innervation. Because the ratio of preganglionic to postganglionic communication often is 1:1, the effects of the parasympathetic nervous system are much more circumscribed.

Sympathetic Nervous System

The preganglionic neurons of the sympathetic nervous system are located primarily in the thoracic and upper lumbar segments (T1 to L2) of the spinal cord; thus, the sympathetic nervous system often is referred to as the thoracolumbar division of the ANS. These preganglionic neurons, which are located primarily in the ventral horn intermediolateral cell column, have axons that are largely myelinated and relatively short. The postganglionic neurons of the sympathetic nervous system are located in the paravertebral ganglia of the sympathetic chain that lie on either side of the vertebral column, or in prevertebral sympathetic ganglia such as the celiac ganglia (Fig. 36-27). In addition to postganglionic efferent neurons, the sympathetic ganglia contain neurons of the internuncial, short-axon type, similar to those associated with complex circuitry in the brain and spinal cord. Many of these inhibit and others modulate preganglionic-to-postganglionic transmission.

The axons of the preganglionic neurons leave the spinal cord through the ventral root of the spinal nerves (T1 to L2),

TABLE 36-3 Charao

Characteristics of the Sympathetic and Parasympathetic

Nervous Systems		
Characteristic	Sympathetic Outflow	Parasympathetic Outflow
Location of preganglionic cell bodies	T1–T12, L1 and L2	Cranial nerves: III, VII (intermedius), IX, X; sacral segments 2, 3, and 4
Relative length of preganglionic fibers	Short—to paravertebral chain of ganglia or to aortic prevertebral of ganglia	Long—to ganglion cells near or in the innervated organ
General function	Catabolic—mobilizes resources in anticipation of chal- lenge for survival (preparation for "fight-or-flight" response)	Anabolic—concerned with conser- vation, renewal, and storage of resources
Nature of peripheral response	Generalized	Localized
Transmitter between preganglionic ter- minals and postganglionic neurons	ACh	ACh
Transmitter of postganglionic neuron	ACh (sweat glands and skeletal muscle vasodilator fibers); norepinephrine (most synapses); norepineph- rine and epinephrine (secreted by adrenal gland)	ACh

ACh, acetylcholine.

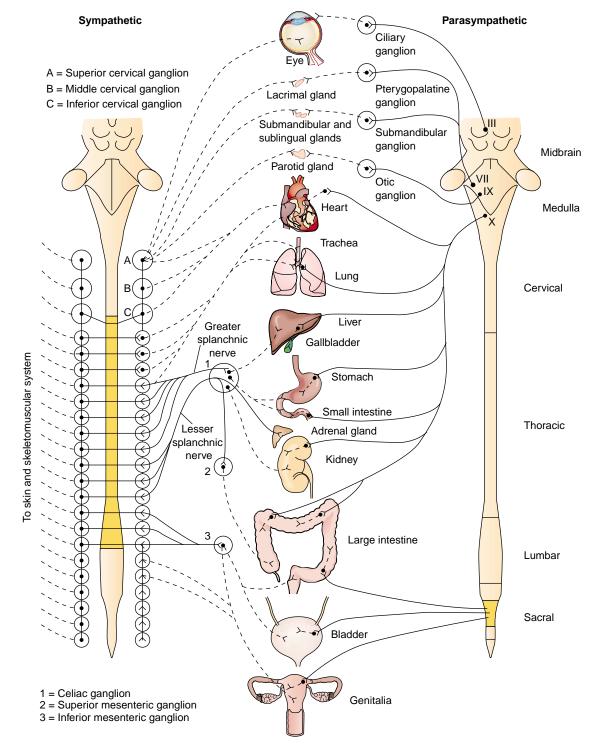

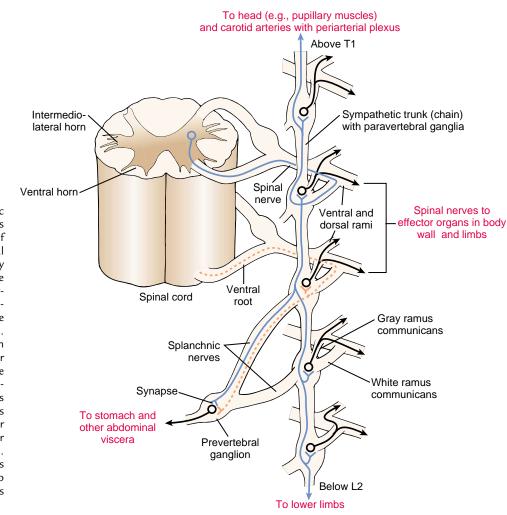

FIGURE 36-27 The autonomic nervous system. The involuntary organs are depicted with their parasympathetic innervation (craniosacral) indicated on the right and sympathetic innervation (thoracolumbar) on the left. Preganglionic fibers are *solid lines*; postganglionic fibers are *dashed lines*. For purposes of illustration, the sympathetic outflow to the skin and skeletomuscular system is shown separately (to the far left); effectors include sweat glands, pilomotor muscles and blood vessels of the skin, and blood vessels of the skeletal muscles and bones. (Modified from Hemer L. [1983]. *The human brain and spinal cord: Functional neuroanatomy and dissection guide.* New York: Springer-Verlag)

■ FIGURE 36-28 ■ Sympathetic pathways. Sympathetic fibers leave the spinal cord by way of the ventral root of the spinal nerves, enter the ventral primary rami, and pass through the white rami to the prevertebral or paravertebral ganglia of the sympathetic chain, where they synapse with postganglionic neurons. Some postganglionic fibers from the paravertebral ganglia reenter the segmental nerves through the gray rami and are then distributed in the spinal nerve branches that innervate the effector organs (eg., sweat glands and arrector pili muscles of skin and vascular smooth muscle of blood vessels). Other postganglionic neurons (dotted lines) travel directly to their destination in the various effector organs.

enter the ventral primary rami, and leave the spinal nerve through white rami of the rami communicantes to reach the paravertebral ganglionic chain (Fig. 36-28). In the sympathetic chain of ganglia, preganglionic fibers may synapse with neurons of the ganglion it enters, pass up or down the chain and synapse with one or more ganglia, or pass through the chain and move outward through a splanchnic nerve to terminate in one of the prevertebral ganglia (*i.e.*, celiac, superior mesenteric, or inferior mesenteric) that are scattered along the dorsal aorta and its branches. The adrenal medulla, which is part of the sympathetic nervous system, contains postganglionic sympathetic neurons that secrete sympathetic neurotransmitters directly into the bloodstream.

Parasympathetic Nervous System

The preganglionic fibers of the parasympathetic nervous system, also referred to as the *craniosacral division* of the ANS, originate in some segments of the brain stem and sacral segments of the spinal cord (see Fig. 36-27). The central regions of origin are the midbrain, pons, medulla oblongata, and the sacral part of the spinal cord. Outflow from the midbrain passes through the oculomotor nerve (cranial nerve III) to supply the pupillary sphincter muscle of each eye and the ciliary muscles that control lens thickness for accommodation. Caudal pontine outflow comes from branches of the facial nerve (cranial nerve VII) that supply the lacrimal and nasal glands. The medullary outflow develops from cranial nerves VII, IX, and X. Fibers in the glossopharyngeal nerve (cranial nerve IX) supply the parotid salivary glands. Approximately 75% of parasympathetic efferent fibers are carried in the vagus nerve (cranial nerve X). The vagus nerve provides parasympathetic innervation for the heart, trachea, lungs, esophagus, stomach, small intestine, proximal half of the colon, liver, gallbladder, pancreas, kidneys, and upper portions of the ureters.

Sacral preganglionic axons leave the S2 to S4 segmental nerves by gathering into the pelvic nerves. The pelvic nerves leave the sacral plexus on each side of the cord and distribute their peripheral fibers to the bladder, uterus, urethra, prostate, distal portion of the transverse colon, descending colon, and rectum. The sacral parasympathetic fibers also supply the venous outflow from the external genitalia to facilitate erectile function.

With the exception of cranial nerves III, VII, and IX, which synapse in discrete ganglia, the long parasympathetic preganglionic fibers pass uninterrupted to short postganglionic fibers located in the organ wall. In the walls of these organs, postganglionic neurons send axons to smooth muscle and glandular cells that modulate their functions.

664 Unit Ten: Alterations in the Nervous System

The gastrointestinal tract has its own intrinsic network of ganglionic cells located between the smooth muscle layers, called the *enteric* (or *intramural*) *plexus*, which controls local peristaltic movements and secretory functions. This network of parasympathetic postganglionic neurons and interneurons runs from the upper portion of the esophagus to the internal anal sphincter. Local afferent sensory neurons respond to mechanical and chemical stimuli and communicate these influences to motor fibers in the enteric plexus. The number of neurons in the enteric neural network (10^8) is so large that it approximates that of the spinal cord. It is thought that this enteric nervous system is capable of independent function without control from CNS fibers. The CNS has a modulating role, by way of preganglionic innervation of the plexus, converting local peristalsis to longer-distance movements, thereby speeding the transit of intestinal contents.

Central Integrative Pathways

General visceral afferent fibers accompany the sympathetic and parasympathetic outflow into the spinal and cranial nerves, bringing chemoreceptor, pressure, and nociceptive information from organs of the viscera to the brain stem, thoracolumbar cord, and sacral cord. Local reflex circuits relating visceral afferent and autonomic efferent activity are integrated into a hierarchic control system in the spinal cord and brain stem. Progressively greater complexity in the responses and greater precision in their control occur at each higher level of the nervous system. Most visceral reflexes contain contributions from the LMNs that innervate skeletal muscles as part of their response patterns.

For most autonomic-mediated functions, the hypothalamus serves as the major control center. The hypothalamus, which has connections with the cerebral cortex, the limbic system, and the pituitary gland, is in a prime position to receive, integrate, and transmit information to other areas of the nervous system. The neurons concerned with thermoregulation, thirst, and feeding behaviors are found in the hypothalamus. The hypothalamus also is the site for integrating neuroendocrine function. Hypothalamic releasing and inhibiting hormones control the secretion of anterior pituitary hormones (see Chapter 30).

The organization of many life-support reflexes occurs in the reticular formation of the medulla and pons. These areas of reflex circuitry, often called *centers*, produce complex combinations of autonomic and somatic efferent functions required for the cough, sneeze, swallow, and vomit reflexes, as well as for the more purely autonomic control of the cardiovascular system. At the hypothalamic level, these reflexes are integrated into more general response patterns, such as rage, defensive behavior, eating, drinking, voiding, and sexual function. Forebrain and especially limbic system control of these behaviors involves inhibiting or facilitating release of the response patterns according to social pressures during learned emotion-provoking situations.

Reflex adjustments of cardiovascular and respiratory function occur at the level of the brain stem. A prominent example is the carotid sinus baroreflex (see Chapter 14). One of the striking features of ANS function is the rapidity and intensity with which it can change visceral function. Within 3 to 5 seconds, it can increase heart rate to approximately twice its resting level. Bronchial smooth muscle tone is largely controlled by parasympathetic fibers carried in the vagus nerve. These nerves produce mild to moderate constriction of the bronchioles.

Other important ANS reflexes are located at the level of the spinal cord. As with other spinal reflexes, these reflexes are modulated by input from higher centers. When there is loss of communication between the higher centers and the spinal reflexes, as occurs in spinal cord injury, these reflexes function in an unregulated manner (see Chapter 38).

Autonomic Neurotransmission

The generation and transmission of impulses in the ANS occur in the same manner as in the CNS. There are self-propagating action potentials with transmission of impulses across synapses and other tissue junctions by way of neurohumoral transmitters. The postganglionic fibers of the ANS form a diffuse neural plexus at the site of innervation. The membranes of the cells of many smooth muscle fibers are connected by conductive protoplasmic bridges, called *gap junctions*, that permit rapid conduction of impulses through whole sheets of smooth muscle, often in repeating waves of contraction. Autonomic neurotransmitters released near a limited portion of these fibers provide a modulating function extending to a large number of effector cells. The muscle layers of the gut and of the bladder wall are examples.

The main neurotransmitters of the autonomic nervous system are acetylcholine and the catecholamines, epinephrine and norepinephrine. Acetylcholine is released at all of the sites of preganglionic transmission in the autonomic ganglia of sympathetic and parasympathetic nerve fibers and at the sites of postganglionic transmission in parasympathetic nerve endings. It also is released at sympathetic nerve endings that innervate the sweat glands and cholinergic vasodilator fibers found in skeletal muscle. Norepinephrine is released at most sympathetic nerve endings. The adrenal medulla, which is a modified prevertebral sympathetic ganglion, produces epinephrine along with small amounts of norepinephrine. Dopamine, which is an intermediate compound in the synthesis of norepinephrine, also acts as a neurotransmitter. It is the principal inhibitory transmitter of internuncial neurons in the sympathetic ganglia. It also has vasodilator effects on renal, splanchnic, and coronary blood vessels when given intravenously and is sometimes used in the treatment of shock (see Chapter 18).

Acetylcholine and Cholinergic Receptors

Acetylcholine is synthesized in the cholinergic neurons from choline and acetyl coenzyme A (acetyl CoA). After acetylcholine is secreted by the cholinergic nerve endings, it is rapidly broken down by the enzyme acetylcholinesterase. The choline molecule is transported back into the nerve ending, where it is used again in the synthesis of acetylcholine.

Receptors that respond to acetylcholine are called *cholinergic receptors*. There are two types of cholinergic receptors: muscarinic and nicotinic. Muscarinic receptors are present on the innervational targets of postganglionic fibers of the parasympathetic nervous system and the sweat glands, which are innervated by the sympathetic nervous system. Nicotinic receptors are found in autonomic ganglia and the end plates of skeletal muscle. Acetylcholine has an excitatory effect on muscarinic and nicotinic receptors, except for those in the heart and lower esophagus, where it has an inhibitory effect. The drug atropine is an antimuscarinic or muscarinic cholinergic-blocking drug that prevents the action of acetylcholine at excitatory and inhibitory muscarinic receptor sites. Because it is a muscarinicblocking drug, it exerts little effect at nicotinic receptor sites.

Catecholamines and Adrenergic Receptors

The catecholamines, which include norepinephrine, epinephrine, and dopamine, are synthesized in the sympathetic nervous system. Synthesis of dopamine and norepinephrine begins in the axoplasm of sympathetic nerve terminals with the conversion of the amino acid tyrosine to dopa; dopa to dopamine; and dopamine to norepinephrine. In the adrenal gland an additional step takes place during which approximately 80% the norepinephrine is transformed into epinephrine.

Each of the steps in sympathetic neurotransmitter synthesis requires a different enzyme, and the type of neurotransmitter that is produced depends on the types of enzymes that are available in a nerve terminal. For example, the postganglionic sympathetic neurons that supply blood vessels have the needed enzymes for the synthesis of norepinephrine, whereas those in the adrenal medulla have the enzymes needed to convert norepinephrine into epinephrine. As the catecholamines are synthesized, they are stored in vesicles. The final step of norepinephrine synthesis occurs in these vesicles. When an action potential reaches an axon terminal, the neurotransmitter molecules are released from the storage vesicles. The storage vesicles provide a means for concentrated storage of the catecholamines and protect them from the cytoplasmic enzymes that degrade the neurotransmitters.

In addition to neuronal synthesis, there is a second major mechanism for replenishment of norepinephrine in sympathetic nerve terminals. This mechanism consists of the active reuptake of the released neurotransmitter into the nerve terminal. Between 50% and 80% of the norepinephrine that is released during an action potential is removed from the synaptic area by an active reuptake process. This process terminates the action of the neurotransmitter and allows it to be reused by the neuron. The remainder of the released catecholamines diffuses into the surrounding tissue fluids or is degraded by two special enzymes: catechol-O-methyltransferase, which is diffusely present in all tissues, and monoamine oxidase (MAO), which is found in the nerve endings themselves.

Catecholamines can cause excitation or inhibition of smooth muscle contraction, depending on the site, dose, and type of receptor present. The excitatory or inhibitory responses of organs to sympathetic neurotransmitters are mediated by interaction with special structures in the cell membrane called *receptors*. There are two types of sympathetic receptors: α and β receptors. In vascular smooth muscle, excitation of α receptors causes vasoconstriction, and excitation of β -adrenergic receptors causes vasodilatation. Constriction of blood vessels in the skin, kidneys, and splanchnic circulation is mediated by α -adrenergic receptors. The β -adrenergic receptors are most prevalent in the heart, the blood vessels of skeletal muscle, and the bronchioles.

 α -Adrenergic receptors have been further subdivided into α_1 and α_2 receptors, and β -adrenergic receptors into β_1 and β_2 receptors. β_1 -Adrenergic receptors are found primarily in the heart and can be selectively blocked by β_1 -receptor–blocking drugs. β_2 -Adrenergic receptors are found in the bronchioles and in other sites that have β -mediated functions. The α_1 receptors are found primarily in postsynaptic effector sites; they mediate responses in vascular smooth muscle. The α_2 receptors are mainly located presynaptically and can inhibit the release of norepinephrine from sympathetic nerve terminals. The α_2 receptors are abundant in the CNS and are thought to influence the central control of blood pressure.

In summary, the ANS regulates, adjusts, and coordinates the visceral functions of the body. The ANS, which is divided into the sympathetic and parasympathetic systems, is an efferent system. It receives its afferent input from visceral afferent neurons. The ANS has CNS and PNS components. The outflow of the sympathetic and parasympathetic nervous system follows a two-neuron pathway, which consists of a preganglionic neuron located in the CNS and a postganglionic neuron located outside the CNS. Sympathetic fibers leave the CNS at the thoracolumbar level, and the parasympathetic fibers leave at the craniosacral level.

In general, the sympathetic and parasympathetic nervous systems have opposing effects on visceral function—if one excites, the other inhibits. The hypothalamus serves as the major control center for most ANS functions; local reflex circuits relating visceral afferent and autonomic efferent activity are integrated in a hierarchic control system in the spinal cord and brain stem.

The main neurotransmitters for the ANS are acetylcholine, the catecholamines, epinephrine, and norepinephrine. Acetylcholine is the transmitter for all preganglionic neurons, for postganglionic parasympathetic neurons, and for selected postganglionic sympathetic neurons. The catecholamines are the neurotransmitters for most postganglionic sympathetic neurons. The ANS neurotransmitters exert their action through specialized cell surface receptors—cholinergic receptors that bind acetylcholine and adrenergic receptors are divided into nicotinic and muscarinic receptors, and adrenergic receptors are divided into α and β receptors.

REVIEW QUESTIONS

The nervous system functions in much the same way as a computer system. Using this analogy, describe the relationship between the PNS and CNS in terms of input, output, and computational functions.

The transmission of impulses in the nervous system occurs by way of chemical or electrical synapses. Compare the two types of synapses in terms of mechanism of impulse generation, speed of conduction, one-way conduction, and in the case of chemical synapses, the mechanism whereby the neurotransmitters are synthesized, stored, released, and inactivated.

The poliovirus produces paralysis of skeletal muscles but does not affect somatosensory or visceral function. Based on your knowledge of cell columns, what neurons are susceptible to attack by the virus.

The inner tract layer of the nervous system contains many of the neuronal processes for reflexes such as those involved in

666 Unit Ten: Alterations in the Nervous System

swallowing and vomiting. Explain the advantages of this arrangement.

State the structures innervated by general somatic afferent, special visceral afferent, general visceral afferent, special somatic afferent, general visceral efferent, pharyngeal efferent, and general somatic efferent neurons.

List the structures of the hindbrain, midbrain, and forebrain and describe their functions.

Name the cranial nerves and cite their location and function.

Describe the characteristics of the CSF and trace its passage through the ventricular system.

State the function of the autonomic nervous system.

Compare the anatomic location and functions of the sympathetic and parasympathetic nervous systems.

A natomically and functionally the brain is the most complex structure in the body. It controls our ability to think, our awareness of things around us, and our interactions with the outside world. Signals to and from various parts of the body are controlled by very specific areas within the brain. This renders the brain much more vulnerable to focal lesions than other organs in the body. For example, an isolated renal infarct would not be expected to have a significant effect on kidney function; whereas, an infarct of comparable size in specific areas of the brain could produce complete paralysis on one side of the body.¹

BRAIN INJURY

The brain is protected from external forces by the rigid confines of the skull and the cushioning afforded by the cerebrospinal fluid (CSF). The metabolic stability required by its electrically active cells is maintained by a number of regulatory mechanisms, including the blood-brain barrier and autoregulatory mechanisms that ensure its blood supply. Nonetheless, the brain remains remarkably vulnerable to injury.

Mechanisms of Injury

Injury to brain tissue can result from a number of conditions, including trauma, tumors, stroke, and metabolic derangements. Brain damage resulting from these disorders involves several common pathways, including the effects of hypoxia and ischemia, cerebral edema, and injury caused by increased intracranial pressure. In many cases, the mechanisms of injury are interrelated.

Hypoxia and Ischemia

The brain relies on the ability of the cerebral circulation to deliver sufficient oxygen for its energy needs. Although the brain makes up only 2% of the body weight, it receives one sixth of the resting cardiac output and accounts for 20% of the oxygen consumption.^{1,2} By definition, *hypoxia* denotes a deprivation of oxygen with maintained blood flow and ischemia, a situation of greatly reduced or interrupted blood flow. The cellular effects of hypoxia and ischemia are quite different, and the brain tends to have different sensitivities to the two conditions. Hypoxia interferes with the delivery of oxygen, and ischemia interferes with the delivery of oxygen and glucose as well as the removal of metabolic wastes.

Hypoxia usually is seen in conditions such as exposure to reduced atmospheric pressure, carbon monoxide poisoning, severe anemia, and failure to oxygenate the blood. Contrary to popular belief, hypoxia is fairly well tolerated, particularly in situations of chronic hypoxia. Neurons are capable of substantial anaerobic metabolism and are fairly tolerant of pure hypoxia; it commonly produces euphoria, listlessness, drowsiness, and impaired problem solving. Unconsciousness and convulsions may occur when hypoxia is sudden and severe. However, the effects of severe hypoxia (*i.e.*, anoxia) on brain function seldom are seen because the condition rapidly leads to cardiac arrest and ischemia.

Ischemia can be global or focal. Focal ischemia involves a single area of the brain, as in stroke. Collateral circulation may provide low levels of blood flow during focal ischemia. The residual perfusion may provide sufficient substrates to maintain a low level of metabolic activity, preserving neuronal integrity.

Global ischemia occurs when blood flow is inadequate to meet the metabolic needs of the entire brain. In contrast to persons with focal ischemia, those with global ischemia have no collateral circulation during the ischemic event.^{1,3} The result is a spectrum of neurologic disorders. Unconsciousness occurs within seconds of severe global ischemia, such as that resulting from complete cessation of blood flow, as in cardiac arrest. If circulation is restored immediately, consciousness is regained quickly. However, if blood flow is not promptly restored, severe pathologic changes take place. Energy sources (*i.e.*, glucose and glycogen) are exhausted in 2 to 4 minutes, and cellular ATP stores are depleted in 4 to 5 minutes. Approximately 50% to 75% of the total energy requirement of neuronal tissue is spent on mechanisms for maintenance of ionic gradients across the cell membrane (*e.g.*, sodium-potassium pump), resulting in fluxes of sodium, potassium, and calcium ions⁴ (Table 37-1). Excessive influx of sodium results in neuronal and interstitial edema. The influx of calcium initiates a cascade of events, including release of intracellular and nuclear enzymes that cause cell destruction.

Within the brain, certain regions and cell populations are more susceptible than others to hypoxic-ischemic injury.¹ For example, neurons are more susceptible to injury than are the glial cells. Among the neurons, the pyramidal cells of the hippocampus, the Purkinje cells of the cerebellum, and the neurons of the globus pallidus of the basal ganglia are particularly sensitive to generalized ischemic-hypoxic injury. The reason for this selectivity is uncertain but appears to be related at least to some extent on local levels and metabolism of certain excitatory neurotransmitters such as glutamate.

Excitatory Amino Acid Injury

Glutamate is the principal excitatory neurotransmitter in the brain, and its interaction with specific receptors is responsible for many higher-order functions, including memory, cognition, movement, and sensation.⁵ Normally, extracellular concentrations of glutamate are tightly regulated, with excess amounts removed and actively transported into astrocytes and neurons. During prolonged ischemia, these transport mechanisms become immobilized, causing extracellular glutamate to accumulate. In the case of cell injury and death, intracellular glutamate is released from the damaged cells.

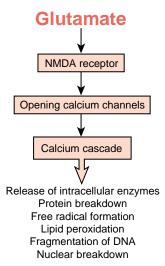

Many of the actions of glutamate are coupled with receptoroperated ion channels. One type of glutamate receptor, called the *glutamate N-methyl-D*-aspartate (NMDA) receptor, has been implicated in causing central nervous system (CNS) injury. The uncontrolled opening of NMDA receptor-operated channels produces an increase in intracellular calcium and leads to a series of calcium-mediated processes called the *calcium cascade* (Fig. 37-1). Activation of the calcium cascade leads to the release of intracellular enzymes that cause protein breakdown,

free radical formation, lipid peroxidation, fragmentation of DNA, and nuclear breakdown. Drugs called neuroprotectants are being developed to interfere with the glutamate-NMDA pathway and thus reduce brain cell injury.

Cerebral Edema

Cerebral edema, or brain swelling, is an increase in tissue volume secondary to abnormal fluid accumulation. There are basically two types of brain edema: vasogenic or cytotoxic.1

Vasogenic Edema. Vasogenic edema results from an increase in the extracellular fluid that surrounds brain cells. It occurs with conditions such as tumors, prolonged ischemia, hemorrhage, brain injury, and infectious processes (e.g., meningitis) that impair the function of the blood-brain barrier and allow water and plasma proteins to leave the capillary and move into the interstitium. Vasogenic edema occurs primarily in the white matter of the brain, possibly because the white matter is more compliant than the gray matter and offers less resistance to fluid accumulation. Vasogenic edema can be localized, as in the case of abscesses or neoplasms, or it may be more generalized. The functional manifestations of vasogenic edema include focal neurologic deficits, disturbances in consciousness, and severe intracranial hypertension.

Cytotoxic Edema. Cytotoxic edema involves the swelling of brain cells. It involves an increase in fluid in the intracellular space, chiefly the gray matter, although the white matter may be involved. Cytotoxic edema can result from hypo-osmotic states, such as water intoxication or severe ischemia, that impair the function of the sodium-potassium membrane pump. This causes rapid accumulation of sodium in the cell, followed by movement of water along the osmotic gradient. Depending on the nature of the insult, cellular edema can occur in the vascular endothelium or smooth muscle cells, astrocytes, the myelin-forming processes of oligodendrocytes, or neurons. Major changes in cerebral function, such as stupor and coma, occur with cytotoxic edema. The edema associated with ischemia may be severe enough to produce cerebral infarction with necrosis of brain tissue.

Increased Intracranial Volume and Pressure

Increased intracranial pressure (ICP) is a common pathway for brain injury from different types of insults and agents. Excessive ICP can obstruct cerebral blood flow, destroy brain cells, displace brain tissue as in herniation, and otherwise damage delicate brain structures.

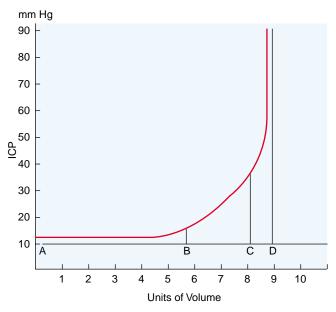

The cranial cavity contains blood (approximately 10%), brain tissue (approximately 80%), and CSF (approximately 10%) within the rigid confines of a nonexpandable skull.⁶ Each of these three volumes contributes to the ICP, which normally is maintained within a range of 0 to 15 mm Hg when measured in the lateral ventricles. The volumes of each of these components can vary slightly without causing marked changes in ICP. This is because small increases in the volume of one component can be compensated for by a decrease in the volume of one or both of the other two components.7 This association is called the Monro-Kellie hypothesis.

Abnormal variation in intracranial volume with subsequent changes in ICP can be caused by a volume change in any of the three intracranial components. For example, an increase in tissue volume can result from a brain tumor, brain edema, or bleeding into brain tissue. An increase in blood volume develops when there is vasodilatation of cerebral vessels or obstruction of venous outflow. Excess production, decreased absorption, or obstructed circulation of CSF affords the potential for an increase in the CSF component.

According to the modified Monro-Kellie hypothesis, reciprocal compensation occurs among the three intracranial compartments.6 Of the three intracranial volumes, the tissue volume is relatively restricted in its ability to undergo change. Initial increases in ICP are buffered by a translocation of CSF to the spinal subarachnoid space and increased reabsorption of CSF. The compensatory ability of the blood compartment is limited by the small amount of blood that is in the cerebral circulation. The cerebral blood vessels contain less than 10% of the intracranial volume, most of which is contained in the low-pressure venous system. As the volume-buffering capacity of this compartment becomes exhausted, venous pressure increases and cerebral blood volume and ICP rise. In addition, cerebral blood flow is highly controlled by autoregulatory mechanisms, which affect its compensatory capacity. Conditions such as ischemia and elevated carbon dioxide (PCO₂) levels produce a compensatory vasodilation of the cerebral blood vessels.

The impact of increases in blood, brain tissue, or CSF volumes on ICP varies among individuals and depends on the amount of increase that occurs, the effectiveness of compensatory mechanisms, and the compliance of brain tissue. Compliance represents the ratio of change in volume to the resulting change in pressure.⁶ As depicted in Figure 37-2 even small changes in volume produce large changes in ICP once the compensatory mechanisms have been exceeded.

The cerebral perfusion pressure (CPP), which represents the difference between the mean arterial blood pressure (MABP) and the ICP, is the pressure perfusing the brain.7 CPP is determined by the pressure gradient between the internal carotid artery and the subarachnoid veins. The MABP and ICP are monitored frequently in persons with brain conditions that increase ICP and impair brain perfusion. Normal CPP ranges from 70 to 100 mm Hg. Brain ischemia develops at levels

■ FIGURE 37-2 ■ Pressure-volume curve. From point A to just before B, the ICP remains constant although there is an addition of volume (compliance is high). At point B, even though the ICP is within normal limits, compliance begins to change, as evidenced by the slight rise in ICP. From points B to C, the ICP rises with an increase in volume (low compliance). From points C to D, ICP rises significantly with each minute increase in volume (compliance is lost). (Hickey J.V. [2003]. *Neurological and neurosurgical nursing* [5th ed., p. 286]. Philadelphia: Lippincott Williams & Wilkins)

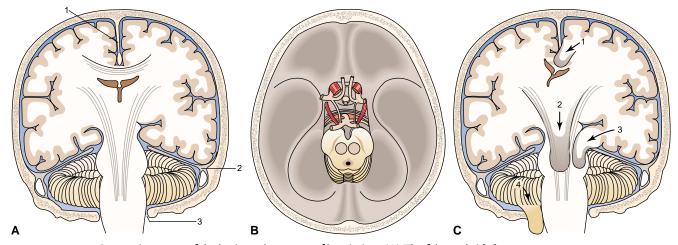

below 50 to 70 mm Hg.⁶ When the ICP approaches or exceeds the MABP, tissue perfusion becomes inadequate, cellular hypoxia results, and if the elevated pressure is maintained, neuronal death may occur. The highly specialized cortical neurons are the most sensitive to oxygen deficit; a decrease in the level of consciousness is one of the earliest and most reliable signs of increased ICP. One of the late reflexes seen with a marked increase in ICP is the CNS ischemic response, which is triggered by ischemia of the vasomotor center in the brain stem. Neurons in the vasomotor center respond directly to ischemia by producing a marked increase in MABP, sometimes to levels as high as 270 mm Hg, accompanied by a widening of the pulse pressure and reflex slowing of the heart rate. These three signs, sometimes called the *Cushing reflex*, are important but late indicators of increased ICP.² The ischemic reflex represents a "last-ditch" effort by the nervous system to maintain the cerebral circulation.

Brain Herniation

The brain is protected by the nonexpandable skull and supporting septa, the falx cerebri and the tentorium cerebelli, that divide the intracranial cavity into *fossae* or compartments that normally protect against excessive movement. The falx cerebri is a sickle-shaped septum that separates the two hemispheres. The tentorium is a tentlike structure, higher in the center than at the sides of the skull, which separates the occipital lobes of the brain from the cerebellum and much of the brain stem (Fig. 37-3A). It creates the area above the tentorium, the supratentorial space, and the area below the tentorium, the infratentorial space. Extending posteriorly into the center of the tentorium is a large semicircular opening called the *incisura* or *tentorial notch*. The brain stem, blood vessels, and accompanying nerves pass through the incisura (see Fig. 37-3B).

Brain herniation is displacement of brain tissue under the falx cerebri or through the incisura of the tentorium cerebelli. It occurs when the presence of cerebral edema or a mass results in shifting or herniation of brain tissue from a compartment of higher pressure to one of lower pressure. The different types of herniation syndromes are based on the area of the brain that has herniated and the structure under which it has been pushed (see Fig. 37-3C). They commonly are divided into two broad categories, supratentorial and infratentorial, based on whether they are located above or below the tentorium.

There are three major patterns of supratentorial herniation: cingulate or across the falx cerebri, uncal or lateral, and trans-

■ FIGURE 37-3 ■ Supporting septa of the brain and patterns of herniation. (A) The falx cerebri [1], tentorium cerebelli [2], foramen magnum [3]. (B) The location of the insicura or tentorial notch in relation to the cerebral arteries and oculomotor nerve. (C) Herniation of the cingulate gyrus under the falx cerebri [1], central or transtentorial herniation [2], herniation of the temporal lobe into the tentorial notch [3], and infratentorial herniation of the cerebellar tonsils [4]. (Courtesy of Carole Hilmer, C.M.I.)

tentorial or central.6 Cingulate herniation involves displacement of the cingulate gyrus and hemisphere beneath the sharp edges of the falx cerebri to the opposite side of the brain. Uncal herniation occurs when a lateral mass pushes the brain tissue centrally and forces the medial aspect of the temporal lobe, which contains the uncus and hippocampal gyrus, under the edge of the tentorial incisura, into the posterior fossa. Transtentorial or central herniation involves the downward displacement of the cerebral hemispheres, basal ganglia, diencephalon, and midbrain through the tentorial incisura.

Each supratentorial herniation syndrome has distinguishing features in the early phases, but as the forced downward displacement on the pons and medulla continues, clinical signs become similar (see Table 37-2). Any of the supratentorial herniation syndromes can compress vascular and CSF flow, which can further complicate the neurologic manifestations of brain lesions. The progressive downward displacement from any of the supraventricular herniation syndromes can result in brain stem herniation, in which the medulla herniates into the foramen magnum. Death is immediate, caused by compression of cardiorespiratory centers in the medulla.

Infratentorial herniation results from increased pressure in the infratentorial compartment. Herniation may occur superiorly (upward) through the tentorial incisura or inferiorly (downward) through the foramen magnum. Upward displacement of brain tissue can cause blockage of the aqueduct of Sylvius and lead to hydrocephalus and coma. Downward displacement of the midbrain through the tentorial notch or of the cerebellar tonsils through the foramen magnum can interfere with medullary functioning and cause cardiac or respiratory arrest. In cases of pre-existing ICP, herniation may occur when the pressure is released from below, such as in a lumbar puncture.

Hydrocephalus

Enlargement of the CSF compartment occurs with hydrocephalus, which is defined as an abnormal increase in CSF volume in any part or all of the ventricular system (see Chapter 36, Fig. 36-25). There are two types of hydrocephalus: noncom-

TABLE 37-2Key Structures andClinical Signs of Cingulate,Transtentorial, and Uncal Herniation			
Herniation Syndrome	Key Structures Involved	Key Clinical Signs	
Cingulate Transtentorial	Anterior cerebral artery Reticular activating system Corticospinal tract	Leg weakness Altered level of consciousness Decorticate posturing Rostral–caudal deterioration	
Uncal	Cerebral peduncle Oculomotor nerve Posterior cerebral artery Cerebellar tonsil Respiratory center	Hemiparesis Pupil dilatation Visual field loss Respiratory arrest	

municating and communicating. Hydrocephalus ex vacuo refers to dilation of the ventricular system and a compensatory increase in CSF volume secondary to a loss of brain tissue. It is commonly associated with other evidence of brain atrophy.^{1,8}

Noncommunicating or obstructive hydrocephalus occurs when obstruction in the ventricular system prevents the CSF from reaching the arachnoid villi. CSF flow can be obstructed by congenital malformations, tumors encroaching on the ventricular system, inflammation, or hemorrhage.8

Communicating hydrocephalus results from impaired reabsorption of CSF from the arachnoid villi into the venous system. Decreased absorption can result from a block in the CSF pathway to the arachnoid villi or a failure of the villi to transfer the CSF to the venous system. It can occur if too few villi are formed, if postinfective (meningitis) scarring occludes them, or if the villi become obstructed with fragments of blood or infectious debris. Normal-pressure hydrocephalus is an important type of communicating hydrocephalus seen in older adults. It is accompanied by ventricular enlargement with compression of cerebral tissue but normal CSF pressure.

Similar pathologic patterns occur with noncommunicating and communicating types of hydrocephalus. The cerebral hemispheres become enlarged, and the ventricular system is dilated behind the point of obstruction. The gyri on the surface of the brain tend to become less prominent as the sulci are compressed and the white matter is reduced in volume. The presence and extent of the increased ICP is determined by the amount of fluid accumulation and the type of hydrocephalus, the age at onset, and the rapidity and degree of pressure rise. Acute-onset hydrocephalus is usually marked by symptoms of increased ICP, including headache and vomiting, followed by edema of the optic disk (papilledema). If the obstruction is not relieved, mental deterioration eventually occurs. Slowly developing hydrocephalus is less likely to produce an increase in ICP, but it may produce deficits such as progressive dementia and gait changes.

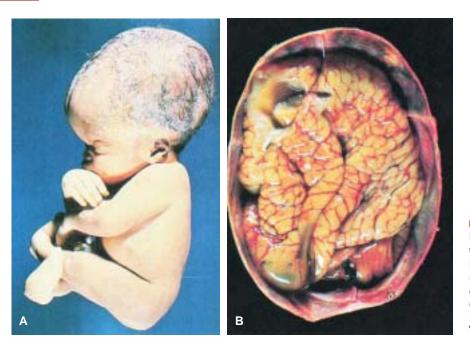

Computed tomographic (CT) scans are used to diagnose all types of hydrocephalus. Treatment depends on the cause of the disorder. In noncommunicating hydrocephalus, shunting procedures are used to provide an alternative route for return of CSF to the circulation. Treatment for communicating hydrocephalus includes attempts to clear the arachnoid villi of exudate; if this is unsuccessful, surgical shunting may be required.⁶

When hydrocephalus develops in utero or before the cranial sutures have fused in infancy, the ventricles expand beyond the point of obstruction, the cranial sutures separate, the head expands, and there is bulging of the fontanels (Fig. 37-4).9 Because the skull is able to expand, signs of increased ICP usually are absent. Surgical placement of a shunt (e.g., a ventriculoperitoneal shunt) that allows for diversion of excess CSF fluid is often used to prevent extreme enlargement of the head. The major complication of shunts is bacterial infection. Children with hydrocephalus are at risk for developmental disorders. Visual problems, including strabismus, visual field defects, and atrophy of the optic nerve, are common.9

Traumatic Head and Brain Injury

The term *head injury* is used to describe all structural damage to the head and has become synonymous with brain injury.^{10,11} In the United States, head injury is the leading cause of death

672 Unit Ten: Alterations in the Nervous System

■ FIGURE 37-4 ■ Congenital hydrocephalus. (A) Hydrocephalus occurring before the fusion of the cranial sutures causes pronounced enlargement of the head. (B) Removal of the calvarium demonstrates an atrophic and collapsed cerebral cortex. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1454]. Philadelphia: Lippincott Williams & Wilkins)

among persons younger than 24 years. The main causes of head injury are road accidents, falls, and assaults, and the most common cause of fatal head injuries is road accidents involving vehicles and pedestrians.¹²

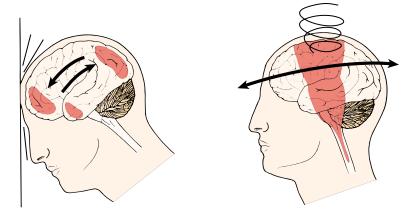

Skull Fractures

Although the skull affords protection for the tissues of the CNS, it also provides the potential for development of ischemic and traumatic brain injuries. This is because it cannot expand to accommodate the increase in volume that occurs when there is swelling or bleeding within its confines. The bony structures themselves can also cause injury to the nervous system. Fractures of the skull can compress sections of the nervous system, or they can splinter and cause penetrating wounds.

Skull fractures can be divided into three groups: simple, depressed, and basilar. A *simple* or *linear* skull fracture is a break in the continuity of bone. A *comminuted* skull fracture refers to a splintered or multiple fracture line. When bone fragments are embedded into the brain tissue, the fracture is said to be *depressed*. Radiologic examination usually is needed to confirm the presence and extent of a skull fracture.

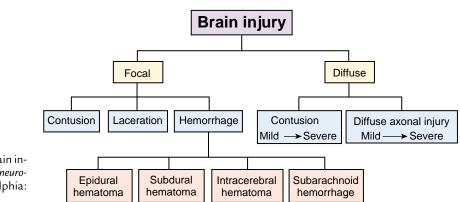

Traumatic Brain Injury

The skull and CSF provide protection for the brain, but they also can contribute to brain trauma at the time of head injury. The two mechanisms responsible for brain injury are acceleration-deceleration and concurrent rotational movement (Fig. 37-5). Because the brain floats freely in the CSF, blunt force to the head can cause the brain to accelerate in the skull and then abruptly decelerate on hitting the inner confines of the skull. At the time of impact to the skull, there is always some acceleration/ deceleration of the brain, whether the head is held in fixed or

■ FIGURE 37-5 ■ Mechanisms of (A) brain acceleration-deceleration injury and (B) rotational injury.

1 LINE

■ FIGURE 37-6 ■ Focal and generalized brain injuries. (Hickey J.V. [1996]. *Neurological and neurosurgical nursing* [4th ed., p. 393]. Philadelphia: Lippincott-Raven).

free position. This results in what are called *coup-contrecoup* injuries.⁶ The injury directly under the area of impact is called a *coup injury* and the injury sustained on the opposite pole of the brain, a *contrecoup injury*.

The effects of traumatic head injuries can be divided into two categories: primary or direct injuries, in which damage is caused by impact, and secondary injuries, in which damage results from the subsequent brain swelling, an intracranial hematoma, infection, or cerebral ischemia. Ischemia is considered to be the most common cause of secondary brain injury. It can cause the hypoxia and hypotension that occur during the resuscitation process or the impairment of regulatory mechanisms that maintain cerebral blood flow and oxygen supply.^{13,14}

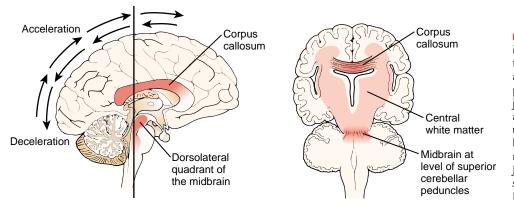

Even if there is no break in the skull, a blow to the head can cause severe and diffuse brain damage. Such closed injuries vary in severity and can be classified as focal or diffuse (Fig. 37-6). Diffuse injuries include concussion and diffuse axonal injury, and focal injuries, contusions, lacerations, and hemorrhage.

Concussion. The term *concussion* refers to a momentary interruption of brain function with or without loss of consciousness. In mild head injury, there may be momentary loss of consciousness without demonstrable neurologic symptoms or residual damage, except for possible residual amnesia. Microscopic changes usually can be detected in the neurons and supporting tissues within hours of injury. Although recovery usually takes place within 24 hours, mild symptoms, such as headache, irritability, insomnia, and poor concentration and memory, may persist for months. This is known as the *postconcussion syndrome*. Because these complaints are vague and subjective, they sometimes are regarded as being of psychological origin.

Diffuse Axonal Injury. Diffuse axonal injury is a primary injury with diffuse microscopic damage to axons in the cerebral hemisphere, corpus callosum, and brain stem. It is responsible for most cases of posttraumatic dementia and, in conjunction with hypoxic-ischemic injury, is the most common cause of persistent vegetative state. The lesions of diffuse axonal injury result from sudden deceleration and/or acceleration forces sufficient to stretch or, in extreme cases, tear nerve cell processes within the white matter of the brain (Fig. 37-7).

Contusion. A contusion is a bruise to the cortical surface of the brain caused by blunt head trauma.^{1,7} Contusions may be single or multiple and occur at any place where the brain comes in contact with the skull; they often occur when the moving head strikes a fixed object (Fig. 37-8). They are most common in the frontal poles, orbital surfaces of the frontal lobes, temporal poles, occipital poles, and posterior cerebellum.¹

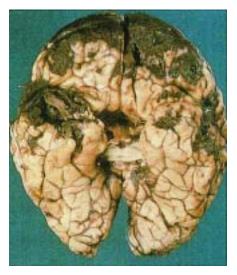

Contusions are generally the result of anteroposterior displacement, when the moving head strikes a fixed object. As the

■ FIGURE 37-7 ■ Diffuse axonal injury. Diffuse axonal injury results from acceleration-deceleration and shearing on the brain. Dependent upon the severity of injury, the areas of the brain most affected are the corpus callosum, the dorsolateral area of the midbrain, and the parasagittal white matter. Adapted from (Hickey J.V. [1996]. Neurological and neurosurgical nursing [4th ed., p. 386]. Philadelphia: Lippincott-Raven).

SHORT

Unit Ten: Alterations in the Nervous System

■ FIGURE 37-8 ■ Recent cerebral contusion. Multiple areas of hemorrhage mark the poles of the frontal and temporal lobes. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1462]. Philadelphia: Lippincott Williams & Wilkins)

brain strikes the rough surface of the cranial vault, brain tissue, blood vessels, nerve tracts, and other structures are bruised and torn. The extent of brain damage that occurs is dependent upon the force causing the injury. If the force is minimal, the contusion is limited to the apex of the gyri. Greater forces destroy larger expanses of the cortex, creating deeper lesions that extend into the white matter or lacerate the cortex and initiate cortical and subcortical hemorrhages. Cerebral contusions, particularly those accompanied by tearing of the superficial layers of the brain, are an important cause of traumatic subarachnoid hemorrhage.

Contusions cause permanent damage to brain tissue.^{1,8} The bruised, necrotic tissue is phagocytized by macrophages, and scar tissue formed by astrocyte proliferation persists as a crater.

Hematomas. Hematomas result from vascular injury and bleeding. Depending on the anatomic position of the ruptured vessel, bleeding may involve the development of an epidural hematoma, the subdural hematoma, or an intracerebral hematoma (Fig. 37-9).

Epidural hematoma is one that develops between the inner table of the bones of the skull and the dura. It usually results from a tear in an artery, most often the middle meningeal, which is located under the thin temporal bone. Because bleeding is arterial in origin, rapid compression of the brain occurs from the expanding hematoma. Epidural hematoma is more common in a young person because the dura is not as firmly attached to the skull surface as it is in an older person. Typically, a person with an epidural hematoma presents with a history of head injury and a brief period of unconsciousness, followed by a lucid period in which consciousness is regained, followed by rapid progression to unconsciousness. The lucid interval does not always occur, but when it does, it is of great diagnostic value. With rapidly developing unconsciousness, there are focal symptoms related to the area of the brain involved. These symptoms can include ipsilateral (same side) pupil dilatation and contralateral (opposite side) hemiparesis. If the hematoma

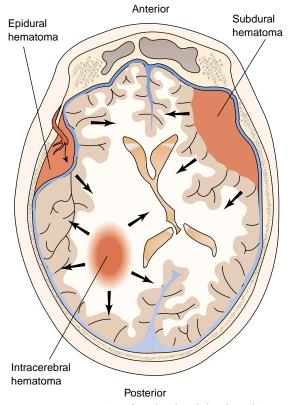

FIGURE 37-9 Location of epidural, subdural, and intracerebral hematomas.

is not removed, the condition progresses, with increased ICP, tentorial herniation, and death. However, prognosis is excellent if the hematoma is removed before loss of consciousness occurs.

A *subdural hematoma* develops in the area between the dura and the arachnoid (subdural space) and usually is the result of a tear in the small bridging veins that connect veins on the surface of the cortex to dural sinuses. These veins are readily snapped in head injury when the brain moves suddenly in relation to the skull. A subdural hematoma develops more slowly than an epidural hematoma because the tear is in the venous, rather than the arterial, system.

Subdural hematomas are classified as acute, subacute, or chronic. Symptoms of an acute subdural hematoma are seen within 24 hours of the injury. Acute subdural hematomas progress rapidly and are associated with a high mortality rate because of the severe secondary injuries related to edema and uncontrolled rise in ICP. Subacute hematomas do not produce symptoms until 2 to 10 days after injury. There may be a period of improvement in the level of consciousness and neurologic symptoms, followed by deterioration if the hematoma is not removed.

The symptoms of chronic subdural hematomas may not arise until several weeks after the injury, so much later that the person may not remember having had a head injury. This is especially true of the older person with fragile vessels whose brain has shrunk away from the dura. Seepage of blood into the subdural space may occur slowly. Because the blood in the subdural space is not absorbed, fibroblastic activity begins,

■ FIGURE 37-10 ■ Subdural hematoma. A chronic subdural hematoma is encapsulated by an outer membrane, evidenced as a narrow brown layer beneath the white dura. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1460]. Philadelphia: Lippincott Williams & Wilkins)

and the hematoma becomes encapsulated⁸ (Fig. 37-10). Within this encapsulated area, the blood cells are slowly lysed, and a fluid with a high osmotic pressure is formed. This creates an osmotic gradient, with fluid from the surrounding subarachnoid space being pulled into the hematoma, causing the mass to increase in size and exert pressure on the surrounding intracranial contents. In some instances, the clinical picture is less defined, with the most prominent symptom being a decreasing level of consciousness indicated by drowsiness, confusion, and apathy. The person also may have headache.

Traumatic Intracerebral Hematomas. Traumatic intracerebral hematomas may be single or multiple. They can occur in any lobe of the brain but are most common in the frontal or temporal lobes. They may occur in association the severe motion that the brain undergoes during head injury, or a contusion can coalesce into a hematoma. Intracerebral hematomas occur more frequently in older persons and alcoholics whose brain vessels are more friable.

The signs and symptoms produced by an intracerebral hematoma depend on its size and location within the brain. Signs of increased ICP can be manifested if the hematoma is large and encroaching on vital structures. A hematoma in the temporal lobe can be dangerous because of the potential for lateral herniation.

Manifestations of Global Brain Injury

Global brain injury, whether caused by head trauma, stroke, or other pathologies, is manifested by alterations in sensory and motor function and by changes in the level of consciousness. In contrast to focal injury, which causes alterations in sensory function (Chapter 39) or motor function (Chapter 37), global injury tends to result in altered levels of consciousness. Severe injury that seriously compromises brain function may result in brain death.

The cerebral hemispheres are the most susceptible to damage, and the most common sign of brain dysfunction is altered level of consciousness and change in behavior. As the brain structures in the diencephalon, midbrain, pons, and medulla are affected, additional respiratory; pupillary and eye movement reflexes, and motor signs become evident (see Table 37-3). Hemodynamic and respiratory instability are the last signs to occur because their regulatory centers are located low in the medulla.

In progressive brain deterioration, the person's neurologic capabilities appear to deteriorate in stepwise fashion. Similarly, as neurologic function returns, there appears to be stepwise progress to higher levels of consciousness. Deterioration of brain function from supratentorial lesions tends to follow a rostral-to-caudal stepwise progression, which is observed as the brain initially compensates for injury and subsequently decompensates with loss of autoregulation and cerebral perfusion. Infratentorial (brain stem) lesions may lead to an early, sometimes abrupt disturbance in consciousness without any orderly rostrocaudal progression of neurologic signs.

Anatomic and Physiologic Basis of Consciousness

Consciousness is the state of awareness of self and the environment and of being able to become oriented to new stimuli.⁶ It has traditionally been divided into two components: (1) arousal and wakefulness and (2) content and cognition. The content and cognition aspects of consciousness are determined by a functioning cerebral cortex. Arousal and wakefulness requires the concurrent functioning of both cerebral hemispheres and an intact reticular activating system (RAS) in the brain stem.

Reticular Activating System

The reticular formation is a diffuse, primitive system of interlacing nerve cells and fibers in the brain stem that receive input from multiple sensory pathways (Fig. 37-11). Anatomically, the reticular formation constitutes the central core of the brain

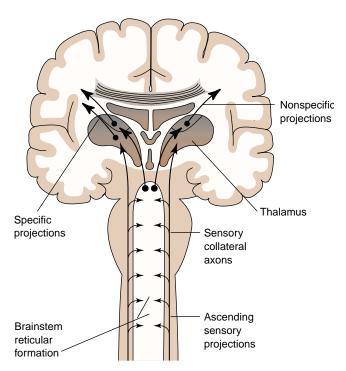

TABLE 37-3	Key Signs	in Rostral-to-Caudal Progression of Brain Lesions
Level of Brain	Injury	Key Clinical Signs
Diencephalon		Impaired consciousness (see Table 37-4); small, reactive pupils; intact oculocephalic re- flex; decorticate posturing; Cheyne-Stokes respirations
Midbrain		Coma, fixed, midsize pupils; impaired oculocephalic reflex; neurogenic hyperventilation; decerebrate posturing
Pons		Coma, fixed, irregular pupils; dysconjugate gaze; impaired cold caloric stimulation; loss of corneal reflex; hemiparesis/quadriparesis; decerebrate posturing; apneustic respirations
Medulla		Coma, fixed pupils, flaccidity, loss of gag and cough reflexes, ataxic/apneic respirations

KEY CONCEPTS

BRAIN INJURY AND LEVELS OF CONSCIOUSNESS

- Consciousness is a global function that depends on a diffuse neural network that includes activity of the reticular activating system (RAS) and both cerebral hemispheres.
- Impaired consciousness implies diffuse brain injury to the RAS at any level (medulla through thalamus) or both cerebral hemispheres simultaneously.
- In contrast, local brain injury causes focal neurologic deficit but does not disrupt consciousness.

stem, extending from the medulla through the pons to the midbrain, which is continuous caudally with the spinal cord and rostrally with the subthalamus, the hypothalamus, and the thalamus.¹⁵ Fibers from the RAS also project to the autonomic nervous system and motor systems. The hypothalamus plays a predominant role in maintaining homeostasis through integration of somatic, visceral, and endocrine functions. Inputs from the reticular formation, vestibulospinal projections, and other motor systems are integrated to provide a continuously

■ FIGURE 37-11 ■ The brain stem reticular formation and reticular activating system. Ascending sensory tracts send axon collateral fibers to the reticular formation. These give rise to fibers synapsing in the nonspecific nuclei of the thalamus. From there the nonspecific thalamic projections influence widespread areas of the cerebral cortex and limbic system. (Rhoades R.A., Tanner G.A. [1996]. *Medical physiology*. Boston: Little, Brown) adapting background of muscle tone and posture to facilitate voluntary motor actions. Reticular formation neurons that function in regulation of cardiovascular, respiratory, and other visceral functions are intermingled with those that maintain other reticular formation functions.

Ascending fibers of the reticular formation, known as the *ascending RAS*, transmit activating information to all parts of the cerebral cortex. The flow of information in the ascending RAS activates the hypothalamic and limbic structures that regulate emotional and behavioral responses such as those that occur in response to pain and loud noises, and they exert facilitatory effects on cortical neurons. Without cortical activation, a person is less able to detect specific stimuli, and the level of consciousness is reduced. The pathways for the ascending RAS travel through the midbrain, and lesions of the midbrain can interrupt RAS activity, leading to altered levels of consciousness and coma.

Any deficit in level of consciousness, from mild confusion to stupor or coma, indicates injury to either the RAS or to both cerebral hemispheres concurrently. For example, consciousness may decline because of severe systemic metabolic derangements that affect both hemispheres, or from head trauma causing shear injuries to white matter of both the RAS and the cerebral hemispheres. Brain injuries that affect a hemisphere unilaterally and also spare the RAS, such as cerebral infarction, usually do not cause impaired consciousness.

Levels of Consciousness

Levels of consciousness reflect an orientation to person, place, and time. A fully conscious person is totally aware of her or his surroundings.⁶ Levels of consciousness exist on a continuum that includes consciousness, confusion, delirium, obtundation, stupor, and coma (Table 37-4).

The earliest signs of diminution in level of consciousness are inattention, mild confusion, disorientation, and blunted responsiveness. With further deterioration, the delirious person becomes markedly inattentive and variably lethargic or agitated. The person may progress to become obtunded and may respond only to vigorous or noxious stimuli, such as shaking.

Because of its simplicity of application, the Glasgow Coma Scale has gained almost universal acceptance as a method for assessing the level of consciousness in persons with brain injury^{6,13,14} (Table 37-5). Numbered scores are given to responses of eye opening, verbal utterances, and motor responses. The total score is the sum of the best response in each category.

Other Manifestations of Deteriorating Brain Function

Additional elements in the initial neurological evaluation of a person with brain injury include checking for abnormalities in the size of the pupils and their reaction to light, weakness and asymmetry of motor function, and evidence of decortication or decerebration posturing.

Pupillary Reflexes and Eye Movements. Although the pupils may initially respond briskly to light, they become unreactive and dilated as brain function deteriorates. A bilateral loss of the pupillary light response is indicative of lesions of the brain stem. A unilateral loss of the pupillary light response may be caused by a lesion of the optic or oculomotor pathways. The oculocephalic reflex (doll's-head eye movement) can be used to determine if the brain stem centers for eye movement are intact (Fig. 37-12). If the oculocephalic reflex is inconclusive, and

TABLE 37-4	Descendin	g Levels of Consciousness and Their Characteristics
Level of Consc	iousness	Characteristics
Confusion		Disturbance of consciousness characterized by impaired ability to think clearly, and to perceive, respond to, and remember current stimuli; also disorientation
Delirium		State of disturbed consciousness with motor restlessness, transient hallucinations, disorientation, and sometimes delusions
Obtundation		Disorder of decreased alertness with associated psychomotor retardation
Stupor		A state in which the person is not unconscious but exhibits little or no spontaneous activity
Coma		A state of being unarousable and unresponsive to external stimuli or internal needs; often deter- mined by the Glasgow Coma Scale

(Data from Bates D. [1993]. The management of medical coma. Journal of Neurology, Neurosurgery, and Psychiatry 56, 590)

if there are no contraindications, the oculovestibular (*i.e.*, cold caloric test, in which cold water is instilled into the ear canal) may be used to elicit nystagmus (see Chapter 40).

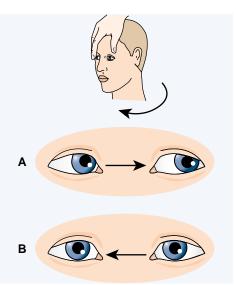

Decorticate and Decerebrate Posturing. With the early onset of unconsciousness there is some combative movement and purposeful movement in response to pain. As coma progresses, noxious stimuli can initiate rigidity and abnormal postures if the motor tracts are interrupted at specific levels. These abnormal postures are called *decortication* and *decerebration*. Decorticate (flexion) posturing is characterized by flexion of the arms, wrists, and fingers, with abduction of the upper extremities, internal rotation, and plantar flexion of the lower extremities (Fig. 37-13A). Decorticate posturing results from lesions of the cerebral hemisphere or internal capsule. Decerebrate (extensor) posturing results from increased muscle excitability (see Fig. 37-13B). It is characterized by rigidity of the arms with palms of the hands turned away from the body and with stiffly extended legs with plantar flexion of the feet. This response occurs when lesions of the diencephalon extend to involve the

midbrain and upper brain stem. Both decerebrate and decorticate posturing are associated with poor prognosis.

Respiratory Responses. Early respiratory changes include yawning and sighing, with progression to Cheyne-Stokes breathing. With progression continuing to the midbrain, respirations change to neurogenic hyperventilation, in which the frequency of respirations may exceed 40 breaths per minute because of uninhibited stimulation of inspiratory and expiratory centers. With medullary involvement, respirations become ataxic (*i.e.*, totally uncoordinated and irregular). Apnea may occur because of a lack of responsiveness to carbon dioxide stimulation. Complete ventilatory assistance is often required at this point.

■ FIGURE 37-12 ■ The *doll's-head eye response* demonstrates the always-present vestibular static reflexes without forebrain interference or suppression. Severe damage to the forebrain or to the brain stem rostral to the pons often results in loss of rostral control of these static vestibular reflexes. If the person's head is moved from side to side or up and down, the eyes will move in conjugate gaze to the opposite side (**A**), much like those of a doll with counterweighted eyes. If the doll's-head phenomenon is observed, brain stem function at the level of the pons is considered intact (in a comatose person). In the unconscious person without intact brain stem function and vestibular static reflexes, the eyes stay in midposition (fixed) or turn in the same direction (**B**) as the head is turned.

■ FIGURE 37-13 ■ Abnormal posturing. (A) Decorticate rigidity. In decorticate rigidity, the upper arms are held at the sides, with elbows, wrists, and fingers flexed. The legs are extended and internally rotated. The feet are plantar flexed. (B) Decerebrate rigidity. In decerebrate rigidity, the jaws are clenched and neck extended. The arms are adducted and stiffly extended at the elbows with the forearms pronated, wrists and fingers flexed. (From Fuller J., Schaller-Ayers J. [1994]. *Health assessment: A nursing approach* [2nd ed.]. Philadelphia: J.B. Lippincott)

Brain Death

Brain death is defined as the irreversible loss of function of the brain, including the brain stem.¹⁶ Irreversibility implies that brain death cannot be reversed. Some conditions such as drug and metabolic intoxication can cause cessation of brain functions that is completely reversible, even when they produce clinical cessation of brain functions and EEG silence. This possibility needs to be excluded before declaring that a person is brain dead.

With advances in scientific knowledge and technology that have provided the means for artificially maintaining ventilatory and circulatory function, the definition of death has had to be continually re-examined. In 1995, the Quality of Standards Subcommittee of the American Academy of Neurology published the clinical parameters for determining brain death and procedures for testing persons older than 18 years.¹⁷ According to these parameters, "brain death is the absence of clinical brain function when the proximate cause is known and demonstrably irreversible."17 Clinical examination must disclose at least the absence of responsiveness, brain stem reflexes, and respiratory effort. Brain death is a clinical diagnosis, and a repeat evaluation at least 6 hours later is recommended.¹⁷ Longer periods of observation of absent brain activity are required in cases of drug overdose (e.g., barbiturates, other CNS depressants), drug toxicity (e.g., neuromuscular blocking drugs, aminoglycoside antibiotics), neuromuscular diseases such as myasthenia gravis, hypothermia, and shock. Medical circumstances may require use of confirmatory tests.

Persistent Vegetative State

Advances in the care of brain-injured persons during the past several decades have resulted in survival of many persons who previously would have died. Unfortunately, some of these persons remain in what often is called a *persistent vegetative state*. The vegetative state is characterized by loss of all cognitive functions and the unawareness of self and surroundings. Reflex and vegetative functions remain.¹⁸ Persons in the vegetative state must be fed and require full nursing care.

The criteria for diagnosis of vegetative state include the absence of awareness of self and environment and an inability to interact with others; the absence of sustained or reproducible voluntary behavioral responses; lack of language comprehension; sufficiently preserved hypothalamic and brain stem function to maintain life; bowel and bladder incontinence; and variably preserved cranial nerve (*e.g.*, pupillary, gag) and spinal cord reflexes.¹⁹ The diagnosis of persistent vegetative state requires that the condition has continued for at least 1 month.

In summary, many of the agents that cause brain damage do so through common pathways, including hypoxia or ischemia, accumulation of excitatory neurotransmitters, increased ICP, and cerebral edema. Deprivation of oxygen (*i.e.*, hypoxia) or blood flow (*i.e.*, ischemia) can have deleterious effects on the brain structures. Ischemia can be focal, as in stroke, or global. Global ischemia occurs when blood flow is inadequate to meet the metabolic needs of the brain, as in cardiac arrest.

The term *head injury* is used to describe all structural damage to the head and has become synonymous with *brain injury*. The effects of traumatic head injuries can be divided into two categories: primary or secondary injuries. In secondary injuries, damage results from the subsequent brain swelling, intracranial hematomas, infection, cerebral hypoxia, and ischemia. Primary injuries result from direct impact. Even if there is no break in the skull, a blow to the head can cause severe and diffuse brain damage. Such closed injuries vary in severity and can be classified as focal or diffuse. Diffuse injuries include concussion and diffuse axonal injury. Focal injuries include contusion, laceration, and hemorrhage.

Brain injury is manifested by alterations in sensory and motor function and by changes in the level of consciousness. Consciousness is a state of awareness of self and environment. It exists on a normal continuum of wakefulness and sleep and a pathologic continuum of wakefulness and coma. In progressive brain injury, coma may follow a rostral-to-caudal progression with characteristic changes in levels of consciousness, respiratory activity, pupillary and oculovestibular reflexes, and muscle tone occurring as the diencephalon through the medulla are affected.

Brain death is defined as the irreversible loss of function of the brain, including that of the brain stem. Clinical examination must disclose at least the absence of responsiveness, brain stem reflexes, and respiratory effort. The vegetative state is characterized by loss of all cognitive functions and the unawareness of self and surroundings, while reflex and vegetative functions remain intact.

CEREBROVASCULAR DISEASE

Cerebrovascular disease encompasses a number of disorders involving vessels in the cerebral circulation. These disorders include stroke and transient ischemic attacks (TIAs), aneurysmal subarachnoid hemorrhage, and arteriovenous malformations.

Cerebral Circulation

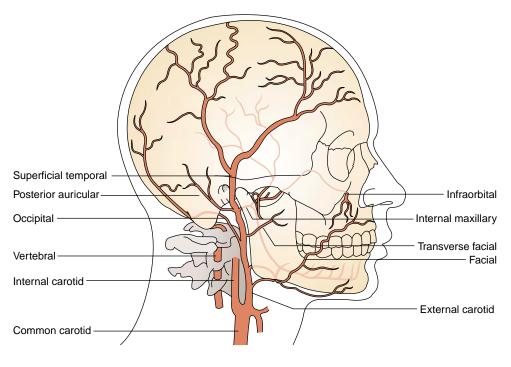

The blood flow to the brain is supplied by the two internal carotid arteries anteriorly and by the two vertebral arteries posteriorly (Fig. 37-14). The internal carotid artery, which provides the major blood supply to the brain, branches into several arteries: the ophthalmic artery, which supplies the eye and orbital structures; the posterior communicating artery, which forms part of the circle of Willis; and the anterior choroidal artery, which supplies the choroid plexus within the lateral ventricles of the brain. The internal carotid terminates by dividing into the anterior and middle cerebral arteries. The anterior cerebral arteries supply most of the medial and superior surfaces of the brain and the frontal lobe. The middle cerebral arteries supply the lateral surface of the brain, including the primary motor and sensory areas of the face and upper limbs, the optic radiations, and the speech area of the brain.

The two vertebral arteries unite to form the basilar artery. Branches of the basilar and vertebral arteries supply the medulla, pons, cerebellum, midbrain, and caudal part of the diencephalon. The basilar artery terminates by dividing into two posterior cerebral arteries that supply the remaining occipital and inferior regions of the temporal lobes and the thalamus. The posterior cerebral arteries also help to form the arterial circle of Willis, which connects the vertebral artery and the internal carotid arterial systems (Fig. 37-15). The union of these two systems provides alternate pathways for blood flow should one of the vessels become occluded.

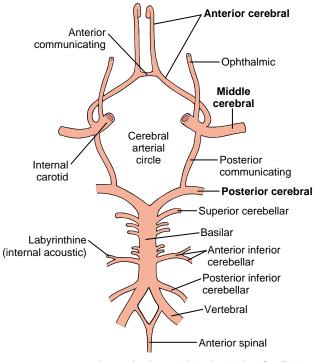

The cerebral blood is drained by two sets of veins that empty into the dural venous sinuses: the deep (great) cerebral venous system and the superficial venous system. The deep system is well protected, in contrast to the superficial cerebral veins that travel through the pia mater on the surface of the cerebral cortex. These vessels connect directly to the sagittal sinuses in the falx cerebri by way of bridging veins. They travel through the CSF-filled subarachnoid space and penetrate the arachnoid and then the dura to reach the dural venous sinuses. This system of sinuses returns blood to the heart primarily by way of the internal jugular veins. Alternate routes for venous flow also exist; for example, venous blood may exit through the emissary veins that pass through the skull and through veins that traverse various foramina to empty into extracranial veins.

Regulation of Cerebral Blood Flow

The blood flow to the brain is maintained at approximately 750 mL/minute or one sixth of the resting cardiac output.² The regulation of blood flow to the brain is controlled largely by autoregulatory mechanisms and by the sympathetic nervous system. The autoregulation of cerebral blood flow responds to the local metabolic needs of the brain tissue and is efficient within an MABP range of approximately 60 to 140 mm Hg.² If blood pressure falls below 60 mm Hg, cerebral blood flow becomes severely compromised, and if it rises above the upper limit of autoregulation, blood flow increases rapidly and overstretches the cerebral vessels. In persons with hypertension, this autoregulatory range shifts to a higher level.

■ FIGURE 37-14 ■ Branches of the right external carotid artery. The internal carotid artery ascends to the base of the brain. The right vertebral artery is also shown as it ascends through the transverse foramina of the cervical vertebrae.

■ FIGURE 37-15 ■ The cerebral arterial circle (circle of Willis).

Although total cerebral blood flow remains relatively stable throughout marked changes in cardiac output and arterial blood pressure, regional blood flow may change markedly in response to local changes in metabolism. At least three metabolic factors affect cerebral blood flow: carbon dioxide concentration, hydrogen ion concentration, and oxygen concentration. Increased carbon dioxide or increased hydrogen ion concentrations increase cerebral blood flow; decreased oxygen concentration also increases blood flow. Carbon dioxide, by way of the hydrogen ion concentration, provides a potent stimulus for control of cerebral blood flow-a doubling of the PCO₂ in the blood results in a doubling of cerebral blood flow. Other substances that alter the pH of the brain produce similar changes in cerebral blood flow. Because increased hydrogen ion concentration greatly depresses neural activity, the increase in blood flow is protective in that it washes the hydrogen ions and other acidic materials away from the brain tissue.2

In addition to the autoregulatory mechanisms that control blood flow in the deep cerebral vessels, the superficial and major cerebral blood vessels are innervated by the sympathetic nervous system. Under normal physiologic conditions, the sympathetic nervous system exerts little effect on superficial cerebral blood flow because local regulatory mechanisms are so powerful that they compensate almost entirely for the effects of sympathetic stimulation. However, when local mechanisms fail, sympathetic control of cerebral blood pressure becomes important.² For example, when the arterial pressure rises to very high levels during strenuous exercise or in other conditions, the sympathetic nervous system constricts the large and intermediate-size superficial blood vessels as a means of protecting the smaller, more easily damaged vessels. Sympathetic reflexes are believed to cause vasospasm in the intermediate and large arteries in some types of brain damage, such as that caused by rupture of a cerebral aneurysm.

Stroke (Brain Attack)

Stroke is an acute focal neurologic deficit from a vascular disorder that injures brain tissue. Stroke remains one of the leading causes of mortality and morbidity in the United States. Each year, 600,000 Americans are afflicted with stroke, and approximately 167,000 of these persons die, and many survivors of stroke are left with at least some degree of neurologic impairment.²⁰ The term *brain attack* has been promoted to highlight that time-dependent tissue damage occurs and to raise awareness of the need for rapid emergency treatment, similar to that with heart attack.

There are two main types of strokes: ischemic stroke and hemorrhagic stroke. Ischemic strokes are caused by an interruption of blood flow in a cerebral vessel and are the most common type of stroke, accounting for 70% to 80% of all strokes. The less common hemorrhagic strokes, which are caused by bleeding into brain tissue, are associated with a much higher fatality rate than are ischemic strokes.

Among the major risk factors for stroke are age, gender, race, heart disease, hypertension, high cholesterol levels, cigarette smoking, prior stroke, and diabetes mellitus.^{20,21} Other risk factors include sickle cell disease, polycythemia, blood dyscrasias, excess alcohol use, cocaine and illicit drug use, obesity, and sedentary lifestyle. The incidence of stroke increases with age, with a 1% per year increased risk for persons 65 to 74 years of age; the incidence of stroke is approximately 19% greater in men than women; and African Americans have a 60% greater risk of death and disability from stroke than do whites.²⁰ Heart disease, particularly atrial fibrillation and other conditions that predispose to clot formation on the wall of the heart or valve leaflets or to paradoxical embolism through right-to-left shunting, predisposes to cardioembolic stroke. Polycythemia, sickle

KEY CONCEPTS

STROKE/BRAIN ATTACK

- Stroke is an acute focal neurologic deficit from an interruption of blood flow in a cerebral vessel (ischemic stroke, the most common type) due to thrombi or emboli or to bleeding into the brain tissue (hemorrhagic stroke).
- During the evolution of an ischemic stroke, there usually is a central core of dead or dying cells surrounded by an ischemic band of minimally perfused cells called a *penumbra*. Whether the cells of the penumbra continue to survive depends on the successful timely return of adequate circulation.
- The realization that there is a window of opportunity during which ischemic but viable brain tissue can be salvaged has led to the use of thrombolytic agents in the early treatment of ischemic stroke.

cell disease (during sickle cell crisis), and blood disorders predispose to clot formation in the cerebral vessels. Alcohol abuse can contribute to stroke in several ways: induction of cardiac arrhythmias and defects in ventricular wall motion that lead to cerebral embolism, induction of hypertension, enhancement of blood coagulation disorders, and reduction of cerebral blood flow.²² Another cause of stroke is cocaine. Cocaine use causes both ischemic and hemorrhagic strokes by inducing vasospasm, enhanced platelet activity, and increased blood pressure, heart rate, body temperature, and metabolic rate. Cocaine stroke victims range in age from newborn (*i.e.*, from maternal cocaine use) to old age.²³

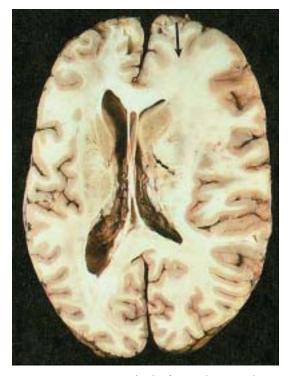

Elimination or control of risk factors for cerebrovascular disease (*e.g.*, use of tobacco, control of blood lipids and blood sugar, reduction of hypertension) offers the best opportunity to prevent cerebral ischemia from cerebral atherosclerosis. Early detection and treatment offer significant advantages over waiting until a serious event has occurred.

Ischemic Stroke

Ischemic strokes are caused by local interruption of blood flow caused by thrombosis or emboli. A common classification system identifies five stroke subtypes and their frequency: 20% large artery atherosclerotic disease (both thrombosis and plaque emboli); 25% small vessel or penetrating artery disease (*lacunar stroke*); 20% cardiogenic embolism; 30% cryptogenic stroke (undetermined cause); and 5% other, unusual causes²⁴ (*i.e.*, migraine, dissection, coagulopathy).

During the evolution of an ischemic stroke, there usually is a central core of dead or infarcted tissue, surrounded by an ischemic band or area of minimally perfused tissue called the *penumbra* (*i.e.*, halo). Brain cells of the penumbra receive marginal blood flow, and their metabolic activities are impaired; although the area undergoes an "electrical failure," the structural integrity of the brain cells is maintained.²⁵ Whether the cells of the penumbra continue to survive depends on the successful timely return of adequate circulation, the volume of toxic products released by the neighboring dying cells, the degree of cerebral edema, and alterations in local blood flow. If the toxic products result in additional death of cells in the penumbra, the core of infarcted tissue enlarges, and the volume of surrounding ischemic tissue increases (Fig. 37-16).

Large Vessel (Thrombotic) Stroke. Cerebral atherosclerosis is the most common cause of ischemic strokes. In the cerebral circulation, atherosclerotic plaques are found most commonly at arterial bifurcations. Common sites of plaque formation include larger vessels of the brain, notably the origins of the internal carotid and vertebral arteries, and junctions of the basilar and vertebral arteries (Fig. 37-17). Cerebral infarction can result from an acute local thrombosis and occlusion at the site of chronic atherosclerosis, with or without embolization of the plaque material distally, or from critical perfusion failure distal to a stenosis. These infarcts often affect the cortex, causing aphasia or neglect, visual field defects, or the retina. In most cases of stroke, a single cerebral artery and its territories are affected. Usually, thrombotic strokes are seen in older persons and frequently are accompanied by evidence of atherosclerotic heart or peripheral arterial disease. The thrombotic stroke is not associated with activity and may occur in a person at rest.

■ FIGURE 37-16 ■ Recent cerebral infarct. A horizontal section of the brain shows expansion and softening in the distribution of the right middle cerebral artery. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1472]. Philadelphia: Lippincott Williams & Wilkins)

Small Vessel Stroke (Lacunar Infarct). Lacunar infarcts are small (1.5 to 2.0 cm) to very small (3 to 4 mm) infarcts located in the deeper, noncortical parts of the brain or in the brain stem. They are found in the territory of single deep penetrating arteries supplying the internal capsule, basal ganglia, or brain stem. They result from occlusion of the smaller branches of large cerebral arteries, commonly the middle cerebral and posterior cerebral arteries and less commonly the anterior cerebral, vertebral, or basilar arteries. In the process of healing, lacunar infarcts leave behind small cavities, or lacunae (lakes). Six basic causes of lacunar infarcts have been proposed: embolism, hypertension, small vessel occlusive disease, hematologic abnormalities, small intracerebral hemorrhages, and vasospasm. Because of their size and location, lacunar infarcts usually do not cause cortical deficits such as aphasia or apraxia. Instead, they produce classic recognizable "lacunar syndromes," such as pure motor hemiplegia, pure sensory hemiplegia, and dysarthria with the clumsy hand syndrome. Because CT scans are not sensitive enough to detect these tiny infarcts, diagnosis used to depend on clinical features alone. The use of magnetic resonance imaging (MRI) has allowed frequent visualization of small vessel infarcts and is obligatory to confirm such a lesion.

Cardiogenic Embolic Stroke. An embolic stroke is caused by a moving blood clot that travels from its origin to the brain. Various cardiac conditions predispose to formation of emboli that produce embolic stroke, including rheumatic heart disease, atrial fibrillation, recent myocardial infarction, ventricular aneurysm, mobile aortic arch atheroma, and bacterial endocarditis. Although most cerebral emboli originate from a

thrombus in the left heart, they also may originate in an atherosclerotic plaque in the carotid arteries.

Embolic strokes usually affect the larger proximal cerebral vessels, often lodging at bifurcations. The most common site is the middle cerebral artery, probably because it offers the path of least resistance, reflecting the large territory of this vessel and its position as the terminus of the carotid artery. Embolic stroke usually has a sudden onset with immediate maximum deficit.

Hemorrhagic Stroke

The most frequently fatal stroke is a spontaneous hemorrhage into the brain substance.²⁶ With rupture of a blood vessel, hemorrhage into the brain tissue occurs, resulting in edema, compression of the brain contents, or spasm of the adjacent blood vessels. The most common predisposing factors are advancing age and hypertension. Other causes of hemorrhage are aneurysm, trauma, erosion of the vessels by tumors, arteriovenous malformations, coagulopathies, vasculitis, and drugs.

A cerebral hemorrhage occurs suddenly, usually when the person is active. Vomiting commonly occurs at the onset, and headache sometimes occurs. Focal symptoms depend on which vessel is involved. In the most common situation, hemorrhage into the basal ganglia results in contralateral hemiplegia, with initial flaccidity progressing to spasticity. The hemorrhage and resultant edema exert great pressure on the brain substance, and the clinical course progresses rapidly to coma and frequently to death.

Transient Ischemic Attacks

A transient ischemic attack (TIA) is characterized by a focal ischemic cerebral neurologic deficit that lasts less than 24 hours (usually less than 1 to 2 hours). A TIA or "ministroke" is equivalent to "brain angina" and reflects a temporary disturbance in focal cerebral blood flow, which reverses before infarction occurs, analogous to angina in relation to heart attack. The causes of TIAs are the same as those of ischemic stroke and include atherosclerotic disease of cerebral vessels and emboli.

TIAs are important because they may provide warning of impending stroke. In fact, the risk of stroke after a TIA is similar to the risk after a first stroke and is maximal immediately after the event: 4% to 8% risk of stroke within 1 month, 12% to 13% risk during the first year, and 24% to 29% risk during the next 5 years.²⁷ Diagnosis of TIA before a stroke may permit surgical or medical intervention that prevents an eventual stroke and the associated neurologic deficits.²⁶

Acute Manifestations of Stroke

The specific manifestations of stroke or TIA are determined by the cerebral artery that is affected, by the area of brain tissue that is supplied by that vessel, and by the adequacy of the collateral circulation. Symptoms of stroke/TIA always are sudden in onset and focal and are usually one-sided. The most common symptom is unilateral weakness of the face and arm or less commonly of the leg. Other frequent stroke symptoms are unilateral numbness, vision loss in one eye or to one side (hemianopia), language disturbance (aphasia) or slurred speech (dysarthria), and sudden loss of balance or ataxia. In the event of TIA, symptoms rapidly resolve spontaneously, although the underlying mechanisms are the same as for stroke. The specific stroke signs depend on the specific vascular territory compromised (Table 37-6). Discrete subsets of these vascular syndromes usually occur, depending on which branches of the involved artery are blocked.

Diagnosis and Treatment

Diagnosis. Accurate diagnosis of stroke is based on a complete history and thorough physical and neurologic examination. A careful history, including documentation of previous TIAs, the time of onset and pattern and rapidity of system progression, the specific focal symptoms (to determine the likely vascular territory), and the existence of any coexisting diseases, can help to determine the type of stroke that is involved. The diagnostic evaluation should aim to determine the presence of hemorrhage or ischemia, identify the stroke or TIA mechanism (large vessel or small vessel atherothrombotic, cardioembolic, other or cryptogenic, hemorrhagic), characterize the severity of clinical deficits, and unmask the presence of risk factors.

Imaging studies document the brain infarction and the anatomy and pathology of the related blood vessels. CT scans and MRI have become essential tools in diagnosing stroke, differentiating cerebral hemorrhage from ischemia, and excluding intracranial lesions that mimic stroke clinically. CT scans are a necessary screening tool in the acute setting for rapid identification of hemorrhage but are insensitive to ischemia within 24 hours and to any brain stem or small infarcts. MRI is supe-

TABLE 37-6	Signs and Symptoms of Stroke by	Involved Cerebral Artery
Cerebral Artery	Brain Area Involved	Signs and Symptoms*
Anterior cerebral	Infarction of the medial aspect of one frontal lobe if lesion is distal to communicating artery; bilateral frontal infarction if flow in other anterior cerebral artery is inadequate	Paralysis of contralateral foot or leg; impaired gait; paresis of con- tralateral arm; contralateral sensory loss over toes, foot, and leg; problems making decisions or performing acts voluntarily; lack of spontaneity, easily distracted; slowness of thought; aphasia depends on the hemisphere involved; urinary incontinence; cognitive and affective disorders
Middle cerebral	Massive infarction of most of lateral hemi- sphere and deeper structures of the frontal, parietal, and temporal lobes; internal capsule; basal ganglia	Contralateral hemiplegia (face and arm); contralateral sensory impairment; aphasia; homonymous hemianopia; altered con- sciousness (confusion to coma); inability to turn eyes toward paralyzed side; denial of paralyzed side or limb (hemiatten- tion); possible acalculia, alexia, finger agnosia, and left–right confusion; vasomotor paresis and instability
Posterior cerebral	Occipital lobe; anterior and medial portion of temporal lobe	Homonymous hemianopia and other visual defects such as color blindness, loss of central vision, and visual hallucinations; mem- ory deficits, perseveration (repeated performance of same verbal or motor response)
	Thalamus involvement	Loss of all sensory modalities; spontaneous pain; intentional tremor; mild hemiparesis; aphasia
	Cerebral peduncle involvement	Oculomotor nerve palsy with contralateral hemiplegia
Basilar and vertebra	l Cerebellum and brain stem	Visual disturbance such as diplopia, dystaxia, vertigo, dysphagia, dysphonia

*Depend on hemisphere involved and adequacy of collaterals.

rior for imaging ischemic lesions in all territories. Arteriography can demonstrate the site of the vascular abnormality and afford visualization of most intracranial vascular areas. The introduction of several Doppler ultrasonographic techniques has facilitated the noninvasive evaluation of the cerebral circulation, especially for detection of carotid stenosis.

Treatment. The treatment of acute ischemic stroke has changed markedly since the early 1990s, with an emphasis on salvaging brain tissue and minimizing long-term disability. The realization that there is a window of opportunity during which ischemic but viable brain tissue can be salvaged has led to the use of thrombolytic (clot disrupting) agents in the early treatment of ischemic stroke.²⁴ Although the results of emergent treatment of hemorrhagic stroke have been less dramatic, continued efforts to reduce disability have been promising.

A subcommittee of the Stroke Council of the American Heart Association has developed guidelines for the use of thrombolytic therapy for acute stroke.^{28,29} The major risk of treatment with thrombolytic agents is intracranial hemorrhage of the infarcted brain. A number of conditions, including use of oral anticoagulant medications, a history of gastrointestinal bleeding, recent myocardial infarction, previous stroke or head injury within 3 months, surgery within the past 14 days, and a blood pressure greater than 200/120 mm Hg, are considered contraindications to thrombolytic therapy.²⁹

The successful treatment of stroke depends on education of the public, paramedics, and health care professionals in emergency care facilities about the need for early diagnosis and treatment. As with heart attack, the message should be "do not wait to decide if the symptoms subside but seek immediate treatment." Effective medical and surgical procedures may preserve brain function and prevent disability. During the acute phase, proper positioning and range-of-motion exercises are essential. Early rehabilitation efforts include all members of the rehabilitation team—physician, nurse, speech therapist, physical therapist, and occupational therapist—and the family.

Stroke and cerebrovascular disorders often cause long-term disabilities, including motor and sensory deficits, language and speech problems, and a condition called the *hemineglect syndrome* (denial of one half of the body and environment on that side of the body). Longer-term treatment is aimed at preventing complications and recurrent stroke and promoting the fullest possible recovery of function.

Aneurysmal Subarachnoid Hemorrhage

An aneurysm is a bulge at the site of a localized weakness in the muscular wall of an arterial vessel. Most cerebral aneurysms are small saccular aneurysms called *berry aneurysms* (Fig. 37-18). They usually occur in the anterior circulation and are found at bifurcations and other junctions of vessels such as those in the circle of Willis (Fig. 37-19). They are thought to arise from a congenital defect in the media of the involved vessels, particularly at bifurcations. Persons with heritable connective tissue disorders such as autosomal dominant polycystic kidney disease, Ehlers-Danlos syndrome, neurofibromatosis type I, and Marfan's syndrome are at particular risk.¹ Other causes of cerebral aneurysms are atherosclerosis, hypertension, and bacterial infections.

Rupture of a cerebral aneurysm results in subarachnoid hemorrhage.^{30,31} The probability of rupture increases with the size of the aneurysm; aneurysms larger than 10 mm in diameter have a 50% chance of bleeding per year.¹ Rupture often occurs with acute increases in ICP. Of the various environmental factors that may predispose to aneurysmal subarachnoid hemorrhage, cigarette smoking and hypertension appear to constitute

■ FIGURE 37-18 ■ Berry aneurysm. A thin-walled aneurysm protrudes from the arterial bifurcation in the circle of Willis. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1466]. Philadelphia: Lippincott Williams & Wilkins)

the greatest threat. The mortality and morbidity rates associated with aneurysmal subarachnoid hemorrhage are high.

The signs and symptoms of cerebral aneurysms can be divided into two phases: those presenting before rupture and bleeding and those presenting after rupture and bleeding. Most small aneurysms are asymptomatic; intact aneurysms frequently are found at autopsy as an incidental finding.¹ Large aneurysms may cause chronic headache, neurologic deficits, or both. Approximately 50% of persons with subarachnoid hemorrhage have a history of atypical headaches occurring days to weeks before the onset of hemorrhage, suggesting the presence of a small leak.^{30,31} These headaches are characterized by sudden onset and often are accompanied by nausea, vomiting, and dizziness. Persons with these symptoms may be mistakenly diagnosed as having tension or migraine headaches.

The onset of subarachnoid aneurysmal rupture often is heralded by a sudden and severe headache, described as "the worst headache of my life." If the bleeding is severe, the headache may be accompanied by collapse and loss of consciousness. Vomiting may accompany the presenting symptoms. Other

■ FIGURE 37-19 ■ Common sites of berry aneurysms.

manifestations include signs of meningeal irritation such as nuchal rigidity (neck stiffness) and photophobia (light intolerance); cranial nerve deficits, especially cranial nerve II, and sometimes III and IV (diplopia and blurred vision); stroke syndrome (motor and sensory deficits); cerebral edema and increased ICP; and pituitary dysfunction (diabetes insipidus and hyponatremia).

The complications of aneurysmal rupture include rebleeding, vasospasm with cerebral ischemia, hydrocephalus, hypothalamic dysfunction, and seizure activity. Rebleeding and vasospasm are the most severe and most difficult to treat. Rebleeding, which has its highest incidence on the first day after the initial rupture, results in further and usually catastrophic neurologic deficits.

Vasospasm is a dreaded complication of aneurysmal rupture. The condition is difficult to treat and is associated with a high incidence of morbidity and mortality. Although the description of aneurysm-associated vasospasm is relatively uniform, its proposed mechanisms are a matter of controversy. Usually, the condition develops within 3 to 10 days (peak, 7 days) after aneurysm rupture and involves a focal narrowing of the cerebral artery or arteries that can be visualized on arteriography. The neurologic status gradually deteriorates as blood supply to the brain in the region of the spasm is decreased; this usually can be differentiated from the rapid deterioration seen in rebleeding.

Another complication of aneurysm rupture is the development of hydrocephalus. It is caused by plugging of the arachnoid villi with products from lysis of blood in the subarachnoid space.

The diagnosis of subarachnoid hemorrhage and intracranial aneurysms is made by clinical presentation, CT scan, lumbar puncture, and angiography. Lumbar puncture may be used to detect blood in the CSF, but the procedure carries with it the risk of rebleeding and brain herniation.

The course of treatment after aneurysm rupture depends on the extent of neurologic deficit. Persons with less severe deficits, with or without headache and no neurologic deficits, may undergo cerebral arteriography and early surgery, usually within 24 to 72 hours. A procedure involving craniotomy and clipping often is used. In this procedure, a specially designed silver clip is inserted and tightened around the neck of the aneurysm. This procedure offers protection from rebleeding and may permit removal of the hematoma. Some persons with subarachnoid hemorrhage are managed medically for 10 days or more in an attempt to improve their clinical status before surgery. The use of endovascular techniques such as balloon embolization and platinum coil electrothrombosis is evolving.

Arteriovenous Malformations

Arteriovenous malformations are a complex tangle of abnormal arteries and veins linked by one or more fistulas (Fig. 37-20).³² These vascular networks lack a capillary bed, and the small arteries have a deficient muscularis layer. Arteriovenous malformations are thought to arise from failure in development of the capillary network in the embryonic brain. As the child's brain grows, the malformation acquires additional arterial contributions that enlarge to form a tangled collection of thin-walled vessels that shunt blood directly from the arterial to the venous circulation. Arteriovenous malformations typically present before 40 years of age and affect men and

■ FIGURE 37-20 ■ Arteriovenous malformation. Abnormal blood vessels replace the cortical gray matter and extend deeply into the underlying white matter. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1466]. Philadelphia: Lippincott Williams & Wilkins)

women equally. Rupture of vessels in the malformation accounts for approximately 2% of all strokes.³²

The hemodynamic effects of arteriovenous malformations are twofold. First, blood is shunted from the high-pressure arterial system to the low-pressure venous system without the buffering advantage of the capillary network. The draining venous channels are exposed to high levels of pressure, predisposing them to rupture and hemorrhage. Second, impaired perfusion affects the cerebral tissue adjacent to the arteriovenous malformation. The elevated arterial and venous pressures and lack of a capillary circulation impair cerebral perfusion by producing a high-flow situation that diverts blood away from the surrounding tissue. Clinically, this is evidenced by slowly progressive neurologic deficits.

The major clinical manifestations of arteriovenous malformations are hemorrhage, seizures, headache, and progressive neurologic deficits. Headaches often are severe, and persons with the disorder may describe them as being throbbing and synchronous with their heart beat. Other, less common symptoms include visual symptoms (*i.e.*, diplopia and hemianopia), hemiparesis, mental deterioration, and speech deficits. Learning disorders have been documented in 66% of adults with arteriovenous malformations.³²

Definitive diagnosis often is obtained through cerebral angiography. Treatment methods include surgical excision, endovascular occlusion, and radiation therapy. Because of the nature of the malformation, each of these methods is accompanied by some risk of complications.

In summary, a stroke, or "brain attack," is an acute focal neurologic deficit caused by a vascular disorder that injures brain tissue. It is the third leading cause of death in the United States and a major cause of disability. There are two main types of stroke: ischemic and hemorrhagic. Ischemic stroke, which is the most common type, is caused by cerebrovascular obstruction by a thrombus or emboli. Hemorrhagic stroke, which is associated with greater morbidity and mortality, is caused by the rupture of a blood vessel and bleeding into the brain. The acute manifestations of stroke depend on the location of the blood vessel that is involved and can include motor, sensory, language, speech, and cognitive disorders. Early diagnosis and treatment with thrombolytic agents has improved the outlook for many persons with ischemic stroke.

A subarachnoid hemorrhage involves bleeding into the subarachnoid space. Most subarachnoid hemorrhages are the result of a ruptured cerebral aneurysm. Presenting symptoms include headache, nuchal rigidity, photophobia, and nausea. Complications include rebleeding, vasospasm, and hydrocephalus. Arteriovenous malformations are congenital abnormal communications between arterial and venous channels that result from failure in the development of the capillary network in the embryonic brain. The vessels in the arteriovenous malformations may enlarge to form a spaceoccupying lesion, become weak and predispose to bleeding, and divert blood away from other parts of the brain; they can cause brain hemorrhage, seizures, headache, and other neurologic deficits.

INFECTIONS AND NEOPLASMS

Infections

Infections of the CNS may be classified according to the structure involved: the meninges, (meningitis); the brain parenchyma (encephalitis); the spinal cord (myelitis); and the brain and spinal cord (encephalomyelitis). They also may be classified by the type of invading organism: bacterial, viral, or other. In general, the pathogens enter the CNS through the bloodstream by crossing the blood-brain barrier or by direct invasion through skull fracture, a bullet hole, or rarely, by contamination during surgery or lumbar puncture.

Meningitis

Meningitis is an inflammation of the pia mater, the arachnoid, and the CSF-filled subarachnoid space. Inflammation spreads rapidly because of CSF circulation around the brain and spinal cord. The inflammation usually is caused by an infection, but chemical meningitis can occur. There are two types of acute infectious meningitis: acute pyogenic meningitis (usually bacterial) and acute lymphocytic (usually viral) meningitis.¹

Bacterial Meningitis. Most cases of bacterial meningitis are caused by *Streptococcus pneumoniae, Haemophilus influenzae,* or *Neisseria meningitidis* (the meningococcus). The incidence of *H. influenzae,* which is the common cause of meningitis in children younger than 5 years, has declined dramatically during recent years because of vaccination against *H. influenza.* Epidemics of meningococcal meningitis occur in settings such as the military, where the recruits must reside in close contact. The very young and the very old are at highest risk for pneumococcal meningitis. Risk factors associated with contracting meningitis include head trauma with basilar skull fractures, otitis media, sinusitis or mastoiditis, neurosurgery, dermal sinus tracts, systemic sepsis, or immunocompromise.

In the pathophysiology of bacterial meningitis, the bacterial organisms replicate and undergo lysis in the CSF, releasing endotoxins or cell wall fragments. These substances initiate the release of inflammatory mediators, which set the stage for a complex but coordinated sequence of events by which neutrophils bind to and damage the endothelial cells of the blood-brain barrier, permitting fluid to move across the capillary wall. This allows pathogens, neutrophils, and albumin to move across the endothelial wall into the CSF. As the pathogens enter the subarachnoid space, they cause inflammation, characterized by a cloudy, purulent exudate. Thrombophlebitis of the bridging veins and dural sinuses may develop, followed by congestion and infarction in the surrounding tissues. Ultimately, the meninges thicken, and adhesions form. These adhesions may impinge on the cranial nerves, giving rise to cranial nerve palsies, or may impair the outflow of CSF, causing hydrocephalus.

The most common symptoms of acute bacterial meningitis are fever and chills; headache; stiff neck; back, abdominal, and extremity pains; and nausea and vomiting. Other signs include seizures, cranial nerve palsies, and focal cerebral signs.³³ A petechial rash is found in most persons with meningococcal meningitis. These petechiae vary from pinhead size to large ecchymoses or even areas of skin gangrene that slough if the person survives. Other types of meningitis also may produce a petechial rash. Persons infected with *H. influenzae* or *S. pneumoniae* may present with difficulty in arousal and seizures, whereas those with *N. meningitidis* infection may present with delirium or coma.³³ The development of brain edema, hydrocephalus, or increased cerebral blood flow can increase ICP.

Meningeal signs (*e.g.*, photophobia and nuchal rigidity), such as those seen in subarachnoid hemorrhage, also may be present. Two assessment techniques can help determine whether meningeal irritation is present. *Kernig's sign* is resistance to extension of the leg while the person is lying with the hip flexed at a right angle. *Brudzinski's sign* is elicited when flexion of the neck results in flexion of the hip and knee. These postures are caused by stretching of the inflamed meninges from the lumbar level to the head. Stretching of the inflamed meninges is extremely painful, producing resistance to stretching. Cranial nerve damage (especially the eighth nerve, with resulting deafness) and hydrocephalus may occur as complications of pyogenic meningitis.

The diagnosis of bacterial meningitis is based on the history and physical examination, along with laboratory data. Lumbar puncture (*i.e.*, spinal tap) findings, which is necessary for accurate diagnosis, includes a cloudy and purulent CSF under increased pressure. The CSF typically contains large numbers of polymorphonuclear neutrophils (up to 90,000/mm³), increased protein content, and reduced sugar content. Bacteria can be seen on smears and can easily be cultured with appropriate media.

Treatment includes antibiotics and corticosteroids. Optimal antibiotic treatment requires that the drug have a bactericidal effect in the CSF. Because bactericidal therapy often results in rapid lysis of the pathogen, treatment can promote the release of biologically active cell wall products into the CSF. The release of these cell wall products can increase the production of inflammatory mediators that have the potential for exacerbating the abnormalities of the blood-brain barrier and the inflammatory process. Because of evidence linking the inflammatory mediators to the pathogenesis of bacterial meningitis, adjunctive corticosteroid therapy usually is administered with or just before the first dose of antibiotics in infants and children. The adjunctive use of corticosteroid therapy in adults is a matter of controversy.

Persons who have been exposed to someone with meningococcal meningitis should be treated prophylactically with antibiotics.³⁴ Effective polysaccharide vaccines are available to protect against meningococcal groups A, C, Y, and W-135.³⁵ These vaccines are recommended for military recruits and college students, who are at increased risk of invasive meningo-coccal disease.

Viral Meningitis. Viral meningitis manifests in much the same way as bacterial meningitis, but the course is less severe, and the CSF findings are markedly different. There are lymphocytes in the fluid, rather than polymorphonuclear cells, the protein content is only moderately elevated, and the sugar content usually is normal. The acute viral meningitides are self-limited and usually require only symptomatic treatment. Viral meningitis can be caused by many different viruses, including mumps, coxsackievirus, Epstein-Barr virus, and herpes simplex type 2. In many cases, the virus cannot be identified.

Encephalitis

Encephalitis represents a generalized infection of the parenchyma of the brain or spinal cord. It usually is caused by a virus, but it also may be caused by bacteria, fungi, and other organisms. The nervous system is subjected to invasion by many viruses, such as arbovirus, poliovirus, and rabies virus. The mode of transmission may be the bite of a mosquito (arbovirus), a rabid animal (rabies virus), or ingestion (poliovirus). A common cause of encephalitis in the United States is herpes simplex virus. Less common causes of encephalitis are toxic substances such as ingested lead and vaccines for measles and mumps. Encephalitis caused by human immunodeficiency virus infection is discussed in Chapter 10.

The pathologic picture of encephalitis includes local necrotizing hemorrhage, which ultimately becomes generalized, with prominent edema. There is progressive degeneration of nerve cell bodies. The histologic picture, although rather general, demonstrates some specific characteristics. For example, the poliovirus selectively destroys the cells of the anterior horn of the spinal cord.

Encephalitis, like meningitis, is characterized by fever, headache, and nuchal rigidity. Patients experience a wide range of neurologic disturbances, such as lethargy, disorientation, seizures, focal paralysis, delirium, and coma. Diagnosis of encephalitis is made by clinical history and presenting symptoms, in addition to traditional CSF studies.

Neoplasms

For most neoplasms, the term *malignant* is used to describe the tumor's lack of cell differentiation, its invasive nature, and its ability to metastasize. However, in the brain even a welldifferentiated and histologically benign tumor may grow and cause death because of its location.

Brain cancer accounts for 2% of all cancer deaths. The American Cancer Society estimates that there were 17,200 new cases and more than 13,100 deaths of brain and CNS cancers in 2001.³⁶ Metastasis to the brain from other sites is even more common.³⁷ In children, brain tumors are second only to leukemia as a cause of death from cancer, and they kill approximately 1600 children and young adults annually.

Although a number of chemical and viral agents can cause brain tumors in laboratory animals, there is no evidence that these agents directly cause brain cancer in humans. Cranial irradiation and exposure to some chemicals may lead to an increased incidence of astrocytomas and meningiomas. There may also be a hereditary factor. Childhood tumors are considered to be developmental in origin.

Types of Tumors

Brain tumors can be divided into three types: primary intracranial tumors of CNS tissue (*e.g.*, neuroglial tumors [gliomas]), primary intracranial tumors that originate in the skull cavity but are not derived from the brain tissue itself (*e.g.*, meninges, pituitary gland, pineal gland), and metastatic tumors.

Primary Neuroglial Tumors. Primary intracranial neoplasms of CNS origin can be classified according to the site of origin and histologic type. They include astrocytomas, oligodendrogliomas, and ependymomas.

Collectively, the neoplasms of astrocyte origin are the most common type of primary brain tumor in the adult. Astrocytomas can be subdivided into fibrillary (filtrating) astrocytic neoplasms and pilocytic astrocytomas.1 Fibrillary or diffuse astrocytomas account for 80% of adult primary brain tumors. They are most commonly seen in adults, but may occur at any age. Although they usually are found in the cerebral hemispheres, they also can occur in the cerebellum, brain stem, or spinal cord. These tumors are subdivided into histologic grades based on their degree of differentiation. The Word Health Organization grading system divides these tumors into three types: (1) the well differentiated lesions, designated astrocytomas; (2) intermediate-grade tumors, designated anaplastic astrocytomas; and (3) the most aggressive lesions, designated glioblastoma multiforme. Astrocytomas have a marked tendency to become more anaplastic with time, so a tumor beginning as an astrocytoma may develop into a glioblastoma. Pilocytic astrocytomas are distinguished from other astrocytomas by their cellular appearance and their benign behavior. Typically, they occur in children and young adults and usually are located in the cerebellum, but they also can be found in the floor and walls of the third ventricle, the optic chiasm and nerves, and occasionally in the cerebral hemispheres.

Oligodendrogliomas comprise approximately 5% to 15% of glial tumors. They are most common in middle life and are found in the cerebral hemispheres.¹ In general, persons with oligodendrogliomas have a better prognosis than do persons with astrocytomas.

Ependymomas are derived from the single layer of epithelium that lines the ventricles and spinal canal. Although they can occur at any age, they are most likely to occur in the first 2 decades of life.¹

Meningiomas. Meningiomas develop from the meningothelial cells of the arachnoid and are outside the brain. They usually have their onset in the middle or later years of life. They are slow-growing, well-circumscribed, and often highly vascular tumors. They usually are benign, and complete removal is possible if the tumor does not involve vital structures.

Metastatic Tumors. The brain is a common site for metastatic tumors. They occur primarily in older persons, paralleling the increase in solid tumors that occurs with increasing age.¹ Hematopoietic tumors, such as lymphomas and leukemias, which occur in children as well as adults, may also spread to the CNS. Among the tumors that commonly metastasize to the brain are lung and breast tumors and malignant melano-

mas. In some cases, particularly in carcinomas arising in the lung cancer, neurologic symptoms may provide the first evidence of cancer.

Clinical Course

Brain tumors can produce either focal or generalized disorders of brain function.³⁷ Focal disturbances result from brain compression, tumor infiltration, disturbances in blood flow, and cerebral edema. Cysts may form in tumors and contribute to brain compression. Generalized disruption of brain function usually reflects an increase in ICP. Because the volume of the intracranial cavity is fixed, brain tumors can cause a generalized increase in ICP when they reach sufficient size. Tumors can obstruct the flow of CSF in the ventricular cavities and produce hydrocephalic dilatation of the proximal ventricles and atrophy of the cerebral hemispheres.

The clinical manifestations of brain tumors depend on the size and location of the tumor. Generalized signs and symptoms include headache, nausea, vomiting, and papilledema. The brain itself is insensitive to pain. The headache that accompanies brain tumors results from compression or distortion of pain-sensitive dural or vascular structures. It may be felt on the same side of the head as the tumor but more commonly is diffuse. In the early stages, the headache, which is caused by irritation, compression, and traction on the dural sinuses or blood vessels, is mild and occurs in the morning when the person awakens.³⁷ It usually disappears after the person has been up for a short time. The headache becomes more constant as the tumor enlarges and often is worsened by coughing, bending, or sudden movements of the head.

Vomiting occurs with or without preceding nausea and is a common symptom of increased ICP and brain stem compression. Direct stimulation of the vomiting center, which is located in the medulla, may contribute to the vomiting that occurs with brain tumors. The vomiting may be projectile. Vomiting caused by brain tumor usually is unrelated to meals and often is associated with headache. Papilledema (edema of the optic disk) results from increased ICP and obstruction of the CSF pathways. It is associated with decreased visual acuity, diplopia, and deficits in the visual fields. Visual defects associated with papilledema often are the reason that persons with brain tumor seek medical care.

Personality and mental changes are common with brain tumors. Persons with brain tumors often are irritable initially and later become quiet and apathetic. They may become forgetful, seem preoccupied, and appear to be psychologically depressed. Because of the mental changes, a psychiatric consultation may be sought before a diagnosis of brain tumor is made.

Focal signs and symptoms are determined by the location of the tumor. Tumors arising in the frontal lobe may grow to large size, increase the ICP, and cause signs of generalized brain dysfunction before focal signs are recognized. Tumors that impinge on the visual system cause visual loss or visual field defects long before generalized signs develop. Certain areas of the brain have a relatively low threshold for seizure activity; tumors arising in relatively silent areas of the brain may produce focal epileptogenic discharges. Temporal lobe tumors often produce seizures as their first symptom. Hallucinations of smell or hearing and déjà vu phenomena are common focal manifestations of temporal lobe tumors. Brain stem tumors commonly produce upper and lower motoneuron signs, such as weakness of facial muscles and ocular palsies that occur with or without involvement of sensory or long motor tracts. Cerebellar tumors often cause ataxia of gait.

Diagnosis and Treatment. Diagnostic procedures for brain tumor include physical and neurologic examinations, visual field and funduscopic examination, CT scans and MRI, skull x-ray films, technetium pertechnetate brain scans, electroencephalography, and cerebral angiography. Physical examination is used to assess motor and sensory function. Because the visual pathways travel through many areas of the cerebral lobes, detection of visual field defects can provide information about the location of tumors. Although CT scanning is used as a screening test, MRI scans are more sensitive than CT scans for mass lesions and can be diagnostic when a clinically suspected tumor is not detected by CT scanning. Skull x-ray films are used to detect calcified areas in a neoplasm or erosion of skull structures caused by tumors. Cerebral angiography can be used to locate a tumor and visualize its vascular supply, information that is important when planning surgery.

The three general methods for treatment of brain tumors are surgery, irradiation, and chemotherapy. Surgery is part of the initial management of virtually all brain tumors; it establishes the diagnosis and achieves tumor removal in many cases. The use of chemotherapy for brain tumors is somewhat limited by the blood-brain barrier. Chemotherapeutic agents can be administered intravenously, intra-arterially, intrathecally (*i.e.*, into the spinal canal), or intraventricularly.

In summary, infections of the CNS may be classified according to the structures involved (*e.g.*, meningitis, encephalitis) or the type of organism causing the infection. The damage caused by infection may predispose to hydrocephalus, seizures, or other neurologic defects.

Brain tumors account for 2% of all cancer deaths and are the second most common type of cancer in children. Primary brain tumors can arise from any structure in the cranial cavity. Most begin in brain tissue, but the pituitary, the pineal region, and the meninges also are sites of tumor development. Brain tumors cause generalized or focal disturbances in brain function. Generalized disruption of brain function usually reflects an increase in ICP. General symptoms such as headache, nausea, vomiting, mental changes, and papilledema usually reflect an increase in ICP. Focal symptoms, such disorders of motor function, result from brain compression, tumor infiltration, disturbances in blood flow, and cerebral edema.

SEIZURE DISORDERS

Seizures, sometimes called *convulsions*, are paroxysmal motor, sensory, or cognitive manifestations of spontaneous, abnormally synchronous discharges of collections of neurons in the cerebral cortex. Approximately 2 million persons in the United States experience recurrent seizures.³⁸ Seizure activity is the most common disorder encountered in pediatric neurology, and among adults, its incidence is exceeded only by cerebrovascular disorders. In most persons, the first seizure episode occurs before 20 years of age. After 20 years of age, a seizure is caused most often by a structural change, trauma, tumor, or stroke.

KEY CONCEPTS

SEIZURES

- Seizures are paroxysmal motor, sensory, or cognitive manifestations of spontaneous, abnormally synchronous electrical discharges from collections of neurons in the cerebral cortex that are thought to result directly or indirectly from changes in excitability of single neurons or groups of neurons.
- Partial seizures originate in a small group of neurons in one hemisphere with secondary spread of seizure activity to other parts of the brain. Simple partial seizures usually are confined to one hemisphere and do not involve loss of consciousness. Complex partial seizures begin in a localized area, spread to both hemispheres, and involve impairment of consciousness.
- Generalized seizures show simultaneous disruption of normal brain activity in both hemispheres from the onset. They include unconsciousness and varying bilateral degrees of symmetric motor responses with evidence of localization to one hemisphere. Absence seizures are generalized nonconvulsive seizure events that are expressed mainly by brief periods of unconsciousness. Tonic-clonic seizures involve unconsciousness along with both tonic and clonic muscle contractions.

A seizure represents the clinical manifestations of an abnormal, uncontrolled electrical discharge from a group of neurons. This uncontrolled neuronal activity causes signs and symptoms that vary according to the location of the originating focus of seizure activity, involvement of surrounding neurons, and spread to other parts of the brain. These signs and symptoms can include strange sensations and perceptions (*e.g.*, hallucinations), unusual or repetitive muscle movements, autonomic visceral activity, and the onset of a confusional state or loss of consciousness.

Many theories have been proposed to explain the cause of the abnormal brain electrical activity that occurs with seizures. Seizures may be caused by alterations in cell membrane permeability or distribution of ions across the neuronal cell membranes. Another cause may be decreased inhibition of cortical or thalamic neuronal activity or structural changes that alter the excitability of neurons. Neurotransmitter imbalances such as an acetylcholine excess or γ -aminobutyric acid (GABA, an inhibitory neurotransmitter) deficiency have been proposed as causes.

Provoked and Unprovoked Seizures

Clinically, seizures may be categorized as unprovoked (primary or idiopathic) or provoked (secondary or acute symptomatic).³⁹ Provoked or symptomatic seizures include febrile seizures, seizures precipitated by systemic metabolic conditions, and those that follow a primary insult to the CNS. Unprovoked or idiopathic seizures are those for which no identifiable cause can be determined.

The most common subgroup of seizures under the category of provoked seizures is that of febrile seizures in children.⁴⁰ They are associated with a high fever, usually with a temperature higher than 104°F. Seizures can also be precipitated by systemic or metabolic disturbances, and primary CNS insults also fall into the category of provoked seizures. Transient systemic metabolic disturbances may precipitate seizures. Examples include electrolyte imbalances, hypoglycemia, hypoxia, hypocalcemia, and alkalosis. Toxemia of pregnancy, water intoxication, uremia, and CNS infections such as meningitis also may precipitate a seizure. The rapid withdrawal of sedative-hypnotic drugs, such as alcohol or barbiturates, is another cause of seizures. Approximately 5% to 10% of those who sustain a CNS insult, such as occurs with cerebral bleeding, edema, or neuronal damage, experience a seizure. Treatment of the immediate cause of these seizures often results in their disappearance.

Multiple episodes or frequent recurrences of apparently unprovoked seizures are considered a seizure disorder. The terms *seizure disorder* and *epileptic syndrome* often are used interchangeably. However, the term *seizure disorder* is often preferred because of the negative connotations associated with the term *epilepsy*. A seizure disorder can be defined as a syndrome in which there is a tendency to have recurrent, paroxysmal seizure activity without evidence of a reversible metabolic cause. It is a chronic condition for which long-term medication may be appropriate.

Classification

The International Classification of Epileptic Seizures is based on symptoms during the seizure and EEG activity. It divides seizures into two broad categories: partial seizures, in which the seizure begins in a specific or focal area of one cerebral hemisphere, and generalized seizures, which begin simultaneously in both cerebral hemispheres⁴¹ (Chart 37-1).

Partial Seizures

Partial or focal seizures are the most common type of seizure among newly diagnosed cases in all persons older than 10 years of age. Partial seizures can be subdivided into three major groups: simple partial (consciousness is not impaired), complex partial (impairment of consciousness), and secondarily generalized partial seizures.

Simple Partial Seizures. Simple partial seizures usually involve only one hemisphere and are not accompanied by loss of consciousness or responsiveness. These seizures also have been referred to as *elementary partial seizures, partial seizures with elementary symptoms,* or *focal seizures.* Simple partial seizures are classified according to motor signs, sensory symptoms, autonomic manifestations, and psychic symptoms.

The observed clinical signs and symptoms depend on the area of the brain where the abnormal neuronal discharge is taking place. If the motor area of the brain is involved, the earliest symptom is motor movement corresponding to the location of onset on the contralateral side of the brain. The motor movement may remain localized or may spread to other cortical areas, with sequential involvement of body parts in an epileptic-type

CHART 37-1 Classification of Epileptic Seizures

Partial Seizures

Simple partial seizures (no impairment of consciousness)
With motor symptoms
With sensory symptoms
With autonomic signs
With psychic symptoms
Complex partial seizures (impairment of consciousness)
Simple partial onset followed by impaired consciousness
Impairment of consciousness at onset
Partial seizures evolving to secondarily generalized seizures
Simple partial leading to generalized seizures
Complex partial leading to generalized seizures

International League Against Epilepsy [1981]. Proposal for revised clinical and electroencephalographic classification of epileptic seizures. *Epilepsia* 22, 489)

"march," known as a *Jacksonian seizure*. If the sensory portion of the brain is involved, there may be no observable clinical manifestations. Sensory symptoms correlating with the location of seizure activity on the contralateral side of the brain may involve somatic sensory disturbance (*e.g.*, tingling and crawling sensations) or special sensory disturbance (*i.e.*, visual, auditory, gustatory, or olfactory phenomena). When abnormal cortical discharge stimulates the autonomic nervous system, flushing, tachycardia, diaphoresis, hypotension or hypertension, or pupillary changes may be evident.

The term *prodrome* or *aura* traditionally has meant a sensory warning sign of impending seizure activity that affected persons could recognize or describe because they were conscious. Simple partial seizures may progress to complex partial seizures or generalized tonic-clonic seizures that result in unconsciousness.

Complex Partial Seizures. Complex partial seizures involve impairment of consciousness and often arise from the temporal lobe. The seizure begins in a localized area of the brain but may progress rapidly to involve both hemispheres. These seizures also may be referred to as *temporal lobe seizures* or *psychomotor seizures*.

Complex partial seizures often are accompanied by automatisms. Automatisms are repetitive, nonpurposeful activity, such as lip smacking, grimacing, patting, or rubbing clothing. Confusion during the postictal state (after a seizure) is common. Hallucinations and illusional experiences such as *déjà vu* (familiarity with unfamiliar events or environments) or *jamais vu* (unfamiliarity with a known environment) have been reported. There may be overwhelming fear, uncontrolled forced thinking or a flood of ideas, and feelings of detachment and depersonalization.

Secondarily Generalized Partial Seizures. These seizures are focal at onset but then become generalized as the seizure activity spreads, involving deeper structures of the brain, such as the thalamus or the reticular formation. Discharges spread to both hemispheres, resulting in progression to tonic-clonic seizure activity. These seizures may start as simple or complex partial seizures and may be preceded by an aura. The aura, often a stereotyped peculiar sensation that precedes the seizure, is the result of partial seizure activity. A history of an aura is clinically useful to identify the seizure as partial and not generalized in onset. However, absence of an aura does not reliably exclude a focal onset because many partial seizures generalize too rapidly to generate an aura.

Generalized Seizures

Generalized seizures begin with initial involvement of both hemispheres. Generalized-onset seizures are the most common type in young children. These seizures are classified as primary or generalized when clinical signs, symptoms, and supporting EEG changes indicate involvement of both hemispheres at onset. The clinical symptoms include unconsciousness and involve varying degrees of symmetric bilateral motor responses without evidence of localization to one hemisphere.

These seizures are divided into four broad categories: absence seizures (typical and atypical), atonic seizures, myoclonic seizures, and major motor (tonic-clonic) seizures.⁴¹

Absence Seizures. Absence seizures, formerly referred to as petit mal seizures, are generalized, nonconvulsive epileptic events and are expressed mainly as disturbances in consciousness. Absence seizures typically occur only in children and cease in adulthood or evolve to generalized motor seizures. Children may present with a history of school failure that predates the first evidence of seizure episodes. Although typical absence seizures have been characterized as a blank stare, motionlessness, and unresponsiveness, motion occurs in many cases of typical absence seizures. This motion may take the form of automatisms such as lip smacking, mild clonic motion (usually in the eyelids), increased or decreased postural tone, and autonomic phenomena. There often is a brief loss of contact with the environment. The seizure usually lasts only a few seconds, and then the child is able to resume normal activity immediately. The manifestations often are so subtle that they may pass unnoticed.

Atypical absence seizures are similar to typical absence seizures except for greater alterations in muscle tone and less abrupt onset and cessation. In practice, it is difficult to distinguish typical from atypical absence seizures without benefit of supporting EEG findings. Because automatisms and unresponsiveness are common to complex partial seizures, the latter may be mistakenly labeled as absence seizures. However, it is important to distinguish between the two types of seizures because the drug treatment is different. Medications that are effective for partial seizures may increase the frequency of absence seizures.

Atonic Seizures. In atonic or akinetic seizures, there is a sudden, split-second loss of muscle tone leading to slackening of the jaw, drooping of the limbs, or falling to the ground. These seizures also are known as *drop attacks*.

Myoclonic Seizures. Myoclonic seizures involve brief involuntary muscle contractions induced by stimuli of cerebral origin. A myoclonic seizure involves bilateral jerking of muscles, generalized or confined to the face, trunk, or one or more extremities. Tonic seizures are characterized by a rigid, violent contraction of the muscles, fixing the limbs in a strained position. Clonic seizures consist of repeated contractions and relaxations of the major muscle groups.

Tonic-Clonic Seizures. Tonic-clonic seizures, formerly called *grand mal seizures*, are the most common major motor seizure. Frequently, a person has a vague warning (probably a simple partial seizure) and experiences a sharp tonic contraction of the muscles with extension of the extremities and immediate loss of consciousness. Incontinence of bladder and bowel is common. Cyanosis may occur from contraction of airway and respiratory muscles. The tonic phase is followed by the clonic phase, which involves rhythmic bilateral contraction and relaxation of the extremities. At the end of the clonic phase, the person remains unconscious until the RAS begins to function again. This is called the *postictal phase*. The tonic-clonic phases last approximately 60 to 90 seconds.

Unclassified Seizures

Unclassified seizures are those that cannot be placed in one of the previous categories. These seizures are observed in the neonatal and infancy periods. Determination of whether the seizure is focal or generalized is not possible. Unclassified seizures are difficult to control with medication.

Diagnosis and Treatment

The diagnosis of seizure disorders is based on a thorough history and neurologic examination, including a full description of the seizure. The physical examination and laboratory studies help exclude any metabolic disease (*e.g.*, hyponatremia) that could precipitate seizures. Skull radiographs and CT or MRI scans are used to identify structural defects. One of the most useful diagnostic tests is the EEG, which is used to record changes in the brain's electrical activity. It is used to support the clinical diagnosis of epilepsy, to provide a guide for prognosis, and to assist in classifying the seizure disorder.

The first rule of treatment is to protect the person from injury during a seizure, preserve brain function by aborting or preventing seizure activity, and treat any underlying disease. Persons with epilepsy should be advised to avoid situations that could be dangerous or life threatening if seizures occur.

Anticonvulsant Medications

Since the late 1970s, the therapy for epilepsy has changed drastically because of an improved classification system, the ability to measure serum anticonvulsant levels, and the availability of potent new anticonvulsant drugs. With proper drug management, 60% to 80% of persons with epilepsy can obtain good seizure control. More than 20 drugs are available in the United States for the treatment of epilepsy.⁴² Antiseizure drugs act mainly by suppressing repetitive firing of isolated neurons that act as epileptogenic foci for seizure activity or by inhibiting the transmission of electrical impulses involved in seizure activity. Because of their selective mechanisms of action, different drugs are used to treat the different types of seizures. For example, ethosuximide is the drug of choice for absence seizures, but it is not effective for tonic-clonic seizures that progress from partial seizures.

The goal of pharmacologic treatment is to bring the seizures under control with the least possible disruption in lifestyle and minimum side effects from medication. When possible, a single drug should be used. Monotherapy eliminates drug interactions and additive side effects. Determining the proper dose of the anticonvulsant drug is often a long and tedious process, which can be very frustrating for the person with epilepsy. Often blood tests are used to determine that the blood concentration is within the therapeutic range. Consistency in taking the medication is essential. Anticonvulsant drug use never should be discontinued abruptly. Special consideration is needed when a person taking an anticonvulsant medication becomes ill and must take additional medications. Some drugs act synergistically, and others interfere with the actions of anticonvulsant medications. This situation needs to be carefully monitored to avoid overmedication or interference with successful seizure control.

Women of childbearing age require special consideration concerning fertility, contraception, and pregnancy. Many of the drugs interact with oral contraceptives; some affect hormone function or decrease fertility. All such women should be advised to take folic acid supplementation. For women with epilepsy who become pregnant, antiseizure drugs increase the risk of congenital abnormalities and other perinatal complications.

Surgical Therapy

Surgical treatment may be an option for persons with epilepsy that is refractory to drug treatment.⁴³ With the use of modern neuroimaging and surgical techniques, a single epileptogenic lesion can be identified and removed without leaving a neurologic deficit.

Generalized Convulsive Status Epilepticus

Seizures that do not stop spontaneously or occur in succession without recovery are called *status epilepticus*. There are as many types of status epilepticus as there are types of seizures. Tonicclonic status epilepticus is a medical emergency and, if not promptly treated, may lead to respiratory failure and death.

The disorder occurs most frequently in the young and old. Morbidity and mortality rates are highest in elderly persons and persons with acute symptomatic seizures, such as those related to anoxia or cerebral infarction.⁴⁴ Approximately one third of patients have no history of a seizure disorder, and in another one third, status epilepticus occurs as an initial manifestation of epilepsy.⁴⁴

Treatment consists of appropriate life-support measures. If status epilepticus is caused by neurologic or systemic disease, the cause needs to be identified and treated immediately. Medications are given to control seizure activity.

In summary, seizures are caused by spontaneous, uncontrolled, paroxysmal, transitory discharges from cortical centers in the brain. Seizures may occur as a reversible symptom of another disease condition or as a recurrent condition called epilepsy. Epileptic seizures are classified as partial or generalized seizures. Partial seizures have evidence of local onset, beginning in one hemisphere. They include simple partial seizures, in which consciousness is not lost, and complex partial seizures, which begin in one hemisphere but progress to involve both. Because consciousness is not lost, an aura is now considered to be part of a simple partial seizure. Generalized seizures involve both hemispheres and include unconsciousness and rapidly occurring, widespread, bilateral symmetric motor responses. They include minor motor seizures, such as absence and akinetic seizures, and major motor or grand mal seizures.

DEMENTIAS

Dementia is a syndrome of intellectual deterioration severe enough to interfere with occupational or social performance. It may involve disturbances in memory, language use, perception, and motor skills and may interrupt the ability to learn necessary skills, solve problems, think abstractly, and make judgments. The dementias include Alzheimer's disease, multiinfarct dementia, Pick's disease, Creutzfeldt-Jakob disease, Wernicke-Korsakoff syndrome, and Huntington's chorea.

Depression is the most common treatable illness that may masquerade as dementia, and it must be excluded when a diagnosis of dementia is considered. This is important because cognitive functioning usually returns to baseline levels after depression is treated.

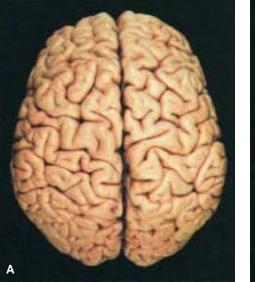

Alzheimer's Disease

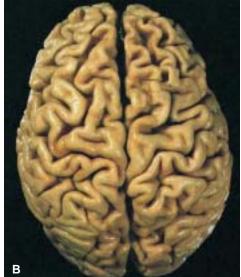

Dementia of the Alzheimer's type occurs in middle or late life and accounts for 50% to 70% of all cases of dementia. The disorder affects approximately 4 million Americans and may be the fourth leading cause of death in the United States.⁴⁵ The risk of Alzheimer's disease increases with age, and it occurs in nearly half of persons 85 years of age and older.

Pathophysiology

Alzheimer's disease is characterized by cortical atrophy and loss of neurons, particularly in the parietal and temporal lobes (Fig. 37-21). With significant atrophy, there is ventricular enlargement (*i.e.*, hydrocephalus) from the loss of brain tissue. Neurochemically, Alzheimer's disease has been associated with a decrease in the level of choline acetyltransferase activity in the cortex and hippocampus. This enzyme is required for the synthesis of acetylcholine, a neurotransmitter that is associated with memory. The reduction in choline acetyltransferase is quantitatively related to the numbers of neuritic plaques and severity of dementia.

The major microscopic features of Alzheimer's disease are the presence of amyloid-containing neuritic plaques and neurofibrillary tangles.⁸ The neurofibrillary tangles, which

■ FIGURE 37-21 ■ Alzheimer's disease. (A) Normal brain. (B) The brain of a patient with Alzheimer's disease shows cortical atrophy, characterized by slender gyri and prominent sulci. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1511]. Philadelphia: Lippincott Williams & Wilkins)

are found in the cytoplasm of abnormal neurons, consist of fibrous proteins that are wound around each other in a helical fashion. These tangles are resistant to chemical or enzymatic breakdown, and they persist in brain tissue long after the neuron in which they arose has died and disappeared. The senile plaques are patches or flat areas composed of clusters of degenerating nerve terminals arranged around a central core of β -amyloid (A β).⁸ These plaques are found in areas of the cerebral cortex that are linked to intellectual function. Aß is a fragment of a much larger membrane-spanning amyloid precursor protein (APP). The function of APP is unclear, but it appears to be associated with the cytoskeleton of nerve fibers. Normally, the degradation of APP involves enzymatic cleavage, with formation of soluble nonpathogenic fragments. In Alzheimer's disease, cleavage of the APP molecule results in the formation of the less soluble A β peptide, which tends to aggregate into the amyloid fibrils found in the senile plaques.8

Some plaques and tangles can be found in the brains of older persons who do not show cognitive impairment. The number and distribution of the plaques and tangles appear to contribute to the intellectual deterioration that occurs with Alzheimer's disease. In persons with the disease, the plaques and tangles are found throughout the neocortex and in the hippocampus and amygdala, with relative sparing of the primary sensory cortex.¹ Hippocampal function in particular may be compromised by the pathologic changes that occur in Alzheimer's disease. The hippocampus is crucial to information processing, acquisition of new memories, and retrieval of old memories. The development of neurofibrillary tangles in the entorhinal cortex and superior portion of the hippocampal gyrus interferes with cortical input and output, thereby isolating the hippocampus from the remainder of the cortex and rendering it functionless.

It is likely that Alzheimer's disease is caused by several factors that interact differently in different persons. Progress on the genetics of inherited early-onset Alzheimer's disease shows

that mutations in at least three genes—the APP gene on chromosome 21; presenilin-1 (PS1), a gene on chromosome 14; and presenilin-2 (PS2), a gene on chromosome 1-can cause Alzheimer's disease in certain families.^{8,46,47} The APP gene is associated with an autosomal dominant form of early-onset Alzheimer's disease and can be tested clinically. Persons with Down's syndrome (trisomy 21) experience the pathologic changes of Alzheimer's disease and a comparable decline in cognitive functioning at a relatively young age. Virtually all persons with Down's syndrome who survive past 50 years experience the full-blown pathologic features of dementia. Because the APP gene is located on chromosome 21, it is thought that the additional dosage of the gene product in trisomy 21 predisposes to accumulation of BAP.8 There is some indication that PS1 and PS2 are mutant proteins that alter the processing of APP.⁸ A fourth gene, an allele of the apolipoprotein E gene, APOE e4, has been identified as a risk factor for late-onset Alzheimer's disease.

Clinical Course

Alzheimer's-type dementia follows an insidious and progressive course. The hallmark symptoms are loss of short-term memory and a denial of such memory loss, with eventual disorientation, impaired abstract thinking, apraxias, and changes in personality and affect. Three stages of Alzheimer's dementia have been identified, each characterized by progressive degenerative changes.

The *first stage*, which may last for 2 to 4 years, is characterized by short-term memory loss that often is difficult to differentiate from the normal forgetfulness that occurs in the elderly, and usually is reported by caregivers and denied by the patient. Although most elderly have trouble retrieving from memory incidental information and proper names, persons with Alzheimer's disease randomly forget important and unimportant details. They forget where things are placed, get lost easily, and have trouble remembering appointments and performing novel tasks. Mild changes in personality, such as lack of spontaneity, social withdrawal, and loss of a previous sense of humor, occur during this stage.

As the disease progresses, the person with Alzheimer's disease enters the second or confusional stage of dementia. This stage may last several years and is marked by a more global impairment of cognitive functioning. During this stage, there are changes in higher cortical functioning needed for language, spatial relationships, and problem solving. Depression may occur in persons who are aware of their deficits. There is extreme confusion, disorientation, lack of insight, and inability to carry out the activities of daily living. Personal hygiene is neglected, and language becomes impaired because of difficulty in remembering and retrieving words. Wandering, especially in the late afternoon or early evening, becomes a problem. The sundown syndrome, which is characterized by confusion, restlessness, agitation, and wandering, may become a daily occurrence late in the afternoon. Some persons may become hostile and abusive toward family members. Persons who enter this stage become unable to live alone and should be assisted in making decisions about supervised placement with family members or friends or in a community-based facility.

Stage 3 is the terminal stage. It usually is relatively short (1 to 2 years) compared with the other stages, but it has been known to last for as long as 10 years.48 The person becomes incontinent, apathetic, and unable to recognize family or friends. It usually is during this stage that the person is institutionalized.

Diagnosis and Treatment

Alzheimer's disease is essentially a diagnosis of exclusion. There are no peripheral biochemical markers or tests for the disease. The diagnosis can be confirmed only by microscopic examination of tissue obtained from a cerebral biopsy or at autopsy. The diagnosis is based on clinical findings. A diagnosis of Alzheimer's disease requires the presence of dementia established by clinical examination, mental status tests, and the absence of systemic or brain disorders that could account for the memory or cognitive deficits.^{48,49} Brain imaging, CT scan, or MRI is done to exclude other brain disease. Metabolic screening should be done for known reversible causes of dementia, such as vitamin B₁₂ deficiency, thyroid dysfunction, and electrolyte imbalance.

There is no curative treatment for Alzheimer's dementia. Drugs are used primarily to slow the progression and to control depression, agitation, or sleep disorders. Two major goals of care are maintaining the person's socialization and providing support for the family. Day care and respite centers are available in many areas to provide relief for caregivers and appropriate stimulation for the patient.

Although there is no current drug therapy that is curative for Alzheimer's disease, some show promise in terms of slowing the progress of the disease. Several drugs have been shown to be effective in slowing the progression of the disease by potentiating the available acetylcholine. The drugs-tacrine, donepezil, rivastigmine, and galantamine-inhibit acetylcholinesterase, preventing the metabolism of endogenous acetylcholine. Thus far, such therapy has not halted disease progression, but it can establish a meaningful plateau in decline.⁵⁰ There also is interest in the use of agents such as antioxidants (e.g., vitamin E, ginkgo) and anti-inflammatory agents to prevent or delay the onset of the disease.

Other Types of Dementia

Vascular Dementia

Dementia associated with cerebrovascular disease does not result directly from atherosclerosis, but rather is caused by multiple infarctions throughout the brain, thus the name vascular or multi-infarct dementia. Approximately 20% to 25% of dementias are vascular in origin, and the incidence is closely associated with hypertension. Other contributing factors are arrhythmias, myocardial infarction, peripheral vascular disease, diabetes mellitus, and smoking. The usual onset is between the ages of 55 and 70 years. The disease differs from Alzheimer's dementia in its presentation and tissue abnormalities. The onset may be gradual or abrupt, the course usually is a stepwise progression, and there should be focal neurologic symptoms related to local areas of infarction.

Pick's Disease

Pick's disease is a rare form of dementia characterized by atrophy of the frontal and temporal areas of the brain. The neurons in the affected areas contain cytoplasmic inclusions called *Pick* bodies. The average age at onset of Pick's disease is 38 years. The disease is more common in women than men. Behavioral manifestations may be noticed earlier than memory deficits, taking the form of a striking absence of concern and care, a loss of initiative, echolalia (i.e., automatic repetition of anything said to the person), hypotonia, and incontinence. The course of the disease is relentless, with death ensuing within 2 to 10 years. The immediate cause of death usually is infection.

Creutzfeldt-lakob Disease

Creutzfeldt-Jakob disease is a rare transmissible form of dementia thought to be caused by an infective protein agent called a prion.⁵¹ Similar diseases occur in animals, including scrapie in sheep and goats, and bovine spongiform encephalitis (BSE; mad cow disease) in cows. The pathogen is resistant to chemical and physical methods commonly used for sterilizing medical and surgical equipment. The disease reportedly has been transmitted through corneal transplants and human growth hormone obtained from cadavers.

Creutzfeldt-Jakob disease causes degeneration of the pyramidal and extrapyramidal systems and is distinguished most readily by its rapid course. Affected persons usually are demented within 6 months of onset. The disease is uniformly fatal, with death often occurring within months, although a few persons may survive for several years.¹ The early symptoms consist of abnormalities in personality and visual-spatial coordination. Extreme dementia, insomnia, and ataxia follow as the disease progresses.51

Wernicke-Korsakoff Syndrome

Wernicke-Korsakoff syndrome results from chronic alcoholism. Wernicke's disease is characterized by acute weakness and paralysis of the extraocular muscles, nystagmus, ataxia, and confusion. The affected person also may have signs of peripheral neuropathy. The person has an unsteady gait and reports diplopia. There may be signs attributable to alcohol withdrawal, such as delirium, confusion, and hallucinations. This disorder is caused by a deficiency of thiamine (vitamin B_1), and many of the symptoms are reversed when nutrition is improved with supplemental thiamine.

The Korsakoff component of the syndrome involves the chronic phase with severe impairment of recent memory. There often is difficulty in dealing with abstractions, and the person's capacity to learn is defective. Confabulation (*i.e.*, recitation of imaginary experiences to fill in gaps in memory) probably is the most distinctive feature of the disease. Polyneuritis also is common. Unlike Wernicke's disease, Korsakoff's psychosis does not improve significantly with treatment.

Huntington's Disease

Huntington's disease is a rare hereditary disorder characterized by chronic progressive chorea, psychological changes, and dementia. The disease is inherited as an autosomal dominant disorder with complete penetrance, meaning that anyone inheriting the gene will eventually experience the disease. The age of onset most commonly is in the fourth and fifth decades, often after affected persons have passed the gene on to their children.¹ Juvenile- or early-onset cases can occur and are more likely to be associated with inheritance from the father than from the mother.

The responsible gene (which encodes a protein called *huntingtin*) has located on chromosome 4.¹ The presence of the mutant huntingtin gene leads to localized death of brain cells. The first and most severely affected neurons are those of the basal ganglia. There is symmetric atrophy of caudate nucleus and lesser involvement of the putamen. There also is atrophy of the frontal cortex. Although the exact mechanisms whereby the mutant gene produces its effects is unclear, it is likely that it causes cell loss by some combination of activation of apoptotic pathways and impairment of normal metabolic processes in susceptible neurons.

Depression and personality changes are the most common early psychological manifestations; memory loss often is accompanied by impulsive behavior, moodiness, antisocial behavior, and a tendency toward emotional outbursts.⁵² Other early signs of the disease are lack of initiative, loss of spontaneity, and inability to concentrate. Fidgeting or restlessness may represent early signs of dyskinesia, followed by choreiform and some dystonic posturing. Eventually, progressive rigidity and akinesia (rather than chorea) develop in association with dementia.

There is no cure for Huntington's disease. The treatment is largely symptomatic. Drugs may be used to treat the dyskinesias and behavioral disturbances. The discovery of a marker probe for the gene locus has enabled testing that can predict whether a person will experience the disease.

In summary, cognitive disorders can be caused by any disorder that permanently damages large cortical or subcortical areas of the hemispheres. The most common cause of dementia is Alzheimer's disease, which is a major health problem among the elderly. It is characterized by cortical atrophy and loss of neurons, the presence of neuritic plaques, granulovacuolar degeneration, and cerebrovascular deposits of amyloid. The disease follows an insidious and progressive course that begins with memory impairment and terminates in an inability to recognize family or friends and the loss of control over bodily functions. Multi-infarct dementia is associated with vascular disease and Pick's disease with atrophy of the frontal and temporal lobes. Creutzfeldt-Jakob disease is a rare transmissible form of dementia. Wernicke-Korsakoff syndrome results from chronic alcoholism. Huntington's disease is a rare hereditary disorder characterized by chronic and progressive chorea, psychological change, and dementia.

Compare cytotoxic and vasogenic cerebral edema in terms of pathophysiology and distribution with brain tissue.

Characterize the role of excitatory amino acids as a common pathway for neurologic disorders.

Compare the brain damage associated with concussion, diffuse axonal injury, contusion, and intracerebral hemorrhage and hematoma.

State the determinants of intracranial pressure and describe compensatory mechanisms used to prevent large changes in intracranial pressure when there are changes in brain, blood, and cerebrospinal fluid volumes.

Compare the causes of communicating and noncommunicating hydrocephalus.

Define consciousness and trace the rostral-to-caudal progression of unconsciousness in terms of arousal and cognition, pupillary changes, muscle tone and motor function, and respiration.

Compare the pathologies of ischemic and hemorrhagic stroke.

Compare the pathology, manifestations, and outcomes associated with meningitis and encephalitis.

List the major categories of brain tumors and interpret the meaning of *benign* and *malignant* as related to brain tumors.

Differentiate between the origin of seizure activity in partial and generalized forms of epilepsy and compare the manifestations of simple partial seizures with those of complex partial seizures and major and minor motor seizures.

ffective motor function requires that muscles move and that the mechanics of their movement be programmed in a manner that provides for smooth and coordinated movement. In some cases, purposeless and disruptive movements can be almost as disabling as relative or complete absence of movement.

THE ORGANIZATION AND CONTROL OF MOTOR FUNCTION

As with other parts of the nervous system, the motor systems are organized in functional hierarchy, with each concerned with levels of function (Fig. 38-1). The highest level of function, which occurs at the level of the frontal cortex, is concerned with the purpose and planning of the movement.¹ The lowest level of the hierarchy occurs at the level of the spinal cord, which contains the basic reflex circuitry needed to coordinate the function of the motor units involved in the planned movement. Several anatomically distinct pathways project in parallel to the spinal cord from the higher motor centers. Above the spinal cord is the brain stem, and above the brain stem is the cerebellum and basal ganglia, structures that modulate the actions of the brain stem systems. Overseeing these supraspinal structures are the motor centers in the cerebral cortex.

The Motor Unit

The major effects of the elaborate processing of movement information that takes place in the brain has to do with contraction of skeletal muscles. The neurons that control skeletal

■ FIGURE 38-1 ■ The motor control system. The final common pathway transmits all central nervous system commands to the skeletal muscles. This path is influenced by sensory input from the muscle spindles and tendon organs (*dashed lines*) and descending signals from the cerebral cortex and brain stem. The cerebellum and basal ganglia influence the motor function indirectly, using brain stem and cortical pathways.

muscle contraction are referred to as *motoneurons* or sometimes as *alpha motoneurons*. A motor unit consists of one motoneuron and the group of muscle fibers it innervates in a skeletal muscle. The motoneurons supplying a motor unit are located in the ventral horn of the spinal cord and are called *lower motoneurons* (LMNs) (Fig. 38-2). The synapse between a LMN and the muscle fibers of a motor unit is called the *neuromuscular junction*. Upper motoneurons (UMNs), which exert control over LMNs, project from the motor strip in the cerebral cortex to the ventral horn of the spinal cord and are fully contained within the central nervous system (CNS).

Axons of the LMNs exit the spinal cord at each segment to innervate skeletal muscle cells, including those of the limbs, back, abdomen, and chest. Each LMN undergoes multiple branching, making it possible for a single LMN to innervate 10 to 2000 muscle cells. In general, large muscles—those containing hundreds or thousands of muscle cells and providing gross motor movement—have large motor units. This sharply contrasts with those that control the hand, tongue, and eye movements, for which the motor units are small and permit very discrete control.

In addition to the output from LMNs that innervate the motor unit, the body uses information from a vast array of sensory input to ensure the generation of correct patterns of muscle activity. Much of this information goes to spinal cord reflexes that control muscle tone and coordinate the movement of the extensor and flexor muscles used in walking and other motor activities.

The Motor Cortex

Delicate, skillful, intentional movement of distal and especially flexor muscles of the limbs and the speech apparatus is initiated and controlled from the motor cortex located in the posterior part of the frontal lobe. It consists of the primary, premotor, and supplementary motor cortex² (Fig. 38-3). These areas receive information from the thalamus and the somesthetic (sensory) cortex and indirectly from the cerebellum and basal ganglia.

KEY CONCEPTS

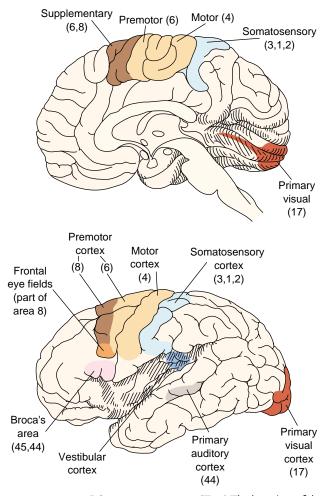

MOTOR SYSTEMS

- Motor systems require upper motoneurons (UMNs) that project from the motor cortex to the brain stem or spinal cord, where they directly or indirectly innervate the lower motoneurons (LMNs) of the contracting muscles; sensory feedback from the involved muscles that is continuously relayed to the cerebellum, basal ganglia, and sensory cortex; and a functioning neuromuscular junction that links nervous system activity with muscle contraction.
- Input from the basal ganglia and cerebellum provides the background for the more crude, supportive movement patterns.
- The efficiency of the movement by the motor system depends on a background of muscle tone provided by the stretch reflex and vestibular system input to maintain stable postural support.

The primary motor cortex (area 4), also called the motor strip, is located on the rostral surface and adjacent portions of the central sulcus. The primary motor cortex controls discrete muscle movement sequences and is the first level of descending control for precise movements. The neurons in the primary motor cortex are arranged in a somatotopic array or distorted map of the body called the *motor homunculus* (Fig. 38-4).³ The body parts that require the greatest dexterity have the largest cortical areas devoted to them. More than one half of the primary motor cortex is concerned with controlling the muscles of the hands, of facial expression, and of speech.²

The premotor cortex (areas 6 and 8), which is located just anterior to the primary motor cortex, sends some fibers into the corticospinal tract but mainly innervates the primary motor strip. A movement pattern to accomplish a particular objective, such as throwing a ball or picking up a fork, is programmed by the prefrontal association cortex and associated thalamic nuclei. The *supplementary motor cortex*, which contains representations of all parts of the body, is located on the medial surface of the hemisphere (areas 6 and 8) in the premotor region. It is intimately involved in the performance of complex, skillful movements that involve both sides of the body.

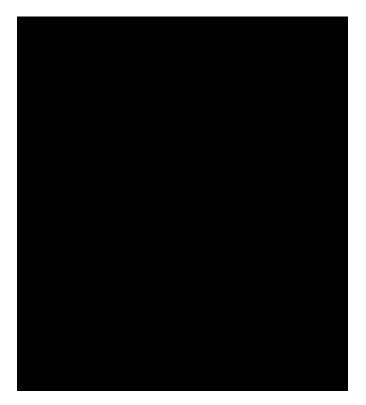

The primary motor cortex contains many layers of pyramidshaped output neurons that project to the same side of the cortex (*i.e.*, premotor and somesthetic areas), project to the opposite side of the cortex, or descend to subcortical structures such as the basal ganglia and thalamus. The large pyramidal cells located in the fifth layer project to the brain stem and spinal cord. The axons of these UMNs project through the subcortical white matter and internal capsule to the deep surface of the brain stem, through the ventral bulge of the pons, and to the ventral surface of the medulla, where they form a ridge or pyramid (see Fig. 38-1). At the junction between the medulla and cervical spinal cord, 80% or more of the UMN axons cross the midline to form the lateral corticospinal tract in the lateral white matter of the spinal cord. This tract extends throughout the spinal

■ FIGURE 38-3 ■ Primary motor cortex. (**Top**) The location of the primary, premotor, and supplementary cortex on the medial surface of the brain. (**Bottom**) The location of the primary and premotor cortex on the lateral surface of the brain. (Courtesy of Carole Russell Hilmer, C.M.I.)

cord, with roughly 50% of the fibers terminating in the cervical segments, 20% in the thoracic segments, and 30% in the lumbosacral segments. Most of the remaining uncrossed fibers travel down the ventral column of the cord, mainly to cervical levels, where they cross and innervate contralateral LMNs.

By convention, motor tracts have been classified as belonging to one of two motor systems: the pyramidal and extrapyramidal systems. According to this classification system, the pyramidal system consists of the motor pathways originating in the motor cortex and terminating in the corticobulbar fibers in the brain stem and the corticospinal fibers in the spinal cord. The corticospinal fibers traverse the ventral surface of the medulla in a bundle called the pyramid before decussating or crossing to the opposite side of the brain at the medulla-spinal cord junction, thus the name pyramidal system. Other fibers from the cortex and basal ganglia also project to the brain stem reticular formation and reticulospinal systems, following a more ancient pathway to LMNs of proximal and extensor muscles. These fibers do not decussate in the pyramids, thus the name extrapyramidal system. Disorders of the pyramidal tracts (e.g., stroke) are characterized by spasticity and paralysis and those affecting

the extrapyramidal tracts (e.g., Parkinson's disease) by involuntary movements, muscle rigidity, and immobility without paralysis. This classification is no longer used extensively. As increased knowledge regarding motor pathways has emerged, it has become evident that the extrapyramidal and pyramidal systems are extensively interconnected and cooperate in the control of movement.1

Spinal Reflexes

Reflexes are coordinated, involuntary motor responses initiated by a stimulus applied to peripheral receptors. Some reflexes, such as the flexion-withdrawal reflex, initiate movements to avoid hazardous situations; whereas others, such as the stretch or crossed-extensor reflex, serve to integrate motor movements so they function in a coordinated manner. The anatomic basis of a reflex consists of (1) an afferent neuron, (2) the connection or synapse with CNS interneurons that communicate with the effector neuron, and (3) the effector neuron that innervates a muscle. Reflexes are essentially "wired into" the CNS so that they are always ready to function; with training, most reflexes can be modulated to become parts of more complicated movements. A reflex may involve neurons in a single cord segment (*i.e.*, segmental reflexes), several or many segments (*i.e.*, intersegmental reflexes), or structures in the brain (i.e., suprasegmental reflexes).

Myotatic or Stretch Reflex

The myotatic ("myo" from the Greek for "muscle," "tatic" from the Greek for "stretch") or stretch reflex controls muscle tone and helps maintain posture. Stretch reflexes can be evoked in many muscles throughout the body and are routinely tested (e.g., knee-jerk reflex) during the clinical examination for the diagnosis of neurologic conditions. Disorders of muscle tone

caused by dysregulated function of the stretch reflex are seen in persons with conditions such as spinal cord injury and stroke.

The myotatic reflex uses specialized afferent sensory endings in skeletal muscles and tendons to relay information regarding the sense of body position, movement, and muscle tone to the CNS. Information from these sensory afferents is relayed to the cerebellum and cerebral cortex and is experienced as the sense of body movement and position (proprio*ception*). To provide this information, the muscles and their tendons are supplied with two types of stretch receptors: muscle spindle receptors and Golgi tendon organs (Fig. 38-5A). The muscle spindles, which are distributed throughout the belly of a muscle, provide information about muscle length and rate of stretch. The Golgi tendon organs are found in muscle tendons and transmit information about muscle tension or force of contraction at the junction of the muscle and the tendon that attaches to bone. A likely role of the tendon organs is to equalize the contractile forces of the separate muscle groups, spreading the load over all the fibers to prevent the local muscle damage that might occur when small numbers of fibers are overloaded.

The muscle spindles consist of a group of specialized miniature skeletal muscle fibers called intrafusal fibers that are encased in a connective tissue capsule and attached to muscle fibers (*i.e.*, extrafusal fibers) of a skeletal muscle (Fig. 38-5A). An afferent sensory neuron, which spirals around the intrafusal fibers, transmits information to the spinal cord. The extrafusal fibers and the intrafusal fibers are innervated by motoneurons that reside in the ventral horns of the spinal cord. Extrafusal fibers are innervated by large alpha motoneurons that produce contraction of the muscle. The intrafusal fibers are innervated by gamma motoneurons that adjust the length of the intrafusal fibers to match that of the extrafusal fibers.

The intrafusal muscle fibers function as stretch receptors. When a skeletal muscle is stretched, the spindle and its intrafusal fibers are stretched, resulting in increased firing of its afferent fibers. The increased firing of the afferent neurons synaptically depolarizes the alpha motoneuron fibers. This causes the extrafusal muscle fibers to contract, thereby shortening the muscle. The knee-jerk reflex that occurs when the knee is tapped with a reflex hammer tests for the intactness of the myotatic reflex arc in the quadriceps muscle (Fig. 38-5B).

Axons of the spindle afferent neurons enter the spinal cord through the several branches of the dorsal root. Some branches end in the segment of entry, and others ascend in the dorsal column of the cord to the medulla of the brain stem. Segmental branches make connections, along with other branches, that pass directly to the anterior gray matter of the spinal cord and establish monosynaptic contact with each of the LMNs that have motor units in the muscle containing the spindle receptor. This produces an opposing muscle contraction. Another segmental branch of the same afferent neuron innervates an internuncial neuron that is inhibitory to motor units of antagonistic muscle groups. Inhibition of these muscle units helps in opposing muscle stretch. Branches of the afferent axon also ascend into the dorsal horn of the adjacent segments, influencing intersegmental reflex function. Ascending fibers from the stretch reflex ultimately provide information about muscle length to the cerebellum and cerebral cortex.

The role of afferent spindle fibers is to inform the CNS of the status of muscle length. When a skeletal muscle lengthens or

■ FIGURE 38-5 ■ (A) Spinal cord innervation of the muscle spindles. Cell bodies from both the alpha motoneuron that innervates the extrafusal muscle fiber and the gamma motoneuron that innervates the intrafusal fiber reside in the ventral horn of the same segment of the spinal cord. (B) The knee-jerk reflex. Stretching of the extrafusal fiber by tapping with a reflex hammer leads to lengthening of the intrafusal fiber and increased firing of the type la afferent fiber. Impulses from the la fiber enter the dorsal horn of the spinal cord and make monosynaptic contact with the ventral horn alpha motoneuron supplying the extrafusal fibers in the quadriceps muscle. The resultant contraction (shortening) of the guadriceps muscle is responsible for the knee-jerk response.

shortens against tension, a feedback mechanism needs to be available for readjustment such that the spindle apparatus remains sensitive to moment-to-moment changes in muscle stretch, even while changes in muscle length are occurring. This is accomplished by the gamma motoneurons that adjust spindle fiber length to match the length of the extrafusal muscle fiber. Descending fibers of motor pathways synapse with and simultaneously activate both alpha and gamma motoneurons so that the sensitivity of the spindle fibers is coordinated with muscle movement.

Central control over the gamma LMN mechanism permits increases or decreases in muscle tone in anticipation of changes in the muscle force required to oppose ongoing conditions, such as when weight is about to be lifted. The CNS, through its coordinated control of the muscle's alpha LMNs and the spindle's gamma LMNs, can suppress the stretch reflex. This occurs during centrally programmed movements, such as pitching a baseball, permitting the muscle to produce its greatest range of motion. Without this programmed adjustability of the stretch reflex, any movement is immediately opposed and prevented.

Crossed-Extensor Reflex

The crossed-extensor reflex, in which the limb on one side of the body extends as the limb on the other side relaxes, provides the basis for postural stability during walking (Fig. 38-6).⁴ For example, when the crossed-extensor reflex produces relaxation of antigravity muscles (with flexion) of one leg as we walk, the contralateral component produces contraction and extension of the opposite leg. Intersegmental connections of the crossed-extensor reflex between the lumbar and cervical spinal segments also accounts for the swinging of the arms that accompanies walking.

Disorders of Muscle Tone and Movement

Disorders of Muscle Tone

In the muscles that are supporting body weight, the stretch reflex operates continuously, producing a continuous resistance to passive stretch called *muscle tone*. Muscle tone is evidenced by the resistance to passive movement around a joint. Disorders of skeletal muscle tone are characteristic of many nervous system pathologies. Any interruption of the myotatic reflex circuit by peripheral nerve injury, pathology of the neuromuscular junction and of skeletal muscle fibers, damage to the corticospinal system, or injury to the spinal cord or spinal nerve root results in disturbance of muscle tone. Muscle tone may be

Chapter 38: Alterations in Neuromuscular Function

701

described as less than normal (hypotonia), absent (flaccidity), or excessive (hypertonia, rigidity, spasticity, or tetany).

Reduced excitability of the stretch reflex results in decreased muscle tone, or *hypotonia*, ranging from postural weakness to total flaccid paralysis. It can result from decreased function of the descending facilitatory systems controlling the gamma LMNs that innervate the muscle or damage to the stretch reflex or peripheral nerves innervating the muscle.

Hypertonia, or spasticity, is an abnormal increase in muscle tone. It can result from increased excitation or loss of inhibition of the spindle's gamma LMNs or changes in the segmental spinal cord circuitry controlling the stretch reflex. It is characterized by hyperactive tendon reflexes and an increase in resistance to rapid muscle stretch. Spasticity commonly occurs with UMN lesions such as those that exist after spinal shock in persons with spinal cord injury.

Rigidity is a greatly increased resistance to movements in all directions. It is caused by increased activation of the alpha LMNs innervating the extrafusal muscle fibers and does not depend on the dorsal root innervation of the intrafusal spindle fibers. It is seen in conditions, such as Parkinson's disease, in which descending CNS inhibition of alpha LMNs is impaired.

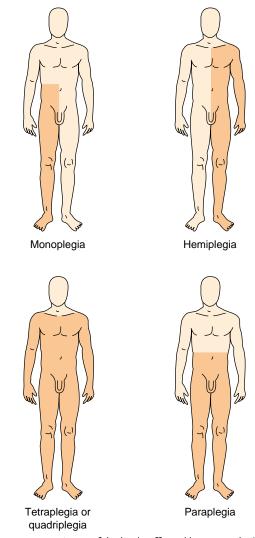

Clonus is the rhythmic contraction and alternate relaxation of a limb that is caused by suddenly stretching a muscle and gently maintaining it in the stretched position. It is seen in the hypertonia of spasticity associated with UMN lesions, such as spinal cord injury. It is caused by an oscillating stimulation of the muscle spindles that occurs when the spindle fibers are activated by an initial muscle stretch. This results in reflex contraction of the muscle and unloading of the spindle fibers with decreased afferent activity. The reduced spindle fiber activity causes the muscle to relax, which causes the spindle fiber to stretch again, and the cycle starts over.

Disorders of Muscle Movement

The suffix *plegia* comes from the Greek word for a blow, a stroke, or paralysis. The terms that are used to describe the extent and anatomic location of motor damage include *paralysis*, meaning loss of movement, and *paresis*, implying weakness or incomplete loss of muscle function. *Monoparesis* or *monoplegia* results from the destruction of pyramidal UMN innervation of one limb; *hemiparesis* or *hemiplegia*, both limbs on one side; *diparesis* or *diplegia* or *paraparesis* or *paraplegia*, both upper or lower limbs; and *tetraparesis* or *tetraplegia*, also called *quadriparesis* or *quadriplegia*, all four limbs⁵ (Fig. 38-7). Paresis or paralysis can be further designated as of UMN or LMN origin.

Upper Motoneuron Lesions. A UMN lesion can involve any part of the CNS: the motor cortex, the internal capsule, or other brain structures through which the corticospinal or corticobulbar tracts descend, or the spinal cord. When the lesion is at or above the level of the pyramids, paralysis affects structures on the opposite side of the body. In UMN disorders involving injury to the L1 level or above, there is an immediate, profound weakness and loss of fine, skilled voluntary lower limb movement, reduced bowel and bladder control, and diminished sexual functioning, followed by an exaggeration of muscle tone. With UMN damage above C7, upper limb movement also is affected (see section on spinal cord injury).

With UMN lesions, the LMN spinal reflexes remain intact, but communication and control from higher brain centers are

■ **FIGURE 38-7** ■ Areas of the body affected by monoplegia, hemiplegia, tetraplegia or quadriplegia, and paraplegia. The *shaded area* shows the extent of motor and sensory loss.

lost. Descending excitatory influences from the pyramidal system and some descending inhibitory influences from other cortical regions are lost after injury, resulting in immediate weakness accompanied by the loss of control of delicate, skilled movements. After several weeks, this weakness becomes converted to hypertonicity or spasticity, which is manifested by an initial increased resistance (stiffness) to the passive movement of a joint at the extremes of range of motion followed by a sudden or gradual release of resistance. The spasticity often is greatest in the flexor muscles of the upper limbs and extensor muscles of the lower limbs. Sometimes, a lesion of the pyramidal tract is less severe and results in a relatively minor degree of weakness. In this case, the finer and more skilled movements are most severely impaired.

Lower Motoneuron Lesions. In contrast to UMN lesions, in which the spinal reflexes remain intact, LMN disorders disrupt communication between the muscle and all neural input from spinal cord reflexes, including the stretch reflex, which maintains muscle tone.

KEY CONCEPTS

SPASTIC VERSUS FLACCID PARALYSIS

- Afferent input from stretch receptors located in muscles and joints is incorporated into spinal cord reflexes that control muscle tone. The activity of the spinal cord reflexes that control muscle tone is constantly monitored and regulated by input from higher brain centers.
- Upper motoneuron lesions that interrupt communication between the spinal cord reflexes and higher brain centers result in unregulated reflex activity, increased muscle tone, and spastic paralysis.
- Lower motoneuron lesions that interrupt communication between the muscle and the spinal cord reflex result in a loss of reflex activity, decreased or absent muscle tone, and flaccid paralysis.

Infection or irritation of the cell body of the LMN or its axon can lead to hyperexcitability, which causes spontaneous contractions of the muscle units. These can be observed as twitching and squirming movements on the muscle surface, a condition called *fasciculations*. Toxic agents, such as the tetanus toxin, produce extreme hyperexcitability of the LMN, which results in continuous firing at maximum rate. The resultant sustained contraction of the muscles is called *tetany*. Tetany of muscles on both sides of a joint produces immobility or tetanic paralysis. When a virus, such as the poliomyelitis virus, attacks an LMN, it first irritates the LMN, causing fasciculations to occur. These fasciculations often are followed by death of LMNs. Weakness and severe muscle wasting or denervation atrophy result. If muscles are totally denervated, total weakness and total loss of reflexes, called *flaccid paralysis*, occurs.

With complete LMN lesions, the muscles of the affected limbs, bowel, bladder, and genital areas become atonic, and it is impossible to elicit contraction by stretching the tendons. One of the outstanding features of LMN lesions is the profound development of muscle atrophy. Damage to an LMN with or without spinal cord damage, often called *peripheral nerve injury*, may occur at any level of the spinal cord. For example, a C7 peripheral nerve injury leads to LMN hand weakness only. All segments below the level of injury that have intact LMNs manifest UMN signs. Usually, injury to the spinal cord at the T12 level or below results in LMN injury and flaccid paralysis to all areas below the level of injury. This occurs because the spinal cord ends at the T12 to L1 level, and from this level, the spinal roots of the LMNs continue caudally in the vertebral canal as part of the cauda equina.

In summary, motor function involves the neuromuscular unit, spinal cord circuitry, brain stem neurons, the cerebellum, the basal ganglia, and the motor cortex. A motor unit consists of one LMN and the group of muscle fibers it innervates in the muscle. Delicate, skillful, intentional movement of distal and especially flexor muscles of the limbs and the speech apparatus is initiated and controlled from the motor cortex located in the posterior frontal lobe. It consists of the primary, premotor, and supplementary motor cortex. These areas receive information from the thalamus and somesthetic cortex and, indirectly, from the cerebellum and basal ganglia. The UMNs in the motor cortex send their axons through the subcortical white matter and internal capsule and the deep surface of the brain stem to the ventral surface to the opposite side of the medulla, where they form a pyramid before crossing the midline to form the lateral corticospinal tract in the spinal cord.

Alterations in musculoskeletal function include muscle tone and movement. Muscle tone is maintained through the combined function of the muscle spindle system and the CNS centers that monitor and buffer UMN innervation of the LMNs. Hypotonia is a condition of less-than-normal muscle tone, and hypertonia or spasticity is a condition of excessive tone. Paresis refers to weakness in muscle function, and paralysis refers to a loss of muscle movement. UMN lesions produce spastic paralysis, and LMN lesions produce flaccid paralysis.

SKELETAL MUSCLE AND PERIPHERAL NERVE DISORDERS

Skeletal Muscle Disorders

Muscle Atrophy

Atrophy describes a decrease in muscle mass. Maintenance of muscle strength requires relatively frequent movements against resistance. When a normally innervated muscle is not used for long periods, the muscle cells shrink in diameter, and although the muscle cells do not die, they lose much of their contractile protein and become weakened. This is called *disuse atrophy*, and it occurs with conditions such as bed rest, application of a cast for fracture healing, and chronic illness.

The most extreme examples of muscle atrophy are found in persons with disorders, such as spinal cord injury, that deprive muscles of their innervation. This form is called *denervation atrophy*. Denervated muscles lose more than half their original bulk within 2 to 3 months.

Muscular Dystrophy

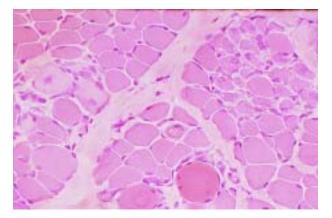

The term dystrophy refers to abnormal growth. *Muscular dystrophy* is a term applied to a number of genetic disorders that produce progressive deterioration of skeletal muscles because of mixed muscle cell hypertrophy, atrophy, and necrosis. They are primary diseases of muscle tissue and probably do not involve the nervous system. As the muscle undergoes necrosis, fat and connective tissue replace the muscle fibers, which increases muscle size and results in muscle weakness. The increase in muscle size resulting from connective tissue infiltration is called *pseudohypertrophy*. The muscle weakness is insidious in onset but continually progressive, varying with the type of disorder.

The most common form of muscular dystrophy is *Duchenne muscular dystrophy*, which has an incidence of approximately 3 cases per 100,000 male children. The disorder is inherited as a recessive single-gene defect on the X chromosome and is transmitted from the mother to her male offspring (see Chapter 4).^{6,7} Despite the X-linked inheritance pattern, about 30% of cases are new mutations and the mother is not the carrier.⁸ Another form of muscular dystrophy, *Becker muscular dystrophy*, is similarly X-linked but manifests later in childhood or adolescence and has a slower course.

The Duchenne muscular dystrophy mutation results in a defective form of a very large protein associated with the muscle cell membrane, called *dystrophin*, which fails to provide the normal attachment site for the contractile proteins. As a result there is necrosis of muscle fibers, a continuous effort at repair and regeneration, and progressive necrosis (Fig. 38-8).⁷

Clinical Course. The postural muscles of the hip and shoulder are affected first in the Duchenne type muscular dystrophy, and the child usually has no problems until approximately 3 years of age, when frequent falling begins to occur. Imbalances between agonist and antagonist muscles lead to abnormal postures and the development of contractures and joint immobility. Scoliosis is common. Wheelchairs usually are needed at approximately 7 to 12 years of age.⁸ The function of the distal muscles usually is preserved well enough that the child can continue to use eating utensils and a computer keyboard. The function of the extraocular nerves also is well preserved, as is the function of the muscles controlling urination and defecation. Incontinence is an uncommon and late event. Respiratory muscle involvement results in weak and ineffective cough, frequent respiratory infections, and decreasing respiratory reserve. Cardiomyopathy caused by involvement of cardiac muscle is a common feature of the disease. However, the severity of cardiac involvement does not necessarily correlate with skeletal muscle weakness. Some patients die at an early age of severe cardiomyopathy, whereas others maintain adequate cardiac function until the terminal stages of the disease. Death from respiratory and cardiac muscle involvement usually occurs in young adulthood.

Observation of the child's voluntary movement and a complete family history provide important diagnostic data for the disease. Serum levels of the enzyme creatine kinase, which

■ FIGURE 38-8 ■ Duchenne muscular dystrophy: hematoxylin and eosin stain. A section of the vastus lateralis muscle shows necrotic muscle fibers, some of them invaded by macrophages. The endomysial septa are thickened, indicating fibrosis. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1422]. Philadelphia: Lippincott Williams & Wilkins)

leaks out of damaged muscle fibers, can be used to confirm the diagnosis. Muscle biopsy, which shows a mixture of muscle cell degeneration and regeneration and reveals fat and scar tissue replacement, is diagnostic of the disorder. Echocardiography, electrocardiography, and chest radiography are used to assess cardiac function. A specific molecular genetic diagnosis is possible by demonstrating the defective dystrophin in muscle biopsy tissue or by DNA analysis from the peripheral blood. The same methods of DNA analysis may be used on blood samples to establish carrier status in female relatives at risk, such as sisters and cousins. Prenatal diagnosis is possible as early as 12 weeks' gestation by sampling chorionic villi for DNA analysis (see Chapter 4).⁸

Management of the disease is directed toward maintaining ambulation and preventing deformities. Passive stretching, correct or counter posturing, and splints help to prevent deformities. Precautions should be taken to avoid respiratory infections. Although there have been exciting advances in identifying the gene and gene product involved in Duchenne muscular dystrophy, there is no known cure.

Neuromuscular Junction Disorders

The neuromuscular junction serves as a synapse between a motor neuron and a skeletal muscle fiber. It consists of the axon terminals of a motor neuron and a specialized region of the muscle membrane called the end-plate. The transmission of impulses at the neuromuscular junction is mediated by the release of the neurotransmitter acetylcholine from the axon terminals. Acetylcholine binds to specific receptors in the end-plate region of the muscle fiber surface to cause muscle contraction (Fig. 38-9). Acetylcholine is active in the neuromuscular junction only for a brief period, during which an action potential is generated in the innervated muscle cell. Some of the transmitter diffuses out of the synapse, and the remaining transmitter is rapidly inactivated by an enzyme called acetylcholinesterase. The rapid inactivation of acetylcholine allows repeated muscle contractions and gradations of contractile force.

A number of drugs and agents can alter neuromuscular function by changing the release, inactivation, or receptor binding of acetylcholine.⁹ Curare acts on the postjunctional membrane of the motor end-plate to prevent the depolarizing effect of the neurotransmitter. Blocking of neuromuscular transmission by curare-type drugs is used during many types of surgical procedures to facilitate relaxation of involved musculature. Drugs such as physostigmine and neostigmine inhibit the action of acetylcholinesterase and allow acetylcholine released from the motoneuron to accumulate. These drugs are used in the treatment of myasthenia gravis.

Toxins from the botulism organism (*Clostridium botulinum*) produce paralysis by blocking acetylcholine release. Spores from the botulism organism may be found in soil-grown foods that are not properly cooked. A pharmacologic preparation of the botulism toxin (botulism toxin type A [Botox]) has become available for use in treating eyelid and eye movement disorders such as blepharospasm and strabismus. It also is used for treatment of spasmodic torticollis, spasmodic dysphonias (laryngeal dystonia), and other dystonias. The drug is injected into the target muscle using the electrical activity recorded from the tip of a special electromyographic injection needle to guide the

■ FIGURE 38-9 ■ Neuromuscular junction. (A) Acetylcholine (ACh) released from the motoneurons in the myoneural junction crosses the synaptic space to reach receptors that are concentrated in the folds of the end-plate of the muscle fiber. Once released, ACh is rapidly broken down by the enzyme acetylcholinesterase (AChesterase). (B) Decrease in ACh receptors in myasthenia gravis.

injection. The treatment is not permanent and usually needs to be repeated approximately every 3 months.

The organophosphates (e.g., malathion, parathion) that are used in some insecticides bind acetylcholinesterase to prevent the breakdown of acetylcholine. They produce excessive and prolonged acetylcholine action with a depolarization block of cholinergic receptors, including those of the neuromuscular junction.9 The organophosphates are well absorbed from the skin, lungs, gut, and conjunctiva of the eye, making them particularly effective as insecticides but also potentially dangerous to humans. Malathion and certain other organophosphates are rapidly metabolized to inactive products in humans and are considered safe for sale to the general public. The sale of other insecticides, such as parathion, which is not effectively metabolized to inactive products, has been banned. Other organophosphate compounds (e.g., soman) were developed as "nerve gases"; if absorbed in high enough concentrations, they have lethal effects from depolarization block and loss of respiratory muscle function.

Myasthenia Gravis

Myasthenia gravis is a disorder of transmission at the neuromuscular junction that affects communication between the motoneuron and the innervated muscle cell. The disease may occur at any age, but the peak incidence occurs between 20 and 30 years of age and affects women more often than men. A smaller second peak occurs in later life and affects men more often than women.

Now recognized as an autoimmune disease, the disorder is caused by antibody-mediated loss of acetylcholine receptors in the neuromuscular junction (Fig. 38–9).^{6,10} Although the exact mechanism that triggers the autoimmune response is unclear, it is thought to be related to abnormal T-lymphocyte function. Approximately two thirds of persons with myasthenia gravis also have thymic abnormalities, such as a thymoma (*i.e.*, thymus tumor) or thymic hyperplasia.^{6,10}

In persons with myasthenia gravis who have fewer acetylcholine receptors in the postsynaptic membrane, each release of acetylcholine from the presynaptic membrane results in a lower-amplitude end-plate potential. This results in both muscle weakness and fatigability with sustained effort. Most commonly affected are the eye and preorbital muscles. Either ptosis caused by eyelid weakness or diplopia caused by weakness of the extraocular muscles is an initial symptom in approximately 50% of persons with the disease. The disease may progress from ocular muscle weakness to generalized weakness, including respiratory muscle weakness. Chewing and swallowing may be difficult, and persons with the disease often choose to eat soft foods and cereals, rather than meats and hard fruit. Weakness in limb movement usually is more pronounced in proximal than in distal parts of the extremity, so climbing stairs and lifting objects are difficult. As the disease progresses, the muscles of the lower face are affected, causing speech impairment. When this happens, the person often supports the chin with one hand to assist in speaking. In most persons, symptoms are least evident when arising in the morning, but they grow worse with effort and as the day proceeds.

Persons with myasthenia gravis may experience a sudden exacerbation of symptoms and weakness known as *myasthenia crisis*.¹¹ Myasthenia crisis occurs when muscle weakness becomes severe enough to compromise ventilation to the extent that ventilatory support and airway protection are needed. This usually occurs during a period of stress, such as infection, emotional upset, pregnancy, alcohol ingestion, cold, or after surgery. It also can result from inadequate or excessive doses of the anticholinesterase drugs used in treatment of the disorder.

Diagnosis and Treatment. The diagnosis of myasthenia gravis is based on history and physical examination, the anticholinesterase test, nerve stimulation studies, and an assay for acetylcholine receptor antibodies. The anticholinesterase test uses a drug that inhibits acetylcholinesterase, the enzyme that breaks down acetylcholine. When weakness is caused by myasthenia gravis, a dramatic transitory improvement in muscle function occurs when the drug used for the test is administered. Electrophysiologic studies can be done to demonstrate a muscle response to repetitive stimulation of motor nerves. An immunoassay test can be used to detect the presence of acetylcholine receptor antibodies circulating in the blood.

Treatment methods include the use of pharmacologic agents; immunosuppressive therapy, including corticosteroid drugs; management of myasthenic crisis; thymectomy; and plasmapheresis or intravenous immunoglobulin.¹⁰ Pharmacologic treatment with reversible anticholinesterase drugs inhibits the

Chapter 38: Alterations in Neuromuscular Function

breakdown of acetylcholine at the neuromuscular junction by acetylcholinesterase. Corticosteroid drugs, which suppress the immune response, are used in cases of a poor response to anticholinesterase drugs and thymectomy. Immunosuppressant drugs (*e.g.*, azathioprine, cyclosporine) also may be used, often in combination with plasmapheresis.

Plasmapheresis removes antibodies from the circulation and provides short-term clinical improvement. It is used primarily to stabilize the condition of persons in myasthenic crisis or for short-term treatment in persons undergoing thymectomy. Intravenous immunoglobulin also produces improvement in persons with myasthenia gravis. Although the effect is temporary, it may last for weeks to months. The indications for its use are similar to those for plasmapheresis.

Thymectomy, or surgical removal of the thymus, may be used as a treatment for myasthenia gravis. Because the mechanism whereby surgery exerts its effect is unknown, the treatment is a matter of controversy. Thymectomy is performed in persons with thymoma, regardless of age, and in persons 50 to 60 years of age or older with recent onset of moderate disease.

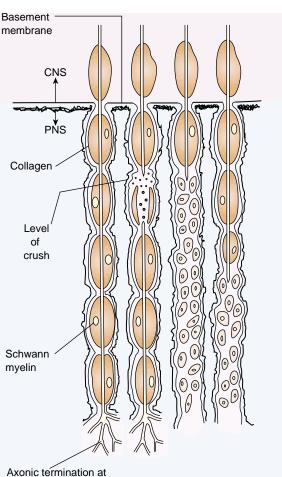

Peripheral Nerve Disorders

The peripheral nervous system consists of the motor and sensory branches of the cranial and spinal nerves, the peripheral parts of the autonomic nervous system (ANS), and peripheral ganglia. Unlike the nerves of the CNS, peripheral nerves are fairly strong and resilient. They contain a series of connective tissue sheaths that enclose their nerve fibers. An outer fibrous sheath called the *epineurium* surrounds the medium to large nerves; inside, a sheath called the *perineurium* invests each bundle of nerve fibers, and within each bundle, a delicate sheath of connective tissue known as the *endoneurium* surrounds each nerve fiber (see Chapter 36, Fig. 36-3). Small peripheral nerves lack the epineurial covering. In its endoneurial sheath, each nerve fiber is invested by a segmented sheath of Schwann cells. The Schwann cells produce the myelin sheath that surrounds the peripheral nerves.

Peripheral Nerve Injury and Repair

Neurons exemplify the general principle that the more specialized the function of a cell type, the less able it is to regenerate. Although the entire neuron cannot be replaced, it often is possible for the dendritic and axonal cell processes to regenerate as long as the cell body remains viable.

When a peripheral nerve is destroyed by a crushing force or by a cut that penetrates the nerve, the portion of the nerve fiber that is separated from the cell body rapidly undergoes degenerative changes, whereas the central stump and cell body of the nerve often are able to survive. Because the cell body synthesizes the material required for nourishing and maintaining the axon, it is likely that the loss of these materials results in the degeneration of the separated portion of the nerve fibers. In crushing injuries in which the endoneurial tube remains intact, the outgrowing fiber will grow back down this tube to the structure that was originally innervated by the neuron (Fig. 38-10). However, it can take weeks or months for the regrowing fiber to reach its target organ and for communicative function to be re-established. More time is required for the Schwann cells to form new myelin segments and for the axon to recover its original diameter and conduction velocity. However, if the injury involves the severing of a nerve, the outgrowing branch must

neuromuscular junction

come in contact with its original endoneurial tube if it is to be reunited with its original target structure.

The successful regeneration of a nerve fiber in the peripheral nervous system depends on many factors. If a nerve fiber is destroyed relatively close to the neuronal cell body, the chances are that the nerve cell will die, and if it does, it will not be replaced. The degree of axonal regeneration that occurs after injury to a peripheral nerve also depends on the amount of scar tissue that develops at the site of injury and how quickly reinnervation occurs. If reinnervation occurs after the muscle cells have degenerated, no recovery is possible.

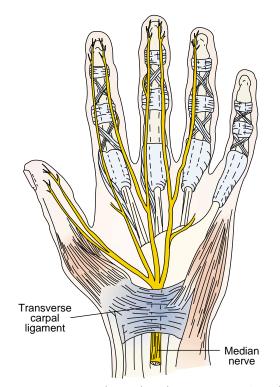

Perhaps the most difficult problem in the treatment of peripheral nerve injuries is the alignment of the proximal and distal endoneurial tubes so that a regenerating fiber can return down its former tube and innervate its former organ. Microscopic alignment of the cut edges during microsurgical repair results in improved success.

Peripheral Neuropathies

A peripheral neuropathy is any primary disorder of the peripheral nerves. The result usually is muscle weakness caused by LMN damage, with or without atrophy and sensory changes. The disorder can involve a single nerve (mononeuropathy) or multiple nerves (polyneuropathy). **Mononeuropathies.** Mononeuropathies usually are caused by localized conditions such as trauma, compression, or infections that affect a single spinal nerve, plexus, or peripheral nerve trunk. Fractured bones may lacerate or compress nerves; excessively tight tourniquets may injure nerves directly or produce ischemic injury; and infections such as herpes zoster may affect a single segmental afferent nerve distribution.

Carpal Tunnel Syndrome. Carpal tunnel syndrome is an example of a compression-type mononeuropathy that is relatively common. It is caused by compression of the median nerve as it travels with the flexor tendons through a canal made by the carpal bones and transverse carpal ligament (Fig. 38-11). The condition can be caused by a variety of conditions that produce a reduction in the capacity of the carpal tunnel (*i.e.*, bony or ligament changes) or an increase in the volume of the tunnel contents (i.e., inflammation of the tendons, synovial swelling, or tumors).¹² Carpal tunnel syndrome can be a feature of many systemic diseases such as rheumatoid arthritis, hyperthyroidism, acromegaly, and diabetes mellitus.¹² The condition can result from wrist injury; it can occur during pregnancy and use of birth control drugs; and it is seen in persons with repetitive use of the wrist (i.e., flexion-extension movements and stress associated with pinching and gripping motions).

Carpal tunnel syndrome is characterized by pain, paresthesia, and numbness of the thumb and first two and one-half digits of the hand; pain in the wrist and hand, which worsens at night; atrophy of abductor pollicis muscle; and weakness in precision grip. All of these abnormalities may contribute to clumsiness of fine motor activity.

■ FIGURE 38-11 ■ Carpal tunnel syndrome: compression of the median nerve by the transverse carpal ligament. (Courtesy Carole Russell Hilmer, C.M.I.)

Diagnosis usually is based on sensory disturbances confined to median nerve distribution. Electromyography and nerve conduction studies often are done to confirm the diagnosis and exclude other causes of the disorder.

Treatment includes avoidance of use, splinting, and antiinflammatory medications. Measures to decrease the causative repetitive movements should be initiated. Splints may be confined to nighttime use. When splinting is ineffective, corticosteroids may be injected into the carpal tunnel to reduce inflammation and swelling. Surgical intervention consists of operative division of the volar carpal ligaments as a means of relieving pressure on the medial nerve.

Polyneuropathies. Polyneuropathies involve demyelination or axonal degeneration of multiple peripheral nerves that leads to symmetric sensory, motor, or mixed sensorimotor deficits. Typically, the longest axons are involved first, with symptoms beginning in the distal part of the extremities. If the autonomic nervous system is involved, there may be postural hypotension, constipation, and impotence. Polyneuropathies can result from immune mechanisms (*e.g.*, Guillain-Barré syndrome), toxic agents (*e.g.*, arsenic polyneuropathy, lead polyneuropathy, alcoholic polyneuropathy), and metabolic diseases (*e.g.*, diabetes mellitus, uremia). Different causes tend to affect axons of different diameters and to affect sensory, motor, or autonomic neurons to different degrees.

Guillain-Barré Syndrome. Guillain-Barré syndrome is an acute inflammatory polyneuropathy. The annual incidence of Guillain-Barré syndrome is approximately 1 case per 50,000 persons, and it is more common with increasing age.¹³ Approximately 80% to 90% of persons with the disease achieve a spontaneous recovery.

The disorder involves an infiltration of mononuclear cells around the capillaries of the peripheral neurons, edema of the endoneurial compartment, and demyelination of ventral spinal roots. The cause of Guillain-Barré syndrome is unknown. Approximately two thirds of cases follow an infection that is seemingly mundane and often of viral origin.⁶ There is an association with preceding gastrointestinal tract infection with *Campylobacter jejuni*.¹⁴ A widely studied outbreak of the disorder followed the swine flu vaccination program of 1976 and 1977.¹⁵ It has been suggested that an altered immune response to peripheral nerve antigens contributes to the development of the disorder.

The disorder is characterized by progressive ascending muscle weakness of the limbs, producing a symmetric flaccid paralysis. Symptoms of paresthesia and numbness often accompany the loss of motor function. The rate of disease progression varies, and there may be disproportionate involvement of the upper or lower extremities. Paralysis may progress to involve the respiratory muscles; approximately 20% of persons with the disorder require ventilatory assistance.¹³ ANS involvement that causes postural hypotension, arrhythmias, facial flushing, abnormalities of sweating, and urinary retention is common.

Guillain-Barré syndrome usually presents as a medical emergency. There may be a rapid development of ventilatory failure and autonomic disturbances that threaten circulatory function. Treatment includes support of vital functions and prevention of complications such as skin breakdown and thrombophlebitis. Clinical trials have shown the effectiveness of plasma-

Chapter 38: Alterations in Neuromuscular Function

pheresis in decreasing morbidity and shortening the course of the disease. Treatment is most effective if initiated early in the course of the disease.

Back Pain and Intervertebral Disk Injury

Back Pain

Low back pain is an exceeding common health problem. The differential diagnosis is broad and includes muscle strain, primary spine disease (*e.g.*, disk herniation, degenerative arthritis [discussed in Chapter 43]), and systemic disease (*e.g.*, metastatic cancer). Although acute back problems commonly are attributed to a herniated intervertebral disk, most are caused by other, less serious conditions, such as muscle strain. It has been reported that 90% of persons with acute lower back problems of less than 3 months' duration experience spontaneous recovery.¹⁶ The diagnostic challenge is to identify those persons who require more extensive evaluation for more serious problems, including disk herniation.¹⁶

Treatment of back pain usually is conservative and consists of analgesic medications and education on how to protect the back. Pain relief usually can be provided using nonsteroidal anti-inflammatory drugs, although short-term use of opioid pain medications may be required for severe pain. Muscle relaxants may be used on a short-term basis. Bed rest, once the mainstay of conservative therapy, is now understood to be ineffective for acute back pain.¹⁷ Instruction in the correct mechanics for lifting and methods of protecting the back is important. Conditioning exercises of the trunk muscles, particularly the back extensors, may be recommended for persons with acute low back problems, particularly if the problem persists. Surgical treatment may be indicated when herniation is documented by some imaging procedure or in the presence of consistent pain or consistent neurologic deficit that has failed to respond to conservative therapy.

Herniated Intervertebral Disk

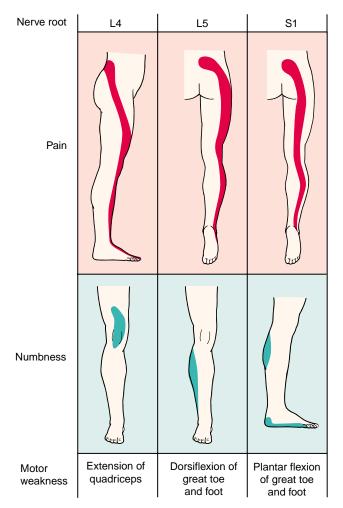

The intervertebral disk is considered the most critical component of the load-bearing structures of the spinal column. The intervertebral disk consists of a soft, gelatinous center called the *nucleus pulposus*, which is encircled by a strong, ringlike collar of fibrocartilage called the *annulus fibrosus*. The structural components of the disk make it capable of absorbing shock and changing shape while allowing movement. With dysfunction, the nucleus pulposus can be squeezed out of place and herniate through the annulus fibrosus, a condition referred to as a *herniated* or *slipped disk* (Fig. 38-12A and B).

The intervertebral disk can become dysfunctional because of trauma, the effects of aging, or degenerative disorders of the spine. Trauma accounts for 50% of disk herniations. It results from activities such as lifting while in the flexed position, slipping, falling on the buttocks or back, or suppressing a sneeze. With aging, the gelatinous center of the disk dries out and loses much of its elasticity, causing it to fray and tear. Degenerative processes such as osteoarthritis or ankylosing spondylitis predispose to malalignment of the vertebral column.

The cervical and lumbar regions are the most flexible area of the spine and are most often involved in disk herniations. Usually, herniation occurs at the lower levels of the lumbar spine, where the mass being supported and the bending of the vertebral column are greatest. Approximately 90% to 95% of lumbar herniations occur in the L4 or L5 to S1 regions. With herniations of the cervical spine, the most frequently involved levels are C6 to C7 and C5 to C6.⁵ Protrusion of the nucleus pulposus usually occurs posteriorly and toward the intervertebral foramen and its contained spinal nerve root, where the anulus fibrosus is relatively thin and poorly supported by either the posterior or anterior ligaments¹⁸ (see Fig. 38-12A).

The level at which a herniated disk occurs is important (Fig. 38-12C). When the injury occurs in the lumbar area, only the cauda equina is irritated or crushed. Because these elongated dorsal and ventral roots contain endoneurial tubes of connective tissue, regeneration of the nerve fibers is likely. However, several weeks or months are required for full recovery to occur because of the distance to the innervated muscle or skin of the lower limbs.

The signs and symptoms of a herniated disk are localized to the area of the body innervated by the nerve roots and include both motor and sensory manifestations (Fig. 38-13). Pain is the

■ FIGURE 38-13 ■ Dermatomes of the leg (L1 through S5) where pain and numbness would be experienced with spinal root irritation.

first and most common symptom of a herniated disk. The nerve roots of L4, L5, S1, S2, and S3 give rise to a syndrome of back pain that spreads down the back of the leg and over the sole of the foot. The pain is usually intensified with coughing, sneezing, straining, stooping, standing, and the jarring motions that occur during walking or riding. Slight motor weakness may occur, although major weakness is rare. The most common sensory deficits from spinal nerve root compression are paresthesias and numbness, particularly of the leg and foot. Knee and ankle reflexes also may be diminished or absent.

A herniated disk must be differentiated from other causes such as traumatic injury or fracture of the vertebral column, tumor, infection, cauda equina syndrome (see spinal cord injury), or other conditions that cause back pain.¹⁶ Diagnostic measures include history and physical examination. Neurologic assessment includes testing of muscle strength and reflexes. Other diagnostic methods include radiographs of the back, magnetic resonance imaging (MRI), myelography, and computed tomography (CT).¹⁹ Myelography, MRI, and CT usually are reserved for persons suspected of having more complex causes of back pain.

In summary, disorders of motor function include disorders of the skeletal muscle, the neuromuscular junction, and the peripheral nerves. *Muscular dystrophy* is a term used to describe a number of disorders that produce progressive deterioration of skeletal muscle. Muscle necrosis is followed by fat and connective tissue replacement. One form, Duchenne muscular dystrophy, is inherited as a X-linked trait and transmitted by the mother to her male offspring.

Myasthenia gravis is a disorder of the neuromuscular junction resulting from a deficiency of functional acetylcholine receptors, which causes weakness of the skeletal muscles. Because the disease affects the neuromuscular junction, there is no loss of sensory function. The most common manifestations are weakness of the eye muscles, with ptosis and diplopia; the jaw muscles, which make chewing and swallowing difficult; and proximal muscles and extremities, which make climbing stairs and lifting objects difficult.

Disorders of peripheral nerves include mononeuropathies and polyneuropathies. Mononeuropathies involve a single spinal nerve, plexus, or peripheral nerve trunk. Carpal tunnel syndrome, a mononeuropathy, is caused by compression of the medial nerve that passes through the carpal tunnel in the wrist. Polyneuropathies involve multiple peripheral nerves and produce symmetric sensory, motor, and mixed sensorimotor deficits. Guillain-Barré syndrome is a subacute polyneuropathy of uncertain origin. It causes progressive ascending motor, sensory, and ANS manifestations. Respiratory involvement may occur and necessitate mechanical ventilation.

Acute back pain is most commonly the result of conditions such as muscle strain, with treatment that focuses on measures to improve activity tolerance. A herniated intervertebral disk is characterized by protrusion of the nucleus pulposus into the spinal canal with irritation or compression of the nerve root. Usually, herniation occurs at the lower levels of the lumbar and sacral (L4 or L5 to S1) and cervical (C6 to C7 and C5 to C6) regions of the spine. The signs and symptoms of a herniated disk are localized to the area of the body innervated by the nerve roots and include pain and both motor and sensory manifestations.

BASAL GANGLIA AND CEREBELLUM DISORDERS

The Basal Ganglia

The basal ganglia are a group of deep, interrelated subcortical nuclei that play an essential role in control of movement. They receive indirect input from the cerebellum and from all sensory ganglia systems, including vision, and the motor cortex. The structural components of the basal ganglia include the caudate nucleus, putamen, and the globus pallidus in the forebrain. The caudate and putamen are collectively referred to as the neostriatum, and the putamen and the globus pallidus form a wedge-shaped region called the lentiform nucleus. Two other structures, the subthalamic nucleus of the diencephalon and the substantia nigra of the midbrain, are considered part of the basal ganglia (Fig. 38-14). The substantia nigra contains cells that use dopamine as a neurotransmitter and are rich in a black pigment called *melanin*. The high concentration of melanin gives the structure a black color, thus the name substantia nigra. The axons of the substantia nigra form the *nigrostriatal pathway*, which supplies dopamine to the striatum. The dopamine released from the substantia nigra regulates the overall excitability of the striatum and release of other neurotransmitters.

The basal ganglia have input structures that receive afferent information from outside structures, internal circuits that connect the various structures of the basal ganglia, and output structures that deliver information to other brain centers. The neostriatum represents the major input structure for the basal ganglia. Information coming from virtually all areas of the cortex and thalamus are projected to the neostriatum. The output areas of the basal ganglia have both ascending and descending components. The major ascending output is transmitted to thalamic nuclei, which process all incoming sensory information that is transmitted to the cerebral cortex. Descending output is directed to the midbrain, brain stem, and spinal cord. The output functions of the basal ganglia are mainly inhibitory.

The most is known about the inhibitory basal ganglia loop involved in modulating cortical motor control. This loop regulates release of stereotyped movement patterns that add efficiency and gracefulness to precise and delicate cortically

controlled movements. These movements include inherited patterns that add efficiency, balance, and gracefulness to motion, such as the swinging of the arms during walking and running, and the highly learned automatic postural and followthrough movements of throwing a ball or swinging a bat.

Chapter 38: Alterations in Neuromuscular Function

An additional modulating circuit involves a neostriatal inhibitory projection on the substantia nigra. The substantia nigra projects dopaminergic axons back on the neostriatum. A deficiency in the dopaminergic projection of this modulating circuit is implicated in Parkinson's syndrome. The function of the neostriatum also involves local cholinergic interneurons, and their destruction is thought to be related to the choreiform movements of Huntington's chorea, another basal gangliarelated syndrome (see Chapter 37).

Movement Disorders

Disorders of the basal ganglia comprise a complex group of motor disturbances characterized by involuntary movements, alterations in muscle tone, and disturbances in body posture. Unlike disorders of the motor cortex and corticospinal tract, lesions of the basal ganglia disrupt movement but do not cause paralysis.

Movement disorders associated with dysfunction of the basal ganglia include bradykinesis, hyperkinesis, and abnormal movements. Hyperfunction of the basal ganglia inhibitory loop result in excessive inhibition of cortical function, resulting in *bradykinesia* or *hypokinesis*. Reduced function of the basal ganglia loop results in *hyperkinesis*, or release of movement patterns at inappropriate times or sometimes continuously. Pathologically released patterns that often are disabling include rigidity and movement disorders. These movement patterns are not under cortical control and often are referred to as *involuntary movements*.

Involuntary movements include tremor, tics, choreiform movements, athetoid movements, and ballismus. These disorders are summarized in Table 38-1. Tremor is caused by involuntary, oscillating contractions of opposing muscle groups around a joint. It usually is fairly uniform in frequency and amplitude. Certain tremors are considered physiologic in that they are transitory and normally occur under conditions of increased muscle tone, as in highly emotional situations, or they may be related to muscle fatigue or reduced body temperature (*i.e.*, shivering). Toxic tremors are produced by hyperexcitability related to conditions such as thyrotoxicosis. The tremor of Parkinson's disease is caused by degenerative changes in the basal ganglia. Tics involve sudden and irregularly occurring contractions of whole muscles or major portions of a muscle. These are particularly evident in the muscles of the face but can occur elsewhere.

Choreiform movements are sudden, jerky, and irregular but are coordinated and graceful. They can involve the distal limb, face, tongue, or swallowing muscles. Choreiform movements, such as those seen in Huntington's disease (see Chapter 40), are accentuated by movement and by environmental stimulation; they often interfere with normal movement patterns. The word *chorea* originated from the Greek word meaning "to dance." There may be grimacing movements of the face; raising of the eyebrows; rolling of the eyes; and curling, protrusion, and withdrawal of the tongue. In the limbs, the movements largely are distal; there may movements that mimic piano playing with alternating extension and flexion of the fingers. The shoulders may be elevated and depressed or rotated. Movements

TABLE 38-1 Involuntary Movements Disorders Associated With Extrapyramidal Disorders

Movement Disorder Characteristics

Tremor	Rhythmic oscillating contractions or movements of whole muscles or major portions of a muscle. They can occur as resting tremors, which are prominent at rest and decrease or disappear with movement; intention tremors, which increase with activity and become worse when the target is reached; and postural tremors, which appear when the affected part is maintained in a stabilized position.
Tics	Irregularly occurring brief, repetitive, stereotyped, coordinated movements such as winking, grimacing, or shoulder shrugging
Chorea	Brief, rapid, jerky, and irregular movements that are coordinated and graceful. The face, head, and distal limbs are most commonly involved. They often interfere with normal movement patterns.
Athetosis	Continuous, slow, wormlike, twisting and turning motions of a limb or body that most commonly involve the face and distal extremities and are often associated with spasticity
Ballismus	Involve violent sweeping, flinging-type limb movements, especially on one side of the body (hemiballismus)
Dystonia	Abnormal maintenance of posture results from a twisting, turning motion of the limbs, neck, or trunk. Motions are similar to athetosis but involve larger portions of the body. They can result in grotesque and twisted postures.
Dyskinesias	Rhythmic, repetitive, bizarre movements that chiefly involve the face, mouth, jaw, or tongue, causing grimac- ing, pursing of the lips, protrusion of the tongue, opening and closing of the mouth, and deviations of the jaw. The limbs are affected less often.

(From Bates B. [1991]. A guide to physical examination and history taking [5th ed., pp. 554–556]. Philadelphia: J.B. Lippincott)

of the face or limbs may occur alone or, more commonly, in combination.

Athetoid movements are relatively continuous, wormlike twisting and turning motions of the joints of a limb or body, such as those seen in one form of cerebral palsy. These result from continuous and prolonged contraction of agonist and antagonistic muscle groups. The term *ballismus* originated from a Greek word meaning "to jump around." Ballistic movements are violent, sweeping, flinging motions, especially of the limbs on one side of the body (hemiballismus). They may occur as the result of a small stroke involving the subthalamic nucleus on the opposite side of the brain.

Dystonia refers to the abnormal maintenance of a posture resulting from a twisting, turning movement of the limbs, neck, or trunk. These postures often result from simultaneous contraction of agonist and antagonist muscles. Long-sustained simultaneous hypertonia across a joint can result in degenerative changes and permanent fixation in unusual postures. These effects can occur as a side effect of some antipsychotic medications. Spasmodic torticollis, the most common type of dystonia, affects the muscles of the neck and shoulder. The condition, which is caused by bilateral and simultaneous contraction of the neck and shoulder muscles, results in unilateral head turning or head extension, sometimes limiting rotation. Elevations of the shoulder commonly accompany the spasmodic movements of the head and neck. Immobility of the cervical vertebrae eventually can lead to degenerative fixation in the twisted posture. Torsional spasm involving the trunk also can occur.

Dyskinesias are rhythmic, repetitive, bizarre movements. They frequently involve the face, mouth, jaw, and tongue, causing grimacing, pursing of the lips, or protrusion of the tongue. The limbs are affected less often. Tardive dyskinesia is an untoward reaction that can develop with long-term use of some of the antipsychotic medications.

Parkinson's Disease

Parkinson's disease is a degenerative disorder of basal ganglia function that results in variable combinations of tremor, rigidity, and bradykinesia. The disorder is characterized by progressive destruction of the nigrostriatal pathway, with subsequent reduction in striatal concentrations of dopamine. As many as 1.5 million people in the United States are affected by the disease.²⁰ It usually begins after 50 years of age; most cases are diagnosed in the sixth and seventh decade of life.

The clinical syndrome arising from the degenerative changes in basal ganglia function often is referred to as parkinsonism. Parkinson's disease, the most common form of parkinsonism, is named after James Parkinson, a British physician who first described the disease in a paper he published in 1817 on the "shaking palsy."²¹ In Parkinson's disease, also known as idiopathic parkinsonism, dopamine depletion results from degeneration of the dopamine nigrostriatal system. Parkinsonism can also develop as a postencephalitic syndrome, as a side effect of therapy with antipsychotic drugs that block dopamine receptors, as a toxic reaction to a chemical agent, or as an outcome of severe carbon monoxide poisoning. Symptoms of parkinsonism also may accompany conditions such as cerebral vascular disease, brain tumors, repeated head trauma, or degenerative neurologic diseases that structurally damage the nigrostriatal pathway.

Drug-induced parkinsonism can follow the administration of antipsychotic drugs in high doses (*e.g.*, phenothiazines, butyrophenones). These drugs block dopamine receptors and dopamine output by the cells of the substantia nigra. Of interest in terms of research was the development of Parkinson's disease in several persons who had attempted to make a narcotic drug and instead synthesized a compound called MPTP (1-methyl-phenyl-2,3,6-tetrahydropyridine).²² This compound selectively destroys the dopaminergic neurons of the substantia nigra. This incident prompted investigations into the role of toxins that are produced by the body as a part of metabolic processes and those that enter the body from outside sources in the pathogenesis of Parkinson's disease. One theory is that the auto-oxidation of catecholamines such as dopamine during melanin synthesis has the potential for injuring neurons in the substantia nigra. Accordingly, the development of Parkinson's disease may be related to oxidative metabolites of this process and the inability of neurons to render these products harmless. MPTP is an inhibitor of the metabolic pathway that functions in the inactivation of these metabolites, suggesting that it may produce Parkinson's disease in a manner similar to the naturally occurring disease.⁶

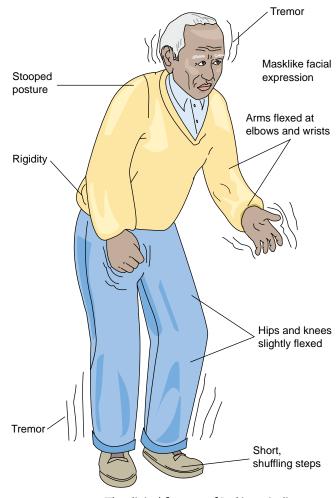

A recent discovery suggests that genetic susceptibility may play a role in the pathogenesis of early-onset (before 45 years of age) Parkinson's disease. A mutation in a gene called the *Parkin gene* has been identified in a high percentage of family members and persons with early-onset Parkinson's disease.²³

Clinical Course. The cardinal manifestations of Parkinson's disease are tremor, rigidity, and bradykinesia or slowness of movement.²⁴ Other advanced-stage parkinsonian manifestations are falls, fluctuations in motor function, neuropsychiatric disorders, and sleep disorders.

Tremor is the most visible manifestation of the disorder. The tremor affects the distal segments of the limbs, mainly the hands and feet; head, neck, face, lips, and tongue; or jaw. It is characterized by rhythmic, alternating flexion and contraction movements (four to six beats per minute) that resemble the motion of rolling a pill between the thumb and forefinger. The tremor usually is unilateral, occurs when the limb is supported and at rest, and disappears with movement and sleep. The tremor eventually progresses to involve both sides of the body. Although the most noticeable sign of Parkinson's disease, tremor usually is the least disabling because of the dampening effect of purposeful movement.

Rigidity is defined as resistance to movement of both flexors and extensors throughout the full range of motion. It is most evident during passive joint movement and involves jerky, cogwheel-type or ratchet-like movements that require considerable energy to perform. Flexion contractions may develop as a result of the rigidity. As with tremor, rigidity usually begins unilaterally but progresses to involve both sides of the body.

Bradykinesia is characterized by slowness in initiating and performing movements and difficulty in sudden, unexpected stopping of voluntary movements. Unconscious associative movements occur in a series of disconnected steps, rather than in a smooth, coordinated manner. This is the most disabling of the symptoms of Parkinson's disease. Persons with Parkinson's disease have difficulty initiating walking and difficulty turning. While walking, they may freeze in place and feel as if their feet are glued to the floor, especially when moving through a doorway or preparing to turn. When they walk, they lean forward to maintain their center of gravity and take small, shuffling steps without swinging their arms, and they have difficulty in changing their stride (Fig. 38-15). Loss of postural reflexes predisposes them to falling, often backward. Emotional and voluntary facial movements become limited and slow as the disease progresses, and facial expression becomes stiff and masklike. There is loss of the blinking reflex and a failure to express emotion. The tongue, palate, and throat muscles become

■ FIGURE 38-15 ■ The clinical features of Parkinson's disease.

rigid; the person may drool because of difficulty in moving the saliva to the back of the mouth and swallowing it. The speech becomes slow and monotonous, without modulation and poorly articulated.

Because the basal ganglia also influence the ANS, persons with Parkinson's disease often have excessive and uncontrolled sweating, sebaceous gland secretion, and salivation. Autonomic symptoms such as lacrimation, dysphagia, orthostatic hypotension, thermal regulation, constipation, impotence, and urinary incontinence may be present, especially late in the disease.

Dementia is an important feature associated with Parkinson's disease. It occurs in approximately 20% of persons with the disease and develops late in the course of the disease.²⁴ The mental state of some persons with Parkinson's disease may be indistinguishable from that seen in Alzheimer's disease. It has been suggested that many of the brain changes in both diseases may result from degeneration of acetylcholine-containing neurons.

Treatment. The approach to treatment of Parkinson's disease must be highly individualized. It includes nonpharmacologic, pharmacologic, and when indicated, surgical methods. Non-pharmacologic interventions offer group support, education,

daily exercise, and adequate nutrition. Botulism toxin injections may be used in the treatment of dystonias such as eyelid spasm and limb dystonias that frequently are associated with Parkinson's disease.²⁵

Pharmacologic treatment usually is determined by the severity of symptoms. Antiparkinson drugs act by increasing the functional ability of the underactive dopaminergic system, or they reduce the excessive influence of excitatory cholinergic neurons. They include drugs that increase dopamine levels (*e.g.*, levodopa), augment the release of dopamine (*e.g.*, amantadine), function as dopamine agonists or directly stimulate dopamine receptors (*e.g.*, bromocriptine, pergolide, pramipexole, ropinirole), or inhibit the metabolic breakdown of dopamine (*e.g.*, selegiline). Because dopamine transmission is disrupted in Parkinson's disease, there is a preponderance of cholinergic activity, which may be treated with anticholinergic drugs.

Surgical treatment includes thalamotomy or pallidectomy performed using stereotactic surgery. With these procedures, part of the thalamus or globus pallidum in the basal ganglia is destroyed using an electrical stimulator or supercooled tip of a metal probe (cryothalamotomy). Brain mapping is done during the surgery to identify and prevent injury to sensory and motor tracts. Surgery is generally confined to one side of the brain and is usually restricted to persons who have not experienced satisfactory response to drug therapy.

The Cerebellum

The cerebellum, or "little brain," constitutes only 10% of the total volume of the brain but contains more than half of all its neurons.¹ The cerebellum is responsible for smoothing the temporal and spatial aspects of rapid movement anywhere in the body. It does this by evaluating disparities between intention and action and by adjusting the operation of motor centers in the cortex while the movement is in progress as well as during repetitions of the same movement. The cerebellum also appears to have a role in learning both motor and cognitive tasks in which skilled responses are developed through repeated practice. It does not alter sensory thresholds or the strength of muscle contraction.

The cerebellum is located in the posterior fossa of the cranium superior to the pons (see Chapter 36, Fig. 36–19). It is separated from the cerebral hemispheres by a fold of dura mater, the tentorium cerebelli. The cerebellum consists of a small, unpaired median portion, called the *vermis*, and two large lateral masses, the *cerebellar hemispheres*. In contrast to the brain stem with its external white matter and internal gray nuclei, the cerebellum, like the cerebrum, has an outer cortex of gray matter overlying the white matter. Several masses of gray matter, called the *deep cerebellar nuclei*, border the roof of the fourth ventricle. Cells of the cerebellar cortex and the deep nuclei interact and axons from the latter send information to many regions, particularly to the motor cortex by means of a thalamic relay.

Synergistic (*i.e.*, temporal and spatial smoothing) functions of the cerebellum participate in all movements of limbs, trunk, head, larynx, and eyes, whether the movement is part of a voluntary movement or of a highly learned semiautomatic or automatic movement. During highly skilled movements, the motor cortex sends signals to the cerebellum, informing it about the movement that is to be performed. The cerebellum makes continuous adjustments, resulting in smoothness of movement, particularly during delicate maneuvers. Highly skillful movement requires extensive motor training, and considerable evidence suggests many of these learned movement patterns involve cerebellar circuits.

The cerebellum receives proprioceptor input from the vestibular system; feedback from the muscles, tendons, and joints; and indirect signals from the somesthetic, visual, and auditory systems that provide background information for ongoing movement. Sensory and motor information from a given area of the body is sent to the same area in the cerebellum. In this way, the cerebellum can assess continuously the status of each body part—position, rate of movement, and forces such as gravity that are opposing movement. The cerebellum compares what is actually happening with what is intended to happen. It then transmits the appropriate corrective signals back to the motor system, instructing it to increase or decrease the activity of the participating muscle groups so that smooth and accurate movements can be performed.

Cerebellar Dysfunction

Cerebellar dysfunction can be caused by injuries, global ischemia, occlusion of any of the cerebellar arteries, cerebral hemorrhage, and neoplastic lesions. Massive cerebellar infarction may lead to coma, tonsillar herniation, and death. Chronic alcoholism can lead to atrophy of the superior vermis of the cerebellulum.⁷

The signs of cerebellar dysfunction can be grouped into three classes: (1) vestibulocerebellar disorders, (2) cerebellar ataxia or decomposition of movement, and (3) cerebellar tremor. These disorders occur on the side of cerebellar damage. The abnormality of movement occurs whether the eyes are open or closed. Visual monitoring of movement cannot compensate for cerebellar defects.

Damage to the part of the cerebellum associated with the vestibular system leads to difficulty or inability to maintain a steady posture of the trunk, which normally requires constant readjusting movements. This is seen as an unsteadiness of the trunk, called *truncal ataxia*, and it can be so severe that standing is not possible. The ability to fix the eyes on a target also can be affected. Constant conjugate readjustment of eye position, called *nystagmus*, results and makes reading extremely difficult, especially when the eyes are deviated toward the side of cerebellar damage.

Cerebellar ataxia and tremor are different aspects of defects in the smooth, continuously correcting functions. Cerebellar dystaxia or, if severe, ataxia includes a decomposition of movement; each succeeding component of a complex movement occurs separately instead of being blended into a smoothly proceeding action. Because ethanol specifically affects cerebellar function, persons who are inebriated often walk with a staggering and unsteady gait. Rapid alternating movements such as supination-pronation-supination of the hands are jerky and performed slowly (dysdiadochokinesia). Reaching to touch a target breaks down into small sequential components, each going too far, followed by overcorrection. The finger moves jerkily toward the target, misses, corrects in the other direction, and misses again, until the target is finally reached. This is called *over-and-under reaching*. Tests of cerebellar function (walking a straight line and touching the nose with the index finger) are often used; these are the same tests used by law enforcement officials for screening persons suspected of driving while intoxicated.

Cerebellar tremor is a rhythmic back-and-forth movement of a finger or toe that worsens as the target is approached. The tremor results from the inability of the damaged cerebellar system to maintain ongoing fixation of a body part and to make smooth, continuous corrections in the trajectory of the movement; overcorrection occurs, first in one direction and then the other. Often, the tremor of an arm or leg can be detected during the beginning of an intended movement. The common term for cerebellar tremor is *intention tremor*. Cerebellar function as it relates to tremor can be assessed by asking a person to touch one heel to the opposite knee, to gently move the toes along the back of the opposite shin, or to move the hand so as to touch the nose with a finger.

Cerebellar function also can affect the motor skills of chewing and swallowing (dysphagia) and of speech (dysarthria). Normal speech requires smooth control of respiratory muscles and highly coordinated control of the laryngeal, lip, and tongue muscles. Cerebellar dysarthria is characterized by slow, slurred speech of continuously varying loudness. Rehabilitative efforts directed by speech therapists include learning to slow the rate of speech and to compensate as much as possible through the use of less-affected muscles.

In summary, alterations in coordination of muscle movements and abnormal muscle movements result from disorders of the basal ganglia and cerebellum. The basal ganglia organize basic movement patterns into more complex patterns and release them when commanded by the motor cortex, contributing gracefulness to cortically initiated and controlled skilled movements. Disorders of the basal ganglia are characterized by involuntary movements, alterations in muscle tone, and disturbances in posture. These disorders include tremor, tics, hemiballismus, chorea, athetosis, dystonias, and dyskinesias.

Parkinsonism, a disorder of the basal ganglia, is characterized by destruction of the nigrostriatal pathway, with a subsequent reduction in striatal concentrations of dopamine. This results in an imbalance between the inhibitory effects of dopaminergic basal ganglia functions and an increase in the excitatory cholinergic functions. The disorder is manifested by combinations of slowness of movement (*i.e.*, bradykinesia), increased muscle tonus and rigidity, rest tremor, gait disturbances, and impaired autonomic postural responses.

The cerebellum is responsible for smoothing the temporal and spatial aspects of rapid movement anywhere in the body. It does this by evaluating disparities between intention and action and by adjusting the operation of motor centers in the cortex while the movement is in progress as well as during repetitions of the same movement. The cerebellum also appears to have a role in learning both motor and cognitive tasks in which skilled responses are developed through repeated practice. Cerebellar disorders include vestibulocerebellar dysfunction, cerebellar ataxia, and cerebellar tremor.

UPPER AND LOWER MOTONEURON DISORDERS

Upper and Lower motoneurons innervate the skeletal muscles and are essential for motor function. The UMNs are fully contained within the CNS. They include the motor neurons arising in the motor areas of the cortex and their fibers as they project through the brain and descend in the spinal cord. Disorders that affect UMNs include multiple sclerosis and spinal cord injury (discussed later). Stroke, which is a common cause of UMN damage, is discussed in Chapter 37. Amyotrophic lateral sclerosis is a mixed UMN and LMN disorder.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as *Lou Gehrig's disease* after the famous New York Yankees baseball player, is a devastating neurologic disorder that selectively affects motor function. ALS is primarily a disorder of middle to late adulthood, affecting persons between 55 and 60 years of age, with men developing the disease nearly twice as often as women. The disease typically follows a progressive course, with a mean survival period of 2 to 5 years from the onset of symptoms.

ALS affects motoneurons in three locations: the anterior horn cells of the spinal cord; the motor nuclei of the brain stem, particularly the hypoglossal nuclei; and the UMNs of the cerebral cortex.²⁶ The fact that the disease is more extensive in the distal, rather than the proximal, parts of the affected tracts in the lower spinal cord suggests that affected neurons first undergo degeneration at their distal terminals and that the disease proceeds in a centripetal direction until ultimately the parent nerve cell dies. A remarkable feature of the disease is that the entire sensory system, the regulatory mechanisms of control and coordination of movement, and the intellect remain intact. The neurons for eye movement and the parasympathetic neurons in the sacral spinal cord also are spared.

Degeneration and loss of neurons in the primary motor cortex leads to loss of fibers within the corticospinal tract and lateral and anterior columns of the spinal cord.⁶ It is this fiber atrophy, called *amyotrophy*, that appears in the name of the disease. The loss of nerve fibers in lateral columns of the white matter of the spinal cord along with fibrillary gliosis imparts a firmness or sclerosis to this CNS tissue; the term *lateral sclerosis* designates these changes.

The cause of LMN and UMN destruction in ALS is uncertain. Five percent to 10% of cases are familial; the others are believed to be sporadic, with no family history of the disease. Recently, mutations to a gene encoding superoxide dismutase 1 (SOD1) was mapped to chromosome 21. This enzyme functions in the prevention of free radical formation (see Chapter 2). The mutation accounts for 20% of familial ALS, with the remaining 80% being caused by mutations in other genes.²⁶ Five percent of persons with sporadic ALS also have SOD1 mutations. Possible targets of SOD1-induced toxicity include the neurofilament proteins, which function in the axonal transport of molecules necessary for the maintenance of axons.²⁶ Another suggested mechanism of pathogenesis in ALS is exotoxic injury through activation of glutamate-gated ion channels, which are distinguished by their sensitivity to *N*-methyl-D-aspartic acid

(see Chapter 37). The possibility of glutamate excitotoxicity in the pathogenesis of ALS was suggested by the finding of increased glutamine levels in the cerebrospinal fluid of patients with sporadic ALS.²⁶ Although autoimmunity has been suggested as a cause of ALS, the disease does not respond to the immunosuppressant agents that normally are used in treatment of autoimmune disorders.

Clinical Course

The symptoms of ALS may be referable to UMN or LMN involvement. Manifestations of UMN lesions include weakness, spasticity or stiffness, and impaired fine motor control.^{26,27} Dysphagia (difficulty swallowing), dysarthria (impaired articulation of speech), and dysphonia (difficulty making the sounds of speech) may result from brain stem LMN involvement or from dysfunction of UMNs descending to the brain stem. Manifestations of LMN destruction include fasciculations, weakness, muscle atrophy, and hyporeflexia. Muscle cramping involving the distal legs often is an early symptom. The most common clinical presentation is slowly progressive weakness and atrophy in distal muscles of one upper extremity. This is followed by regional spread of clinical weakness, reflecting involvement of neighboring areas of the spinal cord. Eventually, UMNs and LMNs involving multiple limbs and the head are affected. In the more advanced stages, muscles of the palate, pharynx, tongue, neck, and shoulders become involved, causing impairment of chewing, swallowing, and speech. Dysphagia with recurrent aspiration and weakness of the respiratory muscles produces the most significant acute complications of the disease. Death usually results from involvement of cranial nerves and respiratory musculature.

Currently, there is no cure for ALS. Rehabilitation measures assist persons with the disorder to manage their disability, and respiratory and nutritional support allows persons with the disorder to survive longer than would otherwise have been the case. An antiglutamate drug, riluzole, is the only drug approved by the U.S. Food and Drug Administration (FDA) for treatment of ALS. The drug is designed to decrease glutamate accumulation and slow the progression of the disease.²⁶

Multiple Sclerosis

Multiple sclerosis (MS), a demyelinating disease of the CNS, is a major cause of neurologic disability among young and middleaged adults. Approximately two thirds of persons with MS experience their first symptoms between 20 and 40 years of age. In approximately 80% of the cases, the disease is characterized by exacerbations and remissions over many years in several different sites in the CNS.²⁸ Initially, there is normal or nearnormal neurologic function between exacerbations. As the disease progresses, there is less improvement between exacerbations and increasing neurologic dysfunction.

The prevalence of MS varies considerably around the world. The disease is more prevalent in the colder northern latitudes; it is more common in the northern Atlantic states, the Great Lakes region, and the Pacific Northwest than in the southern parts of the United States. Other high-incidence areas include northern Europe, Great Britain, southern Australia, and New Zealand.²⁹ The incidence among women is almost double that of men. Although MS is not directly inherited, there is a familial predisposition in some cases, suggesting a genetic influence on susceptibility. For example, there is evidence of a genetic linkage of MS susceptibility to the inherited major histocompatibility complex DR2 haplotype (Chapter 8).^{6,28}

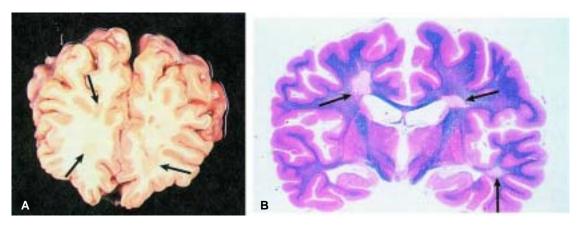

The pathophysiology of MS involves the demyelination of nerve fibers in the white matter of the brain, spinal cord, and optic nerve. In the CNS, myelin is formed by the oligodendrocytes, chiefly those lying among the nerve fibers in the white matter. The properties of the myelin sheath—high electrical resistance and low capacitance—permit it to function as an electrical insulator. Demyelinated nerve fibers display a variety of conduction abnormalities, ranging from decreased conduction velocity to conduction blocks.

The lesions of MS consist of hard, sharp-edged demyelinated or sclerotic patches that are macroscopically visible throughout the white matter of the CNS⁷ (Fig. 38-16). These lesions, which represent the end result of acute myelin breakdown, are called *plaques*. The lesions have a predilection for the optic nerves, periventricular white matter, brain stem, cerebellum, and spinal cord white matter.²⁸ In an active plaque, there is evidence of ongoing myelin breakdown. The sequence of myelin breakdown is not well understood, although it is known that the lesions contain small amounts of myelin basic proteins and increased amounts of proteolytic enzymes, macrophages, lymphocytes, and plasma cells. Oligodendrocytes are decreased in number and may be absent, especially in older lesions. Acute, subacute, and chronic lesions often are seen at multiple sites throughout the CNS.

The lesions of MS are generally thought to result from an immune-mediated inflammatory response that occurs in genetically susceptible individuals. The demyelination process in MS is marked by prominent lymphocytic invasion in the lesion. The infiltrate in plaques contains both CD8⁺ and CD4⁺ T cells as well as macrophages. Both macrophages and cytotoxic CD8⁺ T cells are thought to induce oligodendrocyte injury. There also is evidence of antibody-mediated damage involving myelin oligodendroglial protein.⁶ Magnetic resonance imaging has shown that the lesions of MS may occur in two stages: a first stage that involves the sequential development of small inflammatory lesions, and a second stage during which the lesions extend and consolidate and when demyelination and gliosis (scar formation) occur. It is not known whether the inflammatory process, present during the first stage, is directed against the myelin or against the oligodendrocytes that produce myelin. There is evidence that remyelination can occur in the CNS if the process that initiated the demyelination is halted before the oligodendrocyte dies.²⁸

Clinical Course

The interruption of neural conduction in the demyelinated nerves is manifested by a variety of symptoms, depending on the location and extent of the lesion. Areas commonly affected by MS are the optic nerve (visual field), corticobulbar tracts (speech and swallowing), corticospinal tracts (muscle strength), cerebellar tracts (gait and coordination), spinocerebellar tracts (balance), medial longitudinal fasciculus (conjugate gaze function of the extraocular eye muscles), and posterior cell columns of the spinal cord (position and vibratory sensation). Typically, an otherwise healthy person presents with an acute or subacute episode of paresthesias, optic neuritis (*i.e.*, visual clouding or loss of vision in part of the visual field with pain on movement of the globe), diplopia, or specific types of gaze paralysis.

■ FIGURE 38-16 ■ Multiple sclerosis. (A) In this unfixed brain, the plaques of multiple sclerosis in the white matter (*arrows*) assume the darker color of the cerebral cortex. (B) A coronal section of the brain from a patient with long-standing multiple sclerosis, which has been stained for myelin, shows discrete areas of demyelination (*arrows*) with characteristic involvement of the superior angles of the lateral ventricles. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1497]. Philadelphia: Lippincott Williams & Wilkins)

Paresthesias are evidenced as numbness, tingling, a burning sensation, or pressure on the face or involved extremities; symptoms can range from annoying to severe. Pain from spasticity also may be a factor that can be aided by appropriate stretching exercises. Other common symptoms are abnormal gait, bladder and sexual dysfunction, vertigo, nystagmus, fatigue, and speech disturbance. These symptoms usually last for several days to weeks, and then completely or partially resolve. After a period of normal or relatively normal function, new symptoms appear. Psychological manifestations, such as mood swings, may represent an emotional reaction to the nature of the disease or, more likely, involvement of the white matter of the cerebral cortex. Depression, euphoria, inattentiveness, apathy, forgetfulness, and loss of memory may occur. Fatigue is one of the most common problems for persons with MS. It often is described as a generalized low-energy feeling not related to depression and different from weakness.

The course of the disease may fall into one of four categories: relapsing-remitting, secondary progressive, primary progressive, or progressive relapsing.^{31,32} The *relapsing-remitting* form of the disease is characterized by episodes of acute worsening with recovery and a stable course between relapses. *Secondary progressive disease* involves a gradual neurologic deterioration with or without superimposed acute relapses in a person with previous relapsing-remitting disease. *Primary progressive disease* is characterized by nearly continuous neurologic deterioration from onset of symptoms. The *progressive relapsing category* of disease involves gradual neurologic deterioration from the onset of symptoms but with subsequent superimposed relapses.

Diagnosis

The diagnosis of MS is based on established clinical, MRI, and laboratory findings in cerebrospinal fluid analysis. Examination of the cerebrospinal fluid is used for detecting signs of inflammation and immune responses. A large percentage of patients with MS have elevated immunoglobulin G (IgG) levels, and some have oligoclonal patterns (*i.e.*, discrete electrophoretic bands) even with normal IgG levels. Total protein or lymphocyte levels may be mildly elevated in the cerebrospinal fluid. These test results can be altered in a variety of inflammatory neurologic disorders and are not specific for MS. Advances in MRI have greatly simplified the diagnosis and evaluation of MS. MRI studies can detect the multiplicity of lesions even when CT scans appear normal. A computer-assisted method of MRI can measure lesion size. Many new areas of myelin abnormality are asymptomatic. Serial MRI studies can be done to detect asymptomatic lesions, monitor the progress of existing lesions, and evaluate the effectiveness of treatment. Electrophysiologic evaluations (*e.g.*, evoked potential studies) and CT scans may assist in the identification and documentation of lesions.

Treatment

Most treatment measures for MS are directed at modifying the course and managing the primary symptoms of the disease. The variety of symptoms, unpredictable course, and lack of specific diagnostic methods have made the evaluation and treatment of MS difficult. Persons who are minimally affected by the disorder require no specific treatment. The person should be encouraged to maintain as healthy a lifestyle as possible, including good nutrition and adequate rest and relaxation. Physical therapy may help maintain muscle tone. Every effort should be made to avoid excessive fatigue, physical deterioration, emotional stress, viral infections, and extremes of environmental temperature, which may precipitate an exacerbation of the disease.

The pharmacologic agents used in the treatment of MS fall into four categories: (1) those used to treat acute symptoms of the disease, (2) those used to modify the course of the disease, (3) those used to interrupt progressive disease, and (4) those used to treat the symptoms of the disorder.³¹ Corticosteroids are the mainstay of treatment for acute relapses of MS. These agents are thought to reduce the inflammation, improve nerve conduction, and have important immunologic effects. However, long-term administration does not appear to alter the course of the disease and can have harmful side effects. Adrenocorticotropic hormone (ACTH) also may be used in treatment of MS. Plasmapheresis has proved beneficial in some cases.

The agents used to modify the course of the disease include interferon beta and glatiramer acetate.³¹ Both agents have shown some benefit in reducing exacerbations in persons with relapsing-remitting MS. Interferon beta is a cytokine that acts as an immune enhancer. Glatiramer acetate is a synthetic polypeptide that simulates parts of the myelin basic protein. Although the exact mechanism of action is unknown, the drug seems to block myelin-damaging T cells by acting as a myelin decoy.

Progressive MS may be treated with immunosuppressive drugs such as methotrexate, cyclophosphamide, mitoxantrone, and cyclosporine. The drugs used to treat symptoms of the disease include muscle relaxants (*e.g.*, dantrolene, baclofen, diazepam), which are used to relieve spasticity; cholinergic drugs, which are used to treat bladder problems; and antidepressant drugs, which are used for depression.

In summary, UMNs and LMNs innervate the skeletal muscles and are essential for motor function. Amyotrophic lateral sclerosis is a mixed UMN and LMN disorder. Degeneration and loss of neurons in the UMNs in the primary motor cortex leads to loss of fibers within the corticospinal tract and lateral and anterior columns of the spinal cord. Disease of the LMNs leads to weakness, fasciculations, and atrophy of the affected muscle. A remarkable feature of the disease is that the entire sensory system and the intellect remain intact. The neurons for eye movement and the parasympathetic neurons in the sacral spinal cord also are spared. In the more advanced stages, muscles of the palate, pharynx, tongue, neck, and shoulders become involved, causing impairment of chewing, swallowing, and speech. Death usually results from involvement of cranial nerves and respiratory musculature.

MS is an example of a demyelinating disease of the CNS in which there is a slowly progressive breakdown of myelin and formation of plaques but sparing of the axis cylinder of the neuron. Interruption of neural conduction in MS is manifested by a variety of disabling signs and symptoms that depend on the neurons that are affected. The most common symptoms are paresthesias, optic neuritis, and motor weakness. The disease usually is characterized by exacerbations and remissions. Initially, near-normal function returns between exacerbations. The variety of symptoms, course of the disease, and lack of specific diagnostic tests make diagnosis and treatment of the disease difficult.

SPINAL CORD INJURY

Spinal cord injury (SCI) represents damage to the neural elements of the spinal cord. SCI is a disorder primarily of young adults, the most common cause being motor vehicle accidents, followed by falls, violence, sports injuries, and other types of injuries, including attempted suicide and occupational injuries. Of sports-related injuries, 66% are from diving.³³

Most spinal cord injuries involve damage to the vertebral column and or supporting ligaments as well as the spinal cord. Because of extensive tract systems that connect sensory afferent neurons and LMNs with high brain centers, spinal cord injuries commonly involve both sensory and motor function.

Injury to the Vertebral Column

Injuries to the vertebral column include fractures, dislocations, and subluxations. A fracture can occur at any part of the bony vertebrae, causing fragmentation of the bone. It most often involves the pedicle, lamina, or processes (*e.g.*, facets). Dislocation or subluxation (partial dislocation) injury causes the vertebral bodies to become displaced, with one overriding another and preventing correct alignment of the vertebral column. Damage to the ligaments or bony vertebrae may make the spine unstable. In an unstable spine, further unguarded movement of the spinal column can impinge on the spinal canal, causing compression or overstretching of neural tissue.

Most injuries result from some combination of compressive force or bending movement. Flexion injuries occur when forward bending of the spinal column exceeds the limits of normal movement. A typical flexion injury results when the head is struck from behind, such as in a fall with the back of the head as the point of impact. Extension injuries occur with excessive forced bending (*i.e.*, hyperextension) of the spine backward. A typical extension injury involves a fall in which the chin or face is the point of impact, causing hyperextension of the neck. Injuries of flexion and extension occur more commonly in the cervical spine (C4 to C6) than in any other area. Limitations imposed by the ribs, spinous processes, and joint capsules in the thoracic and lumbar spine make this area less flexible and less susceptible to flexion and extension injuries than the cervical spine.

A compression injury, causing the vertebral bones to shatter, squash, or even burst, occurs when there is spinal loading from a high-velocity blow to the top of the head or when landing forcefully on the feet (38-17A). This typically occurs at the cervical level (*e.g.*, diving injuries) or in the thoracolumbar area (*e.g.*, falling from a distance and landing on the feet). Compression injuries may occur when the vertebrae are weakened by conditions such as osteoporosis and cancer with bone metastasis. Axial rotation injuries can produce highly unstable injuries. Maximal axial rotation occurs in the cervical region, especially between C1 and C2 and at the lumbosacral joint (Fig. 38-17B). Coupling of vertebral motions is common in injury when two or more individual motions occur (*e.g.*, lateral bending and axial rotation).

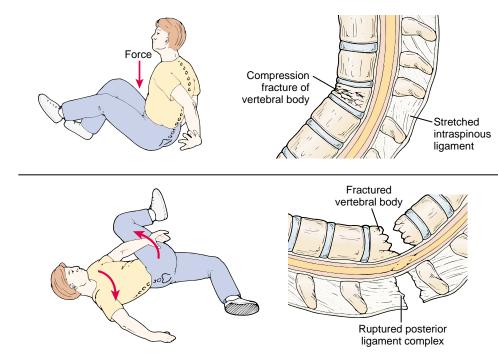

Types and Classification of Spinal Cord Injury

Spinal cord injury involves damage to the neural elements of the spinal cord. The damage may result from direct trauma to the cord from penetrating wounds or indirect injury resulting from vertebral fractures, fracture-dislocations, or subluxations of the spine. The spinal cord may be contused, not only at the site of injury, but also above and below the trauma site (Fig. 38-18). Traumatic injury may be complicated by blood flow to the cord, with resulting infarction.

Primary and Secondary Injuries

The pathophysiology of SCI can be divided into two types: primary and secondary.^{5,34} The *primary neurologic injury* occurs at the time of mechanical injury and is irreversible. It is charac-

Chapter 38: Alterations in Neuromuscular Function

■ **FIGURE 38-17** ■ (**A**) Compression vertebral fracture secondary to axial loading as occurs when a person falls from a height and lands on the buttocks. (B) Rotational injury, in which there is concurrent fracture and tearing of the posterior ligamentous complex, is caused by extreme lateral flexion or twisting of the head or neck.

■ FIGURE 38-18 ■ Cervical contusion. Hyperflexion injury caused forward angulation of the cervical cord, with fracture of the anterior lip of the underlying vertebral body. The cord is angulated over the superior-posterior ridge of the fixed underlying cervical body. (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 1465]. Philadelphia: Lippincott Williams & Wilkins)

terized by small hemorrhages in the gray matter of the cord, followed by edematous changes in the white matter that lead to necrosis of neural tissue. This type of pathology results from the forces of compression, stretch, and shear associated with fracture or compression of the spinal vertebrae, dislocation of vertebrae (e.g., flexion, extension, subluxation), and contusions caused by jarring of the cord in the spinal canal. Penetrating injuries produce lacerations and direct trauma to the cord and may occur with or without spinal column damage. Lacerations occur when there is cutting or tearing of the spinal cord, which injures nerve tissue and causes bleeding and edema.

Secondary injuries follow the primary injury and promote the spread of injury. Although there is considerable debate about the pathogenesis of secondary injuries, the tissue destruction that occurs ends in progressive neurologic damage. After SCI, several pathologic mechanisms come into play, including vascular damage, neuronal injury that leads to loss of reflexes below the level of injury, and release of vasoactive agents and cellular enzymes. Vascular pathology (i.e., vessel trauma and hemorrhage) can lead to ischemia, increased vascular permeability, and edema. Blood flow to the spinal cord may be further compromised by spinal shock that results from a loss of vasomotor tone and neural reflexes below the level of injury. The release of vasoactive substances (i.e., norepinephrine, serotonin, dopamine, and histamine) from the wound tissue causes vasospasm and impedes blood flow in the microcirculation, producing further necrosis of blood vessels and neurons. The release of proteolytic and lipolytic enzymes from injured cells causes delayed swelling, demyelination, and necrosis in the neural tissue in the spinal cord.

717

Classification

Alterations in body function that result from SCI depend on the level of injury and the amount of cord involvement. *Tetraplegia*, sometimes referred to as quadriplegia, is the impairment or loss of motor or sensory function (or both) after damage to neural structures in the cervical segments of the spinal cord.³⁵ It results in impairment of function in the arms, trunk, legs, and pelvic organs (see Fig. 38-7). *Paraplegia* refers to impairment or loss of motor or sensory function (or both) in the thoracic, lumbar, or sacral segments of the spinal cord from damage of neural elements in the spinal canal. With paraplegia, arm functioning is spared, but depending on the level of injury, functioning of the trunk, legs, and pelvic organs may be involved. Paraplegia includes conus medullaris and cauda equina injuries (to be discussed).

Further definitions of SCI describe the extent of neurologic damage as *complete* or *incomplete*. The prognosis for return of function is better in an incomplete injury because of preservation of axonal function.

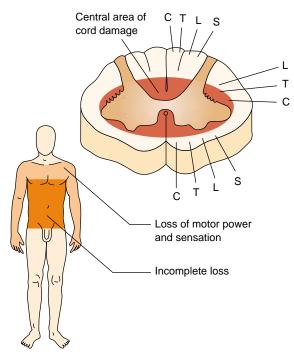

Incomplete Spinal Cord Injuries. Incomplete SCI implies there is some residual motor or sensory function below the level of injury.³⁶ Incomplete injuries may manifest in a variety of patterns but can be organized into certain patterns or "syndromes" that occur more frequently and reflect the predominant area of the cord that is involved. Types of incomplete lesions include the central cord syndrome, anterior cord syndrome, Brown-Séquard syndrome, and the conus medullaris syndrome.

A condition called *central cord syndrome* occurs when injury is predominantly in the central gray or white matter of the cord⁵ (Fig. 38-19). Because the corticospinal tract fibers are organized with those controlling the arms located more centrally and those controlling the legs located more laterally, some external axonal transmission may remain intact. Motor function of the upper extremities is affected, but the lower extremities may not be affected or may be affected to a lesser degree, with some sparing of sacral sensation. Bowel, bladder, and sexual functions usually are affected to various degrees and may parallel the degree of lower extremity involvement. This syndrome occurs almost exclusively in the cervical cord, rendering the lesion a UMN lesion with spastic paralysis. Central cord damage is more common in elderly persons with narrowing or stenotic changes in the spinal canal that are related to arthritis. Damage also may occur in persons with congenital stenosis.

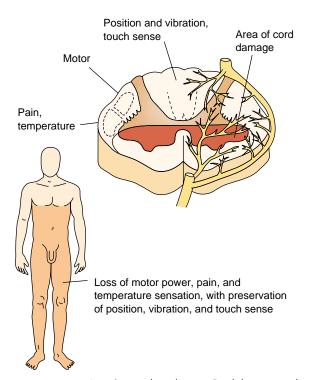

Anterior artery or anterior cord syndrome usually is caused by damage from infarction of the anterior spinal artery, resulting in damage to the anterior two thirds of the cord⁵ (Fig. 38-20). The deficits result in loss of motor function provided by the corticospinal tracts and loss of pain and temperature sensation from damage to the lateral spinothalamic tracts. The posterior one third of the cord is relatively unaffected, preserving the dorsal column axons that convey position, vibration, and touch sensation.

A condition called *Brown-Séquard syndrome* results from damage to a hemisection of the anterior and posterior cord⁵ (Fig. 38-21). The effect is a loss of voluntary motor function from the corticospinal tract, proprioception loss from the ipsilateral side of the body, and contralateral loss of pain and temperature sensation from the lateral spinothalamic tracts for all levels below the lesion.

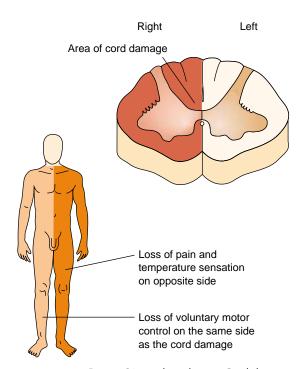

Conus medullaris syndrome involves damage to the conus medullaris or the sacral cord (*i.e.*, conus) and lumbar nerve

■ FIGURE 38-19 ■ Central cord syndrome. A cross-section of the cord shows central damage and the associated motor and sensory loss. (C, cervical; T, thoracic; L, lumbar; S, sacral). (Hickey J.V. [2003]. *The clinical practice of neurological and neurosurgical nursing* [5th ed., p. 420]. Philadelphia: Lippincott Williams & Wilkins)

■ FIGURE 38-20 ■ Anterior cord syndrome. Cord damage and associated motor and sensory loss are illustrated. (Hickey J.V. [2003]. *The clinical practice of neurological and neurosurgical nursing* [5th ed., p. 420]. Philadelphia: Lippincott Williams & Wilkins)

■ FIGURE 38-21 ■ Brown-Séquard syndrome. Cord damage and associated motor and sensory loss are illustrated. (Hickey J.V. [2003]. The clinical practice of neurological and neurosurgical nursing [5th ed., p. 421]. Philadelphia: Lippincott Williams & Wilkins)

roots in the neural canal. Functional deficits resulting from this type of injury usually result in flaccid bowel, bladder, and sexual function. Sacral segments occasionally show preserved reflexes if only the conus is affected. Motor function in the legs and feet may be impaired without significant sensory impairment. Damage to the lumbosacral nerve roots in the spinal canal usually results in LMN and sensory neuron damage known as cauda equina syndrome. Functional deficits present as various patterns of asymmetric flaccid paralysis, sensory impairment, and pain.

Complete Spinal Cord Injuries. Complete SCI implies there is an absence of motor and sensory function below the level of injury. Complete cord injuries can result from severance of the cord, disruption of nerve fibers although they remain intact, or interruption of blood supply to that segment, resulting in complete destruction of neural tissue and UMN or LMN paralysis. Approximately 3% of persons with signs of complete injuries on initial examination experience some recovery within 24 hours.36

Acute Spinal Cord Injury

Sudden complete transection of the spinal cord results in complete loss of motor, sensory, reflex, and autonomic function below the level of injury. This immediate response to spinal cord injury is often referred to as spinal cord shock. It is characterized by flaccid paralysis with loss of tendon reflexes below the level of injury, absence of somatic and visceral sensations below the level of injury, and loss of bowel and bladder function. Loss of systemic sympathetic vasomotor tone may result in vasodilation, increased venous capacity, and hypotension. These manifestations occur regardless of whether the level of the lesion eventually will produce spastic (UMN) or flaccid (LMN) paralysis. The basic mechanisms accounting for transient spinal shock are unknown. Spinal shock may last for hours, days, or weeks. Usually, if reflex function returns by the time the person reaches the hospital, the neuromuscular changes are reversible. This type of reversible spinal shock may occur in football-type injuries, in which jarring of the spinal cord produces a concussion-like syndrome with loss of movement and reflexes, followed by full recovery within days. In persons in whom the loss of reflexes persists, hypotension and bradycardia may become critical but manageable problems. In general, the higher the level of injury, the greater is the effect.

Management. The goal of management of acute SCI is to reduce the neurologic deficit and prevent any additional loss of neurologic function. The specific steps in resuscitation and initial evaluation can be carried out at the trauma site or in the emergency room, depending on the urgency of the situation.^{34,37} Most traumatic injuries to the spinal column render it unstable, mandating measures such as immobilization with collars and backboards and limiting the movement of persons at risk for or with known SCI. Every person with multiple trauma or head injury, including victims of traffic and sporting accidents, should be suspected of having sustained an acute SCI.34,37

The nature of the injury determines further methods of stabilization and treatment. In unstable injuries of the cervical spine, cervical traction improves or restores spinal alignment, decompresses neural structures, and facilitates recovery. Fractures and dislocations of the thoracic and lumbar vertebrae may be initially stabilized by restricting the person to bed rest and turning him or her in a log-rolling manner to keep the spine rigid. Gunshot or stab wounds of the spinal column may not produce structural instability and require immobilization. The goal of early surgical intervention for an unstable spine is to provide internal skeletal stabilization so that early mobilization and rehabilitation can occur.

One of the more important aspects of early SCI care is the prevention and treatment of spinal or systemic shock and the hypoxia associated with compromised respiration. Correcting hypotension or hypoxia is essential to maintaining circulation to the injured cord.³⁸ The use of high-dose methylprednisolone has been shown to improve the outcome from SCI when given shortly after injury. Methylprednisolone is a short-acting corticosteroid that has been used extensively in the treatment of inflammatory and allergic disorders. In acute SCI, it is thought to stabilize cell membranes, enhance impulse generation, improve blood flow, and inhibit free radical formation.

Disruption of Functional Abilities

Functional abilities after SCI are subject to various degrees of somatosensory and skeletal muscle function loss and altered reflex activity based on the level of cord injury and extent of cord damage (Table 38-2).

Somatosensory and Skeletal Muscle Function

Motor function in cervical injuries ranges from complete dependence to independence with or without assistive devices in activities of mobility and self-care. The functional levels of cervical injury are related to C5, C6, C7, or C8 innervation. At the

C6	Fully innervated shoulder; wrist exten- sion or dorsiflexion	Independent or with minimal assistance	Independent or with minimal assistance	Independent in transfers and wheelchair	
C7 to C8	Full elbow extension; wrist plantar flexion; some finger control	Independent	Independent	Independent; manual wheelchair	
T1 to T5	Full hand and finger control; use of intercostal and thoracic muscles	Independent	Independent	Independent; manual wheelchair	
T6 to T10	Abdominal muscle control, partial to good balance with trunk muscles	Independent	Independent	Independent; manual wheelchair	
T11 to L5	Hip flexors, hip abductors (L1–3); knee extension (L2–4); knee flexion and ankle dorsiflexion (L4–5)	Independent	Independent	Short distance to full ambulation with assistance	
S1 to S5	Full leg, foot, and ankle control; inner- vation of perineal muscles for bowel, bladder, and sexual function (S2–4)	Independent	Normal to impaired bowel and blad- der function	Ambulate independently with or without assistance	

TABLE 38-2 Functional Abilities by Level of Cord Injury

*Assistance refers to adaptive equipment, setup, or physical assistance.

C5 level, deltoid and biceps function is spared, allowing full head, neck, and diaphragm control with good shoulder strength and full elbow flexion. At the C6 level, wrist dorsiflexion by the way of wrist extensors is functional, allowing tenodesis, which is the natural bending inward and flexion of the fingers when the wrist is extended and bent backward. Tenodesis is a key movement because it can be used to pick up objects when finger movement is absent. A functional C7 injury allows full elbow flexion and extension, wrist plantar flexion, and some finger control. At the C8 level, finger flexion is added.

Thoracic cord injuries (T1 to T12) allow full upper extremity control with limited to full control of intercostal and trunk muscles and balance. Injury at the T1 level allows full fine motor control of the fingers. Because of the lack of specific functional indicators at the thoracic levels, the level of injury usually is determined by sensory level testing.

Functional capacity in the L1 through L5 nerve innervations allows hip flexors, hip abductors (L1 to L3), movement of the knees (L2 to L5), and ankle dorsiflexion (L4 to L5). Sacral (S1 to S5) innervation allows for full leg, foot, and ankle control and innervation of perineal musculature for bowel, bladder, and sexual function.

Altered Reflex Activity. Spinal cord reflexes are fully integrated within the spinal cord and can function independent of input from higher centers. Altered spinal reflex activity after SCI is essentially determined by the level of injury and whether UMNs or LMNs are affected. With UMN injuries at T12 and above, the cord reflexes remain intact, while communication

pathways with higher centers have been interrupted. This results in spasticity of involved skeletal muscle groups and of smooth and skeletal muscles that control bowel, bladder, and sexual function. In LMN injuries at T12 or below, the reflex circuitry itself has been damaged at the level of the spinal cord or spinal nerve, resulting in a decrease or absence of reflex function. The LMN injuries cause flaccid paralysis of involved skeletal muscle groups and the smooth and skeletal muscles that control bowel, bladder, and sexual function. However, injuries near the T12 level may result in mixed UMN and LMN deficits (*e.g.*, spastic paralysis of the bowel and bladder with flaccid muscle tone).

After the period of spinal shock in a UMN injury, isolated spinal reflex activity and muscle tone that is not under the control of higher centers returns. This may result in hypertonia and spasticity of skeletal muscles below the level of injury. These spastic movements are involuntary, instead of voluntary, a distinction that needs to be explained to persons with SCI and their families. The antigravity muscles, the flexors of the arms and extensors of the legs, are predominantly affected. Spastic movements usually are heightened initially after injury, reaching a peak and then becoming stable in approximately 2 years.

The stimuli for reflex muscle spasm arise from somatic and visceral afferent pathways that enter the cord below the level of injury. The most common of these stimuli are muscle stretching, bladder infections or stones, fistulas, bowel distention or impaction, pressure areas or irritation of the skin, and infections. Because the stimuli that precipitate spasms vary from person to person, careful assessment needs to be done to identify the factors that precipitate spasm in each person. Passive range-of-motion exercises to stretch the spastic muscles help to prevent spasm induced by muscle stretching such as occurs with change in body position.

Spasticity in and of itself is not detrimental and may even facilitate maintenance of muscle tone to prevent muscle wasting, improve venous return, and aid in mobility. Spasms become detrimental when they impair safety or reduce the ability to make functional gains in mobility and activities of daily living. Spasms also may cause trauma to bones and tissues, leading to joint contractures and skin breakdown.

Respiratory Muscle Function. Ventilation requires movement of the expiratory and inspiratory muscles, all of which receive innervation from the spinal cord. The main muscle of ventilation, the diaphragm, is innervated by segments C3 to C5 through the phrenic nerves. The intercostal muscles, which function in elevating the rib cage and are needed for coughing and deep breathing, are innervated by spinal segments T1 through T7. The major muscles of expiration are the abdominal muscles, which receive their innervation from levels T6 to T12.

Although the ability to inhale and exhale may be preserved at various levels of SCI, functional deficits in ventilation are most apparent in the quality of the breathing cycle and the ability to oxygenate tissues, eliminate carbon dioxide, and mobilize secretions. Cord injuries involving C1 to C3 result in a lack of respiratory effort, and affected patients require assisted ventilation. Although a C3 to C5 injury allows partial or full diaphragmatic function, ventilation is diminished because of the loss of intercostal muscle function, resulting in shallow breaths and a weak cough. Below the C5 level, as less intercostal and abdominal musculature is affected, the ability to take a deep breath and cough is less impaired. Maintenance therapy consists of muscle training to strengthen existing muscles for endurance and mobilization of secretions. The ability to speak is compromised with assisted ventilation, whether continuous or intermittent. Thus, ensuring adequate communication of needs is also essential.

Autonomic Nervous System Function

In addition to its effects on skeletal muscle function, SCI interrupts ANS function below the site of injury. This includes sympathetic outflow from the thoracic and lumbar cord and parasympathetic outflow from the sacral cord. Because of their site of exit from the CNS, the cranial nerves, such as the vagus, are unaffected. Dependent upon the level of injury, the spinal reflexes that control ANS function are largely isolated from the rest of the CNS. Afferent sensory input that enters the spinal cord is unaffected, as is the efferent motor output from the cord. Lacking is the regulation and integration of reflex function by centers in the brain and brain stem. This results in a situation in which the autonomic reflexes below the level of injury are uncontrolled, while those above the level of injury function in a relatively controlled manner.

The sympathetic nervous system regulation of circulatory function and thermoregulation present some of the most severe problems in SCI. The higher the level of injury and the greater the surface area affected, the more profound are the effects on circulation and thermoregulation. Persons with injury at the T6 level or above experience problems in regulating vasomotor tone; those with injuries below the T6 level usually have sufficient sympathetic function to maintain adequate vasomotor function. The level of injury and its corresponding problems may vary among persons, and some dysfunctional effects may be seen at levels below T6. With lower lumbar and sacral injuries, sympathetic function remains essentially unaltered.

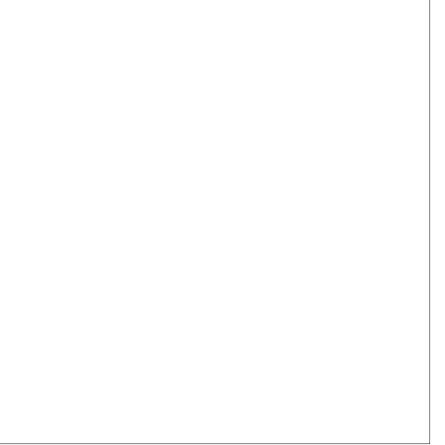

The Vasovagal Response. The vagus nerve (cranial nerve X) normally exerts a continuous inhibitory effect on heart rate. Vagal stimulation that causes a marked bradycardia by way of the vagus nerve is called the *vasovagal response.* Visceral afferent input to the vagal centers in the brain stem of persons with tetraplegia or high-level paraplegia can produce marked bradycardia when unchecked by a dysfunctional sympathetic nervous system. Severe bradycardia and even asystole can result when the vasovagal response is elicited by deep endotracheal suctioning or rapid position change. Preventive measures, such as hyperoxygenation before, during, and after suctioning, are advised. Rapid position changes should be avoided or anticipated, and anticholinergic drugs should be immediately available to counteract severe episodes of bradycardia.

Autonomic Dysreflexia. Autonomic dysreflexia, also known as *autonomic hyperreflexia*, represents an acute episode of exaggerated sympathetic reflex responses that occur in persons with injuries at T6 and above, in which CNS control of sympathetic responses is lost (see Fig. 38-22). It does not occur until spinal shock has resolved and autonomic reflexes return, most often within the first 6 months after injury. It is most unpredictable during the first year after injury but can occur throughout the person's lifetime.

Autonomic dysreflexia, is characterized by vasospasm, hypertension ranging from mild (20 mm Hg above baseline) to severe (as high as 240/120 mm Hg or higher), skin pallor, and goose flesh associated with the piloerector response. Because baroreceptor function and parasympathetic control of heart rate travels by way of the cranial nerves, these responses remain intact. Continued hypertension produces a baroreflex-mediated vagal slowing of the heart rate to bradycardic levels. There is an accompanying baroreflex-mediated vasodilatation with flushed skin and profuse sweating above the level of injury, headache ranging from dull to severe and pounding, nasal stuffiness, and feelings of anxiety. A person may experience one, several, or all of the symptoms with each episode.

The stimuli initiating the dysreflexic response include visceral distention, such as a full bladder or rectum; stimulation of pain receptors, such as occurs with pressure ulcers, ingrown toenails, dressing changes, and diagnostic or operative procedures; and visceral contractions, such as ejaculation, bladder spasms, or uterine contractions. In many cases, the dysreflexic response results from a full bladder.

Autonomic dysreflexia is a clinical emergency, and without prompt and adequate treatment, convulsions, loss of consciousness, and even death can occur. The major components of treatment include monitoring blood pressure while removing or correcting the initiating cause or stimulus. The person should be placed in an upright position, and all support hose or binders should be removed to promote venous pooling of blood and reduce venous return, thereby decreasing blood pressure. If the stimuli have been removed or the stimuli cannot

■ **FIGURE 38-22** ■ Mechanisms of autonomic hyperreflexia.

be identified and the upright position is established but the blood pressure remains elevated, drugs that block autonomic function are administered. Prevention of the type of stimuli that trigger the dysreflexic event is advocated.

Postural Hypotension. Postural, or orthostatic, hypotension usually occurs in persons with injuries at T4 to T6 and above and is related to the interruption of descending control of sympathetic outflow to blood vessels in the extremities and abdomen. Pooling of blood, along with gravitational forces, impairs venous return to the heart, and there is a subsequent decrease in cardiac output when the person is placed in an upright position. The signs of orthostatic hypotension include dizziness, pallor, excessive sweating above the level of the lesion, complaints of blurred vision, and possibly fainting. Postural hypotension usually is prevented by slow changes in position and measures to promote venous return.

Other Functions

Edema and Deep Vein Thrombosis. Edema and deep vein thrombosis are common problems in persons with SCI. The development of edema is related to decreased peripheral vascular resistance, areflexia or decreased tone in the paralyzed limbs, and immobility that causes increased venous pressure and abnormal pooling of blood in the abdomen, lower limbs, and upper extremities. Edema in the dependent body parts usually is relieved by positioning to minimize gravitational forces or by using compression devices (*e.g.*, support stockings, binders) that encourage venous return.

Deep vein thrombosis also is of concern because of the venous pooling and loss of skeletal muscle movement below the level of injury. Although it is seen more frequently in the postacute phase of SCI, it often has its origin during the events surrounding the initial injury. Prevention includes assessment of risk and measures to prevent venous pooling of blood, especially in the paralyzed limbs (*e.g.*, range-of-motion exercises and vascular compression devices).

Bladder, Bowel, and Sexual Function. Among the most devastating consequences of SCI is the loss of bowel and bladder function. Loss of bladder function results from disruption of neural pathways between the bladder and the reflex voiding center at the S2 to S4 level (*i.e.*, an LMN lesion) or between the reflex voiding center and higher brain centers for communication and coordinated sphincter control (*i.e.*, a UMN lesion). Persons with UMN lesions or spastic bladders lack awareness of bladder filling (*i.e.*, storage) and voluntary control of voiding (*i.e.*, evacuation). In LMN lesions or flaccid bladder dysfunction, lack of awareness of bladder filling and lack of bladder tone render the person unable to void voluntarily or involuntarily.

Bowel elimination is a coordinated function involving the enteric nervous system, the ANS, and the CNS. Persons with SCI above S2 to S4 develop spastic functioning of the defecation reflex and loss of voluntary control of the external anal sphincter. Damage to the cord at the S2 to S4 level causes flaccid functioning of the defecation reflex and loss of anal sphincter tone. Even though the enteric nervous system innervation of the bowel remains intact, without the defecation reflex, peristaltic movements are ineffective in evacuating stool.

Sexual function, as in bladder and bowel control, is mediated by the S2 to S4 segments of the spinal cord. The genital sexual response in SCI, which is manifested by an erection in men and vaginal lubrication in women, may be initiated by mental or touch stimuli, depending on the level of injury. The T11 to L2 cord segments have been identified as the mentalstimuli, or psychogenic, sexual response area, where autonomic nerve pathways in communication with the forebrain leave the cord and innervate the genitalia. The S2 to S4 cord segments have been identified as the sexual-touch reflex center. In T10 or higher injuries (UMN lesion), reflex sexual response to genital touch may occur freely. However, a sexual response to mental stimuli (T11 to L2) does not occur because of the spinal lesion blocking the communication pathway. In an injury at T12 or below (LMN lesion), the sexual reflex center may be damaged, and there may be no response to touch.

In men, the lack of erectile ability or inability to experience penile sensations or orgasm is not a reliable indicator of fertility, which should be evaluated by an expert. In women, fertility is parallel to menses; usually, it is delayed 3 months to 5 months after injury. There are hazards to pregnancy, labor, and birth control devices relative to SCI that require knowledgeable health care providers.

Skin Integrity. The entire surface of the skin is innervated by cranial or spinal nerves organized into dermatomes that show cutaneous distribution. The CNS and ANS also play a vital role in skin function. The sympathetic nervous system, through control of vasomotor and sweat gland activity, influences the health of the skin by providing adequate circulation, excretion of body fluids, and temperature regulation. The lack of sensory warning mechanisms and voluntary motor ability below the level of injury, coupled with circulatory changes, place the person with SCI at major risk for disruption of skin integrity. Significant factors associated with disruption of skin integrity are pressure, shearing forces, and localized trauma and irritation. Relieving pressure, allowing adequate circulation to the skin, and skin inspection are primary ways of maintaining skin integrity. Of all the complications after SCI, skin breakdown is the most preventable.

In summary, spinal cord injury is a disabling neurologic condition most commonly caused by motor vehicle accidents, falls, and sports injuries. Dysfunctions of the nervous system after SCI comprise various degrees of sensorimotor loss and altered reflex activity based on the level of injury and extent of cord damage. Depending on the level of injury, the physical problems of SCI include spinal shock; ventilation and communication problems; ANS dysfunction that predisposes to the vasovagal response, autonomic hyperreflexia, impaired body temperature regulation, and postural hypotension; impaired muscle pump and venous innervation leading to edema of dependent areas of the body and risk of deep vein thrombosis; altered sensorimotor integrity that contributes to uncontrolled muscle spasms, altered pain responses, and threat to skin integrity; alterations in bowel and bladder elimination; and impaired sexual function.

REVIEW QUESTIONS

Define a motor unit and characterize its mechanism of controlling muscle movement.

Describe muscle atrophy and differentiate between disuse and degenerative atrophy.

Describe the pathology associated with Duchenne muscular dystrophy.

Relate the clinical manifestations of myasthenia gravis to its cause.

Compare the cause and manifestations of peripheral mononeuropathies with peripheral polyneuropathies.

Describe the functional organization of the basal ganglia and communication pathways with the thalamus and cerebral cortex.

State the possible mechanisms responsible for the development of Parkinson's disease and characterize the manifestations and treatment of the disorder.

Relate the functions of the cerebellum to production of vestibulocerebellar ataxia, decomposition of movement, and cerebellar tremor.

Relate the pathologic UMN and LMN changes that occur in amyotrophic lateral sclerosis to the manifestations of the disease.

Explain the significance of demyelination and plaque formation in multiple sclerosis.

Describe the manifestations of multiple sclerosis.

Explain how loss of UMN function contributes to the muscle spasms that occur after recovery from spinal cord injury.

State the effects of spinal cord injury on ventilation and communication, the ANS, cardiovascular function, sensorimotor function, and bowel and bladder function.

Sensory mechanisms provide individuals with a continuous stream of information about their bodies, the outside world, and the interactions between the two. The somatosensory component of the nervous system provides an awareness of body sensations such as touch, temperature, limb position, and pain.

ORGANIZATION AND CONTROL OF SOMATOSENSORY FUNCTION

The somatosensory system is designed to provide the central nervous system (CNS) with information about the body. Sensory neurons can be divided into three types that vary in distribution and the type of sensation detected: general somatic, special somatic, and general visceral afferent neurons (see Chapter 36). *General somatic afferent neurons* have branches with widespread distribution throughout the body and with many distinct types of receptors that result in sensations such as pain, touch, and temperature. *Special somatic afferent neurons* have receptors located primarily in muscles, tendons, and joints. These receptors sense position and movement of the body. *General visceral afferent neurons* have receptors on various visceral structures and sense fullness and discomfort.

Sensory Systems

Sensory systems can be conceptualized as a serial succession of neurons consisting of first-order, second-order, and third-order neurons. The *first-order neurons* contain the sensory receptors and transmit sensory information from the periphery to the CNS. The *second-order neurons* communicate with various reflex networks and sensory pathways in the spinal cord and contain the ascending pathways that travel to the thalamus. *Third-order neurons* relay information from the thalamus to the cerebral cortex (Fig. 39-1). Many interneurons process and modify the sensory information at the level of the second- and third-order neurons, and many more participate before coordinated and appropriate learned-movement responses occur.

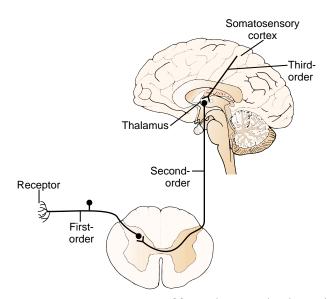

The Sensory Unit

The somatosensory experience arises from information provided by a variety of receptors distributed throughout the body. There are four major modalities of sensory experience: (1) discriminative touch, which is required to identify the size and shape of objects and their movement across the skin; (2) temperature sensation; (3) sense of movement of the limbs and joints of the body; and (4) nociception or pain sense.

Each of the somatosensory modalities is mediated by a distinct system of receptors and pathways to the brain. However, all somatosensory information from the limbs and trunk shares a common class of sensory neurons called *dorsal root ganglion neurons*. Somatosensory information from the face and cranial structures is transmitted by the trigeminal sensory neurons, which function in the same manner as the dorsal root ganglion neurons. The cell body of the dorsal root ganglion neuron, its receptor (which innervates a small area of periphery), and its central axon (which projects to the CNS) form a *sensory unit*. Individual dorsal root ganglion neurons respond selectively to specific types of stimuli because of their specialized peripheral terminals, or receptors.

Dermatomal Pattern of Dorsal Root Innervation

The somatosensory innervation of the body, including the head, retains a basic segmental organizational pattern that was established during embryonic development. The region of the body wall that is supplied by a single pair of dorsal root ganglia is called a *dermatome*. These dorsal root ganglion-

■ **FIGURE 39-1** ■ Arrangement of first-order, second-order, and third-order neurons of the somatosensory system.

KEY CONCEPTS

THE SOMATOSENSORY SYSTEM

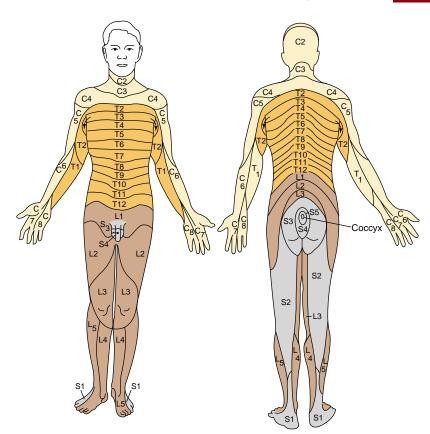

- The somatosensory system relays information to the CNS about four major body sensations: touch, temperature, pain, and body position. Stimulation of receptors on regions of the body wall is required to initiate the sensory response.
- The system is organized into dermatomes, with each segment supplied by a single dorsal root ganglion that sequentially relays the sensory information to the spinal cord, the thalamus, and the sensory cortex.
- Two pathways carry sensory information through the CNS. The discriminative pathway crosses in the medulla and relays touch and body position. The anterolateral pathway crosses in the spinal cord and relays temperature and pain sensation from the opposite side of the body.

innervated strips occur in a regular sequence moving upward from the second coccygeal segment through the cervical segments, reflecting the basic segmental organization of the body and the nervous system (Fig. 39-2). The cranial nerves that innervate the head send their axons to equivalent nuclei in the brain stem. Neighboring dermatomes overlap one another sufficiently so that a loss of one dorsal root or root ganglion results in reduced but not total loss of sensory innervation of a dermatome (Fig. 39-3). Dermatome maps are helpful in interpreting the level and extent of sensory deficits that are the result of segmental nerve and spinal cord damage.

Spinal Circuitry and Ascending Neural Pathways

On entry into the spinal cord, the central axons of the somatosensory neurons branch extensively and project to nuclei in the spinal gray matter. Some branches become involved in local spinal cord reflexes and directly initiate motor reflexes (*e.g.*, flexor-withdrawal reflex). Two parallel pathways, the rapid conducting *discriminative pathway* and the slower conducting *anterolateral pathway*, transmit information from the spinal cord to the thalamic level of sensation, each taking a different route through the CNS.

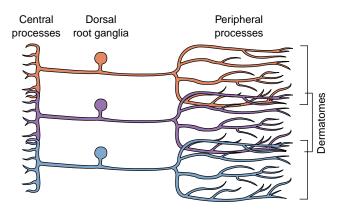

The Discriminative Pathway. The discriminative pathway, which crosses at the base of the medulla, is used for the rapid transmission of sensory information such as discriminative touch (Fig. 39-4). It contains branches of primary afferent axons that travel up the ipsilateral (*i.e.*, same side) dorsal columns of the spinal cord white matter and synapse with highly evolved somatosensory input association neurons in the medulla. The discriminative pathway uses only three neurons to transmit information from a sensory receptor to the somatosensory strip of parietal cerebral cortex of the opposite side of the brain: (1) the primary dorsal root ganglion neuron, which projects its central axon to the dorsal column nuclei; (2) the dorsal column neuron, which sends its axon through a rapid

■ FIGURE 39-2 ■ Cutaneous distribution of spinal nerves (dermatomes). (Barr, M. [1993]. *The human nervous system*. New York: Harper & Row)

conducting tract, called the *medial lemniscus*, that crosses at the base of the medulla and travels to the thalamus on the opposite side of the brain, where basic sensation begins; and (3) the thalamic neuron, which projects its axons through the somatosensory radiation to the primary sensory cortex. The medial lemniscus is joined by fibers from the sensory nucleus of the trigeminal nerve (cranial nerve V) that supplies the face. Sensory information arriving at the sensory cortex by this route can be discretely localized and discriminated in terms of intensity.

One of the distinct features of the discriminative pathway is that it relays precise information regarding spatial orientation. This is the only pathway taken by the sensations of muscle and joint movement, vibration, and delicate discriminative touch,

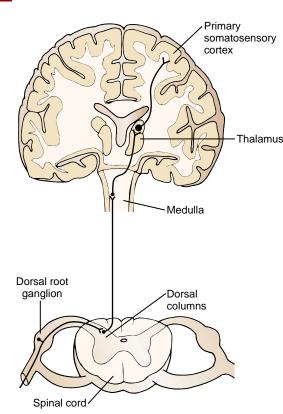

■ FIGURE 39-3 ■ The dermatomes formed by the peripheral processes of adjacent spinal nerves overlap on the body surface. The central processes of these fibers also overlap in their spinal distribution.

as is required to differentiate correctly the location of touch on the skin at two neighboring points (i.e., two-point discrimination). One of the important functions of the discriminative pathway is to integrate the input from multiple receptors. The sense of shape and size of an object in the absence of visualization, called stereognosis, is based on precise afferent information from muscle, tendon, and joint receptors. For example, a screwdriver is perceived as being different from a knife in terms of its texture (tactile sensibility) and shape based on the relative position of the fingers as they move over the object. This complex interpretive perception requires that the discriminative system must be functioning optimally and that higherorder parietal association cortex processing and prior learning must have occurred. If the discriminative somatosensory pathway is functional but the parietal association cortex has become discretely damaged, the person can correctly describe the object but does not recognize that it is a screwdriver. This deficit is called *astereognosis*.

The Anterolateral Pathway. The anterolateral pathways (anterior and lateral spinothalamic pathways), which crosses within the first few segments of entering the spinal cord, consists of bilateral multisynaptic slow-conducting tracts (Fig. 39-5). These pathways provide for transmission of sensory information such as pain, thermal sensations, crude touch, and pressure that does not require discrete localization of signal source or fine discrimination of intensity. The fibers of the anterolateral pathway originate in the dorsal horns at the level of the segmental nerve, where the dorsal root neurons enter the spinal cord. They cross in the anterior commissure of the cord, within a few segments of origin, to the opposite anterolateral pathway, where they ascend upward toward the brain. The spinothalamic tract

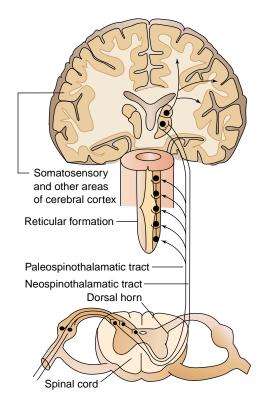

728 Unit Ten: Alterations in the Nervous System

■ FIGURE 39-4 ■ Discriminative pathway. This pathway is an ascending system for rapid transmission of sensations that relate joint movement (kinesthesis), body position (proprioception), vibration, and delicate touch. Primary afferents travel up the dorsal columns of the spinal cord white matter and synapse with somatosensory input association neurons in the medulla. Secondary neurons project through the brain stem to the thalamus and synapse with tertiary neurons, which relay the information to the primary somatosensory cortex on the opposite side of the brain.

fibers synapse with several nuclei in the thalamus, but en route they give off numerous branches that travel to the reticular activating system of the brain stem. These projections provide the basis for increased wakefulness or awareness after strong somatosensory stimulation and for the generalized startle reaction that occurs with sudden and intense stimuli. They also stimulate autonomic nervous system responses, such as an increase in blood pressure and heart rate, dilation of the pupils, and the pale, moist skin that results from constriction of the cutaneous blood vessels and activation of the sweat glands.

There are two subdivisions in the anterolateral pathway: the outer *neospinothalamic tract* and the inner *paleospinothalamic tract* (Fig. 39-5). The neospinothalamic tract, which carries bright pain, consists of a sequence of at least three neurons with long axons. It provides for relatively rapid transmission of sensory information to the thalamus. The paleospinothalamic tract, which is phylogenetically older than the neospinothalamic system, consists of bilateral, multisynaptic slowconducting tracts that transmit sensory signals that do not require discrete localization of signal source or discrimination of fine gradations in intensity. This slower-conducting pathway also projects into the intralaminar nuclei of the thalamus, which have close connections with the limbic cortical

■ FIGURE 39-5 ■ Neospinothalamic and paleospinothalamic subdivisions of the anterolateral sensory pathway. The neospinothalamic tract runs to the thalamic nuclei and has fibers that project to the somatosensory cortex. The paleospinothalamic tract sends collaterals to the reticular formation and other structures, from which further fibers project to the thalamus. These fibers influence the hypothalamus and the limbic system as well as the cerebral cortex.

systems. This circuitry provides touch with its affective or emotional aspects.

Central Processing of Somatosensory Information

Perception, or the final processing of somatosensory information, involves awareness of the stimuli, localization and discrimination of their characteristics, and interpretation of their meaning. As sensory information reaches the thalamus, it begins to enter the level of consciousness. In the thalamus, the sensory information is roughly localized and perceived as a crude sense. The full localization, discrimination of the intensity, and interpretation of the meaning of the stimuli require processing by the somatosensory cortex.

The somatosensory cortex is located in the parietal lobe, which lies behind the central sulcus and above the lateral sulcus (Fig. 39-6). The strip of parietal cortex that borders the central sulcus is called the *primary somatosensory cortex* because it receives primary sensory information by way of direct projections from the thalamus. A distorted map of the body and head surface, called the *sensory homunculus*, reflects the density of cortical neurons devoted to sensory input from afferents in corresponding peripheral areas. As depicted in Figure 39-7, most of the cortical surface is devoted to areas of the body such as the thumb, forefinger, lips, and tongue, where fine touch and pressure discrimination are essential for normal function.

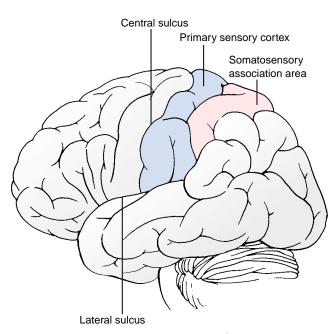

FIGURE 39-6 Primary somatosensory and association somatosensory cortex.

The somatosensory association cortex, which lies parallel to and just behind the primary somatosensory cortex, is required to transform the raw material of sensation into a meaningful experience. It is here that the stimulus pattern from the present sensory experience is integrated with past learning. For instance, a person's past learning plus present tactile sensation provide the perception of sitting on a soft chair, rather than on a hard bicycle seat.

Sensory Modalities

Somatosensory experience can be divided into *modalities*, a term used for qualitative, subjective distinctions between sensations such as touch, heat, and pain. Such experiences require the function of sensory receptors and forebrain structures in the thalamus and cerebral cortex. Sensory experience also involves quantitative sensory discrimination or the ability to distinguish between different levels of sensory stimulation.

The receptive endings of different afferent neurons are particularly sensitive to specific forms of physical and chemical energy. For instance, a receptive ending may be particularly sensitive to a small increase in local skin temperature. Other afferent sensory terminals are most sensitive to slight indentations of the skin, and their signals are subjectively interpreted as touch. Cool versus warm, sharp versus dull pain, and delicate touch versus deep pressure are all based on different populations of afferent neurons or on central integration of simultaneous input from several differently tuned afferents. For example, the sensation of itch results from a combination of high activity in pain- and touch-sensitive afferents, and the sensation of tickle requires a gently moving tactile stimulus over cool skin.

When information from different primary afferents reaches the forebrain, where subjective experience occurs, the qualitative differences between warmth and touch are called *sensory modalities*. Although the receptor-detected information is relayed to the thalamus and cortex over separate pathways, the experience of a modality, such as cold versus warm, is uniquely subjective.

Tactile Sensation

The tactile system, which relays sensory information regarding touch, pressure, and vibration, is considered the basic somatosensory system. Loss of temperature or pain sensitivity leaves the person with no awareness of deficiency. However, if the tactile system is lost, total anesthesia (*i.e.*, numbness) of the involved body part results.

Touch sensation results from stimulation of tactile receptors in the skin and in tissues immediately beneath the skin, pressure from deformation of deeper tissues, and vibration from rapidly repetitive sensory signals. There are at least six types of specialized tactile receptors in the skin and deeper structures: free nerve endings, Meissner's corpuscles, Merkel's disks, pacinian corpuscles, hair follicle end-organs, and Ruffini's endorgans^{1,2} (Fig. 39-8).

Free nerve endings are found in skin and many other tissues, including the cornea. They detect touch and pressure. *Meissner's corpuscles* are present in nonhairy parts of the skin. They are particularly abundant in the fingertips, lips, and other areas where the sense of touch is highly developed. *Meissner's corpuscles* are particularly sensitive to movement of very light objects over the surface of the skin and to low frequency vibration. *Merkel's disks* are found in nonhairy areas and in hairy parts of the skin. They are responsible for giving steady-state signals that allow for continuous determination of touch against the skin.

The *pacinian corpuscle* is located immediately beneath the skin and deep in the fascial tissues of the body and is important in detecting tissue vibration. The *hair follicle end-organs* detect movement on the surface of the body. *Ruffini's end-organs* are found in the skin and deeper structures, including the joint

capsules. These receptors are important for signaling continuous states of deformation, such as heavy and continuous touch and pressure.

The sensory information for tactile sensation enters the spinal cord through the dorsal roots of the spinal nerves. All tactile sensation that requires rapid transmission is transmitted through the discriminative pathway to the thalamus by way of the medial lemniscus. This includes touch sensation requiring a high degree of localization or fine gradations of intensity, vibratory sensation, and sensation that signals movement against the skin. In addition to the ascending discriminative pathway, tactile sensation also uses the more primitive and crude anterolateral pathway. The second-order dorsal horn neurons of this pathway have many branches or collaterals. After several synapses, axons are projected up both sides of the anterolateral aspect of the spinal cord to the thalamus. Few fibers travel all the way to the thalamus. Most synapse on reticular formation neurons that then send their axons on toward the thalamus, where a crude, poorly localized sensation from the opposite side of the body is received. From the thalamus, some projections travel to the somatosensory cortex.

Because of these multiple routes, total destruction of the pathways for tactile sensation seldom occurs. The only time this crude alternative system becomes essential is when the discriminative pathway is damaged. Then, despite projection of the anterolateral system information to the somatosensory cortex, only a poorly localized, high-threshold sense of touch remains. Such persons lose all sense of joint and muscle movement, body position, and two-point discrimination.

Thermal Sensation

Thermal sensation is discriminated by three types of receptors: cold receptors, warmth receptors, and pain receptors. The cold and warmth receptors are located immediately under the skin at discrete but separate points. In some areas, there are more cold receptors than warmth receptors. For example, the lips have 15 to 25 cold receptors per square centimeter, compared with 3 to 5 in the same-sized area of the finger.¹ There are also correspondingly fewer warmth receptors in these areas. The gradations of heat and cold result from selective stimulation of the different types of thermal receptors. The thermal receptors are very sensitive to differences between the temperature

of skin and temperature of objects that are touched. Warmth receptors respond proportionately to increases in skin temperature above resting values of 34°C and cool receptors to temperatures below 34°C.³

The thermal pain receptors are stimulated only by extremes of temperature such as "freezing cold" (temperatures below 5°C) and "burning hot" (temperatures above 45°C) sensations.³ With the exception of pain receptors, thermal receptors tend to adapt rapidly during the first few minutes and then more slowly during the next 30 minutes or so. However, these receptors do not appear to adapt completely, as evidenced by the experience of an intense sense of heat on entering a tub of hot water or the extreme degree of cold initially sensed when going outside on a cold day. On entering the dorsal horn, thermal signals are transmitted by neurons whose axons then cross to the opposite side of the cord and ascend in the multisynaptic, slow-conducting anterolateral system to the opposite side of the brain.

Conduction of thermal information through peripheral nerves is quite slow compared with the rapid tactile afferents that travel through the discriminative system. If a person places a foot in a tub of hot water, the tactile sensation occurs well in advance of the burning sensation. The foot has been removed from the hot water by the local withdrawal reflex well before the excessive heat is perceived by the forebrain. Local anesthetic agents block the small-diameter afferents that carry thermal sensory information before they block the large-diameter axons that carry touch information.

Position Sensation

Position sense refers to the sense of limb and body movement and position without using vision. It is mediated by input from proprioceptive receptors (muscle spindle receptors and Golgi tendon organs) found primarily in muscles, tendons, and joint capsules (see Chapter 38). There are two submodalities of proprioception: the stationary or static component (limb position sense) and the dynamic aspects of position sense (kinesthesia). Both of these depend on constant transmission of information to the CNS regarding the rate of change and degree of angulation of all joints. In addition, there are a number of mechanoreceptors in the joint capsules and ligaments. Many resemble Ruffini's end-organs, pacinian corpuscles, and Merkel's cells. Signals from these receptors are processed through the discriminative pathway. It appears that information from the joint receptors is combined with that from the muscle spindles and Golgi tendon organs, and probably from skin receptors that estimate joint angle. Removing one source of information can be compensated by use of other sources.

In summary, the somatosensory component of the nervous system provides an awareness of body sensations such as touch, temperature, position sense, and pain. There are three primary levels of neural integration in the somatosensory system: the sensory units containing the sensory receptors, the ascending pathways, and the central processing centers in the thalamus and cerebral cortex. A sensory unit consists of a single dorsal root ganglion neuron, its receptors, and its central axon that terminates in the dorsal horn of the spinal cord or medulla. The part of the body innervated by the somatosensory afferent neurons of one set of dorsal root ganglia is called a dermatome. Ascending pathways include the discriminative pathway, which crosses at the base of the medulla, and the anterolateral pathway, which crosses within the first few segments of entering the spinal cord. Perception, or the final processing of somatosensory information, involves centers in the thalamus and somatosensory cortex. In the thalamus, the sensory information is crudely localized and perceived. The full localization, discrimination of the intensity, and interpretation of the meaning of the stimuli require processing by the somatosensory cortex. A distorted map of the body and head surface, called the sensory homunculus, reflects the density of cortical neurons devoted to sensory input from afferents in corresponding peripheral areas.

The tactile system relays the sensations of touch, pressure, and vibration. It uses two anatomically separate pathways to relay touch information to the opposite side of the forebrain: the dorsal column discriminative pathway and the anterolateral pathway. Delicate touch, vibration, position, and movement sensations use the discriminative pathway to reach the thalamus, where third-order relay occurs to the primary somatosensory strip of parietal cortex. Crude tactile sensation is carried by the bilateral slow-conducting anterolateral pathway. Temperature sensations of warm-hot and cool-cold are the result of stimulation to thermal receptors of sensory units projecting to the thalamus and cortex through the anterolateral system on the opposite side of the body. Proprioception is the sense of limb and body movement and position without using vision. It is mediated by input muscle spindle receptors and Golgi tendon organs found in muscles, tendons, and joint capsules and by mechanoreceptors (e.g., Ruffini's endorgans, pacinian corpuscles, and Merkel's cells) in the joint capsules and ligaments.

PAIN

Pain is an "unpleasant sensory and emotional experience associated with potential tissue damage, or described in terms of such damage."⁴ It involves anatomic structures, physiologic behaviors, and psychological, social, cultural, and cognitive factors. Pain can be a prepotent or overwhelming experience, often disruptive of customary behavior, and when severe, it demands and directs all of a person's attention. Pain is the most common symptom that motives a person to seek professional help. It sends those who suffer to a health care facility more often and with more speed than any other symptoms. Its location, radiation, duration, and severity provide important clues as to its cause. Despite its unpleasantness, pain can serve a useful purpose because it warns of impending tissue injury, motivating the person to seek relief. For example, an inflamed appendix could progress in severity, rupture, and even cause death were it not for the warning afforded by the pain.

Pain Theories

Traditionally, two theories have been offered to explain the physiologic basis for the pain experience. The first, *specificity theory*, regards pain as a separate sensory modality evoked by the activity of specific receptors that transmit information to pain centers or regions in the forebrain where pain is experienced.⁵ The second theory includes a group of theories collectively referred to as *pattern theory*. It proposes that pain receptors share endings or pathways with other sensory modalities

KEY CONCEPTS

PAIN SENSATION

- Pain is both a protective and an unpleasant physical and emotionally disturbing sensation originating in pain receptors that respond to a number of stimuli that threaten tissue integrity.
- There are two pathways for pain transmission:
 - \Box The fast pathway for sharply discriminated pain that moves directly from the receptor to the spinal cord using myelinated Aδ fibers and from the spinal cord to the thalamus using the neospinothalamic tract
 - The slow pathway for continuously conducted pain that is transmitted to the spinal cord using unmyelinated C fibers and from the spinal cord to the thalamus using the more circuitous and slower-conducting paleospinothalamic tract.
- The central processing of pain information includes transmission to the somatosensory cortex, where pain information is perceived and interpreted; the limbic system, where the emotional components of pain are experienced; and to brain stem centers, where autonomic nervous system responses are recruited.
- Modulation of the pain experience occurs by way of the endogenous analgesic center in the midbrain, the pontine noradrenergic neurons, and the nucleus raphe magnus in the medulla, which sends inhibitory signals to dorsal horn neurons in the spinal cord.

732 Unit Ten: Alterations in the Nervous System

but that different patterns of activity (*i.e.*, spatial or temporal) of the same neurons can be used to signal painful and nonpainful stimuli.⁵ For example, light touch applied to the skin would produce the sensation of touch through low-frequency firing of the receptor; intense pressure would produce pain through high-frequency firing of the same receptor. Both theories focus on the neurophysiologic basis of pain, and both probably apply. Specific nociceptive afferents have been identified; however, almost all afferent stimuli, if driven at a very high frequency, can be experienced as painful.

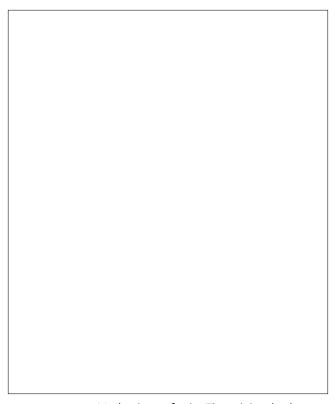

Gate control theory, a modification of specificity theory, was proposed by Melzack and Wall in 1965 to meet the challenges presented by the pattern theories.⁶ This theory postulated the presence of neural gating mechanisms at the segmental spinal cord level to account for interactions between pain and other sensory modalities. According to the gate control theory, the internuncial neurons involved in the gating mechanism are activated by large-diameter, faster-propagating fibers that carry tactile information. The simultaneous firing of the large-diameter touch fibers has the potential for blocking the transmission of impulses from the small-diameter myelinated and unmyelinated pain fibers.

More recently, Melzack has developed the neuromatrix theory to address further the brain's role in pain as well as the multiple dimensions and determinants of pain.⁷ This theory is particularly useful in understanding chronic pain and phantom limb pain, in which there is not a simple one-to-one relationship between tissue injury and pain experience. The neuromatrix theory proposes that the brain contains a widely distributed neural network, called the *body-self neuromatrix*, that contains somatosensory, limbic, and thalamocortical components. Genetic and sensory influences determine the synaptic architecture of an individual's neuromatrix that integrates multiple sources of input and evokes the sensory, affective, and cognitive dimensions of pain experience and behavior. These multiple input sources include somatosensory; other sensory impulses affecting interpretation of the situation; inputs from the brain addressing such things as attention, expectation, culture, and personality; intrinsic neural inhibitory modulation; and various components of stress-regulation systems.

Pain Mechanisms and Pathways

Pain usually is viewed in the context of tissue injury. The term *nociception*, which means "pain sense," comes from the Latin word *nocere* ("to injure"). Nociceptive stimuli are objectively defined as stimuli of such intensity that they cause or are close to causing tissue damage. Researchers often use the withdrawal reflex (*e.g.*, the reflexive withdrawal of a body part from a tissue-damaging stimulus) to determine when a stimulus is nociceptive. Stimuli used include pressure from a sharp object, strong electric current to the skin, or application of heat or cold of approximately 10°C above or below normal skin temperature. At low levels of intensity these noxious stimuli do activate nociceptors (pain receptors) but typically are perceived as painful only when the intensity reaches a level where tissue damage occurs or is imminent.

The mechanisms of pain are many and complex (Fig. 39-9). As with other forms of somatosensation, the pathways are composed of first-, second-, and third-order neurons. The first-order neurons and their receptive endings detect stimuli that threaten

■ FIGURE 39-9 ■ Mechanisms of pain. Tissue injury leads to release of inflammatory mediators with subsequent nociceptor stimulation. Pain impulses are then transmitted to dorsal horn of the spinal cord, where they make contact with second-order neurons that cross to the opposite side of the cord and ascend via the spinothalamic tract to the reticular activating system (RAS) and thalamus. The localization and meaning of pain occurs at the level of the somatosensory cortex.

the integrity of innervated tissues. Second-order neurons are located in the spinal cord and process nociceptive information. Third-order neurons project pain information to the brain. The thalamus and cortex integrate and modulate pain as well as the person's subjective reaction to the pain experience.

Pain Receptors and Mediators

Nociceptors, or pain receptors, are sensory receptors that are activated by noxious insults to peripheral tissues (Fig 39-9). Structurally, the receptive endings of the peripheral pain fibers are free nerve endings. These receptive endings, which are widely distributed in the skin, dental pulp, periosteum, meninges, and some internal organs, translate the noxious stimuli into action potentials that are transmitted by a dorsal root ganglion to the dorsal horn of the spinal cord. Nociceptive action potentials are transmitted through two types of afferent nerve fibers: myelinated Aδ fibers and unmyelinated C fibers. The larger Aδ fibers have considerably greater conduction velocities, transmitting impulses at a rate of 10 to 30 m/second. The C fibers are the smallest of all peripheral nerve fibers; they transmit impulses at the rate of 0.5 to 2.5 m/second. Pain conducted by A δ fibers traditionally is called *fast pain* and typically is elicited by mechanical or thermal stimuli. C-fiber pain often is described as slow-wave pain because it is slower in onset and longer in duration. It typically is incited by chemical stimuli or by persistent mechanical or thermal stimuli. The slow-wave potentials generated in C fibers are now believed to be responsible for central sensitization to chronic pain.

Stimulation of Nociceptors. Unlike other sensory receptors, nociceptors respond to several forms of stimulation, including mechanical, thermal, and chemical. Some receptors respond to a single type of stimuli (mechanical or thermal), and others, called *polymodal receptors*, respond to all three types of stimuli (mechanical, thermal, and chemical). Mechanical stimuli can arise from intense pressure applied to skin or from the violent contraction or extreme stretch of a muscle. Both extremes of heat and cold can stimulate nociceptors. Chemical stimuli arise from a number of sources, including tissue trauma, ischemia, and inflammation. A wide range of chemical mediators are released from injured and inflamed tissues, including hydrogen and potassium ions, prostaglandins, leukotrienes, histamine, bradykinin, acetylcholine, and serotonin. These chemical mediators produce their effects by directly stimulating nociceptors or sensitizing them to the effects of nociceptive stimuli; perpetuating the inflammatory responses that lead to the release of chemical agents that act as nociceptive stimuli; or inciting neurogenic reflexes that increase the response to nociceptive stimuli. For example, bradykinin, histamine, serotonin, and potassium activate and also sensitize nociceptors. Adenosine triphosphate, acetylcholine, and platelets act alone or in concert to sensitize nociceptors through other chemical agents such as prostaglandins. Aspirin and other nonsteroidal analgesic drugs are effective in controlling pain because they block the enzyme needed for prostaglandin synthesis.

Nociceptive stimulation that activates C fibers can cause a response known as *neurogenic inflammation* that produces vasodilation and an increased release of chemical mediators to which nociceptors respond. This mechanism is thought to be mediated by a dorsal root neuron reflex that produces retrograde transport and release of chemical mediators, which in turn causes increasing inflammation of peripheral tissues. This reflex can set up a vicious cycle, which has implications for persistent pain and hyperalgesia.⁸ Local anesthetics (*e.g.*, procaine [Novocain]) can prevent the spread of sensitization and secondary hyperalgesia caused by stimulation of cutaneous nociceptors by blocking the dorsal root neuron reflex.⁹

Mediators in the Spinal Cord. In the spinal cord, the transmission of impulses between the nociceptive neurons and the dorsal horn neurons is mediated by chemical neurotransmitters released from central nerve endings of the nociceptive neurons. Some of these neurotransmitters are amino acids (e.g., glutamate), others are amino acid derivatives (e.g., norepinephrine), and still others are low-molecular-weight peptides composed of two or more amino acids. The amino acid glutamate is a major excitatory neurotransmitter released from the central nerve endings of the nociceptive neurons. Substance P, a neuropeptide, also is released in the dorsal horn by C fibers in response to nociceptive stimulation. Substance P elicits slow excitatory potentials in dorsal horn neurons. Unlike glutamate, which confines its action to the immediate area of the synaptic terminal, some neuropeptides released in the dorsal horn can diffuse some distance because they are not inactivated by reuptake mechanisms. In persistent pain, this may help to explain the excitability and unlocalized nature of many painful

conditions. Neuropeptides such as substance P also appear to prolong and enhance the action of glutamate. If these neurotransmitters are released in large quantities or over extended periods, they can lead to secondary hyperalgesia, a condition in which the second-order neurons are overly sensitive to low levels of noxious stimulation. Understanding how chemical mediators function in nociception is an active area of research that has implications for the development of new treatments for pain.

Spinal Cord Circuitry and Pathways

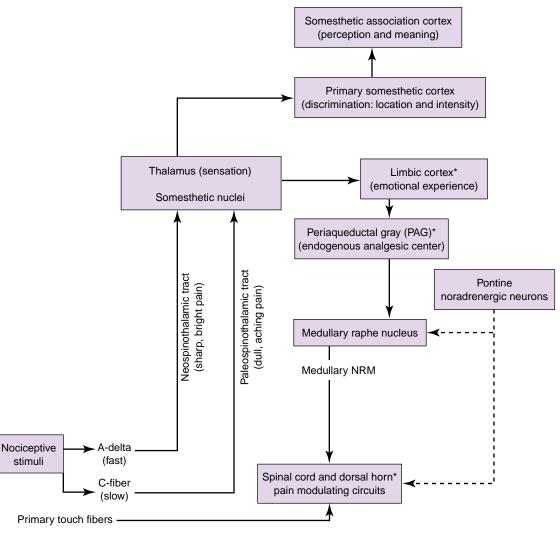

On entering the spinal cord through the dorsal roots, the pain fibers bifurcate and ascend or descend one or two segments before synapsing with association neurons in the dorsal horn. From the dorsal horn, the axons of association projection neurons cross through the anterior commissure to the opposite side and then ascend upward in the previously described neospinothalamic and paleospinothalamic pathways (Fig. 39-10).

The faster-conducting fibers in the neospinothalamic pathway (*i.e.*, lateral spinothalamic tract) are associated mainly with the transmission of sharp-fast pain information to the thalamus.¹ In the thalamus, synapses are made and the pathway continues to the contralateral parietal somatosensory area to provide the precise location of the pain. Typically, the pain is experienced as bright, sharp, or stabbing in nature. There is also a local cord-level withdrawal reflex that is designed to remove endangered tissue from a damaging stimulus.

The paleospinothalamic tracts are slower-conducting, multisynaptic pathways concerned with the diffuse, dull, aching, and unpleasant sensations that commonly are associated with chronic and visceral pain.¹ This information travels through the small, unmyelinated C fibers. Fibers of this system also project up the contralateral (i.e., opposite) anterolateral pathway to terminate in several thalamic regions, including those that project to the limbic system, where it is associated with the emotional aspects of pain. Fibers from the spinoreticular tract project bilaterally to the reticular formation of the brain stem. This component of the paleospinothalamic system facilitates avoidance reflexes at all levels. It also contributes to an increase in the electroencephalographic activity associated with alertness and indirectly influences hypothalamic functions associated with sudden alertness, such as increased heart rate and blood pressure. This may explain the tremendous arousal effects of certain pain stimuli.

Brain Centers and Pain Perception

The basic sensation of hurtfulness, or pain, occurs at the level of the thalamus. In the neospinothalamic system, interconnections between the lateral thalamus and the somatosensory cortex are necessary to add precision and discrimination to the pain sensation. Association areas of the parietal cortex are essential to the learned meaningfulness of the pain experience. For example, if a person is stung on the index finger by a bee and only the thalamus is functional, the person reports pain somewhere on the hand. With the primary sensory cortex functional, the person can localize the pain to the precise area on the index finger. With the association cortex functional, the person can interpret the buzzing and sight of the bee that preceded the pain as being related to the bee sting. The paleospinothalamic system projects diffusely from the intralaminar nuclei of the thalamus to large areas of the limbic cortex. These

* Location of opioid receptors

■ FIGURE 39-10 ■ Primary pain pathways. The transmission of incoming nociceptive impulses is modulated by dorsal horn circuitry that receives input from peripheral touch receptors and from descending pathways that involve the limbic cortical systems (orbital frontal cortex, amygdala, and hypothalamus), periaqueductal endogenous analgesic center in the midbrain, pontine noradrenergic neurons, and the nucleus raphe magnus (NRM) in the medulla. Dashed lines indicate inhibition or modulation.

connections probably are associated with the hurtfulness and the mood-altering and attention-narrowing effect of pain.

Central Pathways for Pain Modulation

A major advance in understanding pain was the discovery of neuroanatomic pathways that arise in the midbrain and brain stem, descend to the spinal cord, and modulate ascending pain impulses. One such pathway begins in an area of the midbrain called the *periaqueductal* gray (PAG) region. Through research it was found that focal stimulation of the midbrain PAG regions produced a state of analgesia. The resultant analgesia lasted for many hours and was sufficient to permit abdominal surgery, although levels of consciousness and reactions to auditory and visual stimuli remained unaffected. A few years later, opioid receptors were found to be highly concentrated in this and other regions of the CNS where electrical stimulation produced analgesia. Because of these findings, the PAG area of the midbrain often is referred to as the *endogenous analgesia center*.

The PAG area receives input from widespread areas of the CNS, including the cerebral cortex, hypothalamus, brain stem reticular formation, and spinal cord by way of the paleospinothalamic and neospinothalamic tracts. This region is intimately connected to the limbic system, which is associated with emotional experience. The neurons of the PAG area in the midbrain have axons that descend into an area called the *nucleus raphe magnus* (NRM) in the rostral medulla. The axons of these NRM neurons project to the dorsal horn of the spinal cord, where they terminate in the same layers as the entering primary pain fibers (Fig. 39-10). Stimulation of the NRM is thought to inhibit pain transmission by dorsal horn projection neurons.¹⁰ There also is evidence of noradrenergic neurons that can inhibit transmission of pain impulses at the level of the spinal cord. The discovery that norepinephrine can block pain transmission led to studies directed at the combined administration of opioids and clonidine, a central-acting α -adrenergic agonist for some types of pain relief.

Serotonin also has been identified as a neuromodulator in the NRM medullary nuclei that project to the spinal cord. It has been shown that tricyclic antidepressant compounds, such as amitriptyline, have analgesic properties independent of their antidepressant effects. These drugs, which enhance the effects of serotonin by blocking its presynaptic uptake, have been found to be effective in the management of certain types of chronic pain.¹¹

Endogenous Analgesic Mechanisms. There is evidence that the endogenous opioid peptides, morphine-like substances synthesized in many regions of the CNS including the spinal cord and PAG, modulate pain in the CNS. Three families of opioid peptides have been identified-the enkephalins, endorphins, and dynorphins. Although the endogenous opioid peptides appear to function as neurotransmitters, their full significance in pain control and other physiologic functions is not completely understood. Probably of greater importance in understanding mechanisms of pain control has been the characterization of receptors that bind the endogenous opioid peptides. The identification of these receptors has facilitated a more thorough understanding of the actions of available opioid drugs, such as morphine, and it also has facilitated ongoing research into the development of newer preparations that are more effective in relieving pain and have fewer side effects.

Pain Threshold and Tolerance

Pain threshold and tolerance affect an individual's response to a painful stimulus. Although the terms often are used interchangeably, pain threshold and pain tolerance have distinct meanings. Pain threshold is closely associated with tissue damage and the point at which a stimulus is perceived as painful. Pain tolerance relates more to the total pain experience; it is defined as the maximum intensity or duration of pain that a person is willing to endure before the person wants something done about the pain. Psychological, familial, cultural, and environmental factors significantly influence the amount of pain a person is willing to tolerate. The threshold to pain is fairly uniform from one person to another, whereas pain tolerance is extremely variable.12 Separation and identification of the role of each of these two aspects of pain continue to pose fundamental problems for the pain management team and for pain researchers.

Types of Pain

The most widely accepted classifications of pain are according to source or location, referral, and duration (acute or chronic). Classification based on associated medical diagnosis (*e.g.*, surgery, trauma, cancer, sickle cell disease, fibromyalgia) is useful in planning appropriate interventions.

Cutaneous and Deep Somatic Pain

Cutaneous pain arises from superficial structures, such as the skin and subcutaneous tissues. A paper cut on the finger is an example of easily localized superficial, or cutaneous, pain. It is

KEY CONCEPTS

TYPES OF PAIN

- Pain can be classified according to location, site of referral, and duration.
- Cutaneous pain is a sharp, burning pain that has its origin in the skin or subcutaneous tissues.
- Deep pain is a more diffuse and throbbing pain that originates in structures such as the muscles, bones, and tendons and radiates to the surrounding tissues.
- Visceral pain is a diffuse and poorly defined pain that results from stretching, distention, or ischemia of tissues in a body organ.
- Referred pain is pain that originates at a visceral site but is perceived as originating in part of the body wall that is innervated by neurons entering the same segment of the nervous system.
- Acute pain usually results from tissue damage and is characterized by autonomic nervous system responses.
- Chronic pain is persistent pain that is accompanied by loss of appetite, sleep disturbances, depression, and other debilitating responses.

a sharp, bright pain with a burning quality and may be abrupt or slow in onset. It can be localized accurately and may be distributed along the dermatomes. Because there is an overlap of nerve fiber distribution between the dermatomes, the boundaries of pain frequently are not as clear-cut as the dermatomal diagrams indicate.

Deep somatic pain originates in deep body structures, such as the periosteum, muscles, tendons, joints, and blood vessels. This pain is more diffuse than cutaneous pain. Various stimuli, such as strong pressure exerted on bone, ischemia to a muscle, and tissue damage, can produce deep somatic pain. This is the type of pain a person experiences from a sprained ankle. Radiation of pain from the original site of injury can occur. For example, damage to a nerve root can cause a person to experience pain radiating along its fiber distribution.

Visceral Pain

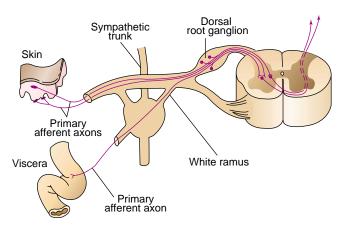

Visceral, or splanchnic, pain has its origin in the visceral organs. Common examples of visceral pain are renal colic, pain caused by cholecystitis, pain associated with acute appendicitis, and peptic ulcer pain. Although the viscera are diffusely and richly innervated, cutting or burning of viscera, as opposed to similar noxious stimuli applied to cutaneous or superficial structures, is unlikely to cause pain. Instead, strong abnormal contractions of the gastrointestinal system, distention, or ischemia affecting the walls of the viscera can induce severe visceral pain. Anyone who has had severe gastrointestinal distress or ureteral colic can readily attest to the misery involved. Visceral pain is transmitted by small unmyelinated pain fibers that travel with the axons of the autonomic nervous system and project to visceral input association neurons of the cord or brain stem. In addition to sending projections to the forebrain, these input association neurons also project through the paleospinal and spinoreticular pathways into visceral reflex circuits. Visceral pain typically is accompanied by autonomic nervous system responses such as nausea, vomiting, sweating, and pallor and, less commonly, is followed by shock.

The visceral pain pathways travel with the parasympathetic distribution for the upper and lower viscera and with the sympathetic distribution for the intervening viscera. Pain from the viscera may be localized only with difficulty. There are several explanations for this. First, innervation of visceral organs is poorly represented at the forebrain levels (*i.e.*, perception). A second possible explanation is that the brain does not easily learn to localize sensations that originate in organs that are only imprecisely visualized. For example, a cut on the third finger of the right hand can be readily seen, identified, and localized, whereas an inflamed internal organ can be localized only vaguely. A third explanation is that sensory information from thoracic and abdominal viscera can travel by two pathways to the CNS.

Referred Pain

Referred pain is pain that is perceived at a site different from its point of origin but innervated by the same spinal segment. It is hypothesized that visceral and somatic afferent neurons converge on the same dorsal horn projection neurons (Fig. 39-11). For this reason, it can be difficult for the brain to correctly identify the original source of pain. Pain that originates in the abdominal or thoracic viscera is diffuse and poorly localized and often perceived at a site far removed from the affected area. For example, the pain associated with myocardial infarction commonly is referred to the left arm, neck, and chest.

Referred pain may arise alone or concurrent with pain located at the origin of the noxious stimuli. This lack of correspondence between the location of the pain and the location

■ FIGURE 39-11 ■ Convergence of cutaneous and visceral inputs onto the same second-order projection neuron in the dorsal horn of the spinal cord. Although virtually all visceral inputs converge with cutaneous inputs, most cutaneous inputs do not converge with other sensory inputs. (From Conn P.M. [1995]. *Neuroscience in medicine*. Philadelphia: J.B. Lippincott)

of the painful stimuli can make diagnosis difficult. Although the term *referred* usually is applied to pain that originates in the viscera and is experienced as if originating from the body wall, it also may be applied to pain that arises from somatic structures. For example, pain referred to the chest wall could be caused by nociceptive stimulation of the peripheral portion of the diaphragm, which receives somatosensory innervation from the intercostal nerves. An understanding of pain referral is of great value in diagnosing illness. The typical pattern of pain referral can be derived from our understanding that the afferent neurons from visceral or deep somatic tissue enter the spinal cord at the same level as the afferent neurons from the cutaneous areas to which the pain is referred (Fig. 39-12).

The sites of referred pain are determined embryologically with the development of visceral and somatic structures that share the same site for entry of sensory information into the CNS and then move to more distant locations. For example, a person with peritonitis may report pain in the shoulder. Inter-

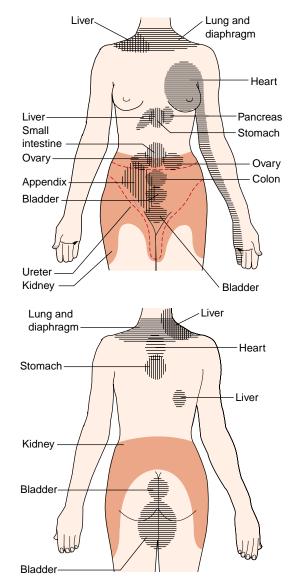

FIGURE 39-12 Areas of referred pain. (**Top**) Anterior view. (**Bottom**) Posterior view.

TADLE 20 1

nally, there is inflammation of the peritoneum that lines the central part of the diaphragm. In the embryo, the diaphragm originates in the neck, and its central portion is innervated by the phrenic nerve, which enters the cord at the level of the third to fifth segments (C3 to C5). As the fetus develops, the diaphragm descends to its adult position between the thoracic and abdominal cavities, while maintaining its embryonic pattern of innervation. Thus, fibers that enter the spinal cord at the C3 to C5 level carry information from both the neck area and the diaphragm, and the diaphragmatic pain is interpreted by the forebrain as originating in the shoulder or neck area.

Muscle spasm, or *guarding*, occurs when somatic structures are involved. Guarding is a protective reflex rigidity; its purpose is to protect the affected body parts (*e.g.*, an abscessed appendix or a sprained muscle). This protective guarding may cause blood vessel compression and give rise to the pain of muscle ischemia, causing local and referred pain.

Acute and Chronic Pain

It is common to classify pain according to its duration. Pain research of the past three decades has emphasized the importance of differentiating acute pain from chronic pain. The diagnosis and therapy for each is distinctive because they differ in cause, function, mechanisms, and psychological sequelae (Table 39-1).

Acute Pain. The classic definition of acute pain is pain that lasts less than 6 months. This somewhat arbitrary cutoff point reflects the notion that acute pain is the result of a tissuedamaging event, such as trauma or surgery, and usually is selflimited, ending when the injured tissues heal. The purpose of acute pain is to serve as a warning system. Besides alerting the person to the existence of actual or impending tissue damage, it prompts a search for professional help. The pain's location, radiation, intensity, and duration as well as those factors that aggravate or relieve it provide essential diagnostic clues.

Acute pain can lead to anxiety and secondary reflex musculoskeletal spasms, which in turn tend to worsen the pain.¹³ Interventions that alleviate the pain usually alleviate the anxiety and musculoskeletal spasms as well. Inadequately treated pain can provoke physiologic responses that alter circulation and tissue metabolism and produce physical manifestations, such as tachycardia, reflective of increased sympathetic activity. Inadequately treated acute pain tends to decrease mobility and respiratory movements such as deep breathing and coughing to the extent that it may complicate or delay recovery.

Chronic Pain. Chronic pain classically has been defined as pain lasting 6 months or longer. However, in practice one does not wait an arbitrary 6 months before deciding that the pain is chronic; rather, one considers the normal expected healing time for the underlying cause of the pain. The International Association for the Study of Pain defines chronic pain as that which persists beyond the expected normal time of healing.¹³ Chronic pain can be quite variable. It may be unrelenting and extremely severe, as in metastatic bone pain. It can be relatively continuous with or without periods of escalation, as with some forms of back pain. Some conditions with recurring episodes of acute pain are particularly problematic because they have characteristics of both acute and chronic pain. These include the pain associated with sickle cell crisis or migraine headaches.

and Chronic Pain

component Associated depress Somatic p occupa Withdraw outside Decreased	sion pre- ition
Other types of Decreased response Decreased Appetite of	d libido

*Responses are approximately proportional to intensity of the stimulus.

Chronic pain is a leading cause of disability in the United States. Unlike acute pain, persistent chronic pain usually serves no useful function. In contrast, it imposes physiologic, psychological, familial, and economic stresses and may exhaust a person's resources.

Persons with chronic pain may not exhibit the somatic, autonomic, or affective behaviors often associated with acute pain. As painful conditions become prolonged and continuous, autonomic nervous system responses decrease. Decreased pain tolerance, which may result from the depletion of serotonin and endorphins, and depression are common in individuals with chronic pain. There is often loss of appetite, sleep disturbances, and depression.14 The link between depression and decreased pain tolerance may be explained by the similar manner in which both respond to changes in the biologic pathways of serotonergic and noradrenergic systems.¹⁴ Tricyclic antidepressants and other medications with serotonergic and noradrenergic effects have been shown to relieve a variety of chronic pain syndromes, lending credence to the theory that chronic pain and depression share a common biologic pathway.14

Pain Management

Assessment

Careful assessment of pain assists clinicians in diagnosing, managing, and relieving the patient's pain. Assessment includes such things as the nature, severity, location, and radiation of the pain. As with other disease states, it is preferable to eliminate the cause of the pain, rather than simply to treat the symptom. A careful history often provides information about the triggering factors (i.e., injury, infection, or disease) and the site of nociceptive stimuli (i.e., peripheral receptor or visceral organ). Although the observation of facial expression and posture may provide additional information, current AHCPR practice guidelines emphasize that "the single most reliable indicator of the existence and intensity of acute pain-and any resultant affective discomfort or distress—is the patient's self report."15,16 A comprehensive pain history should include pain onset; description, localization, radiation, intensity, quality, and pattern of the pain; anything that relieves or exacerbates it; and the individual's personal reaction to the pain.

Unlike many other bodily responses, such as temperature and blood pressure, the nature, severity, and distress of pain cannot be measured objectively. To overcome this problem, various methods have been developed for quantifying a person's pain. Most of these are based on the patient's report. They include numeric pain intensity, visual analog, and verbal descriptor scales.

Treatment

The therapeutic approaches to acute and chronic pain differ markedly. In acute pain, therapy is directed at providing pain relief by interrupting the nociceptive stimulus. Acute pain should be aggressively managed and pain medication provided before the pain becomes severe. This allows the person to be more comfortable and active and to assume a greater role in directing his or her own care. Because the pain is self-limited, in that it resolves as the injured tissues heal, long-term therapy usually is not needed.

Chronic pain management is much more complex and is based on multiple considerations. It usually requires early attempts to prevent pain and adequate therapy for acute bouts of pain. Specific treatment depends on the cause of the pain, the natural history of the underlying health problem, and the life expectancy of the individual. If the organic illness causing the pain cannot be cured, noncurative methods of pain control become the cornerstone of treatment. Treatment methods for chronic pain can include pharmacological and nonpharmacological interventions. Pharmacological treatment includes the use of non-narcotic and narcotic medications. Non-narcotic medications such as tricyclic antidepressants, antiseizure medications, and nonsteroidal anti-inflammatory drugs (NSAIDs) serve as useful adjuncts to opioids for the treatment of different types of chronic pain. Nonpharmacological interventions include neural blockade, electrical modalities (e.g., transcutaneous electrical nerve stimulation [TENS]), physical therapy, and cognitive behavioral interventions (e.g., imagery and relaxation strategies). Chronic pain is best handled by a multidisciplinary team that includes specialists in areas such as anesthesiology, nursing, physical therapy, social services, and surgery.

Cancer is a common cause of chronic pain. The goal of chronic cancer pain management should be pain alleviation and prevention.¹⁶ Preemptive therapy tends to reduce sensitization of pain pathways and provides for more effective pain control. Pharmacological and nonpharmacological interventions are the same as those used for other types of chronic pain. Depending on the form and stage of the cancer, other treatments such as palliative radiation, antineoplastic therapies, and palliative surgery may help to control the pain. The World Health Organization has created an analgesic ladder for cancer pain that assists clinicians in choosing the appropriate analgesic medications.¹⁷

Pharmacologic Treatment. An analgesic drug is a medication that acts on the nervous system to decrease or eliminate pain without inducing loss of consciousness. Analgesic drugs do not cure the underlying cause of the pain, but their appropriate use may prevent acute pain from progressing to chronic pain. Pain medications are commonly divided into three categories: non-narcotic analgesics, opioid or narcotic analgesics, and adjuvant analgesics.

Non-narcotic Analgesics. Common non-narcotic oral analgesic medications include aspirin, other NSAIDs, and acetaminophen. Aspirin, or acetylsalicylic acid, acts centrally and peripherally to block the transmission of pain impulses. It also has antipyretic and anti-inflammatory properties. Aspirin and the other NSAIDs inhibit several forms of prostaglandins through the inhibition of cyclooxygenase, an enzyme in the prostanoid pathway. Prostaglandins affect the sensation of pain by sensitizing nociceptors to chemical mediators such as bradykinin and histamine. Independent of prostaglandins, NSAIDs also decrease the sensitivity of blood vessels to bradykinin and histamine, affect lymphokine production by T lymphocytes, reverse vasodilation, and decrease the release of inflammatory mediators from granulocytes, mast cells, and basophils. Acetaminophen is an alternative to the NSAIDs. Although usually considered equivalent to aspirin as an analgesic and antipyretic agent, it lacks anti-inflammatory properties.

Opioid Analgesics. The term opioid or narcotic is used to refer to a group of medications, natural or synthetic, with morphine-like actions. The opioids (e.g., morphine, codeine, and many other semisynthetic congeners of morphine) exert their action through opioid receptors. There are three major categories of opioid receptors in the CNS, designated mu (μ , for "morphine"), delta (δ), and kappa (κ).¹⁸ Analgesia, as well as respiratory depression, miosis, reduced gastrointestinal motility (causing constipation), feelings of well-being or euphoria, and physical dependence result principally from morphine and morphine-like opioid analgesics that act at mu receptors. Part of the pain-relieving properties of exogenous opioids such as morphine involves the release of endogenous opioids.¹⁸

Opioids are used in the management of acute and chronic pain. When given for temporary relief of severe pain, such as that occurring after surgery, there is much evidence that opioids given routinely before the pain starts or becomes extreme are far more effective than those administered in a sporadic manner. Persons who are treated in this manner seem to require fewer doses and are able to resume regular activities sooner. Opioids also are used for persons with chronic pain such as that caused by cancer. Too often, because of undue concern about the possibility of addiction, many individuals with chronic pain receive inadequate pain relief. Addiction is not considered a problem in patients with cancer.¹⁹ Most pain experts agree that it is appropriate to provide the level of opioid necessary to relieve the severe intractable pain of persons whose life expectancy is limited. Morphine remains the most useful strong opioid, and the World Health Organization has recommended that oral morphine be part of the essential medication list and made available throughout the world as the medication of choice for cancer pain.²⁰

Adjuvant Analgesics. Adjuvant analgesics include medications such as tricyclic antidepressants, antiseizure medications, and neuroleptic anxiolytic agents. The fact that the pain suppression system has nonendorphin synapses raises the possibility that potent, centrally acting, nonopiate medications may be useful in relieving pain. Serotonin has been shown to play an important role in producing analgesia. The tricyclic antidepressant medications block the removal of serotonin from the synaptic cleft to produce pain relief in some persons. These medications are particularly useful in some chronic painful conditions, such as postherpetic neuralgia. Certain antiseizure medications, such as carbamazepine and phenytoin, have analgesic effects in some pain conditions. These medications, which suppress spontaneous neuronal firing, are particularly useful in the management of pain that occurs after nerve injury. Other agents, such as the corticosteroids, may be used to decrease inflammation and nociceptive stimuli responsible for pain.

Surgical Intervention. The effects of surgical interventions may be curative or palliative. Surgical interventions that remove the source of the pain (*e.g.*, inflamed appendix) are curative. In other instances, surgery is used for symptom management, rather than for cure. Surgery for severe, intractable pain of peripheral or central origin has met with some success. It can be used to remove the cause or block the transmission of intractable pain from phantom limb pain, severe neuralgia, inoperable cancer of certain types, and causalgia.

In summary, pain is an elusive and complex phenomenon; it is a symptom common to many illnesses. It is a highly individualized experience that is shaped by a person's culture and previous life experiences, and it is difficult to measure. Traditionally, there have been two principal theories of pain: the specificity and pattern theories. Scientifically, pain is viewed within the context of nociception. Nociceptors are receptive nerve endings that respond to noxious stimuli. Pain receptors respond to mechanical, thermal, and chemical stimuli. Nociceptive neurons transmit impulses to the dorsal horn neurons using chemical neurotransmitters. The neospinothalamic and the paleospinothalamic paths are used to transmit pain information to the brain. Several neuroanatomic pathways as well as endogenous opioid peptides modulate pain in the CNS.

Pain can be classified according to location, referral, and duration as well as associated medical diagnoses. Pain can arise from cutaneous, deep somatic, or visceral locations. Referred pain is pain perceived at a site different from its origin. Acute pain is self-limiting pain that ends when the injured tissue heals, whereas chronic pain is pain that lasts much longer than the anticipated healing time for the underlying cause of the pain. Pain threshold, pain tolerance, age, gender, and other factors affect an individual's reaction to pain.

Treatment modalities for pain include the use of nonpharmacologic and pharmacologic agents used singly or in combination. It is becoming apparent that even with chronic pain, the most effective approach is early treatment or even prevention. After pain is present, the greatest success in pain assessment and management is achieved with the use of an interdisciplinary approach.

ALTERATIONS IN PAIN SENSITIVITY AND SPECIAL TYPES OF PAIN

Alterations in Pain Sensitivity

Sensitivity and perception of pain varies among persons and in the same person under different conditions and in different parts of the body. Irritation, mild hypoxia, and mild compression of a peripheral nerve often result in hyperexcitability of the sensory nerve fibers or cell bodies. This is experienced as unpleasant hypersensitivity (*i.e.*, *hyperesthesia*) or increased painfulness (*i.e.*, *hyperalgesia*). Possible causes of increased sensitivity to noxious stimuli include a decrease in the threshold of nociceptors, an increase in pain produced by suprathreshold stimuli, and the windup phenomenon. Primary hyperalgesia occurs at the site of injury. Secondary hyperalgesia occurs in nearby uninjured tissue.

Hyperpathia is a syndrome in which the sensory threshold is raised, but when it is reached, continued stimulation, especially if repetitive, results in a prolonged and unpleasant experience. This pain can be explosive and radiates through a peripheral nerve distribution. It is associated with pathologic changes in peripheral nerves, such as localized ischemia. Spontaneous, unpleasant sensations called *paresthesias* occur with more severe irritation (*e.g.*, the pins-and-needles sensation that follows temporary compression of a peripheral nerve). The general term *dysesthesia* is given to distortions (usually unpleasant) of somesthetic sensation that typically accompany partial loss of sensory innervation.

More severe pathologic processes can result in reduced or lost tactile (*e.g., hypoesthesia, anesthesia*), temperature (*e.g., hypothermia, athermia*), and pain sensation (*i.e., hypalgesia*). Analgesia is the absence of pain on noxious stimulation or the relief of pain without loss of consciousness. The inability to sense pain may result in trauma, infection, and even loss of a body part or parts. Inherited insensitivity to pain may take the form of congenital indifference or congenital insensitivity to pain. In the former, transmission of nerve impulses appears normal, but the appreciation of painful stimuli at higher levels appears to be absent. In the latter, a peripheral nerve defect apparently exists such that transmission of painful nerve impulses does not result in perception of pain. Whatever the cause, persons who lack the ability to perceive pain are at constant risk of tissue damage because pain is not serving its protective function.

Allodynia (Greek allo, "other," and odynia, "painful") is the term used for the puzzling phenomenon of pain that follows a non-noxious stimulus to apparently normal skin. This term is

740 Unit Ten: Alterations in the Nervous System

intended to refer to instances in which otherwise normal tissues may be abnormally innervated or may be referral sites for other loci that give rise to pain with non-noxious stimuli. It may be that an area is hypersensitive because of inflammation, injury, or another cause, and a normally subthreshold stimulus is sufficient to trigger the sensation of pain. This response is thought to be chemically mediated, possibly the result of tissue damage in the surrounding area. Trigger points are highly localized points on the skin or mucous membrane that can produce immediate intense pain at that site or elsewhere when stimulated by light tactile stimulation. Myofascial trigger points are foci of exquisite tenderness found in many muscles and can be responsible for pain projected to sites remote from the points of tenderness. Trigger points are widely distributed in the back of the head and neck and in the lumbar and thoracic regions. These trigger points cause reproducible myofascial pain syndromes in specific muscles. These pain syndromes are the major source of pain in clients at chronic pain treatment centers.

Special Types of Pain

Neuropathic Pain

When peripheral nerves are affected by injury or disease, it can lead to unusual and sometimes intractable sensory disturbances. These include numbness, paresthesias, and pain. Depending on the cause, few or many axons could be damaged and the condition could be unilateral or bilateral. Causes of neuropathic pain can be categorized according to the extent of peripheral nerve involvement. Conditions that can lead to pain by causing damage to peripheral nerves in a single area include nerve entrapment, nerve compression from a tumor mass, and various neuralgias (e.g., trigeminal, postherpetic, and post-traumatic). Conditions that can lead to pain by causing damage to peripheral nerves in a wide area include diabetes mellitus, long-term alcohol use, hypothyroidism, renal insufficiency, and drug treatment with neurotoxic agents.²¹ Injury to a nerve also can lead to a multisymptom, multisystem syndrome called complex regional pain syndrome (previously known as causalgia or reflex sympathetic dystrophy). Nerve damage associated with amputation is believed to be a cause of phantom limb pain.

Neuropathic pain can vary with the extent and location of disease or injury. There may be allodynia or pain that is stabbing, jabbing, burning, or shooting. The pain may be persistent or intermittent. The diagnosis depends on the mode of onset, the distribution of abnormal sensations, the quality of the pain, and other relevant medical conditions (*e.g.*, diabetes, hypothyroidism, alcohol use, rash, or trauma). Injury to peripheral nerves sometimes results in pain that persists beyond the time required for the tissues to heal. Peripheral pathologic processes (*e.g.*, neural degeneration, neuroma formation, and generation of abnormal spontaneous neural discharges from the injured sensory neuron) and neural plasticity (*i.e.*, changes in CNS function) are the primary working hypotheses to explain persistent neuropathic pain.

Treatment methods include measures aimed at restoring or preventing further nerve damage (*e.g.*, surgery to resect a tumor causing nerve compression, improving glycemic control for diabetic patients with painful neuropathies), and interventions for the palliation of pain. Although many adjuvant analgesics are used for neuropathic pain, pain control often is difficult. The initial approach in seeking adequate pain control is to try these drugs in sequence and then in combination. If there has been a poor response to the adjuvant analgesics, opioids also can be used. Nonpharmacologic therapies such as electrical stimulation of the peripheral nerve or spinal cord can be used for radiculopathies and neuralgias. As a last resort, neurolysis or neurosurgical blockade sometimes is used.

Neuralgia

Neuralgia is characterized by severe, brief, often repetitive attacks of lightning-like or throbbing pain. It occurs along the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve.

Trigeminal Neuralgia. Trigeminal neuralgia, or *tic douloureux*, is one of the most common and severe neuralgias. It is manifested by facial tics or grimaces and characterized by stabbing, paroxysmal attacks of pain that usually are limited to the unilateral sensory distribution of one or more branches of the trigeminal nerve, most often the maxillary or mandibular divisions. Although intermittent, the pain often is excruciating and may be triggered by light touch. The treatment of trigeminal neuralgia may include carbamazepine, an antiseizure drug, or surgery to release the vessels or scar tissue, or destroy or block branches of cranial nerve V. Other interventions include avoidance of precipitating factors (*e.g.*, stimulation of trigger spots) and eye injury caused by irritation; provision for adequate nutrition; and avoidance of social isolation.

Postherpetic Neuralgia. Postherpetic pain is pain that persists as a complication of herpes zoster or shingles. It describes the presence of pain more than 1 month after the onset of the acute attack. Postherpetic neuralgia develops in from 10% to 70% of patients with shingles²²; the risk increases with age. The pain of postherpetic neuralgia occurs in the areas of innervation of the infected ganglia. During the acute attack of herpes zoster, the reactivated virus travels from the ganglia to the skin of the corresponding dermatomes, causing localized vesicular eruption and hyperpathia (i.e., abnormally exaggerated subjective response to pain). In the acute infection, proportionately more of the large nerve fibers are destroyed. Regenerated fibers appear to have smaller diameters. Because there is a relative loss of large fibers with age, elderly persons are particularly prone to suffering because of the shift in the proportion of large- to small-diameter nerve fibers. Older patients have pain, dysesthesia, and hyperesthesia after the acute phase; these are increased by minor stimuli.

Early treatment of shingles with high doses of systemic corticosteroids and an oral antiviral drug such as acyclovir or valacyclovir, a medication that inhibits herpesvirus DNA replication, may reduce the incidence of postherpetic neuralgia. Initially, postherpetic neuralgia can be treated with a topical anesthetic agent. A tricyclic antidepressant medication may be used for pain relief. Regional nerve blockade (*i.e.*, stellate ganglion, epidural, local infiltration, or peripheral nerve block) has been used with limited success.

Complex Regional Pain Syndrome

Recently, the International Association for the Study of Pain created the terms *complex regional pain syndrome I* and *complex regional pain syndrome II*. These terms refer, respectively, to re-

flex sympathetic dystrophy and causalgia. Trauma, frequently minor, to a nerve is the major cause. However, injury to soft tissue or a broken bone also can cause these pain syndromes. The hallmark is pain and mobility problems more severe than the injury warrants. Characteristically, the pain is severe and burning with or without deep aching. Usually, the pain can be elicited with the slightest movement or touch to the affected area; it increases with repetitive stimulation; and it lasts even after the stimulation has stopped. The pain can be exacerbated by emotional upsets or any increased peripheral sympathetic nerve stimulation. The variations of complex regional pain syndromes include sympathetic components. These are characterized by vascular and trophic (e.g., dystrophic or atrophic) changes to the skin, soft tissue, and bone, and can include rubor or pallor, sweating or dryness, edema (often sharply demarcated), skin atrophy, and with time, patchy osteoporosis.

According to the clinical practice guideline the cornerstone of treatment is promoting normal use of the affected part to the extent possible.²³ Initially, oral analgesics (including the adjuvant analgesics), TENS, and physical activity are used. Interruption of sympathetic innervation may considered. If treatment by sympathetic blockade provides relief from pain, sympathectomy may be considered. If not, electrical stimulation of the spinal cord or narcotics may be considered.

Phantom Limb Pain

Phantom limb pain, a type of neurologic pain, follows amputation of a limb or part of a limb. As many as 70% of those who under amputation experience phantom pain.²⁴ The pain often begins as sensations of tingling, heat and cold, or heaviness, followed by burning, cramping, or shooting pain. It may disappear spontaneously or persist for many years. One of the more troublesome aspects of phantom pain is that the person may experience painful sensations that were present before the amputation, such as that of a painful ulcer or bunion.

Several theories have been proposed as to the causes of phantom pain.²⁴ One theory is that the end of a regenerating nerve becomes trapped in the scar tissue of the amputation site. It is known that when a peripheral nerve is cut, the scar tissue that forms becomes a barrier to regenerating outgrowth of the axon. The growing axon often becomes trapped in the scar tissue, forming a tangled growth (*i.e.*, neuroma) of smalldiameter axons, including primary nociceptive afferents and sympathetic efferents. It has been proposed that these afferents show increased sensitivity to innocuous mechanical stimuli and to sympathetic activity and circulating catecholamines. A related theory moves the source of phantom limb pain to the spinal cord, suggesting that the pain is caused by the spontaneous firing of spinal cord neurons that have lost their normal sensory input from the body. In this case, a closed self-exciting neuronal loop in the posterior horn of the spinal cord is postulated to send impulses to the brain, resulting in pain. Even the slightest irritation to the amputated limb area can initiate this cycle. Other theories propose that the phantom limb pain may arise in the brain. In one hypothesis, the pain is caused by changes in the flow of signals through somatosensory areas of the brain. Treatment of phantom limb pain has been accomplished by the use of sympathetic blocks, TENS of the large myelinated afferents innervating the area, hypnosis, and relaxation training.

In summary, pain may occur with or without an adequate stimulus, or it may be absent in the presence of an adequate stimulus—either of which describes a pain disorder. There may be analgesia (absence of pain), hyperalgesia (increased sensitivity to pain), hypalgesia (a decreased sensitivity to painful stimuli), hyperpathia (an unpleasant and prolonged response to pain), hyperesthesia (an abnormal increase in sensitivity to sensation), hypoesthesia (an abnormal decrease in sensitivity to sensations), paresthesia (abnormal touch sensation such as tingling or "pins and needles" in the absence of external stimuli), or allodynia (pain produced by stimuli that do not normally cause pain).

Neuropathic pain may be caused by trauma or disease of neurons in a focal area or in a more global distribution (e.g., from endocrine disease or neurotoxic medications). Neuralgia is characterized by severe, brief, often repetitiously occurring attacks of lightning-like or throbbing pain that occurs along the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve. Trigeminal neuralgia, or tic douloureux, is one of the most common and severe neuralgias. It is manifested by facial tics or grimaces. Postherpetic neuralgia is a chronic pain that can occur after shingles, an infection of the dorsal root ganglia and corresponding areas of innervation by the herpes zoster virus. Complex regional pain syndrome is an extremely painful condition that may follow sudden and traumatic deformation of peripheral nerves. Phantom limb pain, a neurologic pain, can occur after amputation of a limb or part of a limb.

HEADACHE

Headache is a common health problem. Seventy-six percent of women and 57% of men report at least one headache a month.²⁵ Headache is caused by a number of conditions. Some headaches represent primary disorders, and others occur secondary to other disease conditions in which head pain is a symptom.

The most common types of primary or chronic headaches are migraine headache, tension-type headache, and cluster headache. In 1988, the International Headache Society published a proposed classification of headaches that lists diagnostic criteria for both primary headache syndromes and headaches that occur secondary to other medical conditions (see Chart 39-1 for a summary of the components of the system).²⁶

Although most causes of secondary headache are benign, some are indications of serious disorders, such as meningitis, brain tumor, or cerebral aneurysm. The sudden onset of a severe, intractable headache in an otherwise healthy person is more likely related to a serious intracranial disorder, such as subarachnoid hemorrhage or meningitis, than to a chronic headache disorder. Headaches that disturb sleep, exertional headaches, and headaches accompanied by neurologic symptoms such as drowsiness, visual or limb disturbances, or altered mental status also are indicative of underlying intracranial lesions or other pathology.

CHART 39-1 Classification and Diagnostic Criteria for Headache Disorders, Cranial Neuralgias, and Facial Pain

- 1. Migraine
 - 1.1 Migraine without aura
 - 1.2 Migraine with aura
 - 1.3 Ophthalmoplegic migraine
 - 1.4 Retinal migraine
 - 1.5 Childhood periodic syndromes that may be precursors to or associated with migraine
 - 1.6 Complications with migraine
 - 1.7 Migrainous disorder not fulfilling above criteria
- 2. Tension-type headache
 - 2.1 Episodic tension-type headache
 - 2.2 Chronic tension-type headache
 - 2.3 Headache of the tension type not fulfilling the above criteria
- 3. Cluster headache and chronic paroxysmal hemicrania
- 4. Miscellaneous headaches unassociated with structural lesion
- 5. Headache associated with head trauma
- 6. Headache associated with vascular disorders
- 7. Headache associated with nonvascular intracranial disorders
- 8. Headache associated with substances or their withdrawal
- 9. Headache associated with noncephalic infection
- 10. Headache associated with metabolic disorder
- 11. Headache or facial pain associated with disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
- 12. Cranial neuralgias, nerve trunk pain, and deafferentation pain
- 13. Headache not classifiable

(Adapted from Oleson J. [1988]. Classification and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain. *Cephalgia* 8 [Suppl 7], 13–19)

The diagnosis and classification of headaches often is difficult. It requires a comprehensive history and physical examination to exclude secondary causes. The history should include factors that precipitate headache, such as foods and food additives, missed meals, and association with the menstrual period. A careful medication history is essential because many medications can provoke or aggravate headaches. Alcohol also can cause or aggravate headache. A headache diary in which the person records his or her headaches and concurrent or antecedent events may be helpful in identifying factors that contribute to headache onset. Appropriate laboratory and imaging studies of the brain may be done to rule out secondary headaches.

Migraine Headache

Migraine headaches affect more than 10 million persons in the United States. They occur more frequently in women than men and result in considerable time lost from work and other activities.²⁷ Migraine headaches tend to run in families and are

thought to be inherited as an autosomal dominant trait with incomplete penetrance.²⁵

There are two categories of migraine headache-migraine without aura, which accounts for approximately 85% of migraines, and migraine with aura, which accounts for most of the remaining migraines. Migraine without aura is a pulsatile, throbbing, unilateral headache that typically lasts 1 to 2 days and is aggravated by routine physical activity. The headache is accompanied by nausea and vomiting, which often is disabling, and a sensitivity to light and sound. Visual disturbances occur quite commonly and consist of visual hallucinations such as stars, sparks, and flashes of light. Migraine with aura has similar symptoms, but with the addition of visual or neurologic symptoms that precede the headache. The aura usually develops over a period of 5 to 20 minutes and lasts less than an hour. Although only a small percentage of persons with migraine experience an aura before an attack, many persons without aura have prodromal symptoms, such as fatigue and irritability, that precede the attack by hours or even days.

Subtypes of migraine include ophthalmoplegic migraine, hemiplegic migraine, aphasic migraine, and retinal migraine, in which transient visual and motor deficits occur. Ophthalmoplegic migraine is characterized by diplopia, caused by a transient paralysis of the muscles that control eye movement (usually the third cranial nerve), and localized pain around the eye. Migraine headache also can present as a mixed headache, including symptoms typically associated with tension-type headache or chronic daily headache. These are called *transformed migraine* and are difficult to classify.

The mechanisms of migraine attacks are poorly understood. There is increasing evidence to support a neurogenic basis for migraine. Supporting this neurogenic concept is the common presence of premonitory symptoms before the headache begins; the presence of focal neurologic disturbances, which cannot be explained in terms of cerebral blood flow; and the numerous accompanying symptoms, including autonomic and constitutional dysfunction.²⁵ The pathophysiologic process of migraine probably involves alterations in serotonin function and occurrence of inflammatory disturbances in the trigeminal vascular system.²⁵ Hormonal variations, particularly in estrogen levels, play a role in the pattern of migraine attacks. For many women, migraine headaches coincide with their menstrual periods. The greater predominance of migraine headaches in women is thought to be related to the aggravating effect of estrogen on the migraine mechanism.²⁵ Dietary substances, such as monosodium glutamate, aged cheese, and chocolate, also may precipitate migraine headaches. The actual triggers for migraine are the chemicals in the food, not allergens.

The treatment of migraine headaches includes preventative and abortive nonpharmacologic and pharmacologic treatment. In 1998, the U.S. Headache Consortium, a multidisciplinary panel, produced a set of evidence-based guidelines for the nonpharmacologic and pharmacologic management and prevention of migraine headaches in primary care settings.²⁷

Nonpharmacologic treatment includes the avoidance of migraine triggers, such as foods, that precipitate an attack. Many persons with migraines benefit from maintaining regular eating and sleeping habits. Measures to control stress, which also can precipitate an attack, also are important. During an attack, many persons find it helpful to retire to a quiet, darkened room until symptoms subside.

Pharmacologic treatment involves both abortive therapy for acute attacks and preventive therapy. A wide range of medications is used to treat the acute symptoms of migraine headache.²⁸ These include 5-HT₁ (serotonin) receptor agonists (*e.g.*, the triptans), ergotamine derivatives, analgesics (*e.g.*, acetylsalicylic acid, acetaminophen, and NSAIDs such as naproxen sodium), sedatives (*e.g.*, butalbital), and antiemetic medications. Frequent use of abortive headache medications may cause rebound headache or perpetuate chronic daily headaches.

Preventative pharmacologic treatment may be necessary if migrainous headaches are disabling or occur more than two or three times a month. In most cases, preventative treatment must be taken daily for months to years. The β -adrenergic blocking medications are usually the first choice for prophylactic treatment because of empiric support for their effectiveness, safety, efficacy, and favorable side effect profile. Several other medications that may be effective prophylactically for migraine headache are antidepressants, selective serotonin reuptake inhibitors, calcium channel blockers, antiseizure medications (*e.g.*, divalproex sodium, valproic acid), ergot derivatives (methysergide), and NSAIDs (naproxen sodium).²⁹ When a decision to discontinue preventive therapy is made, the medications should be gradually withdrawn.

There may be serious side effects with some of the antimigraine medications. Because of the risk of coronary vasospasm, the serotonin receptor agonists should not be given to persons with coronary artery disease. Ergotamine preparations can cause uterine contractions and should not be given to pregnant women. They also can cause vasospasm and should be used with caution in persons with peripheral vascular disease.

Migraine Headache in Children

Migraine headaches occur in children as well as adults.^{30,31} Before puberty, migraine headaches are equally distributed between the sexes. The essential diagnostic criterion for migraine in children is the presence of recurrent headaches separated by pain-free periods. Diagnosis is based on at least three of the following symptoms or associated findings: abdominal pain, nausea or vomiting, throbbing headache, unilateral location, associated aura (visual, sensory, motor), relief during sleep, and a positive family history.³¹ Symptoms vary widely among children, from those that interrupt activities and cause the child to seek relief in a dark environment, to those detectable only by direct questioning. A common feature of migraine in children is intense nausea and vomiting. The vomiting may be associated with abdominal pain and fever; thus, migraine may be confused with other conditions such as appendicitis. More than half of children with migraine undergo spontaneous prolonged remission after their 10th birthday. Because headaches in children can be a symptom of other, more serious disorders, including intracranial lesions, it is important that other causes of headache that require immediate treatment be excluded.

Cluster Headache

Cluster headaches are relatively uncommon headaches that affect men more often than women. These headaches tend to occur in clusters over weeks or months, followed by a long, headache-free remission period. Typically the symptoms in cluster headaches include severe, unrelenting, unilateral pain located, in order of decreasing frequency, in the orbital, retroorbital, temporal, supraorbital, and infraorbital region. The pain is of rapid onset and builds to a peak in approximately 10 to 15 minutes, lasting for 15 to 180 minutes. The pain behind the eye radiates to the ipsilateral trigeminal nerve (*e.g.*, temple, cheek, gum). The headache frequently is associated with one or more symptoms such as conjunctival redness, lacrimation, nasal congestion, rhinorrhea, forehead and facial sweating, miosis, ptosis, and eyelid edema. Because of their location and associated symptoms, cluster headaches are often mistaken for sinus infections or dental problems.²⁵

The underlying pathophysiologic mechanisms of cluster headaches are unknown. Hypotheses include the interplay of vascular, neurogenic, metabolic, and humoral factors. Although the trigeminovascular system appears to be involved in the pathogenesis of cluster headache, a theory to explain the symptoms, periodicity, and circadian regularity of cluster headaches does not exist. The regularity in the timing of cluster headache may be caused by dysfunction of the hypothalamic biologic clock mechanisms. Ipsilateral lacrimation, nasal stuffiness, and rhinorrhea are thought to result from parasympathetic overactivity. Pain and vasodilation are thought to result from activation of the trigeminovascular system.

Because of the relatively short duration and self-limited nature of cluster headache, oral preparations typically take too long to reach therapeutic levels. The most effective treatments are those that act quickly (*e.g.*, oxygen inhalation and subcutaneous sumatriptan). Intranasal lidocaine also may be effective.²⁵ Oxygen inhalation may be indicated for home use. Prophylactic medications for cluster headaches include ergotamine, verapamil, methysergide, lithium carbonate, corticosteroids, sodium valproate, and indomethacin.

Tension-type Headache

The most common type of headache is tension-type headache. Unlike migraine and cluster headaches, tension-type headache usually is not sufficiently severe that it interferes with daily activities. Tension-type headaches frequently are described as dull, aching, diffuse, nondescript headaches, occurring in a hatband distribution around the head, and not associated with nausea or vomiting or worsened by activity. They can occur infrequently or be episodic or chronic.

The exact mechanisms of tension-type headache are not known, and the hypotheses of causation are contradictory. One popular theory is that tension-type headache results from sustained tension of the muscles of the scalp and neck; however, some research has found no correlation between muscle contraction and tension-type headache. Many authorities now believe that tension-type headaches are forms of migraine headache.²⁵ It is thought that migraine headache may be transformed gradually into chronic tension-type headache. Tension-type headaches also may be caused by oromandibular dysfunction, psychogenic stress, anxiety, depression, and muscular stress. They also may result from overuse of analgesics or caffeine. Daily use of caffeine, whether in beverages or medications, can produce addiction, and a headache can develop in such persons who go without caffeine for several hours.²⁵

Tension-type headaches often are more responsive to nonpharmacologic techniques, such as biofeedback, massage, acupuncture, relaxation, imagery, and physical therapy, than are other types of headache. For persons with poor posture, a combination of range-of-motion exercises, relaxation, and posture improvement may be helpful.²⁶

The medications of choice for acute treatment of tensiontype headaches are analgesics, including acetylsalicylic acid, acetaminophen, and NSAIDs. Persons with infrequently occurring tension-type headaches usually self-medicate using over-the-counter analgesics to treat the acute pain and do not require prophylactic medication. These agents should be used cautiously because rebound headaches can develop when the medications are taken regularly.

Because the "dividing lines" between tension-type headache, migraine, and chronic daily headache often are vague, addition of medications as well as the entire range of migraine medications may be tried in refractory cases. Other medications used concomitantly with analgesics include sedatives (*e.g.*, butalbital), anxiolytics (*e.g.*, diazepam), and skeletal muscle relaxants (*e.g.*, orphenadrine). Prophylactic treatment can include antidepressants (*e.g.*, amitriptyline, doxepin).

Temporomandibular Joint Pain

A common cause of head pain is temporomandibular joint (TMJ) syndrome. It usually is caused by an imbalance in joint movement because of poor bite, bruxism (*i.e.*, teeth grinding), or joint problems such as inflammation, trauma, and degenerative changes.³² The pain almost always is referred and commonly presents as facial muscle pain, headache, neck ache, or earache. Referred pain is aggravated by jaw function. Headache associated with this syndrome is common in adults and children and can cause chronic pain problems.

Treatment of TMJ pain is aimed at correcting the problem, and in some cases this may be difficult. The initial therapy for TMJ should be directed toward relief of pain and improvement in function. Pain relief often can be achieved with use of the NSAIDs. Muscle relaxants may be used when muscle spasm is a problem. In some cases, the selected application of heat or cold, or both, may provide relief. Referral to a dentist who is associated with a team of therapists, such as a psychologist, physical therapist, or pain specialist, may be indicated.³²

Head pain is a common disorder that is caused by a number of conditions. Some headaches represent primary disorders and others occur secondary to another disease state in which head pain is a symptom. Primary headache disorders include migraine headache, tension-type headache, and cluster headache. Although most causes of secondary headache are benign, some are indications of serious disorders, such as meningitis, brain tumor, or cerebral aneurysm. TMJ syndrome is one of the major causes of headaches. It usually is caused by an imbalance in joint movement because of poor bite, teeth grinding, or joint problems such as inflammation, trauma, and degenerative changes.

PAIN IN CHILDREN AND OLDER ADULTS

Pain frequently is underrecognized and undertreated in both children^{33,34} and the elderly.³⁵ In addition to the common obstacles to adequate pain management, such as concern about

the effects of analgesia on respiratory status and the potential for addiction to opioids, there are additional deterrents to adequate pain management in children and the elderly. With regard to both children and the elderly, there are stereotypic beliefs that they feel less pain than do other patients.^{33–36} These beliefs may affect a clinician's opinion about the need for pain control. In very young children and confused elderly, there are several additional factors. These include the extreme difficulty of assessing the location and intensity of pain in individuals who are cognitively immature or cognitively impaired, and the argument that even if they feel pain, they do not remember it.

Pain in Children

Human responsiveness to painful stimuli begins in the neonatal period and continues through the life span. Although the specific and localized behavioral reactions are less marked in the younger neonate or the more cognitively impaired individual, protective or withdrawal reflexes in response to nociceptive stimuli are clearly demonstrated. Pain pathways, cortical and subcortical centers, and neurochemical responses associated with pain transmission are developed and functional by the last trimester of pregnancy. As infants mature and children grow, their responses to pain become more complex and reflective of their maturing cognitive and developmental processes.³⁶ Children do feel pain and have been shown reliably and accurately to report pain at as young as 3 years of age. They also remember pain, as evidenced in studies of children with cancer, whose distress during painful procedures increases over time without intervention, and in neonates in intensive care units, who demonstrate protective withdrawal responses to a heel stick after repeated episodes.

The assessment of pain in children is somewhat complicated, but research has led to the development of a variety of developmentally appropriate measurement tools. These include scales with faces of actual children or cartoon faces that can be used to elicit a pain report from young children. In older children and adolescents, numeric scales (*i.e.*, 1 to 10) and word graphic scales (*i.e.*, "none," "a little," "most I have ever experienced") can be used. Another strategy for assessing a child's pain is to use a body outline and ask the child to indicate where the hurt is located. Particular care must be taken is assessing children's reports of pain because their report may be influenced by a variety of factors, including age, anxiety and fear levels, and parental presence.

The management of children's pain basically falls into two categories: pharmacologic and nonpharmacologic. In terms of pharmacologic interventions, many of the analgesics used in adults can be used safely and effectively in children and adolescents. However, it is critical when using specific medications to determine that the medication has been approved for use with children and that it is dosed appropriately according to the child's weight. As with any person in pain, the type of analgesic used should be matched to the type and intensity of pain; and whether the patient is a child or adult, the management of chronic pain may require a multidisciplinary team. The overriding principle in all pediatric pain management is to treat each child's pain on an individual basis and to match the analgesic agent with the cause and the level of pain. A second principle involves maintaining the balance between the level of side effects and pain relief such that pain relief is obtained with

as little opioid and sedation as possible. One strategy toward this end is to time the administration of analgesia so that a steady blood level is achieved and, as much as possible, pain is prevented. This requires that the child receive analgesia on a regular dosing schedule, not "as needed."

Nonpharmacologic strategies can be very effective in reducing the overall amount of pain and amount of analgesia used. In addition, some nonpharmacologic strategies can reduce anxiety and increase the child's level of self-control during pain. In full-term infants, ingesting 2 mL of a sucrose solution has been found to relieve the pain from a heel stick.37 Children as young as 4 years of age can use TENS, and they can be taught to use simple distraction and relaxation and other techniques such as application of heat and cold.³⁸ Other nonpharmacologic techniques can be taught to the child to provide psychological preparation for a painful procedure or surgery. These include positive self-talk, imagery, play therapy, modeling, and rehearsal. The nonpharmacologic interventions must be developmentally appropriate and, if possible, the child and parent should be taught these techniques when the child is not in pain (e.g., before surgery or a painful procedure) so that it is easier to practice the technique.

Pain in Older Adults

Among adults, the prevalence of pain in the general population increases with age.³⁵ It is estimated that from 25% to 50% of community-dwelling elders³⁹ and 80% of individuals in longterm care facilities report experiencing pain.⁴⁰ Research is inconsistent about whether there are age-related changes in pain perception. Some apparent age-related differences in pain may be attributable to differences in willingness to report the pain, rather altered pain perception. The elderly may be reluctant to report pain so as not to be a burden or out of fear of the diagnoses, tests, medications, or costs that may result from an attempt to diagnose or treat their pain.

The assessment of pain in the elderly may be relatively simple in a well-informed, alert, cognitively intact individual with pain from a single source and no comorbidities. In contrast it may to extraordinarily difficult to assess pain in a frail individual with severe dementia and many concurrent health problems. When possible, patient report of pain is the gold standard, but outward signs of pain should be considered as well. Accurately diagnosing pain when the individual has many health problems or some decline in cognitive function can be particularly challenging. In recent years, there has been increased awareness of the need to address issues of pain in individuals with dementia. The Assessment for Discomfort in Dementia Protocol is one example of the efforts to improve assessment and pain management in these individuals. It includes behavioral criteria for assessing pain and recommended interventions for pain. Its use has been shown to improve pain management.35,41

Treatment of pain in the elderly can be complicated. The elderly may have physiologic changes that affect the pharmacokinetics of medications prescribed for pain management. These changes include decreased blood flow to organs, delayed gastric motility, reduced kidney function, and decreased albumin related to poor nutrition. Physiologic changes may affect the choice of medications or dosing. In addition, the elderly often have many coexisting health problems, leading to polypharmacy. When multiple medications are being taken, there is an increased risk of drug interactions and of noncompliance because of the complexity of the treatment regimen.

In summary, children experience and remember pain, and even fairly young children are able accurately and reliably to report their pain. Recognition of this has changed the clinical practice of health professionals involved in the assessment of children's pain. Pain management in children is improving as exaggerated fears and misconceptions concerning the risks of addiction and respiratory depression in children treated with opioids also are dispelled. Pharmacologic (including opioids) and nonpharmacologic pain management interventions have been shown to be effective in children. Nonpharmacologic techniques must be based on the developmental level of the child and should be taught to both children and parents.

Pain is a common symptom in the elderly. Assessment, diagnosis, and treatment of pain in the elderly can be challenging. The elderly may be reluctant or cognitively unable to report their pain. Diagnosis and treatment can be complicated by comorbidities and age-related changes in cognitive and physiologic function.

REVIEW QUESTIONS

Compare the tactile, thermal, and position sense modalities in terms of receptors, adequate stimuli, ascending pathways, and central integrative mechanisms.

- Describe the organization of the somatosensory system in terms of first-, second-, and third-order neurons.
- Compare the discriminative pathway with the anterolateral pathway, and explain the clinical usefulness of this distinction.
- Differentiate among the specificity, pattern, gate control, and neuromatrix theories of pain.
- State the difference between the Aδ- and C-fiber neurons in the transmission of pain information.
- Trace the transmission of pain signals with reference to the neospinothalamic, paleospinothalamic, and reticulospinal pathways, including the role of chemical mediators and factors that modulate pain transmission.

Differentiate acute pain from chronic pain in terms of mechanisms, manifestations, and treatment.

Describe the mechanisms of referred pain, and list the common sites of referral for cardiac and other types of visceral pain.

Describe the cause and characteristics and treatment of neuropathic pain, trigeminal neuralgia, postherpetic neuralgia, and complex regional pain syndrome.

Differentiate between the periodicity of occurrence and manifestations of migraine headache, cluster headache, tensiontype headache, and headache caused by temporomandibular joint syndrome.

State how the pain response may differ in children and older adults.

he special senses allow us to view and hear what is going on around us, to maintain our balance, and to communicate effectively with others. This chapter focuses on the eye and disorders of vision; the ear and disorders of hearing; and the vestibular system and disorders of equilibrium and balance.

THE EYE AND DISORDERS OF VISION

Almost 17.3 million persons in the United States have some degree of visual impairment; of these, 1.1 million are legally blind.¹ The prevalence of vision impairment increases with age. An estimated 26% of persons 75 years of age and older report visual impairment severe enough to interfere with recognizing a friend across the room or reading newspaper print even when wearing glasses.¹ At the other end of the age spectrum, an estimated 95,100 children younger than 18 years of age are severely visually impaired.¹

The optic globe, or eyeball, is a remarkable, mobile, nearly spherical structure contained in a pyramid-shaped cavity of the skull called the *orbit* (Fig. 40-1). The eyeball consists of

748 Unit Ten: Alterations in the Nervous System

■ **FIGURE 40-1** ■ The eye and its appendages, lateral view.

three layers: an outer supporting fibrous layer, the sclera; a vascular layer, the uveal tract; and a neural layer, the retina. Its interior is filled with transparent media, the aqueous and vitreous humors, which allow the penetration and transmission of light to photoreceptors in the retina. Exposed surfaces of the eyes are protected by the eyelids, which are mucous membrane-lined skin flaps that provide a means for shutting out most light. Tears bathe the anterior surface of the eye; they prevent friction between it and the lid, maintain hydration of the cornea, and protect the eye from irritation by foreign objects. The two eyes, with their associated extraocular muscles that permit directional rotation of the eyeball, provide different images of the same object. This results in binocular vision with depth perception.

The Conjunctiva

The conjunctiva is a thin transparent mucous membrane that lines the inner surface of both eyelids and covers the anterior surface of the optic globe to the limbus, or corneoscleral junction (Fig. 40-1). When the eyes are closed, the conjunctiva lines the closed conjunctival sac.

Conjunctivitis

Conjunctivitis, or inflammation of the conjunctiva (*i.e.*, red eye or pink eye), is one of the most common forms of eye disease. It may result from bacterial or viral infection, allergens, chemical agents, physical irritants, or radiant energy. Infections may extend from areas adjacent to the conjunctiva or may be bloodborne, such as in measles or chickenpox. Newborns can contract conjunctivitis during the birth process.

Dependent upon the cause, conjunctivitis can vary in severity from a mild hyperemia (redness) with tearing to severe conjunctivitis with purulent drainage. The conjunctiva is extremely sensitive to irritation and inflammation. Important symptoms

KEY CONCEPTS

VISION

- Vision is a special sensory function that incorporates the visual receptor functions of the eyeball, the optic nerve, and visual pathways that carry and distribute sensory information from the optic globe to the central nervous system, and the primary and visual association cortices that translate the sensory signals into visual images.
- The eyeball is a hollow spherical structure that functions in the reception of the light rays that provide the stimuli for vision. The refractive surface of the cornea and accommodative properties of the lens serve to focus the light signals from near and far objects on the photoreceptors in the retina.
- Visual information is carried to the brain by axons of the retinal cells that form the optic nerve. The two optic nerves fuse in the optic chiasm, where axons of the nasal retina of each eye cross to the contralateral side and travel with axons of the ipsilateral temporal retina to form the fibers of the optic radiations that travel to the visual cortex.
- Binocular vision depends on the coordination of three pairs of extraocular nerves that provide for the conjugate eye movements, with optical axes of the two eyes maintained parallel to one another.

of conjunctivitis are a foreign body sensation, a scratching or burning sensation, itching, and photophobia.

Bacterial Conjunctivitis. Bacterial conjunctivitis may present as a hyperacute, acute, or chronic infection. Common agents of bacterial conjunctivitis are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*. The infection usually has an abrupt onset and is characterized by large amounts of yellow-green drainage. The eyelids are sticky, and there may be excoriation of the lid margins. Treatment may include local application of antibiotics. The disorder usually is self-limited, lasting approximately 10 to 14 days if untreated.²

Hyperacute conjunctivitis is a severe, sight-threatening ocular infection. The most common causes of hyperacute purulent conjunctivitis are *Neisseria gonorrhoeae* and *Neisseria meningitidis*, with *N. gonorrhoeae* being the most common.³ The symptoms, which typically are progressive, include conjunctival redness and edema (chemosis); lid swelling and tenderness; and swollen preauricular lymph nodes. Gonococcal ocular infections that are left untreated result in corneal ulceration with ultimate perforation and sometimes permanent loss of vision.³ Treatment includes systemic antibiotics supplemented with ocular antibiotics. Because of the increasing prevalence of penicillin-resistant *N. gonorrhoeae*, antibiotic choice should be determined by current information regarding antibiotic sensitivity.

Chronic bacterial conjunctivitis most commonly is caused by *Staphylococcus* species, although other bacteria may be involved. It often is associated with inflammation and bacterial colonization of eyelid margins. The symptoms of chronic bacterial conjunctivitis vary and can include itching, burning, foreign body sensation, and morning eyelash crusting. There may be flaky debris and erythema along the lid margins, as well as eyelash loss and eye redness. Some people with chronic bacterial conjunctivitis also have recurrent inflammation or infection of the meibomian glands (stye) in the lid margins.³ Treatment includes good eyelid hygiene and application of topical antibiotics.

Viral Conjunctivitis. One of the most common causes of viral conjunctivitis is adenovirus type 3. Conjunctivitis caused by this agent usually is associated with pharyngitis, fever, and malaise.^{4,5} It causes generalized hyperemia, excessive tearing, and minimal exudate. Children are affected more often than adults. Swimming pools contaminated because of inadequate chlorination are common sources of infection. Infections caused by adenoviruses types 4 and 7 often are associated with acute respiratory disease. These viruses are rapidly disseminated when large groups mingle with infected individuals (*e.g.*, military recruits). There is no specific treatment for this type of viral conjunctivitis; it usually lasts 7 to 14 days. Preventive measures include hygienic measures and avoiding shared use of eyedroppers, eye makeup, goggles, and towels.

Herpes simplex virus (HSV) conjunctivitis is characterized by unilateral infection, irritation, mucoid discharge, pain, and mild photophobia. Herpetic vesicles may develop on the eyelids and lid margins. Although the infection usually is caused by the HSV type 1, it also can be caused by the HSV type 2. It often is associated with herpes simplex virus keratitis, in which the cornea shows discrete epithelial lesions. Treatment involves the use of systemic or local antiviral agents. Local corticosteroid preparations increase the activity of the herpes virus, apparently by enhancing the destructive effect of collagenase on the collagen of the cornea. The use of these medications should be avoided in those suspected of having herpes simplex conjunctivitis or keratitis.

Chlamydial Conjunctivitis. Inclusion conjunctivitis usually is a benign suppurative conjunctivitis transmitted by the type of *Chlamydia trachomatis* (serotypes D through K) that causes venereal infections. It is spread by contaminated genital secretions and occurs in newborns of mothers with *C. trachomatis* infections of the birth canal. It also can be contracted through swimming in unchlorinated pools. The incubation period varies from 5 to 12 days, and the disease may last for several months if untreated. The infection usually is treated with appropriate oral antibiotics.

A more serious form of infection is caused by a different strain of *C. trachomatis* (serotypes A through C). This form of chlamydial infection affects the conjunctiva and causes ulceration and scarring of the cornea. It is the leading cause of preventable blindness in the world. Although the agent is widespread, it is seen mostly in developing countries, particularly those of Africa, Asia, and the Middle East.⁶ It is transmitted by direct human contact, contaminated objects (fomites), and flies.

Ophthalmia Neonatorum. Ophthalmia neonatorum is a form of conjunctivitis that occurs in infants younger than 1 month of age. It is usually contracted during or soon after vaginal delivery. There are many causes, including *N. gonorrhoeae, Pseudomonas*, and *C. trachomatis.*⁷ Epidemiologically, these infections reflect those sexually transmitted diseases most common in a particular area. Currently, *C. trachomatis* is the most common organism causing ophthalmia neonatorum. Drops of 0.5% erythromycin or 1% silver nitrate are applied immediately after birth to prevent gonococcal ophthalmia. Ophthalmia neonatorum is a potentially blinding condition, and it can cause serious and potentially systemic manifestations. It requires immediate diagnosis and treatment.

Allergic Conjunctivitis. Ocular allergy encompasses a spectrum of conjunctival conditions usually characterized by itching. The most common of these is seasonal allergic rhinoconjunctivitis or hay fever. Seasonal allergic conjunctivitis is an IgE-mediated hypersensitivity reaction precipitated by small airborne allergens such as pollens. It typically causes bilateral tearing, itching, and redness of the eyes.

The treatment of seasonal allergic rhinoconjunctivitis usually includes allergen avoidance, the use of cold compresses, oral antihistamines, and vasoconstrictor eye drops. Allergic conjunctivitis also has been successfully treated with topical mast cell stabilizers and topical nonsteroidal anti-inflammatory drugs.⁴

The Cornea

The cornea functions as a transparent membrane through which light passes as it moves toward the retina (Fig. 40-2). The cornea also contributes to the refraction (*i.e.*, bending) of light rays and focusing of vision. Three layers of tissue form the cornea: an extremely thin outer epithelial layer, which is continuous with the ocular conjunctiva; a middle layer called the *substantia propria* or

■ **FIGURE 40-2** ■ Transverse section of the eyeball.

stroma; and an inner endothelial layer (Bowman's membrane), which lies next to the aqueous humor of the anterior chamber. The substantia propria is composed of regularly arranged collagen bundles embedded in a mucopolysaccharide matrix. This organization of the collagen fibers makes the substantia propria transparent and is necessary for light transmission. Hydration within a limited range is necessary to maintain the spacing of the collagen fibers and transparency.

The cornea is avascular and obtains its nutrient and oxygen supply by diffusion from blood vessels of the adjacent sclera, from the aqueous humor at its deep surface, and from tears.

Disorders of the Cornea

The corneal epithelium is heavily innervated by sensory neurons. Epithelial injury causes discomfort that ranges from a foreign body sensation and burning of the eyes to severe pain. Because the cornea serves as the window of the eye and refracts light, vision is often blurred. Photophobia may occur as the result of painful contraction of the inflamed iris. Reflex tearing is common.

Trauma that causes abrasions of the cornea can be extremely painful, but if minor, the abrasions usually heal in a few days. The epithelium is an effective barrier to entrance of microorganisms into the cornea. It is capable of regeneration, and small defects heal without scarring. If the stroma is damaged, healing occurs more slowly, and the danger of infection is increased. Injuries to Bowman's membrane and the stromal layer heal with scar formation and permanent opacification. Opacities of the cornea impair the transmission of light. A minor scar can severely distort vision because it disturbs the refractive surface of the eye. **Corneal Edema.** The integrity of the epithelium and the endothelium is necessary to maintain hydration of the cornea within a limited range. Damage to either structure leads to edema and loss of transparency. Among the causes of corneal edema is the prolonged and uninterrupted wearing of hard contact lenses, which can deprive the epithelium of oxygen. The edema disappears spontaneously when the cornea comes in contact with the atmosphere. With corneal edema, the cornea appears dull, uneven, and hazy; visual acuity decreases; and iridescent vision (*i.e.*, rainbows around lights) occurs.

Keratitis. Keratitis refers to inflammation of the cornea. It can be caused by infections, hypersensitivity reactions, ischemia, defects in tearing, trauma, and interruption in sensory innervation, as occurs with local anesthesia. Scar tissue formation caused by keratitis is the leading cause of blindness and impaired vision throughout the world. Most of this vision loss is preventable if the condition is diagnosed early and appropriate treatment is instituted.

Keratitis can be divided into two types: nonulcerative and ulcerative. In nonulcerative or interstitial keratitis, all the layers of the epithelium are affected, but the epithelium remains intact. It is associated with a number of diseases, including syphilis, tuberculosis, and lupus erythematosus. It also may result from a viral infection entering through a small defect in the cornea. Treatment usually is symptomatic.

Ulcerative keratitis is an inflammatory process, in which parts of the epithelium, stroma, or both are destroyed. Causes of ulcerative keratitis include infectious agents such as those causing conjunctivitis (*e.g.*, *Staphylococcus*, *S. pneumoniae*, *Chlamydia*), exposure trauma, and use of extended-wear contact lens. Bacterial keratitis tends to be aggressive and demands immediate care. Exposure trauma may result from deformities of the lid, paralysis of the lid muscles, or severe exophthalmos. Mooren's ulcer is a chronic, painful, indolent ulcer that occurs in the absence of infection. It usually is seen in older persons and may affect both eyes. Although the cause is unknown, an autoimmune origin is suspected.

Herpes simplex virus keratitis is the most common cause of corneal ulceration and most common corneal cause of blindness in the United States.² Most cases are caused by HSV type 1 infections. An exception is neonatal keratitis, which is caused by HSV type 2 acquired during the birth process.8 HSV keratitis occurs as a primary or recurrent infection. Primary ocular herpes usually occurs in young children. It is manifested by vesicular blepharoconjunctivitis, occasionally with corneal involvement. It generally is self-limited, without causing corneal damage. After the initial primary infection, the virus may persist in a quiescent or latent state, remaining in the trigeminal ganglion and possibly in the cornea without causing signs of infection. Recurrent infection may be precipitated by various poorly understood, stress-related factors that reactivate the virus. The first symptoms are usually irritation, photophobia, and tearing. There is often a history of fever blisters, but the corneal lesion may be the only sign of recurrent HSV infection. Because corneal anesthesia occurs early in the course of the infection, symptoms may be minimal and the person may delay seeking medical attention. The most common lesion is a dendritic, or branching ulcer, involving the epithelial layer of the cornea. Epithelial ulcers usually respond to debridement and patching and usually heal without scarring. Topical antiviral agents may be used to increase the rate of healing. Corticosteroid drugs are contraindicated for use in the treatment of epithelial HSV lesions because they increase viral replication.

Stromal HSV keratitis produces increasingly severe corneal ulceration and scarring. It is often associated with an immunologic response to the virus, and topical antiviral agents alone are usually insufficient to control stromal keratitis. Thus, topical corticosteroids may be cautiously used in combination with appropriate antiviral agents. Corneal grafting may be indicated for persons with severe corneal scarring.

Corneal Transplantation. Advances in ophthalmologic surgery permit corneal transplantation using a cadaver cornea. Unlike kidney or heart transplantation procedures, which are associated with considerable risk of rejection of the transplanted organ, the use of cadaver corneas entails minimal danger of rejection because this tissue is not exposed to the vascular and therefore the immunologic defense system. Instead, the success of this type of transplantation operation depends on the prevention of scar tissue formation, which would limit the transparency of the transplanted cornea.

Aqueous Humor and Intraocular Pressure

The aqueous humor, which fills the space between the cornea and the lens, serves a nutritive function for the lens and posterior cornea (Fig. 40-2). The aqueous humor is produced by the ciliary epithelium in the posterior chamber and passes between the anterior surface of the lens and posterior surface of the iris, through the pupil, and into the anterior chamber. It leaves through the iridocorneal angle between the iris and the sclera. Here it filters through the trabecular meshwork and enters the canal of Schlemm for return to the venous circulation.

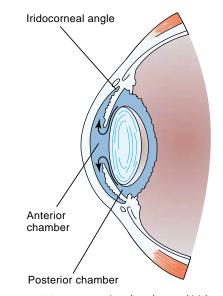

The hydrostatic pressure of the aqueous humor results from a balance of several factors, including the rate of aqueous secretion, resistance to flow through the narrow opening between the iris and the ciliary body at the entrance to the anterior chamber, and resistance to resorption at the trabeculated region of the sclera at the iridocorneal angle. Normally, the rate of aqueous production is equal to the rate of aqueous outflow, and the intraocular pressure is maintained within a normal range of 9 to 21 mm Hg.

Glaucoma

Glaucoma includes a group of conditions that produce an elevation in intraocular pressure. If left untreated, the pressure may increase sufficiently to cause ischemia and degeneration of the optic nerve, leading to progressive blindness. Glaucoma is a major contributor to blindness in the United States.^{1,9} The condition often is asymptomatic, and a significant loss of peripheral vision may occur before medical attention is sought, emphasizing the need for routine screening for early diagnosis and treatment.

Glaucoma commonly is classified as closed-angle (*i.e.*, narrow-angle) or open-angle (*i.e.*, wide-angle) glaucoma, depending on the location of the compromised aqueous humor circulation and resorption. Glaucoma may occur as a congenital or an acquired condition, and it may manifest as a primary or secondary disorder. Primary glaucoma occurs without evidence of pre-existing ocular or systemic disease. Secondary glaucoma can result from inflammatory processes that affect the eye, from tumors, or from the blood cells of traumaproduced hemorrhage that obstruct the outflow of aqueous humor.

Closed-Angle Glaucoma. In closed-angle glaucoma, the anterior chamber is narrow, and outflow becomes impaired when the iris thickens as the result of pupillary dilation (Fig. 40-3).

■ FIGURE 40-3 ■ Narrow anterior chamber and iridocorneal angle in closed-angle (narrow-angle) glaucoma.

As the iris thickens, it restricts the circulation between the base of the iris and the sclera, blocking the circulation between the posterior and anterior chambers and reducing or eliminating access to the angle where aqueous reabsorption occurs.⁹ Approximately 5% to 10% of all cases of glaucoma fall into this category. Closed-angle glaucoma usually occurs as the result of an inherited anatomic defect that causes a shallow anterior chamber. This defect is exaggerated by the anterior displacement of the peripheral iris that occurs in older persons because of the increase in lens size that occurs with aging.

The symptoms of closed-angle glaucoma are related to sudden, intermittent increases in intraocular pressure. These occur after prolonged periods in the dark, emotional upset, and other conditions that cause extensive and prolonged dilation of the pupil. Administration of pharmacologic agents such as atropine that cause pupillary dilation (mydriasis) also can precipitate an acute episode of increased intraocular pressure in persons with the potential for closed-angle glaucoma. Attacks of increased intraocular pressure are manifested by ocular pain and blurred or iridescent vision caused by corneal edema. The pupil may be enlarged and fixed. The symptoms often are spontaneously relieved by sleep and conditions that promote pupillary constriction. With repeated or prolonged attacks, the eye becomes reddened, and edema of the cornea may develop, giving the eye a hazy appearance. A unilateral, often excruciating, headache is common. Nausea and vomiting may occur, causing the headache to be confused with migraine.

Some persons with congenitally narrow anterior chambers never experience symptoms, and others experience symptoms only when they are elderly. Because of the dangers of vision loss, those with narrow anterior chambers should be warned about the significance of blurred vision, halos, and ocular pain. Sometimes, decreased visual acuity and an unreactive pupil may be the only clue to closed-angle glaucoma in the elderly.

The treatment of acute closed-angle glaucoma is primarily surgical. It involves creating an opening between the anterior and posterior chambers with laser or incisional iridectomy to allow aqueous humor to bypass the pupillary block. The anatomic abnormalities responsible for closed-angle glaucoma usually are bilateral, and prophylactic surgery often is performed on the other eye.

Primary Open-Angle Glaucoma. Primary open-angle glaucoma is the most common form of glaucoma. It tends to manifest after 35 years of age, with an incidence of 0.5% to 2% among persons 40 years of age and older.8 The condition is characterized by an abnormal increase in intraocular pressure that occurs in the absence of obstruction at the iridocorneal angle, thus the name open-angle glaucoma. Instead, it usually occurs because of an abnormality of the trabecular meshwork that controls the flow of aqueous humor into the canal of Schlemm. Risk factors for this disorder include an age of 40 years and older, family history of the disorder, diabetes mellitus, and myopia (nearsightedness). In some persons, the use of moderate amounts of topical corticosteroid medications can cause an increase in intraocular pressure. Sensitive persons also may sustain an increase in intraocular pressure with the use of systemic corticosteroid drugs.

Primary open-angle glaucoma usually is asymptomatic and chronic, causing progressive loss of visual field unless it is appropriately treated. The elevation in intraocular pressure in persons with open-angle glaucoma usually is treated pharmacologically or, in cases where pharmacologic treatment fails, by increasing aqueous outflow through a surgically created pathway.

Congenital or Infantile Glaucoma. Congenital glaucoma is caused by a disorder in which the anterior chamber retains its fetal configuration, with aberrant trabecular meshwork extending to the root of the iris, or is covered by a membrane. An X-linked recessive mode of inheritance is common, producing a high incidence among males.⁷ The earliest symptoms are excessive lacrimation and photophobia. Affected infants tend to be fussy, have poor eating habits, and rub their eyes frequently. Diffuse edema of the cornea usually occurs, giving the eye a grayish-white appearance. Chronic elevation of the intraocular pressure before the age of 3 years causes enlargement of the entire globe. Early surgical treatment is necessary to prevent blindness.

The Lens

The lens is a remarkable structure that functions to bring images into focus on the retina. The lens is an avascular, transparent, biconvex body, the posterior side of which is more convex than the anterior side. A thin highly elastic lens capsule, which is attached to the surrounding ciliary body by delicate suspensory radial ligaments called *zonules*, holds the lens in place (see Fig. 40-2). The suspensory ligaments and lens capsule normally are under tension, causing the lens to have a flattened shape for distant vision. Contraction of the muscle fibers of the ciliary body narrows the diameter of the ciliary body, relaxes the fibers of the suspensory ligaments, and allows the lens to relax to a more spherical or convex shape for near vision.

Disorders of Refraction

Refraction can be defined as a bending of light rays as they pass from one transparent medium (such as air) to a second transparent medium with a different density (such as a glass lens). When light rays pass through the center of a lens, their direction is not changed; however, other rays passing peripherally through a lens are bent (Fig. 40-4). The refractive power of a lens usually is described as the distance (in meters) from its surface to the point at which the rays come into focus (*i.e.*, focal length). Usually, this is reported as the reciprocal of this distance (*i.e.*, diopters). For example, a lens that brings an object into focus at 0.5 m has a refractive power of 2 diopters (1.0/0.5 = 2.0). With a fixed-power lens, the closer an object is to the lens, the further behind the lens is its focus point.

In the eye, the major refraction of light begins at the convex corneal surface. Further refraction occurs as light moves from the posterior corneal surface to the aqueous humor, from the aqueous humor to the anterior lens surface, and from the posterior lens surface to the vitreous humor. A perfectly shaped optic globe and cornea result in optimal visual acuity, producing a sharp image in focus at all points on the retinal surface in the posterior part, or fundus, of the eye (see Fig. 40-4). Unfortunately, individual differences in formation and growth of the eyeball and cornea frequently result in inappropriate focal image formation. If the anterior-posterior dimension of the eyeball is too short, the image is focused posterior to (behind)

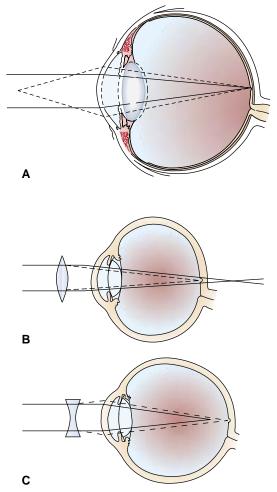

FIGURE 40-4 (A) Accommodation. The *solid lines* represent rays of light from a distant object, and the *dotted lines* represent rays from a near object. The lens is flatter for the former and more convex for the latter. In each case, the rays of light are brought to a focus on the retina. (B) Hyperopia corrected by a biconvex lens, shown by the *dotted lines*. (C) Myopia corrected by a biconcave lens, shown by the *dotted lines*.

the retina. This is called *hyperopia* or *farsightedness*. In such cases, the accommodative changes of the lens can bring distant images into focus, but near images become blurred. Appropriate biconvex lenses correct this type of defect. If the anterior-posterior dimension of the eyeball is too long, the focus point for an infinitely distant target is anterior to the retina. This condition is called *myopia* or *nearsightedness* (see Fig. 40-4). Persons with myopia can see close objects without problems because accommodative changes in their lens bring near objects into focus, but distant objects are blurred. Myopia can be corrected with an appropriate biconcave lens. Radial keratotomy, a form of refractive corneal surgery, can be performed to correct the defect. This surgical procedure involves the use of radial incisions to alter the corneal curvature.

Nonuniform curvature of the refractive medium (*e.g.*, horizontal vs. vertical plane) is called *astigmatism*. Astigmatism usually is the result of a defect in the cornea, but it can result from defects in the lens or the retina.

Disorders of Accommodation

Accommodation is the process whereby a clear image is maintained as gaze is shifted from a far to a near object. Accommodation requires convergence of the eyes, pupillary constriction, and thickening of the lens through contraction of the ciliary muscle.

In near vision, pupillary constriction (*i.e., miosis*) improves the clarity of the retinal image. This must be balanced against the resultant decrease in light intensity reaching the retina. During changes from near to far vision, pupillary dilation partially compensates for the reduced size of the retinal image by increasing the light entering the pupil. A third component of accommodation involves the reflex narrowing of the lid opening during near vision and widening during far vision.

The term *presbyopia* refers to changes in vision that occur because of aging. The lens consists of transparent fibers arranged in concentric layers, of which the external layers are the newest and softest. No loss of lens fibers occurs with aging; instead, additional fibers are added to the outermost portion of the lens. As the lens ages, it thickens, and its fibers become less elastic, so that the range of focus or accommodation is diminished to the point where reading glasses become necessary for near vision.

Cataracts

A cataract is a lens opacity that interferes with the transmission of light to the retina. Cataracts are the most common cause of age-related visual loss in the world; they are found in approximately 50% of those between 65 and 74 years of age and in 70% of those older than 75 years of age.¹

The cause of cataract development is thought to be multifactorial, with different factors being associated with different types of opacities. Several risk factors have been proposed, including the effects of aging, genetic influences, environmental and metabolic influences, drugs (*e.g.*, triparanol, chlorpromazine, corticosteroids), and injury.^{10,11} Metabolically induced cataracts are caused by disorders of carbohydrate metabolism (diabetes) or inborn errors of metabolism. Long-term exposure to sunlight (ultraviolet B radiation) and heavy smoking have been associated with increased risk of cataract formation.¹⁰ In some cases, cataracts occur as a developmental defect (*i.e.*, congenital cataracts) or secondary to trauma or diseases.

With normal aging, the nucleus and the cortex of the lens enlarge as new fibers are formed in the cortical zones of the lens. In the nucleus, the older fibers become more compressed and dehydrated, the lens proteins become more insoluble, and concentrations of calcium, sodium, potassium, and phosphate increase. During the early stages of cataract formation, a yellow pigment and vacuoles accumulate in the lens fibers. The unfolding of protein molecules, cross-linking of sulfhydryl groups, and conversion of soluble to insoluble proteins lead to the loss of lens transparency. The onset is usually gradual, and the only symptoms are increasingly blurred vision and visual distortion.

The manifestations of cataract depend on the extent of opacity and whether the defect is bilateral or unilateral. With the exception of traumatic or congenital cataract, most cataracts are bilateral. Age-related cataracts are characterized by increasingly blurred vision and visual distortion. Vision for far and near objects decreases. Dilation of the pupil in dim light improves vision. Central lens opacities may divide the visual axis and cause an optical defect in which two or more blurred images are seen. In addition to decreased visual acuity, cataracts tend to cause light entering the eye to be scattered, thereby producing glare or the abnormal presence of light in the visual field. On ophthalmoscopic examination, cataracts may appear as a gross opacity filling the pupillary aperture or as an opacity silhouetted against the red background of the fundus.

There is no effective medical treatment for cataract. Use of strong bifocals, magnification, appropriate lighting, and visual aids may be used as the cataract progresses. Surgery is the only treatment for correcting cataract-related vision loss. Surgery usually involves lens extraction and intraocular lens implantation. The cataract lens usually is removed using phacoemulsification techniques. Phacoemulsification involves ultrasonic fragmentation of the lens into fine pieces, which then are aspirated from the eye. Surgery commonly is performed on an outpatient basis and with the use of local anesthesia.

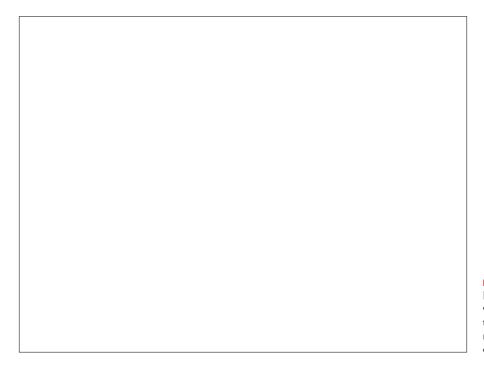

The Retina

The function of the retina is to receive visual images, partially analyze them, and transmit this modified information to the brain. Disorders of the retina and its function include ischemic conditions caused by disorders of the retinal blood supply; disorders of the retinal vessels such as retinopathies that cause hemorrhage and the development of opacities; separation of the pigment and sensory layers of the retina (*i.e.*, retinal detachment); and macular degeneration. Because the retina has no pain fibers, most diseases of the retina are painless and do not cause redness of the eye.

The retina is composed of two layers: an outer pigment (melanin-containing) epithelium and an inner neural layer (Fig. 40-2). The outer pigmented layer, a single-cell-thick lining abuts the choroid, and extends anteriorly to cover the ciliary body and the posterior side of the iris. Its pigmented epithelial cells, like those of the choroid, absorb light and prevent it from scattering. The pigment layer also stores large quantities of vitamin A, which is an important precursor of the photosensitive visual pigments.

The importance of melanin in the pigment layer is well illustrated by its absence in people with a condition called *albinism*. Albinism is a genetic deficiency of tyrosinase, the enzyme needed for the synthesis of melanin by the melanocytes. Affected persons have white hair, pink skin, and light blue eyes. In these persons, excessive light penetrates the unpigmented iris and choroid and is reflected in all directions, so that their photoreceptors are flooded with excess light, and visual acuity is markedly reduced. Excess stimulation of the photoreceptors at normal or high illumination levels is experienced as painful photophobia.

The light-sensitive inner neural retina covers the inner aspect of the eyeball. The neural retina is composed of three layers of neurons: a posterior layer of photoreceptors, a middle layer of bipolar cells, and an inner layer of ganglion cells that communicate with the photoreceptors. Light must pass through the transparent inner layers of the sensory retina before it reaches the photoreceptors. Local currents produced in response to light spread from the photoreceptors to the bipolar neurons and other interneurons and then to the innermost ganglionic cells, where action potentials are generated. The interneurons, which are composed of horizontal and amacrine cells, have cell bodies in the bipolar layer, and they play an important role in modulating retinal function. A superficial marginal layer contains the axons of the ganglion cells as they collect and leave the eye by way of the optic nerve (Fig. 40-5). The optic disk, where the optic nerve exits the eye, is the weak part of the eye because it is not reinforced by the sclera. The optic disk also forms the blind spot, because it is not reinforced by photoreceptors, and light focused on it cannot be seen. People do not notice the blind spot because of a sophisticated visual function

■ FIGURE 40-5 ■ Organization of the human retina. The visual pathway begins with photoreceptors (rods and cones) in the retina. The responses of the photoreceptors are transmitted by the bipolar cells to the ganglion cell layer of the retina.

called "filling in," which the brain uses to deal with missing visual input. Local retinal damage caused by small vascular lesions (*i.e.*, retinal stroke) and other localized pathologies can produce additional blind spots.

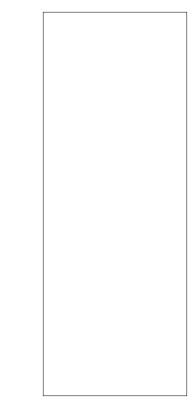

Two types of photoreceptors are present in the retina: rods, capable of black-white discrimination, and cones, capable of color discrimination. Rod-based vision is particularly sensitive to detecting light, especially moving light stimuli, at the expense of clear pattern discrimination. Rod vision is particularly adapted for night and low-level illumination. Dark adaptation is the process by which rod sensitivity increases to the optimum level. This requires approximately 4 hours in total or near-total darkness and involves only rods. Cone receptors, which are selectively sensitive to different wavelengths of light, provide the basis for color vision. Three types of cones, or cone-color systems, respond to the blue, green, and red portions of the visible electromagnetic spectrum. Cones do not have the dark adaptation of rods. Consequently, the dark-adapted eye is a rod receptor eye with only black-gray-white experience (scotopic or night vision). The light-adapted eye (photopic vision) adds the capacity for color discrimination.

Both rods and cones contain chemicals that decompose on exposure to light and, in the process, generate the currents that lead to the action potentials generated by the ganglionic cells. The light-sensitive chemical in the rods is called rhodopsin, and the light-sensitive chemicals in the cones are called cone or color pigments. Both types of photoreceptors are thin, elongated, mitochondria-filled cells with a single, highly modified cilium (see Fig. 40-6). The cilium has a short base, or inner segment, and a highly modified outer segment. The plasma membrane of the outer segment is tightly folded to form membranous disks (rods) or conical shapes (cones) containing visual pigment. Both rhodopsin and color pigment are incorporated into membranes of these disks in the form of transmembrane proteins. These disks are continuously synthesized at the base of the outer segment and shed at the distal end. The discarded membranes are phagocytized by the retinal pigment cells. If this phagocytosis is disrupted, as in retinitis pigmentosa, the sensory retina degenerates.

An area approximately 1.5 mm in diameter near the center of the retina, called the *macula lutea* (*i.e.*, "yellow spot"), is especially adapted for acute and detailed vision. This area is composed entirely of cones. In the central portion of the macula, the *fovea centralis*, the blood vessels and innermost layers are displaced to one side instead of resting on top of the cones (Fig. 40-2). This allows light to pass unimpeded to the cones without passing through several layers of the retina. Many of these cones are connected one-to-one with ganglion cells, an arrangement that favors high acuity.

Blood Supply and Vascular Lesions

The blood supply for the retina is derived from two sources: the choriocapillaris of the choroid and the branches of the central retinal artery. The cones and rods of the outer neural layer receive nutrients from the choriocapillaris, a fine layer of capillaries on the inner surface of the choroids against which the retina is pressed. Because the choriocapillary layer provides the only blood supply for the fovea centralis, detachment of this part of the sensory retina from the pigment epithelium causes irreparable visual loss. The central retinal artery, which is a branch of the ophthalmic, supplies the rest of the retina. A cor-

■ FIGURE 40-6 ■ Retinal rod, showing its component parts and the distribution of its organelles. Its outer segment contains the disks (rods). The connecting structure joined the outer and inner segments. The inner segment contains the mitochondria, the ribosomal endoplasmic reticulum, the free ribosomes, and the Golgi saccules. The synaptic body forms the site where the photo receptors synapse with subsequent nerve cells.

responding system of retinal veins unites to form the central vein of the retina.

Funduscopic examination of the eye with an ophthalmoscope provides an opportunity to examine the retinal blood vessels and other aspects of the retina (Fig. 40-7). Dilating the pupil pharmacologically enables more thorough examination of the retina.

Papilledema. The central retinal artery enters the eye through the *optic papilla* in the center of the optic nerve. The central vein of the retina exits the eye along the same path. The entrance and exit of the central artery and vein of the retina through the tough scleral tissue at the optic papilla can be compromised by any condition causing persistent increased intracranial pressure. The most common of these conditions are cerebral tumors, subdural hematomas, hydrocephalus, and malignant hypertension.

The thin-walled, low-pressure veins are the first to collapse, with the consequent backup and slowing of arterial blood flow. Under these conditions, capillary permeability increases, and leakage of fluid results in edema of the optic papilla, called *papilledema*. The interior surface of the papilla normally is cupshaped and can be evaluated through an ophthalmoscope.

KEY CONCEPTS

DISORDERS OF THE RETINAL BLOOD SUPPLY

- The blood supply for the retina is derived from the central retinal artery, which supplies blood flow for the entire inside of the retina, and from vessels in the choroid, which supply the rods and cones.
- Central retinal occlusion interrupts blood flow to the inner retina and results in unilateral blindness.
- The retinopathies, which are disorders of the retinal vessels, interrupt blood flow to the visual receptors, leading to visual impairment.
- Retinal detachment separates the visual receptors from the choroid, which provides their major blood supply.

With papilledema, sometimes called *choked disk*, the optic cup is distorted by protrusion into the interior of the eye (Fig. 40-8). Because this sign does not occur until the intracranial pressure is significantly elevated, compression damage to the optic nerve fibers may have begun. As a warning sign, papilledema occurs quite late. Unresolved papilledema results in the destruction of the optic nerve axons and blindness.

Retinopathies

The retinopathies involve the small blood vessels of the retina. They involve changes in blood vessel structure, development of microaneurysms, and formation of new fragile vessels (neovascularization). Breakdown of the blood-retinal barrier at the level of the capillary endothelium can develop, allowing fluid and plasma constituents to escape into the surrounding retina. Vessel weakness can lead to rupture of the vessel wall and hemorrhage. **Diabetic Retinopathy.** Diabetic retinopathy is the third leading cause of blindness for all ages in the United States. It ranks first as the cause of newly reported cases of blindness in persons between the ages of 20 and 74 years, and current estimates suggest it is responsible for 12,000 to 24,000 new cases of blindness in the United States each year.¹²

Diabetic retinopathy can be divided into two types: nonproliferative (i.e., background) and proliferative. Background or nonproliferative retinopathy is a progressive disorder of the small retinal vessels. It is characterized by thickening and hyperpermeability of the retinal capillary walls. The capillaries develop tiny outpouching called *microaneurysms*, while the retinal veins become dilated and tortuous. These vessels tend to leak plasma, resulting in localized edema that gives the retina a hazy appearance. Ruptured capillaries cause small intraretinal hemorrhages, and microinfarcts may cause cotton-wool exudates. A sensation of glare (because of the scattering of light) is a common complaint. The most common cause of decreased vision in persons with background retinopathy is macular edema.^{12,13} It represents fluid accumulation in the retina stemming from a breakdown in the bloodretina barrier.

Proliferative diabetic retinopathy represents a more severe retinal change than background retinopathy. It is characterized by formation of new fragile blood vessels (*i.e.*, neovascularization) at the disk and elsewhere in the retina. These vessels grow in front of the retina along the posterior surface of the vitreous or into the vitreous. These new blood vessels threaten vision in two ways. First, because they are abnormal, they tend to bleed easily, leaking blood into the vitreous cavity and decreasing visual acuity. Second, the blood vessels attach firmly to the retinal surface and posterior surface of the vitreous, such that normal movement of the vitreous may exert a pull on the retina, causing retinal detachment and progressive blindness.

Preventing diabetic retinopathy from developing or progressing is considered the best approach to preserving vision.¹⁴ Growing evidence suggests that careful control of blood sugar levels in persons with diabetes mellitus may retard the onset

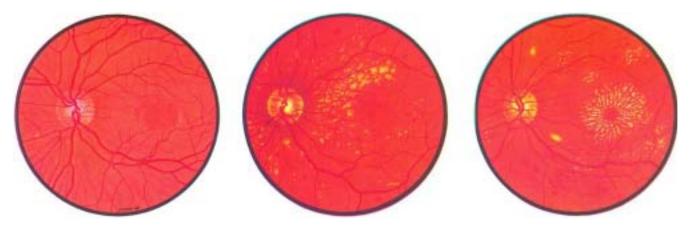

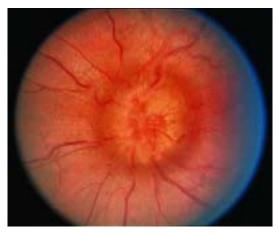

FIGURE 40-7 Fundus of the eye as seen in retinal examination with an ophthalmoscope: (**left**) normal fundus; (**middle**) diabetic retinopathy—combination of microaneurysms, deep hemorrhages, and hard exudates of background retinopathy; (**right**) hypertensive retinopathy with purulent exudates. Some exudates are scattered, while others radiate from the fovea to form a macular star. (Bates B. [1995]. *A guide to physical examination and history taking* (pp. 208, 210). Philadelphia: J.B. Lippincott Company)

■ FIGURE 40-8 ■ Chronic papilledema. The optic nerve head is congested and protrudes anteriorly toward the interior of the eye. It has blurred margins, and vessels within it are poorly seen. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1558]. Philadelphia: Lippincott Williams & Wilkins)

and progression of retinopathy. Both hypertension and hyperlipidemia are thought to increase the risk of diabetic retinopathy in persons with diabetes.¹³

Because early proliferative diabetic retinopathy is likely to be asymptomatic, it must be identified early, before bleeding occurs and leads to fibrosis and retinal attachment. The American Diabetes Association, American College of Physicians, and American Academy of Ophthalmology have developed screening guidelines for diabetic retinopathy.^{13,15}

Photocoagulation using an argon laser provides the major direct treatment modality for diabetic retinopathy.¹³ Treatment strategies include laser photocoagulation applied directly to leaking microaneurysms and grid photocoagulation with a checkerboard pattern of laser burns applied to diffuse areas of leakage and thickening.¹² Vitrectomy has proved effective in removing vitreous hemorrhage and severing vitreoretinal membranes that develop.

Hypertensive Retinopathy. Long-standing systemic hypertension results in the compensatory thickening of arteriolar walls, which effectively reduces capillary perfusion pressure. Ordinarily, a retinal blood vessel is transparent and seen as a red line; in venules, the red cells resemble a string of boxcars. On ophthalmoscopy, arteries in persons with long-standing hypertension appear paler than veins because they have thicker walls. The thickened arterioles in chronic hypertension become opaque and have a copper-wiring appearance. Edema, microaneurysms, intraretinal hemorrhages, exudates, and cottonwool spots all are observed.⁶ Malignant hypertension involves swelling of the optic disk as a result of the local edema produced by escaped fluid. If the condition is permitted to progress long enough, serious visual deficits result.

Protective thickening of arteriolar walls cannot occur with sudden increases in blood pressure. Therefore, hemorrhage is likely to occur. Trauma to the optic globe or the head, sudden high blood pressure in eclampsia, and some types of renal disease characteristically are accompanied by edema of the retina and optic disk and by an increased likelihood of hemorrhage. Atherosclerosis of Retinal Vessels. In atherosclerosis, the lumen of the arterioles becomes narrowed. As a result, the retinal arteries become tortuous and narrowed. At sites where the arteries cross and compress veins, the red cell column of the vein appears distended. Exudate accumulates on arteriolar walls as "fluffy," white plaques (cotton wool patches). These patches

Chapter 40: Alterations in Special Sensory Function

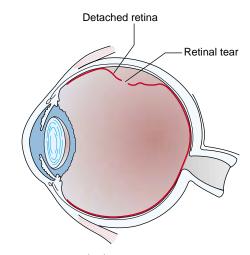

are damaged axons that on cross-section resemble "crystalloid bodies." Deep and superficial hemorrhages are common. Atheromatous plaques of the central artery are associated with increased danger of stasis, thrombi of the central veins, and occlusion.

Retinal Detachment

Retinal detachment involves the separation of the sensory retina from the pigment epithelium (Fig. 40-9). It occurs when traction on the inner sensory layer or a tear in this layer allows fluid, usually vitreous, to accumulate between the two layers. Retinal detachment that results from breaks in the sensory layer of the retina is called *rhegmatogenous detachment* (*rhegma* in Greek, meaning "rent" or "hole"). The vitreous normally is adherent to the retina at the optic disk, macula, and periphery of the retina. When the vitreous shrinks, it separates from the retina at the posterior pole of the eye (posterior vitreous detachment), but at the periphery, the vitreous pulls on the attached retina, which can lead to tearing of the retina. Vitreous fluid can enter the tear and contribute to further separation of the retina from its overlying pigment layer.

Persons with high grades of myopia may have abnormalities in the peripheral retina that predispose to sudden detachment. Intraocular surgery such as cataract extraction may produce traction on the peripheral retina that causes eventual detachment months or even years after surgery.¹² Detachment may result from exudates that separate the two retinal layers. Exudative detachment may be caused by intraocular inflammation, intraocular tumors, or certain systemic diseases. Inflammatory processes include posterior scleritis, uveitis, or parasitic invasion. Retinal detachment also can follow trauma immediately or at some later time.

Detachment of the neural retina from the retinal pigment layer separates the receptors from their major blood supply, the choroid. If retinal detachment continues for some time,

■ FIGURE 40-9 ■ Detached retina.

permanent destruction and blindness of that part of the retina occur. The primary symptom of retinal detachment is loss of vision. Sometimes, flashing lights or sparks, followed by small floaters or spots in the field of vision, occur as the retina pulls away from the posterior pole of the eye. There is no pain. As detachment progresses, the person perceives a dark curtain progressing across the visual field. Because the process begins in the periphery and spreads circumferentially and posteriorly, initial visual disturbances may involve only one quadrant of the visual field. Large peripheral detachments may occur without involvement of the macula, so that visual acuity remains unaffected. However, the tendency is for detachments to enlarge until the entire retina is detached.

Treatment is aimed at closing retinal tears and reattaching the retina. Rhegmatogenous detachment usually requires surgical treatment.

Macular Degeneration

Macular degeneration is characterized by destructive changes of the yellow-pigmented area surrounding the central fovea resulting from vascular disorders. Age-related macular degeneration is the leading cause of blindness among persons older than 75 years of age and of newly reported cases of blindness among those older than 65 years of age.¹ The cause of macular degeneration is unknown, although nutritional, hemodynamic, degenerative, and phototoxic factors are under investigation.

Macular degeneration is characterized by the loss of central vision, usually in both eyes. Age-related macular degeneration can be classified into early and late stages.¹ The early stage is associated with minimal visual impairment. There are pigmentary abnormalities and pale yellow spots that may occur individually or in groups throughout the macula, called *drusen*. Only eyes with large drusen are at risk for late-stage age-related macular degeneration. Persons with late-stage disease often find it difficult to see at long distances (*e.g.*, in driving), do close work (*e.g.*, reading), see faces clearly, or distinguish colors. However, the person may not be severely incapacitated because the peripheral retinal function usually remains intact.

There are two types of age-related macular degeneration: an atrophic nonexudative or "dry" form and an exudative or "wet" form.¹⁶ The atrophic form is characterized by a gradual, progressive bilateral vision loss from atrophy and degeneration of the rod and cone photoreceptors. It does not involve leakage of blood or serum; thus, it is called *dry age-related macular degen*eration. The exudative form is characterized by the formation of a choroidal neovascular membrane that separates the pigmented epithelium from the neuroretina. These new blood vessels have weaker walls than normal and are prone to leakage; thus, this condition is called wet age-related macular degeneration. The leakage of serous or hemorrhagic fluid into the subretinal space causes separation of the pigmented epithelium from the neurosensory retina. With time, the subretinal hemorrhages organize to form scar tissue. When this happens, retinal tissue death and loss of all visual function in the corresponding macular area occurs.

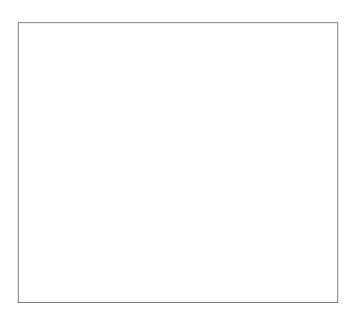

Although there is no treatment for the dry form of macular degeneration, argon laser photocoagulation may be useful in treating the neovascularization that occurs with the wet form.¹⁷ Another method that has been used to halt neovascularization is photodynamic therapy. It is a nonthermal process leading to localized production of reactive oxygen species that mediate

cellular, vascular, and immunologic injury and destruction of new blood vessels.

Neural Pathways. Full visual function requires the normally developed brain-related functions of photoreception and the pupillary reflex. These functions depend on the integrity of all visual pathways, including retinal circuitry and the pathway from the optic nerve to the visual cortex and other visual regions of the brain and brain stem.

Visual information is carried to the brain by axons of the retinal ganglion cells, which form the optic nerve. The two optic nerves meet and fuse in the optic chiasm, beyond which they are continued as the optic tracts (Fig. 40-10). In the optic chiasm, axons from the nasal retina of each eye cross to the opposite side and join with the axons of the temporal retina of the contralateral eye to form the optic tracts. One optic tract contains fibers from both eyes that transmit information from the same visual field.

Fibers of the optic tracts synapse in the lateral geniculate nucleus (LGN) of the thalamus. Axons from these neurons in the LGN form the optic radiations to the primary visual cortex in the occipital lobe. The pattern of information transmission established in the optic tract is retained in the optic radiations. For example, the axons from the right visual field, represented by the nasal retina of the right eye and the temporal retina of the left eye, are united at the chiasm. They continue through the left optic tract and left optic radiation to the left visual cortex, where visual experience is first perceived. The left primary visual cortex receives two representations of the right visual

■ FIGURE 40-10 ■ Diagram of optic pathways. The red lines indicate right visual field and the blue lines the left visual field. Note the crossing of fibers from the medial half of each retina at the optic chiasm. Lesion 1 (right optic nerve) produces unilateral blindness. Lesion 2 (optic chiasm) may involve only those fibers that originate in the nasal half of each retina and cross to the opposite side in the optic chiasm, visual loss involves the temporal half of each field (bitemporal hemianopia). Lesion 3 (right optic tract) interrupts fibers (and vision) originating on the same side of both eyes (homonymous) with loss of vision from half of each field (hemianopia).

field. Physical separation of information from the left and right visual fields is maintained in the visual cortex. Interaction between these disparate representations occurs and provides the basis for the sensation of depth in the near visual field.

The primary visual cortex (area 17) surrounds the calcarine fissure, which lies in the occipital lobe. It is at this level that visual sensation is first experienced (Fig. 40-11). Immediately surrounding area 17 are the visual association cortices (areas 18 and 19) and several other association cortices. These association cortices, with their thalamic nuclei, must be functional for added meaningfulness of visual perception. This higher-order aspect of the visual experience depends on previous learning.

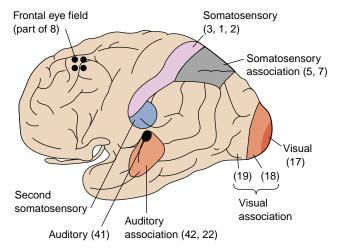

Disorders of the Optic Pathways

Among the disorders that can interrupt the visual pathway are trauma, tumors, and vascular lesions. Trauma and tumors can produce direct injury or impinge on the optic pathways. Vascular insufficiency in any one of the arterial systems of the retina or visual pathways can seriously affect vision. For example, normal visual function depends on adequacy of blood flow in the ophthalmic artery and its branches; the central artery of the retina; the anterior and middle cerebral arteries, which supply the intracranial optic nerve, chiasm, and optic tracts; and the posterior cerebral artery, which supplies the LGN, optic radiation, and visual cortex. The adequacy of posterior cerebral artery function depends on that of the vertebral and basilar arteries that supply the brain stem.

Visual Field Defects

The visual field refers to the area that is visible during fixation of vision in one direction. As with a camera, the simple lens system of the eye inverts the image of the external world on each retina (Fig. 40-10). In addition, the right and left sides of the visual field also are reversed. The right binocular visual field (the nasal half of the right eye and the temporal half of the left eye) is seen by the left retinal halves of each eye. Likewise, the left binocular field is seen by the right retinal halves of each eye.

Most of the visual field is *binocular*, or seen by both eyes. This binocular field is subdivided into central and peripheral portions. Central portions of the retina provide high visual acu-

■ FIGURE 40-11 ■ Lateral view of the cortex illustrating the location of the visual, visual association, auditory, and auditory association areas.

ity and correspond to the field focused on the central fovea. The peripheral and surrounding portion provides the capacity to detect objects, particularly moving objects. Beyond the visual field shared by both eyes, the left lateral periphery of the visual field is seen exclusively by the left nasal retina, and the right peripheral field by the right nasal retina.

Visual field defects result from damage to the visual pathways or the visual cortex (Fig. 40-10). The testing of visual fields of each eye and of the two eyes together are useful in localizing lesions affecting the system. Perimetry or visual field testing, in which the visual field of each eye is measured and plotted in an arc, is used to identify defects and determine the location of lesions.

Blindness in one eye is called anopia. If half of the visual field for one eye is lost, the defect is called *hemianopia*; loss of a quarter field is called quadrantanopia. Enlarging pituitary tumors can produce longitudinal damage through the optic chiasm with loss of the medial fibers of the optic nerve representing both nasal retinas and both temporal visual half-fields. Loss of the temporal or peripheral visual fields on both sides results in a narrow binocular field, commonly called tunnel vision. The loss of different half-fields in the two eyes is called a heteronymous loss, and the abnormality is called heteronymous hemianopia. Destruction of one or both lateral halves of the chiasm is common with multiple aneurysms of the circle of Willis (see Chapter 37). In this condition, the function of one or both temporal retinas is lost, and the nasal fields of one or both eves are lost. The loss of the temporal fields (nasal retina) of both eyes is called bitemporal heteronymous anopia. With both eyes open, the person with bilateral defects still has the full binocular visual field.

Loss of the optic tract, LGN, full optic radiation, or complete visual cortex on one side results in loss of the corresponding visual half-fields in each eye. Homonymous means "the same for both eyes. In left-side lesions, the right visual field is lost for each eve and is called *complete right homonymous hemianopia*. Partial injury to the left optic tract, LGN, or optic radiation can result in the loss of a quarter of the visual field in both eyes. This is called homonymous quadrantanopia, and depending on the lesion, it can involve the upper (superior) or lower (inferior) fields. The LGN, optic radiation, and visual cortex all receive their major blood supply from the posterior cerebral artery; unilateral occlusion of this artery results in complete loss of the opposite field (*i.e.*, homonymous hemianopia). Bilateral occlusion of these arteries results in total cortical blindness.

The Extraocular Eye Muscles and Disorders of Eye Movements

For complete function of the eyes, it is necessary that the two eves point toward the same fixation point and that the retinal and central nervous system (CNS) visual acuity mechanisms function. Despite slight variations in the view of the external world for each eye, it is important that these two images become fused, which is a forebrain function. Binocular fusion is controlled by ocular reflex mechanisms that adjust the orientation of each eye to produce a single image. If these reflexes fail, diplopia or double vision occurs.

Binocular vision depends on three pairs of extraocular muscles-the medial and lateral recti, the superior and inferior recti, and the superior and inferior obliques (Fig. 40-12). Each of the three sets of muscles in each eye is reciprocally innervated **FIGURE 40-12** Extraocular eye muscles of the right eye.

so that one muscle relaxes when the other contracts. Reciprocal contraction of the medial and lateral recti moves the eye from side to side (adduction and abduction); the superior and inferior recti move the eye up and down (elevation and depression). The oblique muscles rotate (intorsion and extorsion) the eye around its optic axis. A seventh muscle, the levator palpebrae superioris, elevates the upper lid.

The extraocular muscles are innervated by three cranial nerves. The trochlear nerve (CN IV) innervates the superior oblique, the abducens nerve (CN VI) innervates the lateral rectus, and the oculomotor nerve (CN III) innervates the remaining four muscles. Table 40-1 describes the function and innervation of the extraocular muscles.

Normal vision depends on the coordinated action of the entire visual system and a number of central control systems. It is through these mechanisms that an object is simultaneously imaged on the fovea of both eyes and perceived as a single image. Strabismus and amblyopia are two disorders that affect this highly integrated system. Although strabismus may develop in later life, it is seen most commonly in children.

Strabismus

Strabismus, or squint, refers to any abnormality of eye coordination or alignment that results in loss of binocular vision (Fig. 40-13). When images from the same spots in visual space

*In the schema of the functional roles of the six extraocular muscles, the major directional force applied by each muscle is indicated on the top. These muscles are arranged in functionally opposing pairs per eye and in parallel opposing pairs for conjugate movements of the two eyes. The numbers associated with each muscle indicate the cranial nerve innervation: 3, oculomotor (III) cranial nerve; 4, trochlear (IV) cranial nerve; 6, abducens (VI) cranial nerve.

Chapter 40: Alterations in Special Sensory Function

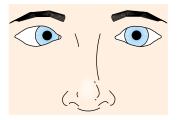

do not fall on corresponding points of the two retinas, diplopia, or double vision, occurs.

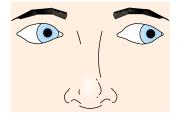

In standard terminology, the disorders of eve movement are described according to the direction of movement. Esotropia refers to medial deviation, exotropia refers to lateral deviation, hypertropia refers to upward deviation, hypotropia refers to downward deviation, and cyclotropia refers to torsional deviation. The term concomitance refers to equal deviation in all directions of gaze. A nonconcomitant strabismus is one that varies with the direction of gaze. Strabismus may be divided into paralytic (nonconcomitant) forms, in which there is weakness or paralysis of one or more of the extraocular muscles, and nonparalytic (concomitant) forms, in which there is no primary muscle impairment. Strabismus is called intermittent, or *periodic*, when there are periods in which the eyes are parallel. It is monocular when the same eye always deviates and the fellow eye fixates. Figure 40-14 illustrates abnormalities in eye movement associated with esotropia and exotropia.

Strabismus affects approximately 4% of children younger than 6 years of age.¹⁸ Because 30% to 50% of these children sustain permanent secondary loss of vision, or amblyopia, if the condition is left untreated, early diagnosis and treatment are essential.19

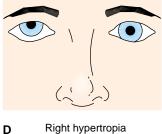

Paralytic Strabismus. Paralytic strabismus results from paresis (*i.e.*, weakness) or plegia (*i.e.*, paralysis) of one or more of the extraocular muscles. When the normal eye fixates, the affected

Right exotropia

Ε

eye is in the position of primary deviation. In the case of esotropia, there is weakness of one of the lateral rectus muscles, usually the result of weakness of the abducens nerve (CN VI). When the affected eye fixates, the unaffected eye is in a position of secondary deviation. The secondary deviation of the unaffected eye is greater than the primary deviation of the affected eye. This is because the affected eye requires an excess of innervational impulse to maintain fixation; the excess impulses also are distributed to the unaffected eye, causing overaction of its muscles.²

Paralytic strabismus is uncommon in children but accounts for nearly all cases of adult strabismus; it can be caused by a number of conditions. Paralytic strabismus is seen most commonly in adults who have had cerebral vascular accidents and also may occur as the first sign of a tumor or inflammatory condition involving the CNS. One type of muscular dystrophy exerts its effects on the extraocular muscles. Initially, eye movements in all directions are weak, with later progression to bilateral optic immobility. Weakness of eye movement and lid elevation often is the first evidence of myasthenia gravis. The pathway of the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves through the cavernous sinus and the back of the orbit make them vulnerable to basal skull fracture and tumors of the cavernous sinus (e.g., cavernous sinus syndrome) or orbit (e.g., orbital syndrome).²⁰ In infants, paralytic strabismus can be caused by birth injuries affecting the extraocular muscles or the cranial nerves supplying these muscles. It also can result from congenital anomalies of the muscles. In general, paralytic strabismus in an adult with previously normal binocular vision causes diplopia. This does not occur in persons who have never developed binocular vision.

Nonparalytic Strabismus. In nonparalytic strabismus, there is no extraocular muscle weakness or paralysis, and the angle of deviation is always the same in all fields of gaze. With persistent deviation, secondary abnormalities may develop because of overaction or underaction of the muscles in some fields of gaze. Nonparalytic esotropia is the most common type of strabismus. The disorder may be accommodative, nonaccommodative, or a combination of the two. Accommodative strabismus is caused by disorders such as uncorrected hyperopia, in which the esotropia occurs with accommodation. The onset of this type of esotropia characteristically occurs between 18 months and 4 years of age because accommodation is not well developed until that time. The disorder most often is monocular but may be alternating. Approximately 50% of the cases of esotropia are accommodative. The causes of nonaccommodative strabismus are obscure. The disorder may be related to faulty muscle insertion, fascial abnormalities, or faulty innervation. There is evidence that idiopathic strabismus may have a genetic basis; siblings may have similar disorders.

Diagnosis and Treatment. All infants and children should be examined for visual alignment. Alignment of the visual axis occurs in the first 3 months of life. All infants should have consistent, synchronized eye movement by 5 to 6 months of age.²¹ Infants who have reached this age and whose eyes are not aligned at all times during waking hours should be examined by a qualified practitioner.

Treatment of strabismus is directed toward the development of normal visual acuity, correction of the deviation, and superimposition of the retinal images to provide binocular vision. Nonsurgical and surgical methods can be used. In children, early treatment is important; the ideal age to begin is 6 months. Nonsurgical treatment includes occlusive patching, pleoptics (*i.e.*, eye exercises), and prism glasses. Because prolonged occlusive patching leads to loss of useful vision in the covered eye, patching is alternated between the affected and unaffected eye. This improves the vision in the affected eye without sacrificing vision in the unaffected eye. Prism glasses compensate for an abnormal alignment of an optic globe. Occasionally, longacting miotics in low doses are used to cause pharmacologic accommodation in place of or in combination with corrective lenses.¹⁸ Surgical procedures may be used to strengthen or weaken a muscle by altering its length or attachment site.

Amblyopia

Amblyopia describes a condition of diminished vision (uncorrectable by lenses) in which no detectable organic lesion of the eye is present.²² This condition sometimes is referred to as *lazy eye*. Types of amblyopia include deprivation occlusion, strabismus, refractive, and organic amblyopia. It is caused by visual deprivation (*e.g.*, cataracts, severe ptosis) or abnormal binocular interactions (*e.g.*, strabismus, anisometropia) during visual immaturity. Normal development of the thalamic and cortical circuitry necessary for binocular visual perception requires simultaneous binocular use of each fovea during a critical period early in life (0 to 5 years of age).

In conditions causing abnormal binocular interactions, one image is suppressed to provide clearer vision. In esotropia, vision of the deviated eye is suppressed to prevent diplopia. A similar situation exists in anisometropia, in which the refractive indexes of the two eyes are different. Although the eyes are correctly aligned, they are unable to focus together, and the image of one eye is suppressed.

The reversibility of amblyopia depends on the maturity of the visual system at the time of onset and the duration of the abnormal experience. If esotropia is involved, some persons alternate eyes and do not experience diplopia. With late adolescent or adult onset, this habit pattern must be unlearned after correction.

Peripheral vision is less affected than central foveal vision in amblyopia. Suppression becomes more evident with high illumination and high contrast. It is as if the affected eye did not possess central vision and the person learns to fixate with the nonfoveal retina. If bilateral congenital blindness or near blindness (*e.g.*, from cataracts) occurs and remains uncorrected during infancy and early childhood, the person remains without pattern vision and has only overall field brightness and color discrimination. This is essentially bilateral amblyopia.

The treatment of children with the potential for development of amblyopia must be instituted well before the age of 6 years to avoid the suppression phenomenon. Severe refractive errors should be corrected. In strabismus, alternately blocking vision in one eye and then the other forces the child to use both eyes for form discrimination. The duration of occlusion of vision in the good eye must be short (2 to 5 hours per day) and closely monitored, or deprivation amblyopia can develop in the good eye as well.

In infants with congenital unilateral cataracts that are dense, central, and larger than 2 mm in diameter, treatment should be started before 2 months of age.² Although bilateral cataracts

Chapter 40: Alterations in Special Sensory Function 763

may require less urgent management, surgical treatment should be done as soon as possible to permit normal development of vision. The surgery for each eye is done separately, with as short an interval as possible between the surgery on the two eyes.

In summary, the optic globe, or eyeball, is a nearly spherical structure protected posteriorly by the bony structures of the orbit and anteriorly by the eyelids. A conjunctiva lines the inner surface of the eyelids and covers the optic globe to the junction of the cornea and sclera. Conjunctivitis, also called *red eye* or *pink eye*, may result from bacterial or viral infection, allergic reactions, or the injurious effects of chemical agents, physical agents, or radiant energy. Keratitis, or inflammation of the cornea, can be caused by infections, hypersensitivity reactions, ischemia, trauma, defects in tearing, or trauma. Trauma or disease that involves the stromal layer of the cornea heals with scar formation and permanent opacification. These opacities interfere with the transmission of light and may impair vision.

Interiorly, the eye is divided into a smaller, fluid-filled anterior cavity and a larger, vitreous-filled posterior segment. The anterior segment of the eye is divided into an anterior and posterior chamber, separated by the pupil and closely adjacent lens. Glaucoma, which is one of the leading causes of blindness in the United States, is characterized by an increase in intraocular pressure resulting from the overproduction or impeded outflow of aqueous humor from the anterior chamber of the eye. Closed-angle glaucoma is caused by a narrow anterior chamber and blockage of the outflow channels at the angle formed by the iris and the cornea. Open-angle glaucoma is caused by an imbalance between aqueous humor production and outflow.

Refraction refers to the ability to focus an object on the retina. In hyperopia, or farsightedness, the image falls behind the retina. In myopia, or nearsightedness, the image falls in front of the retina. Accommodation is the process by which a clear image is maintained as the gaze is shifted from afar to a near object. Presbyopia is a change in the lens that occurs because of aging such that the lens becomes thicker and less able to change shape and accommodate for near vision. A cataract is characterized by increased lens opacity. It can occur as the result of congenital influences, metabolic disturbances, infection, injury, and aging.

The retina covers the inner aspect of the posterior two thirds of the eyeball and is continuous with the optic nerve. It contains the photoreceptors for vision: the rods, for black and white discrimination, and the cones, for color vision. Disorders of retinal vessels can result from a number of local and systemic disorders, including diabetes mellitus and hypertension. They cause vision loss through changes that result in hemorrhage, the production of opacities, and the separation of the pigment epithelium and sensory retina. Retinal detachment involves separation of the sensory receptors from their blood supply; it causes blindness unless reattachment is accomplished promptly. Macular degeneration, which is a leading cause of blindness in the elderly, is characterized by loss of central vision resulting from destructive changes in the central fovea.

Visual information is carried to the brain by axons of the retinal ganglion cells that form the optic nerve. The two optic

nerves meet and cross at optic chiasm, with the axons from each nasal retina joining the uncrossed fibers of the temporal retina of the opposite eye in the optic tract. The fibers in the optic tract pass to the LGN in the thalamus and then to the primary visual cortex, which is located in the occipital lobe. Damage to the visual pathways leads to visual field defects that can be identified through visual field testing or perimetry.

Eve movement, which is controlled by the extraocular muscles, provides for alignment of the eyes and binocular vision. Strabismus refers to abnormalities in the coordination of eye movements with loss of binocular eye alignment. This inability to focus a visual image on corresponding parts of the two retinas results in diplopia. Paralytic strabismus is caused by weakness or paralysis of the extraocular muscles. Nonparalytic strabismus results from the inappropriate length or insertion of the extraocular muscles or from accommodation disorders. The neural pathways for vision develop during infancy. Amblyopia (i.e., lazy eye) is a condition of diminished vision that cannot be corrected by lenses and in which no detectable organic lesion in the eye can be observed. It results from inadequately developed CNS circuitry because of visual deprivation (e.g., cataracts) or abnormal binocular interactions (e.g., strabismus, anisometropia) during the period of visual immaturity.

THE EAR AND DISORDERS OF AUDITORY FUNCTION

The ears are paired organs consisting of an external and middle ear, which function in capturing, transmitting, and amplifying sound, and an inner ear that contains the receptive organs that are stimulated by sound waves (*i.e.*, hearing) or head position and movement (*i.e.*, vestibular function). Otitis media, or inflammation of the middle ear, is a common disorder of childhood. Hearing loss is one of the most common disabilities experienced by persons in the United States, particularly among the elderly.

External Ear

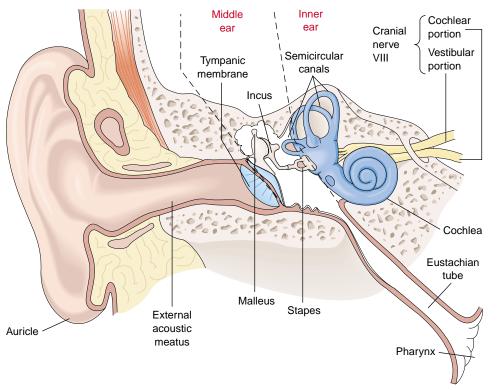

The external ear is a funnel-shaped structure that conducts sound waves to the tympanic membrane. It consists of the auricle, the external acoustic meatus, and the lateral surface of the tympanic membrane (see Fig. 40-15). A thin layer of skin containing fine hairs, sebaceous glands, and ceruminous glands lines the ear canal. Ceruminous glands secrete cerumen, or earwax, which has certain antimicrobial properties and is thought to serve a protective function.

Disorders of the External Ear

The function of the external ear is disturbed when sound transmission is obstructed by impacted cerumen, inflammation (*i.e.*, otitis externa), or drainage from the external ear (otorrhea).

Impacted Cerumen. Although the ear normally is self-cleaning, the cerumen can accumulate and narrow the canal. Impacted cerumen is a common cause of reversible hearing loss.²³ It usually produces no symptoms until the canal becomes completely

764 Unit Ten: Alterations in the Nervous System

■ **FIGURE 40-15** ■ External, middle, and internal subdivisions of the ear.

occluded, at which point the person experiences a feeling of fullness, loss of hearing, tinnitus (*i.e.*, ringing in the ears), or coughing because of vagal stimulation.

In most cases, cerumen can be removed by gentle irrigation using a bulb syringe and warm tap water. Warm water is used to avoid inducing a feeling of disequilibrium caused by the vestibular caloric response. Alternatively, health care professionals may remove cerumen using an otoscope and a wire loop or blunt cerumen curette.

Otitis Externa. Otitis externa is an inflammation of the external ear that can vary in severity from a mild eczematoid dermatitis to severe cellulitis. It can be caused by infectious agents, irritation (e.g., wearing earphones), or allergic reactions. Predisposing factors include moisture in the ear canal after swimming (*i.e.*, swimmer's ear) or bathing and trauma resulting from scratching or attempts to clean the ear. Most infections are caused by gram-negative bacteria (e.g., Pseudomonas, Proteus) or fungi that grow in the presence of excess moisture.²⁴ Otitis externa commonly occurs in the summer and is manifested by itching, redness, tenderness, and narrowing of the ear canal because of swelling. Inflammation of the auricle and external acoustic meatus makes movement of the ear painful. There may be watery or purulent drainage and intermittent hearing loss. Treatment usually includes the use of ear drops containing an appropriate antimicrobial or antifungal agent in combination with a corticosteroid to reduce inflammation.

The Middle Ear and Eustachian Tube

The middle ear is a small air-filled cavity located with the petrous (stony) portion of the middle ear. Its lateral wall is formed by the tympanic membrane and its medial wall by the

bone dividing the middle and inner ear (see Fig. 40-15). Posteriorly, the middle ear is connected with small air pockets in the temporal bone called *mastoid air spaces* or *cells*.

Three tiny bones, the auditory ossicles, are suspended from the roof of the middle ear cavity and connect the tympanic membrane with the oval window (see Fig. 40-15). They are connected by synovial joints and are covered with the epithelial lining of the cavity. The malleus ("hammer") has its handle firmly fixed to the upper portion of the tympanic membrane. The head of the malleus articulates with the incus ("anvil"), which articulates with the *stapes* ("stirrup"), which is inserted and sealed into the oval window by an annular ligament. Arrangement of the ear ossicles is such that their lever movements transmit vibrations from the tympanic membrane to the oval window and from there to the fluid in the inner ear. Two tissue-covered openings in the medial wall, the oval and the round windows, provide for the transmission of sound waves between the air-filled middle ear and the fluid-filled inner ear. It is the piston-like action of the stapes footplate that sets up compression waves in the inner ear fluid.

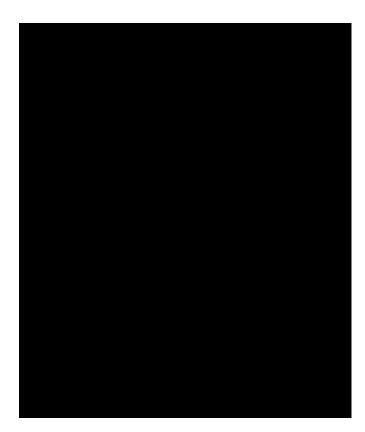

The middle ear is connected to the nasopharynx by the eustachian or auditory tube, which is located in a gap in the bone between the anterior and medial walls of the middle ear (Fig. 40-16). The eustachian tube is lined with a mucous membrane that is continuous with the pharynx and the mastoid air cells.²⁵ The nasopharyngeal entrance to the eustachian tube, which usually is closed, is opened by the action of the *tensor veli palatini muscles* (Fig. 40-17). Opening of the eustachian tube, which normally occurs with swallowing and yawning reflexes, provides the mechanism for equalizing the pressure of the middle ear with that of the atmosphere. This equalization ensures that the pressures on both sides of the tympanic membrane are the same, so that sound transmission is not reduced and rup-

ture does not result from sudden changes in external pressure, as occurs during plane travel.

Disorders of the Eustachian Tube

Abnormalities in eustachian tube function are important factors in the pathogenesis of middle ear infections. There are two important types of eustachian tube dysfunction: abnormal patency and obstruction. The *abnormally patent tube* does not close or does not close completely. In infants and children with an abnormally patent tube, air and secretions often are pumped into the eustachian tube during crying and nose blowing.

Obstruction can be functional or mechanical (see Fig. 40-17). *Functional obstruction* results from the persistent collapse of the eustachian tube due to a lack of tubal stiffness or poor function of the tensor veli palatini muscle that controls the opening of the eustachian tube. It is common in infants and young children because the amount and stiffness of the cartilage supporting the eustachian tube are less than in older children and adults. Changes in the craniofacial base also render the tensor

KEY CONCEPTS

DISORDERS OF THE MIDDLE EAR

- The middle ear is a small air-filled compartment in the temporal bone. It is separated from the outer ear by the tympanic membrane, contains tiny bony ossicles that aid in the amplification and transmission of sound to the inner ear, and is ventilated by the eustachian tube, which is connected to the nasopharynx.
- The eustachian tube, which is lined with a mucous membrane that is continuous with the nasopharynx, provides a passageway for pathogens to enter the middle ear.
- Otitis media (OM) refers to inflammation of the middle ear, usually associated with an acute infection (acute OM) or an accumulation of fluid (OME). It commonly is associated with disorders of eustachian tube function.
- Impaired conduction of sound waves and hearing loss occur when the tympanic membrane has been perforated; air in the middle ear has been replaced with fluid (OME); or the function of the bony ossicles has been impaired (otosclerosis).

muscle less efficient for opening the eustachian tube in this age group. In infants and children with craniofacial disorders, such as a cleft palate, or abnormalities in attachment of the tensor muscles may produce functional obstruction of the eustachian tube.

Mechanical obstruction results from internal obstruction or external compression of the eustachian tube. The most common cause of internal obstruction is swelling and secretions resulting from allergy and viral respiratory infections. With obstruction, air in the middle ear is absorbed, causing a negative pressure and the transudation of serous capillary fluid into the middle ear.

Otitis Media

Otitis media (OM) is an infection of the middle ear that is associated with a collection of fluid. Although OM may occur in any age group, it is the most common diagnosis made by health care providers who care for children. Almost all children have had at least one ear infection by 7 years of age, and one third have three or more episodes by 3 years of age.²⁶ Infants and young children are at highest risk, with the peak incidence between 6 and 13 months. The incidence is higher in boys, infants who are not breast-fed, those who use pacifiers beyond infancy, children in large day care settings, children exposed to tobacco smoke, those with siblings or parents with a significant history of OM, those with allergic rhinitis, and children with congenital or acquired immune deficiencies (e.g., acquired immunodeficiency syndrome).27 The incidence of OM also is higher among children with craniofacial anomalies (e.g., cleft palate, Down's syndrome) and among Canadian and Alaskan Eskimos, and Native Americans.²⁸ It is more common during the winter months, reflecting the seasonal patterns of upper respiratory tract infections.

There are two reasons for the increased risk of OM in infants and young children. First, the eustachian tube is shorter, more horizontal, and wider in this age group than in older children and adults. Second, the infection can spread more easily through the eustachian canal of infants who spend most of their day lying supine. Bottle-fed infants have a higher incidence of OM than breast-fed infants, probably because they are held in a more horizontal position during feeding, and swallowing while in the horizontal position facilitates the reflux of milk into the middle ear. Breast-feeding also provides for the transfer of protective maternal antibodies to the infant.

Otitis media may present as acute otitis media (AOM), recurrent OM, or OM with effusion (OME) or fluid in the middle ear. This effusion may be thin and watery (serous), thick and mucus-like (mucoid), or purulent (containing pus). The characteristics of the fluid vary depending on the type of OM.

Acute Otitis Media. Acute OM is characterized by the presence of fluid in the middle ear in combination with signs and symptoms of an acute or systemic infection.²⁹ AOM can fail to resolve despite antibiotic treatment (persistent OM), or it may resolve and then recur (recurrent OM). Most cases of AOM follow an upper respiratory tract infection that has been present for several days. AOM may be of either bacterial or viral origin. There may be more than one type of bacteria present in some children. S. pneumoniae causes the largest proportion (40% to 50%) of cases generated by a single organism, and it is the least likely to resolve without treatment.³⁰ Emergence of a multiple–drug-resistant strain of *S. pneumoniae* (DRSP) has led to increased numbers of treatment failures.

Acute OM is characterized by otalgia (earache), fever, and hearing loss. Children older than 3 years of age may have rhinorrhea or running nose, vomiting, and diarrhea. In contrast, younger children often have nonspecific signs and symptoms that manifest as ear tugging, irritability, nighttime awakening, and poor feeding. Ear pain usually increases as the effusion accumulates behind the tympanic membrane. Perforation of the tympanic membrane may occur acutely, allowing purulent material from the eustachian tube to drain into the external auditory canal. This may prevent spread of the infection into the temporal bone or intracranial cavity.

Diagnosis of AOM is made by associated signs and symptoms and otoscopic examination.³¹ The treatment of AOM includes the use of medications for fever and pain relief and the judicious use of antibiotic therapy in high-risk children. If the tympanic membrane is bulging and painful because of the accumulation of purulent drainage, a myringotomy (surgical incision in the eardrum) may be done to relieve the pressure, thus reducing pain and hearing loss. In addition, this procedure prevents the ragged opening that can follow spontaneous rupture of the tympanic membrane.

Residual middle ear effusions are part of the continuum of AOM and persist regardless of whether antibiotics have been used. The effusion usually clears spontaneously within 1 to 3 months and does not require further treatment unless it persists beyond this period.

Recurrent Otitis Media. Recurrent OM is defined as three new AOM episodes within 6 months or four episodes in 1 year that occur with almost every upper respiratory tract infection. Re-inforcement of environmental controls, such as avoidance of passive tobacco smoke, is important. Children with recurrent OM should be evaluated to rule out any anatomic variations (*e.g.*, enlarged adenoids) and immunologic disorders.

Recurrent OM may be managed with prophylactic antibiotic therapy. However, the emergence of bacterial resistance has raised concerns about the injudicious use of prophylactic antibiotics. Another approach to prevent recurrent OM is immunization with pneumococcal and influenza vaccines. Placement of tympanostomy tubes is another alternative, particularly for children who have experienced five or more OM episodes within a 12-month period.

Otitis Media With Effusion. Otitis media with effusion is a condition in which the tympanic membrane is intact and there is an accumulation of fluid in the middle ear without signs or symptoms of infection. The type of effusion often is described as serous, nonsuppurative, or secretory, but these terms may not be correct in all cases. In comparison to children with AOM, those with OME do not have a fever or other signs and symptoms of infection, although some may report a feeling of ear fullness.

Most cases of persistent middle ear effusion resolve spontaneously within 3 months. The management options for this duration include observation only, antibiotic therapy, or combination antibiotic and corticosteroid therapy. Because there is concern about hearing loss and its effect on learning and speech, a hearing evaluation may be indicated and usually is done after 6 weeks. If the effusion persists for 3 months or longer and is accompanied by hearing loss of 20 decibels (dB) or greater in children of normal development, tympanostomy tube placement may be indicated.²⁷

Complications of Otitis Media. The complications of OM include hearing loss and extratemporal complications, including those affecting the middle ear, mastoid, adjacent structures of the temporal bone, and intracranial structures.

Hearing loss, which is a common complication of OM, usually is conductive and temporary based on the duration of the effusion. Hearing loss that is associated with fluid collection usually resolves when the effusion clears. Permanent hearing loss may occur as the result of damage to the tympanic membrane or other middle ear structures. Cases of sensorineural hearing loss are rare. Persistent and episodic conductive hearing loss in children may impair their cognitive, linguistic, and emotional development. However, the degree and duration of hearing loss required to produce such effects are unknown.

Adhesive OM involves an abnormal healing reaction in an inflamed middle ear. It produces irreversible thickening of the mucous membranes and may cause impaired movement of the ossicles and possibly conductive hearing loss. Tympanosclerosis involves the formation of whitish plaques and nodular deposits on the submucosal surface of the tympanic membrane, with possible adherence of the ossicles and conductive hearing loss.

A *cholesteatoma* is a saclike mass containing silvery-white debris of keratin, which is shed by the squamous epithelial lining of the tympanic membrane. As the lining of the epithelium sheds and desquamates, the lesion expands and erodes the surrounding tissues. The lesion, which is associated with chronic middle ear infection, is insidiously progressive, and erosion may involve the temporal bone, causing intracranial complications. Treatment involves microsurgical techniques to remove the cholesteatomatous material.

The mastoid antrum and air cells constitute a portion of the temporal bone and may become inflamed as an extension of acute or chronic OM. The disorder causes necrosis of the mastoid process and destruction of the bony intercellular matrix, which are visible by radiologic examination. Mastoid tenderness and drainage of exudate through a perforated tympanic membrane can occur. Chronic mastoiditis can develop as the result of chronic middle ear infection. Mastoid or middle ear surgery, along with other medical treatment, may be indicated.

Intracranial complications are uncommon since the advent of antimicrobial therapy. Although rare, these complications can develop if the infection spreads through vascular channels, by direct extension, or through preformed pathways such as the round window. These complications are seen more often with chronic suppurative OM and mastoiditis. They include meningitis, focal encephalitis, brain abscess, lateral sinus thrombophlebitis or thrombosis, labyrinthitis, and facial nerve paralysis.

Otosclerosis

SHORT

Otosclerosis refers to the formation of new spongy bone around the stapes and oval window, which results in progressive deafness.³ In most cases, the condition is familial and follows an autosomal dominant pattern with variable penetrance. Otosclerosis may begin at any time in life but usually does not appear until after puberty, most frequently between the ages of 20 and 30 years. The disease process accelerates during pregnancy.

Otosclerosis begins with resorption of bone in one or more foci. During active bone resorption, the bone structure appears spongy and softer than normal (*i.e.*, osteospongiosis). The resorbed bone is replaced by an overgrowth of new, hard, sclerotic bone. The process is slowly progressive, involving more areas of the temporal bone, especially in front of and posterior to the stapes footplate. As it invades the footplate, the pathologic bone increasingly immobilizes the stapes, reducing the transmission of sound. The pressure of otosclerotic bone on inner ear structures or the vestibulocochlear nerve (CN VIII) may contribute to the development of tinnitus, sensorineural hearing loss, and vertigo (to be discussed later in this chapter).

The symptoms of otosclerosis involve an insidious hearing loss. Initially, the affected person is unable to hear a whisper or someone speaking at a distance. In the earliest stages, the bone conduction by which the person's own voice is heard remains relatively unaffected. At this point, the person's own voice sounds unusually loud, and the sound of chewing becomes intensified. Because of bone conduction, most of these persons can hear fairly well on the telephone, which provides an amplified signal. Many are able to hear better in a noisy environment, probably because the masking effect of background noise causes other persons to speak more loudly.

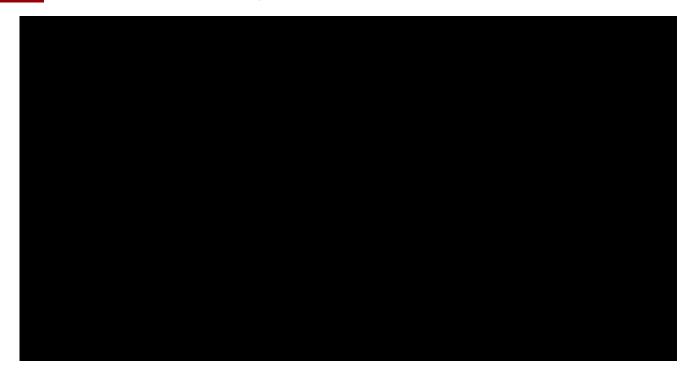

The treatment of otosclerosis can be medical or surgical. A carefully selected, well-fitting hearing aid may allow a person with conductive deafness to lead a normal life. Sodium fluoride has been used with some success in the medical treatment of osteospongiosis. Because much of the conductive hearing loss associated with otosclerosis is caused by stapedial fixation, surgical treatment involves stapedectomy with reconstruction using the patient's own stapes or a prosthetic device.

The Inner Ear and Auditory Pathways

The inner ear contains a labyrinth, or system of intercommunicating channels, and the receptors for hearing and position sense. An outer bony wall, or bony labyrinth, encloses a thin walled, membranous labyrinth, which floats in the bony labyrinth. Two separate fluids are found in the inner ear. The *periotic fluid* or *perilymph* separates the bony labyrinth from the membranous labyrinth, and the *otic fluid* or *endolymph* fills the membranous labyrinth. Periotic fluid composition is similar to that of the CSF, and a tubular perilymphatic duct connects the periotic fluid with the CSF in the arachnoid space of the posterior fossa. Otic fluid has a potassium content that is similar to that of intracellular fluid.

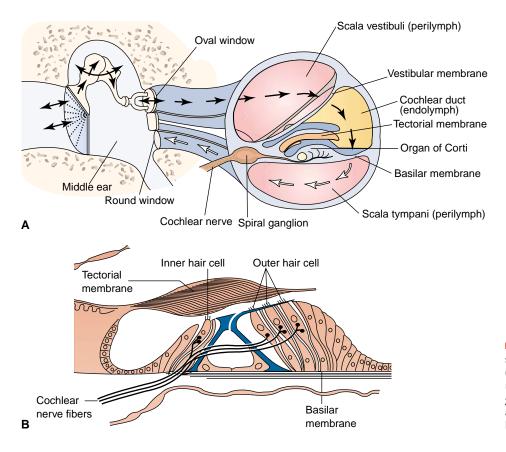

Localized dilatations of the membranous labyrinth develop into three specialized sensory regions: the ampulla of each semicircular canal, the maculae of the utricle and sacculus, and the cochlea (Fig. 40-18). The cochlea is enclosed in a bony tube shaped like a snail shell that winds around a central bone column called the *modiolus*. Running through its center is the triangular membranous cochlear duct, which houses the spiral organ of Corti, the receptor organ for hearing. The cochlear duct and the spiral lamina, a thin shelflike extension that spirals

768 Unit Ten: Alterations in the Nervous System

up the modiolus divides the cavity of the cochlea into three chambers: the scala vestibuli, the scala tympani, and the scala media (Fig. 40-19A). The organ of Corti, which rests atop the basilar membrane in the scala media, is composed of supporting cells and several long rows of cochlear hair cells: one row

of inner hair cells and three rows of outer hair cells (Fig. 40-19B). Afferent fibers from the cochlear nerve are coiled around the bases of the hair cells. Sound waves, delivered to the oval window by the stapes footplate, are transmitted to the periotic fluid in the scala vestibuli and scala tympani. Transduction of sound

■ FIGURE 40-19 ■ (A) Path taken by sound waves reaching the inner ear. (B) Spiral organ of Corti has been removed from the cochlear duct and greatly enlarged to show the inner and outer hair cells, the basilar membrane, and cochlear nerve fibers. stimuli occurs when the trapped cilia of the hair cells in the organ of Corti are bent by the sound-induced movement of the basilar membrane.

Afferent fibers from the organ of Corti have their cell bodies in the spiral ganglion in the central portion of the cochlea. Nerve fibers from the spiral ganglion (i.e., vestibulocochlear or auditory nerve [CN VIII]) travel to the cochlear nuclei in the caudal pons. Many secondary nerve fibers from the cochlear nuclei pass to the nuclei on the opposite side of the pons or rostrally toward the inferior colliculus of the midbrain. From the inferior colliculus, the auditory pathway passes to the primary auditory cortex (area 41) in the temporal lobe via relays in the medial geniculate nucleus of the thalamus (Fig. 40-11). The auditory association cortex (areas 42 and 22), which is necessary for the meaningfulness of sound, borders the primary cortex. Because some of the fibers from each ear cross, each auditory cortex receives impulses from both ears.

Disorders of the Inner Ear and Central Auditory Pathways

Disorders of the cochlear component of the inner ear and auditory pathways can lead to the presence of tinnitus or sensorineural hearing loss.

Tinnitus. Tinnitus (from the Latin *tinniere*, meaning "to ring") is the perception of abnormal ear or head noises not produced by an external stimulus.³³ Although it often is described as "ringing of the ears," it may also assume a hissing, roaring, buzzing, or humming sound. It has been estimated that 35 million people in the United States have the disorder. The condition affects males and females equally, is most prevalent between 40 and 70 years of age, and occasionally affects children.33

Tinnitus may be constant, intermittent, and unilateral or bilateral. Intermittent periods of mild, high-pitched tinnitus lasting for several minutes are common in normal-hearing persons. Impacted cerumen is a benign cause of tinnitus, which resolves after the ear wax is removed. Medications such as aspirin and stimulants such as nicotine and caffeine can cause transient tinnitus. Although tinnitus is a subjective experience, for clinical purposes it is subdivided into objective and subjective tinnitus. Objective tinnitus refers to those rare cases in which the sound is detected or potentially detectable by another observer. Typical causes of objective tinnitus include vascular abnormalities or neuromuscular disorders. For example, in some vascular disorders, sounds generated by turbulent blood flow (e.g., arterial bruits or venous hums) are conducted to the auditory system. Vascular disorders typically produce a pulsatile form of tinnitus. Subjective tinnitus refers to noise perception when there is no noise stimulation of the cochlea. The physiologic mechanism underlying subjective tinnitus is largely unknown. It seems likely that there are several mechanisms, including abnormal firing of auditory receptors, dysfunction of cochlear neurotransmitter function or ionic balance, and alterations in central processing of the signal.

Treatment measures for tinnitus are designed to treat the symptoms, rather than effect a cure. They include elimination of drugs or other substances such as caffeine, some cheeses, red wine, and foods containing monosodium glutamate that are suspected of causing tinnitus. The use of an externally produced sound (noise generators or tinnitus-masking devices) may be used to mask or inhibit the tinnitus.

Disorders of the Central Auditory Pathways. The auditory pathways in the brain involve communication between the two sides of the brain at many levels. As a result, strokes, tumors, abscesses, and other focal abnormalities seldom produce more than a mild reduction in auditory acuity on the side opposite the lesion. For intelligibility of auditory language, lateral dominance becomes important. On the dominant side, usually the left side, the more medial and dorsal portion of the auditory association cortex is of crucial importance. This area is called Wernicke's area, and damage to it is associated with auditory receptive aphasia (and agnosia of speech). Persons with damage to this area of the brain can speak intelligibly and read normally but are unable to understand the meaning of major aspects of audible speech.

Irritative foci that affect the auditory radiation or the primary auditory cortex can produce roaring or clicking sounds, which appear to come from the auditory environment of the opposite side (i.e., auditory hallucinations). Focal seizures that originate in or near the auditory cortex often are immediately preceded by the perception of ringing or other sounds preceded by a prodrome (*i.e.*, aura). Damage to the auditory association cortex, especially if bilateral, results in deficiencies of sound recognition and memory (*i.e.*, auditory agnosia). If the damage is in the dominant hemisphere, speech recognition can be affected (*i.e.*, sensory or receptive aphasia).

Hearing Loss

Nearly 30 million Americans have hearing loss. It affects persons of all age groups. One of every 1000 infants born in the United States is completely deaf, and more than 3 million children have hearing loss.³⁴ Thirty percent to 40% of people older than 75 years have hearing loss.

The level of hearing is measured in decibels, where 0 dB is the threshold for perception of sound at a given frequency in persons with normal hearing.³⁵ A 10-fold increase in sound pressure level from 0 dB is measured as 20 dB. Hearing loss is qualified as mild, moderate, severe, or profound. "Hard of hearing" is defined as hearing loss greater than 20 to 25 dB in adults and greater than 15 dB in children. Profound deafness is defined as hearing loss greater than 100 dB³⁶ or 70 dB in children.37

There are many causes of hearing loss or deafness. Most fit into the categories of conductive, sensorineural, or mixed

KEY CONCEPTS

HEARING LOSS

- Hearing loss represents impairment of the ability to detect and perceive sound.
- Conductive hearing loss is caused by disorders in which auditory stimuli are not transmitted through the structures of the outer and middle ears to the sensory receptors in the inner ear.
- Sensorineural hearing loss is caused by disorders that affect the inner ear, auditory nerve, or auditory pathways.

deficiencies that involve a combination of conductive and sensorineural function deficiencies of the same ear.³⁵ Chart 40-1 summarizes common causes of hearing loss. Hearing loss may be genetic or nongenetic, sudden or progressive, unilateral or bilateral, partial or complete, reversible or irreversible. Age and suddenness of onset provide important clues as to the cause of hearing loss.

Conductive Hearing Loss

Conductive hearing loss occurs when auditory stimuli are not adequately transmitted through the auditory canal, tympanic membrane, middle ear, or ossicle chain to the inner ear. Temporary hearing loss can occur as the result of impacted cerumen in the outer ear or fluid in the middle ear. Foreign bodies, including pieces of cotton and insects, may impair hearing. More permanent causes of hearing loss are thickening or damage of the tympanic membrane or involvement of the bony structures

CHART 40-1 Common Causes of Conductive and Sensorineural Hearing Loss

Conductive Hearing Loss

- External ear conditions
- Impacted ear wax or foreign body
- Otitis externa
- Middle ear conditions
- Trauma
- Otitis media (acute and with effusion)
- Otosclerosis
- Tumors

Sensorineural Hearing Loss

- Trauma
- Head injury
- Noise
- Central nervous system infections (e.g., meningitis)
- Degenerative conditions
- Presbycusis
- Vascular
- Atherosclerosis
- Sudden deafness
- Ototoxic drugs (*e.g.*, aminoglycosides, salicylates, loop diuretics)
- Tumors
 - Vestibular schwannoma (acoustic neuroma)
- Meningioma
- Metastatic tumors
- Idiopathic
 - Ménière's disease

Mixed Conductive and Sensorineural Hearing Loss

- Middle ear conditions
 - Barotrauma
 - Cholesteatoma
- Otosclerosis
- Temporal bone fractures

(ossicles and oval window) of the middle ear caused by otosclerosis or Paget's disease.

Sensorineural Hearing Loss

Sensorineural, or perceptive, hearing loss occurs with disorders that affect the inner ear, auditory nerve, or auditory pathways of the brain. With this type of deafness, sound waves are conducted to the inner ear, but abnormalities of the cochlear apparatus or auditory nerve decrease or distort the transfer of information to the brain. Tinnitus often accompanies cochlear nerve irritation. Abnormal function resulting from damage or malformation of the central auditory pathways and circuitry is included in this category.

Sensorineural hearing loss may have a genetic cause or may result from intrauterine infections, such as maternal rubella, or developmental malformations of the inner ear. Genetic hearing loss may result from mutation in a single gene (monogenetic) or from a combination of mutations in different genes and environmental factors (multifactorial).³⁶ It has been estimated that 50% of profound deafness in children has a monogenetic basis.^{36,38} The inheritance pattern for monogenetic hearing loss is autosomal recessive in approximately 75% of cases.³⁶ Hearing loss may begin before development of speech (prelingual) or after speech development (postlingual). Most prelingual forms are present at birth. Genetic forms of hearing loss also can be classified as being part of a syndrome in which other abnormalities are present, or as nonsyndromic, in which deafness is the only abnormality.

Sensorineural hearing loss also can result from trauma to the inner ear, tumors that encroach on the inner ear or sensory neurons, vascular disorders with hemorrhage, or thrombosis of vessels that supply the inner ear. Other causes of sensorineural deafness are infections and drugs. Sudden sensorineural hearing loss represents an abrupt loss of hearing that occurs instantaneously or on awakening. It most commonly is caused by viral infections, circulatory disorders, or rupture of the labyrinth membrane that can occur during tympanotomy.³⁹ Hypothyroidism is a potential cause of sensorineural hearing loss in older persons.

Environmentally induced deafness can occur through direct exposure to excessively intense sound, as in the workplace or at a concert. This is a particular problem in older adults who were working in noisy environments before the mid-1960s, when there were no laws mandating use of devices for protective hearing. Sustained or repeated exposure to noise pollution at sound intensities greater than 100 to 120 dB can cause corresponding mechanical damage to the organ of Corti. If damage is severe, permanent sensorineural deafness to the offending sound frequencies results. Wearing earplugs or ear protection is important under many industrial conditions and for musicians and music listeners exposed to high sound amplification.

A number of infections can cause sensorineural hearing loss. Deafness or some degree of hearing impairment is the most common serious complication of bacterial meningitis in infants and children, reportedly resulting in sensorineural hearing loss in 5% to 35% of persons who survive the infection.³⁸ The mechanism causing hearing impairment seems to be a suppurative labyrinthitis or neuritis resulting in the loss of hair cells and damage to the auditory nerve. Untreated suppurative

771

OM also can extend into the inner ear and cause sensorineural hearing loss through the same mechanisms.

Among the neoplasms that impair hearing are *acoustic neuromas*. Acoustic neuromas are benign Schwann cell tumors affecting CN VIII. These tumors usually are unilateral and cause hearing loss by compressing the cochlear nerve or interfering with blood supply to the nerve and cochlea. Other neoplasms that can affect hearing include meningiomas and metastatic brain tumors. The temporal bone is a common site of metastases. Breast cancer may metastasize to the middle ear and invade the cochlea.

Drugs that damage inner ear structures are labeled ototoxic. Vestibular symptoms of ototoxicity include light-headedness, giddiness, and dizziness; if toxicity is severe, cochlear symptoms consisting of tinnitus or hearing loss occur. Hearing loss is sensorineural and may be bilateral or unilateral, transient or permanent. Several classes of drugs have been identified as having ototoxic potential, including the aminoglycoside antibiotics and some other basic antibiotics, antimalarial drugs, some chemotherapeutic drugs, loop diuretics, and salicylates. The symptoms of drug-induced hearing loss may be transient, as often is the case with salicylates and diuretics, or they may be permanent. The risk of ototoxicity depends on the total dose of the drug and its concentration in the bloodstream. It is increased in persons with impaired kidney functioning and in those previously or currently treated with another potentially ototoxic drug.

Presbycusis

The term *presbycusis* is used to describe degenerative hearing loss that occurs with advancing age. Approximately 23% of persons between 65 and 75 years of age and 40% of the population older than 75 years are affected.⁴⁰ Men are affected earlier and experience a greater loss than women.

The degenerative changes that impair hearing may begin in the fifth decade of life and not be clinically apparent until later.⁴¹ Onset may be associated with chronic noise exposure or vascular disorders. The disorder involves loss of neuroepithelial (hair) cells, neurons, and the stria vascularis. High-frequency sounds are affected more than low-frequency sounds because high and low frequencies distort the base of the basilar membrane, but only low frequencies affect the distal (apical) region. Through the years, permanent mechanical damage to the organ of Corti is more likely to occur near the base of the cochlea, where the high sonic frequencies are discriminated. Loss of high-frequency discrimination is characterized by difficulty in understanding words in noisy environments, in hearing a speaker in an adjacent room, or hearing a speaker whose back is turned.

Although hearing loss is a common problem in the elderly, many older persons are not appropriately assessed for hearing loss. When assessing an older person's ability to hear, it is important to ask both the person and the family about awareness of hearing loss.

Detection and Treatment of Hearing Loss

Diagnosis of hearing loss is aided by careful history of associated otologic factors such as otalgia, otorrhea, tinnitus, and self-described hearing difficulties; physical examination to detect the presence of conditions such as otorrhea, impacted cerumen, or injury to the tympanic membrane; and hearing tests. Testing for hearing loss includes a number of methods, including a person's reported ability to hear an observer's voice, use of a tuning fork to test air and bone conduction, audioscopes, and auditory brain stem evoked responses (ABRs).

Tuning forks are used to differentiate conductive and sensorineural hearing loss. Audioscopes can be used to assess a person's ability to hear pure tones at 1000 to 2000 Hz (usual speech frequencies). The ABR is a noninvasive method that permits functional evaluation of certain defined parts of the central auditory pathways. Electroencephalographic (EEG) electrodes and high-gain amplifiers are required to produce a record of the electrical wave activity elicited during repeated acoustic stimulations of either or both ears. ABR recording involves subjecting the ear to loud clicks and using a computer to pick up nerve impulses as they are processed in the midbrain. Imaging studies such as computed tomography (CT) scans and magnetic resonance imaging (MRI) can be done to determine the site of a lesion and the extent of damage.³⁴

Because hearing impairment can have a major impact on the development of a child, early identification through screening programs is strongly advocated. The American Academy of Pediatricians endorses the goal of universal detection of hearing loss in infants before 3 months of age, with proper intervention no later than 6 months of age.⁴²

Treatment. Untreated hearing loss can have many consequences. In infants and children, hearing loss can greatly affect language development and hearing-associated learning. Social isolation and depressive disorders are common in hearingimpaired elderly. Hearing-impaired people may avoid social situations where background noise makes conversation difficult to hear. Safety issues, both in and out of the home, may become significant. Treatment of hearing loss ranges from simple removal of impacted cerumen in the external auditory canal to surgical procedures such as those used to reconstruct the tympanic membrane. For other people, particularly the frail elderly, hearing aids remain an option. Cochlear implants also are an option for those with profound hearing loss.

In summary, hearing is a specialized sense whose external stimulus is the vibration of sound waves. Anatomically, the auditory system consists of the outer ear, middle ear, and inner ear, the auditory pathways, and the auditory cortex. The middle ear is a tiny air-filled cavity in the temporal bone. The inner ear contains the receptors for hearing.

Disorders of the auditory system include infections of the external and middle ear, otosclerosis, and conduction and sensorineural deafness. Otitis externa is an inflammatory process of the external ear. The middle ear is a tiny, air-filled cavity located in the temporal bone. The eustachian tube, which connects the middle ear to the nasopharynx allows equalization of pressure between the middle ear and the atmosphere. Infections can travel from the nasopharynx to the middle ear along the eustachian tube, causing OM or inflammation of the middle ear. The eustachian tube is shorter and more horizontal in infants and young children, and infections of the middle ear are a common problem in these age groups. OM may present as AOM, recurrent OM, or OME. AOM usually follows an upper respiratory tract infection and is characterized by otalgia, fever, and hearing loss. The effusion that accompanies OM can persist for weeks or months, interfering with hearing and impairing speech development. Otosclerosis is a familial disorder of the otic capsule. It causes bone resorption followed by excessive replacement with sclerotic bone. The disorder eventually causes immobilization of the stapes and conduction deafness.

Deafness, or hearing loss, can develop as the result of a number of auditory disorders. It can be conductive, sensorineural, or mixed. Conduction deafness occurs when transmission of sound waves from the external to the inner ear is impaired. Sensorineural deafness can involve cochlear structures of the inner ear or the neural pathways that transmit auditory stimuli. Sensorineural hearing loss can result from genetic or congenital disorders, trauma, infections, vascular disorders, tumors, or ototoxic drugs. Treatment of hearing loss includes the use of hearing aids and, in some cases of profound deafness, implantation of a cochlear prosthesis.

THE VESTIBULAR SYSTEM AND MAINTENANCE OF EQUILIBRIUM

The vestibular receptive organs, which are located in the inner ear, and their CNS connections, contribute to the reflex activity needed for effective posture and movement and serve to maintain a stable visual field despite changes in head position. Because the vestibular apparatus is part of the inner ear and located in the head, it is head motion and acceleration that are sensed.

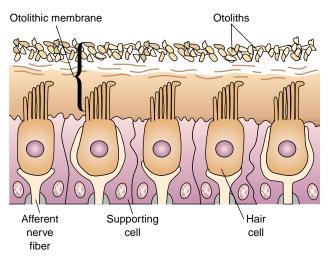

KEY CONCEPTS

DISORDERS OF THE VESTIBULAR SYSTEM

- The vestibular system, which is located in the inner ear and senses head motion and acceleration, contributes to the reflex activity needed for effective posture and movement, and it serves to maintain a stable visual field despite changes in head position.
- The vestibular system, which has extensive interconnections with neural pathways controlling vision, hearing, chemotactic receptor trigger zone, the cerebellum, and the autonomic nervous system, is characterized by vertigo, nystagmus, tinnitus, nausea and vomiting, and autonomic nervous system manifestations.
- Disorders of vestibular function can result from repeated stimulation of the vestibular system, such as during car, air, and boat travel (motion sickness); distention of the endolymphatic compartment of the inner ear (Ménière's disease); or dislodgment of otoliths that participate in the receptor function of the vestibular system (benign paroxysmal positional vertigo).

The peripheral apparatus of the vestibular system is contained in the bony labyrinth of the inner ear next to and continuous with the cochlea of the auditory system. It is divided into five prominent structures: three semicircular ducts, a utricle, and a saccule (Fig. 40-19). Receptors in these structures are differentiated into the angular acceleration-deceleration receptors of the semicircular ducts and the linear accelerationdeceleration and static gravitational receptors of the utricle and saccule. Small patches of hair cells are located in the floor of the utricle (utricular macula), in the sidewall of the saccule (saccular macula), at the base of each semicircular duct (cristae), and in the organ of Corti along the floor of the cochlear duct (Fig. 40-20). Each hair cell has several microvilli and one true cilium, called a kinocilium. At the apical end of each inner hair cell is a projecting bundle of rodlike structures called stereocilia. The stereocilia of the hair cells extend into a flattened gelatinous mass, the otolithic membrane, which is studded with tiny stones (calcium carbonate crystals) called otoliths. Although small, the density of the otoliths increases the membrane's weight and its resistance to change in motion. When the head is tilted, the gelatinous mass shifts its position because of the pull of the gravitational field, bending the stereocilia of the macular hair cells. Although each hair cell becomes less or more excitable, depending on the direction in which the cilia are bending, the hair cells are oriented in all directions, making these sense organs sensitive to static or changing head position in relation to the gravitational field.

The nerve fibers from the ganglionic cells that supply the vestibular apparatus become the superior and inferior vestibular nerves, which become part of the eighth cranial nerve. Impulses from the vestibular nerves initially pass to one of two destinations: the vestibular nuclear complex in the stem or the cerebellum. The vestibular nuclei, which form the main integrative center for balance, also receives input from visual and somatic receptors, particularly from proprioceptors in the neck muscles that report the angle or inclination of the head. The vestibular nuclei integrate this information and then send im-

■ FIGURE 40-20 ■ The relation of the otoliths to the sensory cells in the macula of the utricle and saccule. (Adapted from Selkurt F.D. [Ed.]. [1982]. *Basic physiology for the health sciences* [2nd ed.]. Boston: Little, Brown)

pulses to the brain stem centers that control the extrinsic eye movements (CN III, IV, and VI) and reflex movements of the neck, limb, and trunk muscles (via the vestibulospinal tracts). Reflex movements of the eyes and body allow for quick adjustment of body position to maintain or regain balance. Neurons of the vestibular nuclei also project to the thalamus, the temporal cortex, the somesthetic area of the parietal cortex, and the chemoreceptor trigger zone. The thalamic and cortical projections provide the basis for the subjective experiences of position in space and of rotation. Connections with the chemoreceptor trigger zone stimulate the vomiting center in the brain (see Chapter 26). This accounts for the nausea and vomiting that often are associated with vestibular disorders.

Nystagmus

The term nystagmus is used to describe the vestibulo-ocular reflexes that occur in response to ongoing head rotation. The vestibulo-ocular reflexes produce slow compensatory conjugate eve rotations that occur in the direction precisely opposite to ongoing head rotation and provide for continuous, ongoing reflex stabilization of the binocular fixation point. This reflex can be demonstrated by holding a pencil vertically in front of the eyes and moving it from side to side through a 10-degree arc at a rate of approximately five times per second. At this rate of motion, the pencil appears blurred, because a different and more complex reflex, smooth pursuit, cannot compensate quickly enough. However, if the pencil is maintained in a stable position and the head is moved back and forth at the same rate, the image of the pencil is clearly defined. The eye movements are the same in both cases. The reason that the pencil image remains clear in the second situation is because the vestibuloocular reflexes keep the image of the pencil on the retinal fovea. When compensatory vestibulo-ocular reflexes carry the conjugate eye rotations to their physical limit, a very rapid conjugate movement (i.e., saccade) moves the eyes in the direction of head rotation to a new fixation point, followed by a slow vestibulo-ocular reflex as the head continues to rotate past the new fixation point. This pattern of slow-fast-slow movements is called *nystagmus*.

Spontaneous nystagmus that occurs without head movement or visual stimuli is always pathologic. It seems to appear more readily and more severely with fatigue and to some extent can be influenced by psychological factors. Nystagmus caused by CNS pathology, in contrast to vestibular end-organ or vestibulocochlear nerve sources, seldom is accompanied by vertigo. If present, the vertigo is of mild intensity.

Vertigo

Disorders of vestibular function are characterized by a condition called *vertigo*, in which an illusion of motion occurs. It is either an exaggerated sense of motion when there is no motion or motion in response to a given bodily movement. Persons with vertigo frequently describe a sensation of spinning or tumbling, a "to-and-fro" motion, or falling forward or backward. Vertigo should be differentiated from light-headedness, faintness, unsteadiness, or syncope (loss of consciousness; Table 40-2).^{43,44} Vertigo or dizziness can result from peripheral or central vestibular disorders. Approximately 85% of persons with vertigo have a peripheral vestibular disorder, whereas only 15% have a central disorder. Vertigo caused by peripheral disorders tends to be severe in intensity and episodic or brief in duration. In contrast, vertigo attributable to central causes tends to be mild and constant and chronic in duration.

Diagnostic methods include the Romberg test (discussed later in this section), an evaluation of gait, and observations for the presence of nystagmus.⁴⁵ Laboratory investigations include audiologic evaluation, electronystagmography, CT scan or MRI, and auditory brain stem evoked responses (ABRs). These tests help to distinguish between central and peripheral causes of vertigo and to identify causes requiring specific treatment.

Motion Sickness

Motion sickness is a form of normal physiologic vertigo. It is caused by repeated rhythmic stimulation of the vestibular system, such as is encountered in car, air, or boat travel. Vertigo, malaise, nausea, and vomiting are the principal symptoms. Autonomic signs, including lowered blood pressure, tachycardia, and excessive sweating, may occur. Some persons experience a variant of motion sickness, reporting sensing the rocking motion of the boat after returning to ground. This usually resolves after the vestibular system becomes accustomed to the stationary influence of being back on land.

Motion sickness can usually be suppressed by supplying visual signals that more closely match the motion signals being supplied to the vestibular system. For example, looking out the window and watching the environment move when experiencing motion sickness associated with car travel provides the vestibular system with the visual sensation of motion. Among

TABLE 40-2	Differences in Pathology and Manifestations of Dizziness Associated
	Positional Vertigo, Presyncope, and Disequilibrium State

Type of Disorder	Pathology	Symptoms
Benign positional vertigo	Disorder of otoliths	Vertigo initiated by a change in head position, usually lasts less than a minute
Presyncope Disequilibrium	Orthostatic hypotension Sensory (<i>e.g.,</i> vision, proprioception) deficits	Light-headedness and feeling faint on assumption of standing position Dizziness and unsteadiness when walking, especially when turning; re- lieved by additional proprioceptive stimulation such as touching wall or table

the drugs used to suppress, reduce, or ameliorate the symptoms of motion sickness are the antihistamines (*e.g.*, meclizine, cyclizine, dimenhydrinate, and promethazine) and the anticholinergic drugs (*e.g.*, scopolamine, atropine).

Disorders of Peripheral Vestibular Function

Disorders of peripheral vestibular function occur when these signals from the vestibular organs in the inner ear are distorted, such as in benign paroxysmal positional vertigo, or unbalanced by unilateral involvement of one of the vestibular organs, such as in Ménière's disease. The inner ear is vulnerable to injury caused by fracture of the petrous portion of the temporal bones; by infection of nearby structures, including the middle ear and meninges; and by blood-borne toxins and infections. Alcohol can cause transient episodes of vertigo.

Ménière's Disease

Ménière's disease is a disorder of the inner ear caused by distention of the endolymphatic compartment of the inner ear, causing a triad of hearing loss, vertigo, and tinnitus.^{46,47} The primary lesion appears to be in the endolymphatic sac, which is thought to be responsible for endolymph filtration and excretion. A number of pathogenic mechanisms have been postulated, including an increased production of endolymph, decreased production of perilymph accompanied by a compensatory increase in volume of the endolymphatic sac, and decreased absorption of endolymph caused by malfunction of the endolymphatic sac or blockage of endolymphatic pathways.

The cause of Ménière's disease is unknown. A number of conditions, such as trauma, infection (*e.g.*, syphilis), and immunologic, endocrine (adrenal-pituitary insufficiency and hypothyroidism), and vascular disorders have been proposed as possible causes of Ménière's disease.⁴⁷ The most common form of the disease is an idiopathic form thought to be caused by a single viral injury to the fluid transport system of the inner ear.

Ménière's disease is characterized by fluctuating episodes of tinnitus, feelings of ear fullness, and violent rotary vertigo that often renders the person unable to sit or walk. There is a need to lie quietly with the head fixed in a comfortable position, avoiding all head movements that aggravate the vertigo. Symptoms referable to the autonomic nervous system, including pallor, sweating, nausea, and vomiting, usually are present. The more severe the attack, the more prominent are the autonomic manifestations. A fluctuating hearing loss occurs, with a return to normal after the episode subsides. Initially the symptoms tend to be unilateral, resulting in rotary nystagmus caused by an imbalance in vestibular control of eye movements. Because initial involvement usually is unilateral and because the sense of hearing is bilateral, many persons with the disorder are not aware of the full extent of their hearing loss. However, as the disease progresses, the hearing loss stops fluctuating and progressively worsens, with both ears tending to be affected so that the prime disability becomes one of deafness.⁴⁷ The episodes of vertigo diminish and then disappear, although the person may be unsteady, especially in the dark.

Methods used in the diagnosis of Ménière's disease include audiograms, vestibular testing by electronystagmography, and petrous pyramid radiographs. The administration of hyperosmolar substances, such as glycerin and urea, often produces acute temporary hearing improvement in persons with Ménière's disease and sometimes is used as a diagnostic measure of endolymphatic hydrops.

The management of Ménière's disease focuses on attempts to reduce the distention of the endolymphatic space and can be medical or surgical. Pharmacologic management consists of suppressant drugs (*e.g.*, prochlorperazine, promethazine, diazepam), which act centrally to decrease the activity of the vestibular system. Diuretics are used to reduce endolymph fluid volume. A low-sodium diet is recommended in addition to these medications. Corticosteroid medications (*e.g.*, prednisone) may be used to maintain satisfactory hearing and resolve dizziness. Gentamicin therapy has been used for ablation of the vestibular system.^{47,48} This treatment is mainly effective in controlling vertigo and does not alter the underlying pathology.

Surgical methods include the creation of an endolymphatic shunt, in which excess endolymph from the inner ear is diverted into the subarachnoid space or the mastoid (endolymphatic sac surgery), and vestibular nerve section.

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo (BPPV) is the most common cause of pathologic vertigo and usually develops after the fourth decade. It is characterized by brief periods of vertigo, usually lasting less than 1 minute, that are precipitated by a change in head position.⁴⁹ The most prominent symptom of BPPV is vertigo that occurs in bed when the person rolls into a lateral position. It also commonly occurs when the person is getting in and out of bed, bending over and straightening up, or extending the head to look up. It also can be triggered by amusement rides that feature turns and twists.

BPPV is thought to result from damage to the delicate sensory organs of the inner ear, the semicircular ducts, and otoliths. In persons with BPPV, the calcium carbonate particles (otoliths) from the utricle become dislodged and become freefloating debris in the endolymph (otic fluid) of the posterior semicircular duct, which is the most dependent part of the inner ear.⁴⁹ Movement of the free-floating debris causes this portion of the vestibular system to become more sensitive, such that any movement of the head in the plane parallel to the posterior duct may cause vertigo and nystagmus. There usually is a several-second delay between head movement and onset of vertigo, representing the time it takes to generate the exaggerated endolymph activity. Symptoms usually subside with continued movement, probably because the movement causes the debris to be redistributed throughout the endolymph system and away from the posterior duct.

Diagnosis is based on tests that involve the use of a change in head position to elicit vertigo and nystagmus. BPPV often is successfully treated with drug therapy to control vertigoinduced nausea. Nondrug therapies using habituation exercises and canalith repositioning are successful in many people (to be discussed).⁴⁹ Otolith repositioning involves a series of maneuvers in which the head is moved to different positions in an effort to reposition the free-floating debris in the endolymph of the semicircular canals.

Disorders of Central Vestibular Function

Abnormal nystagmus and vertigo can occur as a result of CNS lesions involving the cerebellum and lower brain stem. Central causes of vertigo include brain stem ischemia, tumors, and multiple sclerosis.⁴⁵ When brain stem ischemia is the cause of vertigo, it usually is associated with other brain stem signs, such as diplopia, ataxia, dysarthria, or facial weakness. Compression of the vestibular nuclei by cerebellar tumors invading the fourth ventricle results in progressively severe signs and symptoms. In addition to abnormal nystagmus and vertigo, vomiting and a broad-based and dystaxic gait become progressively more evident. The central demyelinating effects of multiple sclerosis can present with vertigo as often as 10% of the time, and as many as one third of persons with multiple sclerosis experience vertigo and nystagmus some time in the course of the disease.⁴⁵

Centrally derived nystagmus usually has equal excursion in both directions (*i.e.*, pendular). In contrast to peripherally generated nystagmus, CNS-derived nystagmus is relatively constant, rather than episodic; can occur in any direction, rather than being primarily in the horizontal or torsional (rotatory) dimensions; often changes direction through time; and cannot be suppressed by visual fixation. Repeated induction of nystagmus results in rapid diminution or "fatigue" of the reflex with peripheral abnormalities, but fatigue is not characteristic of central lesions. Abnormal nystagmus can make reading and other tasks that require precise eye positional control difficult.

Diagnosis and Treatment

Tests of Vestibular Function

Diagnosis of vestibular disorders is based on a description of the symptoms, a history of trauma or exposure to agents that are destructive to vestibular structures, and physical examination. Tests of eye movements (*i.e.*, nystagmus) and muscle control of balance and equilibrium often are used. The tests of vestibular function focus on the horizontal semicircular reflex because it is the easiest reflex to stimulate rotationally and calorically and to record using electronystagmography.

Electronystagmography. Electronystagmography (ENG) is a precise and objective diagnostic method of evaluating nystagmus eye movements. Electrodes are placed lateral to the outer canthus of each eye and above and below each eye. A ground electrode is placed on the forehead. With ENG, the velocity, frequency, and amplitude of spontaneous or induced nystagmus and the changes in these measurements brought by a loss of fixation, with the eyes open or closed, can be quantified. The advantages of ENG are that it is easily administered, is noninvasive, does not interfere with vision, and does not require head restraint.

Caloric Stimulation. Caloric testing involves elevating the head 30 degrees and irrigating each external auditory canal separately with 30 to 50 mL of ice water. The resulting changes in temperature, which are conducted through the petrous portion of the temporal bone, set up convection currents in the otic fluid that mimic the effects of angular acceleration. In an unconscious person with a functional brain stem and intact oculovestibular reflexes, the eyes exhibit a jerk nystagmus lasting 2 to 3 minutes, with the slow component toward the irrigated ear followed by rapid movement away from the ear. With impairment of brain stem function, the response becomes perverted and eventually disappears. An advantage of the caloric stimulation method is the ability to test the vestibular appara-

tus on one side at a time. The test is never done on a person who does not have an intact eardrum or those who have blood or fluid collected behind the eardrum.

Rotational Tests. Rotational testing involves rotation using a rotatable chair or motor-driven platform. Unlike caloric testing, rotational testing depends only on the inner ear and is unrelated to conditions of the external ear or temporal bone. A major disadvantage of the method is that both ears are tested simultaneously. Motor-driven chairs or platforms can be precisely controlled, and multiple graded stimuli can be delivered in a relatively short period. For rotational testing, the person is seated in a chair mounted on the motor-driven platform. Testing usually is performed in the dark without visual influence and with selected light stimuli. Eye movements are usually monitored using ENG.

Romberg Test. The Romberg test is used to demonstrate disorders of static vestibular function. The person being tested is requested to stand with feet together and arms extended forward so that the degree of sway and arm stability can be observed. The person then is asked to close his or her eyes. When visual clues are removed, postural stability is based on proprioceptive sensation from the joints, muscles, and tendons and from static vestibular reception. Deficiency in vestibular static input is indicated by greatly increased sway and a tendency for the arms to drift toward the side of deficiency. If vestibular input is severely deficient, the subject falls toward the deficient side.

Treatment of Vestibular Disorders

Pharmacologic Treatment. Depending on the cause, vertigo may be treated pharmacologically. There are two types of drugs used in the treatment of vertigo. First are the drugs used to suppress the illusion of motion. These include drugs such as antihistamines (*e.g.*, meclizine [Antivert], cyclizine [Marezine], dimenhydrinate [Dramamine], and promethazine [Phenergan]) and anticholinergic drugs (*e.g.*, scopolamine, atropine) that suppress the vestibular system. Although the antihistamines have long been used in treating vertigo, little is known about their mechanism of action. The second type includes drugs used to relieve the nausea and vomiting that commonly accompany the condition. Antidopaminergic drugs (*e.g.*, phenothiazines) and benzodiazepines commonly are used for this purpose.

Vestibular Rehabilitation. Vestibular rehabilitation, a relatively new treatment modality for peripheral vestibular disorders, has met with considerable success.^{50,51} It commonly is done by physical therapists and uses a home exercise program that incorporates habituation exercises, balance retraining exercises, and a general conditioning program.⁵¹ The habituation exercises take advantage of physiologic fatigue of the neurovegetative response to repetitive movement or positional stimulation and are done to decrease motion-provoked vertigo, light-headedness, and unsteadiness. The exercises are selected to provoke the vestibular symptoms. The person moves quickly into the position that causes symptoms, holds the position until the symptoms subside (*i.e.*, fatigue of the neurovegetative response), relaxes, and then repeats the exercise for a prescribed number of times. The exercises usually are repeated twice daily.

The habituation effect is characterized by decreased sensitivity and duration of symptoms. It may occur in as little as 2 weeks or take as long as 6 months.⁵¹

Balance-retraining exercises consist of activities directed toward improving individual components of balance that may be abnormal. General conditioning exercises, a vital part of the rehabilitation process, are individualized to the person's preferences and lifestyle. They should consist of motion-oriented activity that the person is interested in and should be done on a regular basis, usually four to five times per week.⁵¹

In summary, the vestibular system plays an essential role in the equilibrium sense, which is closely integrated with the visual and proprioceptive (position) senses. Receptors for the vestibular system, in the semicircular ducts of the inner ear, respond to changes in linear and angular acceleration of the head. The vestibular nerve fibers travel in CN VIII to the vestibular nuclei at the junction of the medulla and pons; some fibers pass through the nuclei to the cerebellum.

Disorders of peripheral vestibular function, which involve the inner ear sensory organs, include Ménière's disease and benign paroxysmal positional vertigo. Ménière's disease, which is caused by an overaccumulation of endolymph, is characterized by severe, disabling episodes of tinnitus, feelings of ear fullness, and violent rotary vertigo. Benign paroxysmal positional vertigo is thought to be caused by free-floating particles in the posterior semicircular canal. It presents as a sudden onset of dizziness or vertigo that is provoked by certain changes in head position. Among the methods used in treatment of the vertigo that accompanies vestibular disorders are habituation exercises (for BPPV) and antivertigo drugs.

REVIEW QUESTIONS

Describe the formation and outflow of aqueous humor from the eye and relate it to the development of glaucoma and to the pathogenesis of closed-angle and open-angle glaucoma.

Explain the difference between myopia and hyperopia.

Describe the changes in eye structure that occur with cataract.

Describe the pathogenesis of background and proliferative diabetic retinopathies and their mechanisms of visual impairment.

Discuss the cause of retinal detachment.

Explain the pathology and visual changes associated with macular degeneration.

Characterize what is meant by a visual field defect.

Explain the need for early diagnosis and treatment of eye movement disorders in children.

Relate the functions of the eustachian tube to the development of middle ear problems, including acute otitis media and otitis media with effusion.

Describe anatomic variations as well as risk factors that make infants and young children more prone to acute otitis media. Differentiate among conductive, sensorineural, and mixed hearing loss and cite the more common causes of each.

Define the term *presbycusis* and describe factors that contribute to its development.

Compare the manifestations and pathologic processes associated with benign positional vertigo and Ménière's disease.

Eleven

Alterations in the Skeletal and Integumentary Systems

CHAPTER

Structure and Function of the Skeletal System

Characteristics of Skeletal Tissue Cartilage Bone Types of Bone **Bone Cells** Periosteum and Endosteum Bone Growth and Remodeling Hormonal Control of Bone Formation and Metabolism Parathyroid Hormone Calcitonin Vitamin D **Skeletal Structures Classification of Bones Tendons and Ligaments** Joints and Articulations **Synarthroses Diarthroses Blood Supply and Innervation Bursae** Intra-articular Menisci

ithout the skeletal system, movement in the external environment would not be possible. The bones of the skeletal system serve as a framework for the attachment of muscles, tendons, and ligaments. The skeletal system protects and maintains soft tissues in their proper position, provides stability for the body, and maintains the body's shape. The bones act as a storage reservoir for calcium, and the central cavity of some bones contains the hematopoietic connective tissue in which blood cells are formed.

The skeletal system consists of the axial and appendicular skeleton. The axial skeleton, which is composed of the bones of the skull, thorax, and vertebral column, forms the axis of the body. The appendicular skeleton consists of the bones of the upper and lower extremities, including the shoulder and hip. For our purposes, the skeletal system is considered to include the bones and cartilage of the axial and appendicular skeleton, as well as the connective tissue structures (*i.e.*, ligaments and tendons) that connect the bones and join muscles to bone.

CHARACTERISTICS OF SKELETAL TISSUE

Two types of connective tissue are found in the skeletal system: cartilage and bone. Each of these connective tissue types consists of living cells, nonliving intercellular protein fibers, and an amorphous (shapeless) ground substance. The tissue cells are responsible for secreting and maintaining the intercellular substances in which they are housed. These substances provide the structural characteristics of the tissue. For example,

KEY CONCEPTS

THE SKELETAL SYSTEM

- The skeletal system consists of the bones of the skull, thorax, and vertebral column, which form the axial skeleton, and the bones of the upper and lower extremities, which form the appendicular skeleton.
- Two types of connective tissue are found in the skeletal system: (1) cartilage, a semirigid and slightly flexible structure that plays an essential role in prenatal and childhood development of the skeleton and as a surface for the articulating ends of skeletal joints; and (2) bones, which provide for the firm structure of the skeleton and serve as a reservoir for calcium and phosphate storage.
- Both bone and cartilage are composed of living cells and a nonliving intercellular matrix that is secreted by the living cells.
- Bone matrix is maintained by three types of cells: osteoblasts, which synthesize and secrete the constituents of bone; osteoclasts, which resorb surplus bone and are required for bone remodeling; and the osteocytes, which make up the osteoid tissue of bone.

the intercellular matrix of bone is impregnated with calcium salts, providing the hardness that is characteristic of this tissue.

Two main types of intercellular fibers are found in skeletal tissue: collagenous and elastic. Collagen is an inelastic and insoluble fibrous protein. Because of its molecular configuration, collagen has great tensile strength; the breaking point of collagenous fibers found in human tendons is reached with a force of several hundred kilograms per square centimeter. Fresh collagenous fibers generally appear white. The collagen fibers in tendons and ligaments give these structures their white color. Elastin is the major component of elastic fibers that allows them to stretch several times their length and rapidly return to their original shape when the tension is released. Ligaments and structures that must undergo repeated stretching contain a high proportion of elastic fibers.

Cartilage

Cartilage is a firm but flexible type of connective tissue consisting of cells and intercellular fibers embedded in an amorphous, gel-like material. It has a smooth and resilient surface and a weight-bearing capacity exceeded only by that of bone.

Cartilage is essential for growth before and after birth. It is able to undergo rapid growth while maintaining a considerable degree of stiffness. In the embryo, most of the axial and appendicular skeleton is formed first as a cartilage model and is replaced by bone. In postnatal life, cartilage continues to play an essential role in the growth of long bones and persists as articular cartilage in the adult. There are three types of cartilage: elastic cartilage, hyaline cartilage, and fibrocartilage. *Elastic cartilage* contains some elastin in its intercellular substance. It is found in areas, such as the ear, where some flexibility is important. Pure cartilage is called *hyaline cartilage* (from a Greek word meaning "glass") and is pearly white. It is the type of cartilage seen on the articulating ends of fresh soup bones found in the supermarket. *Fibrocartilage* has characteristics that are intermediate between dense connective tissue and hyaline cartilage. It is found in the intervertebral disks, in areas where tendons are connected to bone, and in the symphysis pubis.

Hyaline cartilage is the most abundant type of cartilage. It forms much of the cartilage of the fetal skeleton. In the adult, hyaline cartilage forms the costal cartilages that join the ribs to the sternum and vertebrae, many of the cartilages of the respiratory tract, the articular cartilages, and the epiphyseal plates.

Cartilage cells, which are called *chondrocytes*, are located in lacunae. These lacunae are surrounded by an uncalcified, gellike intercellular matrix of collagen fibers and ground substance. Cartilage is devoid of blood vessels and nerves. The free surfaces of most hyaline cartilage, with the exception of articular cartilage, are covered by a layer of fibrous connective tissue called the *perichondrium*.

It has been estimated that approximately 65% to 80% of the wet weight of cartilage is water held in its gel structure. Because cartilage has no blood vessels, this tissue fluid allows the diffusion of gases, nutrients, and wastes between the chondrocytes and blood vessels outside the cartilage. Diffusion cannot take place if the cartilage matrix becomes impregnated with calcium salts, and cartilage dies if it becomes calcified.

Bone

Bone is connective tissue in which the intercellular matrix has been impregnated with inorganic calcium salts so that it has great tensile and compressible strength but is light enough to be moved by coordinated muscle contractions. The intercellular matrix is composed of two types of substances—organic matter and inorganic salts. The organic matter, including bone cells, blood vessels, and nerves, constitutes approximately one third of the dry weight of bone; the inorganic salts make up the other two thirds.

The organic matter consists primarily of collagen fibers embedded in an amorphous ground substance. The inorganic matter consists of hydroxyapatite, an insoluble macrocrystalline structure of calcium phosphate salts, and small amounts of calcium carbonate and calcium fluoride. Bone may also take up lead and other heavy metals, thereby removing these toxic substances from the circulation. This can be viewed as a protective mechanism. The antibiotic tetracycline is readily bound to calcium deposited in newly formed bones and teeth. When tetracycline is given during pregnancy, it can be deposited in the teeth of the fetus, causing discoloration and deformity. Similar changes can occur if the drug is given for long periods to children younger than 6 years of age.

Types of Bone

There are two types of mature bones, cancellous and compact bone (Fig. 41-1). Both types are formed in layers and thus are called *lamellar bone*. Cancellous (spongy) bone is found in the

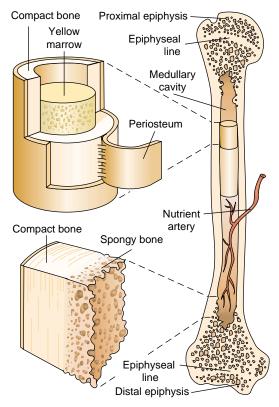

FIGURE 41-1 A long bone shown in longitudinal section.

interior of bones and is composed of *trabeculae*, or *spicules*, of bone that form a latticelike pattern. These latticelike structures are lined with osteogenic cells and filled with red or yellow bone marrow. Cancellous bone is relatively light, but its structure is such that it has considerable tensile strength and weight-bearing properties. Compact (cortical) bone, which forms the outer shell of a bone, has a densely packed calcified intercellular matrix that makes it more rigid than cancellous bone. The relative quantity of compact and cancellous bone varies in different types of bones throughout the body and in different parts of the same bone, depending on the need for strength and lightness. Compact bone is the major component of tubular bones. It is also found along the lines of stress on long bones and forms an outer protective shell on other bones.

Bone Cells

Four types of bone cells participate in the formation and maintenance of bone tissue: osteogenic cells, osteoblasts, osteocytes, and osteoclasts (Table 41-1).

Osteogenic Cells. The undifferentiated osteogenic cells are found in the periosteum, endosteum, and epiphyseal plate of growing bone. These cells differentiate into osteoblasts and are active during normal growth; they may also be activated in adult life during healing of fractures and other injuries. Osteogenic cells also participate in the continual replacement of worn-out bone tissue.

Osteoblasts. The osteoblasts, or bone-building cells, are responsible for the formation of the bone matrix. Bone formation

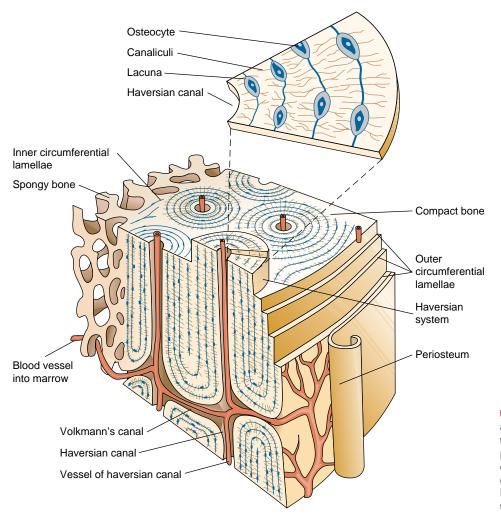

TABLE 41-1	Function of Bone Cells	
Type of Bone Cell	Function	
Osteogenic cells	Undifferentiated cells that differentiate into osteoblasts. They are found in the perios- teum, endosteum, and epiphyseal growth plate of growing bones.	
Osteoblasts	Bone-building cells that synthesize and se- crete the organic matrix of bone. Osteo- blasts also participate in the calcification of the organic matrix.	
Osteocytes	Mature bone cells that function in the main- tenance of bone matrix. Osteocytes also play an active role in releasing calcium into the blood.	
Osteoclasts	Bone cells responsible for the resorption of bone matrix and the release of calcium and phosphate from bone.	

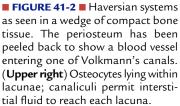

occurs in two stages: ossification and calcification. Ossification involves the formation of osteoid, or prebone. Calcification of bone involves the deposition of calcium salts in the osteoid tissue. The osteoblasts synthesize collagen and other proteins that make up osteoid tissue. They also participate in the calcification process of the osteoid tissue, probably by controlling the availability of calcium and phosphate. Osteoblasts secrete the enzyme *alkaline phosphatase*, which is thought to act locally in bone tissue to raise calcium and phosphate levels to the point at which precipitation occurs. The activity of the osteoblasts undoubtedly contributes to the increase in serum levels of alkaline phosphatase that follows bone injury and fractures.

Osteocytes. The osteocytes are mature bone cells that are actively involved in maintaining the bony matrix. Death of the osteocytes results in the resorption of this matrix. The osteocytes lie in a small lake filled with extracellular fluid, called a *lacuna*, and are surrounded by a calcified intercellular matrix. Extracellular fluid-filled passageways permeate the calcified matrix and connect with the lacunae of adjacent osteocytes. These passageways are called *canaliculi*. Because diffusion does not occur through the calcified matrix of bone, the canaliculi serve as communicating channels for the exchange of nutrients and metabolites between the osteocytes and the blood vessels on the surface of the bone layer.

The osteocytes, together with their intercellular matrix, are arranged in layers, or lamellae. In compact bone, 4 to 20 lamellae are arranged concentrically around a central haversian canal, which runs essentially parallel to the long axis of the bone. Each of these units is called a *haversian system*, or *osteon*. The haversian canals contain blood vessels that carry nutrients and wastes to and from the canaliculi (Fig. 41-2). The blood vessels from the periosteum enter the bone through tiny openings called *Volkmann's canals* and connect with the haversian systems. Cancellous bone is also composed of lamellae, but its trabeculae usually are not penetrated by blood vessels. Instead, the bone cells of cancellous bone are nourished by diffusion from the endosteal surface through canaliculi, which interconnect their lacunae and extend to the bone surface.

782 Unit Eleven: Alterations in the Skeletal and Integumentary Systems

Osteoclasts. Osteoclasts are "bone-chewing" cells that function in the resorption of bone, removing the mineral content and the organic matrix. They are large phagocytic cells of monocyte/ macrophage lineage. Although the mechanism of osteoclast formation and activation remains elusive, it is known that parathyroid hormone (PTH) increases the number and resorptive function of the osteoclasts. Calcitonin is thought to reduce the number and resorptive function of the osteoclasts. Estrogen also reduces the number and function of the osteoclasts; thus, the decrease in estrogen levels that occur at menopause results in increased reabsorption of bone. The mechanism whereby osteoclasts exert their resorptive effect on bone is unclear. These cells may secrete an acid that removes calcium from the bone matrix, releasing the collagenic fibers for digestion by osteoclasts or mononuclear cells. The osteoclastic cells, by virtue of their phagocytic lineage, also imbibe minute particles of bone matrix and crystals, eventually dissolving and releasing them into the blood.

Periosteum and Endosteum

Bones are covered, except at their articular ends, by a membrane called the *periosteum* (see Fig. 41-1). The periosteum has an outer fibrous layer and an inner layer that contains the osteogenic cells needed for bone growth and development. The peri-

osteum contains blood vessels and acts as an anchorage point for vessels as they enter and leave the bone. The endosteum is the membrane that lines the spaces of spongy bone, the marrow cavities, and the haversian canals of compact bone. It is composed mainly of osteogenic cells. These osteogenic cells contribute to the growth and remodeling of bone and are necessary for bone repair.

Bone Growth and Remodeling

The skeletal system develops from the mesoderm, the thin middle layer of embryonic tissue. Development of the vertebrae of the axial skeleton begins at approximately the fourth week in the embryo; during the ninth week, ossification begins with the appearance of ossification centers in the lower thoracic and upper lumbar vertebrae. The paddle-shaped limb buds of the lower extremities make their appearance late in the fourth week. The hand pads are developed by days 33 to 36, and the finger rays are evident on days 41 to 43 of embryonic development.¹

During the first two decades of life, the skeleton undergoes general overall growth. The long bones of the skeleton, which grow at a relatively rapid rate, are provided with a specialized structure called the *epiphyseal growth plate*. As long bones grow in length, the deeper layers of cartilage cells in the growth plate multiply and enlarge, pushing the articular cartilage farther away from the metaphysis and diaphysis of the bone.² As this happens, the mature and enlarged cartilage cells at the metaphyseal end of the plate become metabolically inactive and are replaced by bone cells (Fig. 41-1). This process allows bone growth to proceed without changing the shape of the bone or causing disruption of the articular cartilage. The cells in the growth plate stop dividing at puberty, at which time the epiphysis and metaphysis fuse.

Several factors can influence the growth of cells in the epiphyseal growth plate. Epiphyseal separation can occur in children as the result of trauma. The separation usually occurs in the zone of the mature enlarged cartilage cells, which is the weakest part of the growth plate. The blood vessels that nourish the epiphysis pass through the growth plate. These vessels are ruptured when the growth plate separates. This can cause cessation of growth and a shortened extremity.

The growth plate also is sensitive to nutritional and metabolic changes. Scurvy (*i.e.*, vitamin C deficiency) impairs the formation of the organic matrix of bone, causing slowing of growth at the epiphyseal plate and cessation of diaphyseal growth. In rickets (*i.e.*, vitamin D deficiency), calcification of the newly developed bone on the metaphyseal side of the growth plate is impaired. Thyroid and growth hormones are required for normal growth. Alterations in these and other hormones can affect growth (see Chapter 31).

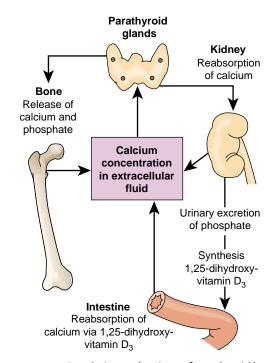

Growth in the diameter of bones occurs as new bone is added to the outer surface of existing bone along with an accompanying resorption of bone on the endosteal or inner surface. Such oppositional growth allows for widening of the marrow cavity while preventing the cortex from becoming too thick and heavy. In this way, the shape of the bone is maintained. As a bone grows in diameter, concentric rings are added to the bone surface, much as rings are added to a tree trunk; these rings form the lamellar structure of mature bone. Osteocytes, which develop from osteoblasts, become buried in the rings. Haversian channels form as periosteal vessels running along the long axis become surrounded by bone.

Hormonal Control of Bone Formation and Metabolism

The process of bone formation and mineral metabolism is complex. It involves the interplay among the actions of PTH, calcitonin, and vitamin D. Other hormones, such as cortisol, growth hormone, thyroid hormone, and the sex hormones, also influence bone formation directly or indirectly.

Parathyroid Hormone

PTH is one of the important regulators of calcium and phosphate levels in the blood. PTH prevents serum calcium levels from falling below and serum phosphate levels from rising above normal physiologic concentrations (see Chapter 31). The secretion of PTH is regulated by negative feedback levels of ionized calcium. PTH maintains serum calcium levels by initiation of calcium release from bone, by conservation of calcium by the kidney, by enhanced intestinal absorption of calcium through activation of vitamin D, and by reduction of serum phosphate levels (Fig. 41-3). PTH also increases the movement of calcium and phosphate from bone into the

■ FIGURE 41-3 ■ Regulation and actions of parathyroid hormone.

extracellular fluid. Calcium is immediately released from the canaliculi and bone cells; a more prolonged release of calcium and phosphate is mediated by increased osteoclast activity. In the kidney, PTH stimulates tubular reabsorption of calcium while reducing the reabsorption of phosphate. The latter effect ensures that increased release of phosphate from bone during mobilization of calcium does not produce an elevation in serum phosphate levels. This is important because an increase in calcium and phosphate levels could lead to crystallization in soft tissues. PTH increases intestinal absorption of calcium because of its ability to stimulate activation of vitamin D by the kidney.

Calcitonin

Whereas PTH increases blood calcium levels, the hormone calcitonin lowers blood calcium levels. Calcitonin, sometimes called *thyrocalcitonin*, is secreted by the parafollicular, or C, cells of the thyroid gland. Calcitonin inhibits the release of calcium from bone into the extracellular fluid. It is thought to act by causing calcium to become sequestered in bone cells and by inhibiting osteoclast activity. Calcitonin also reduces the renal tubular reabsorption of calcium and phosphate; the decrease in serum calcium level that follows administration of pharmacologic doses of calcitonin may be related to this action.

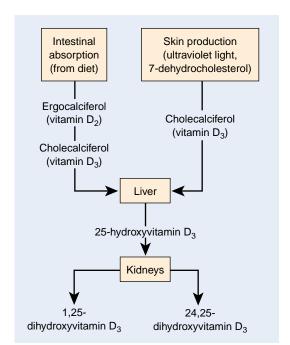

The major stimulus for calcitonin synthesis and release is an increase in serum calcium. The role of calcitonin in overall mineral homeostasis is uncertain. There are no clearly definable syndromes of calcitonin deficiency or excess, which suggests that calcitonin does not directly alter calcium metabolism. It has been suggested that the physiologic actions of calcitonin are related to the postprandial handling and processing of dietary calcium. This theory proposes that after meals, calcitonin maintains parathyroid secretion at a time when it normally would be reduced by calcium entering the blood from the digestive tract. Although excess or deficiency states associated with alterations in physiologic levels of calcitonin have not been observed, it has been shown that pharmacologic doses of the hormone reduce osteoclastic activity. Because of this action, calcitonin has proved effective in the treatment of Paget's disease (see Chapter 43). The hormone is also used to reduce serum calcium levels during hypercalcemic crises.

Vitamin D

Vitamin D and its metabolites are not vitamins but steroid hormones. There are two forms of vitamin D: vitamin D₂ (ergocalciferol) and vitamin D₃ (cholecalciferol). The two forms differ by the presence of a double bond, but they have identical biologic activity. The term *vitamin* D is used to indicate both forms.

Vitamin D has little or no activity until it has been metabolized to compounds that mediate its activity. Figure 41-4 depicts sources of vitamin D and pathways for activation. The first step of the activation process occurs in the liver, where vitamin D is hydroxylated to form the metabolite 25-hydroxyvitamin D₃ [25-(OH)D₃]. From the liver, 25-(OH)D₃ is transported to the kidneys, where it undergoes conversion to 1,25-dihydroxyvitamin D₃ [1,25-(OH)₂D₃] or 24,25-dihydroxyvitamin D₃ [24,25-(OH)₂D₃]. Other metabolites of vitamin D have been and still are being discovered.

There are two sources of vitamin D: intestinal absorption and skin production. Intestinal absorption occurs mainly in the jejunum and includes vitamin D_2 and vitamin D_3 . The most important dietary sources of vitamin D are fish, liver, and irradiated milk. Because vitamin D is fat soluble, its absorption is mediated by bile salts and occurs by means of the lymphatic vessels. In the skin, ultraviolet radiation from sunlight spontaneously converts 7-dehydrocholesterol provitamin D_3 to vitamin D_3 . A circulating vitamin D-binding protein provides a mechanism to remove vitamin D from the skin and make it available to the rest of the body.

■ FIGURE 41-4 ■ Sources and pathway for activation of vitamin D.

With adequate exposure to sunlight, the amount of vitamin D that can be produced by the skin is usually sufficient to meet physiologic requirements. The importance of sunlight exposure is evidenced by population studies that report lower vitamin D levels in countries, such as England, that have less sunlight than the United States. Elderly persons who are housebound or institutionalized frequently have low vitamin D levels. The deficiency often goes undetected until there are problems such as pseudofractures or electrolyte imbalances. Seasonal variations in vitamin D levels probably reflect changes in sunlight exposure.

The most potent of the vitamin D metabolites is 1,25- $(OH)_2D_3$. This metabolite increases intestinal absorption of calcium and promotes the actions of PTH on resorption by the osteoclasts is increased, and bone formation by the osteoblasts is decreased; there is also an increase in acid phosphatase and a decrease in alkaline phosphatase. Intestinal absorption and bone resorption increase the amount of calcium and phosphorus available to the mineralizing surface of the bone. The role of 24,25-(OH)_2D_3 is less clear. There is evidence that 24,25-(OH)_2D_3, in conjunction with 1,25-(OH)_2D_3, may be involved in normal bone mineralization.

The regulation of vitamin D activity is influenced by several hormones. PTH and prolactin stimulate $1,25-(OH)_2D_3$ production by the kidney. States of hyperparathyroidism are associated with increased levels of $1,25-(OH)_2D_3$, and hypoparathyroidism leads to lowered levels of this metabolite. Prolactin may have an ancillary role in regulating vitamin D metabolism during pregnancy and lactation. Calcitonin inhibits $1,25-(OH)_2D_3$ production by the kidney. In addition to hormonal influences, changes in the concentration of ions such as calcium, phosphate, hydrogen, and potassium exert an effect on $1,25-(OH)_2D_3$ and $24,25-(OH)_2D_3$ production. Under conditions of deprivation of phosphate and calcium, $1,25-(OH)_2D_3$ levels are increased, whereas hyperphosphatemia and hypercalcemia decrease the levels of metabolite.

In summary, skeletal tissue is composed of two types of connective tissue: cartilage and bone. These skeletal structures are composed of similar tissue types; each has living cells and nonliving intercellular fibers and ground substance that is secreted by the cells. Cartilage is a firm, flexible type of skeletal tissue that is essential for growth before and after birth. There are three types of cartilage: elastic, hyaline, and fibrocartilage. Hyaline cartilage, which is the most abundant type, forms the costal cartilages that join the ribs to the sternum and vertebrae, many of the cartilages of the respiratory tract, and the articular cartilages.

The characteristics of the various skeletal tissue types are determined by the intercellular matrix. In bone, this matrix is impregnated with calcium salts to provide hardness and strength. There are four types of bone cells: osteocytes, or mature bone cells; osteoblasts, or bone-building cells; osteoclasts, which function in bone resorption; and osteogenic cells, which differentiate into osteoblasts. Densely packed compact bone forms the outer shell of a bone, and latticelike cancellous bone forms the interior. The periosteum, the membrane that covers bones, contains blood vessels and acts as an anchorage point for vessels as they enter and leave the bone. The endosteum is the membrane that lines the spaces of spongy bone, the marrow cavities, and the haversian canals of compact bone.

The process of bone formation and mineral metabolism involves the interplay among the actions of PTH, calcitonin, and vitamin D. PTH acts to maintain serum levels of ionized calcium; it increases the release of calcium and phosphate from bone, the conservation of calcium and elimination of phosphate by the kidney, and the intestinal reabsorption of calcium through vitamin D. Calcitonin inhibits the release of calcium from bone and increases renal elimination of calcium and phosphate, thereby serving to lower serum calcium levels. Vitamin D functions as a hormone in regulating body calcium. It increases absorption of calcium from the intestine and promotes the actions of PTH on bone.

SKELETAL STRUCTURES

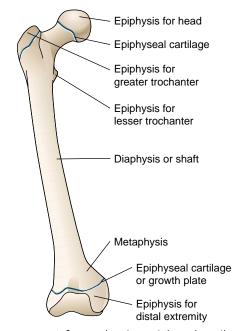

Classification of Bones

Bones are classified by shape as long, short, flat, and irregular. Long bones are found in the upper and lower extremities. Short bones are irregularly shaped bones located in the ankle and the wrist. Except for their surface, which is compact bone, these bones are spongy throughout. Flat bones are composed of a layer of spongy bone between two layers of compact bone. They are found in areas such as the skull and rib cage, where extensive protection of underlying structures is needed, or, as in the scapula, where a broad surface for muscle attachment must be provided. Irregular bones, because of their shapes, cannot be classified in any of the previous groups. This group includes bones such as the vertebrae and the bones of the jaw.

A typical long bone has a shaft, or *diaphysis*, and two ends, called *epiphyses*. Long bones usually are narrow in the midportion and broad at the ends so that the weight they bear can be distributed over a wider surface. The shaft of a long bone is formed mainly of compact bone roughly hollowed out to form a marrow-filled medullary canal. The ends of long bones are covered with articular cartilage that rests on a bony plate, the subchondral bone.

In growing bones, the part of the bone shaft that funnels out as it approaches the epiphysis is called the *metaphysis* (Fig. 41-5). It is composed of bony trabeculae that have cores of cartilage. In the child, the epiphysis is separated from the metaphysis by the cartilaginous growth plate. After puberty, the metaphysis and epiphysis merge, and the growth plate is obliterated.

Bone marrow occupies the medullary cavities of the long bones throughout the skeleton and the cavities of cancellous bone in the vertebrae, ribs, sternum, and flat bones of the pelvis. The cellular composition of the bone marrow varies with age and skeletal location. Red bone marrow contains developing red blood cells and is the site of blood cell formation. Yellow bone marrow is composed largely of adipose cells. At birth, nearly all of the marrow is red and hematopoietically active. As the need for red blood cell production decreases during postnatal growth, red marrow is gradually replaced with yellow

■ FIGURE 41-5 ■ A femur, showing epiphyseal cartilages for the head, metaphysis, trochanters, and distal end of the bone.

bone marrow in most of the bones. In the adult, red marrow persists in the vertebrae, ribs, sternum, and ilia.

Tendons and Ligaments

In the skeletal system, tendons and ligaments are dense connective tissue structures that connect muscles and bones. Tendons connect muscles to bone, and ligaments connect the movable bones of joints. Tendons can appear as cordlike structures or as flattened sheets, called *aponeuroses*, such as in the abdominal muscles.

The dense connective tissue found in tendons and ligaments has a limited blood supply and is composed largely of intercellular bundles of collagen fibers arranged in the same direction and plane. This type of connective tissue provides great tensile strength and can withstand tremendous pull in the direction of fiber alignment. At the sites where tendons or ligaments are inserted into cartilage or bone, a gradual transition from pure dense connective tissue to bone or cartilage occurs. In cartilage, this transitional tissue is called *fibrocartilage*.

Tendons that may rub against bone or other frictiongenerating surfaces are enclosed in double-layered sheaths. An outer connective tissue tube is attached to the structures surrounding the tendon, and an inner sheath encloses the tendon and is attached to it. The space between the inner and outer sheath is filled with a fluid similar to synovial fluid.

Joints and Articulations

Articulations, or joints, are areas where two or more bones meet. The term *arthro* is the prefix used to designate a joint. For example, *arthrology* is the study of joints, and *arthroplasty* is the repair of a joint. There are two classes of joints, based on movement and the presence of a joint cavity: synarthroses and diarthroses.

KEY CONCEPTS

SKELETAL JOINTS

- Joints, or articulations, are sites where two or more bones meet to hold the skeleton together and give it mobility.
- There are two types of joints: synarthroses, which are immovable joints, and diarthroses, which are freely movable joints.
- All limb joints are synovial diarthrodial joints, which are enclosed in a joint cavity containing synovial fluid.
- The articulating surfaces of synovial joints are covered with a layer of avascular cartilage that relies on oxygen and nutrients contained in the synovial fluid.
- Regeneration of articular cartilage of synovial joints is slow, and the healing of injuries often is slow and unsatisfactory.

Synarthroses

Synarthroses are joints that lack a joint cavity and move little or not at all. There are three types of synarthroses: synostoses, synchondroses, and syndesmoses. *Synostoses* are nonmovable joints in which the surfaces of the bones are joined by dense connective tissue or bone. The bones of the skull are joined by synostoses; they are joined by dense connective tissue in children and young adults and by bone in older persons. *Synchondroses* are joints in which bones are connected by hyaline cartilage and have limited motion. The ribs are attached to the sternum by this type of joint. *Syndesmoses* permit a certain amount of movement; they are separated by a fibrous disk and joined by interosseous ligaments. The symphysis pubis of the pelvis and the bodies of the vertebrae that are joined by intervertebral disks are examples of syndesmoses.

Diarthroses

Diarthrodial joints (*i.e.*, synovial joints) are freely movable joints. Most joints in the body are of this type. Although they are classified as freely movable, their movement ranges from almost none (*e.g.*, sacroiliac joint), to simple hinge movement (*e.g.*, interphalangeal joint), to movement in many planes (*e.g.*, shoulder or hip joint). The bony surfaces of these joints are covered with thin layers of articular cartilage, and the cartilaginous surfaces of these joints slide past each other during movement. As discussed in Chapter 43, diarthrodial joints are the joints most frequently affected by rheumatic disorders.

In a diarthrodial joint, the articulating ends of the bones are not connected directly but are indirectly linked by a strong fibrous capsule (*i.e.*, joint capsule) that surrounds the joint and is continuous with the periosteum (Fig. 41-6). This capsule supports the joint and helps to hold the bones in place. Additional support may be provided by ligaments that extend between the bones of the joint.

The joint capsule consists of two layers: an outer fibrous layer and an inner membrane, the synovium. The synovium

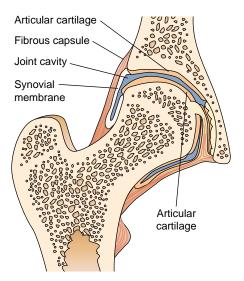

FIGURE 41-6 Diarthrodial joint, showing the articular cartilage, fibrous joint capsule, joint cavity, and synovial membrane.

surrounds the tendons that pass through the joints and the free margins of other intra-articular structures, such as ligaments and menisci. The synovium forms folds that surround the margins of articulations but do not cover the weightbearing articular cartilage. These folds permit stretching of the synovium so that movement can occur without tissue damage.

The synovium secretes a slippery fluid with the consistency of egg white called *synovial fluid*. This fluid acts as a lubricant and facilitates the movement of the articulating surfaces of the joint. Normal synovial fluid is clear or pale yellow, does not clot, and contains fewer than 100 cells/mm³. The cells are predominantly mononuclear cells derived from the synovium. The composition of the synovial fluid is altered in many inflammatory and pathologic joint disorders. Aspiration and examination of the synovial fluid play an important role in the diagnosis of joint diseases.

The articular cartilage is an example of hyaline cartilage and is unique in that its free surface is not covered with perichondrium. It has only a peripheral rim of perichondrium, and calcification of the portion of cartilage abutting the bone may limit or preclude diffusion from blood vessels supplying the subchondral bone. Articular cartilage is apparently nourished by the diffusion of substances contained in the synovial fluid bathing the cartilage. Regeneration of most cartilage is slow; it is accomplished primarily by growth that requires the activity of perichondrium cells. In articular cartilage, which has no perichondrium, superficial injuries heal slowly.

Blood Supply and Innervation

The blood supply to a joint arises from blood vessels that enter the subchondral bone at or near the attachment of the joint capsule and form an arterial circle around the joint. The synovial membrane has a rich blood supply, and constituents of plasma diffuse rapidly between these vessels and the joint cavity. Because many of the capillaries are near the surface of the synovium, blood may escape into the synovial fluid after relatively minor injuries. Healing and repair of the synovial membrane usually are rapid and complete. This is important because synovial tissue is injured in many surgical procedures that involve the joint.

The nerve supply to joints is provided by the same nerve trunks that supply the muscles that move the joints. These nerve trunks also supply the skin over the joints. As a rule, each joint of an extremity is innervated by all the peripheral nerves that cross the articulation; this accounts for the referral of pain from one joint to another. For example, hip pain may be perceived as pain in the knee.

The tendons and ligaments of the joint capsule are sensitive to position and movement, particularly stretching and twisting. These structures are supplied by the large sensory nerve fibers that form proprioceptor endings (see Chapter 38). The proprioceptors function reflexively to adjust the tension of the muscles that support the joint and are particularly important in maintaining muscular support for the joint. For example, when a weight is lifted, there is a proprioceptor-mediated reflex contraction and relaxation of appropriate muscle groups to support the joint and protect the joint capsule and other joint structures. Loss of proprioception and reflex control of muscular support leads to destructive changes in the joint.

The synovial membrane is innervated only by autonomic fibers that control blood flow. It is relatively free of pain fibers, as evidenced by the fact that surgical procedures on the joint are often done under local anesthesia. The joint capsule and the ligaments have pain receptors; these receptors are more easily stimulated by stretching and twisting than are other joint structures. Pain arising from the capsule tends to be diffuse and poorly localized.

Bursae

In some diarthrotic joints, the synovial membrane forms closed sacs that are not part of the joint. These sacs, called *bursae*, contain synovial fluid. Their purpose is to prevent friction on a tendon. Bursae occur in areas where pressure is exerted because of close approximation of joint structures (Fig. 41-7). Such conditions occur when tendons are deflected over bone or where skin must move freely over bony tissue. Bursae may

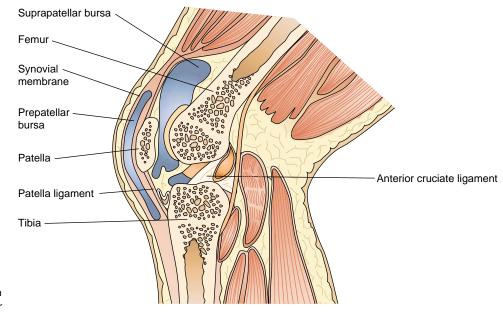

become injured or inflamed, causing discomfort, swelling, and limitation in movement of the involved area. A bunion is an inflamed bursa of the metatarsophalangeal joint of the great toe.

Intra-articular Menisci

Intra-articular menisci are fibrocartilage structures that develop from portions of the articular disk that occupied the space between articular cartilage surfaces during fetal development. Menisci may extend part way through the joint and have a free inner border, as at the lateral and medial articular surfaces of the knee, or they may extend through the joint, separating it into two separate cavities, as in the sternoclavicular joint. The menisci of the knee joint may be torn as the result of an injury (see Chapter 42).

In summary, bones are classified on the basis of their shape as long, short, flat, or irregular. Long bones are found in the upper and lower extremities; short bones in the ankle and wrist; flat bones in the skull and rib cage; and irregular bones in the vertebrae and jaw. Tendons and ligaments are dense connective skeletal tissue that connect muscles and bones. Tendons connect muscles to bones, and ligaments connect the movable bones of joints.

Articulations, or joints, are areas where two or more bones meet. Synarthroses are joints in which bones are joined together by fibrous tissue, cartilage, or bone; they lack a joint cavity and have little or no movement. Diarthrodial or synovial joints are freely movable. The surfaces of the articulating ends of bones in diarthrodial joints are covered with a thin layer of articular cartilage, and they are enclosed in a fibrous joint capsule. The joint capsule consists of two layers: an outer fibrous layer and an inner membrane, the synovium. The synovial fluid, which is secreted by the synovium into the joint capsule, acts as a lubricant and facilitates movement of the joint's articulating surfaces. Bursae, which are closed sacs containing synovial fluid, prevent friction in areas where tendons

■ FIGURE 41-7 ■ Sagittal section of knee joint, showing prepatellar and suprapatellar bursae. are deflected over bone or where skin must move freely over bony tissue.

Menisci are fibrocartilaginous structures that develop from portions of the articular disk that occupied the space between the articular cartilage during fetal development. The menisci may have a free inner border, or they may extend through the joint, separating it into two cavities. The menisci in the knee joint may be torn as a result of injury. Explain why pain is often experienced in all the joints of an extremity when only a single joint is affected by a disease process.

Describe the structure and function of a bursa.

REVIEW QUESTIONS

Cite the common components of cartilage and bone.

Compare the properties of the intercellular collagen and elastic fibers of skeletal tissue.

Cite the characteristics and name at least one location of elastic cartilage, hyaline cartilage, and fibrocartilage.

State the function of parathyroid hormone, calcitonin, and vitamin D in terms of bone formation and metabolism.

State the location and function of the periosteum and the endosteum.

State the characteristics of tendons and ligaments.

State the difference between synarthrodial and diarthrodial joints.

The musculoskeletal system includes the bones, joints, and muscles of the body together with associated structures such as ligaments and tendons. This system, which constitutes more than 70% of the body, is subject to a large number of disorders. These disorders affect persons in all age groups and walks of life and cause pain, disability, and deformity. The discussion in this chapter focuses on alterations and the effects of trauma, infections, ischemia, and neoplasms on structures of the musculoskeletal system. Disorders of skeletal growth and development in children are discussed at the end of the chapter.

INJURY AND TRAUMA OF MUSCULOSKELETAL STRUCTURES

A broad spectrum of musculoskeletal injuries results from numerous physical forces, including blunt tissue trauma, disruption of tendons and ligaments, and fractures of bony structures. Many of the forces that cause injury to the musculoskeletal system are typical for a particular environmental setting, activity, or age group. Trauma resulting from high-speed motor accidents is ranked as the number one killer of adults younger than 45 years of age.¹ Motorcycle accidents are especially common in young men, with fractures of the distal tibia, midshaft femur, and radius occurring most often. Trauma in children is usually the result of an accident. The most common causes of childhood injuries are falls, bicycle-related injuries, and sports injuries. Falls are the most common cause of injury in people 65 years of age and older. Impaired vision and hearing, dizziness, and unsteadiness of gait contribute to falls in older persons. These falls are often compounded by osteoporosis, or bone atrophy, which makes fractures more likely. Fractures of the hip and proximal humerus are particularly common in this age group.

Soft Tissue Injuries

Most skeletal injuries are accompanied by soft tissue injuries. These injuries include contusions, hematomas, and lacerations. They are discussed here because of their association with musculoskeletal injuries.

A *contusion* is an injury to soft tissue that results from direct trauma and is usually caused by striking a body part against a hard object. With a contusion, the skin overlying the injury remains intact. Initially, the area becomes ecchymotic (*i.e.*, black and blue) because of local hemorrhage; later, the discoloration gradually changes to brown and then to yellow as the blood is reabsorbed.

A large area of local hemorrhage is called a *hematoma*. Hematomas cause pain as blood accumulates and exerts pressure on nerve endings. The pain increases with movement or when pressure is applied to the area. The pain and swelling of a hematoma take longer to subside than that accompanying a contusion. A hematoma may become infected because of bacterial growth. Unlike a contusion, which does not drain, a hematoma may eventually split the skin because of increased pressures and produce drainage. The treatment for a contusion and a hematoma consists of elevating the affected part and applying cold for the first 24 hours to reduce the bleeding into the area. A hematoma may need to be aspirated.

A *laceration* is an injury in which the skin is torn or its continuity is disrupted. The seriousness of a laceration depends on the size and depth of the wound and on whether there is contamination from the object that caused the injury. Puncture wounds from nails or rusted material may result in the growth of toxic bacteria, leading to gas gangrene or tetanus. Lacerations are usually treated by wound closure, which is done after the area is sufficiently cleaned; the closed wound is covered with a sterile dressing. It is important to minimize contamination of the wound and to control bleeding. Contaminated wounds and open fractures are copiously irrigated and debrided, and the skin usually is left open to heal to prevent the development of an anaerobic infection or a sinus tract.

Joint (Musculotendinous) Injuries

Joints, or articulations, are sites where two or more bones meet. Joints (*i.e.*, diarthrodial) are supported by tough bundles of collagenous fibers called *ligaments* that attach to the joint capsule and bind the articular ends of bones together, and by *ten*- *dons* that join muscles to the periosteum of the articulating bones. Joint injuries involve mechanical overloading or forcible twisting or stretching.

Strains and Sprains

A *strain* is a stretching injury to a muscle or a musculotendinous unit caused by mechanical overloading. This type of injury may result from an unusual muscle contraction or an excessive forcible stretch. Although there usually is no external evidence of a specific injury, pain, stiffness, and swelling exist. The most common sites for muscle strains are the lower back and the cervical region of the spine. The elbow and the shoulder are also supported by musculotendinous units that are subject to strains. Foot strain is associated with the weight-bearing stresses of the feet; it may be caused by inadequate muscular and ligamentous support, overweight, or excessive exercise such as standing, walking, or running.

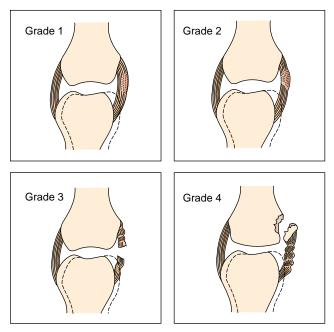

A sprain, which involves the ligamentous structures surrounding the joint, resembles a strain, but the pain and swelling subside more slowly. It usually is caused by abnormal or excessive movement of the joint. With a sprain, the ligaments may be incompletely torn or, as in a severe sprain, completely torn or ruptured (Fig. 42-1). The signs of sprain are pain, rapid swelling, heat, disability, discoloration, and limitation of function. Any joint may be sprained, but the ankle joint is most commonly involved, especially in higher-risk sports such as basketball. Most ankle sprains occur in the lateral ankle when the foot is turned inward under a person, forcing the ankle into inversion beyond the structural limits. Other common sites of sprain are the knee (the collateral ligament and anterior cruciate ligament) and elbow (the ulnar side). As with a strain, the soft tissue injury that occurs with a sprain is not evident on the radiograph. However, occasionally a chip of bone is evident when the entire ligament, including part of its bony attachment, has been ruptured or torn from the bone.

Healing of the dense connective tissues in tendons and ligaments is similar to that of other soft tissues. If properly treated,

KEY CONCEPTS

JOINT INJURIES

- Joints are the weakest part of the skeletal system and common sites for injury due to mechanical overloading or forcible twisting or stretching.
- Injury can include damage to the tendons, which connect muscle to bone; ligaments, which hold bones together; or the cartilage that covers the articular surface.
- Healing of the dense connective tissue involved in joint injuries requires time to restore the structures so that they are strong enough to withstand the forces imposed on the joint. Ligamentous injuries may require surgical intervention with approximation of many fibrous strands to facilitate healing.

■ FIGURE 42-1 ■ Degrees of sprain on the medial side of the right knee: grade 1, mild sprain of the medial collateral ligament; grade 2, moderate sprain with hematoma formation; grade 3, severe sprain with total disruption of the ligament; and grade 4, severe sprain with avulsion of the medial femoral condyle at the insertion of the medial collateral ligament. (Adapted from Spickler L.L. [1983]. Knee injuries of the athlete. *Orthopedic Nursing* 2 [5], 12–13)

injuries usually heal with the restoration of the original tensile strength. Repair is accomplished by fibroblasts from the inner tendon sheath or the loose connective tissue that surrounds the tendon. Capillaries infiltrate the injured area during the initial healing process and supply the fibroblasts with the materials they need to produce large amounts of collagen. Formation of the new collagen fibrils begins within 4 to 5 days and al-though tensile strength increases steadily thereafter, it is not sufficient to permit strong tendon pulls for about 7 weeks.² During the first 3 weeks, there is a danger that muscle contraction will pull the injured ends apart, causing the tendon to heal in the lengthened position. There is also a danger that adhesions will develop in areas where tendons pass through fibrous channels, such as in the distal palm of the hands, rendering the tendon useless.

The treatment of muscle strains and ligamentous sprains is similar in several ways. For an injured extremity, such as the ankle, elevation of the part followed by local application of cold may be sufficient.³ Compression, accomplished through the use of adhesive wraps or a removable splint, helps reduce swelling and provides support. A cast is applied for severe sprains, especially those severe enough to warrant surgical repair. Immobilization for a muscle strain is continued until the pain and swelling have subsided. In a sprain, the affected joint is immobilized for several weeks. Immobilization may be followed by graded active exercises. Early diagnosis, treatment, and rehabilitation are essential in preventing chronic ligamentous instability.

Dislocations

Dislocation of a joint is the loss of articulation of the bone ends in the joint capsule caused by displacement or separation of the bone end from its position in the joint. It usually follows a severe trauma that disrupts the holding ligaments. Dislocations are seen most often in the shoulder and acromioclavicular joints. A *subluxation* is a partial dislocation in which the bone ends in the joint are still in partial contact with each other.

Dislocations can be congenital, traumatic, or pathologic. Congenital dislocations occur in the hip and knee. Traumatic dislocations occur after falls, blows, or rotational injuries. For example, car accidents often cause dislocations of the hip and accompanying acetabular fractures because of the direction of impact. In the shoulder and patella, dislocations may become recurrent, especially in athletes. They recur with the same motion but require less and less force each time. Less common sites of dislocation, seen mainly in young adults, are the wrist and midtarsal region. They usually are the result of direct force, such as a fall on an outstretched hand. Pathologic dislocation in the hip is a late complication of infection, rheumatoid arthritis, paralysis, and neuromuscular diseases.

Diagnosis of a dislocation is based on history, physical examination, and radiologic findings. The symptoms are pain, deformity, and limited movement. The treatment depends on the site, mechanism of injury, and associated injuries such as fractures. Dislocations that do not reduce spontaneously usually require manipulation or surgical repair. Various surgical procedures also can be used to prevent redislocation of the patella, shoulder, or acromioclavicular joints. Immobilization is necessary for several weeks after reduction of a dislocation to allow healing of the joint structures. In dislocations affecting the knee, alternatives to surgery are isometric quadricepsstrengthening exercises and a temporary brace. Surgical procedures, such as joint replacement, may be necessary in certain pathologic dislocations.

Loose Bodies

Loose bodies are small pieces of bone or cartilage within a joint space. These can result from trauma to the joint or may occur when cartilage has worn away from the articular surface, causing a necrotic piece of bone to separate and become free floating. The symptoms are painful catching and locking of the joint. Loose bodies are commonly seen in the knee, elbow, hip, and ankle. The loose body repeatedly gets caught in the crevice of a joint, pinching the underlying healthy cartilage; unless the loose body is removed, it may cause osteoarthritis and restricted movement. The treatment consists of removal using operative arthroscopy.

Shoulder and Rotator Cuff Injuries

The glenohumeral (shoulder) joint is a ball-and-socket joint that permits a wide range of motion, a factor that makes the joint relatively unstable.⁴ The support and movement of the shoulder joint relies heavily on the support of four relatively small muscle-tendon groups collectively known as the rotator cuff (Fig. 42-2). The space between the acromion of the shoulder blade and superior part of the humeral head is called the impingement interval. This space is normally narrow and is maximally narrow when the arm if abducted or moved above the horizontal.

Rotator cuff impingement, tendonitis, and tears are common among athletes. The rotator cuff is commonly injured during repetitive movements that carry the arm above the shoulder, such as those used by baseball pitchers, tennis and racquet ball players, swimmers, and weight lifters.⁴ Among the relevant muscles, the supraspinous is the one most often affected. Rotator cuff tears may be partial or full thickness. Partial tears do not completely severe the tendon and respond well to nonsurgical treatment. Full thickness tears require surgery.

Recurrent inflammation or tendonitis of the rotator cuff inflammation, also known as *shoulder impingement syndrome*, is characterized by pain and swelling of the cuff tendons and the surrounding bursa. It occurs most often in people with loose joints, people with abnormal bony anatomy in the shoulder, and people who do repetitive lifting above the shoulder level. It is common in baseball pitchers. Lifting overhead or just moving the arm above the head may cause pinching or impingement of one of the tendons of the rotator cuff. Tendonitis may progress to a partial or complete rotator cuff tear caused by progressive weakening of the tendon fibers.

Calcific tendonitis is a self-limiting calcification of the rotator cuff.⁵ It involves the deposition of calcium crystals in the tendon of the rotator cuff. It is most common in women, ages 30 to 60 years, and workers in sedentary jobs. The disorder involves four stages: (1) precalcific phase with asymptomatic fibrocartilaginous transformation within the cuff, (2) deposition of calcium crystals, (3) the resorptive phase, and (4) the postcalcific healing and repair phase. The third phase is usually the most incapacitating because the movement of the calcium crystals in the subacromial bursa during the resorptive process may cause constant and severe pain and restriction of motion that typically lasts for several weeks.

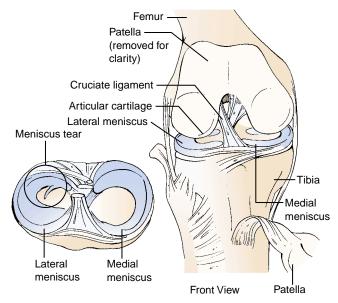

Many physical examination maneuvers are used to define shoulder pathology. The history and mechanism of injury are important. In addition to standard radiographs, an arthrogram, computed tomography (CT) scan, or magnetic resonance imaging (MRI) scan may be obtained. Arthroscopic examination under anesthesia is done for diagnostic purposes and operative arthroscopy to repair severe tears. Conservative treatment with anti-inflammatory agents, corticosteroid injections, and physical therapy often is done. A period of rest is followed by a customized exercise and rehabilitation program to improve strength, flexibility, and endurance.

Knee Injuries

The knee is a common site of injury, particularly sport-related injuries in which the knee is subjected to abnormal twisting and compression forces. These forces can result in injury to the menisci, rupture of the anterior cruciate ligament, patellar subluxation and dislocation, and chondromalacia. Knee injuries in young adulthood and both knee and hip injuries in middle age substantially increase the risk of osteoarthritis in the same joint later in life.⁶

Meniscus Injuries. The menisci are C-shaped plates of fibrocartilage that are superimposed between the condyles of the femur and tibia. The menisci play a major role in load bearing and shock absorption; they help to stabilize the knee; they assist in joint lubrication; and they serve as a source of nutrition for articular cartilage in the knee. There are two menisci in each knee, a lateral and medial meniscus (Fig. 42-3). The menisci are thicker at their external margins and taper to thin, unattached edges at their interior margin. They are firmly attached at their ends to the intercondylar area of the tibia and are supported by the coronary and transverse ligaments of the knee.

Any action of the knee that causes injury to the knee ligaments can also cause a meniscal tear.⁷ Meniscus injury commonly occurs as the result of a rotational injury from a sudden or sharp pivot or a direct blow to the knee, as in hockey, basketball, or football. The injured knee is edematous and painful,

■ FIGURE 42-3 ■ The knee showing the lateral and medial meniscus (with the patella removed for clarity). Insert (**lower left**) shows meniscus tear.

especially with hyperflexion and hyperextension. A loose fragment may cause knee instability and locking.

Diagnosis is made by examination and confirmed by methods such as arthroscopy and radiologic, CT scans, MRI, and radionuclide imaging.⁸ Initial treatment of meniscal injuries may be conservative. The knee may be placed in a removable knee immobilizer. Isometric quadriceps exercises may be prescribed. Activity usually is restricted until complete motion is recovered. Arthroscopic meniscectomy may be performed when there is recurrent or persistent locking, recurrent effusion, or disabling pain.

Rupture of the Anterior Cruciate Ligament. The cruciate ligaments (CL) secure the femur to the tibia in a crossed position (Fig. 42-3). The anterior CL (ACL) and posterior CL (PCL) control flexion and lateral rotation of the knee. The ACL is the weaker ligament and is often ruptured with a lateral blow to the knee. People with knees that are unstable as the result of ACL tears are at risk for early degenerative joint disease, as well as subsequent damage to other structures of the knee.⁹

About 85% of people who have an ACL tear are immediately disabled and not able to continue their activity. They often report the feeling of "giving way" and hearing or feeling a "pop" at the time of injury. Swelling is usually caused by hemarthrosis.

Diagnosis is based on the history, physical examination of the knee, and MRI. The selection of treatment methods, which include surgical repair, alterations in lifestyle, and bracing, depend on the person's activity level and expectation. Surgical repair is usually the treatment of choice for athletes who want to continue activities requiring twisting or rapid changes in direction.

Patellar Subluxation and Dislocations. Recurrent subluxation and dislocation of the patella (*i.e.*, knee cap) are common injuries in young adults. They account for approximately 10% of all athletic injuries and are more common in women. Sports such as skiing or tennis may cause stress on the patella. These sports involve external rotation of the foot and lower leg with knee flexion, a position that exerts rotational stresses on the knee. Congenital knee variations are also a predisposing factor.

There is often a sensation of the patella "popping out" when the dislocation occurs. Other complaints include the knee giving out, swelling, crepitus, stiffness, and loss of range of motion.

Treatment can be difficult, but nonsurgical methods are used first. They include immobilization with the knee extended, bracing, administration of anti-inflammatory agents, and isometric quadriceps-strengthening exercises. Surgical intervention often is necessary.

Chondromalacia. Chondromalacia, or softening of the articular cartilage, is seen most commonly on the undersurface of the patella and occurs most frequently in young adults. It can be the result of recurrent subluxation of the patella or overuse in strenuous athletic activities. Persons with this disorder typically report pain, particularly when climbing stairs or sitting with the knees bent. Occasionally, the person experiences weakness of the knee.

The treatment consists of rest, isometric exercises, and application of ice after exercise. Part of the patella may be surgically removed in severe cases. In less severe cases, the soft portion is shaved using a saw inserted through an arthroscope.

Fractures

A fracture, or discontinuity of the bone, is the most common type of bone lesion. Normal bone can withstand considerable compression and shearing forces and, to a lesser extent, tension forces. A fracture occurs when more stress is placed on the bone than it is able to absorb. Grouped according to cause, fractures can be divided into three major categories: (1) fractures caused by sudden injury, (2) fatigue or stress fractures, and (3) pathologic fractures. The most common fractures are those resulting from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from falling on an outstretched hand.

A *fatigue fracture* results from repeated wear on a bone. Pain associated with overuse injuries of the lower extremities, especially posterior medial tibial pain, is one of the most common symptoms that physically active persons, such as runners, experience. *Stress fractures* in the tibia may be confused with "shin splints," a nonspecific term for pain in the lower leg from overuse in walking and running, because they frequently do not appear on x-ray films until 2 weeks after the onset of symptoms.

A *pathologic fracture* occurs in bones that already are weakened by disease or tumors. Fractures of this type may occur spontaneously with little or no stress. The underlying disease state can be local, as with infections, cysts, or tumors, or it can be generalized, as in osteoporosis, Paget's disease, or disseminated tumors.

Classification

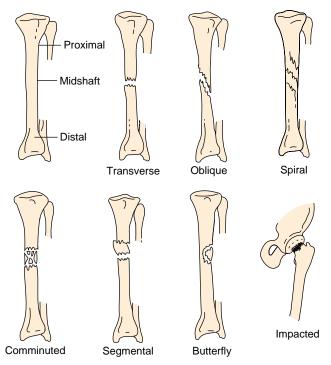

Fractures usually are classified according to location, type, and direction or pattern of the fracture line (Fig. 42-4). A fracture of the long bone is described in relation to its position in the bone—proximal, midshaft, and distal. Other descriptions are used when the fracture affects the head or neck of a bone,

KEY CONCEPTS

FRACTURE HEALING

- Fractures are caused by forces that disrupt the continuity of bone.
- Fracture healing depends on the extent of the injury, the ability to align the bone fragments, and immobilizing the fracture site so that healing can take place.
- Bone healing occurs by replacement of injured bone cells. It involves formation of a hematoma that provides the foundation for blood vessel and fibroblast infiltration, proliferation of bone repair cells (osteoblasts), callus formation, ossification of the callus, and remodeling of the fracture site.

Unit Eleven: Alterations in the Skeletal and Integumentary Systems

■ **FIGURE 42-4** ■ Classification of fractures. Fractures are classified according to location (proximal, midshaft, or distal), the direction of fracture line (transverse, oblique, or spiral), and type (comminuted, segmental, butterfly, or impacted).

involves a joint, or is near a prominence such as a condyle or malleolus.

The type of fracture is determined by its communication with the external environment, the degree of break in continuity of the bone, and the character of the fracture pieces.¹⁰ A fracture can be classified as open or closed. When the bone fragments have broken through the skin, the fracture is called an *open* or *compound fracture*. In a closed fracture, there is no communication with the outside skin.

The degree of a fracture is described in terms of a partial or complete break in the continuity of bone. A *greenstick fracture*, which is seen in children, is an example of a partial break in bone continuity and resembles that seen when a young sapling is broken. This kind of break occurs because children's bones, especially until approximately 10 years of age, are more resilient than the bones of adults.

The character of the fracture pieces may also be used to describe a fracture. A *comminuted fracture* has more than two pieces. A *compression fracture*, as occurs in the vertebral body, involves two bones that are crushed or squeezed together. A fracture is called *impacted* when the fracture fragments are wedged together. This type usually occurs in the humerus, often is less serious, and usually is treated without surgery.

The direction of the trauma or mechanism of injury produces a certain configuration or pattern of fracture. *Reduction* is the restoration of a fractured bone to its normal anatomic position. The pattern of a fracture indicates the nature of the trauma and provides information about the easiest method for reduction. *Transverse fractures* are caused by simple angulatory forces. A *spiral fracture* results from a twisting motion, or torque. A transverse fracture is not likely to become displaced or lose its position after it is reduced. On the other hand, spiral, oblique, and comminuted fractures often are unstable and may change position after reduction.

Manifestations

The signs and symptoms of a fracture include pain, tenderness at the site of bone disruption, swelling, loss of function, deformity of the affected part, and abnormal mobility. The deformity varies according to the type of force applied, the area of the bone involved, the type of fracture produced, and the strength and balance of the surrounding muscles.

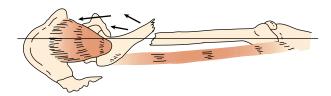

In long bones, three types of deformities-angulation, shortening, and rotation—are seen. Severely angulated fracture fragments may be felt at the fracture site and often push up against the soft tissue to cause a tenting effect on the skin. Bending forces and unequal muscle pulls cause angulation. Shortening of the extremity occurs as the bone fragments slide and override each other because of the pull of the muscles on the long axis of the extremity (Fig. 42-5). Rotational deformity occurs when the fracture fragments rotate out of their normal longitudinal axis; this can result from rotational strain produced by the fracture or unequal pull by the muscles that are attached to the fracture fragments. A crepitus or grating sound may be heard as the bone fragments rub against each other. In the case of an open fracture, there is bleeding from the wound where the bone protrudes. Blood loss from a pelvic fracture or multiple long bone fractures can cause hypovolemic shock in a trauma victim.

Shortly after the fracture has occurred, nerve function at the fracture site may be temporarily lost. The area may become numb, and the surrounding muscles may become flaccid. This condition has been called *local shock*. During this period, which may last for a few minutes to half an hour, fractured bones may be reduced with little or no pain. After this brief period, the pain sensation returns and, with it, muscle spasms and contractions of the surrounding muscles.

Diagnosis and Treatment

Diagnosis is the first step in the care of fractures and is based on history and physical manifestations. X-ray examination is used to confirm the diagnosis and direct the treatment. The ease of diagnosis varies with the location and severity of the fracture. In the trauma patient, the presence of other, more serious injuries may make diagnosis more difficult.

Treatment depends on the general condition of the person, the presence of associated injuries, the location of the fracture and its displacement, and whether the fracture is open or closed. A *splint* is a device for immobilizing the movable fragments of a fracture. When a fracture is suspected, the injured part always should be splinted before it is moved. This is essential for preventing further injury.

■ FIGURE 42-5 ■ Displacement and overriding of fracture fragments of a long bone (femur) caused by severe muscle spasm.

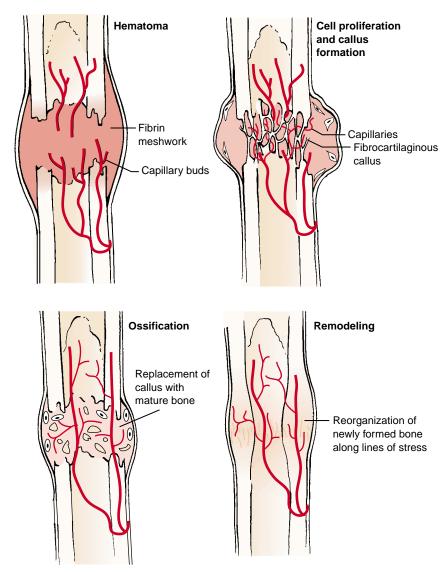

794

There are three objectives for treatment of fractures: (1) reduction of the fracture, (2) immobilization, and (3) preservation and restoration of the function of the injured part. Reduction of a fracture is directed toward replacing the bone fragments to as near normal anatomic position as possible. This can be accomplished by closed manipulation or surgical (open) reduction. Closed manipulation uses methods such as manual pressure and traction. Fractures are held in reduction by external or internal fixation devices. Surgical reduction involves the use of various types of hardware to accomplish internal fixation of the fracture fragments (Fig. 42-6). Immobilization prevents movement of the injured parts and is the single most important element in obtaining union of the fracture fragments. Immobilization can be accomplished through the use of external devices, such as splints, casts, external fixation devices, or traction, or by means of internal fixation devices inserted during surgical reduction of the fracture. Preservation and restoration of the function of muscles and joints are an ongoing process in the unaffected and affected extremities during the period of immobilization required for fracture healing. Exercises designed to preserve function, maintain muscle strength, and reduce joint stiffness should be started early.

Bone Healing

Bone healing occurs in a manner similar to soft tissue healing. However, it is a more complex process and takes longer. There are five stages involved in bone healing: (1) hematoma formation, (2) cellular proliferation, (3) callus formation, (4) ossification, and (5) remodeling (Fig. 42-6). The degree of response during each of these stages is in direct proportion to the extent of trauma.

Hematoma Formation. Hematoma formation occurs during the first 48 to 72 hours after fracture. It develops as blood from torn vessels in the bone fragments and surrounding soft tissue leaks between and around the fragments of the fractured bone. The hematoma is thought to be necessary for the initiation of the cellular events essential to fracture healing.¹¹⁻¹³ As the result of hematoma formation, clotting factors remain in the injured area to initiate the formation of a fibrin meshwork, which serves as a framework for the ingrowth of fibroblasts and new

■ FIGURE 42-6 ■ The stages of bone healing. The hematoma stage provides the fibrin meshwork and capillary buds needed for subsequent cellular invasion. Cellular proliferation and callus formation represent the stages during which osteoblasts enter the area and form the fibrocartilaginous callus that joins the bone fragments. The ossification stage involves the mineralization of the fibrocartilaginous callus; and the remodeling stage, the reorganization of mineralized bone along the lines of mechanical stress. capillary buds. Granulation tissue, the result of fibroblast and new capillary growth, gradually invades and replaces the clot. When a large hematoma develops, healing is delayed because macrophages, platelets, oxygen, and nutrients for callus formation are prevented from entering the area.

Cellular Proliferation. Three layers of bone structure are involved in the cellular proliferation that occurs during bone healing: the periosteum, or outer covering of the bone; the endosteum, or inner covering; and the medullary canal, which contains the bone marrow. During this process, the osteoblasts, or bone-forming cells, multiply and differentiate into a fibrocartilaginous callus. The fibrocartilaginous callus is softer and more flexible than callus. Cellular proliferation begins distal to the fracture site, where there is a greater supply of blood. After a few days, a fibrocartilage "collar" becomes evident around the fracture site. The collar edges on either side of the fracture eventually unite to form a bridge, which connects the bone fragments.

Callus Formation. During the early stage of callus formation, the fracture site becomes "sticky" as osteoblasts continue to move in and through the fibrin bridge to help keep it firm. Cartilage forms at the level of the fracture, where there is less circulation. In areas of the bone with muscle insertion, periosteal circulation is better, bringing in the nutrients necessary to bridge the callus. The bone calcifies as mineral salts are deposited. This stage usually occurs during the third to fourth week of fracture healing.

Ossification. Ossification involves the final laying down of bone. This is the stage at which the fracture has been bridged and the fracture fragments are firmly united. Mature bone replaces the callus, and the excess callus is gradually resorbed by the osteoclasts. The fracture site feels firm and immovable and appears united on the radiograph. At this point, it is safe to remove the cast.

Remodeling. Remodeling involves resorption of the excess bony callus that develops in the marrow space and encircles the external aspect of the fracture site. The remodeling process is directed by mechanical stress and direction of weight bearing.

Healing Time. Union of a fracture has occurred when the fracture is solid enough to withstand normal stresses and it is clinically and radiologically safe to remove the external fixation. Healing time depends on the site of the fracture, the condition of the fracture fragments, hematoma formation, and other local and host factors. In children, fractures usually heal within 4 to 6 weeks; in adolescents, they heal within 6 to 8 weeks; and in adults, they heal within 10 to 18 weeks. The increased rate of healing among children compared with adults may be related to the increased cellularity and vascularity of the child's periosteum.¹³ In general, fractures of long bones, displaced fractures, and fractures with less surface area heal more slowly. Function usually returns within 6 months after union is complete. However, return to complete function may take longer.

Impaired Bone Healing. Factors that influence bone healing are specific to the person, the type of injury sustained, and local factors that disrupt healing (Chart 42-1). Individual factors that

CHART 42-1 Factors Affecting Fracture Healing

- Nature of the injury or the severity of the trauma, including fracture displacement, edema, and arterial occlusion with crushing injuries
- Degree of bridge formation that develops during bone healing
- Amount of bone loss (*e.g.*, it may be too great for the healing to bridge the gap)
- Type of bone that is injured (*e.g.*, cancellous bone heals faster than cortical bone)
- Degree of immobilization that is achieved (*e.g.*, movement disrupts the fibrin bridge and cartilage forms instead of bone)
- Local infection, which retards or prevents healing
- Local malignancy, which must be treated before healing can proceed
- Bone necrosis, which prevents blood flow into the fracture site

may delay bone healing are the patient's age; current medications; debilitating diseases, such as diabetes and rheumatoid arthritis; local stress around the fracture site; circulatory problems and coagulation disorders; and poor nutrition.

Malunion is healing with deformity, angulation, or rotation that is visible on x-ray films.¹³ Early, aggressive treatment, especially of the hand, can prevent malunion and result in earlier alignment and return of function. Malunion is caused by inadequate reduction or alignment of the fracture.

Delayed union is the failure of a fracture to unite within the normal period (*e.g.*, 20 weeks for a fracture of the tibia or femur in an adult). Intra-articular fractures (those through a joint) may heal more slowly and may eventually produce arthritis. *Nonunion* is failure to produce union and cessation of the processes of bone repair. It is seen most often in the tibia, especially with open fractures or crushing injuries. It is characterized by mobility of the fracture site and pain on weight bearing. Muscle atrophy and loss of range of motion may occur. Non-union usually is established 6 to 12 months after the time of the fracture.¹³ The complications of fracture healing are summarized in Table 42-1.

Treatment methods for impaired bone healing encompass surgical interventions, including bone grafts, bracing, external fixation, or electrical stimulation of the bone ends. Electrical stimulation is thought to stimulate the osteoblasts to lay down a network of bone. Three types of commercial bone growth stimulators are available: a noninvasive model, which is placed outside the cast; a seminoninvasive model, in which pins are inserted around the fracture site; and a totally implantable type, in which a cathode coil is wound around the bone at the fracture site and operated by a battery pack implanted under the skin.

Complications of Fractures and Other Musculoskeletal Injuries

The complications of fractures and other orthopedic injuries are associated with loss of skeletal continuity, injury from bone fragments, pressure from swelling and hemorrhage (*e.g.*, frac-

TABLE 42-1	Complications of Fracture Healing		
Complication	Manifestations	Contributing Factors	
Delayed union	Failure of fracture to heal within predicted time as determined by x-ray	Large displaced fracture Inadequate immobilization Large hematoma Infection at fracture site Excessive loss of bone Inadequate circulation

ture blisters, compartment syndrome), involvement of nerve fibers (*e.g.*, reflex sympathetic dystrophy and causalgia), or development of fat emboli.

Fracture Blisters. Fracture blisters are skin bullae and blisters representing areas of epidermal necrosis with separation of epidermis from the underlying dermis by edema fluid. They are seen with more severe, twisting types of injuries (e.g., motor vehicle accidents and falls from heights) but can also occur after excessive joint manipulation, dependent positioning, and heat application, or from peripheral vascular disease. They can be solitary, multiple, or massive, depending on the extent of injury. Most fracture blisters occur in the ankle, elbow, foot, knee, or areas where there is little soft tissue between the bone and the skin. The development of fracture blisters reportedly is reduced by early surgical intervention in persons requiring operative repair.¹⁴ This probably reflects the early operative release of the fracture hematoma, reapproximation of the disrupted soft tissues, ligation of bleeding vessels, and fixation of bleeding fracture surfaces. Prevention of fracture blisters is important because they pose an additional risk of infection.

Compartment Syndrome. Compartment syndrome is the result of increased pressure in a limited anatomic space that compromises circulation and threatens the viability and function of the nerves and muscles (see Chapter 15). It can be acute or chronic. Acute compartment syndrome can occur after a fracture or crushing injury, when excessive swelling around the site of injury results in increased pressure in a closed compartment. This increase in pressure occurs because fascia, which covers and separates muscles, is inelastic and unable to stretch and compensate for the extreme swelling. The most common sites are the four compartments of the lower leg (*i.e.*, deep posterior, superficial posterior, lateral, and anterior compartments) and the dorsal and volar compartments of the forearm.

The condition is characterized by pain that is out of proportion to the original injury or physical findings.^{14,15} Nerve compression may cause changes in sensation (*e.g.*, paresthesias such as burning or tingling or loss of sensation), diminished reflexes, and eventually the loss of motor function. Symptoms usually begin within a few hours but can be delayed as long as 64 hours.¹⁴ Compression of blood vessels may cause muscle ischemia and loss of function. In contrast to the diminished or absent pulses that occur when ischemia is caused by a tight bandage or cast, the arterial pulses often are normal in compartment syndrome. Pallor and loss of the pulse, when they occur, are late findings.

Treatment of compartment syndrome is directed at reducing the compression of blood vessels and nerves. Constrictive dressings and casts are loosened. Intracompartmental pressure can be measured by means of a catheter or needle inserted into the compartment. A fasciotomy, or surgical transection of the fascia that is restricting the muscle compartment, may be required. Delay in diagnosis and treatment of compartment syndrome can lead to irreversible nerve and muscle damage.

Reflex Sympathetic Dystrophy and Causalgia. Reflex sympathetic dystrophy, also known as the complex regional pain syndrome, is a complication of orthopedic injuries that causes pain out of proportion to the injury and autonomic nervous system dysfunction manifested by hyperhidrosis (increased sweating) and vasomotor instability (either flushed and warm or cold and pale).^{14,16} The disorder often produces long-term disability and chronic pain syndromes (see Chapter 39).

Pain, which is the prominent symptom of the disorder, is described as severe, aching, or burning. It usually increases in intensity with movement and with noxious and non-noxious stimuli. The cause of the pain is unclear but is thought to have a sympathetic nervous system component. Muscle wasting, thin and shiny skin, and abnormalities of the nails and bone can occur. Decreased muscle strength and disuse can lead to contractures and osteoporosis.

Treatment focuses on pain management and prevention of disability. Physical therapy interventions such as hot/cold baths and elevation of the limb are used to maximize range of motion and minimize pain. Medications include anti-inflammatory agents, vasodilators, and antidepressant medications. Sympathetic nerve blocks may be used.

Fat Embolism Syndrome. The fat embolism syndrome (FES) refers to a constellation of clinical manifestations resulting from the presence of fat droplets in the small blood vessels of the lung or other organs after a long-bone fracture or other major trauma.¹⁴ The fat emboli are thought to be released from the bone marrow or adipose tissue at the fracture site into the venous system through torn veins.

Clinically, the incidence of fat embolization is related to fractures of bones containing the most marrow (*i.e.*, long bones and the bones of the pelvis). An increase in intramedullary pressure in the femur is the most important pathogenic factor in the development of emboli. Although fat embolization occurs with fractures or operative fixation of fractures, FES occurs in only a small percentage of cases, supporting the hypothesis that factors other than mechanical forces may be necessary in the development of FES.

The main clinical features of FES are respiratory failure, cerebral dysfunction, and skin petechiae.^{14,17} Initial symptoms begin within a few hours to 3 to 4 days after injury and do not appear beyond 1 week after the injury. The first symptoms include a subtle change in behavior and signs of disorientation resulting from emboli in the cerebral circulation combined with respiratory depression. There may be complaints of substernal chest pain and dyspnea accompanied by tachycardia and a lowgrade fever. Diaphoresis, pallor, and cyanosis become evident as respiratory function deteriorates. A petechial rash that does not blanch with pressure often occurs 2 to 3 days after the injury. This rash usually is found on the anterior chest, axillae, neck, and shoulders. It also may appear on the soft palate and conjunctiva. The rash is thought to be related to embolization of the skin capillaries or thrombocytopenia.

Three degrees of severity are seen: subclinical, overt clinical, and fulminating. Although the subclinical and overt clinical forms of FES respond well to treatment, the fulminating form often is fatal. An important part of the treatment of fat emboli is early diagnosis. Arterial blood gases should be assayed immediately after recognition of clinical manifestations. Treatment is directed toward correcting hypoxemia and maintaining adequate fluid balance. Mechanical ventilation may be required. Corticosteroid drugs are administered to decrease the inflammatory response of lung tissues, decrease the edema, stabilize the lipid membranes to reduce lipolysis, and combat the bronchospasm. Corticosteroids are also given prophylactically to high-risk persons. The only preventive approach to FES is early stabilization of the fracture.

Osteonecrosis

Osteonecrosis, or death of a segment of bone, is a condition caused by the interruption of blood supply to the marrow, medullary bone, or cortex. It is a relatively common disorder and can occur in the medullary cavity of the metaphysis and the subchondral region of the epiphysis, especially in the proximal femur, distal femur, and proximal humerus. It is a common complicating disorder of Legg-Calvé-Perthes disease, sickle cell disease, steroid therapy, and hip surgery.^{18,19} The rates of osteonecrosis among persons treated with corticosteroids range from 5% to 25%. More than 10% of 500,000 joint replacements performed annually in the United States are for treatment of osteonecrosis.¹⁸

Although bone necrosis results from ischemia, the mechanisms producing the ischemia are varied and include mechanical vascular interruption such as occurs with a fracture; thrombosis and embolism (*e.g.*, sickle cell disease, nitrogen bubbles caused by inadequate decompression during deep sea diving); vessel injury (*e.g.*, vasculitis, radiation therapy); and increased intraosseous pressure with vascular compression (*e.g.*, steroidinduced osteonecrosis). In many cases, the cause of the necrosis is uncertain. Other than fracture, the most common causes of bone necrosis are idiopathic (*i.e.*, those of unknown cause) and prior steroid therapy. Chart 42-2 lists disorders associated with osteonecrosis.

Bone has a rich blood supply that varies from site to site. The flow in the medullary portion of bone originates in nutrient vessels from an interconnecting plexus that supplies the marrow, trabecular bone, and endosteal half of the cortex. The outer cortex receives its blood supply from periosteal, muscular, metaphyseal, and epiphyseal vessels that surround the bone. Some bony sites, such as the head of the femur, have only limited collateral circulation so that interruption of the flow, such as with a hip fracture, can cause necrosis and irreversible damage to a substantial portion of medullary and cortical bone.

The pathologic features of bone necrosis are the same, regardless of cause. The site of the lesion is related to the vessels involved. There is necrosis of cancellous bone and marrow. The cortex usually is not involved because of collateral blood flow. In subchondral infarcts (*i.e.*, ischemia below the cartilage), a triangular or wedge-shaped segment of tissue that has the subchondral bone plate as its base and the center of the epiphysis as its apex undergo necrosis. When medullary infarcts occur in

fatty marrow, death of bone results in calcium release and necrosis of fat cells with the formation of free fatty acids. Released calcium forms an insoluble "soap" with free fatty acids. Because bone lacks mechanisms for resolving the infarct, the lesions remain for life.

One of the most common causes of osteonecrosis is that associated with administration of corticosteroids.^{18,19} Despite numerous studies, the mechanism of steroid-induced osteonecrosis remains unclear. The condition may develop after the administration of very high, short-term doses, during longterm treatment, or even from intra-articular injection. Although the risk increases with the dose and duration of treatment, it is difficult to predict who will be affected. The interval between corticosteroid administration and onset of symptoms rarely is less than 6 months and may be more than 3 years. There is no satisfactory method for preventing progression of the disease.

The symptoms associated with osteonecrosis are varied and depend on the extent of infarction. Typically, subchondral infarcts cause chronic pain that is initially associated with activity but that gradually becomes more progressive until it is experienced at rest. Subchondral infarcts often collapse and predispose the patient to severe secondary osteoarthritis.

Diagnosis of osteonecrosis is based on history, physical findings, radiographic findings, and the results of special imaging studies, including CT scans and technetium-99m bone scans. MRI is particularly effective in the diagnosis of osteonecrosis. Plain radiographs are used to define and classify the course of the disease, particularly of the hip.

Treatment of osteonecrosis depends on the underlying pathology. In some cases, only short-term immobilization, nonsteroidal anti-inflammatory drugs, exercises, and limitation in weight bearing are used. Osteonecrosis of the hip is particularly difficult to treat. In persons with early disease, limitation of weight bearing through the use of crutches may allow the condition to stabilize. Although several surgical approaches have been used, the most definitive treatment of advanced osteonecrosis of the knee or hip is total joint replacement.

In summary, many external physical agents can cause trauma to the musculoskeletal system. Particular factors, such as environments, activity, or age, can place a person at greater risk for injury. Some soft tissue injuries such as contusions, hematomas, and lacerations are relatively minor and easily treated. Muscle strains and ligamentous sprains are caused by mechanical overload on the connective tissue. They heal more slowly than the minor soft tissue injuries and require some degree of immobilization. Healing of soft tissue begins within 4 to 5 days of the injury and is primarily the function of fibroblasts, which produce collagen. Joint dislocation is caused by trauma to the supporting structures. Repeated trauma to the joint can cause articular softening (i.e., chondromalacia) or the separation of small pieces of bone or cartilage, called loose bodies, in the joint. The knee and shoulder are common sites for injuries in athletes. The rotator cuff is a common site for shoulder injuries. Knee injuries include injury to the menisci, anterior cruciate ligament tears, patellar subluxation and dislocation, and chondromalacia.

Fractures occur when more stress is placed on a bone than the bone can absorb. The nature of the stress determines the type of fracture and the character of the resulting bone fragments. Healing of fractures is a complex process that takes place in five stages: hematoma formation, cellular proliferation, callus formation, ossification, and remodeling. For satisfactory healing to take place, the affected bone has to be reduced and immobilized. This is accomplished with external fixation devices (e.g., splints, casts, or traction) or surgically implanted internal fixation devices. The complications of fractures are associated with loss of skeletal continuity (malunion or nonunion), pressure from swelling and hemorrhage (fracture blisters and compartment syndrome), involvement of nerve fibers (reflex sympathetic dystrophy and causalgia), or development of fat emboli.

Osteonecrosis, or death of a segment of bone, is a condition caused by the interruption of blood supply to the marrow, medullary bone, or cortex. Sites with poor collateral circulation, such as the femoral head, are most seriously affected. It is a common complicating disorder of Legg-Calvé-Perthes disease, sickle cell disease, steroid therapy, and hip surgery. Symptoms include pain that varies in severity, depending on the extent of infarction. Total joint replacement is the most frequently used treatment for advanced osteonecrosis.

BONE INFECTIONS

Bone infections are difficult to treat and eradicate. Their effects can be devastating; they can cause pain, disability, and deformity. Chronic bone infections may drain for years because of a sinus tract. This occurs when a passageway develops from an abscess or cavity in the bone to an opening through the skin.

Osteomyelitis

Osteomyelitis represents an acute or chronic pyogenic infection of the bone. The term osteo refers to bone, and myelo refers to the marrow cavity, both of which are involved in this disease. Osteomyelitis can be caused by direct extension or contamination of an open fracture or wound (contiguous invasion); seeding through the bloodstream (hematogenous

KEY CONCEPTS

BONE INFECTIONS

- Bone infections may be caused by a wide variety of microorganisms introduced during injury, during operative procedures, or from the bloodstream.
- Once localized in bone, the microorganisms proliferate, produce cell death, and spread within the bone shaft, inciting a chronic inflammatory response with further destruction of bone.
- Bone infections are difficult to treat and eradicate. Measures to prevent infection include careful cleaning and debridement of skeletal injuries and strict operating room protocols.

spread); or from skin infections in persons with vascular insufficiency. In most cases, *Staphylococcus aureus* is the infecting organism.^{20,21} *S. aureus* has two characteristics that favor its ability to produce osteomyelitis: (1) it is able to produce a collagen-binding adhesion molecule that allows it to adhere to the connective tissue elements of bone; and (2) it has the ability to be internalized and survive in osteoblasts, making the microorganism more resistant to antibiotic therapy.²⁰ The term *acute osteomyelitis* is used to describe a newly recognized bone infection. *Chronic osteomyelitis* refers to recurrence of a previously treated or untreated infection.

The pathogenesis of osteomyelitis includes the presence of the infecting agent, inflammation and the protective efforts of inflammatory cells, and bone destruction. The infective microorganisms present in osteomyelitis incite an inflammatory process with recruitment of phagocytic cells. In an attempt to contain the invading microorganisms, the phagocytes generate toxic oxygen radicals and release proteolytic enzymes that destroy surrounding tissues.²⁰ The purulent drainage that ensues spreads into blood vessels in the bone, increasing the intraosseous pressure and impairing blood flow. The loss of blood flow leads to ischemic necrosis of bone. The blood supply to the bone may become obstructed by septic thrombi, in which case the ischemic bone becomes necrotic. As the process continues, the necrotic bone separates from the viable surrounding bone to form devascularized fragments, called sequestra (Fig. 42-7). One of the characteristics of chronic osteomyelitis is the presence of necrotic bone and the absence of living osteocytes.

Direct Contamination

The most common cause of osteomyelitis is the direct contamination of bone from an open wound. It may be the result of an open fracture, a gunshot wound, or a puncture wound. Inadequate irrigation or debridement, introduction of foreign material into the wound, and extensive tissue injury increase the bone's susceptibility to infection. If the infection is not sufficiently treated, the acute infection may become chronic. Osteomyelitis may also occur as a complication of surgery, such as in the sternum after open heart surgery or in extremities after bone allograft or total joint replacement.

Osteomyelitis after trauma or bone surgery usually is associated with persistent or recurrent fevers, increased pain at the operative or trauma site, and poor incisional healing, which often is accompanied by continued wound drainage and wound separation. Prosthetic joint infections present with joint pain, fever, and cutaneous drainage.

Diagnosis requires both confirming the infection and identifying the offending microorganism. The diagnosis of skeletal infection entails use of various imaging strategies, including conventional radiology, nuclear imaging studies, CT scans, and MRI. Bone biopsy may be used to identify the causative microorganisms. Treatment includes the use of antibiotics and selective use of surgical interventions.

■ FIGURE 42-7 ■ Hematogenous osteomyelitis of the fibula of 3 months' duration. The entire shaft has been deprived of its blood supply and has become a sequestrum (S) surrounded by new immature bone, involucrum (Iv). Pathologic fractures are present in the lower tibia and fibula. (Wilson F.C. [1980]. *The musculoskeletal system*. [2nd ed., p. 150]. Philadelphia: J.B. Lippincott)

Hematogenous Osteomyelitis

Hematogenous osteomyelitis occurs as the result of localization of a blood-borne infection in the bone. It is seen most commonly in children younger than 10 years of age²¹ but is seen occasionally in the elderly.²⁰

In children, it commonly begins in the metaphyseal region of long bones and usually is preceded by staphylococcal or streptococcal infections of the skin, sinuses, teeth, or middle ear. Thrombosis occurring as the result of local trauma may predispose to localization of the infection consequent to bacteremia.²¹

In the adult, hematogenous osteomyelitis usually affects the axial skeleton and the irregular bones in the wrist and ankle. It is most common in debilitated patients and in those with a history of chronic skin infections, chronic urinary tract infections, intravenous drug use, and in those who are immunologically suppressed. Intravenous drug users are at risk for infections with *Streptococcus* and *Pseudomonas*.

The signs and symptoms of acute hematogenous osteomyelitis are those of bacteremia accompanied by symptoms referable to the site of the bone lesion. Bacteremia is characterized by chills, fever, and malaise. There often is pain on movement of the affected extremity, loss of movement, and local tenderness followed by redness and swelling. X-ray studies may appear normal initially, but they show evidence of periosteal elevation and increased osteoclastic activity after an abscess has formed.

The treatment of hematogenous osteomyelitis begins with identification of the causative organism through blood cultures, aspiration cultures, and Gram's stain.²² Antibiotics are given first intravenously and then orally. Debridement and surgical drainage also may be necessary.

Chronic Osteomyelitis

SHORT

Chronic osteomyelitis has long been recognized as a disease. However, the incidence has decreased in the past century because of improvements in surgical techniques and antibiotic therapy. Chronic osteomyelitis includes all inflammatory processes of bone, excluding those in rheumatic diseases, that are caused by microorganisms. It may be the result of delayed or inadequate treatment of acute hematogenous osteomyelitis or osteomyelitis caused by direct contamination of bone. Acute osteomyelitis is considered to have become chronic when the infection persists beyond 6 to 8 weeks or when the acute process has been adequately treated and is expected to resolve but does not. Chronic osteomyelitis can persist for years; it may appear spontaneously, after a minor trauma, or when resistance is lowered.

The hallmark feature of chronic osteomyelitis is the presence of infected dead bone, a sequestrum, that has separated from the living bone. A sheath of new bone, called the involucrum, forms around the dead bone. Radiologic techniques such as x-ray films, bone scans, and sinograms are used to identify the infected site. Chronic osteomyelitis or infection around a total joint prosthesis can be difficult to diagnose because the classic signs of infection are not apparent and the blood leukocyte count may not be elevated. A subclinical infection may exist for years. Bone scans are used in conjunction with bone biopsy for a definitive diagnosis.²³

Treatment includes the use of antibiotics. Wound cultures are used to identify the microorganism and its sensitivity to

antibiotic therapy. Initial antibiotic therapy is followed by surgery to remove foreign bodies (*e.g.*, metal plates, screws) or sequestra and by long-term antibiotic therapy. Immobilization of the affected part usually is necessary, with restriction of weight bearing on a lower extremity.

Osteomyelitis With Vascular Insufficiency

In persons with vascular insufficiency, osteomyelitis may develop from a skin lesion. It is seen most commonly associated with chronic or ischemic foot ulcers in persons with longstanding diabetes or other chronic vascular disorders. It is characterized by local cellulitis with inflammation and necrosis. Treatment depends on the oxygen tension of the involved tissues. Debridement and antibiotic therapy may benefit persons who have good oxygen tension in the infected site. Amputation is indicated when oxygen tension is inadequate.

Tuberculosis of the Bone or Joint

Tuberculosis can spread from one part of the body, such as the lungs or the lymph nodes, to the bones and joints. When this happens, it is called *extrapulmonary* or *miliary tuberculosis*. It is caused by *Mycobacterium tuberculosis*. The disease is localized and progressively destructive but not as contagious as primary pulmonary tuberculosis. In approximately 50% of cases, it affects the vertebrae, but it also frequently is seen in the hip and knee.²⁴ Tuberculosis also can affect the joints and soft tissues. The disease is characterized by bone destruction and abscess formation. Local symptoms include pain, immobility, and muscle atrophy; joint swelling, mild fever, and leukocytosis also may occur. Diagnosis is confirmed by a positive culture. The most important part of the treatment is antituberculosis drug therapy. Conservative treatment is usually as effective as surgery, especially for earlier and milder cases.

Because of improved methods to prevent and treat tuberculosis, its incidence had diminished in recent decades. However, tuberculosis has re-emerged as a health problem, affecting one third of the global population and 10 million people in the United States.²⁵ Tuberculosis has increased because of the spread of disease in communal settings (*e.g.*, jails, shelters, nursing homes), the human immunodeficiency virus epidemic, and the influx of immigrants who have come to the United States from countries where the disease is endemic.²⁶ Unfortunately, the diagnosis of tuberculosis in the bones and joints still may be missed, especially when the musculoskeletal infection is the sole presenting sign. CT scans and MRI can be used as aids for early diagnosis.

In summary, bone infections occur because of the direct or indirect invasion of the skeletal circulation by microorganisms, most commonly *S. aureus*. Osteomyelitis, or infection of the bone and marrow, can be an acute or chronic disease. Acute osteomyelitis is seen most often as a result of the direct contamination of bone by a foreign object. Chronic osteomyelitis is a long-term process that can recur spontaneously at any time throughout a person's life. Tuberculosis of the bone, which is characterized by bone destruction and abscess formation, is caused by spread of the infection from the lungs or lymph nodes.

NEOPLASMS

Neoplasms in the skeletal system usually are referred to as *bone tumors*. Like other types of neoplasms, bone tumors may be benign or malignant (see Table 42-2). Primary bone tumors may arise from any of the skeletal components, including osseous bone tissue, cartilage, and bone marrow. Primary malignant tumors of the bone are uncommon, constituting approximately 1% of all adult cancers and 15% of pediatric malignancies.²⁷ However, metastatic disease of the bone is relatively common.

There are three major symptoms of bone tumors: pain, presence of a mass, and impairment of function (Chart 42-3). Pain is a feature common to almost all malignant tumors but may or may not occur with benign tumors. For example, a benign bone cyst usually is asymptomatic until a fracture occurs. Pain that persists at night and is not relieved by rest suggests malignancy. A mass or hard lump may be the first sign of a bone tumor. A malignant tumor is suspected when a painful mass exists that is enlarging or eroding the cortex of the bone. The ease of discovery of a mass depends on the location of the tumor; a small lump arising on the surface of the tibia is easy to detect, whereas a tumor that is deep in the medial portion of the thigh may grow to a considerable size before it is noticed. Benign and malignant tumors may cause the bone to erode to the point where it cannot withstand the strain of ordinary use. In such cases, even a small amount of bone stress or trauma precipitates a pathologic fracture. A tumor may produce pressure on a peripheral nerve, causing decreased sensation, numbness, a limp, or limitation of movement.

Benign Neoplasms

Benign bone tumors usually are limited to the confines of the bone, have well-demarcated edges, and are surrounded by a thin rim of sclerotic bone. The four most common types of be-

CHART 42-3 Symptoms of Bone Cancer

- Bone pain in an adult or child that comes on slowly but lasts for as long as a week, is constant or intermittent, and may be worse at night.
- Unexplained swelling or lump on the bones of the arms, legs, thighs, or other parts of the body that is firm and slightly tender and may be felt through the skin. It may interfere with normal movement and can cause the bone to break.

These symptoms are not sure signs of cancer. They also may be caused by other, less serious problems. Only a physician can tell for sure.

(Adapted from U.S. Department of Health and Human Services [1993]. What you need to know about cancers of the bone. NIH publication no. 93-1517. Bethesda, MD: U.S. Government Printing Office)

nign bone tumors are osteoma, chondroma, osteochondroma, and giant cell tumor.

An *osteoma* is a small bony tumor found on the surface of a long bone, flat bone, or the skull. It usually is composed of hard, compact (ivory osteoma), or spongy (cancellous) bone. It may be excised or left alone.

A *chondroma* is a tumor composed of hyaline cartilage.¹⁰ It may arise on the surface of the bone (*i.e.*, ecchondroma) or within the medullary cavity (*i.e.*, endochondroma). These tumors may become large and are especially common in the hands and feet. A chondroma may persist for many years and then take on the attributes of a malignant chondrosarcoma. A chondroma usually is not treated unless it becomes unsightly or uncomfortable.

An *osteochondroma* is the most common form of benign tumor in the skeletal system, representing 50% of all benign bone tumors and approximately 15% of all primary skeletal lesions.²⁷ It grows only during periods of skeletal growth, originating in the epiphyseal cartilage plate and growing out of the bone like a mushroom. An osteochondroma is composed of cartilage and bone and usually occurs singly but may affect several bones in a condition called *multiple exostoses*. Malignant changes are rare, and excision of the tumor is done only when necessary.

A giant cell tumor, or osteoclastoma, is an aggressive tumor of multinucleated cells that often behaves like a malignant tumor, metastasizing through the bloodstream and recurring locally after excision. It occurs most often in young adults, predominantly females, and is found most commonly in the knee, wrist, or shoulder. The tumor begins in the metaphyseal region, grows into the epiphysis, and may extend into the joint surface. Pathologic fractures are common because the tumor destroys the bone substance. Clinically, pain may occur at the tumor site, with gradually increasing swelling. X-ray films show destruction of the bone with expansion of the cortex.

The treatment of giant cell tumors depends on their location. If the affected bone can be eliminated without loss of function, such as the clavicle or fibula, the entire bone or part of it may be removed. When the tumor is near a major joint, such as the knee or shoulder, a local excision is done. Irradiation may be used to prevent recurrence of the tumor.

Malignant Bone Tumors

In contrast to benign tumors, malignant tumors tend to be ill defined, lack sharp borders, and extend beyond the confines of the bone, showing that it has destroyed the cortex. Specific types of bone tumors affect different age groups. They are virtually unknown in infancy, rare in children younger than 10 years of age, and peak during the teenage years. Adolescents have the highest incidence, with a rate of 3 cases per 100,000.²⁷ The two major forms of bone cancer in children and young adults are osteosarcoma and Ewing's sarcoma. It is unusual for either condition to be seen after 20 years of age and older.¹⁰

The methods used in the diagnosis of malignant bone tumors include radiographic studies, CT scans, MRI, and bone biopsy. Radiographs give the most general diagnostic information, such as malignant versus benign and primary versus metastatic status. The radiograph demonstrates the region of bone involvement, extent of destruction, and amount of reactive bone formed. Radioisotope scans are used to estimate the local intramedullary extent of the tumor and screen for other skeletal areas of involvement. CT scans further aid diagnosis and anatomic localization and can identify small pulmonary metastases not seen by conventional radiographs. MRI is the most accurate method of evaluating the intramedullary extent of bone tumor and can demarcate the soft structures in relation to neurovascular structures without the use of contrast media. It is best used in conjunction with a CT scan.²⁷ A bone biopsy is used to determine the type of tumor that is present.

Osteosarcoma

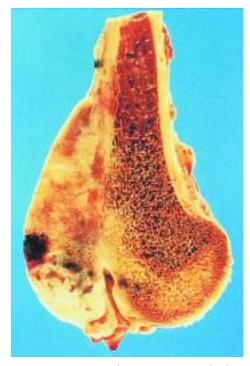

Osteosarcoma represents 60% of all bone tumors occurring in children and adolescents. Osteosarcoma has a bimodal distribution, with 75% occurring in persons younger than 20 years of age. A second peak occurs in the elderly with predisposing factors such as Paget's disease, bone infarcts, or prior irradiation.¹⁰ The male-to-female ratio increases to approximately 1.6 to 1 during late adolescence and adulthood. It is seen most commonly during periods of maximal growth. In younger persons, the primary tumor most often is located at the anatomic sites associated with maximum growth velocity—the distal femur, proximal tibia, and proximal humerus. Persons affected with osteosarcoma usually are tall and are found to have a high plasma level of somatomedin. Bone tumors in the elderly are more common in the humerus, pelvis, and proximal femur.

Osteosarcoma is a malignant tumor of mesenchymal cells, characterized by the direct formation of osteoid or immature bone by malignant osteoblasts. These cells synthesize thin, wispy, and purposeless fragments of bone. Osteogenic sarcomas are aggressive tumors that grow rapidly; they often are eccentrically placed in the bone and move from the metaphysis of the bone out to the periosteum, with subsequent spread to adjacent soft tissues.

The causes of osteosarcoma are unknown. The correlation of age and location of most of the tumors with the period of maximum growth suggests some relation to increased osteoblastic activity. Paget's disease, which is linked to osteosarcoma in adults, also is associated with increased osteoblastic activity. Irradiation from an internal source, such as the radioactive pharmaceutical technetium used in bone scans, or an external source, such as x-ray films, also has been associated with osteosarcoma.

The primary clinical feature of osteosarcoma is localized pain and swelling in the affected bone, usually of sudden onset. Patients and their families often associate the symptoms with recent trauma.28 The skin overlying the tumor may be warm, shiny, and stretched, with prominent superficial veins. The range of motion of the adjacent joint may be restricted. Osteosarcoma usually begins as a firm white or reddish mass and later becomes softer with a viscous interior (Fig. 42-8). The tumor infrequently metastasizes to the lymph nodes because the cells are unable to grow in the node. Nodal metastases usually occur only in the late course of disseminated disease. Most often, the tumor cells exit the primary tumor through the venous end of the capillary, and early metastasis to the lung is common. Lung metastases, even if massive, usually are relatively asymptomatic. The prognosis for a patient with osteosarcoma depends on the aggressiveness of the disease, radiologic features, presence or absence of pathologic fracture, size of the tumor, rapidity of tumor growth, and gender of the person.

The treatment for sarcomas is surgery in combination with multiagent chemotherapy used both before and after surgery.^{28,29} Osteosarcomas are relatively resistant to radiation therapy. In the past, treatment usually entailed amputation above the level of the tumor. Limb salvage surgical procedures, using a metal prosthesis or cadaver allografts, are becoming a standard alternative. Studies have shown that limb salvage surgery has no adverse effects on the long-term survival

■ FIGURE 42-8 ■ Juxtacortical osteosarcoma. The lower femur contains a malignant tumor arising from the periosteal surface of the bone and sparing the medullary cavity. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1386]. Philadelphia: Lippincott Williams & Wilkins)

of persons with osteosarcoma. Chemotherapy using various drug combinations is the most effective treatment for metastatic osteosarcoma.

Ewing's Sarcoma

Ewing's sarcoma is the third most common type of primary bone tumor, and it is highly malignant. It commonly occurs in males younger than 25 years of age, with the incidence highest among teenagers.²⁸ Ewing's tumor arises from immature bone marrow cells and causes bone destruction from within. It usually occurs in the shaft of long bones or any portion of the pelvis and often metastasizes to bone marrow.

Manifestations of Ewing's tumor include pain, limitation of movement, and tenderness over the involved bone or soft tissue. It often is accompanied by systemic manifestations such as fever or weight loss, which may serve to confuse the diagnosis. There also may be a delay in diagnosis when the pain and swelling associated with the tumor are attributed to a sports injury. Pathologic fractures are common because of bone destruction.

Treatment methods incorporate a combination of multiagent chemotherapy, surgery, and radiation therapy. There is controversy about the potential superiority of surgical resection compared with radiation therapy.²⁸ Radiation therapy is associated with risk of radiation-induced second malignancies, especially osteosarcoma.

Chondrosarcoma

Chondrosarcoma, a malignant tumor of cartilage that can develop in the medullary cavity or peripherally, is the second most common form of malignant bone tumor. It occurs primarily in middle or later life and slightly more often in males. The tumor arises from points of muscle attachment to bone, particularly the knee, shoulder, hip, and pelvis. Chondrosarcomas can arise from underlying benign lesions such as osteo-chondroma, chondroblastoma, or fibrous dysplasia.¹⁰

Chondrosarcomas are slow growing, metastasize late, and often are painless. They can remain hidden in an area such as the pelvis for a long time. This type of tumor, like many primary malignancies, tends to destroy bone and extend into the soft tissues beyond the confines of the bone of origin. Chondrosarcomas mainly affect the bones of the trunk, pelvis, or proximal femur and rarely develop in the distal portion of a bone. Irregular flecks and ringlets of calcification often are prominent radiographic findings. Early diagnosis is important because chondrosarcoma responds well to early radical surgical excision. It usually is resistant to radiation therapy and available chemotherapeutic agents. Not infrequently, these tumors transform into a highly malignant tumor, mesenchymal chondrosarcoma, which requires a more aggressive treatment, including combination chemotherapy.

Metastatic Bone Disease

Skeletal metastases are the most common malignancy of osseous tissue. Approximately half of all people with cancer have bone metastasis at some point in their disease.³⁰ Metastatic lesions are seen most often in the spine, femur, pelvis, ribs, sternum, proximal humerus, and skull, and are less common in anatomic sites that are further removed from the trunk of the body. Tumors that frequently spread to the skeletal system are those of the breast, lung, prostate, kidney, and thyroid, although any cancer can ultimately involve the skeleton. More than 85% of bone metastases result from primary lesions in the breast, lung, or prostate.³¹ The incidence of metastatic bone disease is highest in persons older than 40 years of age.

The major symptom of bone metastasis is pain with evidence of an impending pathologic fracture. It usually develops gradually, over weeks, and is more severe at night. Pain is caused by stretching of the periosteum of the involved bone or by nerve entrapment, as in the nerve roots of the spinal cord by the vertebral body. Pathologic fractures occur in approximately 10% to 15% of persons with metastatic bone disease. The affected bone appears to be eaten away on x-ray images and, in severe cases, crumbles on impact, much like dried toast. Many pathologic fractures occur in the femur, humerus, and vertebrae. In the femur, fractures occur because the proximal aspect of the bone is under great mechanical stress.³¹

X-ray examinations are used along with CT or bone scans to detect, diagnose, and localize metastatic bone lesions. Approximately one third of persons with skeletal metastases have positive bone scans without radiologic findings. This is because 50% of the trabecular bone must be destroyed before a lesion is visible on plain radiographs.³² Arteriography using radiopaque contrast media may be helpful in outlining the tumor margins. A bone biopsy usually is done when there is a question regarding the diagnosis or treatment. A closedneedle biopsy with CT localization is particularly useful with spine lesions. Serum levels of alkaline phosphatase and calcium often are elevated in persons with metastatic bone disease.

The primary goals in treatment of metastatic bone disease are to prevent pathologic fractures and promote survival with maximum functioning, allowing the person to maintain as much mobility and pain control as possible. Treatment methods include chemotherapy, irradiation, and surgical stabilization. Radiation therapy is primarily used as a palliative treatment to alleviate pain and prevent pathologic fractures. After a pathologic fracture has occurred, bracing, intramedullary nailing of the femur, and spine stabilization may be done. Because adequate fixation often is difficult in diseased bone, cement (*i.e.*, methylmethacrylate) often is used with internal fixation devices to stabilize the bone.

In summary, bone tumors, like any other type of neoplasm, may be benign or malignant. Benign bone tumors grow slowly and usually do not destroy the surrounding tissues. Malignant tumors can be primary or metastatic. Primary bone tumors are rare, grow rapidly, metastasize to the lungs and other parts of the body through the bloodstream, and are associated with a high mortality rate. Metastatic bone tumors usually are multiple, originating primarily from cancers of the breast, lung, and prostate. The incidence of metastatic bone disease is increasing probably because improved treatment methods enable persons with cancer to live longer. Advances in chemotherapy, radiation therapy, and surgical procedures have substantially increased the survival and cure rates for many types of bone cancers. A primary goal in metastatic bone disease is the prevention of pathologic fractures.

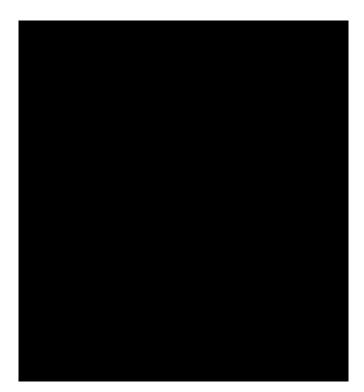

During childhood, skeletal structures grow in length and diameter and sustain a large increase in bone mass. Alterations in musculoskeletal structure and function may develop as a result of normal growth and developmental processes or as a result of impairment of skeletal development caused by hereditary or congenital influences.

Alterations During Normal Growth Periods

Infants and children undergo changes in muscle tone and joint motion during growth and development. Toeing-in, toeingout, bowlegs, and knock-knees occur frequently in infancy and childhood.³³ These changes usually cause few problems and are corrected during normal growth processes. The normal folded position of the fetus in utero causes physiologic flexion contractures of the hips and a froglike appearance of the lower extremities (Fig. 42-9). The hips are externally rotated, and the patellae point outward, whereas the feet appear to point forward because of the internal pulling force of the tibiae. During the first year of life, the lower extremities begin to straighten out in preparation for walking. Internal and external rotation become equal, and the hips extend. Flexion contractures of the shoulders, elbows, and knees also are commonly seen in newborns, but they should disappear by 4 to 6 months of age.34

Torsional Deformities

All infants and toddlers have lax ligaments that become tighter with age and assumption of the weight-bearing posture. The hypermobility that accompanies joint laxity coupled with the torsional, or twisting, forces exerted on the limbs during

KEY CONCEPTS

DEVELOPMENTAL SKELETAL DISORDERS

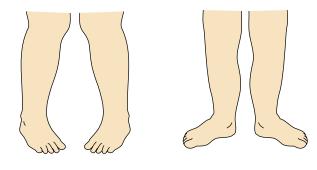

- Many disorders of early infancy are caused by intrauterine positions and resolve as the child grows.
- Infants and toddlers have lax ligaments that predispose to skeletal disorders caused by twisting or torsional forces.
- Bone growth in infants and children occurs at the epiphysis. Separation of the epiphyseal growth plate ruptures the blood vessels that nourish the epiphysis, causing cessation of growth and shortened extremity length.

growth are responsible for a number of variants seen in young children. Torsional forces caused by intrauterine positions or sleeping and sitting patterns twist the growing bones and can produce the deformities as a child grows and develops.

In infants, the femur normally is rotated to an anteverted position with the femoral head and neck rotated anteriorly with respect to the femoral condyles. Femoral anteversion (*i.e.*, medial rotation) decreases from an average 40 degrees at birth to approximately 15 degrees at maturity. The normal tibia is externally rotated approximately 5 degrees at birth and 15 degrees at maturity. Torsional abnormalities frequently demonstrate a familial tendency.

Toeing-in and Toeing-out. The foot progression angle describes the angle between the axis of the foot and the line of progression. It is determined by watching the child walking and running. Figure 42-10 illustrates the position of the foot in toeing-in and toeing-out.

Toeing-in (*i.e.*, metatarsus adductus) is the most common congenital foot deformity, affecting boys and girls equally. It can be caused by torsion in the foot, lower leg, or entire leg. Toeing-in caused by adduction of the forefoot (*i.e.*, congenital metatarsus adductus) usually is the result of the fetal position maintained in utero. It may occur in one foot or both feet. A supple deformity can be passively manipulated into a straight position and requires no treatment. Treatment consisting of

Toeing-in Toeing-out ■ FIGURE 42-10 ■ Position of feet in toeing-in and toeing-out. serial long leg casting or a brace that pushes the metatarsals (not the hindfoot) into abduction usually is required in a fixed deformity (*i.e.*, one in which the forefoot cannot be passively manipulated into a straight position).

Toeing-out is a common problem in children and is caused by external femoral torsion. This occurs when the femur can be externally rotated to approximately 90 degrees but internally rotated only to a neutral position or slightly beyond. Because the femoral torsion persists when a child habitually sleeps in the prone position, an external tibial torsion also may develop. If external tibial torsion is present, the feet point lateral to the midline of the medial plane. External tibial torsion rarely causes toeing-out; it only intensifies the condition. Toeing-out usually corrects itself as the child becomes proficient in walking. Occasionally, a night splint is used. Toeingin and toeing-out are less noticeable when the child is running or barefoot. Overcorrection of a supple foot deformity can cause flatfoot deformity, but a rigid deformity that is untreated can cause pain and improper fitting of footwear.

Tibial Torsion. Tibial torsion is determined by measuring the thigh-foot angle, which is done with the ankle and knee positioned at 90 degrees (Fig. 42-11A). In this position, the foot

normally rotates outward. *Internal tibial torsion* (*i.e.*, bowing of the tibia) is a rotation of the tibia that makes the feet appear to turn inward. It is the most common cause of toeing-in in children younger than 2 years of age. It is present at birth and may fail to correct itself if children sleep on their knees with the feet turned in or sit on in-turned feet. It is thought to be caused by genetic factors and intrauterine compression, such as an unstretched uterus during a first pregnancy or intrauterine crowding with twins or multiple fetuses. Tibial torsion improves naturally with growth, but this may take years.³⁵ The Denis Browne splint, a bar to which shoes are attached, may be used to put the feet into mild external rotation while the child is sleeping.

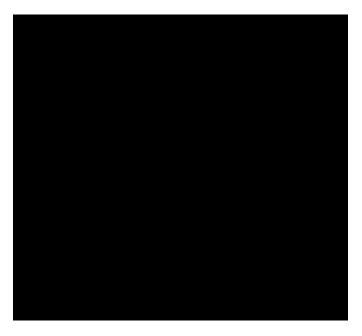

External tibial torsion, a much less common disorder, is associated with calcaneovalgus foot and is caused by a normal variation of intrauterine positioning or a neuromuscular disorder. It is characterized by an abnormally positive thigh-foot angle of 30 to 50 degrees. The condition corrects itself naturally, and treatment is observational. Significant improvement begins during the first year with the onset of ambulation and usually is complete by 2 to 3 years of age.³⁴ The normal adult exhibits 20 degrees of tibial torsion.

Femoral Torsion. Femoral torsion refers to abnormal variations in hip rotation. Hip rotation is measured at the pelvic level with the child in the prone position and the knees flexed at a 90-degree angle. In this position, the hip is in a neutral position. Rotating the lower leg outward produces internal or medial femoral rotation; rotating it inward produces external or lateral rotation (see Fig. 42-11B). During measurement of hip rotation, the legs are allowed to fall to full internal rotation by gravity alone; lateral rotation is measured by allowing the legs to fall inward and cross. Hip rotation in flexion and extension also can be measured with computed tomography (CT). By 1 year of age, there is normally approximately 45 degrees of internal and 45 degrees of external rotation.³⁴

Internal femoral torsion, also called femoral anteversion, is a normal variant commonly seen during the first 6 years of life, especially in 3- and 4-year-old girls.³³ Characteristically, there is 80 to 90 degrees of internal rotation of the hip in the prone position.³⁴ The condition is thought to be related to increased laxity of the anterior capsule of the hip such that it does not provide the stable pressure needed to correct the anteversion that is present at birth. Children are most comfortable sitting in the "W" position with their hips between their knees (Fig. 42-12). It is believed that this position allows the lower leg to act as a lever, producing torsional changes in the femur. When the child stands, the knees turn in and the feet appear to point straight ahead; when the child walks, knees and toes point in. Children with this problem are encouraged to sit cross-legged or in the so-called *tailor position*. If left untreated, the tibiae compensate by becoming externally rotated so that by 8 to 12 years of age the knees may turn in but the feet no longer do. This can result in patellofemoral malalignment with patellar subluxation or dislocation and pain. A derotational osteotomy may be done in severe cases or if there is functional disability.

Genu Varum and Genu Valgum

Genu varum or *bowlegs* is an outward bowing of the knees greater than 1 inch when the medial malleoli of the ankles are touching (Fig. 42-13). Most infants and toddlers have some

bowing of their legs up to age 2 years. If there is a large separation between the knees (>15 degrees) after 2 years of age, the child may require bracing. The child also should be evaluated for diseases such as rickets or tibia vara (*i.e.*, Blount's disease to be discussed).

■ FIGURE 42-13 ■ Normal genu varum (bowlegs) in a toddler (*left*) and genu valgum (knock-knees) in a toddler (*right*), which is often seen in children between 2 and 6 years of age. (From Weinstein S.L., Buckwalter J.A. [1994]. *Turek's orthopaedics* [5th ed.]. Philadelphia: J.B. Lippincott)

Genu valgum or knock-knees is a deformity in which there is decreased space between the knees (see Fig. 42-13). The medial malleoli in the ankles cannot be brought in contact with each other when the knees are touching. It is seen most frequently in children between the ages of 3 and 5 years and should resolve by 5 to 8 years of age.³⁴ The condition usually is the result of lax medial collateral ligaments of the knee and may be exacerbated by sitting in the "M" position. Genu valgum can be ignored to age 7 years, unless it is more than 15 degrees, unilateral, or associated with short stature. It usually resolves spontaneously and rarely requires treatment. If genu varum or genu valgum persists and is uncorrected, osteoarthritis may develop in adulthood as a result of abnormal intra-articular stress. Genu varum can cause gait awkwardness and increased risk of sprains and fractures. Uncorrected genu valgum may cause subluxation and recurrent dislocation of the patella, with a predisposition to chondromalacia and joint pain and fatigue.

Hereditary and Congenital Deformities

Congenital deformities are abnormalities that are present at birth. They range in severity from mild limb deformities, which are relatively common, to major limb malformations, which are relatively rare. There may be a simple webbing of the fingers or toes (syndactyly), the presence of an extra digit (*i.e.*, polydactyly), or the absence of a bone such as the phalanx, rib, or clavicle. Joint contractures and dislocations produce more severe deformity, as does the absence of entire bones, joints, or limbs. An epidemic of limb deformities occurred from 1957 to 1962 as a result of maternal ingestion of thalidomide. This drug was withdrawn from the market in 1961.

Congenital deformities are caused by many factors, some unknown. These factors include genetic influences, external agents that injure the fetus (*e.g.*, radiation, alcohol, drugs, viruses), and intrauterine environmental factors. Many of the organic bone matrix components have been identified only recently, and their interactions found to be more complex than originally thought. Diseases associated with abnormalities in bone matrix include those with deficient collagen synthesis and decreased bone mass.

Osteogenesis Imperfecta

Osteogenesis imperfecta is a hereditary disease characterized by defective synthesis of type I collagen.³⁶ It is one of the most common hereditary bone diseases, with an occurrence rate of approximately 1 case in 10,000 births.¹² Although it usually is transmitted as an autosomal dominant trait, a distinct form of the disorder with multiple lethal defects is thought to be inherited as an autosomal recessive trait.¹⁰ In some cases the defect is caused by a spontaneous mutation.

The clinical manifestations of osteogenesis imperfecta include a spectrum of disorders marked by extreme skeletal fragility. Four major subtypes have been identified.¹⁰ Type II is at one end of the spectrum and is uniformly fatal in utero or during early perinatal life. Less severe disease occurs when the disorder is inherited as a dominant trait. The skeletal system is not so weakened, and fractures often do not appear until the child becomes active and starts to walk, or even later in childhood. These fractures heal rapidly, although with a poor-quality callus. Other problems associated with defective connective tissue synthesis include short stature, thin skin, blue or gray sclera, abnormal tooth development, hypotonic muscles, loose-jointedness, scoliosis, and a tendency toward hernia formation. Hearing loss caused by otosclerosis of the middle and inner ear is common in affected adults.

There is no known medical treatment for correction of the defective collagen synthesis that is characteristic of osteogenesis imperfecta. Instead, treatment modalities focus on preventing and treating fractures.

Congenital Clubfoot

Clubfoot, or talipes, is a congenital deformity of the foot that can affect one or both feet. Like congenital dislocation of the hip, its occurrence follows a multifactorial inheritance pattern. The condition has an incidence of 1 case per 1000 live births and occurs twice as often in males as in females.³⁷ Clubfoot is associated with chromosomal abnormalities and may be associated with other congenital syndromes that are transmitted by mendelian inheritance patterns (see Chapter 4). However, it is most commonly idiopathic and found in healthy infants in whom no genetic or chromosomal abnormality or other extrinsic cause can be found.

Although the exact cause of clubfoot is unknown, three theories are generally accepted: an anomalous development occurs during the first trimester of pregnancy, the leg fails to rotate inward and move from the equinovarus position at approximately the third month, or the soft tissues in the foot do not mature and lengthen. Maternal smoking is associated with occurrence of clubfoot, and the risk increases enormously when combined with a family history.³⁸

In forefoot adduction, which accounts for approximately 95% of idiopathic cases, the foot is plantar flexed and inverted. This is the so-called *equinovarus type* in which the foot resembles a horse's hoof (Fig. 42-14). The other 5% of cases are of the calcaneovalgus type, or reverse clubfoot, in which the foot is dorsiflexed and everted. The reverse clubfoot can occur as an isolated condition or in association with multiple congenital

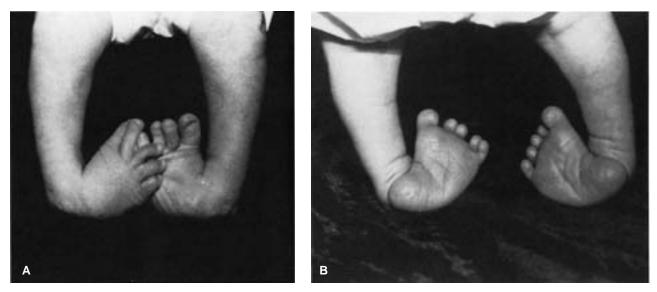

defects. At birth, the feet of many infants assume one of these two positions, but they can be passively overcorrected or brought back into the opposite position. If the foot cannot be overcorrected, some type of correction may be necessary.

Clubfoot varies in severity from a mild deformity to one in which the foot is completely inverted. Treatment is begun as soon as the diagnosis is made and usually is effective within a short period. Serial manipulations and casting are used to gently correct each component in the forefoot varus, the hindfoot varus, and the equinus. The treatment is continued until the foot is in a normal position with full correction evident clinically and on radiographic studies. Surgery may be required for severe deformities or when nonoperative treatment methods are unsuccessful.

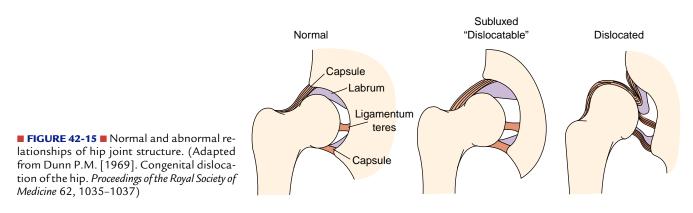

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip, formerly known as *congenital dislocation of the hip*, is an abnormality in hip development that leads to a wide spectrum of hip problems in infants and children, including hips that are unstable, malformed, subluxated, or dislocated.¹⁰⁻¹² In less severe cases, the hip joint may be unstable, with excessive laxity of the joint capsule, or subluxated, so that the joint surfaces are separated and there is a partial dislocation (Fig. 42-15). With dislocated hips, the head of the femur is located outside of the acetabulum.

The results of newborn screening programs have shown that 1 of 100 infants have some evidence of hip instability; however, dislocation of the hip is seen in 1.5 of every 1000 live births.¹² The left hip is involved three times more frequently than the right hip because of the left occipital intrauterine positioning of most infants.³⁹ In white infants, developmental dysplasia of the hips occurs most frequently in first-born children and is six times more common in female than in male infants.⁴⁰ The cause of developmental dysplasia of the hip is multifactorial, with physiologic, mechanical, and postural factors playing a role. A positive family history and generalized

■ FIGURE 42-14 ■ Severe clubfoot deformity. (A) The heel is in severe varus, and the forefoot is adducted and inverted. (B) The cavus deformity results from the slightly pronated position of the forefoot in relation to the hindfoot. (From Weinstein S.L., Buckwalter J.A. [1994]. *Turek's orthopaedics* [5th ed.]. Philadelphia: J.B. Lippincott)

laxity of the ligaments are related. The increased frequency in girls is thought to result from their susceptibility to maternal estrogens and other hormones associated with pelvic relaxation. Dislocation also may result from environmental factors such as fetal position, a tight uterus that prevents fetal movement, and breech delivery.

Early diagnosis of a developmental dysplasia of the hip is important because treatment is easiest and most effective if begun during the first 6 months of life. Repeated dislocation causes damage to the femoral head and the acetabulum. Clinical examinations to detect dislocation of the hip should be done at birth and every several months during the first year of life. In infants, signs of dislocation include asymmetry of the hip or gluteal folds, shortening of the thigh so that one knee (on the affected side) is higher than the other, and limited abduction of the affected hip (Fig. 42-16). The asymmetry of gluteal folds is not definitive but indicates the need for further evaluation. In the older child, instability of the hip may produce a delay in walking or eventually cause a characteristic waddling gait. Diagnosis is confirmed by radiography. Ultrasound is used to diagnose the conditions in newborns and infants from birth to 4 months of age.40

The treatment of a developmental dysplasia should be individualized and depends on whether the hip is subluxated or dislocated. Mild instability often resolves without treatment. The best results are obtained if the treatment is begun before

■ FIGURE 42-16 ■ An 18-month-old girl has congenital dysplasia of the left hip. (From Weinstein S.L., Buckwalter J.A. [1994]. *Turek's orthopaedics* [5th ed.]. Philadelphia: J.B. Lippincott)

changes in the hip structure (*e.g.*, 2 to 3 months) prevent it from being reduced by gentle manipulation or abduction devices. Infants with dislocated hips caused by anatomic changes and toddlers who may lack development of the acetabular socket require more aggressive treatment, such as open reduction and joint reconstruction. Treatment at any age includes reduction of the dislocation and immobilization of the legs in an abducted position. With children younger than 3 years, skin traction is used when reduction cannot be easily obtained. This treatment is followed by several months of immobilization in a hip spica cast, plaster splints, or an abduction splint. Older children or adults with an unreduced dislocatable hip may require hip surgery because of damage to the articulating surface of the joint.

Disorders of Later Development

Developmental disorders of bones and joints are those that are not present at birth but make their appearance during later periods of development. Some may have a genetic component, some present during periods of rapid growth, and others may develop as the result of trauma and stress imposed by activities associated with various periods of development.

Developmental Disorders of the Hip

Legg-Calvé-Perthes Disease. Legg-Calvé-Perthes disease, or coxa plana, is an osteonecrotic disease of the proximal femoral (capital) epiphysis, which is the growth center for the head of the femur. It occurs in 1 of 1200 children, affecting primarily those between ages 2 and 13 years, with a peak incidence between 4 and 9 years.⁴¹ It occurs primarily in boys and is much more common in whites than African Americans. Although no definite genetic pattern has been established, it occasionally affects more than one family member.

The cause of Legg-Calvé-Perthes disease is unknown. The disorder usually is insidious in onset and occurs in otherwise healthy children. However, it may be associated with acute trauma. Affected children usually have a shorter stature. Undernutrition has been suggested as a causative factor. When girls are affected, they usually have a poorer prognosis than boys because they are skeletally more mature and have a shorter period for growth and remodeling than do boys of the same age. Although both legs can be affected, in 85% of cases, only one leg is involved.³⁵

The primary pathologic feature of Legg-Calvé-Perthes disease is an avascular necrosis of the bone and marrow involving the epiphyseal growth center in the femoral head. The disorder may be confined to part of the epiphysis, or it may involve the entire epiphysis. In severe cases, there is a disturbance in the growth pattern that leads to a broad, short femoral neck. The necrosis is followed by slow absorption of the dead bone during a period of 2 to 3 years. Although the necrotic trabeculae eventually are replaced by healthy new bone, the epiphysis rarely regains its normal shape.

Legg-Calvé-Perthes disease has an insidious onset with a prolonged course. The main symptoms are pain in the groin, thigh, or knee and difficulty in walking. The child may have a painless limp with limited abduction and internal rotation and a flexion contracture of the affected hip. The age of onset is important because young children have a greater capability for remodeling of the femoral head and acetabulum, so less flattening of the femoral head occurs. Early diagnosis is important and is based on correlating physical symptoms with radiographic findings that are related to the stage of the disease.

The goal of treatment is to reduce deformity and preserve the integrity of the femoral head. Conservative and surgical interventions are used in the treatment of Legg-Calvé-Perthes disease. Treatment involves abduction casts or braces to keep the legs separated in abduction with mild internal rotation. Surgery may be done to contain the femoral head in the acetabulum. The best surgical results are obtained when surgery is done early, before the epiphysis becomes necrotic.

Slipped Capital Femoral Epiphysis. Normally, the proximal femoral epiphysis unites with the neck of the femur between 16 and 19 years of age. Before this time (10 to 14 years of age in girls and 10 to 16 years in boys), the femoral head may slip from its normal position directly at the head of the femur and become displaced medially and posteriorly.⁴¹ The head is held in the acetabulum by the ligamentum teres, and the neck of the femur is pulled upward and outward. This produces an anterolateral and superior adduction with extension deformity. The condition occurs with an estimated frequency of between 1 in 100,000 to 1 in 800,000.³⁵ It is the most common disorder of the hip in adolescents.

The cause of slipped capital femoral epiphysis is obscure, but it may be related to the child's susceptibility to stress on the femoral neck as a result of genetics or abnormal structure. Boys are affected twice as often as girls, and in approximately one half of cases, the condition is bilateral. Affected children often are overweight with poorly developed secondary sex characteristics or, in some instances, are extremely tall and thin. In many cases, there is a history of rapid skeletal growth preceding displacement of the epiphysis. The condition also may be affected by nutritional deficiencies or endocrine disorders such a hypothyroidism, hypopituitarism, and hypogonadism. Rapid growth after administration of growth hormone has been associated with displacement of the epiphysis.

Children with the condition often report referred knee pain accompanied by difficulty in walking, fatigue, and stiffness. The diagnosis is confirmed by radiographic studies in which the degree of slipping is determined and graded according to severity. Early treatment is imperative to prevent lifelong crippling. Avoidance of weight bearing on the femur and bed rest are essential parts of the treatment. Traction or gentle manipulation under anesthesia is used to reduce the slip. Surgical insertion of pins to keep the femoral neck and head of the femur aligned is a common method of treatment for children with moderate or severe slips. Crutches are used for several months after surgical correction to prevent full weight bearing until the growth plate is sealed by the bony union.

Children with the disorder must be followed up closely until the epiphyseal plate closes. Long-term prognosis depends on the amount of displacement that occurs. Complications include avascular necrosis, leg shortening, malunion, and problems with the internal fixation. Degenerative arthritis may develop, requiring joint replacement later in life.

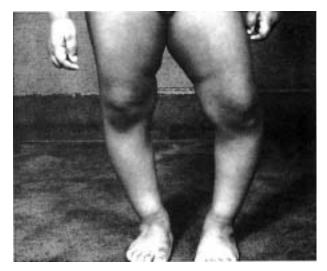

Disorders of the Knee

Blount's Disease. Idiopathic tibia vara, or Blount's disease, is a developmental deformity of the medial half of proximal tibial epiphysis that results in a progressive varus angulation below the knee (Fig. 42-17). It is the most common cause of pathologic genu varum and seen most often in black children, females, obese children, and early walkers.⁴² Onset can occur early in infancy or later, during adolescence. Adolescent Blount's disease occurs in the second decade of life, is seen in persons who are above the 95th percentile in height and weight, and is usually unilateral.⁴²

Long leg braces are used for treatment in early-onset disease. If progression occurs, or onset is late, surgery is done to correct the angulation and prevent further progression.

Osgood-Schlatter Disease. Osgood-Schlatter disease involves microfractures in the area where the patellar tendon inserts into the tibial tubercle, which is an extension of the proximal tibial epiphysis.³⁴ This area is particularly vulnerable to injury caused by sudden or continued strain from the patellar tendon during periods of growth, particularly in athletic individuals. It occurs most frequently in boys between the ages of 11 and 15 years and in girls between 8 and 13 years.

The disorder is characterized by pain in the front of the knee that is associated with inflammation and thickening of the patellar tendon. The pain usually is associated with specific activities, such as kneeling, running, bicycle riding, or stair climbing. There is swelling, tenderness, and increased prominence of the tibial tubercle. The symptoms usually are self-limiting.

■ FIGURE 42-17 ■ Rotational deformity of the proximal tibia, especially when unilateral, suggests tibia vera (Blount's disease). (From Weinstein S.L., Buckwalter J.A. [1994]. *Turek's orthopaedics* [5th ed.]. Philadelphia: J.B. Lippincott)

They may recur during growth periods but usually resolve after closure of the tibial growth plate. In some cases, limitations on activity, tibial bands or braces to immobilize the knee, antiinflammatory agents, and application of cold are necessary to relieve the pain. The objective of treatment is to release tension on the quadriceps to permit revascularization and reossification of the tibial tubercle. Complete resolution of symptoms through healing (physical close) of the tibia tubercle usually requires 12 to 24 months.³⁴ Occasionally, minor symptoms or an increased prominence of the tibial tubercle may continue into adulthood. In some cases, a high-riding patella can cause dislocation with chondromalacia of the patella and result in degenerative arthritis.

Scoliosis

Scoliosis is a lateral deviation of the spinal column that may or may not include rotation or deformity of the vertebrae. It has been estimated that more than 500,000 adults in the United States have scoliosis.⁴³ It is most commonly seen during adolescence and is eight times more common among girls than boys. Scoliosis can develop as the result of another disease condition, or it can occur without known cause. Idiopathic scoliosis accounts for 75% to 80% of cases of the disorder. The other 20% to 25% of cases result from more than 50 different causes, including poliomyelitis, congenital hemivertebrae, neurofibromatosis, and cerebral palsy. Although minor curves are relatively common (affecting approximately 2% of the population), it has been estimated that less than 0.1% of U.S. schoolchildren have severe idiopathic scoliosis.

Types of Scoliosis

Scoliosis is classified as postural or structural. With postural scoliosis, there is a small curve that corrects with bending. It can be corrected with passive and active exercises. Structural scoliosis does not correct with bending. It is a fixed deformity classified according to the cause: congenital, neuromuscular, and idiopathic.

Congenital Scoliosis. Congenital scoliosis is caused by disturbances in vertebral development during the sixth to eighth week of embryologic development. There are structural anomalies in the vertebrae that can cause a severe curvature. The child may have other anomalies and neurologic complications if the spine is involved. Early diagnosis and treatment of progressive curves are essential for children with congenital scoliosis.

Neuromuscular Scoliosis. Neuromuscular scoliosis develops from neuropathic or myopathic diseases. Neuropathic scoliosis is seen with cerebral palsy, myelodysplasia, and poliomyelitis. There is often a long, "C"-shaped curve from the cervical to the sacral region. In children with cerebral palsy, severe deformity may make treatment difficult. Myopathic neuromuscular scoliosis develops with Duchenne's muscular dystrophy and usually is not severe.

Idiopathic Scoliosis. Idiopathic scoliosis is a structural spinal curvature for which no cause has been established. It seems likely that genetics is involved, and mother-daughter pairings are common. Growth and mechanical factors also seem to play a role.

Idiopathic scoliosis can be divided into three groups on the basis of age at onset: infantile (birth to 3 years), juvenile (4 to

10 years), and adolescent (11 years and older).⁴⁴ Adolescent scoliosis is the most common type of idiopathic scoliosis. It accounts for approximately 80% of cases, and is seen most commonly in girls. An increase in joint laxity, which causes excessive joint motion and is found commonly in girls, has been associated with development of idiopathic scoliosis. Delayed puberty and menarche are other risk factors for the development of scoliosis.⁴⁵ Although the curve may be present in any area of the spine, the most common curve is a right thoracic curve, which produces a rib prominence on the convex side and hypokyphosis from rotation of the vertebral column around its long axis as the spine begins to curve.

Scoliosis usually is first noticed because of the deformity it causes. A high shoulder, prominent hip, or projecting scapula may be noticed by a parent or in a school screening program. Idiopathic scoliosis usually is a painless process, although pain may be present in severe cases, usually in the lumbar region. The pain may be caused by pressure on the ribs or on the crest of the ilium. There may be shortness of breath as a result of diminished chest expansion and gastrointestinal disturbances from crowding of the abdominal organs. Adults with less severe deformity may experience mild backache. If scoliosis is left untreated, the curve may progress to an extent that compromises cardiopulmonary function and creates a risk for neurologic complications.

Early diagnosis of scoliosis can be important in the prevention of severe spinal deformity. The cardinal signs of scoliosis are uneven shoulders or iliac crest, prominent scapula on the convex side of the curve, malalignment of spinous processes, asymmetry of the flanks, asymmetry of the thoracic cage, and rib hump or paraspinal muscle prominence when bending forward (Fig. 42-18). A complete physical examination is necessary for

children with scoliosis because the defect may be indicative of other, underlying pathology. Diagnosis of scoliosis is confirmed by radiographs, CT scans, MRI, or myelography.

The treatment of scoliosis depends on the severity of the deformity and the likelihood of progression. A brace may be used to control the progression of the curvature during growth and can provide some correction. Surgical intervention with instrumentation and spinal fusion is done in severe cases. Unlike bracing, which is intended to halt progression of the curvature, surgical intervention is used to decrease the curve.

In summary, skeletal disorders can result from congenital or hereditary influences or from factors that occur during normal periods of skeletal growth and development. Newborn infants undergo normal changes in muscle tone and joint motion, causing torsional conditions of the femur or tibia. Many of these conditions are corrected as skeletal growth and development take place.

Osteogenesis imperfecta is a rare autosomal hereditary disorder characterized by defective synthesis of connective tissue, including bone matrix. It results in poorly developed bones that fracture easily. Developmental dysplasia of the hip includes a range of structural abnormalities. Dislocated hips are always treated to prevent changes in the anatomic structure. Other childhood skeletal disorders, such as the osteochondroses, slipped capital femoral epiphysis, and scoliosis, are not corrected by the growth process. These disorders are progressive, can cause permanent disability, and require treatment. Disorders such as congenital dislocation of the hip and congenital clubfoot are present at birth. Both of these disorders are best treated during infancy.

Scoliosis represents a lateral deviation of the spinal column that may or may not include rotation or deformity of the vertebrae. It can occur as the result of congenital deformities of the vertebrae, neuromuscular diseases that produce weakness of the muscles that support the spinal column, or curvature for which no cause has been established (idiopathic scoliosis). Idiopathic scoliosis, which is the most common form, occurs more frequently in girls than boys. Treatment depends on the severity of the deformity and the likelihood of progression. If left untreated, large curves may progress to the extent that they compromise cardiopulmonary function and create a risk of neurologic complications.

REVIEW QUESTIONS

- Compare muscle strains and ligamentous sprains.
- Describe the healing process of soft tissue injuries.
- Differentiate open fractures from closed ones.

Describe the fracture healing process and relate individual and local factors to the healing process in bone.

Explain the importance of immobilization for fracture healing.

Describe the pathogenesis of osteomyelitis and differentiate among osteomyelitis caused by spread from a contaminated wound, hematogenous osteomyelitis, and osteomyelitis caused by vascular insufficiency in terms of etiologies, manifestations, and treatment.

Define osteonecrosis and cite major causes of osteonecrosis.

Differentiate between the properties of benign and malignant bone tumors.

Describe common torsional deformities that occur in infants and small children, proposed mechanisms of development, diagnostic methods, and treatment.

Define genu varum and genu valgum.

List the problems that occur because of defective tissue synthesis in osteogenesis imperfecta.

Characterize the abnormalities associated with developmental dysplasia of the hip and methods of diagnosis.

Define the term osteochondroses and describe the pathology and symptomatology of Legg-Calvé-Perthes disease and Osgood-Schlatter disease.

Describe the pathology associated with a slipped capital femoral epiphysis and explain why early treatment is important.

Discuss the diagnosis and treatment of idiopathic scoliosis.

he skeletal system provides the basic framework that supports the body, protects its organs, and provides for movement. For example, the bones of the lower extremities act as a pillar when we stand, and the ribs provide a cage that supports and protects our heart and lungs. Joints hold the bones of our skeleton together, making movement possible. This chapter focuses on two types of skeletal disorders: metabolic bone disorders, which disrupt bone integrity, and joint disorders, which disrupt mobility.

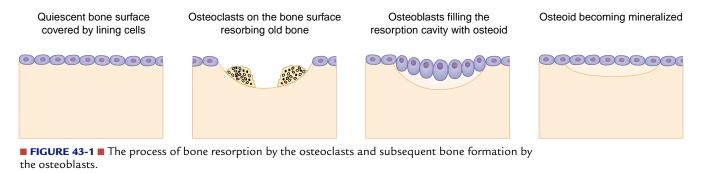

METABOLIC BONE DISEASE

Bone integrity depends on a process of bone resorption and formation, or bone remodeling, which is continuous throughout life. In the adult, approximately 25% of cancellous or spongy bone is replaced each year, compared with 3% of compact bone.¹ In the adult skeleton, bone remodeling proceeds in cycles that involve resorption of old bone by osteoclasts and subsequent formation of new bone by osteoblasts (Fig. 43-1). The sequence of bone resorption and bone formation is activated by many stimuli, including the actions of parathyroid hormone (PTH) and calcitonin. It begins with osteoclastic resorption of existing bone, during which the organic (protein matrix) and the inorganic (mineral) components are removed. The sequence proceeds to the formation of new bone by osteoblasts. In the adult, the length of one sequence (i.e., bone resorption and formation) is approximately 4 months. Ideally, the replaced bone should equal the absorbed bone. If it does not, there is a net loss of bone. In the elderly, for example, bone resorption and formation no longer are perfectly coupled, and bone mass is lost.

There are three major factors that influence bone remodeling: (1) mechanical stress, (2) extracellular calcium and phosphate levels, and (3) hormones, local growth factors, and cytokines. Mechanical stress stimulates osteoblastic activity and formation of the organic matrix. It is important in preventing bone atrophy and in healing fractures. Bone serves as a storage site for extracellular calcium and phosphate ions. Consequently, alterations in the extracellular levels of these

Dr Murtadha Alshareifi e-Library

Chapter 43: Alterations in the Skeletal System: Metabolic and Rheumatoid Disorders

ions affect their deposition in bone (see Chapter 6). Blood levels of calcium and phosphate are regulated by PTH and calcitonin (see Chapter 41). PTH promotes bone resorption, and calcitonin inhibits bone resorption.

Osteoclasts and osteoblasts have their origin in the bone marrow and the periosteum (see Chapter 41).¹ The osteoblasts, which are bone-building cells, originate from osteoprogenitor cells in the periosteum and the stromal or supporting cells within the marrow cavity. The osteoclasts, which are boneresorptive cells, are a member of the hematopoietic monocyte/ macrophage family. However, the development of osteoclasts from their monocyte/macrophage precursors cannot take place unless stromal-osteoblastic cells are present. The differentiation and function of osteoclasts and osteoblasts are regulated by chemical messengers, including colony-stimulating factors (CSF) and other cytokines (see Chapter 8). Interleukin-6, which is produced in response to systemic hormones such as PTH and vitamin D, stimulates the early stages of osteoclast development. Interleukin-6 is thought to be involved in the abnormal bone resorption associated with Paget's disease.

Recent evidence suggests that an interaction between a chemical messenger called the *RANK ligand*, which is produced by the stromal/osteoblastic cells, and RANK receptors on the macrophage/osteoclastic precursor cell is essential for the differentiation and proliferation of osteoclasts (Fig. 43-2). There also is evidence of a blocking molecule called *osteoprotegrin* (OPG) that can prevent the RANK ligand from binding to the RANK receptor, thus inhibiting the formation of osteoclasts. It is now believed that dysregulation of the RANK ligand/receptor pathway plays a prominent role in the pathogenesis of bone diseases such as osteoprorsis.²

815

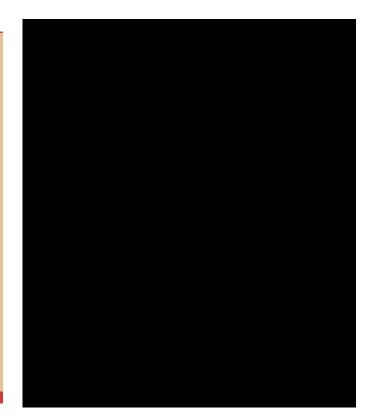

Osteopenia

Osteopenia is a condition that is common to all metabolic bone diseases. It is characterized by a reduction in bone mass greater than expected for age, race, or sex, and it occurs because of a decrease in bone formation, inadequate bone mineralization, or excessive bone deossification. *Osteopenia* is not

KEY CONCEPTS

METABOLIC BONE DISORDERS

- Metabolic bone disorders have their origin in the bone remodeling process that involves an orderly sequence of osteoclastic bone reabsorption, the formation of new bone by the osteoblasts, and mineralization of the newly formed osteoid tissue.
- Osteoporosis represents an increased loss of total bone mass due to an imbalance between bone absorption and bone formation, most often related to the aging process and decreased estrogen levels in postmenopausal women.
- Osteomalacia and rickets represent a softening of bone due to inadequate mineralization of the bone matrix caused by a deficiency of calcium or phosphate.
- Paget's disease is a disorder involving excessive bone destruction and repair, resulting in structural deformities of long bones, spine, pelvis, and cranium.

a diagnosis but a term used to describe an apparent lack of bone seen on x-ray studies. The major causes of osteopenia are osteoporosis, osteomalacia, malignancies such as multiple myeloma, and endocrine disorders such as hyperparathyroidism and hyperthyroidism.

Osteoporosis

Osteoporosis is skeletal disorder characterized by the loss of bone mass and deterioration of the architecture of cancellous bone with a subsequent increase in bone fragility and susceptibility to fractures.³ Osteoporosis can be classified as primary or secondary. Primary osteoporosis occurs in postmenopausal women and in elderly persons of both sexes. Secondary osteoporosis is associated with a definite cause, including a variety of endocrine disorders and genetic abnormalities.

Primary osteoporosis is extremely common in the United States. Ten million Americans already have osteoarthritis, and another 34 million have low bone mass placing them at risk for the disease. Osteoporosis is responsible for more than 1.5 million fractures annually, including 300,000 hip fractures and approximately 700,000 vertebral fractures.³

Pathogenesis

Regardless of cause, osteoporosis reflects enhanced bone resorption relative to bone formation. Although both of these factors play a role in most cases of osteoporosis, their relative contribution to bone loss may vary dependent upon age, sex, nutritional status, and genetic predisposition.

Under normal conditions, bone mass increases steadily during childhood, reaching a peak in the young adult years. The peak bone mass is an important determinant of the subsequent risk of osteoporosis. It is determined in part by genetic factors, gonadal (estrogen) levels, exercise, calcium intake and absorption, and environmental factors. Genetic factors are linked, in largest part, to the maximal amount of bone in a given person, referred to as peak bone mass. Bone mass positively correlates with the amount of skin pigmentation; whites have the least bone mass, and African Americans have the most. Mexican-American women have bone mass intermediate between non-Hispanic white women and African American women. Although osteoporosis is uncommon among African-American women, many cases are seen among postmenopausal women with brown and yellow skin.⁴ Exercise may prevent osteoporosis by increasing peak bone mineral density during periods of growth. Poor nutrition or an age-related decrease in intestinal absorption of calcium because of deficient activation of vitamin D may contribute to the development of osteoporosis, particularly in the elderly.

Hormonal factors play a significant role in the development of osteoporosis, particularly in postmenopausal women. Postmenopausal osteoporosis, which is caused by an estrogen deficiency, is manifested by a loss of cancellous bone and a predisposition to fractures of the vertebrae and distal radius. The loss of bone mass is greatest during early menopause, when estrogen levels are withdrawing. Several factors appear to influence the increased loss of bone mass associated with an estrogen deficiency. Decreased estrogen levels are associated with an increase in cytokines (*e.g.*, interleukins-1, interleukin-6, and tumor necrosis factor [TNF]) that stimulate the production of osteoclast precursors. Recent studies indicate that estrogen deficiency also influences osteoclast differentiation via the RANK receptor pathways.² Estrogen stimulates the production of OPG and thus inhibits the formation of osteoclasts, and it also blunts the responsiveness of osteoclast precursors to the RANK ligand. With menopause and its accompanying estrogen deficiency, this inhibition of osteoclast production is lost.² Evidence also suggests that estrogen deficiency, as well as normal aging, may lead to decreased osteoblastic activity and new bone formation. Thus, the bone loss associated with estrogen deficiency may be caused by a combination of increased bone resorption and decreased bone formation. Testosterone deficiency may contribute to bone loss in men with senile osteoporosis, although the effect is not of the same magnitude as that caused by estrogen deficiency.

Age-related changes in bone density occur in all individuals and contribute to the development of osteoporosis in both sexes. After maximal bone mass is attained at about 30 years of age, the rate of bone loss for both sexes is approximately 0.7% per year, and it increases to approximately 1% per year or more in menopausal women.² The age-related loss of bone reflects decreased osteoblast activity as well as an increase in osteoclastic activity. The greatest losses occur in areas containing abundant cancellous bone, such as the spine and femoral neck. Thus, these are common sites for fractures in persons with osteoporosis.

Secondary osteoporosis is associated with many conditions, including endocrine disorders, malabsorption disorders, malignancies, alcoholism, and certain medications. Persons with endocrine disorders such as hyperthyroidism, hyperparathyroidism, Cushing's syndrome, or diabetes mellitus are at high risk for the development of osteoporosis. Hyperthyroidism causes an acceleration of bone turnover. Some malignancies (e.g., multiple myeloma) secrete osteoclast-activating factor, causing significant bone loss. Alcohol is a direct inhibitor of osteoblasts and may also inhibit calcium absorption. Glucocorticoid use is the common form of drug-related osteoporosis, and its long-term use in treatment of disorders such as rheumatoid arthritis and chronic obstructive lung disease is associated with a high rate of fractures.³ The prolonged use of medications that increase calcium excretion, such as aluminum-containing antacids, corticosteroids, and anticonvulsants, also is associated with bone loss.⁵ Persons with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) who are being treated with antiretroviral therapy may have a lower bone density and signs of osteoporosis and osteopenia.6

Several groups of children and adolescents are at increased risk of decreased bone mass, including premature and lowbirth-weight infants who have lower than expected bone mass in the early weeks of life; children who require treatment with corticosteroid drugs (*e.g.*, those with childhood inflammatory diseases and transplant recipients); children with cystic fibrosis; and those with hypogonadal states (*e.g.*, anorexia nervosa and the female athlete triad).² Children with cystic fibrosis often have impaired gastrointestinal function that reduces the absorption of calcium and other nutrients, and many also require the frequent use of corticosteroid drugs.

Premature osteoporosis is being seen increasingly in female athletes because of an increased prevalence of eating disorders and amenorrhea.⁷ The *female athlete triad* refers to a pattern of disordered eating that leads to amenorrhea and eventually osteoporosis. Poor nutrition, combined with intense training, can lead to an energy deficit that causes a lack of estrogen production by the ovary and secondary amenorrhea.⁸ The lack of estrogen combined with the lack of calcium and vitamin D from dietary deficiencies results in a loss of bone density and increased risk of fractures.⁸ There is a concern that athletes with low bone mineral density will be at increased risk for fractures during their competitive years. It is unclear if osteoporosis induced by amenorrhea is reversible. It most frequently affects women engaged in endurance sports, such as running and swimming; in activities where appearance is important, such as figure skating, diving, and gymnastics; or sports with weight categories, such as horse racing, martial arts, and rowing.⁹

Clinical Manifestations

Osteoporotic changes occur in the diaphysis and metaphysis of bone. The diameter of the bone enlarges with age, causing the outer supporting cortex to become thinner. In severe osteoporosis, the bones begin to resemble the fragile structure of a fine porcelain vase. There is loss of trabeculae from cancellous bone and thinning of the cortex to such an extent that minimal stress causes fractures (Fig. 43-3).

The first clinical manifestations of osteoporosis are pain accompanied by skeletal fractures—a vertebral compression fracture or fractures of the hip, pelvis, humerus, or any other bone. Fractures usually represent an end stage of the disease. Fracture occurs with a force less than typically is needed. Women who present with fractures are much more likely to sustain another fracture than are women of the same age without osteoporosis. Wedging and collapse of vertebrae causes a loss of height in the vertebral column and kyphosis, a condition commonly referred to as *dowager's hump*. Usually, there is no generalized

■ FIGURE 43-3 ■ Osteoporosis. A section of the vertebral column, in which the bone marrow has been washed out, demonstrates a loss of bone tissue and a compression fracture of a vertebral body (*top*). (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1367]. Philadelphia: Lippincott Williams & Wilkins)

bone tenderness. When pain occurs, it is related to fractures. Systemic symptoms such as weakness and weight loss suggest that the osteoporosis may be caused by underlying disease.

Diagnosis and Treatment

An important advance in diagnostic methods used for the identification of osteoporosis has been the use of bone mass density (BMD) studies. Several different techniques have been developed to measure BMD in multiple skeletal sites, including the vertebral column, hip, and spine. Excessive loss of height indicates some probability of low bone mass.¹⁰ Measurement of serial heights in older adults is another simple way to screen for osteoporosis. A further advance in the diagnosis of osteoporosis is the refinement of risk factors, permitting better analysis of risk pertaining to particular persons.

Prevention and early detection of osteoporosis are essential to the prevention of the associated deformities and fractures. It is important to identify persons in high-risk groups so treatment can begin early. Postmenopausal women of small stature or lean body mass, those with sedentary lifestyles, those with poor calcium intake, and those with diseases that demineralize bone are at greatest risk. Other risk factors include an age of 80 years or greater, maternal history of hip fracture, consumption of caffeine-containing beverages, previous hyperthyroidism, and current anticonvulsant therapy. Excessive intake of diet soda that is high in phosphate also can deplete calcium stores. Other risk factors found to be associated with osteoporosis are a diet high in protein, cigarette smoking, and alcohol ingestion. Risk factors for osteoporosis are listed in Chart 43-1.

Regular exercise and adequate calcium intake are important factors in preventing osteoporosis. Weight-bearing exercises

CHART 43-1 Risk Factors Associated With Osteoporosis

Primary

Advanced Age Female White (fair, thin skin) Small bone structure Postmenopausal Family History Contributing factors Sedentary lifestyle Calcium deficiency (long-term)

Secondary

Cushing's disease Diabetes Hyperparathyroidism Hyperthyroidism Malignancy Malabsorption disorders Chronic alcoholism Medications Anticonvulsants Aluminum-containing antacids Corticosteroids Heparin such as walking, jogging, rowing, and weight lifting are important in the maintenance of bone mass. Studies have indicated that premenopausal women need more than 1000 mg and postmenopausal women need 1500 mg of calcium daily.¹¹ This means that adults should drink three to four glasses of milk daily or substitute other foods that are high in calcium. Because most older American women do not consume a sufficient quantity of dairy products to meet their calcium needs, calcium supplementation is recommended. Deficient activation of vitamin D may be an important factor in the impaired intestinal absorption of calcium in the elderly. A daily intake of 400 to 800 IU of vitamin D is recommended because vitamin D optimizes calcium absorption and inhibits parathyroid secretion, which stimulates calcium resorption from bone.¹⁰

Active treatment of osteoporosis uses four types of agents: gonadal hormones (estrogen), calcitonin, and bisphosphonates. The development of selective estrogen receptor modulators (SERMs) has been an important advance in osteoporosis research. These agents maximize the beneficial effects of estrogen on bone, while minimizing the effects on breast and endometrial tissues.² Calcitonin can be used to decrease osteoclastic activity and has some effect on bone pain. The bisphosphonates are analogs of endogenous inorganic pyrophosphate that the body cannot break down. In bone, they bind to hydroxyapatite and prevent bone resorption through the inhibition of osteoclast activity.

Osteomalacia and Rickets

In contrast to osteoporosis, which causes a loss of total bone mass and results in brittle bones, osteomalacia and rickets produce a softening of the bones and do not involve the loss of bone matrix.

Osteomalacia

Osteomalacia is a generalized bone condition in which inadequate mineralization of bone results from a calcium or phosphate deficiency, or both. It is sometimes referred to as the adult form of rickets.

There are two main causes of osteomalacia: (1) insufficient calcium absorption from the intestine because of a lack of dietary calcium or deficiency or resistance to the action of vitamin D and (2) phosphate deficiency caused by increased renal losses or decreased intestinal absorption. Vitamin D deficiency is caused most commonly by reduced vitamin D absorption as a result of biliary tract or intestinal diseases that impair fat and fat-soluble vitamin absorption. Lack of vitamin D in the diet is rare in the United States because many foods are fortified with the vitamin. Anticonvulsant medications, such as phenobarbital and phenytoin, induce hepatic hydroxylases that accelerate breakdown of the active forms of vitamin D.

A form of osteomalacia called *renal rickets* occurs in persons with chronic renal failure. It is caused by the inability of the kidney to activate vitamin D and excrete phosphate and is accompanied by hyperparathyroidism, increased bone turnover, and increased bone resorption (see Chapter 24). Another form of osteomalacia results from renal tubular defects that cause excessive phosphate losses. This form of osteomalacia is commonly referred to as *vitamin D-resistant rickets* and often is a familial disorder.¹² It is inherited as an X-linked dominant gene passed by mothers to one half of their children and by fathers to their daughters only. This form of osteomalacia affects boys more severely than girls. Long-standing primary hyperparathyroidism causes increased calcium resorption from bone and hypophosphatemia, which can lead to rickets in children and osteomalacia in adults.

The incidence of osteomalacia is high among the elderly because of diets deficient in calcium and vitamin D and often is compounded by the intestinal malabsorption problems that accompany aging. Osteomalacia often is seen in cultures in which the diet is deficient in vitamin D, such as in northern China, Japan, and northern India. Women in these areas have a higher incidence of the disorder than do men because of the combined effects of pregnancy, lactation, and more indoor confinement. Osteomalacia occasionally is seen in strict vegetarians, persons who have had a gastrectomy, and those on long-term anticonvulsant, tranquilizer, sedative, muscle relaxant, or diuretic drugs. There also is a greater incidence of osteomalacia in the colder regions of the world, particularly during the winter months, probably because of lessened exposure to sunlight.

The clinical manifestations of osteomalacia are bone pain, tenderness, and fractures as the disease progresses. In severe cases, muscle weakness often is an early sign. The cause of muscle weakness is unclear. The combined effects of gravity, muscle weakness, and bone softening contribute to the development of deformities. There may be a dorsal kyphosis in the spine, rib deformities, a heart-shaped pelvis, and marked bowing of the tibiae and femurs. Osteomalacia predisposes a person to pathologic fractures in the weakened areas, especially in the distal radius and proximal femur. In contrast to osteoporosis, it is not a significant cause of hip fractures. There may be delayed healing and poor retention of internal fixation devices. Osteomalacia usually is accompanied by a compensatory or secondary hyperparathyroidism stimulated by low serum calcium levels.

Diagnostic methods include x-ray studies and laboratory tests such as serum calcium, phosphate, PTH, and vitamin D levels. Bone density studies help to confirm the diagnosis. A bone biopsy may be done to confirm the diagnosis of osteomalacia.

The treatment of osteomalacia is directed at the underlying cause. If the problem is nutritional, restoring adequate amounts of calcium and vitamin D to the diet may be sufficient. Vitamin D is specific for adult osteomalacia and vitamin Dresistant rickets, but large doses usually are needed to overcome the resistance to its calcium-absorption action and to prevent renal loss of phosphate. If osteomalacia is caused by malabsorption, the treatment is directed toward correcting the primary disease. For example, adequate replacement of pancreatic enzymes is of paramount importance in pancreatic insufficiency. In renal tubular disorders, the treatment is directed at the altered renal physiology.

Rickets

Rickets is a disorder of vitamin D deficiency, inadequate calcium absorption, and impaired mineralization of bone in children. Children with rickets manifest inadequate mineralization not only of bone, but also of the cartilaginous matrix of the epiphyseal growth plate. Rickets occurs primarily in underdeveloped areas of the world and among immigrants to developed countries. The causes are inadequate exposure to sunlight (e.g., children are often kept clothed and indoors) and prolonged breast-feeding without vitamin D supplementation.¹³ Although the vitamin D content of human milk is low, the combination of breast milk and sunlight exposure usually provides sufficient vitamin D. Another cause of rickets is the use of commercial alternative milks (e.g., soy or rice beverages) that are not fortified with vitamin D.14 A dietary deficiency in calcium and phosphorous may also contribute to the development of rickets. A newly discovered genetic mutation also can cause vitamin D deficiency rickets, a condition that does not respond to simple vitamin supplementation. The mutation results in the absence of a critical enzyme in vitamin D metabolism.15

The pathology of rickets is the same as that of osteomalacia seen in adults. Because rickets affects children during periods of active growth, the structural changes seen in the bone are somewhat different. Bones become deformed; ossification at epiphyseal plates is delayed and disordered, resulting in widening of the epiphyseal cartilage plate. Any new bone that does grow is unmineralized.

The symptoms of rickets usually are noticed between 6 months and 3 years of age. The child usually has stunted growth, with a height sometimes far below the normal range. Weight often is not affected so that the children, many of whom present with a protruding abdomen (i.e., rachitic potbelly), have been described as presenting a Buddha-like appearance when sitting. Early symptoms are lethargy and muscle weakness, which may be accompanied by convulsions or tetany related to hypocalcemia. Irritability is common. In severe cases, children lose their skin pigment, acquire flabby subcutaneous tissue, and have poorly developed musculature. The ends of long bones and ribs are enlarged. The thorax may be abnormally shaped, with prominent rib cartilage (*i.e.*, rachitic rosary). The legs exhibit bowlegged or knock-kneed deformities. The skull is enlarged and soft, and closure of the fontanels is delayed. Teeth are slow to develop, and the child may have difficulty standing.

Rickets is treated with a balanced diet sufficient in calcium, phosphorus, and vitamin D. Exposure to sunlight also is important, especially for premature infants and those receiving artificial milk feedings. Supplemental vitamin D in excess of normal requirements is given for several months. Maintenance of good posture, positioning, and bracing in older children are used to prevent deformities. After the disease is controlled, deformities may have to be surgically corrected as the child grows.

Paget's Disease

Paget's disease (*i.e.*, osteitis deformans) is not a true metabolic disease. It is a progressive skeletal disorder that involves excessive bone destruction and repair and is characterized by increasing structural changes of the long bones, spine, pelvis, and cranium. The disease usually begins during midadulthood and becomes progressively more common thereafter.²

The cause of Paget's disease is unknown. It may be caused by a virus capable of inciting osteoclastic activity.^{2,12} It has been suggested that the virus may induce secretion of interferon-6, which is a potent stimulator of osteoclastic recruitment and resorptive activity.² The disease usually begins insidiously and progresses slowly over many years. An initial osteolytic phase is followed by an osteoblastic sclerotic phase. During the initial osteolytic phase, abnormal osteoclasts proliferate. Bone resorption occurs so rapidly that new bone formation cannot keep up, and the bone is replaced by fibrous tissue. The two processes of destruction and rebuilding occur simultaneously. The bones increase in size and thickness because of accelerated bone resorption followed by abnormal regeneration. Irregular bone formation results in sclerotic and osteoblastic lesions. The result is a thick layer of coarse, thick bundles of trabecular bone with a rough and pitted outer surface that has the appearance of pumice (Fig. 43-4).

The clinical manifestations of Paget's disease depend on the specific area involved. Approximately 20% of persons with the disorder are totally asymptomatic, and the disease is discovered incidentally.¹⁶ Involvement of the skull causes headaches, intermittent tinnitus, vertigo, and eventual hearing loss. In the spine, collapse of the anterior vertebrae causes kyphosis of the thoracic spine. The femur and tibia become bowed (Fig. 43-4). Softening of the femoral neck can cause coxa vara (*i.e.*, reduced angle of the femoral neck). Coxa vara, in combination with softening of the sacral and iliac bones, causes a waddling gait. When the lesion affects only one bone, it may cause only mild pain and stiffness. Progressive deossification weakens and distorts the bone structure. The deossification process begins along the inner cortical surfaces and continues until the substance of the bone disappears. Pathologic fractures may occur, especially in the bones subjected to the greatest stress (e.g., upper femur, lower spine, pelvic bones). These fractures often heal poorly, with excessive and poorly distributed callus.

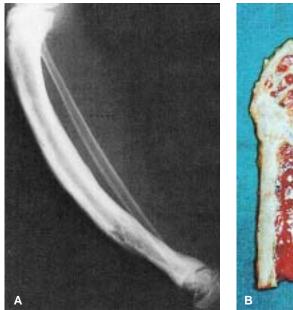

Other manifestations of Paget's disease include nerve palsy syndromes from lesions in the upper extremities, mental deterioration, and cardiovascular disease. Cardiovascular disease is the most serious complication and is listed as the most common cause of death in those with advanced generalized Paget's disease. It is caused by vasodilation of the vessels in the skin and subcutaneous tissues overlying the affected bones. When one third to one half of the skeleton is affected, the increased blood flow may lead to high-output cardiac failure. Ventilatory capacity may be limited by rib and spine involvement.

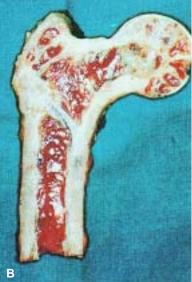

Osteogenic sarcomas occur in 5% to 10% of persons with severe disease.² One fifth of all osteogenic sarcomas in persons 50 years of age or older originate in people with Paget's disease.¹⁷ The bones most often affected, in order of frequency, are the femur, pelvis, humerus, and tibia.

Diagnosis of Paget's disease is based on characteristic bone deformities and x-ray changes. Elevated levels of serum alkaline phosphatase and urinary hydroxyproline support the diagnosis, and continued surveillance of these levels may be used to monitor the effectiveness of treatment. Technetium pyrophosphate bone scans are used to detect the rapid bone turnover indicative of active disease and to monitor the response to treatment. The scan cannot identify bone activity resulting from malignant lesions. Bone biopsy may be done to differentiate the lesion from osteomyelitis or a primary or metastatic bone tumor.

The treatment of Paget's disease is based on the degree of pain and the extent of the disease. Pain can be reduced with nonsteroidal or other anti-inflammatory agents. Suppressive agents such as the hormone calcitonin, mithramycin, and

820 Unit Eleven: Alterations in the Skeletal and Integumentary Systems

■ FIGURE 43-4 ■ Paget disease. (A) Radiograph of the leg shows marked involvement of the tibia by Paget disease with thickening and disorganization of the cortex. Note the normal appearance of the fibula. (B) The proximal end of a femur affected by Paget disease shows replacement of the normal cancellous architecture by coarse, thick bundles of trabecular bone. The cortical bone is irregularly thickened and exhibits a coarse, granular appearance instead of the normally smooth cortical bone. Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1377]. Philadelphia: Lippincott Williams & Wilkins)

bisphosphonates are used to manage pain and prevent further spread of the disease and neurologic defects. Calcitonin, administered by nasal spray, inhibits osteoclast-mediated bone resorption. Bisphosphonates are the treatment of choice for Paget's disease. They act by binding directly to bone minerals, inhibiting bone loss by rapidly decreasing bone resorption, followed by a secondary slower decrease in the rate of bone formation.

In summary, in addition to its structural function, the skeleton is a homeostatic organ. Metabolic bone diseases such as osteoporosis, osteomalacia, rickets, and Paget's disease are the result of a disruption in the equilibrium of bone formation and resorption. Osteoporosis, which is the most common of the metabolic bone diseases, occurs when the rate of bone resorption is greater than that of bone formation. It is seen frequently in postmenopausal women and is the major cause of fractures in persons older than 45 years of age. Osteomalacia and rickets are caused by inadequate mineralization of bone matrix, primarily because of a deficiency of vitamin D. Paget's disease results from excessive osteoclastic activity and is characterized by the formation of poor-quality bone.

RHEUMATIC DISORDERS

Rheumatic disorders are characterized by inflammation, pain, and stiffness in the musculoskeletal system. *Arthritis* is a descriptive term applied to more than 100 rheumatic diseases, ranging from localized, self-limiting conditions to those that are systemic, autoimmune processes.^{18,19} Arthritis affects persons in all age groups and is the leading cause of disability in the United States.

The common use of the term *arthritis* oversimplifies the nature of the varied disease processes, the difficulty in differentiating one form of arthritis from another, and the complexity of treatment of these usually chronic conditions. These diverse rheumatic conditions share inflammation of the joint as a prominent or accompanying symptom. In the systemic rheumatic diseases, such as rheumatoid arthritis, the inflammation is primary, resulting from an immune response, probably autoimmune in origin. In rheumatic conditions limited to a single or few diarthrodial joints, such as osteoarthritis, the inflammation is secondary, resulting from the degenerative process and joint irregularities.

Systemic Autoimmune Rheumatic Diseases

Systemic autoimmune rheumatic diseases are a group of chronic disorders characterized by diffuse inflammatory vascular lesions and degenerative changes in connective tissue that share clinical features and may affect many of the same organs. They

KEY CONCEPTS

ARTHRITIS

- Arthritis represents a diverse group of rheumatic conditions that share inflammation of the joint as a prominent or accompanying symptom.
- In the systemic rheumatic diseases, the inflammation is primary, resulting from an immune response, probably autoimmune in origin.
- In rheumatic conditions, such as osteoarthritis, which are limited to a single or few diarthrodial joints, the inflammation is secondary, resulting from the degenerative process and joint irregularities.

include rheumatoid arthritis, systemic lupus erythematosus, and systemic sclerosis, all of which share an autoimmune systemic pathogenesis.

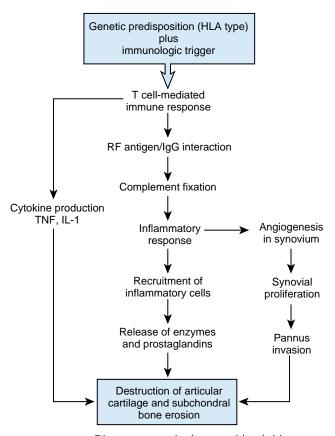

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a systemic inflammatory disease that affects 0.3% to 1.5% of the population, with women affected two to three times more frequently than men.¹⁸ Although the disease occurs in all age groups, its prevalence increases with age. The peak incidence among women is between the ages of 40 and 60 years, with the onset at 30 to 50 years of age.

Although the cause of RA remains uncertain, evidence points to a genetic predisposition and the development of joint inflammation that is immunologically mediated. It has been suggested that the disease is initiated in a genetically predisposed individual by the activation of a T cell-mediated response to an immunologic trigger, such as a microbial agent. The importance of genetic factors in the pathogenesis of RA is supported by the increased frequency of the disease among first-degree relatives and monozygotic twins. There is also a strong association of human leukocyte antigen (HLA) DR4 and/or HLA-DRB1 with RA.¹⁸ Thus, certain HLA-DR molecules may predispose to RA by their capacity to bind arthrogenic antigens, which in turn activate helper T cells and initiate the disease.

Pathogenesis. The pathogenesis of RA can be viewed as an aberrant immune response that leads to synovial inflammation and destruction of the joint architecture. Approximately 85% of those with the disease have a substance called the *rheumatoid factor* (RF), which is an autoantibody that reacts with a fragment of immunoglobulin G (IgG).^{12,20} The RF and IgG form immune complexes that fix complement; attract neutrophils, macrophages, and lymphocytes; and incite the inflammatory response (Fig. 43-5). The presence of high titers of RF is frequently associated with severe and unremitting disease, many systemic complications, and a serious prognosis.¹² However, it is important to note that about 15% persons with RA do not have the RF, and the factor is occasionally found in other disease states (and even healthy people).

Characteristic of RA is the development of an extensive network of new blood vessels in the synovial membrane that contributes to the advancement of the rheumatoid synovitis. This destructive vascular granulation tissue, which is called *pannus*, extends from the synovium to involve the "bare area," a region of unprotected bone at the junction between cartilage and subchondral bone. Pannus is a feature of RA that differentiates it from other forms of inflammatory arthritis²¹ (Fig. 43-6). The inflammatory cells found in the pannus have a destructive effect on the adjacent cartilage and bone. Eventually, pannus develops between the joint margins, leading to reduced joint motion and the possibility of eventual ankylosis. With progression of the disease, joint inflammation and the resulting structural changes can lead to joint instability, muscle atrophy from disuse, stretching of the ligaments, and involvement of the tendons and muscles. The effect of the pathologic changes on joint structure and function is related to the degree of disease activity, which can change at any time. Unfortunately, the destructive changes are irreversible.

■ FIGURE 43-5 ■ Disease process in rheumatoid arthritis.

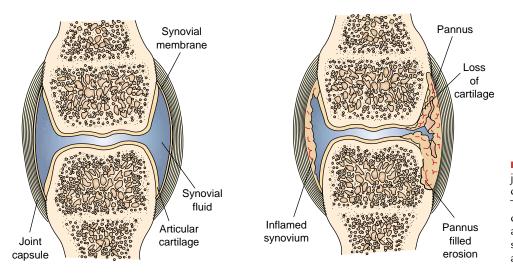

Clinical Manifestations. Rheumatoid arthritis often is associated with systemic as well as joint manifestations. It usually has an insidious onset marked by systemic manifestations such as fatigue, anorexia, weight loss, and low-grade fever when the disease is active. The erythrocyte sedimentation rate (ESR), which commonly is elevated during inflammatory processes, has been found to correlate with the amount of disease activity.²² Anemia associated with a low serum iron level or low iron-binding capacity is common.¹⁸ This anemia usually is resistant to iron therapy.

The disease, which is characterized by exacerbations and remissions, may involve only a few joints for brief durations, or it may be relentlessly progressive and debilitating. Approximately 3% of those with the disease have a progressive, unremitting form that does not respond to aggressive therapy.¹⁸

Joint Manifestations. Joint involvement usually is symmetric and polyarticular. Any diarthrodial joint can be involved. The person may report joint pain and stiffness that lasts 30 minutes and frequently for several hours. The limitation of joint motion that occurs early in the disease usually is caused by pain; later, it is caused by fibrosis. The most frequently affected joints initially are the fingers, hands, wrists, knees, and feet. Later, other diarthrodial joints may become involved. Spinal involvement usually is limited to the cervical region.

In the hands, there usually is bilateral and symmetric involvement of the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints in the early stages of RA; the distal interphalangeal (DIP) joints rarely are affected. The fingers

822 Unit Eleven: Alterations in the Skeletal and Integumentary Systems

■ FIGURE 43-6 ■ (Left) Normal joint structures. (Right) Joint changes in rheumatoid arthritis. The left side denotes early changes occurring within the synovium, and the right side shows progressive disease that leads to erosion and the formation of pannus.

often take on a spindle-shaped appearance because of inflammation of the PIP joints (Fig. 43-7). Progressive joint destruction may lead to subluxation (i.e., dislocation of the joint resulting in misalignment of the bone ends) and instability of the joint and in limitation of movement. Swelling and thickening of the synovium can result in stretching of the joint capsule and ligaments. When this occurs, muscle and tendon imbalances develop, and mechanical forces applied to the joints through daily activities produce joint deformities. In the MCP joints, the extensor tendons can slip to the ulnar side of the metacarpal head, causing ulnar deviation of the finger (Fig. 43-8). Subluxation of the MCP joints may develop when this deformity is present. Hyperextension of the PIP joint and partial flexion of the DIP joint is called a swan neck deformity. After this condition becomes fixed, severe loss of function occurs because the person can no longer make a fist. Flexion of the PIP joint with hyperextension of the DIP joint is called a *boutonnière deformity*.

The knee is one of the most commonly affected joints and is responsible for much of the disability associated with the disease.¹⁸ Active synovitis may be apparent as visible swelling that obliterates the normal contour over the medial and lateral aspects of the patella. The *bulge sign*, which involves milking fluid from the lateral to the medial side of the patella, may be used to determine the presence of excess fluid when it is not visible. Joint contractures, instability, and genu valgus (knock-knee) deformity are other possible manifestations. Severe quadriceps atrophy can contribute to the disability. *Baker's cyst* may occur in the popliteal area behind the knee. This is caused by enlargement of the bursa and usually does not cause symptoms unless the cyst ruptures, in which case symptoms mimicking thrombophlebitis appear.

Because the lower extremity joints are weight-bearing structures, involvement of the foot and ankle causes greater dysfunction and pain than does involvement of the upper extrem-

ities. Disease activity can limit flexion and extension of the ankle, which can create difficulty in walking. Involvement of the metatarsophalangeal joints of the feet can cause subluxation, hallux valgus, and hammer toe deformities.

Neck discomfort is common. In rare cases, long-standing disease can lead to neurologic complications such as occipital headaches, muscle weakness, and numbness and tingling in the upper extremities. More severe but less common neurologic complications are dislocation of the first cervical vertebra and subluxation of the odontoid process of the second vertebra into the foramen magnum, which can lead to paralysis and is potentially fatal.

Extra-articular Manifestations. Although characteristically a joint disease, RA can affect a number of other tissues. Extra-articular manifestations probably occur with a fair degree of frequency but usually are mild enough to cause few problems. They are most likely to occur in persons with the RF.

Rheumatoid nodules are granulomatous lesions that develop around small blood vessels. The nodules may be tender or nontender, movable or immovable, and small or large. Typically, they are found over pressure points such as the extensor surfaces of the ulna. The nodules may remain unless surgically removed, or they may resolve spontaneously.

Vasculitis, involving the small and medium-size arterioles, is an uncommon manifestation of RA in persons with a long history of active arthritis and high titers of RF (see Chapter 15). Manifestations include ischemic areas in the nail fold and digital pulp that appear as brown spots. Ulcerations may occur in the lower extremities, particularly around the malleolar areas. In some cases, neuropathy may be the only symptom of vasculitis. The visceral organs, such as the heart, lungs, and gastrointestinal tract, also may be affected.

Other extra-articular manifestations include eye lesions such as episcleritis and scleritis, hematologic abnormalities, pulmonary disease, cardiac complications, infection, and Felty's syndrome (*i.e.*, leukopenia with or without splenomegaly).

Diagnosis and Treatment. The diagnosis of RA is based on findings of the history, physical examination, and laboratory tests. The criteria for RA developed by the American Rheumatism Association are useful in establishing the diagnosis²³ (Chart 43-2). At least four of the criteria must be present to make a diagnosis of RA. Although these criteria were developed for classification purposes and for use in epidemiological studies, they can be used as guidelines for diagnosing the illness in individual patients.

In the early stages, the disease often is difficult to diagnose. On physical examination, the affected joints show signs of inflammation, swelling, tenderness, and possibly warmth and reduced motion. The joints have a soft, spongy feeling because of the synovial thickening and inflammation. Body movements may be guarded to prevent pain. Changes in joint structure usually are not visible early in the disease.

The RF test results are not diagnostic for RA, but they can be of value in differentiating RA from other forms of arthritis. Radiologic findings also are not diagnostic in RA because joint erosions often are not seen on radiographic images in the early stages of the disorder. Synovial fluid analysis can be helpful in the diagnostic process. The synovial fluid has a cloudy appear-

ance, the white blood cell count is elevated as a result of inflammation, and the complement components are decreased.

The treatment plan for a person with RA includes education about the disease and its treatment, rest, therapeutic exercises, and medications. Because of the chronicity of the disease and the need for continuous, long-term adherence to the prescribed treatment modalities, it is important that the treatment be integrated into the person's lifestyle.

The goals of pharmacologic therapy for RA are to reduce pain, decrease inflammation, maintain or restore joint function, and prevent bone and cartilage destruction. Nonsteroidal anti-inflammatory drugs (NSAIDs) usually are the first choice in the treatment of RA. The NSAIDs, including the salicylates (e.g., aspirin), and the newer COX-2 inhibitors, provide antiinflammatory and analgesic effects. Second-line drug therapy is initiated early in the disease if joint symptoms persist despite use of NSAIDs. Disease-modifying antirheumatic drugs (DMARDs) include gold salts, hydroxychloroquine, sulfasalazine, methotrexate, and azathioprine. Methotrexate, a potent immunosuppressive drug, has become the drug of choice because of its potency. It is also relatively fast acting (i.e., improvement is seen in 1 month) compared with the slower-acting DMARDs, which can take 3 to 4 months to work. Corticosteroid drugs may be used to reduce discomfort.²⁴ To avoid long-term side effects, they are used only in specific situations for short-term therapy at a low dose level. This medication does not modify the disease and is unable to prevent joint destruction. Intra-articular corticosteroid injections can provide rapid relief of acute or subacute inflammatory synovitis in a few joints.

Newer antirheumatic drugs include leflunomide, etanercept, and infliximab. Leflunomide is a pyrimidine synthesis inhibitor that blocks the expansion of T cells.²⁵ Infliximab (Remicade) and etanercept (Enbrel) are biologic responsemodifying agents that block tumor necrosis factor- α (TNF- α), one of the key proinflammatory cytokines in RA.

Surgery also may be a part of the treatment of RA. Synovectomy may be indicated to reduce pain and joint damage when synovitis does not respond to medical treatment. Total joint replacements (*i.e.*, arthroplasty) may be performed to reduce pain and increase motion. Arthrodesis (*i.e.*, joint fusion) is indicated only in extreme cases when there is so much soft tissue damage and scarring or infection that a replacement is impossible.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease that can affect virtually any organ system, including the skin, joints, kidneys, serosal membranes, and heart. SLE is a major rheumatic disease, and more than 90% of persons with the disease have polyarthralgias. SLE is a fairly common disease with a prevalence of approximately 1 case per 2000 persons in certain populations.²⁶ The peak incidence occurs between ages 15 to 40 years. There is a female-to-male ratio of 9 to 1, with the ratio becoming closer to 30 to 1 during the childbearing years. SLE is more common in African Americans, Hispanics, and Asians than whites, and the incidence in some families is higher than in others.¹⁸

The cause of SLE is unknown. The presence of a wide array of autoantibodies suggests a breakdown in the normal surveillance function of the immune system (see Chapter 10). Antibodies have been identified against a host of nuclear and cytoplasmic components of the cell that are neither tissue nor organ specific. Antinuclear antibodies (ANAs) are directed against several nuclear antigens, including DNA, histones, nonhistone proteins bound to RNA, and nucleolar antigens.²⁶ Another group of antibodies is directed against cell surface antigens of blood elements.

The development of autoantibodies is thought to result from a combination of factors, including genetic, hormonal, immunologic, and environmental factors. Genetic predisposition is evidenced by the occurrence of familial cases of SLE, especially among identical twins. In North American white populations there is a positive association between SLE and class II HLA genes, particularly at the HLA-DQ locus (see Chapter 9).²⁷ Studies also suggest that an imbalance in sex hormone levels may play a role in the development of the disease, especially because the disease is so prevalent among women. Androgens appear to protect against and estrogens seem to favor the development of SLE.¹⁸ Possible environmental triggers include ultraviolet (UV) light, certain drugs, and possibly infectious agents. UV light, specifically UVB associated with exposure to the sun or unshielded fluorescent bulbs, may trigger exacerbations. Photosensitivity occurs in approximately one third of patients with SLE.

Pathogenesis. The pathologic process probably begins with exaggerated production of autoantibodies. The autoantibodies combine with corresponding antigens to form immune complexes. These immune complexes are deposited in vascular and tissue surfaces, triggering an inflammatory response and ultimately causing local tissue injury. Some autoantibodies that have been identified in SLE include anti-deoxyribonucleic acid (DNA). Other antibodies may be produced against various cells, including red blood cell surface antigens, platelets, and coagulation factors. Autoantibodies against red blood cells can lead to anemia and those against platelets to thrombocytopenia. Certain drugs may provoke a lupus-like disorder in sus-

ceptible persons, particularly in the elderly. The most common of these drugs are hydralazine and procainamide. Other drugs, such as quinidine, methyldopa, isoniazid, and phenytoin, also have been known to produce this syndrome. The disease usually recedes when use of the drug is discontinued.

Clinical Course. Systemic lupus erythematosus can manifest in a variety of ways. The disease has been called the *great imitator* because it has the capacity for affecting many different body systems, including the musculoskeletal system, the skin, the cardiovascular system, the lungs, the kidneys, the central nervous system (CNS), and the red blood cells and platelets. The onset may be acute or insidious, and the course of the disease is characterized by exacerbations and remissions.²⁷

Arthralgias and arthritis are among the most commonly occurring early symptoms of SLE; approximately 90% of all persons with the disease report joint pain at some point during the course of their disease.²⁷ The polyarthritis of SLE initially can be confused with other forms of arthritis, especially RA, because of the symmetric arthropathy. Ligaments, tendons, and the joint capsule may be involved, causing varied deformities in approximately 30% of persons with the disease. Flexion contractures, hyperextension of the interphalangeal joint, and subluxation of the carpometacarpal joint contribute to the deformity and subsequent loss of function in the hands. Other musculoskeletal manifestations include tenosynovitis, rupture of the intrapatellar and Achilles tendons, and avascular necrosis, frequently of the femoral head.

Skin manifestations can vary greatly and may be classified as acute, subacute, or chronic. The acute skin lesions include the classic malar or "butterfly" rash on the nose and cheeks (Fig. 43-9). This rash is seen in SLE but may be associated with

other skin lesions, such as hives or livedo reticularis (*i.e.*, reticular cyanotic discoloration of the skin, often precipitated by cold) and fingertip lesions, such as periungual erythema, nail fold infarcts, and splinter hemorrhages. Hair loss is common. Mucous membrane lesions tend to occur during periods of exacerbation. Sun sensitivity may occur in SLE even after mild sun exposure. Discoid SLE (*i.e.*, chronic cutaneous lupus) involves plaquelike lesions on the head, scalp, and neck. These lesions first appear as red, swollen patches of skin, and later there can be scarring, depigmentation, and plugging of hair follicles. Ninety percent of patients with discoid lupus have disease that involves only the skin.

Renal involvement occurs in approximately 50% of persons with SLE. Several forms of glomerulonephritis may occur, including mesangial, focal proliferative, diffuse proliferative, and membranous (see Chapter 23). Interstitial nephritis also may occur. Nephrotic syndrome causes proteinuria with resultant edema in the legs, abdomen, and around the eyes.

The heart and lungs frequently are sites of complications in people with SLE.²⁷ Pulmonary involvement in SLE occurs in 40% to 50% of patients and is manifested primarily by pleural effusions or pleuritis. Less frequently occurring pulmonary problems include acute pneumonitis, pulmonary hemorrhage, chronic interstitial lung disease, and pulmonary embolism. Pericarditis, often accompanied by pleural effusions, is the most common of the cardiac manifestations of SLE. Myocarditis affects as many as 25% of those with SLE. Hypertension may be associated with lupus nephritis and long-term corticosteroid use. Ischemic heart disease can occur in older patients with longer-duration SLE. Hematologic disorders may manifest as hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia.

The CNS is involved in 30% to 75% of persons with SLE. The pathologic basis for the CNS symptoms is not entirely clear. It has been ascribed to an acute vasculitis that impedes blood flow, causing strokes or hemorrhage; an immune response involving antineuronal antibodies that attack nerve cells; or production of antiphospholipid antibodies that damage blood vessels and cause blood clots in the brain. Seizures can occur and are more common when renal failure is present. Psychotic symptoms, including depression and unnatural euphoria, as well as decreased cognitive functioning, confusion, and altered levels of consciousness, may develop.

Subacute cutaneous lupus erythematosus (SCLE) is a less severe form of lupus. The skin lesions in this condition may resemble psoriasis. These lesions are found in sun-exposed areas, such as the face, chest, upper back, and arms. Patients with SCLE may have mild systemic problems, which usually are limited to joint and muscle pains.

Diagnosis and Treatment. The diagnosis of SLE is based on a complete history, physical examination, and analysis of blood work. No single test can diagnose SLE in all persons. The most common laboratory test performed is the immunofluorescence test for ANA. Ninety-five percent of persons with untreated SLE have high ANA levels. Although the ANA test is not specific for lupus, it establishes that the differential diagnosis includes autoimmunity. The anti-DNA antibody test is more specific for the diagnosis of SLE.²⁷ Other serum tests may reveal moderate to severe anemia, thrombocytopenia, and leukocytosis or leukopenia. Additional immunologic tests may be done to give

support to the diagnosis or to differentiate SLE from other connective tissue diseases.

Treatment of SLE focuses on managing the acute and chronic symptoms of the disease. The goals of treatment include preventing progressive loss of organ function, reducing the possibility of exacerbations, minimizing disability from the disease process, and preventing complications from medication therapy.²⁸ Treatment with medications may be as simple as a drug to reduce inflammation, such as an NSAID. NSAIDs can control fever, arthritis, and mild pleuritis. An antimalarial drug (*e.g.*, hydroxychloroquine) may be the next medication considered to treat cutaneous and musculoskeletal manifestations of SLE. Corticosteroids are used to treat more significant symptoms of SLE, such as renal and CNS disorders. Immunosuppressive drugs are used in cases of severe disease.

Systemic Sclerosis

Systemic sclerosis, sometimes called *scleroderma*, is an autoimmune disease of connective tissue characterized by excessive collagen deposition in the skin and internal organs, such as the lungs, gastrointestinal tract, heart, and kidneys. In this disorder, the skin is thickened through fibrosis, with an accompanying fixation of subdermal structures, including the sheaths or fascia covering tendons and muscles.²⁹ Systemic sclerosis affects women four times as frequently as men, with a peak incidence in the 35-year to 50-year age group.¹² The cause of this rare disorder is poorly understood. There is evidence of both humoral and cellular immune system abnormalities.

Scleroderma presents as two distinct clinical entities: the diffuse or generalized form of the disease and the limited or CREST variant. In the CREST syndrome, hardening of the skin (scleroderma) is limited to the hands and face; whereas, the skin changes in diffuse scleroderma also involve the trunk and proximal extremities. Almost all persons with scleroderma develop polyarthritis and Raynaud's phenomenon, a vascular disorder characterized by reversible vasospasm of the arteries supplying the fingers (see Chapter 15).

Diffuse scleroderma is characterized by severe and progressive disease of the skin and the early onset of organ involvement. The typical person has a "stone facies" caused by tightening of the facial skin with restricted motion of the mouth. Involvement of the esophagus leads to hypomotility and difficulty swallowing. Malabsorption may develop if the submucosal and muscular atrophy affect the intestine. Pulmonary involvement leads to dyspnea and eventually respiratory failure. Vascular involvement of the kidneys is responsible for malignant hypertension and progressive renal insufficiency. Cardiac problems include pericarditis, heart block, and myocardial fibrosis.

The CREST syndrome is manifest by calcinosis (*i.e.*, calcium deposits in the subcutaneous tissue that erupt through the skin), Raynaud's phenomenon, esophageal dysmotility, sclerodactyly (localized scleroderma of the fingers), and telangiectasia.³⁰

Treatment of systemic sclerosis is largely symptomatic and supportive. The 9-year survival rate is about 40%.³⁰ Studies have indicated that if heart, lung, or kidney involvement is to become severe, it tends to do so early in disease and is a predictor of shortened survival. Patients who survive the first few years without experiencing severe organ involvement are less likely to experience life-threatening involvement later in their illness.³⁰

Seronegative Spondyloarthropathies

The *spondyloarthropathies* are an interrelated group of multisystem inflammatory disorders that primarily affect the axial skeleton, particularly the spine. Because there is an absence of the RF, these disorders often are referred to as *seronegative spondyloarthropathies*. In contrast to RA, the inflammation begins at sites where tendons and ligament insert into bone, rather than in the synovium. Sacroiliitis is the pathologic hallmark. Persons with the disorder may also have inflammation and involvement of the peripheral joints, in which case the signs and symptoms overlap with other inflammatory types of arthritis. The seronegative spondyloarthropathies include ankylosing spondylitis, reactive arthritis, and psoriatic arthritis.

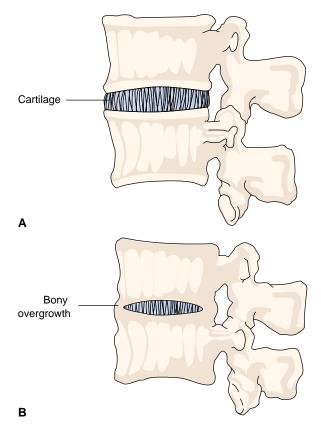

The pathogenesis of the spondyloarthropathies is unclear. However, there is a striking association with the HLA-B27 antigen. The HLA-B27 antigen is also found in the normal population; thus, it is neither necessary nor sufficient for the development of any of the diseases.

Ankylosing Spondylitis

Ankylosing spondylitis is a chronic, systemic inflammatory disease of the joints of the axial skeleton, manifested by pain and progressive stiffening of the spine. The disorder begins in the sacroiliac joints bilaterally and then smaller joints of the posterior elements of the spine. The result is the ultimate destruction of these joints with ankylosis or posterior fusion of the spine. The vertebrae take on a squared appearance, and bone bridges fuse one vertebral body to the next across the intervertebral discs (Fig. 43-10). Progressive spinal changes usually follow an ascending pattern up the spine. Occasionally, large synovial joints (i.e., hips, knees, and shoulders) may be involved. The small peripheral joints usually are not affected. The disease affects approximately 2% to 8% of the HLA-B27positive white population.¹⁸ Clinical manifestations usually begin in late adolescence or early adulthood and are slightly more common in men than in women. The disease spectrum ranges from an asymptomatic sacroiliitis to a progressive disease that can affect many body systems.

The pathogenesis of ankylosing spondylitis remains unclear. The presence of mononuclear cells in acutely involved tissue suggests an immune response in which genetic and environmental factors play a role. The HLA-B27 antigen remains one of the best-known examples of an association between a disease and a hereditary marker. Approximately 90% of those with ankylosing spondylitis have the HLA-B27 antigen, and nearly 100% of those who also have uveitis or aortitis have the marker. Although the mechanism by which HLA-B27 influences the development of ankylosing spondylitis remains to be discovered, it has been proposed that the HLA-B27 antigen and some environmental trigger are structurally related in a manner that induces an autoimmune response.

Clinical Manifestations. The person with ankylosing spondylitis typically reports low back pain, which may be persistent or intermittent. The pain, which becomes worse when resting, particularly when lying in bed, initially may be blamed on muscle strain or spasm from physical activity. Lumbosacral pain also may be present, with discomfort in the buttocks and hip areas. Sometimes, pain can radiate to the thigh in a manner similar to that of sciatic pain. Prolonged stiffness is present in the morning and after periods of rest. Mild physical activity

■ FIGURE 43-10 ■ The bony overgrowth (**B**) of the vertebra characteristic of ankylosing spondylitis is evident when compared with normal vertebra (**A**).

or a hot shower helps reduce pain and stiffness. Sleep patterns frequently are interrupted because of these manifestations. Walking or exercise may be needed to provide the comfort needed to return to sleep. Muscle spasm also may contribute to discomfort.

Loss of motion in the spinal column is characteristic of the disease. The severity and duration of disease activity influence the degree of mobility. Loss of lumbar lordosis occurs as the disease progresses, and this is followed by kyphosis of the thoracic spine and extension of the neck. A kyphotic spine makes it difficult for the patient to look ahead and to maintain balance while walking. The image is one of a person bent over looking at the floor and unable to straighten. X-ray films show a rigid, bamboo-like spine. The heart and lungs are constricted in the chest cavity. Abnormal weight bearing can lead to degeneration and destruction of the peripheral joints, most commonly the hips, shoulders and knees.

The most common extraskeletal involvement is acute anterior uveitis (inflammation of uvea of the eye), which occurs in 25% to 30% of patients sometime in the course of their disease.¹⁸ Systemic features of weight loss, fever, and fatigue may be apparent. Sometimes, the fatigue is a greater problem than pain or stiffness. Osteoporosis can occur, especially in the spine, which contributes to the risk of spinal fracture. Fusion of the costovertebral joints can lead to reduced lung volume.

Diagnosis and Treatment. The diagnosis of ankylosing spondylitis is based on history, physical examination, and x-ray examination. Laboratory findings frequently include an elevated ESR. A mild normocytic normochromic anemia may be present. Because HLA-B27 is found in 8% of the normal population, it is not a specific diagnostic test for the disease. Radiologic evaluations help differentiate sacroiliitis from other diseases.

Treatment is directed at controlling pain and maintaining mobility by suppressing inflammation. Therapeutic exercises are important to assist in maintaining motion in peripheral joints and in the spine. Muscle-strengthening exercises for extensor muscle groups also are prescribed. Immobilizing joints is not recommended. NSAIDs are used to reduce inflammation, which helps to control pain and reduce muscle spasm. Most peripheral joint pain and limitations of motion occur in the hip. Total hip replacement surgery may be used to reduce pain and increase mobility.

Reactive Arthritis

Reactive arthritis refers to a form of peripheral arthritis, often accompanied by one or more extra-articular manifestations, that occurs shortly after certain infections of genitourinary or gastrointestinal systems.^{18,31,32} The majority of affected persons are young men who have inherited the HLA-B27 marker. Two forms of reactive arthritis are Reiter's syndrome and enteropathic arthritis.

Reiter's Syndrome. Reiter's syndrome is considered to be a clinical manifestation of reactive arthritis that may be accompanied by extra-articular symptoms, such as uveitis, bowel inflammation, and carditis. Reiter's syndrome develops in a genetically susceptible host after an infection by bacteria, *Chlamydia trachomatis* in the genitourinary tract, or *Salmonella, Shigella, Yersinia*, or *Campylobacter* in the gastrointestinal tract.

The arthritis is usually asymmetric and frequently involves the large weight-bearing joints (*i.e.*, the knee and ankle); sacroiliitis or ankylosing spondylitis, especially after frequent recurrences. Systemic symptoms include fever and weight loss, both of which are common at the onset of the disease. Several mucocutaneous manifestations, including balanitis, oral lesions, and skin rash are common. The skin rash, which resembles pustular psoriasis, appears most commonly on the soles of feet and palms of hands but may affect any cutaneous area. The toenails and fingernails may become thickened and opaque and may crumble, resembling the changes seen in fungal infections of the nails. Aortitis, with aortic regurgitation occurs in 1% to 2% of persons, typically after longstanding active arthritis. Although most signs of the disease disappear within days or weeks, the arthritis may persist for several months or even years. Recurrences involving any of the combination of clinical manifestations are common and sometimes followed by permanent sequelae, especially in the joints.

The treatment is largely symptomatic. NSAIDs are used to treat the arthritic symptoms. Antibiotics may be of some use in treating the triggering infection.

Enteropathic Arthritis. Arthritis that is associated with an inflammatory bowel disease usually is considered an enteropathic arthritis because the intestinal disease is directly involved in the pathogenesis. Most cases of enteropathic arthritis are classified among the spondyloarthropathies. These include cases in which the arthritis is associated with inflammatory bowel disease (*i.e.*, ulcerative colitis and Crohn's disease), the reactive arthritides triggered by enterogenic bacteria, some of

the undifferentiated spondyloarthropathies, Whipple's disease, and reactions after intestinal bypass surgery.¹⁸ There is no direct relation between the activity of the bowel disease and the degree of arthritis activity.

Psoriatic Arthritis

Psoriatic arthritis occurs in approximately 5% to 7% of people with psoriasis. It is heterogenous disorder with features typical of the spondyloarthropathies in some persons, features of RA in others, and features of both diseases coexisting in yet others.¹⁸

The etiology of psoriasis and psoriatic arthritis is unknown. Genetic, environmental, and immunologic factors appear to influence susceptibility and expression of disease. Environmental factors including infectious agents and physical trauma may play a role in the pathogenesis of the disorder. T cellmediated immune responses also seem to play an important role in the skin and joint manifestations of the disease. Psoriasis improves after treatment with immunosuppressant agents such as cyclosporine.

Psoriatic arthritis may present with a variety of forms, including monoarthritis, asymmetric oligoarthritis, or symmetric polyarthritis. Usually the arthritis is asymmetric with "sausage" appearance of the fingers and toes. Sacroiliac joint involvement is common, and ankylosis of the sacroiliac joints may occur.

Although the arthritis can antedate detectable skin rash, the definitive diagnosis of psoriatic arthritis cannot be made without evidence of skin or nail changes typical of psoriasis. This heterogeneous clinical presentation suggests more than one disease is associated with psoriasis, or various clinical responses to a common cause. At least 20% of those with psoriatic arthritis have an elevated serum level of uric acid. The abnormally elevated serum uric acid level is caused by the rapid skin turnover of psoriasis, the breakdown of nucleic acid, and the metabolism to uric acid. This finding may lead to a misdiagnosis of gout. Psoriatic arthritis tends to be slowly progressive but is associated with a more favorable prognosis than RA.

Basic management is similar to that for the treatment of RA. Suppression of the skin disease may be important in helping control the arthritis. Often, affected joints are surprisingly functional and only minimally symptomatic.

Osteoarthritis Syndrome

Osteoarthritis (OA), formerly called *degenerative joint disease*, is the most prevalent form of arthritis. It is second only to cardiovascular disease as the cause of chronic disability in adults.³³ The term *osteoarthritis* encompasses a heterogeneous collection of syndromes and is more of a disease process than a specific entity. It can occur as a primary idiopathic or a secondary disorder, although this distinction is not always clear. Idiopathic or primary variants of OA occur as localized or generalized (*i.e.*, more than three joints) syndromes. Secondary OA has a known underlying cause, such as congenital or acquired defects of joint structures, trauma, metabolic disorders, or inflammatory diseases (see Chart 43-3).

One third of all adults in the United States have radiographic evidence of osteoarthritis of the hand, foot, knee, or hip. Sex and age interact to influence the time of onset and, with race, the pattern of joint involvement. Men are affected more commonly at a younger age than women, but the rate of women affected exceeds that of men by middle age. Hand OA is more likely to affect white women, whereas knee OA is more

Idiopathic or primary variants	FIGURE 43-11 Disease process in osteoarthritis.

common in black women. Obesity is a risk factor for OA of the knee in women and a contributory biomechanical factor in the pathogenesis of the disease. Excess fat may have a direct metabolic effect on cartilage beyond the effects of excess joint stress. Heredity influences the occurrence of hand OA in the DIP joint. Bone mass may also influence the risk of developing OA. In theory, thinner subchondral bone mass may provide a greater shock-absorbing function than denser bone, allowing less direct trauma to the cartilage.

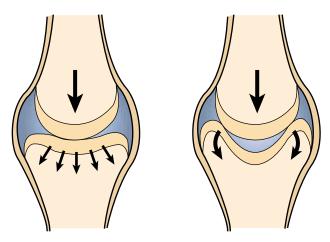

Osteoarthritis is a disorder of the articular cartilage and subchondral bone (*i.e.*, bony plate that supports the articular cartilage) of diarthrodial joints. The joint changes associated with OA are progressive loss of articular cartilage and synovitis resulting from the inflammation caused by the attempts of the bone to remold itself, creating osteophytes or spurs (Fig. 43-11). These changes are accompanied by joint pain, stiffness, limitation of motion, and possibly by joint instability and deformity. Although there may be periods of mild inflammation, it is not the severe, destructive type seen in the inflammatory forms of rheumatic diseases such as RA.

Pathogenesis

The pathogenesis of OA resides in the homeostatic mechanisms that maintain the articular cartilage. Cartilage is a specialized type of connective tissue. As with other types of tissue, it consists of cells (*i.e.*, chondrocytes) nested in an extracellular matrix. In articular cartilage, the extracellular matrix is composed of water, ground substance, collagen, and proteoglycans. The ground substance constitutes a highly hydrated, semisolid gel. Collagen molecules consist of polypeptide chains that form long fibrous strands. The primary function of the collagen fibers is to provide a rigid scaffold to support the chondrocytes and ground substance of cartilage. The proteoglycans, which are large macromolecules made up of disaccharides and amino acids, afford elasticity and stiffness, permitting articular cartilage to resist compression. They also provide a film of interstitial fluid that contributes to the lubrication of the joint. Under high loads such as weight bearing, fluid squeezes out of the cartilage with compression of the opposing surfaces of the joint. The greater the load is, the better the lubrication. With depletion of proteoglycans from the cartilage matrix in OA, the mechanisms that normally operate under high loads to produce a pressurized lubricating film may be impaired.

Articular cartilage plays two essential mechanical roles in joint physiology. First, the articular cartilage serves as a remarkably smooth weight-bearing surface. In combination with synovial fluid, the articular cartilage provides extremely low friction during movement of the joint. Second, the cartilage transmits the load down to the bone, dissipating the mechanical stress. The subchondral bone protects the overlying articular cartilage, providing it with a pliable bed and absorbing the energy of the force (Fig. 43-12).

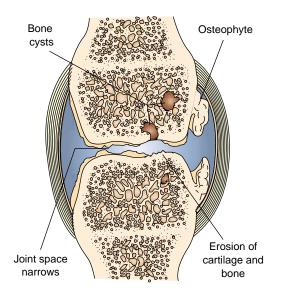

Popularly known as *wear and tear* arthritis, the changes that occur to the articular cartilage in OA are complex. The first recognizable change in OA is edema of the extracellular matrix, principally the intermediate layer. The cartilage loses its smooth aspect, and surface cracks occur allowing synovial fluid to enter and widen the crack. As the crack deepens, the vertical clefts form in the subchondral bone cartilage. Clusters of chondrocytes appear around these clefts and at the surface. Fissures cause fragments of cartilage to become dislodged and enter the articular cavity, creating osteocartilaginous loose bodies and

■ FIGURE 43-12 ■ (Left) A joint normally undergoes deformation of the articular cartilage and the subchondral bone when carrying a load. This maximizes the contact area and spreads the force of the load. (**Right**) If the joint does not deform with a load, the stresses are concentrated and the joint breaks down. (Redrawn from Brandt K.D. & Radin E. [1987]. The physiology of articular stress: Osteoarthroses. *Hospital Practice* [January 15], 111)

uncovering areas of subchondral bone. Sclerosis, or formation of new bone and cysts, usually occurs in the juxta-articular bone (*i.e.*, bone near the joint). New bone that forms at the joint margins is called an *osteophyte*, or spur.

The articular cartilage injury that occurs in OA is thought to result from the release of cytokines such as interleukin-1 and TNF (Fig. 43-13).¹⁸ These chemical messengers stimulate the production and release of proteases (enzymes) that are destructive to joint structures. The resulting damage predisposes the chondrocytes to more injury. The earliest changes in OA are

■ FIGURE 43-13 ■ Joint changes in osteoarthritis. The left side denotes early changes and joint space narrowing with cartilage breakdown. The right side shows more severe disease progression with lost cartilage and osteophyte formation.

the loss of proteoglycans from the surface of the articular cartilage, followed by death of the chondrocytes. Inadequate repair mechanisms and imbalances between the proteases and their inhibitors may contribute further to disease progression.

Immobilization also can produce degenerative changes in articular cartilage. Cartilage degeneration caused by immobility may result from loss of the pumping action of lubrication that occurs with joint movement. These changes are more marked and appear earlier in areas of contact but occur also in areas not subject to mechanical compression. Although cartilage atrophy is rapidly reversible with activity after a period of immobilization, impact exercise during the period of remobilization can prevent reversal of the atrophy. Thus, slow and gradual remobilization may be an important aspect in preventing cartilage injury. Clinically, it has implications for instructions concerning the recommended level of physical activity after removal of a cast.

Clinical Manifestations

The manifestations of OA may occur suddenly or insidiously. Initially, pain may be described as aching and may be somewhat difficult to localize. It worsens with use or activity and is usually relieved by rest. In later stages of disease activity, pain may be experienced during rest and for several hours after the use of the involved joints. Crepitus and grinding may be evident when the joint is moved. As the disease advances, even minimal activity may cause pain because of the limited range of motion resulting from intra-articular and periarticular structural damage.

The most frequently affected joints are the hips, knees, lumbar and cervical vertebrae, proximal and distal joints of the hand, the first carpometacarpal joint, and the first metatarsophalangeal joints of the feet. A single joint or several may be affected. Although a single weight-bearing joint may be involved initially, other joints often become affected because of the additional stress placed on them while trying to protect the original joint. It is not unusual for a person having a knee replacement to discover soon after the surgery is done that the second knee also needs to be replaced. Other clinical features are limitations of joint motion and joint instability. Joint enlargement usually results from new bone formation; the joint feels hard, in contrast to the soft, spongy feeling characteristic of the joint in RA. Sometimes, mild synovitis or increased synovial fluid can cause joint enlargement.

Diagnosis and Treatment

The diagnosis of OA usually is determined by history and physical examination, x-ray studies, and laboratory findings that exclude other diseases. Although OA often is contrasted with RA for diagnostic purposes, the differences are not always readily apparent. Other rheumatic diseases may be superimposed on OA.

Characteristic radiologic changes initially include medial joint space narrowing, followed by subchondral bony sclerosis, formation of spikes on the tibial eminence, and osteophytes. The results of laboratory studies usually are normal because the disorder is not a systemic disease. The ESR may be slightly elevated in generalized OA or erosive inflammatory variations of the disease. If inflammation is present, there may be a slight increase in the blood cell count. The synovial fluid usually is normal. Because there is no cure, the treatment of OA is symptomatic and includes physical rehabilitative, pharmacologic, and surgical measures. Physical measures are aimed at improving the supporting structures of the joint and strengthening opposing muscle groups involved in cushioning weight-bearing forces. These include a balance of rest and exercise, use of splints to protect and rest the joint, use of heat and cold to relieve pain and muscle spasm, and adjusting the activities of daily living. The involved joint should not be further abused, and steps should be taken to protect and rest it. This includes weight reduction (when weight-bearing surfaces are involved) and the use of a cane or walker if the hips and knees are involved. Muscle-strengthening exercises may help protect the joint and decrease pain.³⁴

Pharmacologic treatment is aimed at reducing inflammation or providing analgesia. The most common medications used in the treatment of OA are the NSAIDs, many of which are available without a prescription. For many persons, acetaminophen in doses as high as 4000 mg/day may be as effective and less toxic than NSAIDs. Corticosteroid injections may be used for relieving symptoms, especially for those who have an effusion of the joint. Injections usually are limited to a total of four and not more than three within 1 year because their use is thought to accelerate joint destruction.³⁴

Surgery is considered when the person is having severe pain and joint function is severely reduced. Procedures include arthroscopic lavage and debridement, bunion resections, osteotomies to change alignment of the knee and hip joints, and decompression of the spinal roots in osteoarthritic vertebral stenosis. Total hip replacements have provided effective relief of symptoms and improved range of motion for many persons, as have total knee replacements, although the latter procedure has produced less consistent results.

Crystal-Induced Arthropathies

Crystal deposition in joints produces arthritis. In gout, monosodium urate or uric acid crystals are found in the joint cavity. Another condition in which calcium pyrophosphate dihydrate crystals are found in the joints sometimes is referred to as *pseudogout* or *chondrocalcinosis*. A brief discussion of pseudogout is provided in the section on rheumatic diseases in the elderly.

Gout

Gout is actually a group of diseases known as the *gout syndrome*. It includes acute gouty arthritis with recurrent attacks of severe articular and periarticular inflammation; tophi or the accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage; gouty nephropathy or renal impairment; and uric acid kidney stones.

The term *primary gout* is used to designate cases in which the cause of the disorder is unknown or an inborn error in metabolism and is characterized primarily by hyperuricemia and gout. Primary gout is predominantly a disease of men, with a peak incidence in the fourth or sixth decade. In secondary gout, the cause of the hyperuricemia is known but the gout is not the main disorder. Asymptomatic hyperuricemia is a laboratory finding and not a disease. Most persons with hyperuricemia do not develop gout.

Pathogenesis. The pathogenesis of gout resides in an elevation of the serum uric acid levels. Uric acid is the end product of purine (adenine and guanine from DNA and RNA) metabolism.³⁵ Two pathways are involved in purine synthesis: (1) a de novo pathway, in which purines are synthesized from nonpurine precursors, and (2) the salvage pathway, in which purine bases are recaptured from the breakdown of nucleic acids derived from exogenous (dietary) or endogenous sources. The elevation of uric acid and the subsequent development of gout can result from (1) overproduction of purines, (2) decreased salvage of free purine bases, (3) augmented breakdown of nucleic acids as a result of increased cell turnover, or (4) decreased urinary excretion of uric acid. Primary gout, which constitutes 90% of cases, results from enzyme defects that result in an overproduction of uric acid, inadequate elimination of uric acid by the kidney, or a combination of the two. In most cases, the reason is unknown. In secondary gout the hyperuricemia may be caused by increased breakdown of nucleic acids production, as occurs with rapid tumor cell lysis during treatment for lymphoma or leukemia. Other cases of secondary gout result from chronic renal disease. Some of the diuretics, including the thiazides, can interfere with the excretion of uric acid.

An attack of gout occurs when monosodium urate crystals precipitate in the joint and initiate an inflammatory response. Synovial fluid is a poorer solvent for uric acid than plasma, and uric acid crystals are even less soluble at temperatures below 37°C.12 Crystal deposition usually occurs in peripheral areas of the body, such as the great toe, where the temperatures are cooler than other parts of the body. With prolonged hyperuricemia, crystals and microtophi accumulate in the synovial lining cells and in the joint cartilage. The released crystals are chemotactic to leukocytes and also activate complement, leading to inflammation and destructive changes to the cartilage and subchondral bone. Repeated attacks of acute arthritis eventually lead to chronic arthritis and the formation of tophi. Tophi are large, hard nodules that have irregular surfaces and contain crystalline deposits of monosodium urate¹² (Fig. 43-14). They are found most commonly in the synovium, olecranon bursa, Achilles tendon, subchondral bone, and extensor surface of the forearm and may be mistaken for rheumatoid nodules. Tophi usually do not appear until 10 years or more after the first gout attack. This stage of gout, called chronic tophaceous gout, is characterized by more frequent and prolonged attacks, which often are polyarticular.

Clinical Manifestations. The typical acute attack of gout is monoarticular and usually affects the first metatarsophalangeal joint. The tarsal joints, insteps, ankles, heels, knees, wrists, fingers, and elbows also may be initial sites of involvement. Acute gout often begins at night and may be precipitated by excessive exercise, certain medications, foods, alcohol, or dieting. The onset of pain typically is abrupt, and redness and swelling are observed. The attack may last for days or weeks. Pain may be severe enough to be aggravated even by the weight of a bed sheet covering the affected area.

In the early stages of gout after the initial attack has subsided, the person is asymptomatic, and joint abnormalities are not evident. This is referred to as *intercritical gout*. After the first attack, it may be months or years before another attack. As attacks recur with increased frequency, joint changes occur and become permanent.

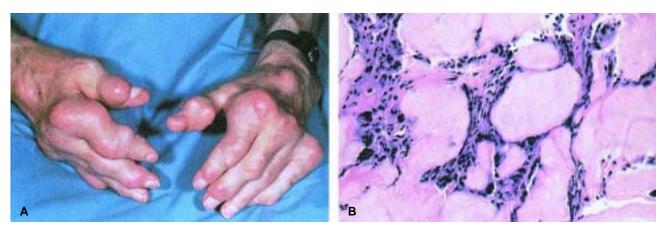

FIGURE 43-14 Gout. (**A**) Gouty tophi project from the fingers as rubbery nodules. (**B**) A section from a trophus shows extracellular masses of urate crystals with accompanying foreign-body giant cells. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1404]. Philadelphia: Lippincott Williams & Wilkins)

Diagnosis and Treatment. Although hyperuricemia is the biochemical hallmark of gout, the presence of hyperuricemia cannot be equated with gout because many persons with this condition never develop gout. A definitive diagnosis of gout can be made only when monosodium urate crystals are in the synovial fluid or in tissue sections of tophaceous deposits. Synovial fluid analysis is useful in excluding other conditions, such as septic arthritis, pseudogout, and RA.³⁶ Diagnostic methods also include measures to determine if the disorder is related to overproduction or to underexcretion of uric acid.

The objectives for treatment of gout include the termination and prevention of the acute attacks of gouty arthritis and the correction of hyperuricemia, with consequent inhibition of further precipitation of sodium urate and absorption of urate crystal deposits already in the tissues. Some changes in lifestyle may be needed, such as maintenance of ideal weight, moderation in alcohol consumption, and avoiding purinerich foods, such as liver, kidney, sardines, anchovies, and sweetbreads, particularly by persons with excessive tophaceous deposits.

Pharmacologic management of acute gout is directed toward reducing joint inflammation. Hyperuricemia and related problems of tophi, joint destruction, and renal problems are treated after the acute inflammatory process has subsided. NSAIDs, particularly indomethacin and ibuprofen, are used for treating acute gouty arthritis. Alternative therapies include colchicine and intra-articular deposition of corticosteroids. Treatment with colchicine is used early in the acute stage. Colchicine produces its anti-inflammatory effects by inhibition of leukocyte migration and phagocytosis.

Treatment of hyperuricemia is aimed at maintaining normal uric acid levels and is lifelong. Two classes of drugs may be used. Allopurinol prevents the production of uric acid, and uricosuric drugs, such as probenecid or sulfinpyrazone, may be used to prevent the tubular reabsorption of urate and increase its excretion.³⁰ Prophylactic colchicine or NSAIDs may be used between gout attacks. If the uric acid level is normal and the person has not had recurrent attacks of gout, the use of these medications may be discontinued.³⁵ **In summary**, rheumatoid arthritis is a chronic systemic inflammatory disorder affecting multiple joints. Women are affected more frequently than men. Joint involvement, which is symmetric, begins with inflammatory changes of the synovium and formation of a destructive granulation tissue called *pannus* that leads to joint instability and eventual deformity. Systemic manifestations include weakness, anorexia, weight loss, and low-grade fever. Extra-articular features include rheumatoid nodules and vasculitis.

Systemic lupus erythematosus is a chronic autoimmune disorder that affects multiple body systems. There is no known cause of SLE, but the disease may result from an immunoregulatory disturbance brought about by a combination of genetic, hormonal, and environmental factors. Some drugs have been shown to induce lupus, especially in the elderly. There is an exaggerated production of autoantibodies, which interact with antigens to produce an immune complex. These immune complexes produce an inflammatory response in affected tissues. Systemic sclerosis, often prefixed by the term *progressive*, is sometimes called *scleroderma*. In this disorder, the skin is thickened through fibrosis with an accompanying fixation to the subdermal structures, including the sheaths or fascia covering tendons and muscles.

The spondyloarthropathies affect the axial skeleton, particularly the spine. Inflammation develops at sites where ligaments insert into bone. Because they lack the RF, they are referred to as *seronegative spondyloarthropathies*. They include ankylosing spondylitis, reactive arthritis, and psoriatic arthritis. Ankylosing spondylitis is considered a prototype of this classification category. Bilateral sacroiliitis is the primary feature of ankylosing spondylitis. The disease spectrum ranges from asymptomatic sacroiliitis to a progressive disorder affecting many body systems. The cause remains unknown; however, a strong association between the HLA-B27 antigen and ankylosing spondylitis has been identified. Loss of motion in the spinal column is characteristic of the disease. Peripheral arthritis may occur in some persons. Osteoarthritis, the most common form of arthritis, is a localized condition affecting primarily the weight-bearing joints. Risk factors for OA progression include older age, OA in multiple joints, neuropathy, and for knees, obesity. The disorder is characterized by degeneration of the articular cartilage and subchondral bone. As cartilage ages, biochemical events such as collagen fatigue and fracture occur with less stress. Attempts at repair by increased matrix synthesis and cellular proliferation maintain the integrity of the cartilage until failure of reparative processes allows the degenerative changes to progress. Pain and stiffness are primary features of the disease. Inflammatory mediators (*e.g.*, prostaglandins) may increase the inflammatory and degenerative response.

Gout is a crystal-induced arthropathy. Acute attacks of arthritis occur with gout and are characterized by the presence of monosodium urate crystals in the joint. The disorder is accompanied by hyperuricemia, which results from overproduction of uric acid or from the reduced ability of the kidney to rid the body of excess uric acid. Management of acute gout is directed first toward the reduction of joint inflammation; then the hyperuricemia is treated. Hyperuricemia is treated with uricosuric agents, which prevent the tubular reabsorption of urate, or with medication that inhibits the production of uric acid.

RHEUMATIC DISEASES IN CHILDREN AND THE ELDERLY

Rheumatic Diseases in Children

Children can be affected with almost all of the rheumatic diseases. In addition to disease-specific differences, these conditions affect not only the child but the family. Growth and development require special attention. Rheumatic disorders of children include juvenile rheumatoid arthritis, systemic lupus erythematosus, and juvenile spondyloarthropathies.

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis (JRA) is a chronic disease that affects approximately 60,000 to 200,000 children in the United States.¹⁸ It is characterized by synovitis and can influence epiphyseal growth by stimulating growth of the affected side. Generalized stunted growth also may occur.

Systemic onset (*i.e.*, Still's disease) affects approximately 20% of children with JRA.¹⁸ The symptoms of Still's disease include a daily intermittent high fever, which usually is accompanied by a rash, generalized lymphadenopathy, hepatosplenomegaly, leukocytosis, and anemia. Most of these children also have joint involvement. Systemic symptoms usually subside in 6 to 12 months. This form of JRA also can make an initial appearance in adulthood. Infections, heart disease, and adrenal insufficiency may cause death.

A second subgroup of JRA, pauciarticular arthritis, affects no more than four joints. This disease affects 55% to 75% of children with JRA. Pauciarticular arthritis affects two distinct groups. The first group generally consists of girls younger than 6 years of age with chronic uveitis. The results of ANA testing in this group usually are positive. The second group, characterized by late-onset arthritis, is made up mostly of boys. The HLA-B27 test results are positive in more than one half of this group. They are affected by sacroiliitis, and the arthritis usually occurs in the lower extremities.

The third subgroup of JRA, accounting for approximately 20% of the total, is polyarticular onset disease. It affects more than four joints during the first 6 months of the disease. This form of arthritis more closely resembles the adult form of the disease than the other two subgroups. RF sometimes is present and may indicate a more active disease process. Systemic features include a low-grade fever, weight loss, malaise, anemia, stunted growth, slight organomegaly (*e.g.*, hepatosplenomegaly), and adenopathy.¹⁸

The prognosis for most children with rheumatoid arthritis is good. NSAIDs are the first-line drugs used in treating JRA. Salicylates have been replaced by agents such as naproxen, ibuprofen, and ketoprofen. The second-line agent is low-dose methotrexate or, less often, sulfasalazine. Gold salts, hydroxychloroquine, and D-penicillamine rarely are used.³⁷ Other aspects of treatment of children with JRA are similar to those used for the adult with rheumatoid arthritis. Children are encouraged to lead as normal a life as possible.

Juvenile Spondyloarthropathies

Ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and spondyloarthropathies associated with ulcerative colitis and regional enteritis can affect children and adults. In children, spondyloarthritis manifests in peripheral joints first, mimicking pauciarticular JRA, with no evidence of sacroiliac or spine involvement for months to years after onset. The spondyloarthropathies are more common in boys and commonly occur in children who have a positive family history. HLA-B27 typing is helpful in diagnosing the disease in children because of the unusual presentation of the disease.

Management of the disease involves physical therapy, education, and attention to school and growth and development issues. Medication includes the use of salicylates or other NSAIDs such as tolmetin or indomethacin. More severe disease or symptoms may require systemic corticosteroids.¹⁸

Rheumatic Diseases in the Elderly

Arthritis is the most common complaint of elderly persons. The pain, stiffness, and muscle weakness affect daily life, often threatening independence and quality of life. Symptoms of the rheumatic diseases also can have an indirect effect and even threaten the duration of life for the elderly. The weakness and gait disturbance that often accompany the rheumatic diseases can contribute to falls and fractures, causing suffering, increased health care costs, further loss of independence, and the potential for a decreased life span.

There are differences in the manifestations, diagnosis, and treatment of some of the rheumatic diseases in the elderly. Older patients often have multiple problems complicating diagnosis and management. The diagnosis of an elderly patient with a musculoskeletal problem must consider a wide variety of disorders that usually are regarded as outside the range of typical rheumatic disease. Among these are metastatic malignancy, multiple myeloma, musculoskeletal disorders accompanying endocrine or metabolic disorders, orthopedic conditions, and neurologic disease.

Osteoarthritis is by far the most common form of arthritis among the elderly. It is the greatest cause of disability and limitation of activity in older populations. The prevalence of rheumatoid arthritis increases with advancing age, at least until 75 years of age.³⁸

Polymyalgia Rheumatica

Of the various forms of rheumatic disease affecting the elderly, polymyalgia rheumatica is one of the more difficult to diagnose and one of the most important to identify. It is a common syndrome of older patients, rarely occurring before age 50 and usually after age 60 years. Elderly women are especially at risk.

The clinical manifestations of polymyalgia rheumatica include pain and stiffness of the shoulder and pelvic girdle areas. The onset can be abrupt, with the patient going to bed feeling well and awakening with pain and stiffness in the neck, shoulders, and hips. These symptoms may be accompanied by fever, malaise, and weight loss. Because of the shoulder and pelvic area weakness, persons with disorder often have trouble combing their hair, putting on a coat, and getting out of a chair.

A certain percentage of patients with polymyalgia rheumatica also have giant cell arteritis (also called temporal arteritis). The two conditions are considered to represent different manifestations of the same disease. Giant cell arteritis, a form of systemic vasculitis, is a systemic inflammatory disease of large and medium-size arteries (see Chapter 15). It predominantly affects branches of arteries originating from the aortic arch, including the superficial temporal, vertebral, ophthalmic, and posterior ciliary arteries. The disorder often is insidious in onset and may be heralded by the sudden onset of headache, tenderness over the artery, swelling and redness of the overlying skin, blurred vision or diplopia, and facial pain.

The diagnosis of polymyalgia rheumatica is based on the pain and stiffness persisting for at least 1 month and an elevated ESR. The diagnosis is confirmed when the symptoms respond dramatically to a small dose of prednisone, a corticosteroid. For patients with an elevated ESR, the diagnosis usually is based on a 3-day trial of prednisone treatment.³⁸ People with polymyalgia rheumatica typically exhibit striking clinical improvement approximately the second day. Treatment with NSAIDs provides relief for some patients, but most require continuing therapy with prednisone, with gradual reduction of the dose over the course of 1.5 to 2 years, using the patient's symptoms as the primary guide. Treatment of persons with giant cell arteritis requires use of high-dose prednisone to prevent loss of vision.

Pseudogout

As part of the tissue-aging process, OA develops with associated cartilage degeneration. Calcium pyrophosphate crystals are shed into the joint cavity. These crystals may produce a low-grade chronic inflammation—the chronic pseudogout syndrome. The accumulation of calcium pyrophosphate and related crystalline deposits in articular cartilage is common in the elderly. There are no medications that can remove the crystals from the joints. Although it may be asymptomatic, presence of the crystals may contribute to more rapid cartilage deterioration. This condition may coexist with severe OA.

In summary, rheumatic diseases that affect children can be similar to the adult diseases, but there also are manifestations unique to the younger population. JRA is a chronic disease, characterized by synovitis, that can influence epiphyseal growth. One subgroup of the JRA (Still's disease) presents with systemic manifestations that include a daily intermittent high fever, rash, generalized lymphadenopathy, hepatosplenomegaly, leukocytosis, and anemia. A second subgroup, pauciarticular JRA, affects no more than four joints. The third subgroup of JRA affects more than four joints during the first 6 months of the disease and is similar to the adult form of the disease. Managing rheumatic diseases in children requires a team approach to address issues of the family, school, growth and development, and coping strategies and requires a comprehensive disease management program.

Arthritis is the most common complaint of the elderly population. The pain, stiffness, and muscle weakness affect daily life, often threatening independence and quality of life. There is a difference in the manifestations, diagnosis, and treatment of some of the rheumatic diseases in the elderly compared with those in the younger population. One form of rheumatic disease that has a predilection for the elderly is polymyalgia rheumatica. A certain percentage of patients with polymyalgia rheumatica also have giant cell arteritis, frequently with involvement of the ophthalmic arteries.

REVIEW QUESTIONS

Describe the roles of osteoclasts and osteoblasts in terms of bone remodeling and relate to the pathogenesis of osteoporosis.

Explain how factors that affect bone mass during childhood and early adult life influence the risk of osteoporosis, and relate factors such as diet, exercise, and gonadal hormones to the risk of the osteoporosis.

Describe the pathogenesis and manifestations of osteomalacia and rickets.

- Characterize the cause and manifestations of Paget's disease.
- Describe the difficulty in defining the term arthritis.
- Compare rheumatoid arthritis and osteoarthritis in terms of pathogenesis, joint involvement, level of inflammation, and local and systemic manifestations.
- Compare rheumatoid arthritis and osteoarthritis in terms of pathogenesis, joint pathology, and treatment.

Describe the immunologic process that occurs in systemic lupus erythematosus.

Contrast and compare ankylosing spondylitis, reactive arthritis, and psoriatic arthritis in terms of cause, pathogenesis, and clinical manifestations.

Describe the clinical manifestations, diagnostic measures, and methods used in the treatment of gouty arthritis.

List three types of juvenile rheumatoid arthritis and differentiate among their major characteristics.

Characterize the manifestations of polymyalgia rheumatica, a common musculoskeletal disorder affecting the elderly.

he skin is one of the most versatile organs of the body. It forms a protective surface that prevents many harmful substances, including microorganisms, from entering the body; it retards the loss of body fluids; it helps regulate body temperature; and it houses sensory receptors, contains immune system cells, synthesizes chemicals, and excretes small quantities of waste products. The skin is also unique in that the manifestations of disease or injury are immediately observable. It also provides a sensitive reflection of many internal disorders. A number of systemic diseases are manifested by skin disorders (*e.g.*, rash associated with systemic lupus erythematosus and jaundice caused by liver disease).

STRUCTURE OF THE SKIN

The skin is one of the largest organs of the body and accounts for about 7% of total body weight in the average adult. The skin, which is also called the *integument*, which simply means "covering," serves as an interface between the internal and external environments.^{1,2} The skin is tough, yet pliable, allowing it to endure the effects of any number of external agents. Although the skin may become bruised, lacerated, burned, or infected, it has remarkable properties that allow for a continuous cycle of healing, shedding, and cell regeneration.

Layers of the Skin

The skin is composed of three rather distinct layers: the epidermis, dermis, and subcutaneous tissues. The layer of subcutaneous tissue binds the dermis to the underlying tissues of the body (Fig. 44-1). The basal lamina (basement membrane) is a layer of intercellular and extracellular matrices that serves as an interface between the dermis and the epidermis. It provides for adhesion of the dermis to the epidermis and serves as a selective filter for molecules moving between the two layers. It is also a major site of immunoglobulin and complement deposition in skin disease. The basal lamina is involved in skin disorders that cause bullae or blister formation.

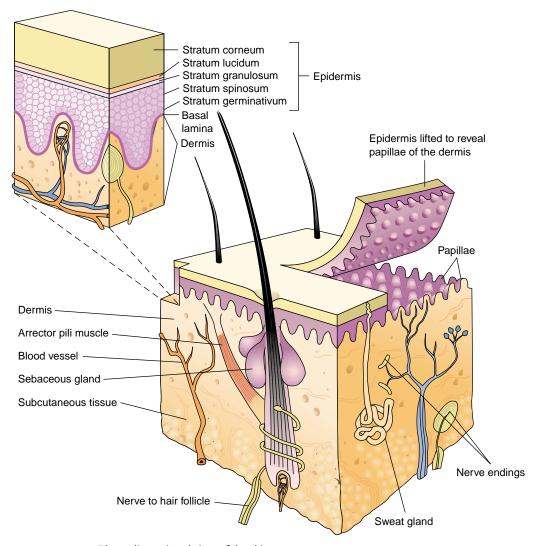

Epidermis

The epidermis contains the keratinocytes, which produce a fibrous protein called *keratin*, which is essential to the protective function of skin. Because of its high keratin content, the outer layer of the epidermis has a rough, horny texture. In addition to the keratinocytes, the epidermis has three other types of cells that arise from its basal layer: melanocytes that pro-

duce a pigment called *melanin*, which is responsible for skin color; Merkel's cells that provide sensory information; and Langerhans' cells that link the epidermis to the immune system. The epidermis contains openings for two types of glands: sweat glands, which produce watery secretions, and sebaceous glands, which produce an oily secretion called *sebum*.

Keratinocytes. The keratinocytes, or keratin-forming cells, are the major cells of the epidermis. They develop into five distinct layers, or strata, as they divide and mature: the stratum germinativum, the stratum spinosum, the stratum granulosum, the stratum lucidum, and the stratum corneum.

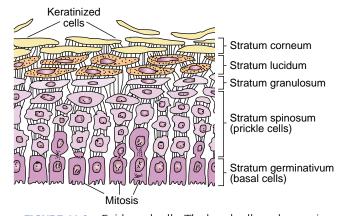

The deepest layer, the *stratum germinativum* or *stratum basale*, consists of a single layer of basal cells that are attached to the basal lamina. The basal cells are the only epidermal cells that are mitotically active. All cells of the epidermis arise from this layer. As new cells form in the basal layer, the older cells change shape and are pushed outward (Fig. 44-2). As these cells near the surface, they die and their cytoplasm is converted to keratin. It normally takes 3 to 4 weeks for the epidermis to replicate itself. This cell turnover is greatly accelerated in diseases such as psoriasis.

SKIN STRUCTURES AND THE MANIFESTATIONS OF SKIN DISORDERS

- The skin has two layers, an outer epidermis and an inner dermis, separated by a basement membrane, all of which can contribute to the development and symptomatology of skin disorders.
- The epidermis, which is avascular, is composed of four to five layers of stratified squamous keratinized epithelial cells that are formed in the deepest layer of the epidermis and migrate to the skin surface to replace cells that are lost during normal skin shedding. The papulosquamous dermatoses, such as psoriasis, involve increased epidermal cell turnover with marked thickening of the epidermis. The avascular layers of the epidermis also serve as a site for superficial fungal infections.
- The basement membrane is a thin adhesive layer that cements the epidermis to the dermis. This is the layer involved in blister formation.
- The dermis is a connective tissue layer that separates the epidermis from the underlying subcutaneous fat layer. It contains the blood vessels that produce hyperemic skin responses and nerve fibers that are the source of pain, discomfort, and itch associated with skin disorders.
- The Langerhans' cells of the epidermis, which bind antigen; the dermal dendrocytes of the dermis, which have phagocytic properties; and immune cells (T cells and mast cells), which are found in the dermis, contribute to the antigen-antibody responses affecting the skin.
- Sebaceous glands in the skin produce an oily secretion called sebum, which is secreted into the hair follicles on the skin. The hair follicle and sebaceous gland form the pilosebaceous unit, which is the site of acne lesions.

The second layer, the *stratum spinosum*, is formed as cells from the basal cell layer move outward toward the skin surface. The stratum spinosum is two to four layers thick. The cells of this layer are commonly referred to as *prickle cells* because they develop a spiny appearance as their cell borders interact. The third layer, the *stratum granulosum* is only a few cells thick; it is composed of flatter cells containing protein granules called *keratohyalin granules*. The *stratum lucidum*, which lies just superficial to the stratum granulosum, is a thin, transparent layer mostly confined to the palms of the hands and soles of the feet. It consists of transitional cells that retain some of the functions of living skin cells from the layers below but otherwise resemble the cells of the stratum corneum.

■ FIGURE 44-2 ■ Epidermal cells. The basal cells undergo mitosis, producing keratinocytes that change their size and shape as they move upward, replacing cells that are lost during normal cell shedding.

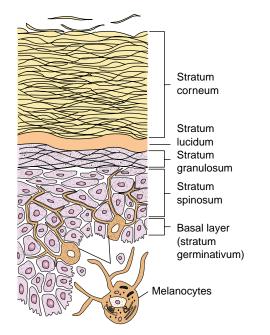

The top or surface layer of the epidermis is the *stratum corneum*. It is made up of stratified layers of dead keratinized cells that are constantly shedding. The stratum corneum contains the most cell layers and the largest cells of any zone of the epidermis. It ranges from 15 layers thick in areas such as the face to 25 layers or more on the arm. Specialized areas, such as the palms of the hands or soles of the feet, have 100 or more layers.

Melanocytes. The melanocytes are pigment-synthesizing cells that are located at or in the basal layer. They function to produce pigment granules called *melanin*, the black or brown substance that gives skin its color. The melanocytes have long, cytoplasm-filled extensions that extend between the keratinocytes. Although the melanocytes remain in the basal layer, melanin is transferred to the keratinocytes through these extensions (Fig. 44-3). Each melanocyte is capable of supplying several keratinocytes with melanin. The primary function of melanin is to protect the skin from harmful ultraviolet sun rays. Exposure to the sun's ultraviolet rays increases the production of melanin, causing tanning to occur. The amount of melanin in the keratinocytes determines a person's skin color. All people have relatively few or no melanocytes in the epidermis of the palms of the hands or soles of the feet.

The ability to synthesize melanin depends on the ability of the melanocytes to produce an enzyme called *tyrosinase*, which converts the amino acid tyrosine to a precursor of melanin. A genetic lack of this enzyme results in a clinical condition called *albinism*. Persons with this disorder lack pigmentation in the skin, hair, and iris of the eye.

Langerhans' Cells. Langerhans' cells are star-shaped macrophages of the immune system (see Chapter 8). They arise from the bone marrow and migrate to the epidermis, where they help activate the immune system. Their slender dendritic, or threadlike processes, extend through the keratinocytes in the epidermis, forming a more or less continuous network recognizing foreign antigens (Fig. 44-4). The Langerhans' cells bind antigen to their surface, process it, and then, bearing the processed antigen, migrate from the epidermis into lymphatic vessels and then into regional lymph nodes. They are the only

838 Unit Eleven: Alterations in the Skeletal and Integumentary Systems

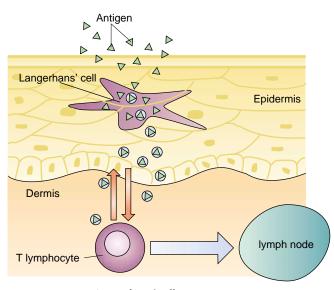

■ FIGURE 44-3 ■ Melanocytes. The melanocytes, which are located in the basal layer of the skin, produce melanin pigment granules that give skin its color. The melanocytes have threadlike cytoplasmic-filled extensions that are used in passing the pigment granules to the keratinocytes.

immune cells in the skin known to be capable of antigenpresentation and therefore may be responsible for allergic reactions affecting the skin.

Dermis

The dermis is the connective tissue layer that separates the epidermis from the subcutaneous fat layer. It supports the epidermis and serves as its primary source of nutrition. The two layers of the dermis, the papillary dermis and the reticular dermis,

[■] FIGURE 44-4 ■ Langerhans' cells.

are composed of cells, fibers, ground substances, nerves, and blood vessels. The hair and glandular structures are embedded in this layer and continue through the epidermis.

Papillary Dermis. The papillary dermis is a thin, superficial layer that lies adjacent to the epidermis. It consists of collagen fibers and ground substance. This layer is densely covered with conical projections called *dermal papillae* (see Fig. 44-1). The basal cells of the epidermis project into the papillary dermis, forming *rete ridges*. It is believed that the dense structure of the dermal papillae serves to minimize the separation of the dermis and the epidermis. Dermal papillae contain capillary venules that nourish the epidermal layers of the skin. Lymph vessels and nerve tissue also are found in this layer.

Reticular Dermis. The reticular dermis is the thicker area of the dermis and forms the bulk of the dermal layer. The reticular dermis is characterized by a complex meshwork of three-dimensional collagen bundles interconnected with large elastic fibers and ground substance, a viscid gel that is rich in mucopolysaccharides. The collagen fibers are oriented parallel to the body's surface in any given area. Collagen bundles may be organized lengthwise, as on the abdomen, or in round clusters, as in the heel. The direction of surgical incisions is often determined by this organizational pattern.

The reticular dermis also contains dendritic cells with threadlike projections, called *dermal dendrocytes*. Dermal dendrocytes, which have phagocytic properties, are believed to possess antigen-presenting functions and play an important part in the immune function of the skin. Immune cells found in the dermis include macrophages, T cells, mast cells, and fibroblasts. The major type of T-cell-mediated immune response in the skin is delayed-type hypersensitivity (see Chapter 10). The mast cells play a prominent role in IgE-mediated hypersensitivity responses.

Subcutaneous Tissue

The subcutaneous tissue layer consists primarily of loose connective and fatty tissues that lend support to the vascular and neural structures supplying the outer layers of the skin. There is controversy about whether the subcutaneous tissue should be considered an actual layer of the skin. Because the eccrine glands and deep hair follicles extend to this layer and several skin diseases involve the subcutaneous tissue, the subcutaneous tissue may be considered part of the skin.

Innervation and Blood Supply

The innervation of the skin is complex. The skin, with its accessory structures, serves as an organ for receiving sensory information from the environment. The dermis is well supplied with sensory neurons as well as nerves that supply the blood vessels, sweat glands, and arrector pili muscles. The receptors for touch, pressure, heat, cold, and pain are widely distributed in the dermis. The papillary layer of the dermis is supplied with free nerve endings that serve as nociceptors (*i.e.*, pain receptors) and thermoreceptors. The dermis also contains encapsulated pressure-sensitive receptors that detect pressure and touch.

The arterial vessels that nourish the skin form two plexuses (*i.e.*, collection of blood vessels), one located between the papillary and reticular layers of the dermis and the other be-

tween the dermis and the subcutaneous tissue layer. Capillary flow that arises from vessels in this plexus extends up and nourishes the overlaying epidermis by diffusion. Blood leaves the skin by way of small veins that accompany the subcutaneous vessels. The lymphatic system of the skin, which aids in combating certain skin infections, also is limited to the dermis.

Most of the skin's blood vessels are under sympathetic nervous system control. The sweat glands are innervated by cholinergic fibers but controlled by the sympathetic nervous system. Likewise, the sympathetic nervous system controls the arrector pili (pilomotor) muscles that cause elevation of hairs on the skin. Contraction of these muscles tends to cause the skin to dimple, producing "goose bumps."

In summary, the skin, which forms the major barrier between the internal organs and the external environment, is primarily an organ of protection. The skin is composed of three layers, the epidermis, dermis, and subcutaneous tissues. The skin also houses a variety of appendages, including hair, nails, and sebaceous and sweat glands. The epidermis, the outermost layer of the skin, contains five layers, or strata. The major cells of the epidermis are the keratinocytes, melanocytes, Langerhans' cells, and Merkel's cells. The stratum germinativum, or basal layer, is the source of the cells in all five layers of the epidermis. The keratinocytes, which are the major cells of the epidermis, are transformed from viable keratinocytes to dead keratin as they move from the innermost layer of the epidermis (i.e., stratum germinativum) to the outermost layer (i.e., stratum corneum). The melanocytes are pigment-synthesizing cells that give skin its color.

The dermis provides the epidermis with support and nutrition and is the source of blood vessels, nerves, and skin appendages. Sensory receptors for touch, pressure, heat, cold, and pain are widely distributed in the dermis. Both the epidermis and dermis participate in the immune functions of the skin; the Langerhans' cells of the epidermis process foreign antigens for presentation to immune cells (T cells, macrophages, mast cells, and fibroblasts) in the dermis. The subcutaneous tissue layer consists primarily of fat and connective tissues that lend support to the vascular and neural structures supplying the outer layers of the skin.

MANIFESTATIONS OF SKIN DISORDERS

Skin disorders are manifested by a variety of primary lesions and rashes (Fig. 44-5). Commonly, secondary lesions result from overtreatment, scratching, and infection that accompanies the primary skin disorders.

Lesions, Rashes, and Vascular Disorders

Rashes are temporary eruptions of the skin, such as those associated with childhood diseases, heat, diaper irritation, or drug-induced reactions. The term *lesion* refers to a traumatic or pathologic loss of normal tissue continuity, structure, or function. The components of a rash sometimes are referred to as *lesions*. Rashes and lesions may range in size from a fraction of a millimeter (*e.g.*, the pinpoint spots of petechiae) to many

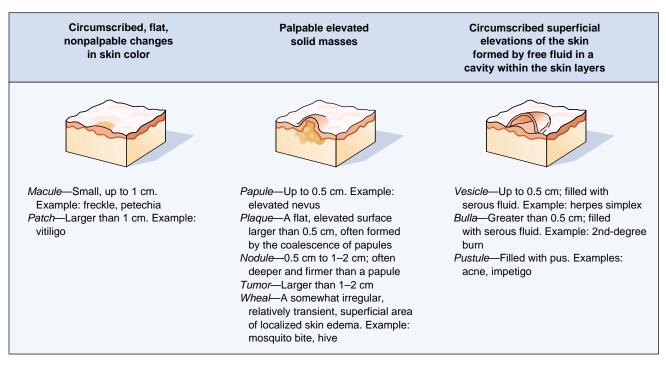

FIGURE 44-5 Primary lesions may arise from previously normal skin. Authorities vary somewhat in their definitions of skin lesions by size. Dimensions given should be considered approximate. (Bates B.B. [1995]. *A guide to physical examination and history taking* [6th ed.]. Philadelphia: J.B. Lippincott)

centimeters (*e.g.*, decubitus ulcer, or pressure sore). They may be blanched (white), erythematous (reddened), hemorrhagic or purpuric (containing blood), or pigmented. Repeated rubbing and scratching can lead to lichenification (thickened and roughened skin characterized by prominent skin markings caused by repeated scratching or rubbing) or excoriation (lesion caused by breakage of the epidermis, producing a raw linear area). Skin lesions may occur as primary lesions arising in previously normal skin, or they may develop as secondary lesions resulting from other disease conditions.

A *blister* is a vesicle or fluid-filled papule. Blisters of mechanical origin form from the friction caused by repeated rubbing on a single area of the skin. Friction blisters most commonly occur on the palmar and plantar surfaces of the hands and feet where the skin is thick enough to form a bleb. Blisters also develop from first-degree and second-degree partial-thickness burns. Histologically, there is degeneration of epidermal cells and a disruption of intercellular junctions that causes the layers of the skin to separate. As a result, fluid accumulates, and a noticeable bleb forms on the skin surface.

A *callus* is a hyperkeratotic plaque of skin caused by chronic pressure or friction. It represents a hyperplasia of the dead keratinized cells that make up the cornified or horny layer of the skin. Increased cohesion between cells results in hyperkeratosis and decreased skin shedding. *Corns* are small, wellcircumscribed, conical keratinous thickenings of the skin. They usually appear on the toes from rubbing or ill-fitting shoes. The actual corn may be either hard with a central horny core or soft, as commonly seen between the toes. They may appear on the hands as an occupational hazard. Corns on the feet often are painful, whereas corns on the hands may be asymptomatic.

Telangiectasis are dilated superficial blood vessels, capillaries, or terminal arteries that appear either red or bluish. They can appear by themselves or as a part of other skin disorders such as rosacea or basal cell carcinoma.

Pruritus

Pruritus, or the sensation of itch, is a symptom common to many skin disorders. Generalized itching in the absence of a primary skin disease may be symptomatic of other organ disorders, such as chronic renal disease, diabetes, or biliary disease. Warmth, touch, and vibration also can act locally to trigger the itch phenomenon.

Itch is mediated by cutaneous receptors. Substances such as histamine, bradykinin, substance P, and bile salts act locally to stimulate the itch receptors. Prostaglandins are modulators of the itch response, lowering the threshold for other mediators. One type of itch, sometimes referred to as *central itch*, is perceived as occurring on the skin, but originates in the central nervous system (CNS).³ For example, the pain reliever morphine promotes itch by acting on central opioid receptors in the CNS.

Scratching, the well-known response to itch, is a neurologic reflex that to varying degrees can be controlled by the individual. Although scratching may temporarily relieve itch, many types of itch are not easily localized and are not relieved by scratching. In many people, excoriations and thickened papular areas develop at the site of repeated scratching or rubbing.

Variations in Black Skin

Some skin disorders common to African Americans are not commonly found in European Americans. Similarly, some skin disorders, such as skin cancers, affect light-skinned persons more commonly than dark-skinned persons. Because of these differences, serious skin disorders may be overlooked, and normal variations in darker skin may be mistaken for anomalies. Skin color is determined by the melanin produced by the melanocytes. Although the number of melanosomes in dark and white skin are the same, black skin produces more melanin and produces it faster than does white skin. Because of their skin color, blacks are better protected against skin cancer and the premature wrinkling and aging of the skin that occurs with sun exposure.

Some conditions common in people with black skin are too much or too little color. Areas of the skin may darken after injury, such as a cut or scrape, or after disease conditions, such as acne.⁴ These darkened areas may take many months or years to fade. Dry or "ashy" skin also can be a problem for people with black skin. It often is uncomfortable, and it also is easily noticed because it gives the skin an ashen, or grayish, appearance. Although using a moisturizer may help relieve the discomfort, it may cause a worsening of acne in predisposed persons.

Normal variations in skin structure and skin tones often make evaluation of dark skin difficult (Table 44-1). The darker pigmentation can make skin pallor, cyanosis, and erythema more difficult to observe. Therefore, verbal histories must be relied on to assess skin changes. The verbal history should include clients' descriptions of their normal skin tone. Changes in skin color, in particular hypopigmentation and hyperpigmentation, often accompany ethnic skin disorders and are very important signs to observe for when diagnosing skin conditions.

TABLE 44-1Common NormalVariations in Dark Skin

Variation	Appearance
Futcher (Voigt's) line	Demarcation between darkly pigmented and lightly pigmented skin in upper arm; follows spinal nerve distribution; com- mon in black and Japanese populations
Midline hypo- pigmentation	Line or band of hypopigmentation over the sternum, dark or faint, lessens with age; common in Latin American and black populations
Nail pigmentation	Linear dark bands down nails or diffuse nail pigmentation, brown, blue or blue-black
Oral pigmentation	Blue to blue-gray pigmentation of oral mucosa; gingivae also affected
Palmar changes	Hyperpigmented creases, small hyperkera- totic papules, and tiny pits in creases
Plantar changes	Hyperpigmented macules, can be multiple with patchy distribution, irregular borders, and variance in color

(Developed from information in Rosen T., Martin S. [1981]. Atlas of black dermatology. Boston: Little, Brown)

In summary, skin lesions and rashes are the most common manifestations of skin disorders. Rashes are temporary skin eruptions. Lesions result from traumatic or pathologic loss of the normal continuity, structure, or function of the skin. Lesions may be vascular in origin; they may occur as primary lesions in previously normal skin; or they may develop as secondary lesions resulting from primary lesions. Blisters, calluses, and corns result from rubbing, pressure, and frictional forces applied to the skin.

Pruritus and dry skin are symptoms common to many skin disorders. Scratching because of pruritus can lead to excoriation, infection, and other complications.

Normal variations in black skin often make evaluation difficult and result in some disorders being overlooked. Changes in color, especially hypopigmentation or hyperpigmentation, often accompany the skin disorders of dark-skinned people.

SKIN DAMAGE CAUSED BY ULTRAVIOLET RADIATION

The skin is the protective shield against harmful ultraviolet rays from the sun. Skin cancers and other skin disorders such as early wrinkling and aging of the skin have been attributed to the damaging effects of sunlight.

Ultraviolet Rays

The earth's sunlight is measured in wavelengths ranging from approximately 290 nm in the ultraviolet region up to approximately 2500 nm in the infrared region. Ultraviolet (UV) radiation is divided into three types: UVC, UVB, and UVA. UVC rays are short (100 to 289 nm) and do not pass through the earth's atmosphere. However, they can be produced artificially and are damaging to the eyes. UVB rays are 290 to 320 nm. These are the rays that are primarily responsible for nearly all the skin effects of sunlight. They are more commonly referred to as sunburn rays. UVA rays are 321 to 400 nm. These rays, which can pass through window glass, are more commonly referred to as suntanning rays. In general, it takes approximately 1000 times more UVA to match the untoward effects of UVB. Nonetheless, UVA contributes to many skin alterations. Artificial sources of UVA, such as tanning salons, may produce the same effects as UVB.5

With UV exposure, skin cells release vasoactive and injurious chemicals, resulting in vasodilation and sunburn. Melanin in the stratum corneum absorbs UV radiation as a means of preventing destruction of the lower skin layers. The skin responds to UV exposure with an increase in melanin content. Components of the immune system in the skin, especially Langerhans' cells, also respond to UV radiation. The number of immune cells is decreased, and their activity is lessened by UV exposure.⁶ It is thought that the immune cells are important in removing sun-damaged cells with malignant potential.

Sunburn

Sunburn is caused by excessive exposure of the epidermal and dermal layers of the skin to UV radiation, resulting in an erythematous inflammatory reaction. Sunburn ranges from mild to severe. A mild sunburn consists of various degrees of skin redness. Inflammation, vesicle eruption, weakness, chills, fever, malaise, and pain accompany more severe forms of sunburn. Scaling and peeling follow any overexposure to sunlight. Black skin also burns and may appear grayish or gray-black.

Severe sunburns are treated with wet Burow's solution soaks and topical creams and lotions to limit inflammation and pain.⁷ Extensive second- and third-degree burns may require hospitalization and specialized burn care techniques.

Drug-Induced Photosensitivity

Some drugs are classified as photosensitive drugs because they produce an exaggerated response to ultraviolet light. Examples include some of the anti-infective agents (sulfonamides, tetra-cyclines, nalidixic acid), antihistamines (cyproheptadine, diphenhydramine), antipsychotic agents (phenothiazines, haloperidol), diuretics (thiazides, acetazolamide, amiloride), and nonsteroidal anti-inflammatory drugs (phenylbutazone, ketoprofen, naproxen).⁸ Severe sunburn can result when persons taking these drugs are exposed to sunlight.

Drug-induced photosensitivity, such as UVA photosensitivity induced by the psoralens, may be used in treating skin conditions, such as psoriasis, that respond well to ultraviolet radiation exposure. Because an increased incidence of cancerous lesions has been reported in people who have been treated with these agents, their use requires caution and careful surveillance.

Sunscreens and Other Protective Measures

The ultraviolet rays of sunlight or other sources can be either completely or partially blocked from the skin surface by sunscreens. The U.S. Food and Drug Administration (FDA) requires a *sun protection factor* (SPF) rating on all commercial preparations based on their ability to obstruct ultraviolet radiation absorption. The ratings usually are on a scale of 1 to 30+; higher ratings block more sunlight.⁹ Products with a higher SPF screen out more UVB rays, which are responsible for acute sun damage.

There are two primary types of sunscreens available on the market—chemical (soluble) agents and physical (insoluble) agents.⁹ Chemical agents (*e.g.*, para-aminobenzoic acid [PABA]) protect the skin from absorbing sunlight, and physical agents (*e.g.*, micronized titanium dioxide and microfine zinc) work by reflecting sunlight.

Other protective measures include knowledge about sunlight and how to protect the skin. Shielding the skin with protective clothing and hats or head coverings helps decrease ultraviolet radiation exposure.

In summary, there has been an alarming increase in skin cancers since the early 1980s, and repeated exposure to the ultraviolet rays of the sun has been implicated as its principal cause. Solar and artificial sources of radiation contribute to the amount of radiation to which human beings are exposed. Sunburn, which is caused by excessive exposure to ultraviolet radiation, is an erythematous inflammatory reaction, ranging from mild to severe. Photosensitive drugs can also produce an exaggerated response to ultraviolet light when they are taken in combination with sun exposure. Sunscreens are protective agents that work by either reflecting sunlight or preventing its absorption.

PRIMARY DISORDERS OF THE SKIN

Primary skin disorders are those originating in the skin. They include infectious processes, acne and rosacea, papulosquamous dermatoses, allergic disorders and drug reactions, and arthropod infestations. Although most of these disorders are not life threatening, they can affect the quality of life.

Infectious Processes

The skin is subject to invasion by a number of microorganisms, including fungi, bacteria, and viruses. Normally, the skin flora, sebum, immune responses, and other protective mechanisms guard the skin against infection. Depending on the virulence of the infecting agent and the competence of the host's resistance, infections may result.

Fungal Infections

Fungi are free-living, saprophytic, plantlike organisms, certain strains of which are considered part of the normal skin flora.¹⁰ Fungal or mycotic infections of the skin are traditionally classified as superficial or deep. The superficial mycoses, more commonly known as *tinea* or *ringworm*, invade only the superficial keratinized tissue (skin, hair, and nails). Deep fungal infections involve the epidermis, dermis, and subcutis. Infections that typically are superficial may exhibit deep involvement in immunosuppressed individuals.

The fungi that cause superficial mycoses live on the dead keratinized cells of the epidermis. They emit an enzyme that enables them to digest keratin, which results in superficial skin scaling, nail disintegration, or hair breakage, depending on the location of the infection. Deeper reactions involving vesicles, erythema, and infiltration are caused by the inflammation that results from exotoxins liberated by the fungus. Fungi also are capable of producing an allergic or immune response.

Superficial Fungal Infections. Superficial fungal infections affect various parts of the body, with the lesions varying according to site and fungal species. Tinea can affect the body (tinea corporis), face and neck (tinea faciei), scalp (tinea capitis), hands (tinea manus), feet (tinea pedis), or nails (tinea unguium).

Tinea corporis (ringworm of the body) can be caused by any of the fungi. Although tinea corporis affects all ages, children seem most prone to infection. Transmission is most commonly from kittens, puppies, and other children who have infections. The lesions vary, depending on the fungal agent. The most common types of lesions are oval or circular patches on exposed skin surfaces and the trunk, back, or buttocks (Fig. 44-6). Less common are foot and groin infections. The lesion begins as a red papule and enlarges, often with a central clearing. Patches have raised red borders consisting of vesicles, papules, or pustules. The borders are sharply defined, but lesions may coalesce. Pruritus, a mild burning sensation, and erythema frequently accompany the skin lesion.

Tinea capitis (ringworm of the scalp) occurs in two forms: primary (noninflammatory) and secondary (inflammatory). Depending on the invading fungus, the lesions of the *noninflammatory type* can vary from grayish, round, hairless patches to balding spots or black dots on the head. The lesions vary in size and are most commonly seen on the back of the

■ FIGURE 44-6 ■ Tinea of the body caused by *Microsporum canis*. (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

head (Fig. 44-7). Mild erythema, crust, or scale may be present. The individual usually is asymptomatic, although pruritus may exist. Children between 3 and 14 years of age are primarily affected, although an increasing number of adults are receiving diagnoses of the infection. The *inflammatory type* of tinea capitis has a rapid onset, and lesions usually are localized to one area. The initial lesion consists of a pustular, scaly, round patch with broken hairs. A secondary bacterial infection is common and may lead to a painful, circumscribed, boggy, and indurated lesion called a *kerion*. The highest incidence is among children and farmers who work with infected animals.

Tinea pedis (athlete's foot, or ringworm of the feet) is a common dermatosis primarily affecting the spaces between the toes, the soles of the feet, or the sides of the feet (Fig. 44-8). The lesions vary from a mildly scaling lesion to a painful, exudative, erosive, inflamed lesion with fissuring. Lesions often are accompanied by pruritus, pain, and foul odor. Some persons are prone to chronic tinea pedis, whereas others have a

■ FIGURE 44-7 ■ Tinea of the scalp caused by Microsporum audouinii. (Sauer G.C., Hall J.C. [1996]. Manual of skin diseases [7th ed.]. Philadelphia: Lippincott-Raven)

■ FIGURE 44-8 ■ Chronic tinea of sole of the foot caused by *Tri-chophyton rubrum*. (Schering Corp.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

milder form that is exacerbated during hot weather or when the feet are exposed to moisture or occlusive shoes. *Tinea manus* (ringworm of the hands) usually is a secondary infection with tinea pedis as the primary infection. In contrast to other skin disorders such as contact dermatitis and psoriasis, which affect both hands, tinea manus usually occurs only on one hand. The characteristic lesion is a blister on the palm or finger surrounded by erythema. Chronic lesions are scaly and dry. Cracking and fissuring may occur. The lesions may spread to the plantar surfaces of the hand. If chronic, tinea manus may lead to tinea of the fingernails.

Tinea unguium is a dermatophyte infection (onychomycosis) of the nails. Toenails are involved more commonly than fingernails. Toenail infection is common in persons prone to chronic infections of tinea pedis. Often, the infection in the toenails becomes a ready source for future infections of the foot. It may begin from a crushing injury to a toenail or from the spread of tinea pedis. The infection often begins at the tip of the nail, where the fungus digests the nail keratin. Initially, the nail appears opaque, white, or silvery (Fig. 44-9). The nail

■ **FIGURE 44-9** Tinea of the fingernail caused by *Trichophyton rubrum*. (Duke Laboratories, Inc.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

then turns yellow or brown. The condition often remains unchanged for years. During this time it may involve only one or two nails and may produce little or no discomfort. Gradually, the nail thickens and cracks as the infection spreads. Permanent discoloration and distortion result as the nail separates from the underlying epidermis. Less common forms of tinea unguium are superficial white onychomycosis, in which areas of the nails become powdery white and erode, and proximal subungual onychomycosis (PSO), in which there is rapid invasion of the nail, leaving it white with no additional thickening of the nail. Although it is one of the less common forms of tinea unguium, PSO has increased among people with acquired immunodeficiency syndrome (AIDS).

Chapter 44: Alterations in Skin Function and Integrity

Diagnosis of superficial fungal infections is primarily done by microscopic examination of skin scrapings for fungal spores, the reproducing bodies of fungi. Potassium hydroxide (KOH) preparations are used to prepare slides of skin scrapings.¹¹ KOH disintegrates human tissue and leaves behind the threadlike filaments, called *hyphae*, that grow from the fungal spores. Cultures also may be done.

Superficial fungal infections may be treated with topical or systemic antifungal agents. Tinea treatment usually follows diagnosis confirmed by KOH preparation or culture, particularly if a systemic agent is to be used. Topical agents, both prescription and over-the-counter preparations, are commonly used in the treatment of tinea infections; however, outcome success often is limited because of the lengthy duration of treatment, poor compliance, and high rates of relapse at specific body sites.

The oral systemic antifungal agents include griseofulvin, the azoles, and the allylamines.¹¹ Griseofulvin is a fungicidal agent derived from a species of Penicillium that is used only in the treatment of dermatophytoses. It acts by binding to the keratin of newly forming skin, protecting the skin from new infection. Because its action is to prevent new infection, it must be administered for 2 to 6 weeks to allow for skin replacement. The azoles (e.g., ketoconazole, itraconazole, and fluconazole) are a group of synthetic antifungal drugs that act by inhibiting the fungal enzymes needed for the synthesis of ergosterol, which is an essential part of fungal cell membranes. Terbinafine, a synthetic allylamine, acts by interrupting ergosterol synthesis, causing the accumulation of a metabolite that is toxic to the fungus. In contrast to griseofulvin, the synthetic agents are fungicidal (i.e., kill the fungus) and thus are more effective in shorter treatment periods.¹⁰ Some of the oral agents can produce serious side effects, such as hepatic toxicity, or interact adversely with other medications being taken. A number of the synthetic fungicides (e.g., ketoconazole, miconazole, clotrimazole, and terbinafine) are available as topical preparations and produce less severe side effects. Topical corticosteroids may be used in conjunction with antifungal agents to relieve itching and erythema secondary to inflammation.

Candidal Infections. Candidiasis (moniliasis) is a fungal infection caused by *Candida albicans.* This yeastlike fungus is a normal inhabitant of the gastrointestinal tract, mouth, and vagina (see Chapter 35). The skin problems result from the release of irritating toxins on the skin surface. Some persons are predisposed to candidal infections by conditions such as diabetes mellitus, antibiotic therapy, pregnancy, use of birth control pills, poor nutrition, and immunosuppressive diseases.

Oral candidiasis may be the first sign of infection with human immunodeficiency virus (HIV).

C. albicans thrives in warm, moist intertriginous areas of the body. The rash is red with well-defined borders. Patches erode the epidermis, and there is scaling. Mild to severe itching and burning often accompany the infection. Severe forms of infection may involve pustules or vesiculopustules. In addition to microscopic analysis, a candidal infection often can be differentiated from a tinea infection by the presence of satellite lesions. These satellite lesions are maculopapular and are found outside the clearly demarcated borders of the candidal infection. Satellite lesions often are diagnostic of diaper rash complicated by *Candida*. The appearance of candidal infections varies according to the site (Table 44-2).

Diagnosis usually is based on microscopic examination of skin or mucous membrane scrapings placed in KOH solution. Depending on the site of infection and extent of involvement, topical and oral antifungal agents may be used in treatment.

Bacterial Infections

Bacteria are considered normal flora of the skin. Most bacteria are not pathogenic, but when pathogenic bacteria invade the skin, superficial or systemic infections may develop. Bacterial skin infections are commonly classified as primary or secondary infections. Primary infections are superficial skin infections such as impetigo or ecthyma. Secondary infections consist of deeper cutaneous infections, such as infected ulcers. Diagnosis usually is based on cultures taken from the infected site. Treatment measures include antibiotic therapy and measures to promote comfort and prevent the spread of infection.

Impetigo. Impetigo is a common superficial bacterial infection caused by *staphylococci* or *group* A β -*hemolytic streptococci* (GABHS), or both. It is common among infants and young children, although older children and adults occasionally con-

TABLE 44-2 Candidal Infections: Locations and Appearance of Lesions

Location	Appearance
Breasts, groin, axillae, anus, umbilicus, toe or fingerwebs Vagina	Red lesions with well-defined bor- ders and presence of satellite le- sions; lesions may be dry or moist Red, oozing lesions with sharply
-	defined borders and inflamed vagina; cervix may be covered with moist, white plaque; cheesy, foul-smelling discharge; presence of pruritus and burning
Glans penis (balanitis)	Red lesions with sharply defined borders; penis may be covered with white plaque; presence of pruritus and burning
Mouth (thrush)	Creamy white flakes on a red, in- flamed mucous membrane; papil- lae on tongue may be enlarged
Nails	Red, painful swelling around nail bed; common in persons who often have their hands in water

tract the disease. Impetigo initially appears as a small vesicle or pustule or as a large bulla on the face or elsewhere on the body. As the primary lesion ruptures, it leaves a denuded area that discharges a honey-colored serous liquid that hardens on the skin surface and dries as a honey-colored crust with a "stuckon" appearance (Fig. 44-10). New vesicles erupt within hours. Pruritus often accompanies the lesions, and the skin excoriations that result from scratching multiply the infection sites. A possible complication of untreated GABHS impetigo is poststreptococcal glomerulonephritis (see Chapter 23). Topical mupirocin, which has few side effects, may be effective for limited disease. If the area is large or if there is concern about complications, systemic antibiotics are used.

Ecthyma is an ulcerative form of impetigo, usually secondary to minor trauma. It is caused by GABHS, *Staphylococcus aureus*, or *Pseudomonas*. It frequently occurs on the buttocks and thighs of children (Fig. 44-11). The lesions are similar to those of impetigo. A vesicle or pustule ruptures, leaving a skin erosion or ulcer that weeps and dries to a crusted patch, often resulting in scar formation. With extensive ecthyma, there is a low-grade fever and extension of the infection to other organs. Treatment usually involves the use of systemic antibiotics.

Viral Infections

Viruses are intracellular pathogens that rely on live cells of the host for reproduction. They have no organized cell structure but consist of a DNA or RNA core surrounded by a protein coat. The viruses seen in skin lesion disorders tend to be DNAcontaining viruses. Viruses invade the keratinocyte, begin to reproduce, and cause cellular proliferation or cellular death. The rapid increase in viral skin diseases has been attributed to the use of corticosteroid drugs, which have immunosuppressive qualities, and the use of antibiotics, which alter the bacterial flora of the skin. As the number of bacterial infections

■ FIGURE 44-10 ■ Impetigo of the face. (Abner Kurten, Folia Dermatologica. No. 2. Geigy Pharmaceuticals.) (Sauer G.C., Hall J.C. [1996]. Manual of skin diseases [7th ed.]. Philadelphia: Lippincott-Raven)

■ FIGURE 44-11 ■ Ecthyma on the buttocks of a 13-year-old boy. (Glaxo-Wellcome Co.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

has decreased, there has been a proportional rise in viral skin diseases.

Verrucae. Verrucae, or warts, are common, benign papillomas caused by DNA-containing human papillomaviruses (HPV). The lesions are circumscribed, symmetrical epidermal neoplasms that are often elevated above the skin and often appear papillary. Histologically, there is an irregular thickening of the stratum spinosum and greatly increased thickening of the stratum corneum.

There are more than 50 types of HPVs found on the skin and mucous membranes of humans that cause several different kinds of warts, including skin warts and genital warts.¹² The skin warts, caused by HPV types 1, 2, 3, and 4, usually are not precancerous. HPV transmission usually occurs through breaks in skin integrity. They are known as common warts, flat warts, and plantar warts. *Common warts* are papillary growths, slightly raised above the skin surface, and varying in size from pin-head sized to large clusters of pea-sized tumors (Fig. 44-12). They are seen most commonly on the hands. Common hand warts can be transmitted by biting the cuticles surrounding the nail. *Flat*

Chapter 44: Alterations in Skin Function and Integrity

warts are small flat tumors that are often barely visible but can occur in clusters of 10 or more. They are commonly seen on the forehead and the dorsum of the hand. Plantar warts are flat to slightly raised painful growths that extend deep into the skin. They are frequently transmitted to the abraded, softened heels of children in gym showers or swimming areas. Genital warts are discussed in Chapter 35. Genital warts are sexually transmitted; some types of HPV may increase the risk of genital (cervix, vulva, and penis) cancers.

Treatment usually is directed at inducing a "wart-free" period without producing scarring. Warts resolve spontaneously when immunity to the virus develops. The immune response may be delayed for years. Removal is usually done by applying a keratolytic agent, such as salicylic acid, that breaks down the wart tissue, or by freezing with liquid nitrogen. Various types of laser surgery, electrosurgery, and the use of cytotoxic or antiviral therapy also have been successful in wart eradication.

Herpes Simplex. Herpes simplex virus (HSV) infections of the skin and mucous membrane (*i.e.*, cold sore or fever blister) are common. Two types of herpesviruses infect humans: type 1 and type 2. HSV-1 usually is confined to the oropharynx, and the organism is spread by respiratory droplets or by direct contact with infected saliva. Genital herpes usually is caused by HSV-2 (see Chapter 35), although HSV-1 also can cause genital herpes.

Infection with HSV-1 may present as a primary or recurrent infection. Primary HSV-1 infections usually are asymptomatic. Symptomatic disease occurs most frequently in young children (1 to 5 years of age). Symptoms include fever, sore throat, painful vesicles, and ulcers of the tongue, palate, gingiva, buccal mucosa, and lips. Primary infection results in the production of antibodies to the virus so that recurrent infections are more localized and less severe. After an initial infection, the herpesvirus persists in the trigeminal and other dorsal root ganglia in the latent state. It is likely that many adults were exposed to HSV-1 during childhood and therefore have antibodies to the virus.

The recurrent lesions of HSV-1 usually begin with a burning or tingling sensation. Vesicles and erythema follow and progress to pustules, ulcers, and crusts before healing (Fig. 44-13). The lesion is most common on the lips, face, and mouth. Pain

■ FIGURE 44-12 Common and periungual warts. (Reed & Carnrick Pharmaceuticals.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

■ FIGURE 44-13 ■ Recurrent herpes simplex of the face. (Dermik Laboratories, Inc.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

is common, and healing takes place within 10 to 14 days. Precipitating factors may be stress, sunlight exposure, menses, or injury. Individuals who are immunocompromised may have severe attacks.

There is no cure for oropharyngeal herpes simplex; most treatment measures are palliative. Penciclovir cream, a topical antiviral agent, applied at the first symptom may be used to reduce the duration of an attack. Application of over-the-counter topical preparations containing antihistamines, antipruritics, and anesthetic agents along with aspirin or acetaminophen may be used to relieve pain. Oral antiviral drugs that inhibit herpesvirus replication may be used prophylactically to prevent recurrences. Sunscreen preparations applied to the lips can prevent sun-induced herpes simplex.

Herpes Zoster. Herpes zoster (shingles) is an acute, localized vesicular eruption distributed over a dermatomal segment of the skin. It is caused by the same herpesvirus, varicella-zoster, that causes chickenpox. It is believed to be the result of reactivation of a latent varicella-zoster virus that was dormant in the sensory dorsal root ganglia since a childhood infection. During an episode of herpes zoster, the reactivated virus travels from the ganglia to the skin of the corresponding dermatome. Although herpes zoster is not as contagious as chickenpox, the reactivated virus can be transmitted to nonimmune contacts.

The incidence of herpes zoster increases with age; it occurs 8 to 10 times more frequently in persons older than 60 years than in younger persons.¹³ The normal age-related decrease in cell-mediated immunity is thought to account for the increased viral activation in this age group.¹⁴ Other persons at increased risk because of impaired cell-mediated immunity are those with conditions such as HIV infection and certain malignancies, chronic corticosteroid users, and those undergoing cancer chemotherapy and radiation therapy.

The lesions of herpes zoster typically are preceded by a prodrome consisting of a burning pain, tingling sensation, extreme sensitivity of the skin to touch, and pruritus along the affected dermatome. This may be present for 1 to 3 days or longer before the appearance of the rash. During this time, the pain may be mistaken for a number of other conditions, such as heart disease, pleurisy, various musculoskeletal disorders, or gastrointestinal disorders.

The rash appears as an eruption of vesicles with erythematous bases that are restricted to skin areas supplied by sensory neurons of a single or associated group of dorsal root ganglia (Fig 44-14). In immunosuppressed persons, the lesions may extend beyond the dermatome. Eruptions usually are unilateral in the thoracic region, trunk, or face. New crops of vesicles erupt for 3 to 5 days along the nerve pathway. The vesicles dry, form crusts, and eventually fall off. The lesions usually clear in 2 to 3 weeks.

Serious complications can accompany eruptions. Eye involvement can result in permanent blindness and occurs in a large percentage of cases involving the ophthalmic division of the trigeminal nerve (see Chapter 38). Pain can persist for several months after the rash disappears. Postherpetic neuralgia, which is pain that persists longer than 1 to 3 months after the resolution of the rash, is an important complication of herpes zoster (see Chapter 38).¹⁴

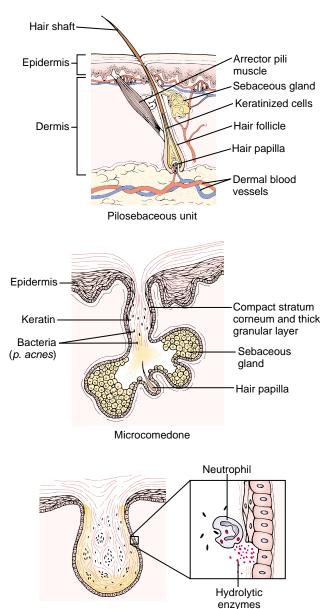

The treatment of choice for herpes zoster is the administration of an antiviral agent. The treatment is most effective when

started within 72 hours of rash development.^{15,16} Narcotic analgesics, tricyclic antidepressants or anticonvulsant drugs, and nerve blocks may be used for the management of herpetic pain. Oral corticosteroids sometimes are used to reduce the inflammation that may contribute to the pain.

Acne and Rosacea

Acne is a disorder of the pilosebaceous unit (hair follicle and sebaceous gland). The hair follicle is a tubular invagination of the epidermis in which hair is produced. The sebaceous glands empty into the hair follicle, and the pilosebaceous unit opens to the skin surface by means of a widely dilated opening called a pore (Fig. 44-15). The sebaceous glands produce a complex lipid mixture called sebum, from the Latin word meaning *tallow* or *grease*. Sebum consists of a mixture of free fatty acids, triglycerides, diglycerides, monoglycerides, sterol esters, wax es-

Open comedone

■ FIGURE 44-15 ■ The pathogenesis of acne vulgaris. The pilosebaceous unit (A) and the development of a microcomedone (whitehead) (B), and an open comedone with an accumulation of melanin (C).

ters, and squalene. Sebum production occurs through what is called a *holocrine process*, in which the sebaceous gland cells that produce the sebum are completely broken down and their lipid contents are emptied through the sebaceous duct into the hair follicle. The amount of sebum produced depends on two factors: the size of the sebaceous gland and the rate of sebaceous cell proliferation. The sebaceous glands are largest on the face, scalp, and scrotum, but are present in all areas of the skin except for the soles of the feet and palms of the hands. Sebaceous cell proliferation and sebum production are uniquely responsive to direct hormonal stimulation by androgens. In men, tes-

Acne lesions consist of comedones (whiteheads and blackheads), papules, pustules, nodules, and, in severe cases, cysts. Whiteheads are pale, slightly elevated papules with no visible orifice. Blackheads are plugs of material that accumulate in sebaceous glands that open to the skin surface. The color of blackheads results from melanin that has moved into the sebaceous glands from adjoining epidermal cells. Papules are raised areas less than 5 mm in diameter. Pustules have a central core of purulent material. Nodules are larger than 5 mm in diameter and may become suppurative or hemorrhagic. Suppurative nodules often are referred to as cysts because of their resemblance to inflamed epidermal cysts. Acne lesions are divided into noninflammatory and inflammatory lesions. Noninflammatory acne consists primarily of comedones. Inflammatory acne consists of papules, pustules, nodules, and cysts. The inflammatory lesions are believed to develop from the escape of sebum into the dermis and the irritating effects of the fatty acids contained in the sebum.

Two types of acne occur during different stages of the life cycle: acne vulgaris, which is the most common form among adolescents and young adults, and acne conglobata, which develops later in life.¹⁷ Other types of acne occur in association with various etiologic agents and influences.

Acne Vulgaris

Acne vulgaris is a common skin condition of adolescence and young adults. The condition is so common during adolescence that is often regarded as a normal part of the maturing process. The acne vulgaris lesions, which consist of comedones (whiteheads and blackheads) or inflammatory lesions (pustules, nodules, or cysts), are found primarily on the face and neck and to a lesser extent, on the back, chest, and shoulders (Fig. 44-16).

The cause of acne vulgaris remains unknown. Several factors are believed to contribute to acne, including (1) the influence of androgens on sebaceous cell activity, (2) increased proliferation of the keratinizing epidermal cells that form the sebaceous cells, (3) increased sebum production in relation to the severity of the disease, (4) decreased amounts of linoleic acid in the sebum, and (5) the presence of the *Propionibacterium acnes*, the microorganism responsible for inflammatory stage of the disorder.^{17,18} These factors probably are interrelated. Increased androgen production results in increased sebaceous cell activity, with a resultant plugging of the pilosebaceous ducts. The excessive sebum provides a medium for the growth of *P. acnes*. The *P. acnes* organism contains lipases that break down the free fatty acids that produce the acne inflammation.

Treatment of acne focuses on clearing up existing lesions, preventing new lesions from forming, and limiting scar formation.^{19,20} Milder forms of acne usually respond to proper cleansing and application of topical keratolytic agents that act chemically to break down keratin, loosen comedones, and exert a peeling effect on the skin. The treatment measures for moderate to severe acne are directed at correcting the defect in epidermal cell proliferation, decreasing sebaceous gland activity, reducing the *P. acnes* population, and limiting the inflammatory process. Often, a combination of keratolytic and antibacterial agents is used. Topically applied antibiotics do not affect existing lesions but prevent future lesions by decreasing the amount of *P. acnes*

848 Unit Eleven: Alterations in the Skeletal and Integumentary Systems

■ FIGURE 44-16 ■ (A) Acne of the face and (B) acne of the chest. (Hall J.C. [1999]. Sauer's manual of skin diseases [8th ed., p. 118]. Philadelphia: Lippincott Williams & Wilkins)

on the skin, thereby reducing subsequent inflammation formed from the presence of sebaceous fatty acid metabolites.

Severe cases of acne are managed with topical vitamin A, systemic antibiotics, and oral retinoids or acid form of vitamin A. The action of topical vitamin A (tretinoin) has been attributed to decreased cohesiveness of epidermal cells and increased epidermal cell turnover. This is thought to result in increased extrusion of open comedones and transformation of closed comedones into open ones. The oral retinoids (isotretinoin) have revolutionized the treatment of recalcitrant cases of acne and cystic acnes. Although the exact mode of action is unknown, isotretinoin decreases sebaceous gland activity, prevents new comedones from forming, reduces the *P. acnes* count through sebum reduction, and has an anti-inflammatory effect. Because of its many side effects, it is used only in persons with severe acne. Isotretinoin is a known teratogen and should not be used in women who are pregnant or may become pregnant.

Acne Conglobata

Acne conglobata occurs later in life and is a chronic form of acne. Comedones, papules, pustules, nodules, abscesses, cysts, and scars occur on the back, buttocks, and chest. Lesions occur to a lesser extent on the abdomen, shoulders, neck, face, upper arms, and thighs.¹⁷ The comedones have multiple openings. Their discharge is odoriferous, serous, and purulent or mucoid. Healing leaves deep keloidal lesions. Affected persons have anemia with increased white blood cell counts, sedimentation rates, and neutrophil counts. The treatment is difficult and stringent. It often includes debridement, systemic corticosteroid therapy, oral retinoids, and systemic antibiotics.

Rosacea

Rosacea, formerly called *acne rosacea*, is a chronic acneform type eruption of the butterfly area of the face that occurs in middle-age and older adults. It is easily confused with acne and may coexist with it. In the early stage of development, there are repeated episodes of blushing, eventually progressing to a persistent erythema on the nose and cheeks that sometimes extends to the forehead and chin (Fig. 44-17). This stage often occurs before 20 years of age. As the person ages, the erythema persists, and telangiectasia with or without acneiform components (*e.g.*, comedones, pustules, nodules) develops. After years of affliction, acne rosacea may develop into an irregular bullous hyperplasia (thickening) of the nose, known as *rhinophyma*. The sebaceous follicles and openings enlarge, and the skin color changes to a purple-red. Rhinophyma occurs mainly in men.¹⁷

The cause of rosacea remains unknown. It is seen more commonly in fair-skinned persons and has been called "the curse of the Celts." The capillaries in the involved facial areas display an increased reactivity to heat and other vascular stimulating agents such as highly spiced food and alcohol.

Treatment measures are similar to those used for acne vulgaris. Rhinophyma can be treated surgically. Because of increased capillary reactivity, people with rosacea are instructed to avoid heat, sunlight, hot liquids, highly seasoned foods, and alcohol.

Atopic Eczema and Nummular Eczema

Atopic eczema (atopic dermatitis) is a common skin disorder that occurs in two clinical forms: infantile and adult.^{21,22} It is associated with a type I hypersensitivity reaction (see Chap-

■ FIGURE 44-17 ■ Chronic rosacea with rhinophyma. (Hoechst Marion Roussel Pharmaceuticals, Inc.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

ter 10). There usually is a family history of asthma, hay fever, or atopic dermatitis. The infantile form is characterized by vesicle formation, oozing, and crusting with excoriations. It usually begins in the cheeks and may progress to involve the scalp, arms, trunk, and legs (Fig. 44-18). The skin of the cheeks may be paler, with extra creases under the eyes, called *Dennie-Morgan folds*. There is marked follicle involvement in persons with black skin. Lesions may be hypopigmented or hyperpigmented or both on a black-skinned person. The infantile form usually becomes milder as the child ages, often disappearing by the age of 15 years. Adolescents and adults usually have dry, leathery, and hyperpigmented or hypopigmented lesions located in the antecubital and popliteal areas. These may spread to the neck, hands, feet, eyelids, and behind the ears. Itching may be severe with both forms. Secondary in-

fections are common. Treatment of atopic eczema is designed to target the underlying abnormalities such as dryness, pruritus, superinfection, and inflammation. It involves allergen control, basic skin care, and medications. Because dry skin and pruritus often exacerbate the condition, hydration of the skin is essential to treating atopic dermitis. Mild or healing lesions may be treated with lotions containing a mild antipruritic agent. Acute weeping lesions are treated with soothing lotions, soaks, or wet dressings. Topical corticosteroids provide an effective form of treatment but can cause local and systemic side effects. Because of their side effects, systemic corticosteroids usually are reserved for severe cases.

FIGURE 44-18 Atopic eczema on an infant's face and on a wrist. (Dome Chemicals.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

The lesions of nummular eczema (discoid eczema) are coinshaped (nummular) papulovesicular patches mainly involving the arms and legs (Fig. 44-19). Lichenification and secondary bacterial infections are common. It is not unusual for the initial lesions seemingly to heal, followed by a secondary outbreak of mirror-image lesions on the opposite side of the body. Most nummular eczema is chronic, with weeks to years between exacerbations. Exacerbations occur more frequently in the cold winter months. The exact cause of nummular eczema is unknown. There usually is a history of asthma, hay fever, or atopic dermatitis. Ingestion of iodides and bromides usually aggravates the condition. Treatment is palliative. Frequent bathing, foods rich in iodides and bromides, and stress should be reduced, whereas the environmental humidity should be increased. Topical corticosteroids, coal tar preparations, and ultraviolet light treatments are prescribed as necessary.

Urticaria

Urticaria, or hives, is characterized by edematous plaques, called *wheals*, that are accompanied by intense itching. Wheals typically appear as raised pink or red areas surrounded by a paler halo. They blanch with pressure and vary in size from a few millimeters to centimeters. Thicker lesions that result from massive transudation of fluid into the dermis or subcutaneous tissue are referred to as *angioedema*. Although angioedema lesions can occur on any skin surface, they typically involve the larynx, causing hoarseness or sore throat, or mucosal surface of the gastrointestinal tract, causing abdominal pain.

Histamine, released from mast cells, is the most common mediator of urticaria. It causes hyperpermeability of the microvessels of the skin and surrounding tissue, allowing fluid to leak into the tissues, causing edema and wheal formation.^{23,24} A variety of immunologic, nonimmunologic, physical, and chemical stimuli can cause urticaria.

Urticaria can be acute or chronic. Daily or almost daily episodes of urticaria persisting for longer than 6 weeks are considered to be chronic. The most common causes of acute urticaria are foods or drinks, medications, or exposure to pollens or chemicals. Food is the most common cause of acute urticaria in children. Although nonsteroidal anti-inflammatory drugs, including aspirin, do not normally cause urticaria, they may exacerbate pre-existing disease.

■ FIGURE 44-19 ■ Nummular eczema of the buttocks. (Johnson & Johnson.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

Chronic urticaria affects primarily adults and is twice as common in women as in men. Usually its cause cannot be determined despite extensive laboratory tests. Some forms of chronic urticaria are associated with histamine-releasing autoantibodies. In rare cases, urticaria is a manifestation of underlying disease, such as certain cancers, collagen diseases, and hepatitis. There is an association between chronic urticaria and autoimmune thyroid disease (*e.g.*, Hashimoto's thyroiditis, Graves' disease, toxic multinodular thyroiditis). A hereditary deficiency of a C1 (complement 1) inhibitor also can cause urticaria and angioedema.

Physical urticarias constitute another form of chronic urticaria.³⁵ Physical urticarias are intermittent, usually last less than 2 hours, are produced by appropriate stimuli, have distinctive appearances and locations, and are seen most frequently in young adults. Dermographism, or skin writing, is one form of physical urticaria in which wheals appear in response to simple rubbing of the skin (Fig. 44-20). The wheals follow the pattern of the scratch or rubbing, appearing within 10 minutes, and dissolving completely within 20 minutes. Other types of physical urticaria are cholinergic (*i.e.*, exercise-induced), cold, delayed pressure, solar (*i.e.*, sunlight), aquagenic (*i.e.*, water), vibratory, and external (localized heat-induced). Appropriate challenge tests (*e.g.*, application of an ice cube to the skin to initiate development of cold urticaria) are used to differentiate physical urticaria from chronic urticaria due to other causes.

Most types of urticaria are treated with antihistamines: drugs that block histamine type 1 (H_1) and less frequently, H_1 in combination with histamine type 2 (H_2). They control urticaria by inhibiting vasodilation and escape of fluid into the surrounding tissues. Severe urticaria and angioedema are treated with epinephrine. Oral corticosteroids may be used in the treatment of refractory urticaria.

Drug-Induced Skin Eruptions

Almost any drug can cause a localized or generalized skin eruption. Topical drugs usually are responsible for a localized contact dermatitis type of rash, whereas systemic drugs cause generalized skin lesions. Most drug eruptions are morbilliform (*i.e.*, measles-like) or exanthematous. Drug eruptions usually occur within 1 to 2 weeks after starting therapy. Some drug reactions progress to more severe skin lesions, necessitating prompt medical attention. Drug-induced skin reactions mimic almost all other skin lesions described in this chapter.

The diagnosis of a drug sensitivity depends almost entirely on accurate reporting by the person because the lesions from drug sensitization vary greatly. Treatment of mild cases is aimed at eliminating the offending drug while treating the symptoms. In mild cases, the lesions usually clear within 7 to 14 days after withdrawal of the offending drug. Severe drug eruptions often require systemic corticosteroid therapy and antihistamines.

Three types of bullous skin manifestations that result from drug reactions end in epidermal skin detachment: erythema multiforme minor, Stevens-Johnson syndrome (erythema multiforme major), and toxic epidermal necrolysis. The latter two are rare occurrences, but they can be life threatening. Both usually are caused by sensitivity to such drugs as sulfonamides and anticonvulsants. Although erythema multiforme minor may be drug induced, it more frequently occurs after infections, especially with herpes simplex. It is self-limiting, with a small amount of skin detachment at the lesion sites.

The lesions of erythema multiforme minor and Stevens-Johnson syndrome are similar. The primary lesion of both is a round, erythematous papule, resembling an insect bite. Within hours to days, these lesions change into several different patterns. The individual lesions may enlarge and coalesce, producing small plaques, or they may change to concentric zones of color appearing as "target" or "iris" lesions (Fig. 44-21). The outermost rings of the target lesions usually are erythematous; the central portion usually is opaque white, yellow, or gray (dusky). In the center, small blisters on the dusky purpuric macules may form, giving them their characteristic target-like appearance. Although there is wide distribution of lesions over the body surface area, there is a propensity for them to occur on the face and trunk. With Stevens-Johnson syndrome, there is more skin detachment.

■ FIGURE 44-20 ■ Dermographism on a patient's back. (Dermik Laboratories, Inc.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

■ FIGURE 44-21 ■ Erythema-multiforme-like eruption on the patient's arm. Notice the dusky, target-like appearance. (Dermik Laboratories, Inc.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

Chapter 44: Alterations in Skin Function and Integrity

Toxic epidermal necrolysis is the most serious and lifethreatening drug reaction. The person experiences a prodromal period of malaise, low-grade fever, and sore throat. Within a few days, widespread erythema and large, flaccid bullae appear, followed by the loss of the epidermis. This leaves a denuded and painful dermis. The skin surrounding large denuded areas may have the typical target-like lesions seen with Stevens-Johnson syndrome. The skin separates easily from the dermis with lateral pressure. The epithelium of mucosal surfaces, especially the mouth and eyes, may be involved.

These three types of bullous skin eruptions are seemingly quite similar. The diagnostic boundary for erythema multiforme minor is that it usually occurs after herpes simplex infection and is self-limiting. Precise diagnostic boundaries between Stevens-Johnson syndrome and toxic epidermal necrolysis have not been established. However, it is generally agreed that cases involving less than 10% of the body surface area are called *Stevens-Johnson syndrome*, and detachment of more than 30% of the epidermis is labeled *toxic epidermal necrolysis*.^{25,26} The mortality rate associated with Stevens-Johnson syndrome is less than 5%, and that for toxic epidermal necrolysis is 30% or greater.²⁶

The skin detachment associated with these drug reactions is different from the desquamation (*i.e.*, peeling) discussed with other skin disorders. For example, with scarlet fever there is peeling of the stratum corneum, the dead keratinized layer. In the bullous disorders discussed here, there is full-thickness detachment (*i.e.*, peeling of the entire epidermis down to the dermis). This leaves the person vulnerable to multiple problems, such as loss of body fluid and thermal control, nutritional deficits, and electrolyte imbalance.

Treatment of erythema multiforme minor and less severe cases of Stevens-Johnson syndrome includes relief of symptoms using compresses, antipruritic drugs, and topical anesthetics. Corticosteroid therapy may be indicated in moderate cases, although its use is a matter of controversy. For severe cases of Stevens-Johnson syndrome or toxic epidermal necrolysis, hospitalization is required for fluid replacement, antibiotics, respiratory care, analgesics, and moist dressings. When large areas of skin are detached, the care is similar to that provided to patients with thermal burns.

Papulosquamous Dermatoses

Papulosquamous dermatoses are a group of skin disorders characterized by scaling papules and plaques. Among the major papulosquamous diseases are psoriasis, pityriasis rosea, and lichen planus.

Psoriasis

Psoriasis is a common skin disease characterized by circumscribed red, thickened plaques with an overlying silvery-white scale. Psoriasis occurs worldwide, although the incidence is lower in warmer, sunnier climates. In the United States, it affects 2.6% or 6 million Americans.²⁷ The average age of onset is in the third decade; its prevalence increases with age. Approximately one third of patients have a genetic history, indicating a hereditary factor. Childhood onset of the disease is more strongly associated with a family history than psoriasis occurring in adults older than 30 years.²⁸ There appears to be an association between psoriasis and arthritis. Psoriatic arthritis occurs in 5% to 7% of persons with psoriasis (see Chapter 43). The cause of psoriasis remains poorly understood and is probably multifactorial. There is evidence of a genetic component. The more severe the disease, the greater is the likelihood of a familial background. Environmental factors may also play a role. A variety of stimuli, such as physical injury, infections, use of certain drugs, and photosensitivity, may precipitate the development or exacerbation of lesions in people who are predisposed to the disease. The reaction of the skin to an original trauma of any type is called the *Köbner reaction*.

Histologically, psoriasis is characterized by increased epidermal cell turnover with marked epidermal thickening, a process called *hyperkeratosis*. The migration time of the keratinocyte from the basal cell layer to the stratum corneum decreases from the normal 14 days to approximately 4 to 7 days. The granular layer of the epidermis is thinned or absent. There is also an accompanying thinning of the epidermal cell layer that overlies the tips of the dermal papillae (suprapapillary plate), and the blood vessels within dermal papillae become tortuous and dilated. These capillary beds show permanent damage even when the disease is in remission or has resolved. The close proximity of the vessels in the dermal papillae to the hyperkeratotic scale accounts for multiple, minute bleeding points that are seen when the scale is lifted.¹²

The lesions of plaque-type psoriasis may occur anywhere on the skin but most often involve the elbows, knees, and scalp (Fig. 44-22). The primary lesions are papules that vary in shape. The papules form thick red plaques with a silvery scale. In darker-skinned persons, the plaques may appear purple. There may be excoriation, thickening, or oozing from the lesions. A differential diagnostic finding is that the plaques bleed from minute points when removed.

There is no cure for psoriasis. The goal of treatment is to suppress the signs and symptoms of the disease: hyperkeratosis, epidermal inflammation, and abnormal keratinocyte

■ FIGURE 44-22 ■ Psoriasis on the elbows of a 17-year-old girl. (Roche Laboratories.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

differentiation.^{27,28} Treatment measures are divided into topical and systemic approaches. Psoriasis has long been treated topically with keratolytic agents, coal tar products, and anthralin.¹⁷ Topical and systemic corticosteroids may be used, depending on the severity of the disease. Severe, generalized psoriasis may be treated with agents such as methotrexate. Methotrexate, which is used for cancer treatment, is an antimetabolite that inhibits DNA synthesis and prevents cell mitosis. Phototherapy after the administration of a psoralen has proven to be effective in many severe cases. Methoxsalen, a psoralen, exerts its actions when exposed to UVA radiation in 320to 400-nm wavelengths. Methoxsalen is given orally before UVA exposure. Activated by the UVA energy, methoxsalen inhibits DNA synthesis, thereby preventing cell mitosis and decreasing the hyperkeratosis that occurs with psoriasis. The combination treatment regimen of psoralen and UVA is known by the acronym PUVA.

Pityriasis Rosea

Pityriasis rosea is a rash that primarily affects young adults. The origin of the rash is unknown, but it is believed to be caused by an infective agent. Numerous viruses have been investigated, but no conclusive evidence has been found. The incidence is highest in winter. Cases occur in clusters and among persons who are in close contact with each other, indicating an infectious spread. However, there are no data to support communicability. It may be an immune response to any number of agents.

The characteristic lesion is an oval macule or papule with surrounding erythema (Fig. 44-23). The lesion spreads with central clearing, much like tinea corporis. This initial lesion is a solitary lesion called the *herald patch* and is usually on the trunk or neck. As the lesion enlarges and begins to fade away (2 to 10 days), successive crops of lesions appear on the trunk and neck. The lesions on the back have a characteristic "Christmas tree" pattern. The extremities, face, and scalp may be involved. Mild to severe pruritus may occur.

The disease is self-limited and usually disappears within 6 to 8 weeks. Treatment measures are palliative and include topical steroids, antihistamines, and colloid baths. Systemic corticosteroids may be indicated in severe cases.

■ FIGURE 44-23 ■ Pityriasis rosea of the thighs. (Syntex Laboratories.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

Lichen Planus

The term *lichen* is of Greek origin and means "tree moss." The term is applied to skin disorders characterized by small (2 to 10 mm), flat-topped papules with irregular, angulated borders (Fig. 44-24).¹⁷ Lichen planus is a relatively common chronic, pruritic disease. It involves inflammation and papular eruption of the skin and mucous membranes. There are variations in the pattern of lesions (*e.g.*, annular, linear) and differences in the sites (*e.g.*, mucous membranes, genitalia, nails, scalp). The characteristic lesion is a purple, polygonal papule covered with a shiny, white, lacelike pattern. The lesions appear on the wrist, ankles, and trunk of the body. Most persons who have skin lesions also have oral lesions, appearing as milky white lacework on the buccal mucosa or tongue.

The etiology of lichen planus is unknown. There is increasing evidence of a cell-mediated response involving the epidermal-dermal junction with damage to the basal cell layer. Although the cause of most cases of lichen planus is unknown, some are linked to medication use or hepatitis C virus infection. The most common offending agents include gold, antimalarial agents, thiazide diuretics, beta blockers, nonsteroidal anti-inflammatory agents, quinidine, and angiotensin-converting enzyme inhibitors.²⁹

Diagnosis is based on the clinical appearance of the lesions and the histopathologic findings from a punch biopsy. For most persons, lichen planus is a self-limited disease. Treatment measures include discontinuation of all medications, followed by treatment with topical corticosteroids and occlusive dressings. Antipruritic agents are helpful in reducing itch. Systemic corticosteroids may be indicated in severe cases. Intralesional corticosteroid injections also may be used.

■ FIGURE 44-24 ■ Lichen planus of the dorsum of the hand and wrist. Notice the violacenous color of the papules and the linear Köbner's phenomenon. (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

Lichen simplex chronicus is a localized lichenoid dermatitis. The term lichen simplex denotes that there was no known predisposing skin disorder in the affected person. It is characterized by the occurrence of itchy, reddened, thickened, and scaly patches of dry skin. Persons with the condition may have a single or, less frequently, multiple lesions. The lesions are seen most commonly at the nape of the neck, wrist, ankles, or anal area. The condition usually begins as a small pruritic patch, which culminates in a repetitive cycle of itching and scratching that develops into a chronic dermatosis. Because of the chronic itching and scratching, excoriations and lichenification with thickening of the skin develop, often giving the appearance of tree bark. Treatment consists of measures to decrease scratching of the area. A moderate-potency corticosteroid is often prescribed to decrease the itching and subsequent inflammatory process.

In summary, primary disorders of the skin include pigmentary skin disorders, infectious processes, inflammatory conditions, immune disorders, and allergic reactions. Pigmentary skin disorders include vitiligo, albinism, and melasma. Although the causes of the disorders vary, all involve changes in the amount of melanin produced by the melanocytes. These disorders appear in people of every skin type; however, the manifestations of the disorders vary among light-skinned and dark-skinned persons. Superficial fungal infections are called dermatophytoses and are commonly known as tinea or ringworm. Impetigo, which is caused by staphylococci or β-hemolytic streptococci, is the most common superficial bacterial infection. Viruses are responsible for verrucae (warts), herpes simplex type 1 lesions (cold sores or fever blisters), and herpes zoster (shingles). Noninfectious inflammatory skin conditions such as acne, lichen planus, psoriasis, and pityriasis rosea are of unknown origin. They usually are localized to the skin and are rarely associated with specific internal disease. Allergic skin responses involve the body's immune system and are caused by hypersensitivity reactions to allergens, environmental agents, drugs, and other substances.

NEVI AND SKIN CANCERS

Nevi

Nevi, or moles, are common congenital or acquired tumors of the skin that are benign. Almost all adults have nevi, some in greater numbers than others. Nevi can be pigmented or nonpigmented, flat or elevated, and hairy or nonhairy.

Nevocellular nevi are pigmented skin lesions resulting from proliferation of melanocytes in the epidermis or dermis. Nevocellular nevi are tan to deep brown, uniformly pigmented, small papules with well-defined and rounded borders. They are formed initially by melanocytes with their long dendritic extensions that are normally interspersed among the basal keratinocytes.¹² These melanocytes are transformed into round or oval melanin-containing cells that grow in nests or clusters along the dermal-epidermal junction. Because of their location, these lesions are called *junctional nevi* (Fig. 44-25). Eventually, most junctional nevi grow into the surrounding dermis as nests

■ **FIGURE 44-25** ■ Junctional nevi of the back of a 16-year-old patient. (Owen Laboratories, Inc.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

or cords of cells. *Compound nevi* contain epidermal and dermal components. In older lesions, the epidermal nests may disappear entirely, leaving a *dermal nevi*. Compound and dermal nevi usually are more elevated than junctional nevi.

Another form of nevi, the *dysplastic nevi*, are important because of their capacity to transform to malignant melanomas. Although the association between dysplastic nevi and malignant melanoma was made more than 175 years ago, it was not until 1978 that the role of dysplastic nevi as a precursor of malignant melanoma was described in detail. Dysplastic nevi are larger than other nevi (often >5 mm in diameter). Their appearance is one of a flat, slightly raised plaque with a pebbly surface, or a target-like lesion with a darker, raised center and irregular border. They vary in shade from brown and red to flesh tones and have irregular borders. A person may have hundreds of these lesions. Unlike other moles or nevi, they occur on both sun-exposed and covered areas of the body. Dysplastic nevi have been documented in multiple members of families prone to the development of malignant melanoma.¹²

Because of the possibility of malignant transformation, any mole that undergoes a change warrants immediate medical attention. The changes to observe and report are changes in size, thickness, or color, and itching or bleeding.

Skin Cancer

There has been an alarming increase in skin cancers during the past several decades. Since the 1970s, the incidence rate of malignant melanoma, the most serious form of skin cancer, has increased significantly.³⁰ These increases are, on average, 4% per year, from 5.7 per 100,000 in 1973 to 13.8 per 100,000 in 1996, with approximately 47,700 new cases and 9600 deaths each year from melanoma. There also are approximately 1.3 million cases each year of highly curable basal cell and squamous cell cancers.

The rising incidence of skin cancer may be attributed primarily to increased sun exposure associated with societal and lifestyle shifts in the United States. The thinning of the ozone layer in the earth's stratosphere is thought to be an important

KEY CONCEPTS

SKIN CANCERS

- Increased and unprotected exposure to the ultraviolet rays of sunlight produces sunburn and increases the risk for development of skin cancer.
- The melanocytes, which protect against sunburn through increased production of melanin and suntanning, are particularly vulnerable to the adverse effects of unprotected exposure to ultraviolet light. Malignant melanoma, which is a malignant tumor of melanocytes, is a rapidly progressive and metastatic form of skin cancer.
- Basal cell carcinoma and squamous cell carcinoma, which also reflect the effects of increased sun exposure, are less aggressive forms of skin cancer and are more easily cured.

factor in this incidence rate. Society's emphasis on suntanning also is implicated. Persons have more leisure time and spend increasing amounts of time in the sun with uncovered skin.

Although the factors linking sun exposure to skin cancer are incompletely understood, both total cumulative exposure and altered patterns of exposure (in the case of melanoma) are strongly implicated. Basal cell and squamous cell carcinomas are associated with total cumulative exposure to ultraviolet radiation, whereas melanomas are associated with intense intermittent exposure. Thus, basal cell and squamous cell carcinomas occur more commonly on maximally sun-exposed parts of the body, such as the face and back of the hands and forearms. In contrast, melanomas occur most commonly in areas of the body that are exposed to the sun intermittently, such as the back in men and the lower legs in women. It is more common in persons with indoor occupations whose exposure to sun is limited to weekends and vacations.

Malignant Melanoma

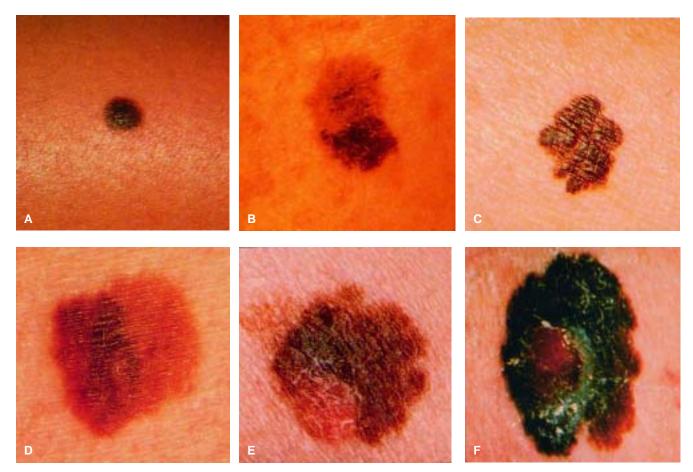

Malignant melanoma is a malignant tumor of the melanocytes. It is a rapidly progressing, metastatic form of cancer. The increased incidence of melanoma that has occurred during the past several decades has been attributed to an increase in sun exposure. The risk is greatest in fair-skinned people, particularly those with blond or red hair who sunburn and freckle easily. Fortunately, the increased risk of melanoma has been associated with a concomitant increase in the 5-year survival rate, from approximately 40% in the 1940s to 90% at present.³¹ Public health screening measures, early diagnosis, increased knowledge of precursor lesions, and greater public knowledge of the disease may account for earlier intervention.

Severe, blistering sunburns in early childhood and intermittent intense sun exposures (trips to sunny climates) contribute to increased susceptibility to melanoma in young and middleage adults. Roughly 90% of malignant melanomas in whites occur on sun-exposed skin. However, in African Americans and Asians, roughly 67% occur on non–sun-exposed areas, such as mucous membranes and subungual, palmar, and plantar surfaces.³² Although sun exposure remains a significant risk factor for melanoma, other potential risk factors have been identified, including atypical mole/dysplastic nevus syndrome, immunosuppression, prior PUVA therapy, and exposure to ultraviolet light at tanning salons. Using statistical analysis, it has been determined that six factors independently influence the risk for development of malignant melanoma: family history of malignant melanoma, presence of blond or red hair, presence of marked freckling on the upper back, history of three or more blistering sunburns before 20 years of age, history of 3 or more years of an outdoor job as a teenager, and presence of actinic keratosis. Persons with two of these risk factors had a 3.5-fold increased risk of malignant melanoma, and those with three or more risk factors had a 20-fold increased risk.³¹

Malignant melanomas differ in size and shape. Usually, they are slightly raised and black or brown. Borders are irregular, and surfaces are uneven. Most seem to arise from pre-existing nevi or new molelike growths (Fig. 44-26). There may be surrounding erythema, inflammation, and tenderness. Periodically, melanomas ulcerate and bleed. Dark melanomas are often mottled with shades of red, blue, and white. These three colors represent three concurrent processes: melanoma growth (blue), inflammation and the body's attempt to localize and destroy the tumor (red), and scar tissue formation (white). Malignant melanomas can appear anywhere on the body. Although they frequently are found on sun-exposed areas, sun exposure alone does not account for their development. In men, they are found frequently on the trunk, head, neck, and arms; in women, they commonly are found on the legs.

Four types of melanomas have been identified: superficial spreading, nodular, lentigo maligna, and acral lentiginous.³⁰ Superficial spreading melanoma is characterized by a raised-edged nevus with lateral growth. It has a disorderly appearance in color and outline. This lesion tends to have biphasic growth, horizontally and vertically. It typically ulcerates and bleeds with growth. This type of lesion accounts for 70% of all melanomas and is most prevalent in persons who sunburn easily and have intermittent sun exposure. Nodular melanomas, which account for 15% to 30% of melanomas, are raised domeshaped lesions that can occur anywhere on the body. They are commonly a uniform blue-black color and tend to look like blood blisters. Nodular melanomas tend to rapidly invade the dermis from the start with no apparent horizontal growth phase. Lentigo maligna melanomas, which account for 4% to 10% of all melanomas, are slow growing, flat nevi that occur primarily on sun-exposed areas of elderly persons. Untreated lentigo maligna tends to exhibit horizontal and radial growth for many years before it invades the dermis to become lentigo maligna melanoma. Acral lentiginous melanoma, which accounts for 2% to 8% of melanomas, occurs primarily on the palms of the hands, soles of the feet, nail beds, and mucous membranes. It has the appearance of lentigo maligna. Unlike other types of melanomas, it has a similar incidence in all ethnic groups.

Because virtually all the known risks of melanoma are related to susceptibility and magnitude of ultraviolet light exposure, protection from the sun's rays plays a critical role in the prevention of malignant melanoma. Early detection is critical with malignant melanoma. Regular self-examination of the total skin surface in front of a mirror under good lighting provides a method for early detection. It requires that a person undress completely and examine all areas of the body using a full

■ FIGURE 44-26 ■ (A) Normal mole with even, round contour and sharply defined borders. (B) Changes in appearance of a mole: *asymmetry*. (C) Changes in appearance of a mole: *border irregularity*. (D) Changes in appearance of a mole: *color and uneven pigmentation*. (E) Changes in the appearance of a mole: *diameter greater than 6 mm*. (F) Changes in the surface of a mole: *scaliness, oozing, and bleeding*. (American Cancer Society. [1995]. *What you should know about melanoma*. Dallas: American Cancer Society)

mirror, handheld mirror, and handheld hair dryer (to examine the scalp). An *ABCD* rule has been developed to aid in early diagnosis and timely treatment of malignant melanoma.³¹ The acronym stands for *asymmetry*, *b*order irregularity, *c*olor variegation, and *d*iameter greater than 0.6 cm (pencil eraser size). People should be taught to watch for these changes in existing nevi or the development of new nevi, as well as other alterations such as bleeding or itching.

Diagnosis of melanoma is based on biopsy findings from a suspect lesion. Treatment is usually surgical excision, the extent of which is determined by the thickness of the lesion, invasion of the deeper skin layers, and spread to regional lymph nodes. Deep and wide excisions, with possible use of skin grafts, are used. Current cancer treatment, such as immunotherapy and chemotherapy, is indicated when the disease becomes systemic. Interferon alfa-2b is approved by the FDA for treatment of melanoma.^{30,31}

The prognosis for malignant melanoma varies. It depends on factors such as tumor thickness (measured in millimeters), anatomic site, type of lesion, and levels of invasion (degree of penetration in the anatomic layers of the skin). Tumor thickness is an important factor in determining prognosis in persons with malignant melanoma.

Basal Cell Carcinoma

Basal cell carcinoma is the most common skin cancer in humans, accounting for 75% of all nonmelanoma skin cancers.³⁴ Like other skin cancers, basal cell carcinoma has increased in incidence during the past several decades. Basal cell carcinoma usually occurs in persons who were exposed to great amounts of sunlight. The incidence is twice as high among men as women and greatest in the 55- to 75-year-old age group.

Basal cell carcinoma usually is a nonmetastasizing tumor that extends wide and deep if left untreated. These tumors are seen most frequently on sun-exposed areas of the body, such as the head and neck, but do occur on other skin surfaces that were not exposed to the sun (Fig. 44-27). Although there are several histologic types of basal cell carcinoma, nodular ulcerative and superficial basal cell carcinomas are the most frequently occurring types. *Nodular ulcerative basal cell carcinoma* is the most common type.³⁴ It is a nodulocystic structure that begins as a small, flesh-colored or pink, smooth, translucent nodule that enlarges with time. Telangiectatic vessels frequently are seen beneath the surface. Over the years, a central depression forms that progresses to an ulcer surrounded by the original shiny, waxy border. Basal cell carcinoma in darker-skinned persons usually is darkly pigmented

■ FIGURE 44-27 ■ Basal cell carcinoma and wrinkling of the hand. (Syntex Laboratories.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

and frequently misdiagnosed as other skin diseases, including melanoma.

The second most common form is *superficial basal cell carcinoma*, which is seen most often on the chest or back. It begins as a flat, nonpalpable, erythematous plaque. The red, scaly areas slowly enlarge, with nodular borders and telangiectatic bases. This type of skin cancer is difficult to diagnose because it mimics other dermatologic problems.

All suspected basal cell carcinomas should undergo biopsy for diagnosis. The treatment depends on the site and extent of the lesion. The most important treatment goal is complete elimination of the lesion. Also important is the maintenance of function and optimal cosmetic effect. Curettage with electrodesiccation, surgical excision, irradiation, and chemosurgery are effective in removing all cancerous cells. Patients should be checked at regular intervals for recurrences.

Squamous Cell Carcinoma

Squamous cell carcinomas are malignant tumors of the outer epidermis. They are commonly found on the sun-exposed area of the skin of people with fair complexions.³⁴ Metastasis is more common with squamous cell carcinoma than with basal cell carcinoma.

The mechanisms of squamous cell carcinoma development are unclear. Most squamous cell cancers occur in sun-exposed areas of the skin, and persons who spend much time outdoors, have lighter skin, and live in lower latitudes are more affected. The increase in the incidence of squamous cell carcinomas is consistent with increased ultraviolet radiation exposure. Other suspected causes include exposure to arsenic (*i.e.*, Bowen's disease), gamma radiation, tars, and oils.

There are two types of squamous cell carcinoma: intraepidermal and invasive. *Intraepidermal squamous cell carcinoma* remains confined to the epidermis for a long time. However, at some unpredictable time, it may penetrate the basement membrane to the dermis and metastasize to the regional lymph nodes. It then converts to *invasive squamous cell carcinoma*. The invasive type can develop from intraepidermal carcinoma or from a premalignant lesion (*e.g.*, actinic keratoses). It may be slow growing or fast growing with metastasis.

■ FIGURE 44-28 ■ Squamous cell carcinoma of the chin. (Syntex Laboratories, Westwood Pharmaceuticals.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven)

Squamous cell carcinoma is a red-scaling, keratotic, slightly elevated lesion with an irregular border, usually with a shallow chronic ulcer (Fig. 44-28). Later lesions grow outward, show large ulcerations, and have persistent crusts and raised, erythematous borders. The lesions characteristically occur on the nose, forehead, helixes of the ears, lower lip, and back of the hands. In blacks, the lesions may appear as hyperpigmented nodules and occur more frequently on non–sunexposed areas.

Treatment measures are aimed at the removal of all cancerous tissue using methods such as electrosurgery, excision surgery, chemosurgery, or radiation therapy. After treatment, the person is observed for the remainder of his or her life for signs of recurrence. The recurrence rate is roughly 50%, with a 70% metastatic rate.³⁵

In summary, nevi are moles that usually are benign. Because they may undergo cancerous transformation, any mole that undergoes a change warrants immediate medical attention. There has been an alarming increase in skin cancers during the past few decades. Repeated exposure to the ultraviolet rays of the sun has been implicated as the principal cause of skin cancer. Neoplasms of the skin include malignant melanoma, basal cell carcinoma, and squamous cell carcinoma. Malignant melanoma is a malignant tumor of the melanocytes. It is a rapidly progressing, metastatic form of cancer. The most important clinical sign is the change in size, shape, and color of a pigmented skin lesion, such as a mole. Early detection through skin self-examination is critical. Squamous cell carcinoma and basal cell carcinoma are of epidermal origin. Basal cell carcinomas are the most common form of skin cancer among whites. They are slow-growing tumors that rarely metastasize. Squamous cell carcinoma is common in pale-skinned elderly persons. The two types of squamous cell carcinoma are intraepidermal and invasive. Intraepidermal squamous cell carcinoma remains confined to the epidermis for a long time. Invasive squamous cell carcinoma can develop from intraepidermal carcinoma or from premalignant lesions such as actinic keratoses.

Many skin problems occur more commonly in certain age groups. Because of aging changes, infants, children, and elderly persons tend to have different skin problems.

Skin Disorders in Infants and Children

Skin disorders in infants and children may be different from those in older children and adults. Certain skin disorders such as diaper rash and cradle cap are seen only in infants. Other conditions such as measles and chickenpox are more common in school age children.

Skin Disorders in Infants

Infancy connotes the image of perfect, unblemished skin. For the most part, this is true. However, several congenital skin lesions, such as mongolian spots, hemangiomas, and nevi, are associated with the early neonatal period.

Vascular and Pigmented Birthmarks. Pigmented and vascular lesions comprise most birthmarks.³⁶ Pigmented birthmarks represent abnormal migration or proliferation of melanocytes. Mongolian spots are caused by selective pigmentation. They usually occur on the buttocks or sacral area and are seen commonly in Asians and blacks. Nevi or moles are small, tan to brown, uniformly pigmented solid macules. Nevocellular nevi are formed initially from aggregates of melanocytes and keratinocytes along the dermal-epidermal border. Congenital melanocytic nevi are collections of melanocytes that are present at birth or develop within the first year of life. They present as macular, papular, or plaquelike pigmented lesions of various shades of brown, with a black or blue focus. The texture of the lesions varies, and they may be with or without hair. They usually are found on the hands, shoulders, buttocks, entire arm, or trunk of the body. Some involve large areas of the body in garment-like fashion. They usually grow proportionately with the child. Congenital melanocytic nevi are clinically significant because of their association with malignant melanoma.

Vascular birthmarks are cutaneous anomalies of angiogenesis and vascular development.³⁶ Two types of vascular birthmarks commonly are seen in infants and small children: bright red raised strawberry hemangiomas and flat, reddish-purple port-wine stains.

The strawberry hemangiomas begin as small, red lesions that are noticed shortly after birth. Hemangiomas are benign vascular tumors produced by proliferation of the endothelial cells. They are seen in approximately 5% to 10% of 1-year-old children.37 Female infants are three times as likely as male infants to have hemangiomas, and there is an increased incidence in premature infants. Approximately 35% of these lesions are present at birth, and the remainder develop within a few weeks after birth. Hemangiomas typically undergo an early period of proliferation during which they enlarge, followed by a period of slow involution in which the growth is reversed, and finally complete resolution. Most strawberry hemangiomas disappear before 5 to 7 years of age without leaving an appreciable scar. Hemangiomas can occur anywhere in the body. Hemangiomas of the airway can be life threatening. Ulceration, the most frequent complication, can be painful and carries the risk of infection, hemorrhage, and scarring.37

■ FIGURE 44-29 ■ Port-wine stain on the face of a boy. (Ortho Dermatology Corp.) (Sauer G.C., Hall J.C. [1996]. Manual of skin diseases [7th ed.]. Philadelphia: Lippincott-Raven)

Port-wine stains are pink or red patches that can occur anywhere on the body and are very noticeable (Fig. 44-29). They represent slow-growing capillary malformations that grow proportionately with the child and persist throughout life. Port-wine stains usually are confined to the skin but may be associated with vascular malformations of the eye or leptomeninges over the cortex, leading to cognitive disorders, seizures, and other neurologic deficits. Cover-up cosmetics are used in an attempt to conceal their disfiguring effects. Laser surgery has been used effectively in the treatment of port-wine stains.

Diaper Rash. The appearance of diaper rash ranges from simple (*i.e.*, widely distributed macules on the buttocks and anogenital areas) to severe (i.e., beefy, red, excoriated skin surfaces in the diaper area).³⁸ It results from a combination of ammonia and other breakdown products of urine. The treatment includes measures to minimize or prevent skin wetness. It includes frequent diaper changes with careful cleaning of the irritated area to remove the waste products. This is particularly important in hot weather. Exposing the irritated area to air is helpful. Secondary candidal (*i.e.*, yeast) infections may occur and require additional treatment (Fig. 44-30).

Prickly Heat. Prickly heat (heat rash) results from constant maceration of the skin because of prolonged exposure to a warm, humid environment. Maceration leads to midepidermal obstruction and rupture of the sweat glands. Although commonly seen during infancy, prickly heat may occur at any age. The treatment includes removing excessive clothing, cooling the skin with warm water baths, drying the skin with powders, and avoiding hot, humid environments.

Cradle Cap. Cradle cap is a greasy crust or scale formation on the scalp. It usually is attributed to infrequent and inadequate washing of the scalp. Cradle cap is treated by mild shampooing and gentle combing to remove the scales. Sometimes oil can be left on the head for minutes to several hours, softening

■ FIGURE 44-30 ■ Candida intertrigo after a course of oral antibiotics in a 1-year-old child. (Owen Laboratories, Inc.) (Sauer G.C., Hall J.C. [1996]. Manual of skin diseases [7th ed.]. Philadelphia: Lippincott-Raven)

the scales before scrubbing. Other emulsifying ointments or creams may be helpful in difficult cases. The scalp may need to be rubbed firmly to remove the buildup of keratinized cells.

Skin Manifestations of Common Infectious Diseases

Infectious childhood diseases that produce rashes include roseola infantum, rubella, rubeola, and varicella. Although these diseases are seen less frequently because of successful immunization programs and the use of antibiotics, they still occur. Immunization has greatly reduced the incidence of rubella and rubeola. Varicella vaccine is also available.

Roseola Infantum. Roseola infantum (i.e., exanthema subitum) is a contagious viral disease of infants and young children, most frequently between 6 and 18 months of age. It is caused by human herpesvirus-6 and produces a characteristic maculopapular rash covering the trunk and spreading to the appendages. The rash is preceded by an abrupt onset of high fever $(\leq 105^{\circ} \text{F})$, inflamed tympanic membranes, and coldlike symptoms usually lasting 3 to 4 days. These symptoms improve at approximately the same time the rash appears. Unlike rubella, no cervical or postauricular lymph node adenopathy occurs. Roseola infantum frequently is mistaken for rubella. Rubella usually can be excluded by the age of the child and the absence of lymph node adenopathy. In general, rubella does not develop in children younger than 6 to 9 months of age because they retain some maternal antibodies. Blood antibody titers may be taken to determine the actual diagnosis. In most cases, there are no long-term effects associated with this disease.

Rubella. Rubella (*i.e.*, 3-day measles or German measles) is a childhood disease caused by the rubella virus. It is characterized by a diffuse, punctate, macular rash that begins on the trunk and spreads to the arms and legs. Mild febrile states occur; usually the fever is less than 100°F. Postauricular, sub-occipital, and cervical lymph node adenopathy is common. Coldlike symptoms (*e.g.*, nasal congestion and cough) usually accompany the disease.

Rubella usually has no long-lasting sequelae; however, the transmission of the disease to pregnant women early in their

gestation periods may result in congenital rubella syndrome. Among the clinical signs of congenital rubella syndrome are cataracts, microcephaly, mental retardation, deafness, patent ductus arteriosus, glaucoma, purpura, and bone defects.

Rubeola. Rubeola (measles, hard measles, 7-day measles) is an acute, highly communicable viral disease caused by Morbillivirus. The characteristic rash is macular and blotchy; sometimes the macules become confluent. The rubeola rash usually begins on the face and spreads to the appendages. There are several accompanying symptoms: a fever of 100°F or greater, Koplik's spots (*i.e.*, small, irregular red spots with a bluish-white speck in the center) on the buccal mucosa, and mild to severe photosensitivity. The patient commonly has coldlike symptoms, general malaise, and myalgia. In severe cases, the macules may hemorrhage into the skin tissue or onto the outer body surface. This form is called *hemorrhagic measles*. The course of measles is more severe in infants, adults, and malnourished children. There may be severe complications, including otitis media, pneumonia, and encephalitis. Antibody titers are determined for a conclusive diagnosis of rubeola.

Varicella. Varicella (chickenpox) is a common communicable childhood disease. It is caused by the varicella-zoster virus, which also is the agent in herpes zoster (shingles). The characteristic skin lesion occurs in three stages: macule, vesicle, and granular scab. The macular stage is characterized by development within hours of macules over the trunk of the body, spreading to the limbs, buccal mucosa, scalp, axillae, upper respiratory tract, and conjunctiva. During the second stage, the macules form vesicles with depressed centers. The vesicles break open, and a scab forms during the third stage. Crops of lesions occur successively, so that all three forms of the lesion usually are visible by the third day of the illness.

Mild to extreme pruritus accompanies the lesions, which can lead to scratching and subsequent development of secondary bacterial infections. Chickenpox also is accompanied by coldlike symptoms and sometimes photosensitivity. Mild febrile states usually occur, typically beginning 24 hours before lesion outbreak. Side effects, such as pneumonia, septic complications, and encephalitis, are rare.

Varicella in adults may be more severe, with a prolonged recovery rate and greater chances for development of varicella pneumonitis or encephalitis. Immunocompromised persons may experience a chronic, painful type.

🙀 Skin Disorders in the Elderly

Elderly persons experience a variety of age-related skin disorders and exacerbations of earlier skin problems. Aging skin is believed to involve a complex process of actinic (solar) damage, normal aging, and hormonal influences.³⁹ Actinic changes primarily involve increased occurrence of lesions on sunexposed surfaces of the body.

Normal Age-Related Changes

Normal aging consists of changes that occur on areas of the body that have not been exposed to the sun. They include thinning of the dermis and the epidermis, diminution in subcutaneous tissue, a decrease in and thickening of blood vessels, and a decrease in the number of melanocytes, Langerhans' cells,

and Merkel's cells. The keratinocytes shrink, but the number of dead keratinized cells at the surface increases. This results in less padding and thinner skin, with color and elasticity changes. The skin also loses its resistance to environmental and mechanical trauma. Tissue repair takes longer.

With aging, there is also less hair and nail growth, and there is permanent hair pigment loss. There is normally less hormonally influenced sebaceous gland activity, although the glands in the facial skin may increase in size. The skin in most persons older than 70 years becomes dry, rough, scaly, and itchy. When there is no underlying pathology, it is called *senile* pruritus. Itching and dryness often become worse during the winter, when the need for home heating lowers the humidity.

Common Skin Lesions

The most common skin lesions in the elderly are skin tags, keratoses, lentigines, and vascular lesions. Most are actinic manifestations; they occur as a result of exposure to sun and weather throughout the years.

Skin Tags. Skin tags are soft, brown or flesh-colored papules. They occur on any skin surface but most frequently the neck, axilla, and intertriginous areas. They range in size from a pinhead to the size of a pea. Skin tags have the normal texture of the skin. They are benign and can be removed with scissors or electrodesiccation for cosmetic purposes.

Keratoses. A keratosis is a horny growth or an abnormal growth of the keratinocytes. A seborrheic keratosis (i.e., seborrheic wart) is a benign, sharply circumscribed, wartlike lesion that has a stuck-on appearance (Fig. 44-31). They vary in size up to several centimeters. They are usually round or oval, tan, brown, or black lesions. Less pigmented ones may appear yellow or pink. Keratoses can be found on the face or trunk as a solitary lesion or sometimes by the hundreds. Seborrheic keratoses are benign, but they must be watched for changes in color, texture, or size, which may indicate malignant transformation to squamous cell carcinoma.

Actinic keratoses are the most common premalignant skin lesions that develop on sun-exposed areas. The lesions usually are less than 1 cm in diameter and appear as dry, brown scaly areas, often with a reddish tinge. Actinic keratoses often are multiple and more easily felt than seen (Fig. 44-32). They often are indistinguishable from squamous cell carcinoma without biopsy. A hyperkeratotic form also exists that is more prominent and palpable. Often, there is a weathered appearance of the surrounding skin. Slight changes, such as enlargement or ulceration, may indicate malignant transformation. Most actinic keratoses are treated with 5-fluorouracil cream, which erodes the lesions. Roughly 20% of actinic keratoses convert to squamous cell carcinomas.

Lentigines. A lentigo is a well-bordered brown to black macule, usually less than 1 cm in diameter. Solar lentigines are tan to brown, benign spots on sun-exposed areas. They are commonly referred to as liver spots. Creams and lotions containing hydroquinone (e.g., Eldoquin, Solaquin) may be used temporarily to bleach the spots. These agents inhibit the synthesis of new pigment without destroying existing pigment. Higher concentrations are available by prescription. Successful treatment depends on avoiding sun exposure and consistent use of sunscreens. Liquid nitrogen applications have been successful in eradicating senile lentigines.

Lentigo maligna (i.e., Hutchinson's freckle) is a slowly progressive (≤20 years) preneoplastic disorder of melanocytes. It occurs on sun-exposed areas, particularly the face. The lesion is a pigmented macule with a well-defined border and grows to 5 cm or sometimes larger. As it grows throughout the years, it may become slightly raised and wartlike. If untreated, a true malignant melanoma often develops. Surgery, curettage, and cryotherapy have been effective at removing the lentigines. Careful monitoring for conversion to melanoma is important.

Vascular Lesions. Vascular lesions are vascular tumors with chronically dilated blood vessels. The small blood vessels lie in

FIGURE 44-32 Multiple actinic keratoses of the face of an 80-year-old man. (Dermik Laboratories, Inc.) (Sauer G.C., Hall J.C. [1996]. Manual of skin diseases [7th ed.]. Philadelphia: Lippincott-Raven)

the middle to upper dermis. *Senile angiomas* (cherry angiomas) are smooth, cherry-red or purple, dome-shaped papules. They usually are found on the trunk. *Telangiectases* are single dilated blood vessels, capillaries, or terminal arteries that appear on areas exposed to sun or harsh weather, such as the cheeks and the nose. The lesions can become large and disfiguring. Pulsed dye lasers have been effective in removing them. *Venous lakes* are small, dark blue, slightly raised papules that have a lakelike appearance. They occur on exposed body parts, particularly the backs of the hands, ears, and lips. They are smooth and compressible. Venous lakes can be removed by electrosurgery, laser therapy, or surgical excision if a person desires.

In summary, some skin problems occur in specific age groups. Common in infants are diaper rash, prickly heat, and cradle cap. Infectious childhood diseases that are characterized by rashes include roseola infantum, rubella, rubeola, and varicella.

Changes in skin that occur with aging involve a complex process of actinic damage, normal aging, and hormonal influences. With aging, there is thinning of the dermis and the epidermis, diminution in subcutaneous tissue, lessening and thickening of blood vessels, and a slowing of hair and nail growth. Dry skin is common among the elderly, becoming worse during the winter months. Among the skin lesions seen in the elderly are skin tags, keratoses, lentigines, and vascular skin lesions.

REVIEW QUESTIONS

Contrast and compare the following lesions: macule, patch, papule, plaque, nodule, pustule, blister, callus, and corn.

Describe the three types of ultraviolet radiation and relate them to sunburn, aging skin changes, and the development of skin cancer.

Relate the behavior of fungi to the production of superficial skin lesions associated with tinea or ringworm.

State the cause and describe the appearance of impetigo and ecthyma.

Compare the viral causes, manifestations, and treatments of verrucae, herpes simplex, and herpes zoster lesions.

Describe the pathogenesis of acne vulgaris and relate it to measures used in treating the disorder.

Describe the differences and similarities between erythema multiforme minor, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

Define the term papulosquamous and use the term to describe the lesions associated with psoriasis, pityriasis rosea, and lichen planus.

Describe the origin of nevi and state their relationship to skin cancers.

Compare the appearance and outcome of basal cell carcinoma, squamous cell carcinoma, and malignant melanoma.

Describe the distinguishing features of rashes associated with the common infectious childhood diseases: roseola infantum, rubeola, rubella, chickenpox, and scarlet fever.

Describe the appearance of skin tags, keratoses, lentigines, and vascular lesions that are commonly seen in the elderly.
