Preface

The widespread acceptance of our textbook, *Pathophysiology*: Concepts of Altered Health States, has led to requests for an essentials version that can be used by students who do not need the extensive breadth or detail of content provided in the larger book. In preparing the essentials version, we have reorganized content, attempted to eliminate nonessential information, and developed or modified illustrations in an effort to produce a comprehensive text that is accurate, up-to-date, and appealing to the reader. Great care also was taken to integrate text and design in a manner that will aid the reader's exploration. Although the chapters are authored by a variety of experts, there is a unified voice and a consistent level of readability.

As a nurse-physiologist, my major emphasis in the preparation of the essentials version, as with current and previous editions of Pathophysiology: Concepts of Altered Health States, has been to relate normal body functioning to the physiologic changes that participate in disease production and occur as a result of disease, as well as the body's remarkable ability to compensate for these changes. The beauty of a physiologic approach is that it integrates all of the aspects of the individual cells and organs of the human body into a total functional whole that can be used to explain both the physical and psychological aspects of altered health. Indeed, it has been my goal to share the beauty of the human body and to emphasize that in disease as in health, there is more "going right" in the body than is "going wrong." This book is an extension of my career and, as such, of my philosophy. It is my hope that readers will learn to appreciate the marvelous potential of the body, incorporating this belief into their own philosophy and ultimately sharing it with their clients.

In the preparation of Essentials of Pathophysiology: Concepts of Altered Health States, every attempt has been made to develop a text that is current, accurate, and well organized. The content has been arranged so that concepts build on one another. Words are defined as content is presented. Concepts from physiology, biochemistry, physics, and other sciences are reviewed as deemed appropriate. Common health problems, including the special needs of children and older adults, are addressed. Although intended as a course textbook, Essentials of Pathophysiology: Concepts of Altered Health States is also intended to serve as a reference book that students can take with them and use in their practice once the course is finished.

The use of full color in the design and illustrations offers visual appeal and enhances conceptual learning, linking text content to illustration content. Icons identify content related to children 📲 , pregnant women 🚔 , and older adults 🐔 Some of the most popular features found in the sixth edition of Pathophysiology: Concepts of Altered Health States have been retained in this Essentials version:

- List of suffixes and prefixes
- Tables of Normal Laboratory Values
- Glossary
- Key Concept Boxes and Summary Boxes, which help the reader retain and use information by showing how individual facts come together to form a larger conceptual unit

Additional features that are new to the Essentials version include:

- Review Questions at the end of each chapter
- An appendix of Website Resources, to encourage readers to investigate areas of individual interest and update knowledge in a world of ever-changing information.

STUDENT AND INSTRUCTOR RESOURCES

A variety of ancillary materials have been developed to support students and instructors alike.

Resources for Students

- A back-of-the-book CD-ROM. This free CD-ROM contains multiple-choice questions for review and animations of selected pathophysiologic processes.
- Study Guide to Accompany Porth's Essentials of Pathophysiology: Concepts of Altered Health States, by Kathleen Schmidt Prezbindowski. This study guide, available for purchase, reinforces the information in the text using a variety of question styles, including multiple choice, fill-in-theblank, matching, short answer, and figure completion exercises.

Resources for Instructors

- Instructor's Resource CD-ROM to Accompany Essentials of Pathophysiology: Concepts of Altered Health States, by Patricia S. Bowne. This CD-ROM contains the following:

 - An Instructor's Manual with lecture outlines and teaching suggestions, plus printable worksheets for student assignments

Preface

- A Test Bank, containing approximately 1100 multiplechoice questions
- An Image Bank, containing approximately 300 images from the text in formats suitable for printing, projecting, and incorporating into web sites
- PowerPoint presentations with incorporated images.

Resources for Students and Instructors

connection-

The writing of this book has been a meaningful endeavor for the authors. It was accomplished through an extensive review of the literature and through the use of critiques provided by students, faculty, and content specialists. As this vast amount of information was processed, inaccuracies or omissions may have occurred. Readers are encouraged to contact us about such errors. Such feedback is essential to the continual development of the book.

СМР

To the Reader

This book was written with the intent of making the subject of pathophysiology an exciting exploration that relates normal body functioning to the physiologic changes that participate in disease production and occur as a result of disease, as well as the body's remarkable ability to compensate for these changes. Indeed, it is these changes that represent the signs and symptoms of disease.

Using a book such as this can be simplified by taking the time to find what is in the book and how to locate information when it is needed. The *table of contents* at the beginning of the book provides an overall view of the organization and content of the book. It also provides clues as to the relationships among areas of content. For example, the location of the chapter on neoplasia within the unit on cell function and growth indicates that neoplasms are products of altered cell growth. The *index*, which appears at the end of the book, can be viewed as a road map for locating content. It can be used to quickly locate related content in different chapters of the book or to answer questions that come up in other courses.

ORGANIZATION

The book is organized into units and chapters. The *units* identify broad areas of content, such as alterations in the circulatory system. The *chapters* focus on specific areas of content, such as heart failure and circulatory shock. The *chapter outline* that appears at the beginning of each chapter provides an outline of the content in the chapter. *Icons* identify specific content related

to infants and children [🚆 , pregnant women, 🚉 , and older adults 🦨 .

Many of the units have a chapter that contains essential information about the structures being discussed in the unit. These chapters provide the foundation for understanding the pathophysiology content presented in the subsequent chapters.

READING AND LEARNING AIDS

In an ever-expanding world of information you will not be able to read, let alone remember, everything that is in this book, or in any book, for that matter. With this in mind, we have developed a number of special features that will help you focus on and master the essential content for your current as well as future needs.

It is essential for any professional to use and understand the vocabulary of his or her profession. Throughout the text, you will encounter terms in italics. This is a signal that a word and the ideas associated with it are important to learn. In addition, two aids are provided to help you expand your vocabulary and improve your comprehension of what you are reading: the glossary and the list of prefixes and suffixes.

The *glossary* contains concise definitions of frequently encountered terms. If you are unsure of the meaning of a term you encounter in your reading, check the glossary in the back of the book before proceeding.

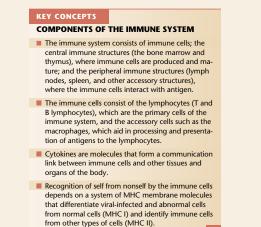

The *list of prefixes and suffixes* is a tool to help you derive the meaning of words you may be unfamiliar with and increase your vocabulary. Many disciplines establish a vocabulary by affixing one or more sounds or letters to the beginning or end of a word or base to form a derivative word. Prefixes are added to the beginning of a word or base, and suffixes are added to the end. If you know the meanings of common prefixes and suffixes, you can usually derive the meaning of a word, even if you have never encountered it before. A list of prefixes and suffixes common to pathophysiology can be found on the inside covers.

BOXES

Boxes are used throughout the text to summarize and highlight key information. You will encounter two types of boxes: Key Concept Boxes and Summary Boxes.

One of the ways to approach learning is to focus on the major ideas or concepts rather than trying to memorize a list of related and unrelated bits of information. As you have probably already discovered, it is impossible to memorize everything that is in a particular section or chapter of the book. First, your brain has a difficult time trying to figure out where to store all the different bits of information. Secondly, your brain doesn't know how to retrieve the information when you need it. Thirdly, memorized lists of content can seldom be applied directly to an actual clinical situation. The *Key Concept Boxes* guide you in identifying the major ideas or concepts that form the foundation for truly understanding the major areas of content. When you understand

the concepts in the Key Concept boxes, you will have a framework for remembering and using all of the facts given in the text.

The *Summary Boxes* at the end of each section provide a review of the main content that has been covered. Use the summaries to assure that you have covered and understand what you have read.

In summary, heart failure occurs when the heart fails to pump sufficient blood to meet the metabolic needs of body tissues. The physiology of heart failure reflects an interplay between a decrease in cardiac output that accompanies impaired function of the failing heart and the compensatory mechanisms designed to preserve the cardiac reserve. Compensatory mechanisms that contribute to maintenance of the cardiac reserve include the Frank-Starling mechanism, sympathetic nervous system responses, the renin-angiotensinaldosterone mechanism, and myocardial hypertrophy. In the failing heart, early decreases in cardiac function may go unnoticed because these compensatory mechanisms maintain the cardiac output. This is called *compensated heart failure*. Unfortunately, the mechanisms were not intended for longterm use, and in severe and prolonged heart failure, the compensatory mechanisms no longer are effective and further impair cardiac function.

Heart failure may be described as high-output or low-output failure, systolic or diastolic failure, and right-sided or leftsided failure. With high-output failure, the function of the heart may be supernormal but inadequate because of excessive metabolic needs, and low-output failure is caused by disorders that impair the pumping ability of the heart. With systolic dysfunction, there is impaired ejection of blood from the heart during systole; with diastolic dysfunction, there is impaired filling of the heart during diastole. Right-sided failure is characterized by congestion in the peripheral circulation, and left-sided failure by congestion in the pulmonary circulation.

The manifestations of heart failure include edema, nocturia, fatigue and impaired exercise tolerance, cyanosis, signs of increased sympathetic nervous system activity, and impaired gastrointestinal function and malnutrition. In rightsided failure, there is dependent edema of the lower parts of the body, engorgement of the liver, and ascites. In left-sided failure, shortness of breath and chronic, nonproductive cough are common.

Acute pulmonary edema is a life-threatening condition in which the accumulation of fluid in the interstitium of the lung and alveoil interferes with lung expansion and gas exchange. It is characterized by extreme breathlessness, crackles, frothy sputum, cyanosis, and signs of hypoxemia. In cardiogenic shock, there is failure to eject blood from the heart, hypotension, inadequate cardiac output, and impaired perfusion of peripheral tissues. Mechanical support devices, including the intra-aortic balloon purmp (for acute failure) and the VAD, sustain life in persons with severe heart failure. Heart transplantation remains the treatment of choice for many persons with end-stage heart failure.

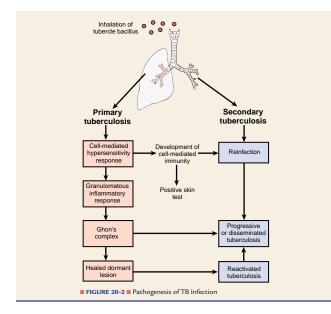

TABLES AND CHARTS

Tables and charts are designed to present complex information in a format that makes it more meaningful and easier to remember. Tables have two or more columns, and are often used for the purpose of comparing or contrasting information. Charts have one column and are used to summarize information.

Hypokalemia Hyperkalemia		
Laboratory Values Laboratory Values Serum potassium <3.5 mEq/L		
Increased thirst Inability to concentrate urine with polyuria and urine with low specific gravity		
Effects of Changes in Membrane Potentials in Neural and Muscle Function Effects of Changes in Membrane Potential on Neural and Muscle Function Gastrointestinal Gastrointestinal Anorexia, nausea, vomiting Nausea, vomiting Abdominal distention Intestinal cramps Paralytic ileus (severe hypokalemia) Diarrhea Nuscle exakness, flabbiness, fatigue Weakness, dizziness Muscle evakness, flabbiness, fatigue Muscle cramps Paratysis (severe hypokalemia) Paresthesias Paratysis (severe hypokalemia) Paresthesias Paratysis (severe hypokalemia) Paresthesias Confusion, depression Cardiovascular Condivoscular Risk of cardiac arrest with severe hyperkalem Predisposition to digitalis toxicity Electrocardiogram changes Cardidox dyshrythmias Cardiac dyshrythmias Acid-Base Balance Metabolic alkalosis		
CHART 5-2 TNM Classification System		
Tx Tumor cannot be adequately assessed T0 No evidence of primary tumor Tis Carcinoma in situ T1-4 Progressive increase in tumor size or involvement		
N (nodes)		
Nx Regional lymph nodes cannot be assessed N0 No evidence of regional node metastasis N 1-3 Increasing involvement of regional lymph nodes		
M (metastasis)		
Mx Not assessed M0 No distant metastasis M1 Distant metastasis present, specify sites		

ILLUSTRATIONS

The full-color illustrations will help you to build your own mental image of the content that is being presented. Each drawing has been developed to fully support and build upon the ideas in the text. Some illustrations are used to help you picture the complex interactions of the multiple phenomena that are involved in the development of a particular disease; others can help you to visualize normal function or understand the mechanisms whereby the disease processes exert their effects. In addition, photographs of pathologic processes and lesions provide a realistic view of selected pathologic processes and lesions.

MATERIALS FOR REVIEW

Several features have been built into the text to help you verify your understanding of the material that you have just read. After you have finished reading and studying the chapter, write down your answers to the *review questions* at the end of the chapter. If you are unable to answer a question, reread the relevant section in the chapter. In addition, you will find *multiple-choice questions* on the back-of-the-book CD-ROM and on the Connection site (http://connection.LWW.com/go/porth). Use these quizzes to test yourself as well.

APPENDICES

Your book contains two appendices. Appendix A, "Laboratory Values," provides rapid access to normal values for many laboratory tests, as well as a description of the prefixes, symbols, and factors (*e.g.*, micro, μ , 10⁻⁶) used for describing these values. Knowledge of normal values can help you to put abnormal values in context. Appendix B, "Weblinks," is provided to help you in obtaining additional information on topics that are of interest to you. The websites in Appendix B will also help you to keep abreast of new information that is constantly evolving. For your convenience, these weblinks are also found on the book's Connection site.

We hope that this guide has given you a clear picture of how to use this book. Good luck and enjoy the journey! 1

he cell is the smallest functional unit that an organism can be divided into and retain the characteristics necessary for life. Cells with similar embryonic origin or function are often organized into larger functional units called *tissues*. These tissues in turn combine to form the various body structures and organs. Although the cells of different tissues and organs vary in structure and function, certain characteristics are common to all cells. Cells are remarkably similar in their ability to exchange materials with their immediate environment, obtaining energy from organic nutrients, synthesizing complex molecules, and replicating themselves. Because most disease processes are initiated at the cellular level, an understanding of cell function is crucial to understanding the disease process. Some diseases affect the cells of a single organ, others affect the cells of a particular tissue type, and still others affect the cells of the entire organism.

FUNCTIONAL COMPONENTS OF THE CELL

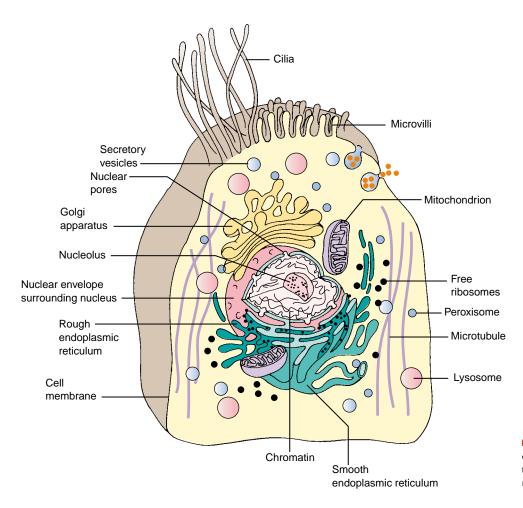

Although diverse in their organization, all eukaryotic cells (cells with a true nucleus) have in common structures that perform unique functions. When seen under a light microscope, three major components of the eukaryotic cell become evident: the nucleus, the cytoplasm, and the cell membrane (Fig. 1-1).

The internal matrix of the cell is called *protoplasm*. Protoplasm is composed of water, proteins, lipids, carbohydrates, and electrolytes. Water makes up 70% to 85% of the cell's protoplasm. The second most abundant constituents (10% to 20%) of protoplasm are the cell proteins, which form cell structures and the enzymes necessary for cellular reactions. Proteins can also be found complexed to other compounds as nucleo-

proteins, glycoproteins, and lipoproteins. Lipids comprise 2% to 3% of most cells. The most important lipids are the phospholipids and cholesterol, which are mainly insoluble in water; they combine with proteins to form the cell membrane and the membranous barriers that separate different cell compartments. Some cells also contain large quantities of triglycerides. In the fat cells, triglycerides can constitute up to 95% of the total cell mass. The fat stored in these cells represents stored energy, which can be mobilized and used wherever it is needed in the body. Few carbohydrates are found in the cell, and these are used primarily for fuel. Potassium, magnesium, phosphate, sulfate, and bicarbonate ions are the major intracellular electrolytes. Small quantities of sodium, chloride, and calcium ions are also present in the cell. These electrolytes facilitate the generation and transmission of electrochemical impulses in nerve and muscle cells. Intracellular electrolytes participate in reactions that are necessary for cellular metabolism.

The Nucleus

The nucleus of the cell appears as a rounded or elongated structure situated near the center of the cell (see Fig. 1-1). It is enclosed in a nuclear membrane and contains chromatin and a distinct region called the *nucleolus*. All eukaryotic cells have at least one nucleus (prokaryotic cells, such as bacteria, lack a nucleus and nuclear membrane). The nucleus is the control center for the cell. It contains deoxyribonucleic acid (DNA) that is

■ FIGURE 1-1 ■ Composite cell designed to show in one cell all of the various components of the nucleus and cytoplasm.

KEY CONCEPTS

THE FUNCTIONAL ORGANIZATION OF THE CELL

- Cells are the smallest functional unit of the body. They contain structures that are strikingly similar to those needed to maintain total body function.
- The nucleus is the control center for the cell. It also contains most of the hereditary material.
- The organelles, which are analogous to the organs of the body, are contained in the cytoplasm. They include the mitochondria, which supply the energy needs of the cell; the ribosomes, which synthesize proteins and other materials needed for cell function; and the lysosomes, which function as the cell's digestive system.

The cell membrane encloses the cell and provides for intracellular and intercellular communication, transport of materials into and out of the cell, and maintenance of the electrical activities that power cell function.

essential to the cell because its genes contain the information necessary for the synthesis of proteins that the cell must produce to stay alive. These proteins include structural proteins and enzymes used to synthesize other substances, including carbohydrates and lipids. The genes also represent the individual units of inheritance that transmit information from one generation to another. The nucleus is also the site of ribonucleic acid (RNA) synthesis. There are three types of RNA: messenger RNA (mRNA), which copies and carries the DNA instructions for protein synthesis to the cytoplasm; ribosomal RNA (rRNA), which moves to the cytoplasm, and becomes the site of protein synthesis; and transfer RNA (tRNA), which also moves into the cytoplasm, where it transports amino acids to the elongating protein as it is being synthesized (see Chapter 3).

The complex structure of DNA and DNA-associated proteins dispersed in the nuclear matrix is called *chromatin*. Each DNA molecule is made up of two extremely long, double-stranded helical chains containing variable sequences of four nitrogenous bases. These bases form the genetic code. In cells that are about to divide, the DNA must be replicated before *mitosis*, or cell division, occurs. During replication, complementary pairs of DNA are generated such that each daughter cell receives an identical set of genes.

The nucleus also contains the darkly stained round body called the *nucleolus*. The rRNA is transcribed exclusively in the nucleolus. Nucleoli are structures composed of regions from five different chromosomes, each with a part of the genetic code needed for the synthesis of rRNA. Cells that are actively synthesizing proteins can be recognized because their nucleoli are large and prominent and the nucleus as a whole is euchromatic.

Surrounding the nucleus is a doubled-layered membrane called the nuclear envelope or nuclear membrane. The nuclear

membrane contains many structurally complex circular pores where the two membranes fuse to form a gap. Many classes of molecules, including fluids, electrolytes, RNA, some proteins, and perhaps some hormones, can move in both directions through the nuclear pores.

The Cytoplasm and Its Organelles

The cytoplasm surrounds the nucleus, and it is in the cytoplasm that the work of the cell takes place. Cytoplasm is essentially a colloidal solution that contains water, electrolytes, suspended proteins, neutral fats, and glycogen molecules. Although they do not contribute to the cell's function, pigments may also accumulate in the cytoplasm. Some pigments, such as melanin, which gives skin its color, are normal constituents of the cell.

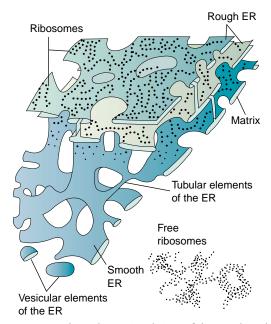

Embedded in the cytoplasm are various *organelles*, which function as the organs of the cell. These organelles include the ribosomes, endoplasmic reticulum, Golgi complex, lysosomes and peroxisomes, and mitochondria.

Ribosomes

The ribosomes serve as sites of protein synthesis in the cell. They are small particles of nucleoproteins (rRNA and proteins) that can be found attached to the wall of the endoplasmic reticulum or as free ribosomes (Fig. 1-2). Free ribosomes are scattered singly in the cytoplasm or joined by strands of mRNA to form functional units called *polyribosomes*. Free ribosomes are involved in the synthesis of proteins, mainly as intracellular enzymes.

Endoplasmic Reticulum

The endoplasmic reticulum (ER) is an extensive system of paired membranes and flat vesicles that connects various parts of the inner cell (see Fig. 1-2). The fluid-filled space, called the

■ FIGURE 1-2 ■ Three-dimensional view of the rough endoplasmic reticulum (ER) with its attached ribosomal RNA and the smooth endoplasmic reticulum.

Unit One: Mechanisms of Disease

matrix, between the paired ER membrane layers is connected with the space between the two membranes of the doublelayered nuclear membrane, the cell membrane, and various cytoplasmic organelles. It functions as a tubular communication system through which substances can be transported from one part of the cell to another. A large surface area and multiple enzyme systems attached to the ER membranes also provide the machinery for a major share of the metabolic functions of the cell.

Two forms of ER exist in cells: rough and smooth. Rough ER is studded with ribosomes attached to specific binding sites on the membrane. The ribosomes, with the accompanying strand of mRNA, synthesize proteins. Proteins produced by the rough ER are usually destined for incorporation into cell membranes and lysosomal enzymes or for exportation from the cell. The rough ER segregates these proteins from other components of the cytoplasm and modifies their structure for a specific function. For example, the production of plasma protein by liver cells take place in the rough ER. All cells require a rough ER for the synthesis of lysosomal enzymes.

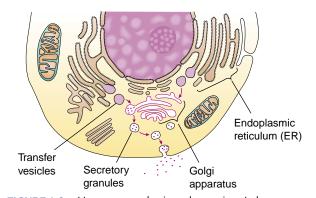

The smooth ER is free of ribosomes and is continuous with the rough ER. It does not participate in protein synthesis; instead, its enzymes are involved in the synthesis of lipid molecules, regulation of intracellular calcium, and metabolism and detoxification of certain hormones and drugs. It is the site of lipid, lipoprotein, and steroid hormone synthesis. The sarcoplasmic reticulum of skeletal and cardiac muscle cells is a form of smooth ER. Calcium ions needed for muscle contraction are stored and released from cisternae of the sarcoplasmic reticulum. Smooth ER of the liver is involved in glycogen storage and metabolism of lipid-soluble drugs.

Golgi Complex

The Golgi apparatus, sometimes called the Golgi complex, consists of stacks of thin, flattened vesicles or sacs. These Golgi bodies are found near the nucleus and function in association with the ER. Substances produced in the ER are carried to the Golgi complex in small, membrane-covered transfer vesicles. Many cells synthesize proteins that are larger than the active product. Insulin, for example, is synthesized as a large, inactive proinsulin molecule that is cut apart to produce a smaller, active insulin molecule within the Golgi complex of the beta cells of the pancreas. The Golgi complex modifies these substances and packages them into secretory granules or vesicles. Enzymes destined for export from the cell are packaged in secretory vesicles. After appropriate signals, the secretory vesicles move out of the Golgi complex into the cytoplasm and fuse to the inner side of the plasma membrane, where they release their contents into the extracellular fluid. Figure 1-3 is a diagram of the synthesis and movement of a hormone through the rough ER and Golgi complex. In addition to its function in producing secretory granules, the Golgi complex is thought to produce large carbohydrate molecules that combine with proteins produced by the rough ER to form glycoproteins.

Lysosomes and Peroxisomes

The lysosomes can be viewed as the digestive system of the cell. They consist of small, membrane-enclosed sacs containing hydrolytic enzymes capable of breaking down worn-out cell parts so they can be recycled. They also break down foreign substances such as bacteria taken into the cell. All of the lysosomal

■ FIGURE 1-3 ■ Hormone synthesis and secretion. In hormone secretion, the hormone is synthesized by the ribosomes attached to the rough endoplasmic reticulum. It moves from the rough ER to the Golgi complex, where it is stored in the form of secretory granules. These leave the Golgi complex and are stored within the cytoplasm until released from the cell in response to an appropriate signal.

enzymes are acid hydrolases, which means that they require an acid environment. The lysosomes provide this environment by maintaining a pH of approximately 5 in their interior. The pH of the cytoplasm is approximately 7.2, which protects other cellular structures from this acidity.

Lysosomal enzymes are synthesized in the rough ER and then transported to the Golgi apparatus, where they are biochemically modified and packaged as lysosomes. Unlike those of other organelles, the sizes and functions of lysosomes vary considerably from one cell to another. The type of enzyme packaged in the lysosome by the Golgi complex determines this diversity. Although enzymes in the secondary lysosomes can break down most proteins, carbohydrates, and lipids to their basic constituents, some materials remain undigested. These undigested materials may remain in the cytoplasm as residual bodies or be extruded from the cell. In some long-lived cells, such as neurons and heart muscle cells, large quantities of residual bodies accumulate as lipofuscin granules or age pigment. Other indigestible pigments, such as inhaled carbon particles and tattoo pigments, also accumulate and may persist in residual bodies for decades.

Lysosomes play an important role in the normal metabolism of certain substances in the body. In some inherited diseases known as *lysosomal storage diseases*, a specific lysosomal enzyme is absent or inactive, in which case the digestion of certain cellular substances does not occur. As a result, these substances accumulate in the cell. In Tay-Sachs disease, an autosomal recessive disorder, the lysosomal enzyme needed for degrading the GM₂ ganglioside found in nerve cell membranes is deficient (see Chapter 4). Although GM₂ ganglioside accumulates in many tissues, such as the heart, liver, and spleen, its accumulation in the nervous system and retina of the eye causes the most damage.

Smaller than lysosomes, spherical membrane-bound organelles called *peroxisomes* contain a special enzyme that degrades peroxides (*e.g.*, hydrogen peroxide). Peroxisomes function in the control of free radicals (see Chapter 2). Unless degraded, these highly unstable chemical compounds would otherwise damage other cytoplasmic molecules. For example, catalase degrades toxic hydrogen peroxide molecules to water. Peroxisomes also contain the enzymes needed for breaking down very-long-chain fatty acids, which are ineffectively degraded by mitochondrial enzymes. In liver cells, peroxisomal enzymes are involved in the formation of the bile acids.

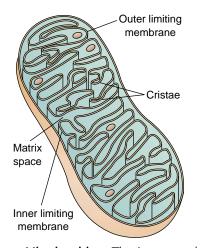

Mitochondria

The mitochondria are literally the "power plants" of the cell because they transform organic compounds into energy that is easily accessible to the cell. Energy is not made here but is extracted from organic compounds. Mitochondria contain the enzymes needed for capturing most of the energy in foodstuffs and converting it into cellular energy. This multistep process requires oxygen and is often referred to as *aerobic metabolism*. Much of this energy is stored in the high-energy phosphate bonds of compounds such as adenosine triphosphate (ATP), which powers the various cellular activities.

Mitochondria are found close to the site of energy consumption in the cell (*e.g.*, near the myofibrils in muscle cells). The number of mitochondria in a given cell type is largely determined by the type of activity the cell performs and how much energy is needed to undertake this activity. For example, large increases in mitochondria have been observed in skeletal muscle that has been repeatedly stimulated to contract.

The mitochondria are composed of two membranes: an outer membrane that encloses the periphery of the mitochondrion and an inner membrane that forms shelflike projections, called *cristae* (Fig. 1-4). The outer and inner membranes form two spaces: an outer intramembranous space and an inner matrix that is filled with a gel-like material. The outer membrane is involved in lipid synthesis and fatty acid metabolism. The inner membrane contains the respiratory chain enzymes and transport proteins needed for the synthesis of ATP.

Mitochondria contain their own DNA and ribosomes and are self-replicating. The DNA is found in the mitochondrial matrix and is distinct from the chromosomal DNA found in the nucleus. Mitochondrial DNA, known as the "other human genome," is a double-stranded, circular molecule that encodes the rRNA and tRNA required for intramitochrondial synthesis of proteins needed for the energy-generating function of the

■ FIGURE 1-4 ■ Mitochondrion. The inner membrane forms transverse folds called cristae, where the enzymes needed for the final step in adenosine triphosphate (ATP) production (*i.e.*, oxidative phosphorylation) are located.

mitochondria. Although mitochondrial DNA directs the synthesis of 13 of the proteins required for mitochondrial function, the DNA of the nucleus encodes the structural proteins of the mitochondria and other proteins needed to carry out cellular respiration.

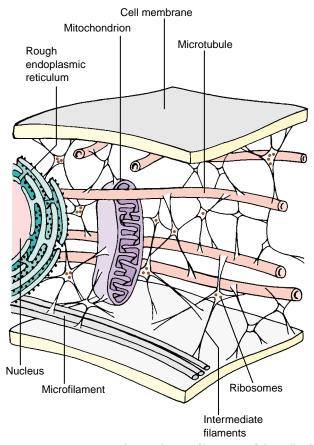

Mitochondrial DNA is inherited matrilineally (*i.e.*, from the mother) and provides a basis for familial lineage studies. Mutations have been found in each of the mitochondrial genes, and an understanding of the role of mitochondrial DNA in certain diseases is beginning to emerge. Most tissues in the body depend to some extent on oxidative metabolism and can therefore be affected by mitochondrial DNA mutations.

The Cytoskeleton

In addition to its organelles, the cytoplasm contains a network of microtubules, microfilaments, intermediate filaments, and thick filaments (Fig. 1-5). Because they control cell shape and movement, these structures are a major component of the structural elements called the *cytoskeleton*.

Microtubules

The microtubules are slender tubular structures composed of globular proteins called *tubulin*. Microtubules function in many ways, including the development and maintenance of

■ FIGURE 1-5 ■ Microtubes and microfilaments of the cell. The microfilaments associate with the inner surface of the cell and aid in cell motility. The microtubules form the cytoskeleton and maintain the position of the organelles.

cell form; participation in intracellular transport mechanisms, including axoplasmic transport in neurons; and formation of the basic structure for several complex cytoplasmic organelles, including the cilia, flagella, centrioles, and basal bodies. Abnormalities of the cytoskeleton may contribute to alterations in cell mobility and function. For example, proper functioning of the microtubules is essential for various stages of leukocyte migration.

Cilia and Flagella. Cilia and flagella are hairlike processes extending from the cell membrane that are capable of sweeping and flailing movements, which can move surrounding fluids or move the cell through fluid media. Cilia are found on the apical or luminal surface of epithelial linings of various body cavities or passages, such as the upper respiratory system. Removal of mucus from the respiratory passages is highly dependent on the proper functioning of the cilia. Flagella form the tail-like structures that provide motility for sperm.

Centrioles and Basal Bodies. Centrioles and basal bodies are structurally identical organelles composed of an array of highly organized microtubules. The centrioles are small, barrel-shaped bodies oriented at right angles to each other. In dividing cells, the two cylindrical centrioles form the mitotic spindle that aids in the separation and movement of the chromosomes. Basal bodies are more numerous than centrioles and are found near the cell membrane in association with cilia and flagella.

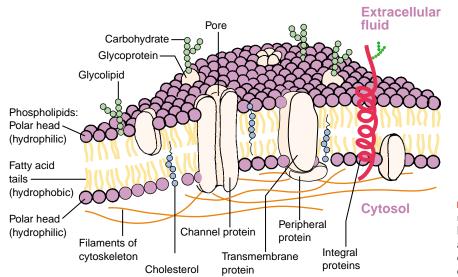

Microfilaments

Microfilaments are thin, threadlike cytoplasmic structures. Three classes of microfilaments exist: (1) thin microfilaments, which are equivalent to the thin actin filaments in muscle; (2) the thick myosin filaments, which are present in muscle cells but may also exist temporarily in other cells; and (3) the intermediate filaments, which are a heterogeneous group of filaments with diameter sizes between the thick and thin filaments. Muscle contraction depends on the interaction between the thin actin filaments and thick myosin filaments. Microfilaments are present in the superficial zone of the cytoplasm in most cells. Contractile activities involving the microfilaments and associated thick myosin filaments contribute to associated movement of the cytoplasm and cell membrane during endocytosis and exocytosis. Microfilaments are also present in the microvilli of the intestine. The intermediate filaments function in supporting and maintaining the asymmetric shape of cells. Examples of intermediate filaments are the keratin filaments that are found anchored to the cell membrane of epidermal keratinocytes of the skin and the glial filaments that are found in astrocytes and other glial cells of the nervous system. The *neurofibrillary tangle* found in the brain in Alzheimer's disease contains microtubule-associated proteins and neurofilaments, evidence of a disrupted neuronal cytoskeleton.

The Cell Membrane

The cell is enclosed in a thin membrane that separates the intracellular contents from the extracellular environment. To differentiate it from the other cell membranes, such as the mitochondrial or nuclear membranes, the cell membrane is often called the *plasma membrane*. In many respects, the plasma membrane is one of the most important parts of the cell. It acts as a semipermeable structure that separates the intracellular and extracellular environments. It provides receptors for hormones and other biologically active substances, participates in the electrical events that occur in nerve and muscle cells, and aids in the regulation of cell growth and proliferation.

The cell membrane consists of an organized arrangement of lipids (phospholipids, glycolipids, and cholesterol), carbohydrates, and proteins (Fig. 1-6). The lipids form a bilayer structure that is essentially impermeable to all but lipid-soluble substances. About 75% of the lipids are phospholipids, each with a hydrophilic (water-soluble) head and hydrophobic (water-insoluble) tails. The phospholipid molecules along with the glycolipids are aligned such that their hydrophobic heads face outward on each side of the membrane and their hydrophobic tails project toward the center of the membrane. The hydrophilic heads retain water and help cells adhere to each other. At

■ FIGURE 1-6 ■ The structure of the cell membrane showing the hydrophilic (polar) heads and the hydrophobic (fatty acid) tails and the position of the integral and peripheral proteins in relation to the interior and exterior of the cell.

Although the basic structure of the cell membrane is provided by the lipid bilayer, most of the specific functions are carried out by proteins. Some proteins, called transmembrane proteins, pass directly through the membrane and communicate with the intracellular and extracellular environments. Many of the transmembrane proteins are tightly bound to lipids in the bilayer and are essentially part of the membrane. These transmembrane proteins are called *integral proteins*. The *peripheral* proteins, a second type of protein, are bound to one or the other side of the membrane and do not pass into the lipid bilayer. Thus, the peripheral proteins are associated with functions involving the inner and outer side of the membrane where they are located. In contrast, the transmembrane proteins can function on both sides of the membrane or transport molecules across it. Many of the integral transmembrane proteins form the ion channels found on the cell surface. These channel proteins have complex structures and are selective with respect to the ions that pass through their channels.

The membrane carbohydrates are incorporated in a fuzzylooking layer, called the *cell coat* or *glycocalyx*, which surrounds the cell surface. The glycocalyx, which is part of the cell membrane, consists of long, complex carbohydrate chains that are attached to proteins and lipids in the form of glycoproteins and glycolipids. The cell coat participates in cell-to-cell recognition and adhesion. It contains tissue transplant antigens that label cells as self or nonself. ABO blood group antigens are contained in the cell coat of red blood cells.

In summary, the cell is a remarkably autonomous structure that functions in a manner strikingly similar to that of the total organism. The nucleus controls cell function and is the mastermind of the cell. It contains DNA, which provides the information necessary for the synthesis of the various proteins that the cell must produce to stay alive and to transmit information from one generation to another.

The cytoplasm contains the cell's organelles. Ribosomes serve as sites for protein synthesis in the cell. The ER functions as a tubular communication system through which substances can be transported from one part of the cell to another and as the site of protein (rough ER), carbohydrate, and lipid (smooth ER) synthesis. Golgi bodies modify materials synthesized in the ER and package them into secretory granules for transport within the cell or for export from the cell. Lysosomes, which can be viewed as the digestive system of the cell, contain hydrolytic enzymes that digest worn-out cell parts and foreign materials. The mitochondria serve as power plants for the cell because they transform food energy into ATP, which is used to power cell activities. Mitochondria contain their own extrachromosomal DNA, which is used in the synthesis of mitochondrial RNAs and proteins used in oxidative metabolism. Microtubules are slender, stiff tubular structures that influence cell shape, provide a means of moving organelles through the cytoplasm, and effect movement of the cilia and of chromosomes during cell division. Several types of threadlike filaments, including actin and myosin filaments, participate in muscle contraction.

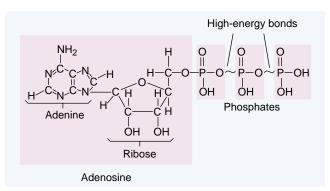

The plasma membrane is a lipid bilayer that surrounds the cell and separates it from its surrounding external environment. It contains receptors for hormones and other biologically active substances, participates in the electrical events that occur in nerve and muscle cells, and aids in the regulation of cell growth and proliferation. The cell surface is surrounded by a fuzzy-looking layer called the cell coat or glycocalyx. The cell coat participates in cell-to-cell recognition and adhesion, and it contains tissue transplant antigens.

CELL METABOLISM AND ENERGY SOURCES

Energy metabolism refers to the processes by which fats, proteins, and carbohydrates from the foods we eat are converted into energy or complex energy sources in the cell. Catabolism and anabolism are the two phases of metabolism. *Catabolism* consists of breaking down stored nutrients and body tissues to produce energy. *Anabolism* is a constructive process in which more complex molecules are formed from simpler ones.

The special carrier for cellular energy is ATP. ATP molecules consist of adenosine, a nitrogenous base; ribose, a fivecarbon sugar; and three phosphate groups (see Fig. 1-7). The last two phosphate groups are attached to the remainder of the molecule by two high-energy bonds, which are indicated by the symbol ~. Each bond releases a large amount of energy when hydrolyzed. ATP is hydrolyzed to form adenosine diphosphate (ADP) with the loss of one high-energy bond and to adenosine monophosphate (AMP) with the loss of two such bonds. The energy liberated from the hydrolysis of ATP is used to drive reactions that require free energy, such as muscle contraction and active transport mechanisms. Energy from foodstuffs is used to convert ADP back to ATP. ATP is often called the *energy currency* of the cell; energy can be "saved" or "spent" using ATP as an exchange currency.

Two types of energy production are present in the cell: the anaerobic (*i.e.*, without oxygen) glycolytic pathway, occurring in the cytoplasm, and the aerobic (*i.e.*, with oxygen) pathways occurring in the mitochondria. The glycolytic pathway serves as the prelude to the aerobic pathways.

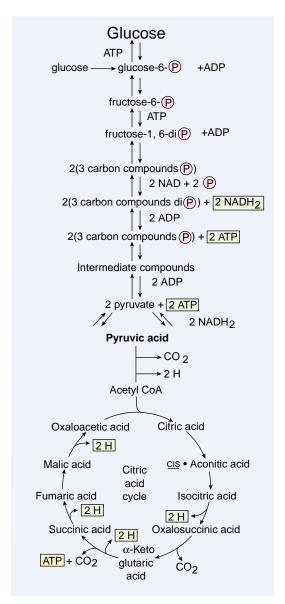

Anaerobic Metabolism

Glycolysis is anaerobic process by which energy is liberated from glucose (Fig. 1-8). It is an important source of energy for cells that lack mitochondria. This process provides energy in situations when delivery of oxygen to the cell is delayed or impaired. Glycolysis involves a sequence of reactions that converts glucose to pyruvate, with the concomitant production of ATP from ADP. The net gain of energy from the glycolysis of one molecule of glucose is two ATP molecules. Although relatively inefficient as to energy yield, the glycolytic pathway is important during periods of decreased oxygen delivery, such as occurs in skeletal muscle during the first few minutes of exercise.

Glycolysis requires the presence of nicotinamide-adenine dinucleotide (NAD⁺), a hydrogen carrier. The end-products of glycolysis are pyruvate and NADH. When oxygen is present, pyruvate moves into the aerobic mitochondrial pathway, and

■ FIGURE 1-8 ■ Glycolytic pathway and citric acid cycle.

NADH subsequently enters into oxidative chemical reactions that remove the hydrogen atoms. The transfer of hydrogen from NADH during the oxidative reactions allows the glycolytic process to continue by facilitating the regeneration of NAD⁺. Under anaerobic conditions, such as cardiac arrest or circulatory shock, pyruvate is converted to lactic acid, which diffuses out of the cells into the extracellular fluid. Conversion of pyruvate to lactic acid is reversible, and after the oxygen supply has been restored, lactic acid is reconverted back to pyruvate and used directly for energy or to synthesize glucose.

Aerobic Metabolism

Aerobic metabolism, which supplies 90% of the body's energy needs, occurs in the cell's mitochondria and requires oxygen. It is here that hydrogen and carbon molecules from dietary fats, proteins, and carbohydrates are broken down and combined with molecular oxygen to form carbon dioxide, and water as energy is released. Unlike lactic acid, which is an end-product of anaerobic metabolism, carbon dioxide and water are relatively harmless and easily eliminated from the body. In a 24-hour period, oxidative metabolism produces 300 to 500 mL of water.

Aerobic metabolism uses the *citric acid cycle*, sometimes called the *tricarboxylic acid* or *Krebs cycle*, as the final common pathway for the metabolism of nutrients (see Fig. 1-8). In the citric acid cycle, each of the two pyruvate molecules formed in the cytoplasm from the glycolysis of one molecule of glucose yields another molecule of ATP along with two molecules of carbon dioxide and eight hydrogen ions. In addition to pyruvate from the glycolysis of glucose, products from amino acid and fatty acid breakdown enter the citric acid cycle.

In the initial stage of the citric acid cycle, acetyl coenzyme A (acetyl-CoA) combines with oxaloacetic acid to form citric acid. The coenzyme A portion of acetyl-CoA can be used again and again to generate more acetyl-CoA from pyruvate, while the acetyl portion becomes part of the citric acid cycle and moves through a series of enzyme-mediated steps that produce carbon dioxide and hydrogen atoms. The carbon dioxide is carried to the lungs and exhaled. The hydrogen atoms are transferred to the electron transport system on the inner mitochondrial membrane for oxidation. Oxidation of hydrogen is accomplished through a series of enzyme-mediated steps that change the hydrogen atoms to hydrogen ions and electrons. The electrons are used to reduce elemental oxygen, which combines with the hydrogen ions to form water. During this sequence of oxidative reactions, large amounts of energy are released and used to convert ADP to ATP. Because the formation of ATP involves the addition of a high-energy phosphate bond to ADP, the process is called oxidative phosphorylation. Cyanide poisoning kills by binding to the enzymes needed for a final step in the oxidative phosphorylation sequence.

In summary, metabolism is the process whereby the carbohydrates, fats, and proteins we eat are broken down and subsequently converted into the energy needed for cell function. Energy is stored in the high-energy phosphate bonds of ATP, which serves as the energy currency for the cell. Two sites of energy conversion are present in cells: the glycolytic or anaerobic pathway in the cell's cytoplasmic matrix and the aerobic or citric acid cycle in the mitochondria. The most efficient of these pathways is the citric acid pathway. This pathway, which requires oxygen, produces carbon dioxide and water as end-products and results in the release of large amounts of energy that is used to convert ADP to ATP. The glycolytic pathway, which is located in the cytoplasm, involves the breakdown of glucose to form ATP. This pathway can function without oxygen by producing lactic acid.

CELL MEMBRANE TRANSPORT, SIGNAL TRANSDUCTION, AND GENERATION OF MEMBRANE POTENTIALS

Movement Across the Cell Membrane

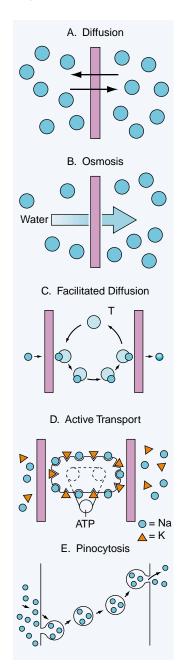

The unique properties of the cell's membrane are responsible for differences in the composition of the intracellular and extracellular fluids. However, a constant movement of molecules and ions across the cell membrane is required to maintain the functions of the cell. Movement through the cell membrane occurs in essentially two ways: passively, without an expenditure of energy, or actively, using energy-consuming processes. The cell membrane can also engulf substances, forming a membrane-coated vesicle; this membrane-coated vesicle is moved into the cell by *endocytosis* or out of the cell by *exocytosis*.

Passive Movement

The passive movement of particles or ions across the cell membrane is directly influenced by chemical or electrical gradients and does not require an expenditure of energy. A difference in the number of particles on either side of the membrane creates a chemical gradient, and a difference in charged particle or ions creates an electrical gradient. Chemical and electrical gradients are often linked and are called *electrochemical gradients*.

Diffusion. Diffusion refers to the process by which molecules and other particles in a solution become widely dispersed and reach a uniform concentration because of energy created by their spontaneous kinetic movements (Fig. 1-9). In the process of reaching a uniform concentration, these molecules and particles move from an area of higher to an area of lower concentration. With ions, diffusion is affected by energy supplied by their electrical charge. Lipid-soluble molecules, such as oxygen, carbon dioxide, alcohol, and fatty acids, become dissolved in the lipid matrix of the cell membrane and diffuse through the membrane in the same manner that diffusion occurs in water. Other substances diffuse through minute pores of the cell membrane. The rate of movement depends on how many particles are available for diffusion and the velocity of the kinetic movement of the particles. Temperature changes the motion of the particles; the greater the temperature, the greater is the thermal motion of the molecules.

Osmosis. Most cell membranes are semipermeable in that they are permeable to water but not all solute particles. Water moves through a semipermeable membrane along a concentration gradient, moving from an area of higher to one of lower con-

■ FIGURE 1-9 ■ Mechanisms of membrane transport. (A) Diffusion, in which particles move to become equally distributed across the membrane. (B) The osmotically active particles regulate the flow of water. (C) Facilitated diffusion uses a carrier system. (D) In active transport, selected molecules are transported across the membrane using the energy-driven (ATP) pump. (E) The membrane forms a vesicle that engulfs the particle and transports it across the membrane, where it is released. This is called pinocytosis.

centration (see Fig. 1-9). This process is called *osmosis*, and the pressure that water generates as it moves through the membrane is called *osmotic pressure*.

Osmosis is regulated by the concentration of nondiffusible particles on either side of a semipermeable membrane. When there is a difference in the concentration of particles, water moves from the side with the lower concentration of particles and higher concentration of water to the side with the higher concentration of particles and lower concentration of water. The movement of water continues until the concentration of particles on both sides of the membrane is equally diluted or until the hydrostatic (osmotic) pressure created by the movement of water opposes its flow.

Facilitated Diffusion. Facilitated diffusion occurs through a transport protein that is not linked to metabolic energy (see Fig. 1-9). Some substances, such as glucose, cannot pass unassisted through the cell membrane because they are not lipid soluble or are too large to pass through the membrane's pores. These substances combine with special transport proteins at the membrane's outer surface, are carried across the membrane attached to the transporter, and then released. In facilitated diffusion, a substance can move only from an area of higher concentration to one of lower concentration. The rate at which a substance moves across the membrane because of facilitated diffusion depends on the difference in concentration between the two sides of the membrane. Also important are the availability of transport proteins and the rapidity with which they can bind and release the substance being transported. It is thought that insulin, which facilitates the movement of glucose into cells, acts by increasing the availability of glucose transporters in the cell membrane.

Active Transport and Cotransport

The process of diffusion describes particle movement from an area of higher concentration to one of lower concentration, resulting in an equal distribution across the cell membrane. However, sometimes different concentrations of a substance are needed in the intracellular and extracellular fluids. For example, the intracellular functioning of the cell requires a much higher concentration of potassium than is present in the extracellular fluid while maintaining a much lower concentration of sodium than in the extracellular fluid. In these situations, energy is required to pump the ions "uphill" or against their concentration gradient. When cells use energy to move ions against an electrical or chemical gradient, the process is called *active transport*.

The active transport system studied in the greatest detail is the sodium–potassium pump, or Na^+/K^+ ATPase pump (see Fig. 1-9). The Na^+/K^+ ATPase pump moves sodium from inside the cell to the extracellular region, where its concentration is approximately 14 times greater than inside; the pump also returns potassium to the inside, where its concentration is approximately 35 times greater than it is outside the cell. If it were not for the activity of the sodium–potassium pump, the osmotically active sodium particles would accumulate in the cell, causing cellular swelling because of an accompanying influx of water (see Chapter 2).

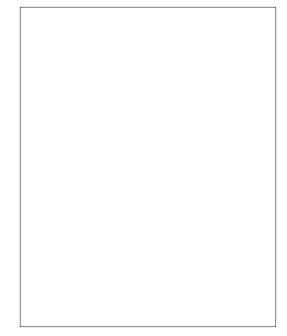

There are two types of active transport: primary active transport and secondary active transport. In *primary active transport*, the source of energy (*e.g.*, ATP) is used directly in the transport of a substance. *Secondary active transport* mechanisms harness the energy derived from the primary active transport of one substance, usually sodium ions, for the cotransport of a second substance. For example, when sodium ions are actively transported out of a cell by primary active transport, a large concentration gradient develops (*i.e.*, high concentration on the out-

side and low on the inside). This concentration gradient represents a large storehouse of energy because sodium ions are always attempting to diffuse into the cell. Similar to facilitated diffusion, secondary transport mechanisms use membrane transport proteins. These proteins have two binding sites: one for sodium ions and the other for the substance undergoing secondary transport. Secondary transport systems are classified into two groups: *cotransport*, in which the sodium ion and solute are transported in the same direction, and *countertransport*, in which sodium ions and the solute are transported in the opposite direction (Fig. 1-10). An example of cotransport occurs in the intestine, where the absorption of glucose and amino acids is coupled with sodium transport.

Endocytosis and Exocytosis

Endocytosis is the process by which cells engulf materials from their surroundings. It includes pinocytosis and phagocytosis. *Pinocytosis* involves the ingestion of small solid or fluid particles. The particles are engulfed into small, membranesurrounded vesicles for movement into the cytoplasm. The process of pinocytosis is important in the transport of proteins and strong solutions of electrolytes (see Fig. 1-9).

Phagocytosis literally means *cell eating* and can be compared with pinocytosis, which means *cell drinking*. Phagocytosis involves the engulfment and subsequent killing or degradation of microorganisms and other particulate matter. During phagocytosis, a particle contacts the cell surface and is surrounded on all sides by the cell membrane, forming a phagocytic vesicle or phagosome. Once formed, the phagosome breaks away from the cell membrane and moves into the cytoplasm, where it eventually fuses with a lysosome, allowing the ingested material to be degraded by lysosomal enzymes. Certain cells, such

■ FIGURE 1-10 ■ Secondary active transport systems. (A) carries the transported solute (S) in the same direction as the Na⁺ ion. (B) Counter-transport carries the solute and Na⁺ in the opposite direction.

as macrophages and polymorphonuclear leukocytes (neutrophils), are adept at engulfing and disposing of invading organisms, damaged cells, and unneeded extracellular constituents (see Chapter 9).

Exocytosis is the mechanism for the secretion of intracellular substances into the extracellular spaces. It is the reverse of endocytosis in that a secretory granule fuses to the inner side of the cell membrane, and an opening occurs in the cell membrane. This opening allows the contents of the granule to be released into the extracellular fluid. Exocytosis is important in removing cellular debris and releasing substances, such as hormones, synthesized in the cell.

During endocytosis, portions of the cell membrane become an endocytotic vesicle. During exocytosis, the vesicular membrane is incorporated into the plasma membrane. In this way, cell membranes can be conserved and reused.

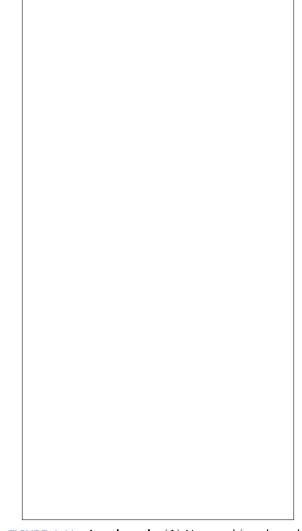

Ion Channels

The electrical charge on small ions such as Na⁺ and K⁺ makes it difficult for these ions to move across the lipid layer of the cell membrane. However, rapid movement of these ions is required for many types of cell functions, such as nerve activity. This is accomplished by facilitated diffusion through selective ion channels. Ion channels are made up of integral proteins that span the width of the cell membrane and are normally composed of several polypeptides or protein subunits that form a gating system. Specific stimuli cause the protein subunits to undergo conformational changes to form an open channel or gate through which the ions can move. In this way, ions do not need to cross the lipid-soluble portion of the membrane but can remain in the aqueous solution that fills the ion channel. Ion channels are highly selective; some channels allow only for passage of sodium ions, and others are selective for potassium, calcium, or chloride ions.

The plasma membrane contains two basic groups of ion channels: nongated and gated channels (Fig. 1-11). Nongated or leakage channels are open even in the unstimulated state, whereas gated channels open and close in response to specific stimuli. There are two types of gated channels: voltage-gated and ligand-gated channels. Voltage-gated channels have electrically operated gates that open when the membrane potential changes beyond a certain point. Ligand-gated channels have chemically operated gates that respond to specific receptorbound ligands, such as the neurotransmitter acetylcholine.

Signal Transduction and Cell Communication

Cells in multicellular organisms need to communicate with one another to coordinate their function and control their growth. Cells communicate with each other by means of chemical messenger systems. In some tissues, messengers move from cell to cell through gap junctions without entering the extracellular fluid. In other tissues, cells communicate by chemical messengers secreted into the extracellular fluid. Many types of chemical messengers that cannot cross the cell membrane bind to receptors on or near the cell surface. These chemical messengers are sometimes called *first messengers* because, by one means or another, their external signal is converted into internal signals carried by a second chemical called a *second messenger*. It is the second messenger that triggers the intracellular changes that produce the desired physiologic effect. Some

■ FIGURE 1-11 ■ Ion channels. (A) Nongated ion channel remains open, permitting free movement of ions across the membrane. (B) Ligand-gated channel is controlled by ligand binding to the receptor. (C) Voltage-gated channel is controlled by a change in membrane potential. (Rhoades R.A., Tanner G.A. [1996]. *Medical physiology.* Boston: Little, Brown)

lipid-soluble chemical messengers move through the membrane and bind to cytoplasmic or nuclear receptors to exert their physiologic effects.

Cell Membrane Receptors

Neurotransmitters, protein and peptide hormones, and other chemical messengers do not exert their effects by entering cells. Instead, they attach to receptors on the cell surface, and their messages are conveyed across the membrane and converted by cell membrane proteins into signals within the cell, a process often called *signal transduction*. Many molecules involved in signal transduction are proteins. A unique property of proteins that allows them to function in this way is their ability to change their shape or conformation, thereby changing their function and consequently the functions of the cell. These conformational changes are often accomplished through

KEY CONCEPTS

CELL COMMUNICATION

- Cells communicate with each other and with the internal and external environments by a number of mechanisms, including electrical and chemical signaling systems that control electrical potentials, the overall function of a cell, and gene activity needed for cell division and cell replication.
- Chemical messengers exert their effects by binding to cell membrane proteins or receptors that convert the chemical signal into signals within the cell, in a process called *signal transduction*.
- Cells regulate their responses to chemical messengers by increasing or decreasing the number of active receptors on their surface.

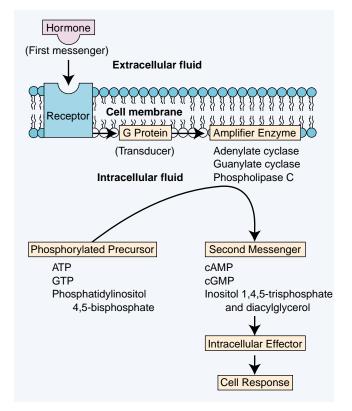

enzymes called *protein kinases* that catalyze the phosphorylation of amino acids in the protein structure.

Each cell type in the body contains a distinctive set of receptor proteins that enable it to respond to a complementary set of signaling molecules in a specific, preprogrammed way. These receptors, which span the cell membrane, relay information to a series of intracellular intermediates that eventually pass the signal to its final destination. Many receptors for chemical messengers have been isolated and characterized. These proteins are not static components of the cell membrane; they increase or decrease in number, according to the needs of the cell. When excess chemical messengers are present, the number of active receptors decreases in a process called *down-regulation*; when there is a deficiency of the messenger, the number of active receptors increases through *up-regulation*. There are three known classes of cell surface receptor proteins: ion channel linked, G protein linked, and enzyme linked.

lon-Channel–Linked Receptors. Ion-channel–linked receptors are involved in the rapid synaptic signaling between electrically excitable cells. This type of signaling is mediated by a small number of neurotransmitters that transiently open or close ion channels formed by integral proteins in the cell membrane. This type of signaling is involved in the transmission of impulses in nerve and muscle cells.

G-Protein–Linked Receptors and Signal Transduction. G proteins constitute the on–off switch for signal transduction. Although there are numerous intercellular messengers, many of them rely on a class of molecules called *G proteins* to convert external signals (first messengers) into internal signals (second messengers). These internal signals induce biochemical changes in the cell that lead to the desired physiologic effects. G proteins are so named because they bind to guanine nucleotides, such as guanine diphosphate (GDP) and guanine triphosphate (GTP).

G-protein-mediated signal transduction relies on a series of orchestrated biochemical events (Fig. 1-12). All signal trans-

■ FIGURE 1-12 ■ Signal transduction pattern common to several second messenger systems. A protein or peptide hormone is the first messenger to a membrane receptor, stimulating or inhibiting a membrane-bound enzyme by means of a G protein. The amplifier enzyme catalyzes the production of a second messenger from a phosphorylated precursor. The second messenger then activates an internal effector, which leads to the cell response. (Redrawn from Rhoades R.A., Tanner G.A. [1996]. *Medical physiology*. Boston: Little, Brown)

duction systems have a receptor component that functions as a signal discriminator by recognizing a specific first messenger. After a first messenger binds to a receptor, conformational changes occur in the receptor, which activates the G protein. The activated G protein, in turn, acts on other membranebound intermediates called *effectors*. Often, the effector is an enzyme that converts an inactive precursor molecule into a second messenger, which diffuses into the cytoplasm and carries the signal beyond the cell membrane.

Although there are differences between the G proteins, all share a number of features. All are found on the cytoplasmic side of the cell membrane, and all incorporate the GTPase cycle, which functions as the on–off switch for G-protein activity. Certain bacterial toxins can bind to the G proteins, causing inhibition or stimulation of its signal function. One such toxin, the toxin of *Vibrio cholerae*, binds and activates the stimulatory G protein linked to the cAMP system that controls the secretion of fluid into the intestine. In response to the cholera toxin, these cells overproduce fluid, leading to severe diarrhea and life-threatening depletion of extracellular fluid volume. There is also interest in the role that G-protein signaling may play in the pathogenesis of cancer. *Enzyme-Linked Receptors.* The receptors for certain protein hormones, such as insulin, and peptide growth factors activate an intracellular domain with enzyme (protein-tyrosine kinase) activity. The enzyme catalyzes the phosphorylation of tyrosine residues of intracellular proteins, thereby transferring an external message to the cell interior. Enzyme-linked receptors mediate cellular responses such as calcium influx, increased sodium/potassium exchange, and stimulation of the uptake of sugars and amino acids.

Growth factors are signal molecules that are similar to hormones in function but act closer to their sites of synthesis. As their name implies, many of the growth factors are important messengers in signaling cell replacement and cell growth. Most of the growth factors belong to one of three groups: factors that foster the multiplication and development of various cell types (*e.g.*, growth factor and epidermal growth factor); lymphokines and cytokines, which are important in the regulation of the immune system; and colony-stimulating factors, which regulate the proliferation and maturation of white and red blood cells.

Messenger-Mediated Control of Nuclear Function

Some messengers, such as thyroid hormone and steroid hormones, do not bind to membrane receptors but move directly across the lipid layer of the cell membrane and are carried to the cell nucleus, where they influence DNA activity. Many of these hormones bind to a cytoplasmic receptor, and together they are carried to the nucleus. In the nucleus, the receptor-hormone complex binds to DNA, thereby increasing transcription of mRNA. The mRNAs are translated in the ribosomes, with the production of increased amounts of proteins that alter cell function.

Membrane Potentials

The human body runs on a system of self-generated electricity. Electrical potentials exist across the membranes of most cells in the body. Because these potentials occur at the level of the cell membrane, they are called *membrane potentials*. In excitable tissues, such as nerve or muscle cells, changes in the membrane potential are necessary for generation and conduction of nerve impulses and muscle contraction. In other types of cells, such as glandular cells, changes in the membrane potential contribute to hormone secretion and other functions.

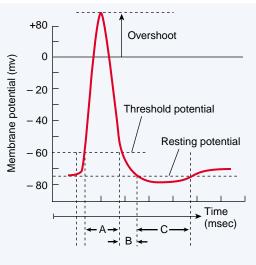

Electrical Potential

Electrical potential, measured in volts (V), describes the ability of separated electrical charges of opposite polarity (+ and –) to do work. The potential difference is the difference between the separated charges. The terms *potential difference* and *voltage* are synonymous. Voltage is always measured with respect to two points in a system. For example, the voltage in a car battery (6 or 12 V) is the potential difference between the two battery terminals. Because the total amount of charge that can be separated by a biologic membrane is small, the potential differences are small and are measured in *millivolts* (1/1000 of a volt). Potential differences across the cell membrane can be measured by inserting a very fine electrode into the cell and another into the extracellular fluid surrounding the cell and connecting the two electrodes to a voltmeter. The movement of charge between two points is called *current*. It occurs when a potential difference has been established and a connection is made such that the charged particles can move between the two points.

Extracellular and intracellular fluids are electrolyte solutions containing approximately 150 to 160 mmol/L of positively charged ions and an equal concentration of negatively charged ions. These are the current-carrying ions responsible for generating and conducting membrane potentials. Usually, a small excess of positively charged ions exists at the outer surface of the cell membrane. This is represented as positive charges on the outside of the membrane and is balanced by an equal number of negative charges on the inside of the membrane. Because of the extreme thinness of the cell membrane, the accumulation of these ions at the surfaces of the membrane contributes to the establishment of a membrane potential.

Action Potentials

Action potentials are abrupt, pulselike changes in the membrane potential that last a few ten thousandths to a few thousandths of a second (Fig 1-13). In a nerve fiber, an action potential can be elicited by any factor that suddenly increases the membrane potential, usually by opening a voltage-gated sodium channel. The *threshold potential* represents the membrane potential at which the ion channels open and neurons and other excitable tissues are stimulated to "fire." In large nerve

A = Absolute refractory period (active potential and partial recovery)

B = Relative refractory period

C=Positive relative refractory period

■ FIGURE 1-13 ■ Time course of the action potential recorded at one point of an axon with one electrode inside and one on the outside of the plasma membrane. The rising part of the action potential is called the spike. The rising phase plus approximately the first half of the repolarization phase is equal to the absolute refractory period (**A**). The portion of the repolarization phase that extends from the threshold to the resting membrane potential represents the relative refractory period (**B**). The remaining portion of the repolarization phase to the resting membrane potential is equal to the negative after potential (**C**). Hyperpolarization is equal to the positive relative refractory period. fibers the sodium channels open at approximately -60 mV. Under normal circumstances, the threshold potential is sufficient to open large numbers of ion channels, triggering massive depolarization of the membrane.

Action potentials can be divided into three phases: (1) resting, (2) depolarization, and (3) repolarization phases. The resting phase is the undisturbed period of the action potential, during which neurons and other excitable tissues are not transmitting impulses. During this phase, the membrane is highly permeable to potassium and there is approximately 70 to 90 mV less charge (-70 mV to -90 mV) on the inside than on the outside of the membrane. This difference in charge is necessary for establishment of current flow once the membrane becomes permeable to the flow of charged ions. During this period, the membrane is said to be polarized because charges of opposite polarity (+ and -) are aligned across the membrane. Depolarization is characterized by the flow of positively charged sodium ions to the interior of the membrane. During the depolarization phase of the action potential, the interior side of the membrane becomes positive (approximately +30 mV to +45 mV). Repolarization is the phase in which the polarity of the resting membrane is re-established. This is accomplished by closure of the sodium channels and opening of the potassium channels. The outflow of positively charged potassium ions returns the membrane potential to negativity. The activity of the Na+/K+ ATPase pump helps to reestablish the resting membrane potential. During repolarization, the membrane remains refractory (i.e., does not fire) until the repolarization is approximately one-third complete. This period, which lasts approximately one half of a millisecond, is called the absolute refractory period (Fig. 1-13). During the relative refractory period, which follows the absolute refractory period, the membrane can be excited, although only by a strongerthan-normal stimuli.

Two main factors alter membrane excitability: (1) the difference in the concentration of ions on the inside and outside of the membrane and (2) changes in membrane permeability. The resting membrane potential is strongly influenced by serum potassium levels and the resulting difference in concentration on the inside and outside of the membrane. When serum levels of potassium are decreased, the resting membrane potential becomes more negative, and nerve and muscle cells become less excitable, sometimes to the extent that they cannot be re-excited (see Chapter 6). An increase in serum potassium has the opposite effect, causing the resting membrane to become more positive, moving closer to threshold. When this happens, the amplitude of the action potential is decreased because the membrane has not been fully repolarized. Should the resting membrane potential reach the level of the threshold potential during the absolute refractory period, the nerve or muscle cell will remain depolarized and unexcitable.

Neural excitability is markedly altered by changes in membrane permeability to current-carrying ions such as sodium. Calcium ions decrease membrane permeability to sodium ions and increase the threshold for initiation of action potentials. If insufficient calcium ions are available, the permeability of the membrane to sodium increases, and as a result, membrane excitability increases, sometimes causing spontaneous muscle movements (tetany) to occur. Local anesthetic agents (*e.g.*, procaine, cocaine) act directly on neural membranes to decrease their permeability to sodium.

In summary, the movement of materials across the cell's membrane is essential for survival of the cell. Diffusion is a process by which substances such as ions move from areas of greater concentration to areas of lesser concentration in an attempt to reach a uniform distribution. Osmosis refers to the diffusion of water molecules through a semipermeable membrane along a concentration gradient. Facilitated diffusion is a passive process, in which molecules that cannot normally pass through the cell's membranes, do so with the assistance of a carrier molecule. Another type of transport, called active transport, requires the cell to expend energy in moving ions against a concentration gradient. The Na⁺/K⁺ ATPase pump is the best-known type of active transport. Endocytosis is a process by which cells engulf materials from the surrounding medium. Small particles are ingested by a process called pinocytosis; larger particles are engulfed by a process called phagocytosis. Exocytosis involves the removal of large particles from the cell and is essentially the reverse of endocytosis. Ion channels are integral transmembrane proteins that span the width of the cell membrane to form a gating system that controls the movement of ions across the cell membrane.

Cells communicate with each other by means of chemical messenger systems. In some tissues, chemical messengers move from cell to cell through gap junctions without entering the extracellular fluid. Other types of chemical messengers bind to receptors on or near the cell surface. There are three known classes of cell surface receptor proteins: ion channel linked, G protein linked, and enzyme linked. Ion-channellinked signaling is mediated by neurotransmitters that transiently open or close ion channels formed by integral proteins in the cell membrane. G-protein-linked receptors rely on a class of molecules called G proteins that function as an on-off switch to convert external signals (first messengers) into internal signals (second messengers). Enzyme-linked receptors interact with certain peptide hormones (e.g., insulin and growth factors) to directly initiate the activity of an intracellular enzyme, which in turn, triggers multiple cellular responses, such as stimulation of glucose and amino acid uptake or transcription of certain genes that control cell proliferation.

Electrical potentials (negative on the inside and positive on the outside) exist across the membranes of most cells in the body. Membrane excitability depends on a separation of charge across the membrane and the permeability of the membrane to the current-carrying ion. Action potentials are abrupt pulselike changes in the membrane potential that last a few ten thousandths to a few thousandths of a second. Action potentials can be divided into three phases: the resting phase, during which neurons and excitable tissues are not generating or transmitting impulses; the depolarization phase, which is characterized by flow of current across the membrane; and the repolarization phase, during which the resting membrane potential is restored.

BODY TISSUES

In the preceding sections, we discussed the individual cell, its metabolic processes, and mechanisms of communication. Although cells are similar, their structure and function vary ac-

cording to the special needs of the body. For example, muscle cells perform functions different from those of skin cells or nerve cells. Groups of cells that are closely associated in structure and have common or similar functions are called *tissues*. Four categories of tissue exist: epithelium, connective (supportive) tissue, muscle, and nerve. These tissues do not exist in isolated units, but in association with each other and in variable proportions, forming different structures and organs. This section provides a brief overview of the cells in epithelial, connective, and muscle tissue. Nervous tissue is described in Chapter 36.

Cell Differentiation

After conception, the fertilized ovum undergoes a series of divisions, ultimately forming approximately 200 different cell types. The formation of different types of cells and the disposition of these cells into tissue types is called cell differentiation, a process controlled by a system that switches genes on and off. Embryonic cells must become different to develop into all of the various organ systems, and they must remain different after the signal that initiated cell diversification has disappeared. The process of cell differentiation is controlled by cell memory, which is maintained through regulatory proteins contained in the individual members of a particular cell type. Cell differentiation also involves the sequential activation of multiple genes and their protein products. This means that after differentiation has occurred, the tissue type does not revert to an earlier stage of differentiation. The process of cell differentiation normally moves forward, producing cells that are more specialized than their predecessors. Usually, highly differentiated cell types,

KEY CONCEPTS

ORGANIZATION OF CELLS INTO TISSUES

- Cells with a similar embryonic origin or function are often organized into larger functional units called *tissues*, and these tissues in turn associate with other, dissimilar tissues to form the various organs of the body.
- Epithelial tissue forms sheets that cover the body's outer surface, lines internal surfaces, and forms glandular tissue. It is supported by a basement membrane, is avascular, and must receive nourishment from capillaries in supporting connective tissues.
- Connective tissue is the most abundant tissue of the body. It is found in a variety of forms, ranging from solid bone to blood cells that circulate in the vascular system.
- Muscle tissue contains actin and myosin filaments that allow it to contract and provide locomotion and movement of skeletal structures (skeletal muscle), pumping of blood through the heart (cardiac muscle), and contraction of blood vessels and visceral organs (smooth muscle).

such as skeletal muscle and nervous tissue, lose their ability to undergo cell division. Cancer is a disorder of cell differentiation in which cells of a single cell line fail to differentiate properly (see Chapter 5).

Embryonic Origin of Tissue Types

All of the approximately 200 different types of body cells can be classified into four basic or primary tissue types: epithelial, connective, muscle, and nervous (Table 1-1). These basic tissue types are often described by their embryonic origin. The embryo is essentially a three-layered tubular structure. The outer layer of the tube is called the *ectoderm*; the middle layer, the *mesoderm*; and the inner layer, the *endoderm*. All of the adult body tissues originate from these three cellular layers. Epithelium has its origin in all three embryonic layers; connective tissue and muscle develop mainly from the mesoderm; and nervous tissue develops from the ectoderm.

Epithelial Tissue

Epithelial tissue forms sheets that cover the body's outer surface, line the internal surfaces, and form the glandular tissue. Underneath all types of epithelial tissue is an extracellular matrix, called the *basement membrane*, which serves to attach the epithelial cells to adjacent connective tissue and provides them with flexible support.

Epithelial cells have strong intracellular protein filaments (*i.e.*, cytoskeleton) that are important in transmitting mechanical stresses from one cell to another. The cells of epithelial tissue are tightly bound together by specialized junctions. These specialized junctions enable these cells to form barriers to the movement of water, solutes, and cells from one body compartment to the next. Epithelial tissue is avascular (*i.e.*, without blood vessels) and must therefore receive oxygen and nutrients from the capillaries of the connective tissue on which the epithelial tissue rests (Fig. 1-14). To survive, the epithelial cells must be kept moist. Even the seemingly dry skin epithelium is kept moist by a nonvitalized, waterproof layer of superficial skin cells called *keratin*, which prevents evaporation of moisture from the deeper living cells. Epithelium is able to regenerate quickly when injured

Epithelial tissues are classified according to the shape of the cells and the number of layers that are present: simple, stratified, and pseudostratified. Glandular epithelial tissue is formed by cells specialized to produce a fluid secretion. The terms *squamous* (thin and flat), *cuboidal* (cube shaped), and *columnar* (resembling a column) refer to the cells' shape (Fig. 1-15).

Simple Epithelium

Simple epithelium contains a single layer of cells, all of which rest on the basement membrane. Simple squamous epithelium is adapted for filtration; it is found lining the blood vessels, lymph nodes, and alveoli of the lungs. The single layer of squamous epithelium lining the heart and blood vessels is known as the *endothelium*. A similar type of layer, called the *mesothelium*, forms the serous membranes that line the pleural, pericardial, and peritoneal cavities and cover the organs of these cavities. A *simple cuboidal epithelium* is found on the surface of the ovary and in the thyroid. *Simple columnar epithelium* lines the intestine. One form of a simple columnar epithelium

TABLE 1-1 Classification of Tissue T	ypes
Tissue Type	Location
Epithelial Tissue	
Covering and lining of body surfaces	
Simple epithelium	
Squamous	Lining of blood vessels, body cavities, alveoli of lungs
Cuboidal	Collecting tubules of kidney; covering of ovaries
Columnar	Lining of intestine and gallbladder
Stratified epithelium	
Squamous keratinized	Skin
Squamous nonkeratinized	Mucous membranes of mouth, esophagus, and vagina
Cuboidal	Ducts of sweat glands
Columnar	Large ducts of salivary and mammary glands; also found in conjunctiva
Transitional	Bladder, ureters, renal pelvis
Pseudostratified	Tracheal and respiratory passages
Glandular	
Endocrine	Pituitary gland, thyroid gland, adrenal, and other glands
Exocrine	Sweat glands and glands in gastrointestinal tract
Neuroepithelium	Olfactory mucosa, retina, tongue
Reproductive epithelium	Seminiferous tubules of testis; cortical portion of ovary
Connective Tissue	
Embryonic connective tissue	
Mesenchymal	Embryonic mesoderm
Mucous	Umbilical cord (Wharton's jelly)
Adult connective tissue	
Loose or areolar	Subcutaneous areas
Dense regular	Tendons and ligaments
Dense irregular	Dermis of skin
Adipose	Fat pads, subcutaneous layers
Reticular	Framework of lymphoid organs, bone marrow, liver
Specialized connective tissue	
Bone	Long bones, flat bones
Cartilage	Tracheal rings, external ear, articular surfaces
Hematopoietic	Blood cells, myeloid tissue (bone marrow)
Muscle Tissue	
Skeletal	Skeletal muscles
Cardiac	Heart muscles
Smooth	Gastrointestinal tract, blood vessels, bronchi, bladder, and others
Nervous Tissue	
Neurons	Central and peripheral neurons and nerve fibers
Supporting cells	Glial and ependymal cells in central nervous system; Schwann and satellite cells in peripheral nervous system
	· · · · · · · · · · · · · · · · · · ·

has hairlike projections called *cilia*, often with specialized mucus-secreting cells called goblet cells. This form of simple columnar epithelium lines the airways of the respiratory tract.

Stratified and Pseudostratified Epithelium

Stratified epithelium contains more than one layer of cells, with only the deepest layer resting on the basement membrane. It is designed to protect the body surface. Stratified squamous keratinized epithelium makes up the epidermis of the skin. Keratin is a tough, fibrous protein existing as filaments in the outer cells of skin. A stratified squamous keratinized epithelium is made up of many layers. The layers closest to the underlying tissues are cuboidal or columnar. The cells become more irregular and thinner as they move closer to the surface. Surface cells become totally filled with keratin and die, are sloughed off, and then replaced by the deeper cells. A stratified squamous nonkeratinized epithelium is found on moist surfaces, such as the mouth and tongue. Stratified cuboidal and columnar epithelia are found in the ducts of salivary glands and the larger ducts of the mammary glands. In smokers, the normal columnar ciliated epithelial cells of the trachea and bronchi are often replaced with stratified squamous epithelium cells that are better able to withstand the irritating effects of cigarette smoke.

Pseudostratified epithelium is a type of epithelium in which all of the cells are in contact with the underlying intercellular matrix, but some do not extend to the surface. A pseudostratified ciliated columnar epithelium with goblet cells forms the lining of most of the upper respiratory tract. All of the tall cells reaching the surface of this type of epithelium are either ciliated cells or mucus-producing goblet cells. The basal cells that do not

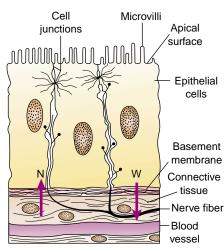

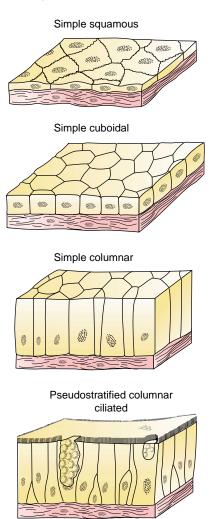

FIGURE 1-14 Typical arrangement of epithelial cells in relation to underlying tissues and blood supply. Epithelial tissue has no blood supply of its own but relies on the blood vessels in the underlying connective tissue for nutrition (N) and elimination of wastes (W).

reach the surface serve as stem cells for ciliated and goblet cells. *Transitional epithelium* is a stratified epithelium characterized by cells that can change shape and become thinner when the tissue is stretched. Such tissue can be stretched without pulling the superficial cells apart. Transitional epithelium is well adapted for the lining of organs that are constantly changing their volume, such as the urinary bladder.

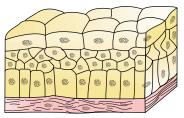

Glandular Epithelium

Glandular epithelial tissue is formed by cells specialized to produce a fluid secretion. This process is usually accompanied by the intracellular synthesis of macromolecules. The chemical nature of these macromolecules is variable. The macromolecules typically are stored in the cells in small, membranebound vesicles called *secretory granules*. For example, glandular epithelia can synthesize, store, and secrete proteins (*e.g.*, insulin), lipids (*e.g.*, adrenocortical hormones, secretions of the sebaceous glands), and complexes of carbohydrates and proteins (*e.g.*, saliva). Less common are secretions such as those produced by the sweat glands, which require minimal synthetic activity.

All glandular cells arise from surface epithelia by means of cell proliferation and invasion of the underlying connective tissue. Epithelial glands can be divided into two groups: exocrine and endocrine glands. Exocrine glands, such as the sweat glands and lactating mammary glands, retain their connection with the surface epithelium from which they originated. This connection takes the form of epithelium-lined tubular ducts through which the secretions pass to reach the surface. Exocrine glands are often classified according to the way secretory products are released by their cells. In holocrine type cells (e.g., sebaceous glands), the glandular cell ruptures, releasing its entire contents into the duct system. New generations of cells are replaced by mitosis of basal cells. Merocrine or eccrine type glands (e.g., salivary glands, exocrine glands of the pancreas) release their glandular products by exocytosis. In apocrine secretions (e.g., mammary glands, certain sweat glands), the apical por-

Transitional

Stratified squamous

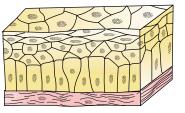

FIGURE 1-15 Representation of the various epithelial tissue types.

tion of the cell, along with small portions of the cytoplasm, is pinched off the glandular cells. *Endocrine glands* are epithelial structures that have had their connection with the surface obliterated during development. These glands are ductless and produce secretions (*i.e.*, hormones) that move directly into the bloodstream.

Connective or Supportive Tissue

Connective tissue (or supportive tissue) is the most abundant tissue in the body. As its name suggests, it connects and binds or supports the various tissues. The capsules that surround organs of the body are composed of connective tissue. Bone, adipose tissue, and cartilage are specialized types of connective tissue that function to support the soft tissues of the body and store fat. Connective tissue is unique in that its cells produce the extracellular matrix that supports and holds tissues together. Connective tissue has a role in tissue nutrition. The close proximity of the extracellular matrix to blood vessels allows it to function as an exchange medium through which nutrients and metabolic wastes pass.

Adult connective tissue proper can be divided into two main types: loose or areolar and dense connective tissue.

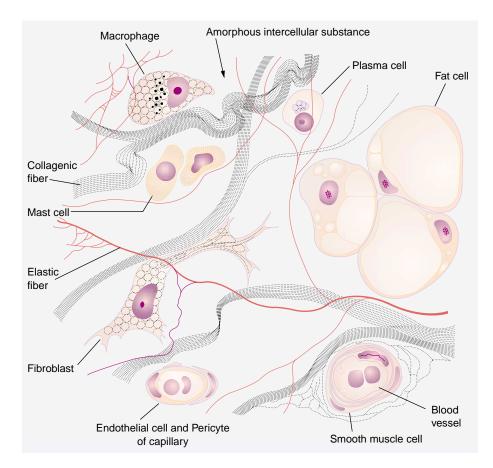

Loose Connective Tissue

Loose connective tissue, also known as areolar tissue, is soft and pliable. Although it is more cellular than dense connective tissue, it contains large amounts of intercellular substance. It fills

spaces between muscle sheaths and forms a layer that encases blood and lymphatic vessels. Areolar connective tissue supports the epithelial tissues and provides the means by which these tissues are nourished. In an organ containing functioning epithelial tissue and supporting connective tissue, the term *parenchymal tissue* is used to describe the functioning epithelium as opposed to the connective tissue framework or stroma.

Cells of loose connective tissue include fibroblasts, mast cells, adipose or fat cells, macrophages, plasma cells, and leukocytes (Fig. 1-16). Loose connective tissue cells secrete substances that form the extracellular matrix that supports and connects body cells. Fibroblasts are the most abundant of these cells. They are responsible for the synthesis of the fibrous and gel-like substance that fills the intercellular spaces of the body and for the production of collagen, elastic, and reticular fibers.

Adipose tissue is a special form of connective tissue in which adipocytes predominate. Adipocytes do not generate an extracellular matrix but maintain a large intracellular space. These cells store large quantities of triglycerides and are the largest repository of energy in the body. Adipose tissue helps fill spaces between tissues and helps to keep organs in place. Subcutaneous layers of fat help to shape the body. Because fat is a poor conductor of heat, adipose tissue serves as thermal insulation for the body. Adipose tissue exists in two forms. Unilocular (white) adipose tissue is composed of cells in which the fat is contained in a single, large droplet in the cytoplasm. Multilocular (brown) adipose tissue is composed of cells that contain multiple droplets of fat and numerous mitochondria.

■ FIGURE 1-16 ■ Diagrammatic representation of cells that may be seen in loose connective tissue. The cells lie in an intercellular matrix that is bathed in tissue fluid that originates in capillaries. (From Cormack D.H. [1987]. *Ham's histology* [9th ed.]. Philadelphia: J.B. Lippincott) *Reticular tissue* is characterized by a network of reticular fibers associated with reticular cells. Reticular fibers provide the framework for capillaries, nerves, and muscle cells. They also constitute the main supporting elements for the blood forming tissues and the liver.

Dense Connective Tissue

Dense connective tissue exists in two forms: dense irregular and dense regular. Dense irregular connective tissue consists of the same components found in loose connective tissue, but there is a predominance of collagen fibers and fewer cells. This type of tissue can be found in the dermis of the skin (*i.e.*, reticular layer), the fibrous capsules of many organs, and the fibrous sheaths of cartilage (*i.e.*, perichondrium) and bone (*i.e.*, periosteum). It also forms the fascia that covers muscles and organs. Dense regular connective tissues are rich in collagen fibers and form the tendons and aponeuroses that join muscles to bone or other muscles and the ligaments that join bone to bone. Tendons and ligaments are white fibers because of an abundance of collagen. Ligaments such as the ligamenta flava of the vertebral column and the true vocal folds are called *yellow fibers* because of the abundance of elastic fibers.

Muscle Tissue

Three types of muscle tissues exist: *skeletal, cardiac,* and *smooth.* Skeletal and cardiac muscles are striated muscles. The actin and myosin filaments are arranged in large parallel arrays in bundles, giving the muscle fibers a striped or striated appearance when they are viewed through a microscope.

Skeletal muscle is the most abundant tissue in the body, accounting for 40% to 45% of the total body weight. Most skeletal muscles are attached to bones, and their contractions are responsible for movements of the skeleton. Cardiac muscle, which is found in the heart, is designed to pump blood continuously. Smooth muscle is found in the iris of the eye, the walls of blood vessels, hollow organs such as the stomach and urinary bladder, and hollow tubes, such as the ureters, that connect internal organs.

Neither skeletal nor cardiac muscle can undergo the mitotic activity needed to replace injured cells. However, smooth muscle may proliferate and undergo mitotic activity. Some increases in smooth muscle are physiologic, as occurs in the uterus during pregnancy. Other increases, such as the increase in smooth muscle that occurs in the arteries of persons with chronic hypertension, are pathologic.

Although the three types of muscle tissue differ significantly in structure, contractile properties, and control mechanisms, they have many similarities. In the following section, the structural properties of skeletal muscle are presented as the prototype of striated muscle tissue. Smooth muscle and the ways in which it differs from skeletal muscle are also discussed. Cardiac muscle is described in Chapter 14.

Skeletal Muscle

Skeletal muscle tissue is packaged into skeletal muscles that attach to and cover the body skeleton. Each skeletal muscle is a discrete organ made up of hundreds and thousands of muscle fibers. Even though muscle fibers predominate, substantial amounts of connective tissue, blood vessels, and nerve fibers are present. In an intact muscle, several different layers of connective tissue hold the individual muscle fibers together. A dense connective tissue covering called the *epimysium* forms the outermost layer surrounding the whole muscle (Fig. 1-17). Each muscle is subdivided into smaller bundles called *fascicles*, which are surrounded by a connective tissue covering called the *perimysium*. The number of fascicles and their size vary among muscles. Fascicles consist of many elongated structures called *muscle fibers*, each of which is surrounded by connective tissue called the *endomysium*.

Skeletal muscles are syncytial or multinucleated structures, meaning there are no true cell boundaries within a skeletal muscle fiber. The cytoplasm or sarcoplasm of the muscle fiber is contained within the sarcolemma, which represents the cell membrane. Embedded throughout the sarcoplasm are the contractile elements actin and myosin, which are arranged in parallel bundles (*i.e., myofibrils*). The thin, lighter-staining myofilaments are composed of actin, and the thicker, darker-staining myofilaments are composed of myosin. Each myofibril consists of regularly repeating units along the length of the myofibril; each of these units is called a sarcomere (see Fig. 1-17). Sarcomeres are the structural and functional units of cardiac and skeletal muscle. A sarcomere extends from one Z line to another Z line. Within the sarcomere are alternating light and dark bands. The central dark band (A band) contains mainly myosin filaments, with some overlap with actin filaments. The lighter I band contains only actin filaments and straddles the Z band; therefore, it takes two sarcomeres to complete an I band. An H zone is found in the middle of the A band and represents the region where only myosin filaments are found. In the center of the H zone is a thin, dark band, the M band or line, that is produced by linkages between the myosin filaments. Z bands consist of short elements that interconnect and provide the thin actin filaments from two adjoining sarcomeres with an anchoring point.

The sarcoplasmic reticulum, which is comparable to the smooth ER, is composed of longitudinal tubules that run parallel to the muscle fiber and surround each myofibril. This network ends in enlarged, saclike regions called the lateral sacs or terminal cisternae. These sacs store calcium to be released during muscle contraction. A second system of tubules consists of the *transverse* or *T* tubules, which are extensions of the plasma membrane and run perpendicular to the muscle fiber. The hollow portion or lumen of the transverse tubule is continuous with the extracellular fluid compartment. Action potentials, which are rapidly conducted over the surface of the muscle fiber, are in turn propagated by the T tubules and into the sarcoplasmic reticulum. As the action potential moves through the lateral sacs, the sacs release calcium, initiating muscle contraction. The membrane of the sarcoplasmic reticulum also has an active transport mechanism for pumping calcium ions back into the reticulum. This prevents interactions between calcium ions and the actin and myosin myofilaments after cessation of a muscle contraction.

Skeletal Muscle Contraction. Muscle contraction involves the sliding of the thick myosin and thin actin filaments over each other to produce shortening of the muscle fiber, while the actual length of the individual thick and thin filaments remains unchanged. The thick myosin filaments consist of a thin tail, which provides the structural backbone for the filament, and a globular head that forms cross-bridges with the thin actin

Unit One: Mechanisms of Disease

■ FIGURE 1-17 ■ (A) Connective tissue components of a skeletal muscle. (B) Structure of the myofibril and the relationship between actin and myosin myofilaments. (C) Sarcoplasmic reticulum and system of transverse tubules.

filaments (Fig. 1-18). Myosin molecules are bundled together side by side in the thick filaments such that one half have their heads toward one end of the filament and their tails toward the other end; the other half are arranged in the opposite manner. Each globular myosin head contains a binding site able to bind to a complementary site on the actin molecule. In addition to the binding site for actin, each myosin head has a separate active site that catalyzes the breakdown of ATP to provide the energy needed to activate the myosin head so it can form a crossbridge with actin. After contraction, myosin also binds ATP, thus breaking the linkage between actin and myosin.

The thin filaments are composed mainly of actin, a globular protein lined up in two rows that coil around each other to form a long helical strand. Associated with each actin filament are two regulatory proteins, tropomyosin and troponin. Tropomyosin, which lies in grooves of the actin strand, provides the site for attachment of the globular heads of the myosin filament. In the noncontracted state, troponin covers the tropomyosin binding sites and prevents formation of cross-bridges between the actin and myosin. During an action potential, calcium ions

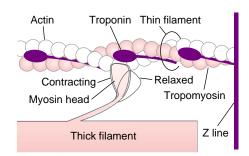

FIGURE 1-18 Molecular structure of the thin actin filament and the thicker myosin filament of striated muscle. The thin filament is a double-stranded helix of actin molecules with tropomyosin and troponin molecules lying along the grooves of the actin strands. During muscle contraction, the ATP-activated heads of the thick myosin filament swivel into position, much like the oars on a boat, form a cross-bridge with a reactive site on tropomyosin, and then pull the actin filament forward. During muscle relaxation, the troponin molecules cover the reactive sites on tropomyosin.

released from the sarcoplasmic reticulum diffuse to the adjacent myofibrils, where they bind to troponin. The binding of calcium to troponin uncovers the tropomyosin binding sites such that the myosin heads can attach and form cross-bridges.

Muscle contraction begins with activation of the crossbridges from the myosin filaments and uncovering of the tropomyosin binding sites on the actin filament. When activated by ATP, the heads of the myosin heads swivel in a fixed arc, much like the oars of a boat, as they become attached to the actin filament. During contraction, each myosin head undergoes its own cycle of movement, forming a bridge attachment and releasing it, and moving to another site where the same sequence of movement occurs. This pulls the thin and thick filaments past each other. Energy from ATP is used to break the actin and myosin cross-bridges, stopping the muscle contraction. With the breaking of the linkage between actin and myosin, the concentration of calcium around the myofibrils decreases as calcium is actively transported into the sarcoplasmic reticulum by a membrane pump that uses energy derived from ATP.

Smooth Muscle

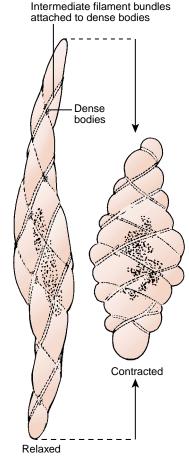

Smooth muscle is often called *involuntary muscle* because its activity arises spontaneously or through activity of the autonomic nervous system. Smooth muscle contractions are slower and more sustained than skeletal or cardiac muscle contractions.

Organization and Structure. Smooth muscle cells are spindle shaped and smaller than skeletal muscle fibers. Each smooth muscle cell has one centrally positioned nucleus. Z bands or M lines are not present in smooth muscle fibers, and the cross-striations are absent because the bundles of filaments are not parallel but crisscross obliquely through the cell. Instead, the actin filaments are attached to structures called *dense bodies*. Some of the dense bodies are attached to the cell membrane, and others are dispersed in the cell and linked together by structural proteins (Fig. 1-19).

The lack of Z lines and regular overlapping of the contractile elements provides a greater range of tension development. This is important in hollow organs that undergo changes in volume, with consequent changes in the length of the smooth muscle fibers in their walls. Even with the distention of a hollow organ, the smooth muscle fiber retains some ability to develop tension, whereas such distention would stretch skeletal muscle beyond the area where the thick and thin filaments overlap.

Smooth muscle usually is arranged in sheets or bundles. In hollow organs, such as the intestines, the bundles are organized into the two-layered muscularis externa, consisting of an outer, longitudinal layer and an inner, circular layer. A thinner muscularis mucosae often lies between the muscularis externa and the endothelium. In blood vessels, the bundles are arranged circularly or helically around the vessel wall.

Smooth Muscle Contraction. As with cardiac and skeletal muscle, smooth muscle contraction is initiated by an increase in intracellular calcium. However, smooth muscle differs from skeletal muscle in the way its cross-bridges are formed. The sarcoplasmic reticulum of smooth muscle is less developed than in skeletal muscle, and no transverse tubules are present. Thus, smooth muscle relies heavily on the entrance

■ FIGURE 1-19 ■ Structure of smooth muscle showing the dense bodies. In smooth muscle, the force of contraction is transmitted to the cell membrane by bundles of intermediate fibers. (Cormack D.H. [1993]. *Essential histology* [p. 229]. Philadelphia: J.B. Lippincott)

of extracellular calcium for muscle contraction. This dependence on movement of extracellular calcium across the cell membrane during muscle contraction is the basis for the action of calcium-blocking drugs used in the treatment of cardiovascular disease.

Smooth muscle also lacks the calcium-binding regulatory protein troponin, which is found in skeletal and cardiac muscle. Instead, it relies on another cytoplasmic protein called *calmodulin*. The calcium–calmodulin complex binds to and activates the myosin-containing thick filaments, which interact with actin.

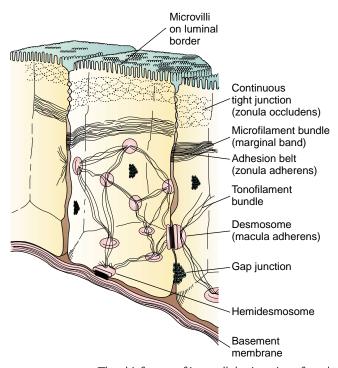

Types of Smooth Muscle. Smooth muscle may be divided into two broad categories according to the mode of activation: multiunit and single-unit smooth muscle. In *multiunit* smooth muscle, each unit operates almost independently of the others and is often enervated by a single nerve, such as occurs in skeletal muscle. It has little or no inherent activity and depends on the autonomic nervous system for its activation. Smooth muscle of this type is found in the iris, in the walls of the vas deferens, and attached to hairs in the skin. The fibers in *single-unit* smooth muscle are in close contact with each

other and can contract spontaneously without nerve or hormonal stimulation. Normally, most muscle fibers contract synchronously, thus the term *single-unit* smooth muscle. Some single-unit smooth muscle, such as that found in the gastrointestinal tract, is self-excitable. This is usually associated with a basic slow-wave rhythm transmitted from cell to cell by nexuses (*i.e.*, gap junctions) formed by the fusion of adjacent cell membranes. The cause of this slow wave is unknown. The intensity of contraction increases with the frequency of the action potential. Certain hormones, other agents, and local factors can modify smooth muscle activity by depolarizing or hyperpolarizing the membrane. The smooth muscle of the uterus and small-diameter blood vessels is also single-unit smooth muscle.

Cell Junctions and Cell-to-Cell Adhesion

Cell junctions occur at many points in cell-to-cell contact, but they are particularly plentiful and important in epithelial tissue. Three basic types of intercellular junctions are observed: tight junctions, adhering junctions, and gap junctions (Fig. 1-20). Often, the cells in epithelial tissue are joined by all three types of junctions. *Continuous tight* or occluding junctions (*i.e.*, zona occludens), which are found only in epithelial tissue, seal the surface membranes of adjacent cells together. This type of intercellular junction prevents materials such as macromolecules present in the intestinal contents from entering the intercellular space.

Adhering junctions represent a site of strong adhesion between cells. The primary role of adhering junctions may be that of preventing cell separation. Adhering junctions are not restricted to epithelial tissue; they provide adherence between ad-

■ FIGURE 1-20 ■ The chief types of intercellular junctions found in epithelial tissue. (From Cormack D.H. [1993]. *Essential histology*. Philadelphia: J.B. Lippincott) jacent cardiac muscle cells as well. Adhering junctions are found as continuous, beltlike adhesive junctions (*i.e.*, zonula adherens), or scattered, spotlike adhesive junctions called *desmosomes* (*i.e.*, macula adherens). A special feature of the adhesion belt junction is that it provides a site for anchorage of microfilaments to the cell membrane. In epithelial desmosomes, bundles of keratin-containing intermediate filaments (*i.e.*, tonofilaments) are anchored to the junction on the cytoplasmic area of the cell membrane.

Gap junctions, or *nexus junctions*, involve the close adherence of adjoining cell membranes with the formation of channels that link the cytoplasm of the two cells. Gap junctions are not unique to epithelial tissue; they play an essential role in many types of cell-to-cell communication. Because they are low-resistance channels, gap junctions are important in cell-to-cell conduction of electrical signals (*e.g.*, between cells in sheets of smooth muscle or between adjacent cardiac muscle cells, where they function as electrical synapses). These multiple communication channels also enable ions and small molecules to pass directly from one cell to another.

Hemidesmosomes are another type of junction. They are found at the base of epithelial cells and help attach the epithelial cell to the underlying connective tissue. They resemble half a desmosome, thus their name.

In summary, body cells are organized into four basic tissue types: epithelial, connective, muscle, and nervous. The epithelium covers and lines the body surfaces and forms the functional components of glandular structures. Epithelial tissue is classified into three types according to the shape of the cells and the number of layers that are present: simple, stratified, and pseudo-stratified. The cells in epithelial tissue are held together by three types of intercellular junctions: tight, adhering, and gap. They are attached to the underlying tissue by hemidesmosomes.

Connective tissue supports and connects body structures; it forms the bones and skeletal system, the joint structures, the blood cells, and the intercellular substances. Adult connective tissue can be divided into four types: loose or areolar, reticular, adipose, and dense (regular and irregular).

Muscle tissue is a specialized tissue designed for contractility. Three types of muscle tissue exist: skeletal, cardiac, and smooth. Actin and myosin filaments interact to produce muscle shortening, a process activated by the presence of calcium. In skeletal muscle, calcium is released from the sarcoplasmic reticulum in response to an action potential. Smooth muscle is often called involuntary muscle because it contracts spontaneously or through activity of the autonomic nervous system. It differs from skeletal muscle in that its sarcoplasmic reticulum is less defined and it depends on the entry of extracellular calcium ions for muscle contraction.

The cells of tissues are joined by cell junctions. There are three basic types of cell junctions: tight junctions, which prevent materials from entering the intercellular space and are found only in epithelial tissue; adhering junctions, which hold cells together and are found in epithelial as well as cardiac tissue; and gap junctions, which contain channels that link the cytoplasm of two cells and are important in cell-to-cell conduction of electrical impulses.

REVIEW QUESTIONS

State why the nucleus is called the "control center" of the cell, and explain the relationships among DNA, genes, and chromosomes.

List the cellular organelles and state their functions.

Explain how the composition of the lipid bilayer structure of the cell membrane controls access to the interior of the cell, and describe how ions, nutrients, water, and other substances cross the cell membrane.

Relate the function of ATP to cell metabolism and compare the processes involved in the aerobic and anaerobic metabolic pathways that generate ATP.

Trace the pathway for cell communication, beginning at the receptor and ending with effector response, and explain why the process is often referred to as "signal transduction."

Two conditions are necessary for a membrane potential to occur by diffusion: the membrane must be selectively permeable to a single type of ion, and the concentration of the diffusible ion must be greater on one side of the membrane than the other. Relate this concept to the role that potassium and sodium ions play in the generation of an action potential.

Describe the characteristics of the simple epithelium, stratified epithelium, and glandular epithelium; loose and dense connective tissue; skeletal and smooth muscle; and the neurons and supporting cells of the nervous system.

Characterize the function of the intracellular adhesions and junctions.

Tissue Adaptation and Injury

Cellular Adaptation Atrophy **Hypertrophy Hyperplasia Metaplasia Dysplasia** Intracellular Accumulations **Cell Injury and Death Causes of Cell Injury Injury From Physical Agents Radiation Injury Chemical Injury Injury From Biologic Agents** Injury From Nutritional Imbalances Mechanisms of Cell Injury Free Radical Injury Hypoxic Cell Injury Impaired Calcium Homeostasis **Reversible Cell Injury and Cell Death Reversible Cell Injury** Cell Death

hen confronted with stresses that endanger its normal structure and function, the cell undergoes adaptive changes that permit survival and maintenance of function. It is only when the stress is overwhelming or adaptation is ineffective that cell injury and death occur.

CELLULAR ADAPTATION

Cells adapt to changes in the internal environment, just as the total organism adapts to changes in the external environment. Cells may adapt by undergoing changes in size, number, and type. These changes, occurring singly or in combination, may

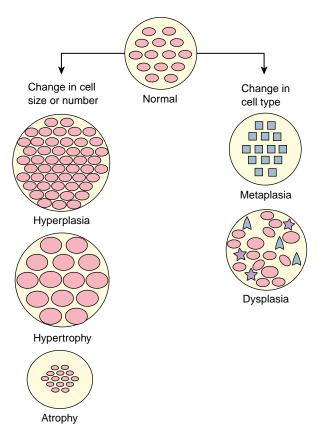

lead to atrophy, hypertrophy, hyperplasia, metaplasia, and dysplasia (Fig. 2-1). Adaptive cellular responses also include intracellular accumulations and storage of products in abnormal amounts.^{1,2}

There are numerous molecular mechanisms mediating cellular adaptation, including factors produced by other cells or by the cells themselves. These mechanisms depend largely on signals transmitted by chemical messengers that exert their effects by altering gene function. In general, the genes expressed in all cells fall into two categories: "housekeeping" genes that are necessary for normal function of a cell, and genes that determine the differentiating characteristics of a particular cell type. In many adaptive cellular responses, the expression of the differentiation genes is altered, whereas that of the housekeeping genes remains unaffected.¹ Thus, a cell is able to change size or form without compromising its housekeeping function. Once the stimulus for adaptation is removed, the effect on expression of the differentiating genes is removed and the cell resumes its previous state of specialized function. Whether adaptive cellular changes are normal or abnormal depends on whether the response was mediated by an appropriate stimulus. Normal adaptive responses occur in response to need and an appropriate stimulus. After the need has been removed, the adaptive response ceases.

Atrophy

When confronted with a decrease in work demands or adverse environmental conditions, most cells are able to revert to a smaller size and a lower and more efficient level of functioning that is compatible with survival. This decrease in cell size is called *atrophy*. Cell size, particularly in muscle tissue, is related to workload. As the workload of a cell diminishes, oxygen consumption and protein synthesis decrease. Cells that are atrophied reduce their oxygen consumption and other cellular functions by decreasing the number and size of their organelles and other structures. There are fewer mitochondria, myofilaments, and endoplasmic reticulum structures. When a sufficient number of cells are involved, the entire tissue or muscle atrophies.

The general causes of atrophy can be grouped into five categories: (1) disuse, (2) denervation, (3) loss of endocrine stimulation, (4) inadequate nutrition, and (5) ischemia or a

■ FIGURE 2-1 ■ Adaptive tissue cell responses (large circles) involving a change in number (hyperplasia), cell size (hypertrophy and atrophy), cell type (metaplasia), or size, shape, and organization (dysplasia).

decrease in blood flow. Disuse atrophy occurs when there is a reduction in skeletal muscle use. An extreme example of disuse atrophy is seen in the muscles of extremities that have been encased in plaster casts. Because atrophy is adaptive and reversible, muscle size is restored after the cast is removed and muscle use is resumed. Denervation atrophy is a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Lack of endocrine stimulation produces a form of disuse atrophy. In women, the loss of estrogen stimulation during menopause results in atrophic changes in the reproductive organs. With malnutrition and decreased blood flow, cells decrease their size and energy requirements as a means of survival.

KEY CONCEPTS

CELLULAR ADAPTATIONS

- Cells are able to adapt to changes in work demands or threats to survival by changing their size (atrophy and hypertrophy), number (hyperplasia), and form (metaplasia).
- Normal cellular adaptation occurs in response to an appropriate stimulus and ceases once the need for adaptation has ceased.

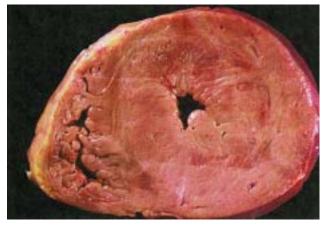

Hypertrophy

Hypertrophy represents an increase in cell size and with it an increase in the amount of functioning tissue mass. It results from an increased workload imposed on an organ or body part and is commonly seen in cardiac and skeletal muscle tissue, which cannot adapt to an increase in workload through mitotic division and formation of more cells. Hypertrophy involves an increase in the functional components of the cell that allows it to achieve equilibrium between demand and functional capacity. For example, as muscle cells hypertrophy, additional actin and myosin filaments, cell enzymes, and adenosine triphosphate (ATP) are synthesized.

Hypertrophy may occur as the result of normal physiologic or abnormal pathologic conditions. The increase in muscle mass associated with exercise is an example of physiologic hypertrophy. Pathologic hypertrophy occurs as the result of disease conditions and may be adaptive or compensatory. Examples of adaptive hypertrophy are the thickening of the urinary bladder from long-continued obstruction of urinary outflow and the myocardial hypertrophy that results from valvular heart disease or hypertension. Compensatory hypertrophy is the enlargement of a remaining organ or tissue after a portion has been surgically removed or rendered inactive. For instance, if one kidney is removed, the remaining kidney enlarges to compensate for the loss.

The precise signal for hypertrophy is unknown. It may be related to ATP depletion, mechanical forces such as stretching of the muscle fibers, activation of cell degradation products, or hormonal factors.¹ Whatever the mechanism, a limit is eventually reached beyond which further enlargement of the tissue mass is no longer able to compensate for the increased work demands. The limiting factors for continued hypertrophy might be related to limitations in blood flow. For example, in hypertension the increased workload required to pump blood against an elevated arterial pressure results in a progressive increase in left ventricular muscle mass (Fig. 2-2).

There has been recent interest in the signaling pathways that control the arrangement of contractile elements in myocardial hypertrophy. Research suggests that certain signal molecules

■ FIGURE 2-2 ■ Myocardial hypertrophy. Cross-section of the heart in a patient with long-standing hypertension. (From Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 9]. Philadelphia: Lippincott Williams & Wilkins)

can alter gene expression controlling the size and assembly of the contractile proteins in hypertrophied myocardial cells. For example, the hypertrophied myocardial cells of well-trained athletes have proportional increases in width and length. This is in contrast to the hypertrophy that develops in dilated cardiomyopathy, in which the hypertrophied cells have a relatively greater increase in length than width. In pressure overload, as occurs with hypertension, the hypertrophied cells have greater width than length.³ It is anticipated that further elucidation of the signal pathways that determine the adaptive and nonadaptive features of cardiac hypertrophy will lead to new targets for treatment.

Hyperplasia

26

Hyperplasia refers to an increase in the number of cells in an organ or tissue. It occurs in tissues with cells that are capable of mitotic division, such as the epidermis, intestinal epithelium, and glandular tissue. Nerve cells and skeletal and cardiac muscle do not divide and therefore have no capacity for hyperplastic growth. There is evidence that hyperplasia involves activation of genes controlling cell proliferation and the presence of intracellular messengers that control cell replication and growth. As with other normal adaptive cellular responses, hyperplasia is a controlled process that occurs in response to an appropriate stimulus and ceases after the stimulus has been removed.

The stimuli that induce hyperplasia may be physiologic or nonphysiologic. Physiologic hyperplasia can occur as the result of hormonal stimulation, increased functional demands, or as a compensatory mechanism. Breast and uterine enlargement during pregnancy are examples of a physiologic hyperplasia that results from estrogen stimulation. An increased demand for parathyroid hormone, as occurs in chronic renal failure, results in hyperplasia of the parathyroid gland. The regeneration of the liver that occurs after partial hepatectomy (i.e., partial removal of the liver) is an example of compensatory hyperplasia. Hyperplasia is also an important response of connective tissue in wound healing, during which proliferating fibroblasts and blood vessels contribute to wound repair. Although hypertrophy and hyperplasia are two distinct processes, they may occur together and are often triggered by the same mechanism.¹ For example, the pregnant uterus undergoes both hypertrophy and hyperplasia as the result of estrogen stimulation.

Most forms of nonphysiologic hyperplasia are due to excessive hormonal stimulation or the effects of growth factors on target tissues.² Excessive estrogen production can cause endometrial hyperplasia and abnormal menstrual bleeding (see Chapter 34). Benign prostatic hyperplasia, which is a common disorder of men older than 50 years of age, is thought to be related to the synergistic action of estrogen and androgens (see Chapter 33). Skin warts are an example of hyperplasia caused by growth factors produced by the human papillomaviruses.

Metaplasia

Metaplasia represents a reversible change in which one adult cell type (epithelial or mesenchymal) is replaced by another adult cell type. Metaplasia is thought to involve the reprogramming of undifferentiated stem cells that are present in the tissue undergoing the metaplastic changes.

Metaplasia usually occurs in response to chronic irritation and inflammation and allows for substitution of cells that are better able to survive under circumstances in which a more fragile cell type might succumb. However, the conversion of cell types never oversteps the boundaries of the primary groups of tissue (e.g., one type of epithelial cell may be converted to another type of epithelial cell, but not to a connective tissue cell). An example of metaplasia is the adaptive substitution of stratified squamous epithelial cells for the ciliated columnar epithelial cells in the trachea and large airways of a habitual cigarette smoker. A vitamin A deficiency also induces squamous metaplasia of the respiratory tract. Although the squamous epithelium is better able to survive in these situations, the protective function that the ciliated epithelium provides for the respiratory tract is lost. In addition, continued exposure to the influences that cause metaplasia may predispose to cancerous transformation of the metaplastic epithelium.

Dysplasia

Dysplasia is characterized by deranged cell growth of a specific tissue that results in cells that vary in size, shape, and appearance. Minor degrees of dysplasia are associated with chronic irritation or inflammation. The pattern is most frequently encountered in metaplastic squamous epithelium of the respiratory tract and uterine cervix. Although dysplasia is abnormal, it is adaptive in that it is potentially reversible after the irritating cause has been removed. Dysplasia is strongly implicated as a precursor of cancer. In cancers of the respiratory tract and the uterine cervix, dysplastic changes have been found adjacent to the foci of cancerous transformation. Through the use of the Papanicolaou (Pap) smear, it has been documented that cancer of the uterine cervix develops in a series of incremental epithelial changes ranging from severe dysplasia to invasive cancer. However, dysplasia is an adaptive process and as such does not necessarily lead to cancer. In many cases, the dysplastic cells revert to their former structure and function.

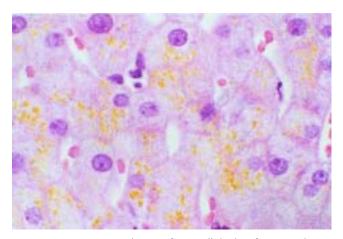

Intracellular Accumulations

Intracellular accumulations represent buildup of substances that cells cannot immediately use or dispose of. The substances may accumulate in the cytoplasm (frequently in the lysosomes) or in the nucleus. In some cases the accumulation may be an abnormal substance that the cell has produced, and in other cases the cell may be storing exogenous materials or products of pathologic processes occurring elsewhere in the body. These substances can be grouped into three categories: (1) normal body substances, such as lipids, proteins, carbohydrates, melanin, and bilirubin, that are present in abnormally large amounts; (2) abnormal endogenous products, such as those resulting from inborn errors of metabolism; and (3) exogenous products, such as environmental agents and pigments that cannot be broken down by the cell.² These substances may accumulate transiently or permanently, and they may be harmless or, in some cases, may be toxic.

The accumulation of normal cellular constituents occurs when a substance is produced at a rate that exceeds its metabolism or removal. An example of this type of process is fatty changes in the liver caused by intracellular accumulation of triglycerides. Liver cells normally contain some fat, which is either oxidized and used for energy or converted to triglycerides. This fat is derived from free fatty acids released from adipose tissue. Abnormal accumulation occurs when the delivery of free fatty acids to the liver is increased, as in starvation and diabetes mellitus, or when the intrahepatic metabolism of lipids is disturbed, as in alcoholism.

Intracellular accumulation can result from genetic disorders that disrupt the metabolism of selected substances. A normal enzyme may be replaced with an abnormal one, resulting in the formation of a substance that cannot be used or eliminated from the cell, or an enzyme may be missing, so that an intermediate product accumulates in the cell. For example, there are at least 10 genetic disorders that affect glycogen metabolism, most of which lead to the accumulation of intracellular glycogen stores. In the most common form of this disorder, von Gierke's disease, large amounts of glycogen accumulate in the liver and kidneys because of a deficiency of the enzyme glucose-6-phosphatase. Without this enzyme, glycogen cannot be broken down to form glucose. The disorder leads not only to an accumulation of glycogen but to a reduction in blood glucose levels. In Tay-Sachs disease, another genetic disorder, abnormal glycolipids accumulate in the brain and other tissues, causing motor and mental deterioration beginning at approximately 6 months of age, followed by death at 2 to 3 years of age. In a similar manner, other enzyme defects lead to the accumulation of other substances.

Pigments are colored substances that may accumulate in cells. They can be endogenous (*i.e.*, arising from within the body) or exogenous (*i.e.*, arising from outside the body). Icterus, also called *jaundice*, is a yellow discoloration of tissue caused by the retention of bilirubin, an endogenous bile pigment. This condition may result from increased bilirubin production from red blood cell destruction, obstruction of bile passage into the intestine, or toxic diseases that affect the liver's ability to remove bilirubin from the blood. Lipofuscin is a yellow-brown pigment that results from the accumulation of the indigestible residues produced during normal turnover of cell structures (Fig. 2-3). The accumulation of lipofuscin increases with age and is sometimes referred to as the *wear-and-tear pig*-

■ FIGURE 2-3 ■ Accumulation of intracellular lipofuscin. A photomicrograph of the liver of an 80-year-old man shows golden cytoplasmic granules, which represent lysosomal storage of lipofuscin. (From Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 13]. Philadelphia: Lippincott Williams & Wilkins)

ment. It is more common in heart, nerve, and liver cells than other tissues and is seen most often in conditions associated with atrophy of an organ.

One of the most common exogenous pigments is carbon in the form of coal dust. In coal miners or persons exposed to heavily polluted environments, the accumulation of carbon dust blackens the lung tissue and may cause serious lung disease. The formation of a blue lead line along the margins of the gum is one of the diagnostic features of lead poisoning. Tattoos are the result of insoluble pigments introduced into the skin, where they are engulfed by macrophages and persist for a lifetime.

The significance of intracellular accumulations depends on the cause and severity of the condition. Many accumulations, such as lipofuscin and mild fatty change, have no effect on cell function. Some conditions, such as the hyperbilirubinemia that causes jaundice, are reversible. Other disorders, such as glycogen storage diseases, produce accumulations that result in organ dysfunction and other alterations in physiologic function.

In summary, cells adapt to changes in their environment and in their work demands by changing their size, number, and characteristics. These adaptive changes are consistent with the needs of the cell and occur in response to an appropriate stimulus. The changes are usually reversed after the stimulus has been withdrawn.

When confronted with a decrease in work demands or adverse environmental conditions, cells atrophy or reduce their size and revert to a lower and more efficient level of functioning. Hypertrophy results from an increase in work demands and is characterized by an increase in tissue size brought about by an increase in cell size and functional components in the cell. An increase in the number of cells in an organ or tissue that is still capable of mitotic division is called hyperplasia. Metaplasia occurs in response to chronic irritation and represents the substitution of cells of a type that are better able to survive under circumstances in which a more fragile cell type might succumb. Dysplasia is characterized by deranged cell growth of a specific tissue that results in cells that vary in size, shape, and appearance. It is a precursor of cancer.

Under some circumstances, cells may accumulate abnormal amounts of various substances. If the accumulation reflects a correctable systemic disorder, such as the hyperbilirubinemia that causes jaundice, the accumulation is reversible. If the disorder cannot be corrected, as often occurs in many inborn errors of metabolism, the cells become overloaded, causing cell injury and death.

CELL INJURY AND DEATH

Cells can be injured in many ways. The extent to which any injurious agent can cause cell injury and death depends in large measure on the intensity and duration of the injury and the type of cell that is involved. Cell injury is usually reversible to a certain point, after which irreversible cell injury and death occur. Whether a specific stress causes irreversible or reversible cell injury depends on the severity of the insult and on vari-

KEY CONCEPTS

CELL INJURY

- Cells can be damaged in a number of ways, including physical trauma, extremes of temperature, electrical injury, exposure to damaging chemicals, radiation damage, injury from biologic agents, and nutritional factors.
- Most injurious agents exert their damaging effects through uncontrolled free radical production, impaired oxygen delivery or utilization, or the destructive effects of uncontrolled intracellular calcium release.
- Cell injury can be reversible, allowing the cell to recover, or it can be irreversible, causing cell death and necrosis.
- In contrast to necrosis, which results from tissue injury, apoptosis is a normal physiologic process designed to remove injured or worn-out cells.

ables such as blood supply, nutritional status, and regenerative capacity. Cell injury and death are ongoing processes, and in the healthy state, they are balanced by cell renewal.

Causes of Cell Injury

Cell damage can occur in many ways. For purposes of discussion, the ways by which cells are injured have been grouped into five categories: (1) injury from physical agents, (2) radiation injury, (3) chemical injury, (4) injury from biologic agents, and (5) injury from nutritional imbalances.

Injury From Physical Agents

Physical agents responsible for cell and tissue injury include mechanical forces, extremes of temperature, and electrical forces. They are common causes of injuries due to environmental exposure, occupational and transportation accidents, and physical violence and assault.

Mechanical Forces. Injury or trauma caused by mechanical forces occurs as the result of body impact with another object. The body or the object can be in motion or, as sometimes happens, both can be in motion at the time of impact. These types of injuries split and tear tissue, fracture bones, injure blood vessels, and disrupt blood flow.

Extremes of Temperature. Extremes of heat and cold cause damage to the cell, its organelles, and its enzyme systems. Exposure to low-intensity heat (43° to 46°C), such as occurs with partial-thickness burns and severe heat stroke, causes cell injury by inducing vascular injury, accelerating cell metabolism, inactivating temperature-sensitive enzymes, and disrupting the cell membrane. With more intense heat, coagulation of blood vessels and tissue proteins occurs. Exposure to cold increases blood viscosity and induces vasoconstriction by direct

action on blood vessels and through reflex activity of the sympathetic nervous system. The resultant decrease in blood flow may lead to hypoxic tissue injury, depending on the degree and duration of cold exposure. Injury from freezing probably results from a combination of ice crystal formation and vasoconstriction. The decreased blood flow leads to capillary stasis and arteriolar and capillary thrombosis.

Electrical Injuries. Electrical injuries can affect the body through extensive tissue injury and disruption of neural and cardiac impulses. The effect of electricity on the body is mainly determined by its voltage, the type of current (*i.e.*, direct or alternating), its amperage, the resistance of the intervening tissue, the pathway of the current, and the duration of exposure.^{2,4}

Lightning and high-voltage wires that carry several thousand volts produce the most severe damage.² Alternating current (AC) is usually more dangerous than direct current (DC) because it causes violent muscle contractions, preventing the person from releasing the electrical source and sometimes resulting in fractures and dislocations. In electrical injuries, the body acts as a conductor of the electrical current. The current enters the body from an electrical source, such as an exposed wire, and passes through the body and exits to another conductor, such as the moisture on the ground or a piece of metal the person is holding. The pathway that a current takes is critical because the electrical energy disrupts impulses in excitable tissues. Current flow through the brain may interrupt impulses from respiratory centers in the brain stem, and current flow through the chest may cause fatal cardiac arrhythmias.

The resistance to the flow of current in electrical circuits transforms electrical energy into heat. This is why the elements in electrical heating devices are made of highly resistive metals. Much of the tissue damage produced by electrical injuries is caused by heat production in tissues that have the highest electrical resistance. Resistance to electrical current varies from the greatest to the least in bone, fat, tendons, skin, muscles, blood, and nerves. The most severe tissue injury usually occurs at the skin sites where the current enters and leaves the body. After electricity has penetrated the skin, it passes rapidly through the body along the lines of least resistancethrough body fluids and nerves. Degeneration of vessel walls may occur, and thrombi may form as current flows along the blood vessels. This can cause extensive muscle and deep tissue injury. Thick, dry skin is more resistant to the flow of electricity than thin, wet skin. It is generally believed that the greater the skin resistance, the greater is the amount of local skin burn, and the less the resistance, the greater are the deep and systemic effects.

Radiation Injury

Electromagnetic radiation comprises a wide spectrum of wavepropagated energy, ranging from ionizing gamma rays to radiofrequency waves. A photon is a particle of radiation energy. Radiation energy above the ultraviolet (UV) range is called *ionizing radiation* because the photons have enough energy to knock electrons off atoms and molecules. *Nonionizing radiation* refers to radiation energy at frequencies below that of visible light. *UV radiation* represents the portion of the spectrum of electromagnetic radiation just above the visible range. It contains increasingly energetic rays that are powerful enough to disrupt intracellular bonds and cause sunburn. *lonizing Radiation.* Ionizing radiation affects cells by causing ionization of molecules and atoms in the cell, by directly hitting the target molecules in the cell, or by producing free radicals that interact with critical cell components.^{1,2,5} It can immediately kill cells, interrupt cell replication, or cause a variety of genetic mutations, which may or may not be lethal. Most radiation injury is caused by localized irradiation that is used in treatment of cancer (see Chapter 5). Except for unusual circumstances, such as the use of high-dose irradiation that precedes bone marrow transplantation, exposure to whole-body irradiation is rare.

The injurious effects of ionizing radiation vary with the dose, dose rate (a single dose can cause greater injury than divided or fractionated doses), and the differential sensitivity of the exposed tissue to radiation injury. Because of the effect on deoxyribonucleic acid (DNA) synthesis and interference with mitosis, rapidly dividing cells of the bone marrow and intestine are much more vulnerable to radiation injury than are tissues such as bone and skeletal muscle. Over time, occupational and accidental exposure to ionizing radiation can result in increased risk for the development of various types of cancers, including skin cancers, leukemia, osteogenic sarcomas, and lung cancer.

Many of the manifestations of radiation therapy result from acute cell injury, dose-dependent changes in the blood vessels that supply the irradiated tissues, and fibrotic tissue replacement. The cell's initial response to radiation injury involves swelling, disruption of the mitochondria and other organelles, alterations in the cell membrane, and marked changes in the nucleus. The endothelial cells in blood vessels are particularly sensitive to irradiation. During the immediate postirradiation period, only vessel dilatation takes place (e.g., the initial erythema of the skin after radiation therapy). Later or with higher levels of radiation, destructive changes occur in small blood vessels such as the capillaries and venules. Acute reversible necrosis is represented by such disorders as radiation cystitis, dermatitis, and diarrhea from enteritis. More persistent damage can be attributed to acute necrosis of tissue cells that are not capable of regeneration and chronic ischemia. Chronic effects of radiation damage are characterized by fibrosis and scarring of tissues and organs in the irradiated area (e.g., interstitial fibrosis of the heart and lungs after irradiation of the chest). Because the radiation delivered in radiation therapy inevitably travels through the skin, radiation dermatitis is common. There may be necrosis of the skin, impaired wound healing, and chronic radiation dermatitis.

Ultraviolet Radiation. Ultraviolet radiation causes sunburn and increases the risk of skin cancers (see Chapter 44). The degree of risk depends on the type of UV rays, the intensity of exposure, and the amount of protective melanin pigment in the skin. Skin damage induced by UV radiation is believed to be caused by reactive oxygen species and by damage to melanin-producing processes in the skin. UV radiation also damages DNA, resulting in the formation of pyrimidine dimers (*i.e.*, the insertion of two identical pyrimidine bases into replicating DNA instead of one). Other forms of DNA damage include the production of single-stranded breaks and formation of DNA-protein cross-links. Normally, errors that occur during DNA replication are repaired by enzymes that remove the faulty section of DNA and repair the damage. The importance of the DNA repair in protecting against UV radiation injury is

evidenced by the vulnerability of persons who lack the enzymes needed to repair UV-induced DNA damage. In a genetic disorder called *xeroderma pigmentosum*, an enzyme needed to repair sunlight-induced DNA damage is lacking. This autosomal recessive disorder is characterized by extreme photosensitivity and a greatly increased risk of skin cancer in sunexposed skin.²

Nonionizing Radiation. Nonionizing radiation includes infrared light, ultrasound, microwaves, and laser energy. Unlike ionizing radiation, which can directly break chemical bonds, nonionizing radiation exerts its effects by causing vibration and rotation of atoms and molecules. All of this vibrational and rotational energy is eventually converted to thermal energy. Lowfrequency nonionizing radiation is used widely in radar, television, industrial operations (e.g., heating, welding, melting of metals, processing of wood and plastic), household appliances (e.g., microwave ovens), and medical applications (e.g., diathermy). Isolated cases of skin burns and thermal injury to deeper tissues have occurred in industrial settings and from improperly used household microwave ovens. Injury from these sources is mainly thermal and, because of the deep penetration of the infrared or microwave rays, tends to involve dermal and subcutaneous tissue injury.

Chemical Injury

Chemicals capable of damaging cells are everywhere around us. Air and water pollution contain chemicals capable of tissue injury, as do tobacco smoke and some processed or preserved foods. Some of the most damaging chemicals exist in our environment, including gases such as carbon monoxide, insecticides, and trace metals such as lead.

Lead is a particularly toxic metal. Small amounts accumulate to reach toxic levels.⁶ There are innumerable sources of lead in the environment, including flaking paint, lead-contaminated dust and soil, lead-contaminated root vegetables, lead water pipes or soldered joints, pottery glazes, and newsprint. Children are exposed to lead through ingestion of peeling lead paint, by breathing dust from lead paint (e.g., during remodeling), or from playing in contaminated soil.⁷ Lead crosses the placenta, exposing the fetus to lead levels comparable to those of the mother. The toxicity of lead is related to its multiple biochemical effects.² It has the ability to inactivate enzymes, compete with calcium for incorporation into bone, and interfere with nerve transmission and brain development. The major targets are the red blood cells, the gastrointestinal tract, the kidneys, and the nervous system. Some of the manifestations of lead toxicity include anemia, acute abdominal pain, signs of kidney damage, and cognitive deficits and neuropathies resulting from demyelination of cerebral and cerebellar white matter and death of cortical nerve cells.

Chemical agents can injure the cell membrane and other cell structures, block enzymatic pathways, coagulate cell proteins, and disrupt the osmotic and ionic balance of the cell. Corrosive substances such as strong acids and bases destroy cells as the substances come into contact with the body. Other chemicals may injure cells in the process of metabolism or elimination. For example, carbon tetrachloride (CCl_4) causes little damage until it is metabolized by liver enzymes to a highly reactive free radical (CCl_3). Carbon tetrachloride is extremely toxic to liver cells.

Drugs. Many drugs—alcohol, prescription drugs, over-thecounter drugs, and street drugs—are capable of directly or indirectly damaging tissues. Ethyl alcohol can harm the gastric mucosa, liver (see Chapter 28), developing fetus (see Chapter 4), and other organs. Antineoplastic (anticancer) and immunosuppressant drugs can directly injure cells. Other drugs produce metabolic end-products that are toxic to cells. Acetaminophen, a commonly used analgesic drug, is detoxified in the liver, where small amounts of the drug are converted to a highly toxic metabolite. This metabolite is detoxified by a metabolic pathway that uses a substance (*i.e.*, glutathione) normally present in the liver. When large amounts of the drug are ingested, this pathway becomes overwhelmed and toxic metabolites accumulate, causing massive liver necrosis.

Injury From Biologic Agents

Biologic agents differ from other injurious agents in that they are able to replicate and can continue to produce their injurious effects. These agents range from submicroscopic viruses to the larger parasites. Biologic agents injure cells by diverse mechanisms. Viruses enter the cell and become incorporated into its DNA synthetic machinery. Certain bacteria elaborate exotoxins that interfere with cellular production of ATP. Other bacteria, such as the gram-negative bacilli, release endotoxins that cause cell injury and increased capillary permeability.

Injury From Nutritional Imbalances

Nutritional excesses and nutritional deficiencies predispose cells to injury. Obesity and diets high in saturated fats are thought to predispose persons to atherosclerosis. The body requires more than 60 organic and inorganic substances in amounts ranging from micrograms to grams. These nutrients include minerals, vitamins, certain fatty acids, and specific amino acids. Dietary deficiencies can occur in the form of starvation, in which there is a deficiency of all nutrients and vitamins, or because of a selective deficiency of a single nutrient or vitamin. Iron-deficiency anemia, scurvy, beriberi, and pellagra are examples of injury caused by the lack of specific vitamins or minerals. The protein and calorie deficiencies that occur with starvation cause widespread tissue damage.

Mechanisms of Cell Injury

The mechanisms by which injurious agents cause cell injury and death are complex. Some agents, such as heat, produce direct cell injury; other factors, such as genetic derangement, produce their effects indirectly through metabolic disturbances and altered immune responses. There seem to be at least three major mechanisms whereby most injurious agents exert their effects: free radical formation, hypoxia and ATP depletion, and disruption of intracellular calcium homeostasis.

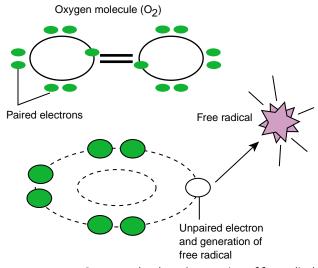

Free Radical Injury

Many injurious agents exert their damaging effects through a reactive chemical species called a *free radical*.^{2,8-10} Free radical injury is rapidly emerging as a final common pathway for tissue damage by many injurious agents.

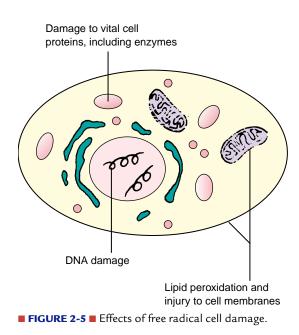

In most atoms, the outer electron orbits are filled with paired electrons moving in opposite directions to balance their spins. A free radical is a highly reactive chemical species arising from an atom that has a single unpaired electron in an outer orbit (Fig. 2-4). In this state, the radical is highly unstable and can enter into reactions with cellular constituents, particularly key molecules in cell membranes and nucleic acids. Moreover, free radicals can establish chain reactions, sometimes thousands of events long, as the molecules they react with in turn form free radicals. Chain reactions may branch, causing even greater damage. Uncontrolled free radical production causes damage to cell membranes, cross-linking of cell proteins, inactivation of enzyme systems, or damage to the nucleic acids that make up DNA.

Free radical formation is a by-product of many normal cellular reactions in the body, including energy generation, breakdown of lipids and proteins, and inflammatory processes. For example, free radical generation is the main mechanism for killing microbes in phagocytic white blood cells. Molecular oxygen (O_2), with its two unpaired outer electrons, is the most common source of free radicals. During the course of normal cell metabolism, cells process energy-producing oxygen into water; in some reactions, a superoxide radical is formed. Lipid oxidation (*i.e.*, peroxidation) is another source of free radicals. Exogenous sources of free radicals include tobacco smoke, certain pollutants and organic solvents, hyperoxic environments, pesticides, and radiation. Some of these compounds and certain medications are metabolized to free radical intermediates that cause oxidative damage to target tissues.

Although the effects of these reactive free radicals are wide ranging, three types of effects are particularly important in cell injury: lipid peroxidation, oxidative modification of proteins, and DNA effects (Fig. 2-5). Destruction of the phospholipids in cell membranes, including the outer plasma membrane and those of the intracellular organelles, results in loss of membrane integrity. Free radical attack on cell proteins, particularly those of critical enzymes, can interrupt vital processes throughout the cell. DNA is an important target of the hydroxyl free radical. Damage can involve single-stranded breaks in DNA, modification of base pairs, and cross-links between strands. In most cases, various DNA repair pathways can repair the damage. However, if the damage is extensive, the cell dies. The effects of free radical-mediated DNA changes have also been implicated in aging and malignant transformation of cells.

■ FIGURE 2-4 ■ Oxygen molecule and generation of free radical.

Under normal conditions, most cells have chemical mechanisms that protect them from the injurious effects of free radicals. These mechanisms commonly break down when the cell is deprived of oxygen or exposed to certain chemical agents, radiation, or other injurious agents. Free radical formation is a particular threat to tissues in which the blood flow has been interrupted and then restored. During the period of interrupted flow, the intracellular mechanisms that control free radicals are inactivated or damaged. When blood flow is restored, the cell is suddenly confronted with an excess of free radicals that it cannot control.

Scientists continue to investigate the use of free radical scavengers to protect against cell injury during periods when protective cellular mechanisms are impaired. Defenses against free radicals include vitamin E, vitamin C, and β -carotene.¹¹ Vitamin E is the major lipid-soluble antioxidant present in all cellular membranes. Vitamin C is an important water-soluble cytosolic chain-breaking antioxidant; it acts directly with superoxide and singlet oxygen radicals. β -carotene, a pigment found in most plants, reacts with singlet oxygen and can also function as an antioxidant.

Hypoxic Cell Injury

Hypoxia deprives the cell of oxygen and interrupts oxidative metabolism and the generation of ATP. The actual time necessary to produce irreversible cell damage depends on the degree of oxygen deprivation and the metabolic needs of the cell. Well-differentiated cells, such as those in the heart, brain, and kidneys, require large amounts of oxygen to provide energy for their special functions. For example, brain cells begin to undergo permanent damage after 4 to 6 minutes of oxygen deprivation. A thin margin can exist between the time involved in reversible and irreversible cell damage. One study found that the epithelial cells of the proximal tubule of the kidney in the rat could survive 20 but not 30 minutes of ischemia.¹²

Hypoxia can result from an inadequate amount of oxygen in the air, respiratory disease, ischemia (*i.e.*, decreased blood flow caused by circulatory disorders), anemia, edema, or inability of the cells to use oxygen. Ischemia is characterized by impaired oxygen delivery and impaired removal of metabolic end-products such as lactic acid. In contrast to pure hypoxia, which affects the oxygen content of the blood and affects all of the cells in the body, ischemia commonly affects blood flow through small numbers of blood vessels and produces local tissue injury. In cases of edema, the distance for diffusion of oxygen may become a limiting factor. In hypermetabolic states, the cells may require more oxygen than can be supplied by normal respiratory function and oxygen transport. Hypoxia also serves as the ultimate cause of cell death in other injuries. For example, toxins from certain microorganisms can interfere with cellular use of oxygen, and a physical agent such as cold can cause severe vasoconstriction and impair blood flow.

Hypoxia literally causes a power failure in the cell, with widespread effects on the cell's functional and structural components. As oxygen tension in the cell falls, oxidative metabolism ceases, and the cell reverts to anaerobic metabolism, using its limited glycogen stores in an attempt to maintain vital cell functions. Cellular pH falls as lactic acid accumulates in the cell. This reduction in pH can have profound effects on intracellular structures. The nuclear chromatin clumps and myelin figures, which derive from destructive changes in cell membranes and intracellular structures, are seen in the cytoplasm and extracellular spaces.

One of the earliest effects of reduced ATP is acute cellular swelling caused by failure of the energy-dependent sodium/ potassium (Na^+/K^+) ATPase membrane pump, which extrudes sodium from and returns potassium to the cell. With impaired function of this pump, intracellular potassium levels decrease, and sodium and water accumulate in the cell. The movement of fluid and ions into the cell is associated with dilatation of the endoplasmic reticulum, increased membrane permeability, and decreased mitochondrial function.² To this point, the cellular changes caused by ischemia are reversible if oxygenation is restored. However, if the oxygen supply is not restored there is a continued loss of essential enzymes, proteins, and ribonucleic acid through the hyperpermeable membrane of the cell. Injury to the lysosomal membranes results in leakage of destructive lysosomal enzymes into the cytoplasm and enzymatic digestion of cell components. Leakage of intracellular enzymes through the permeable cell membrane into the extracellular fluid is used as an important clinical indicator of cell injury and death. These enzymes enter the blood and can be measured by laboratory tests.

Impaired Calcium Homeostasis

Calcium functions as a messenger for the release of many intracellular enzymes. Normally, intracellular calcium levels are kept extremely low compared with extracellular levels. These low intracellular levels are maintained by energy-dependent, membrane-associated calcium/magnesium (Ca²⁺/Mg²⁺) ATPase exchange systems.² Ischemia and certain toxins lead to an increase in cytosolic calcium because of increased influx across the cell membrane and the release of calcium stored in the mitochondria and endoplasmic reticulum. The increased calcium level activates a number of enzymes with potentially damaging effects. The enzymes include the phospholipases responsible for damaging the cell membrane, proteases that damage the cytoskeleton and membrane proteins, ATPases that break down ATP and hasten its depletion, and endonucleases that fragment chromatin.

Reversible Cell Injury and Cell Death

The mechanisms of cell injury can produce sublethal and reversible cellular damage or lead to irreversible injury with cell destruction or death (Fig. 2-6). Cell destruction and removal can involve one of two mechanisms: apoptosis, which is designed to remove injured or worn-out cells, or cell death and necrosis, which occurs in irreversibly damaged cells.

Reversible Cell Injury

Reversible cell injury, although impairing cell function, does not result in cell death. Two patterns of reversible cell injury can be observed under the microscope: cellular swelling and fatty change. Cellular swelling occurs with impairment of the energy-dependent Na⁺/K⁺ ATPase membrane pump, usually as the result of hypoxic cell injury.

Fatty changes are linked to intracellular accumulation of fat. When fatty changes occur, small vacuoles of fat disperse throughout the cytoplasm. The process is usually more ominous than cellular swelling, and although it is reversible, it usually indicates severe injury. These fatty changes may occur because normal cells are presented with an increased fat load or because injured cells are unable to metabolize the fat properly. In obese persons, fatty infiltrates often occur within and between the cells of the liver and heart because of an increased fat load. Pathways for fat metabolism may be impaired during cell injury, and fat may accumulate in the cell as production exceeds use and export. The liver, where most fats are synthesized and metabolized, is particularly susceptible to fatty change, but fatty changes may also occur in the kidney, the heart, and other organs.

Cell Death

In each cell line, the control of cell number is regulated by a balance of cell proliferation and cell death. Cell death can involve apoptosis or necrosis. Apoptotic cell death involves controlled cell destruction and is involved in normal cell deletion and renewal. For example, blood cells that undergo constant renewal from progenitor cells in the bone marrow are removed by apoptotic cell death. Necrotic cell death is a pathologic form of cell death resulting from cell injury. It is characterized by cell swelling, rupture of the cell membrane, and inflammation.

Apoptosis. Apoptosis, from Greek *apo* for "apart" and *ptosis* for "fallen," means fallen apart. Apoptotic cell death, which is equated with cell suicide, eliminates cells that are worn out, have been produced in excess, have developed improperly, or have genetic damage. In normal cell turnover, this process provides the space needed for cell replacement. The process, which was first described in 1972, has become one of the most vigorously investigated processes in biology.¹³ Apoptosis is thought to be involved in several physiologic and pathologic processes. Current research is focusing on the genetic control mechanisms of apoptosis in an attempt to understand the pathogenesis of many disease states such as cancer and autoimmune disease.

Apoptotic cell death is characterized by controlled autodigestion of cell components. Cells appear to initiate their own death through the activation of endogenous enzymes. This results in cell shrinkage brought about by disruption of the cytoskeleton, condensation of the cytoplasmic organelles, disruption and clumping of nuclear DNA, and a distinctive wrinkling of the cell membrane.² As the cell shrinks, the nucleus breaks into spheres, and the cell eventually divides into membranecovered fragments. During the process, membrane changes occur, signaling surrounding phagocytic cells to engulf the cell fragments and complete the degradation process (Fig. 2-7).

Apoptosis is thought to be responsible for several normal physiologic processes, including programmed destruction of cells during embryonic development, hormone-dependent involution of tissues, death of immune cells, cell death by cytotoxic T cells, and cell death in proliferating cell populations. During embryogenesis, in the development of a number of organs such as the heart, which begins as a single pulsating tube and is gradually modified to become a four-chambered pump, apoptotic cell death allows the next stage of organ development. It also separates the webbed fingers and toes of the developing embryo (Fig. 2-8). The control of immune cell numbers and destruction of autoreactive T cells in the thymus have been credited to apoptosis. Cytotoxic T cells and natural killer cells are thought to destroy target cells by inducing apop-

■ FIGURE 2-7 ■ Apoptotic cell removal: (A) shrinking of the cell structures, (B and C) condensation and fragmentation of the nuclear chromatin, (D and E) separation of nuclear fragments and cytoplasmic organelles into apoptotic bodies, and (F) engulfment of apoptotic fragments by phagocytic cell.

totic cell death. Apoptotic cell death occurs in the hormonedependent involution of endometrial cells during the menstrual cycle and in the regression of breast tissue after weaning from breast-feeding.

Apoptosis appears to be linked to several pathologic processes. For example, suppression of apoptosis may be a determinant in the growth of cancers. Apoptosis is also thought to be involved in the cell death associated with certain viral infections, such as hepatitis B and C, and in cell death caused by a variety of injurious agents, such as mild thermal injury and radiation injury. Apoptosis may also be involved in neurodegenerative disorders such as Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis (ALS). The loss of cells in these disorders does not induce inflammation; although the initiating event is unknown, apoptosis appears to be the mechanism of cell death.¹⁴

Several mechanisms appear to be involved in initiating cell death by apoptosis. As in the case of endometrial changes that occur during the menstrual cycle, the process can be triggered by the addition or withdrawal of hormones. In hepatitis B and C, the virus seems to sensitize the hepatocytes to apoptosis.¹⁵ Certain oncogenes and suppressor genes involved in the development of cancer seem to play an active role in stimulation or suppression of apoptosis. Injured cells may induce apoptotic cell death through increased cytoplasmic calcium, which leads to activation of nuclear enzymes that break down DNA. In some instances, gene transcription and protein synthesis, the events that produce new cells, may be the initiating factors. In other cases, cell surface signaling or receptor activation appears to be the influencing force.

Necrosis. Necrosis refers to cell death in an organ or tissue that is still part of a living person.² Necrosis differs from apoptosis in that it involves unregulated enzymatic digestion of cell components, loss of cell membrane integrity with uncontrolled release of the products of cell death into the intracellular space, and initiation of the inflammatory response. In contrast to apoptosis, which functions in removing cells so they can be replaced by new cells, necrosis often interferes with cell replacement and tissue regeneration.

With necrotic cell death, there are marked changes in the appearance of the cytoplasmic contents and the nucleus. These changes often are not visible, even under the microscope, for hours after cell death. The dissolution of the necrotic cell or

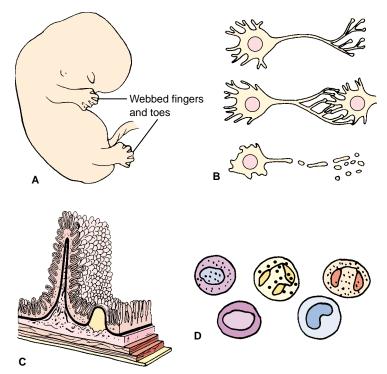

FIGURE 2-8 Examples of apoptosis: (A) separation of webbed fingers and toes in embryo, (B) development of neural connections, (C) removal of cells from intestinal villa, and (D) removal of senescent blood cells.

tissue can follow several paths. The cell can undergo liquefaction (*i.e.*, liquefaction necrosis); it can be transformed to a gray, firm mass (*i.e.*, coagulation necrosis); or it can be converted to a cheesy material by infiltration of fatlike substances (i.e., caseous necrosis). Liquefaction necrosis occurs when some of the cells die but their catalytic enzymes are not destroyed. An example of liquefaction necrosis is the softening of the center of an abscess with discharge of its contents. During coagulation necrosis, acidosis develops and denatures the enzymatic and structural proteins of the cell. This type of necrosis is characteristic of hypoxic injury and is seen in infarcted areas. Infarction (i.e., tissue death) occurs when an artery supplying an organ or part of the body becomes occluded and no other source of blood supply exists. As a rule, the infarct's shape is conical and corresponds to the distribution of the artery and its branches. An artery may be occluded by an embolus, a thrombus, disease of the arterial wall, or pressure from outside the vessel. Caseous necrosis (*i.e.*, soft, cheeselike center) is a distinctive form of coagulation necrosis. It is most commonly associated with tubercular lesions and is thought to result from immune mechanisms.

Gangrene. The term *gangrene* is applied when a considerable mass of tissue undergoes necrosis. Gangrene may be classified as dry or moist. In dry gangrene, the part becomes dry and shrinks, the skin wrinkles, and its color changes to dark brown or black. The spread of dry gangrene is slow, and its symptoms are not as marked as those of wet gangrene. The irritation caused by the dead tissue produces a line of inflammatory reaction (*i.e.*, line of demarcation) between the dead tissue of the gangrenous area and the healthy tissue (Fig. 2-9). Dry gangrene usually results from interference with arterial blood supply to a part without interference with venous return and is a form of coagulation necrosis.

In moist or wet gangrene, the area is cold, swollen, and pulseless. The skin is moist, black, and under tension. Blebs form on the surface, liquefaction occurs, and a foul odor is caused by bacterial action. There is no line of demarcation between the normal and diseased tissues, and the spread of tissue damage is rapid. Systemic symptoms are usually severe, and death may occur unless the condition can be arrested. Moist or

FIGURE 2-9 Gangrenous toes. (Biomedical Communications Group, Southern Illinois University School of Medicine, Springfield, IL)

wet gangrene primarily results from interference with venous return from the part. Bacterial invasion plays an important role in the development of wet gangrene and is responsible for many of its prominent symptoms. Dry gangrene is confined almost exclusively to the extremities, but moist gangrene may affect the internal organs or the extremities. If bacteria invade the necrotic tissue, dry gangrene may be converted to wet gangrene.

Gas gangrene is a special type of gangrene that results from infection of devitalized tissues by one of several *Clostridium* bacteria. These anaerobic and spore-forming organisms are widespread in nature, particularly in soil; gas gangrene is prone to occur in trauma and compound fractures in which dirt and debris are embedded. Some species have been isolated in the stomach, gallbladder, intestine, vagina, and skin of healthy persons. The bacteria produce toxins that dissolve the cell membranes, causing death of muscle cells, massive spreading edema, hemolysis of red blood cells, hemolytic anemia, hemo-globinuria, and renal toxicity.¹⁶ Characteristic of this disorder are the bubbles of hydrogen sulfide gas that form in the muscle. Gas gangrene is a serious and potentially fatal disease. Because the organism is anaerobic, oxygen is sometimes administered in a hyperbaric chamber.

In summary, cell injury can be caused by a number of agents, including physical agents, chemicals, radiation, and biologic agents. Among the physical agents that generate cell injury are mechanical forces that produce tissue trauma, extremes of temperature, electricity, radiation, and nutritional disorders. Chemical agents can cause cell injury through several mechanisms: they can block enzymatic pathways, cause coagulation of tissues, or disrupt the osmotic or ionic balance of the cell. Ionizing radiation affects cells by causing ionization of molecules and atoms in the cell, by directly hitting the target molecules in the cell, or by producing free radicals that interact with critical cell components. Biologic agents differ from other injurious agents in that they are able to replicate and continue to produce injury. Among the nutritional factors that contribute to cell injury are excesses and deficiencies of nutrients, vitamins, and minerals.

Injurious agents exert their effects largely through generation of free radicals, production of cell hypoxia, or unregulated intracellular calcium levels. Partially reduced oxygen species called *free radicals* are important mediators of cell injury in many pathologic conditions. They are an important cause of cell injury in hypoxia and after exposure to radiation and certain chemical agents. Lack of oxygen underlies the pathogenesis of cell injury in hypoxia and ischemia. Hypoxia can result from inadequate oxygen in the air, cardiorespiratory disease, anemia, or the inability of the cells to use oxygen. Increased intracellular calcium activates a number of enzymes with potentially damaging effects.

Injurious agents may produce sublethal and reversible cellular damage or may lead to irreversible cell injury and death. Cell death can involve two mechanisms: apoptosis or necrosis. Apoptosis involves controlled cell destruction and is the means by which the body removes and replaces cells that have been produced in excess, developed improperly, have genetic damage, or are worn out. Necrosis refers to cell death that is characterized by cell swelling, rupture of the cell membrane, and inflammation.

Chapter 2: Tissue Adaptation and Injury

Explain how cell changes that occur with atrophy, hypertrophy, hyperplasia, metaplasia, and dysplasia are adaptive in nature.

Describe the mechanisms whereby physical agents such as blunt trauma, electrical forces, extremes of temperature, and ionizing and nonionizing radiation produce cell injury.

Explain how the injurious effects of biologic agents differ from those produced by physical and chemical agents.

Define *free radical* and relate free radical formation to cell injury and death.

Explain the rationale for the different outcomes in brain tissues of someone who is hypoxic because of severe anemia and someone with an ischemic stroke.

Differentiate cell death associated with necrosis and apoptosis.

Cite the reasons for the changes that occur with the wet and dry forms of gangrene.

enetic information is stored in the structure of *deoxyribonucleic acid* (DNA). DNA is an extremely stable macromolecule found in the nucleus of each cell. Because of the stable structure of DNA, the genetic information can survive the many processes of reduction division, in which the gametes (*i.e.*, ovum and sperm) are formed, and the fertilization process. This stability is also maintained throughout the many mitotic cell divisions involved in the formation of a new organism from the single-celled fertilized ovum called the *zygote*. The term *gene* is used to describe a part of the DNA molecule that contains the information needed to code for the types of proteins and enzymes needed for the day-to-day function of the cells in the body. In addition, a gene is the unit of heredity passed from generation to generation. For example, genes control the type and quantity of hormones that a cell produces, the antigens and receptors that are present on the cell membrane, and the synthesis of enzymes needed for metabolism. Of the estimated 35,000 to 140,000 genes that humans possess, more than 5000 have been identified and more than 2300 have been localized to a particular chromosome. With few exceptions, each gene provides the instructions for the synthesis of a single protein. This chapter includes discussions of genetic regulation of cell function, chromosomal structure, patterns of inheritance, and gene technology.

GENETIC CONTROL OF CELL FUNCTION

The genetic information needed for protein synthesis is encoded in the DNA contained in the cell nucleus. A second type of nucleic acid, *ribonucleic acid* (RNA), is involved in the actual synthesis of cellular enzymes and proteins. Cells contain several types of RNA: messenger RNA, transfer RNA, and ribosomal RNA. *Messenger RNA* (mRNA) contains the transcribed instructions for protein synthesis obtained from the DNA molecule and carries them into the cytoplasm. Transcription is followed by translation, the synthesis of proteins according to the instructions carried by mRNA. *Ribosomal RNA* (rRNA) provides the machinery needed for protein synthesis. *Transfer RNA* (tRNA) reads the instructions and delivers the appropriate amino acids to the ribosome, where they are incorporated into the protein being synthesized.

The mechanism for genetic control of cell function is illustrated in Figure 3-1. The nuclei of all the cells in an organism contain the same accumulation of genes derived from the gametes of the two parents. This means that liver cells contain the same genetic information as skin and muscle cells. For this to be true, the molecular code must be duplicated before each succeeding cell division, or mitosis. In theory, although this has not yet been achieved in humans, any of the highly differentiated cells of an organism could be used to produce a complete, genetically identical organism, or *clone*. Each particular cell type

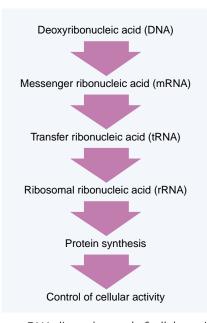

KEY CONCEPTS

FUNCTION OF DNA IN CONTROLLING CELL FUNCTION

- The information needed for the control of cell structure and function is embedded in the genetic information encoded in the stable DNA molecule.
- Although every cell in the body contains the same genetic information, each cell type uses only a portion of the information, depending on its structure and function.
- The production of the proteins that control cell function is accomplished by (1) the transcription of the DNA code for assembly of the protein onto messenger RNA, (2) the translation of the code from messenger RNA and assembly of the protein by ribosomal RNA in the cytoplasm, and (3) the delivery of the amino acids needed for protein synthesis to ribosomal RNA by transfer RNA.

in a tissue uses only part of the information stored in the genetic code. Although information required for the development and differentiation of the other cell types is still present, it is repressed.

Besides nuclear DNA, part of the DNA of a cell resides in the mitochondria. Mitochondrial DNA is inherited from the mother by her offspring (*i.e.*, matrilineal inheritance). Several

■ FIGURE 3-1 ■ DNA-directed control of cellular activity through synthesis of cellular proteins. Messenger RNA carries the transcribed message, which directs protein synthesis, from the nucleus to the cytoplasm. Transfer RNA selects the appropriate amino acids and carries them to ribosomal RNA where assembly of the proteins takes place.

genetic disorders are attributed to defects in mitochondrial DNA. Leber's hereditary optic neuropathy was the first human disease attributed to mutation in mitochondrial DNA.

Gene Structure

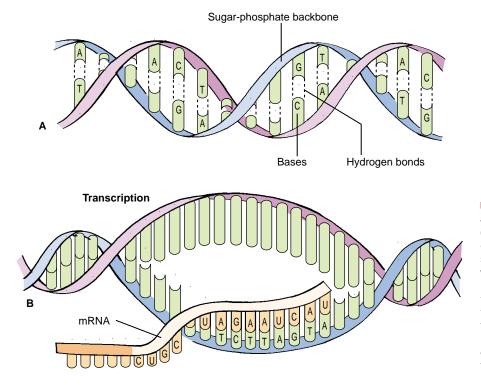

The structure that stores the genetic information in the nucleus is a long, double-stranded, helical molecule of DNA. DNA is composed of nucleotides, which consist of phosphoric acid, a five-carbon sugar called *deoxyribose*, and one of four nitrogenous bases. These nitrogenous bases carry the genetic information and are divided into two groups: the purine bases, adenine and guanine, which have two nitrogen ring structures, and the pyrimidine bases, thymine and cytosine, which have one ring. The backbone of DNA consists of alternating groups of sugar and phosphoric acid; the paired bases project inward from the sides of the sugar molecule. DNA resembles a spiral staircase, with the paired bases representing the steps (Fig. 3-2). A precise complementary pairing of purine and pyrimidine bases occurs in the double-stranded DNA molecule. Adenine is paired with thymine, and guanine is paired with cytosine. Each nucleotide in a pair is on one strand of the DNA molecule, with the bases on opposite DNA strands bound together by hydrogen bonds that are extremely stable under normal conditions. Enzymes called DNA helicases separate the two strands so that the genetic information can be duplicated or transcribed.

Several hundred to almost one million base pairs can represent a gene; the size is proportional to the protein product it encodes. Of the two DNA strands, only one is used in transcribing the information for the cell's polypeptide-building machinery. The genetic information of one strand is meaningful and is used as a template for transcription; the complementary code of the other strand does not make sense and is ignored. However, both strands are involved in DNA duplication. Before cell division, the two strands of the helix separate and a complementary molecule is duplicated next to each original strand. Two strands become four strands. During cell division, the newly duplicated double-stranded molecules are separated and placed in each daughter cell by the mechanics of mitosis. As a result, each of the daughter cells again contains the meaningful strand and the complementary strand joined in the form of a double helix. This type of DNA replication has been termed semiconservative as opposed to conservative (Fig. 3-3).

The DNA molecule is combined with several types of protein and small amounts of RNA into a complex known as *chromatin*. Chromatin is the readily stainable portion of the cell nucleus. Some DNA proteins form binding sites for repressor molecules and hormones that regulate genetic transcription; others may block genetic transcription by preventing access of nucleotides to the surface of the DNA molecule. A specific group of proteins called *histones* are thought to control the folding of the DNA strands.

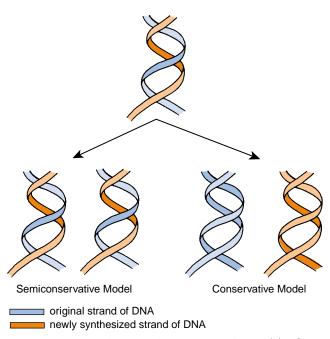

Genetic Code

The four bases—guanine, adenine, cytosine, and thymine (uracil is substituted for thymine in RNA)—make up the alphabet of the genetic code. A sequence of three of these bases forms the fundamental triplet code used in transmitting the genetic information needed for protein synthesis. This triplet code is called

■ FIGURE 3-2 ■ The DNA double helix and transcription of messenger RNA (mRNA). The top panel (**A**) shows the sequence of four bases (adenine [A], cytosine [C], guanine [G], and thymine [T]), which determines the specificity of genetic information. The bases face inward from the sugar-phosphate backbone and form pairs (*dashed lines*) with complementary bases on the opposing strand. In the bottom panel (**B**), transcription creates a complementary mRNA copy from one of the DNA strands in the double helix.

a *codon* (Table 3-1). An example is the nucleotide sequence GCU (guanine, cytosine, and uracil), which is the triplet RNA code for the amino acid alanine. The genetic code is a universal language used by most living cells (*i.e.*, the code for the amino acid tryptophan is the same in a bacterium, a plant, and

■ FIGURE 3-3 ■ Semiconservative vs conservative models of DNA replication as proposed by Meselson and Stahl in 1958. In semiconservative DNA replication, the two original strands of DNA unwind and a complementary strand is formed along each original strand.

a human being). *Stop codes*, which signal the end of a protein molecule, are also present. Mathematically, the four bases can be arranged in 64 different combinations. Sixty-one of the triplets correspond to particular amino acids, and three are stop signals. Only 20 amino acids are used in protein synthesis in humans. Several triplets code for the same amino acid; therefore, the genetic code is said to be redundant or *degenerate*. For example, AUG is a part of the initiation or start signal and the codon for the amino acid methionine. Codons that specify the same amino acid are called *synonyms*. Synonyms usually have the same first two bases but differ in the third base.

Protein Synthesis

Although DNA determines the type of biochemical product that the cell synthesizes, the transmission and decoding of information needed for protein synthesis are carried out by RNA, the formation of which is directed by DNA. The general structure of RNA differs from DNA in three respects: RNA is a single-stranded, rather than a double-stranded, molecule; the sugar in each nucleotide of RNA is ribose, instead of deoxyribose; and the pyrimidine base thymine in DNA is replaced by uracil in RNA. Three types of RNA are known: mRNA, tRNA, and rRNA. All three types are synthesized in the nucleus by RNA polymerase enzymes that take directions from DNA. Because the ribose sugars found in RNA are more susceptible to degradation than the sugars in DNA, the types of RNA molecules in the cytoplasm can be altered rapidly in response to extracellular signals.

Messenger RNA

Messenger RNA is the template for protein synthesis. It is a long molecule containing several hundred to several thousand nucleotides. Each group of three nucleotides forms a codon that

is exactly complementary to the triplet of nucleotides of the DNA molecule. Messenger RNA is formed by a process called *transcription*, in which the weak hydrogen bonds of the DNA are broken so that free RNA nucleotides can pair with their exposed DNA counterparts on the meaningful strand of the DNA molecule (see Fig. 3-2). As with the base pairing of the DNA strands, complementary RNA bases pair with the DNA bases. In RNA, uracil replaces thymine and pairs with adenine.

During transcription, a specialized nuclear enzyme, called RNA polymerase, recognizes the beginning or start sequence of a gene. The RNA polymerase attaches to the double-stranded DNA and proceeds to copy the meaningful strand into a single strand of RNA as it travels along the length of the gene. On reaching the stop signal, the enzyme leaves the gene and releases the RNA strand. The RNA strand then is processed. Processing involves the addition of certain nucleic acids at the ends of the RNA strand and cutting and splicing of certain internal sequences. Splicing often involves the removal of stretches of RNA. Because of the splicing process, the final mRNA sequence is different from the original DNA template. RNA sequences that are retained are called *exons*, and those excised are called introns. The functions of the introns are unknown. They are thought to be involved in the activation or deactivation of genes during various stages of development.

Splicing permits a cell to produce a variety of mRNA molecules from a single gene. By varying the splicing segments of the initial mRNA, different mRNA molecules are formed. For example, in a muscle cell, the original tropomyosin mRNA is spliced in as many as 10 different ways, yielding distinctly different protein products. This permits different proteins to be expressed from a single gene and reduces how much DNA must be contained in the genome.

Transfer RNA

The clover-shaped tRNA molecule contains only 80 nucleotides, making it the smallest RNA molecule. Its function is to deliver the activated form of amino acids to protein molecules in the ribosomes. At least 20 different types of tRNA are known, each of which recognizes and binds to only one type of amino acid. Each tRNA molecule has two recognition sites: the first is complementary for the mRNA codon and the second is for the amino acid itself. Each type of tRNA carries its own specific amino acid to the ribosomes, where protein synthesis is taking place; there it recognizes the appropriate codon on the mRNA and delivers the amino acid to the newly forming protein molecule.

Ribosomal RNA

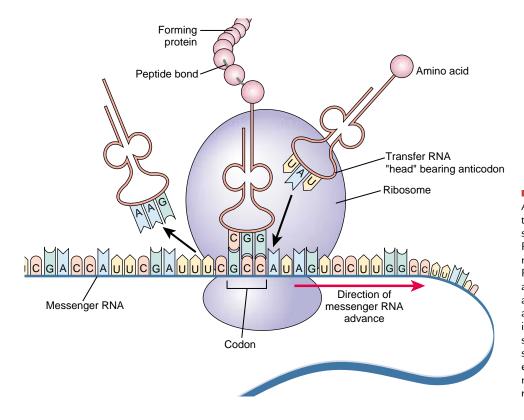

The ribosome is the physical structure in the cytoplasm where protein synthesis takes place. Ribosomal RNA forms 60% of the ribosome, with the remainder of the ribosome composed of the structural proteins and enzymes needed for protein synthesis. As with the other types of RNA, rRNA is synthesized in the nucleus. Unlike other RNAs, ribosomal RNA is produced in a specialized nuclear structure called the *nucleolus*. The formed rRNA combines with ribosomal proteins in the nucleus to produce the ribosome, which is then transported into the cytoplasm. On reaching the cytoplasm, most ribosomes become attached to the endoplasmic reticulum and begin the task of protein synthesis.

Proteins are made from a standard set of amino acids, which are joined end to end to form the long polypeptide chains of protein molecules. Each polypeptide chain may have as many as 100 to more than 300 amino acids in it. The process of protein synthesis is called *translation* because the genetic code is translated into the production language needed for protein assembly. Besides rRNA, translation requires the coordinated actions of mRNA and tRNA. Each of the 20 different tRNA molecules transports its specific amino acid to the ribosome for incorporation into the developing protein molecule. Messenger RNA provides the information needed for placing the amino acids in their proper order for each specific type of protein. During protein synthesis, mRNA contacts and passes through the ribosome, which "reads" the directions for protein synthesis in much the same way that a tape is read as it passes through a tape player (Fig. 3-4). As mRNA passes through the ribosome, tRNA delivers the appropriate amino acids for attachment to the growing polypeptide chain. The long mRNA molecule usually travels through and directs protein synthesis in more than one ribosome at a time. After the first part of the mRNA is read by the first ribosome, it moves onto a second and a third. As a result, ribosomes that are actively involved in protein synthesis are often found in clusters called *polyribosomes*.

Regulation of Gene Expression

Although all cells contain the same genes, not all genes are active all of the time, nor are the same genes active in all cell types. On the contrary, only a small, select group of genes is active in directing protein synthesis in the cell, and this group varies from one cell type to another. For the differentiation

■ FIGURE 3-4 ■ Protein synthesis. A messenger RNA strand is moving through a small ribosomal RNA subunit in the cytoplasm. Transfer RNA transports amino acids to the mRNA strand and recognizes the RNA codon calling for the amino acid by base pairing (through its anticodon). The ribosome then adds the amino acid to the growing polypeptide chain. The ribosome moves along the mRNA strand and is read sequently. As each amino acid is bound to the next by a peptide bond, its tRNA is released.

process of cells to occur in the various organs and tissues of the body, protein synthesis in some cells must be different from that in others. To adapt to an ever-changing environment, certain cells may need to produce varying amounts and types of proteins. Certain enzymes, such as carbonic anhydrase, are synthesized by all cells for the fundamental metabolic processes on which life depends.

The degree to which a gene or particular group of genes is active is called *gene expression*. A phenomenon termed *induction* is an important process by which gene expression is increased. Except in early embryonic development, induction is promoted by some external influence. *Gene repression* is a process whereby a regulatory gene acts to reduce or prevent gene expression. Some genes are normally dormant but can be activated by inducer substances; other genes are naturally active and can be inhibited by repressor substances. Genetic mechanisms for the control of protein synthesis are better understood in microorganisms than in humans. However, it can be assumed that the same general principles apply.

The mechanism that has been most extensively studied is the one by which the synthesis of particular proteins can be turned on and off. For example, in the bacterium *Escherichia coli* grown in a nutrient medium containing the disaccharide lactose, the enzyme galactosidase can be isolated. The galactosidase catalyzes the splitting of lactose into a molecule of glucose and a molecule of galactose. This is necessary if lactose is to be metabolized by *E. coli*. However, if the *E. coli* is grown in a medium that does not contain lactose, very little of the enzyme is produced. From these and other studies, it is theorized that the synthesis of a particular protein, such as galactosidase, requires a series of reactions, each of which is catalyzed by a specific enzyme. At least two types of genes control protein synthesis: *structural genes* that specify the amino acid sequence of a polypeptide chain and *regulator genes* that serve a regulatory function without stipulating the structure of protein molecules. The regulation of protein synthesis is controlled by a sequence of genes, called an *operon*, on adjacent sites on the same chromosome (Fig. 3-5). An operon consists of a set of structural genes that code for enzymes used in the synthesis of a particular product and a promoter site that binds RNA polymerase and initiates transcription of the structural genes. The function of the operon is further regulated by activator and repressor opera-

■ FIGURE 3-5 ■ Function of the operon to control biosynthesis. The synthesized product exerts negative feedback to inhibit function of the operon, in this way automatically controlling the concentration of the product itself. (Guyton A., Hall J.E. [2000]. *Textbook of medical physiology* [10th ed., p. 31]. Philadelphia: W.B. Saunders with permission from Elsevier Science)

tors, which induce or repress the function of the promoter. The activator and repressor sites commonly monitor levels of the synthesized product and regulate the activity of the operon through a negative feedback mechanism. When product levels decrease, the function of the operon is activated, and when levels increase, its function is repressed. Regulatory genes found elsewhere in the genetic complex can exert control over an operon through activator or repressor substances. Not all genes are subject to induction and repression.

Gene Mutations

Rarely, accidental errors in duplication of DNA occur. These errors are called *mutations*. Mutations result from the substitution of one base pair for another, the loss or addition of one or more base pairs, or rearrangements of base pairs. Many of these mutations occur spontaneously; others occur because of environmental agents, chemicals, and radiation. Mutations may arise in somatic cells or in germ cells (ovum or sperm). Only those DNA changes that occur in germ cells can be inherited. A somatic mutation affects a cell line that differentiates into one or more of the many tissues of the body and is not transmissible to the next generation. Somatic mutations that do not have an impact on the health or functioning of a person are called *polymorphisms*. Occasionally, a person is born with one brown eye and one blue eye because of a somatic mutation. The change or loss of gene information is just as likely to affect the fundamental processes of cell function or organ differentiation. Such somatic mutations in the early embryonic period can result in embryonic death or congenital malformations. Somatic mutations are important causes of cancer and other tumors in which cell differentiation and growth get out of control. Each year, hundreds of thousands of random changes occur in the DNA molecule because of environmental events or metabolic accidents. Fortunately, fewer than 1 in 1000 base pair changes result in serious mutations. Most of these defects are corrected by DNA repair mechanisms. Several mechanisms exist, and each depends on specific enzymes such as DNA repair nucleases. Fishermen, farmers, and others who are excessively exposed to the ultraviolet radiation of sunlight have an increased risk for development of skin cancer as a result of potential radiation damage to the genetic structure of the skin-forming cells.

In summary, genes are the fundamental unit of information storage in the cell. They determine the types of proteins and enzymes made by the cell and therefore control inheritance and day-to-day cell function. Genes store information in a stable macromolecule called DNA. Genes transmit information contained in the DNA molecule as a triplet code. The arrangement of the nitrogenous bases of the four nucleotides (i.e., adenine, guanine, thymine [or uracil in RNA], and cytosine) forms the code. The transfer of stored information into production of cell products is accomplished through a second type of macromolecule called RNA. Messenger RNA transcribes the instructions for product synthesis from the DNA molecule and carries it into the cell's cytoplasm, where ribosomal RNA uses the information to direct product synthesis. Transfer RNA acts as a carrier system for delivering the appropriate amino acids to the ribosomes, where the synthesis of cell products occurs. Although all cells contain the same

genes, only a small, select group of genes is active in a given cell type. In all cells, some genetic information is repressed, whereas other information is expressed. Gene mutations represent accidental errors in duplication, rearrangement, or deletion of parts of the genetic code. Fortunately, most mutations are corrected by DNA repair mechanisms in the cell.

CHROMOSOMES

Most genetic information of a cell is organized, stored, and retrieved in small intracellular structures called *chromosomes*. Although the chromosomes are visible only in dividing cells, they retain their integrity between cell divisions. The chromosomes are arranged in pairs; one member of the pair is inherited from the father, the other from the mother. Each species has a characteristic number of chromosomes. In the human, 46 single or 23 pairs of chromosomes are present. Of the 23 pairs of human chromosomes, there are 22 pairs called *autosomes* that are alike in males and females. Each of the 22 pairs of autosomes has the same appearance in all individuals, and each has been given a numeric designation for classification purposes (Fig. 3-6).

The sex chromosomes make up the 23rd pair of chromosomes. Two sex chromosomes determine the sex of a person. All males have an X and Y chromosome (i.e., an X chromosome from the mother and a Y chromosome from the father); all females have two X chromosomes (*i.e.*, one from each parent). Only one X chromosome in the female is active in controlling the expression of genetic traits; however, both X chromosomes are activated during gametogenesis (i.e., formation of the germ cell or ovum). In the female, the active X chromosome is invisible, but the inactive X chromosome can be demonstrated with appropriate nuclear staining. This inactive chromatin mass is seen as the Barr body in epithelial cells or as the drumstick body in the chromatin of neutrophils. The genetic sex of a child can be determined by microscopic study of cell or tissue samples. The total number of X chromosomes is equal to the number of Barr bodies plus one (*i.e.*, an inactive plus an active X chromosome). For example, the cells of a normal female have one Barr body and therefore a total of two X chromosomes. A normal male has no Barr bodies. Males with Klinefelter's syndrome (one Y, an inactive X, plus an active X chromosome) exhibit one Barr body. In the female, whether the X chromosome derived from the mother or that derived from the father is active is determined within a few days after conception; the selection is random for each postmitotic cell line. This is called the Lyon principle, after Mary Lyon, the British geneticist who described it.

Cell Division

There are two types of cell division: mitosis and meiosis. *Meiosis* is limited to replicating germ cells and takes place only once in a cell line. It results in the formation of gametes or reproductive cells (*i.e.*, ovum and sperm), each of which has only a single set of 23 chromosomes. Meiosis is typically divided into two distinct phases, meiotic divisions I and II. Similar to mitosis, cells

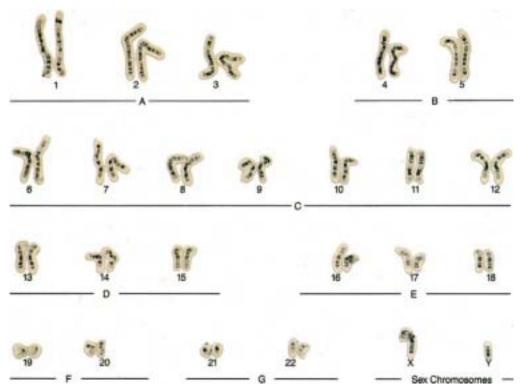

FIGURE 3-6 Karyotype of normal human boy. (Courtesy of the Prenatal Diagnostic and Imaging Center, Sacramento, CA. Frederick W. Hansen, MD, Medical Director)

about to undergo the first meiotic division replicate their DNA during interphase. During metaphase I, homologous chromosomes pair up, forming a synapsis or tetrad (two chromatids per chromosome). They are sometimes called *bivalents*. The X and Y chromosomes are not homologs and do not form bivalents. While in metaphase I, an interchange of chromatid segments can occur. This process is called *crossing over* (Fig. 3-7). Crossing over allows for new combinations of genes, increasing genetic variability. After telophase I, each of the two daughter cells contains one member of each homologous pair of chromosomes and a sex chromosome (23 double-stranded chromosomes).

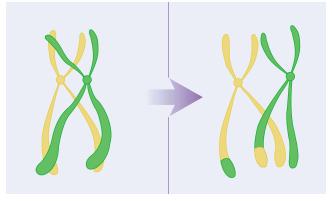

KEY CONCEPTS

CHROMOSOME STRUCTURE

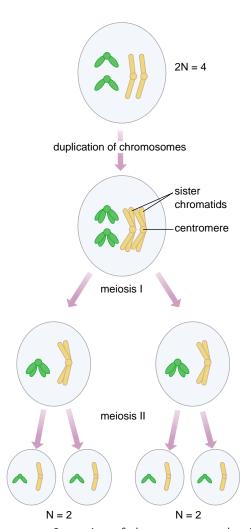

- The DNA that stores genetic material is organized into 23 pairs of chromosomes. There are 22 pairs of autosomes, which are alike for males and females, and one pair of sex chromosomes, with XX pairing in females and XY pairing in males.
- Mitosis refers to the duplication of chromosomes in somatic cell lines, in which each daughter cell receives a pair of 23 chromosomes.
- Meiosis is limited to replicating germ cells and results in the formation of a single set of 23 chromosomes.

No DNA synthesis occurs before meiotic division II. During anaphase II, the 23 double-stranded chromosomes (two chromatids) of each of the two daughter cells from meiosis I divide at their centromeres. Each subsequent daughter cell receives 23 single-stranded chromatids. Thus, a total of four daughter cells are formed by a meiotic division of one cell (Fig. 3-8).

Meiosis, which occurs only in the gamete-producing cells found in either testes or ovaries, has a different outcome in males and females. In males, meiosis (spermatogenesis) results in four viable daughter cells called *spermatids* that differentiate into sperm cells. In females, gamete formation or oogenesis is quite different. After the first meiotic division of a primary oocyte, a secondary oocyte and another structure called a *polar body* are formed. This small polar body contains little cyto-

■ FIGURE 3-7 ■ Crossing over of DNA at the time of meiosis.

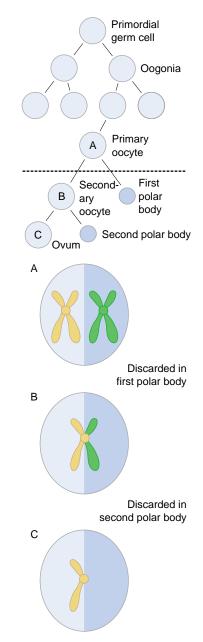

■ FIGURE 3-8 ■ Separation of chromosomes at the time of meiosis.

plasm, but it may undergo a second meiotic division, resulting in two polar bodies (Fig. 3-9). The secondary oocyte undergoes its second meiotic division, producing one mature oocyte and another polar body. Four viable sperm cells are produced during spermatogenesis, but only one ovum from oogenesis.

Chromosome Structure

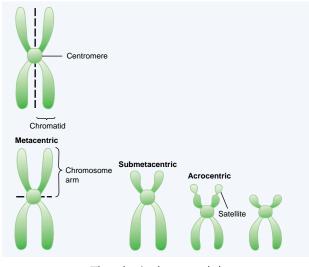

Cytogenetics is the study of the structure and numeric characteristics of the cell's chromosomes. Chromosome studies can be done on any tissue or cell that grows and divides in culture. Lymphocytes from venous blood are frequently used for this purpose. After the cells have been cultured, a drug called *colchicine* is used to arrest mitosis in metaphase. A chromosome spread is prepared by fixing and spreading the chromosomes on a slide. Subsequently, appropriate staining techniques show the chromosomal banding patterns so they can be identified. The chromosomes are photographed, and the photomicrograph of each chromosome is cut out and arranged in pairs according to a standard classification system. The completed picture is called a *karyotype*, and the procedure for preparing the picture is called *karyotyping*. A uniform system of chromosome classification was originally formulated at the 1971 Paris Chro-

■ FIGURE 3-9 ■ Essential stages of meiosis in a female, with discarding of the first and second polar bodies and formation of the ovum with the haploid number of chromosomes. mosome Conference and was later revised to describe the chromosomes as seen in more elongated prophase and prometaphase preparations.

In the metaphase spread, each chromosome takes the form of chromatids to form an "X" or "wishbone" pattern. Human chromosomes are divided into three types according to the position of the centromere (*i.e.*, central constriction; Fig. 3-10). If the centromere is in the center and the arms are of approximately the same length, the chromosome is said to be metacentric; if it is off center and the arms are of clearly different lengths, it is *submetacentric*; and if it is near one end, it is *acrocentric*. The short arm of the chromosome is designated

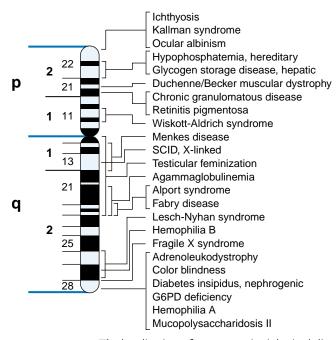

■ FIGURE 3-10 ■ Three basic shapes and the component parts of human metaphase chromosomes. The relative size of the satellite on the acrocentric is exaggerated for visibility. (Adapted from Cormack D.H. [1993]. *Essential histology*. Philadelphia: J.B. Lippincott)

as "p" for "petite," and the long arm is designated as "q" for no other reason than it is the next letter of the alphabet. Arms of the chromosome are indicated by the chromosome number followed by the p or q designation. Chromosomes 13, 14, 15, 21, and 22 have small masses of chromatin called *satellites* attached to their short arms by narrow stalks. At the ends of each chromosome are special DNA sequences called *telomeres*. Telomeres allow the end of the DNA molecule to be replicated completely.

The banding patterns of a chromosome are used in describing the position of a gene. Regions on the chromosomes are numbered from the centromere outward. The regions are further divided into bands and subbands, which are also numbered (Fig. 3-11). These numbers are used in designating the position of a gene on a chromosome. For example, Xp22.2 refers to subband 2, band 2, region 2 of the short arm (p) of the X chromosome.

In summary, the genetic information in a cell is organized, stored, and retrieved as small cellular structures called chromosomes. Forty-six chromosomes arranged in 23 pairs are present in the human being. Twenty-two of these pairs are autosomes. The 23rd pair is the sex chromosomes, which determine the sex of a person. Two types of cell division occur, meiosis and mitosis. Meiosis is limited to replicating germ cells and results in the formation of gametes or reproductive cells (ovum and sperm), each of which has only a single set of 23 chromosomes. Mitotic division occurs in somatic cells and results in the formation of 23 pairs of chromosomes. A karyotype is a photograph of a person's chromosomes. It is prepared by special laboratory techniques in which body cells are cultured, fixed, and then stained to demonstrate identifiable banding patterns. A photomicrograph is then made. Often the individual chromosomes are cut out and regrouped according to chromosome number.

■ FIGURE 3-11 ■ The localization of representative inherited diseases on the X chromosome. Notice the nomenclature of arms (P,Q), regions (1,2), bands (*e.g.*, 11,22). (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 260]. Philadelphia: Lippincott Williams & Wilkins)

PATTERNS OF INHERITANCE

The characteristics inherited from a person's parents are inscribed in gene pairs located along the length of the chromosomes. Alternate forms of the same gene are possible (*i.e.*, one inherited from the mother and the other from the father), and each may produce a different aspect of a trait.

KEY CONCEPTS

TRANSMISSION OF GENETIC INFORMATION

- The transmission of information from one generation to the next is vested in genetic material transferred from each parent at the time of conception.
- Alleles are the alternate forms of a gene (one from each parent), and the locus is the position that they occupy on the chromosome.
- The genotype of a person represents the sum total of the genetic information in the cells and the phenotype the physical manifestations of that information.
- Penetrance is the percentage in a population with a particular genotype in which that genotype is phenotypically manifested, whereas expressivity is the manner in which the gene is expressed.

Genetics has its own set of definitions. The *genotype* of a person is the genetic information stored in the base sequence triplet code. The *phenotype* refers to the recognizable traits, physical or biochemical, associated with a specific genotype. Often, the genotype is not evident by available detection methods. More than one genotype may have the same phenotype. Some brown-eyed persons are carriers of the code for blue eyes, and other brown-eyed persons are not. Phenotypically, these two types of brown-eyed persons are the same, but genotypically they are different.

When it comes to a genetic disorder, not all persons with a mutant gene are affected to the same extent. *Expressivity* refers to the manner in which the gene is expressed in the phenotype, which can range from mild to severe. *Penetrance* represents the ability of a gene to express its function. Seventy-five percent penetrance means 75% of persons of a particular genotype demonstrate a recognizable phenotype. Syndactyly (webbed fingers) and blue sclera are genetic mutations that often do not exhibit 100% penetrance.

The position of a gene on a chromosome is called its *locus*, and alternate forms of a gene at the same locus are called *alleles*. When only one pair of genes is involved in the transmission of information, the term *single-gene trait* is used. Single-gene traits follow the Mendelian laws of inheritance.

Polygenic inheritance involves multiple genes at different loci, with each gene exerting a small additive effect in determining a trait. Most human traits are determined by multiple pairs of genes, many with alternate codes, accounting for some of the dissimilar forms that occur with certain genetic disorders. Polygenic traits are predictable but less so than single-gene traits. *Multifactorial* inheritance is similar to polygenic inheritance in that multiple alleles at different loci affect the outcome; the difference is that multifactorial inheritance includes environmental effects on the genes.

Many other gene–gene interactions are known. These include *epistasis*, in which one gene masks the phenotypic effects of another nonallelic gene; *multiple alleles*, in which more than one allele affects the same trait (*e.g.*, ABO blood types); *complementary genes*, in which each gene is mutually dependent on the other; and *collaborative genes*, in which two different genes influencing the same trait interact to produce a phenotype neither gene alone could produce.

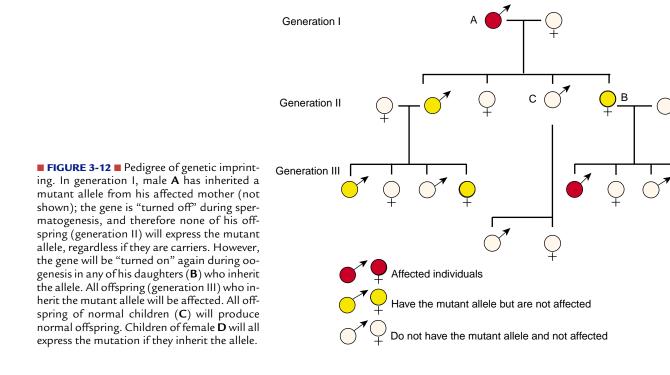

Genetic Imprinting

Besides autosomal and sex-linked genes and mitochondrial inheritance, it was found that certain genes exhibit a "parent of origin" type of transmission, in which the parental genomes do not always contribute equally in the development of an individual (Fig. 3-12). Although rare, it is estimated that approximately 100 genes exhibit genomic, or genetic, imprinting. Evidence suggests there is a genetic conflict over the developing embryo: the male genome attempts to establish larger offspring, whereas the female prefers smaller offspring to conserve her energy for the current and subsequent pregnancies.

An example of a disorder involving parenteral imprinting is uniparental disomy. This occurs when two chromosomes of the same number are inherited from one parent. Normally, this is not a problem, except in cases where a chromosome has been imprinted by a parent. If an allele is inactivated by imprinting, the offspring will have only one working copy of the chromosome, resulting in possible problems.

Mendel's Laws

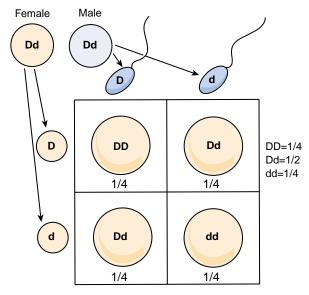

The main feature of inheritance is predictability: given certain conditions, the likelihood of the occurrence or recurrence of a specific trait is remarkably predictable. The units of inheritance are the genes, and the pattern of single-gene expression often

can be predicted using Mendel's laws of genetic transmission. Techniques and discoveries since Gregor Mendel's original work was published in 1865 have led to some modification of his original laws.

Mendel discovered the basic pattern of inheritance by conducting carefully planned experiments with simple garden peas. Experimenting with several phenotypic traits in peas, Mendel proposed that inherited traits are transmitted from parents to offspring by means of independently inherited factors now known as genes—and that these factors are transmitted as recessive and dominant traits. Mendel labeled dominant factors (his round peas) "A" and recessive factors (his wrinkled peas) "a." Geneticists continue to use capital letters to designate dominant traits and lowercase letters to identify recessive traits. The possible combinations that can occur with transmission of single-gene dominant and recessive traits can be described by constructing a figure called a *Punnett square* using capital and lowercase letters (Fig. 3-13).

The observable traits of single-gene inheritance are inherited by the offspring from the parents. During maturation, the primordial germ cells (*i.e.*, sperm and ovum) of both parents undergo meiosis, or reduction division, in which the number of chromosomes is divided in half (from 46 to 23). At this time, the two alleles from a gene locus separate so that each germ cell receives only one allele from each pair (*i.e.*, Mendel's first law). According to Mendel's second law, the alleles from the different gene loci segregate independently and recombine randomly in the zygote. Persons in whom the two alleles of a given pair are the same (AA or aa) are called *homozygotes*. *Heterozygotes* have different alleles (Aa) at a gene locus. A *recessive trait* is one expressed only in a homozygous pairing; a *dominant trait* is one expressed in either a homozygous or a heterozygous pairing. All persons with a dominant allele (depending on the

■ FIGURE 3-13 ■ The Punnett square showing all possible combinations for transmission of a single gene trait (dimpled cheeks). The example shown is when both parents are heterozygous (dD) for the trait. The alleles carried by the mother are on the left and those carried by the father are on the top. The D allele is dominant and the d allele is recessive. The DD and Dd offspring have dimples and the dd offspring does not.

penetrance of the genes) manifest that trait. A *carrier* is a person who is heterozygous for a recessive trait and does not manifest the trait. For example, the genes for blond hair are recessive and those for brown hair are dominant. Therefore, only persons with a genotype having two alleles for blond hair would be blond; persons with either one or two brown alleles would have dark hair.

Pedigree

A pedigree is a graphic method for portraying a family history of an inherited trait. It is constructed from a carefully obtained family history and is useful for tracing the pattern of inheritance for a particular trait.

In summary, inheritance represents the likelihood of the occurrence or recurrence of a specific genetic trait. The genotype refers to information stored in the genetic code of a person, whereas the phenotype represents the recognizable traits, physical and biochemical, associated with the genotype. Expressivity refers to the expression of a gene in the phenotype, and penetrance is the ability of a gene to express its function. The point on the DNA molecule that controls the inheritance of a particular trait is called a gene locus. Alternate forms of a gene at one gene locus are called alleles. The alleles at a gene locus may carry recessive or dominant traits. A recessive trait is one expressed only when there are two copies (homozygous) of the recessive alleles. Dominant traits are expressed with either homozygous or heterozygous pairing of the alleles. A pedigree is a graphic method for portraying a family history of an inherited trait.

GENE MAPPING AND TECHNOLOGY

The genome is the gene complement of an organism. Genomic mapping is the assignment of genes to specific chromosomes or parts of the chromosome. The Human Genome Project, which started in 1990, is an international project to identify and localize the estimated 35,000 to 140,000 genes in the human genome. This is a phenomenal undertaking because there are approximately 3.2 billion base pairs in the human genome. The national effort toward genomic mapping is jointly coordinated by the National Institutes of Health and the Department of Energy. Organizers of the U.S. Human Genome Project hope to have the completed map by the year 2005. It is also anticipated that the project will reveal the chemical basis for as many as 4000 genetic diseases. It is expected to provide tests for screening and diagnosing genetic disorders and the basis for new treatments. To date, chromosomes 14, 20, 21 and 22 have been completely mapped.

Although the human genome project has received most of the publicity, genome sequencing also is underway in a variety of animals, such as the mouse and fruit fly, and other organisms, from bacteria to plants. These and other endeavors will be of benefit in animal husbandry and agriculture and the study of genetic similarities among various species. The human genome project has created an anticipation of future benefits from its undertakings as well as ethical concerns that must be dealt with by both scientists and the public.

Genomic Mapping

Two types of genomic maps exist: genetic maps and physical maps. Genetic maps are like highway maps. They use linkage studies (*e.g.*, dosage, hybridization) to estimate the distances between chromosomal landmarks (*i.e.*, gene markers). Physical maps are similar to a surveyor's map. They measure the actual physical distance between chromosomal elements in biochemical units, the smallest being the nucleotide base.

Genetic maps and physical maps have been refined over the decades. The earliest mapping efforts localized genes on the X chromosome. The initial assignment of a gene to a particular chromosome was made in 1911 for the color blindness gene inherited from the mother (*i.e.*, following the X-linked pattern of inheritance). In 1968, the specific location of the Duffy blood group on the long arm of chromosome 1 was determined. The locations of more than 2300 expressed human genes have been mapped to a specific chromosome and most of them to a specific region on the chromosome. However, genetic mapping is continuing so rapidly that these numbers are constantly being updated. Documentation of gene assignments to specific human chromosomes is updated almost daily in the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/Omim), an encyclopedia of expressed gene loci. Another source is the Human Genome Project, which is the central database for mapped genes and an international repository for most mapping information. Many methods have been used for developing genetic maps. The most important ones are family linkage studies, gene dosage methods, and hybridization studies. Often, the specific assignment of a gene is made using information from several mapping techniques.

Most of the genome mapping has been accomplished by a method called *transcript mapping*. The two-part process begins with isolating mRNAs immediately after they are transcribed. Next, the complementary DNA molecule is prepared. Although transcript mapping may provide knowledge of the gene sequence, it does not automatically mean that the function of the genetic material has been determined.

Linkage Studies

Mendel's laws were often insufficient to explain the transmission of several well-known traits, such as color blindness and hemophilia A. In some families it was noted that these two conditions were transmitted together.

Linkage studies assume that genes occur in a linear array along the chromosomes. During meiosis, the paired chromosomes of the diploid germ cell exchange genetic material because of the crossing-over phenomenon (see Fig. 3-7). This exchange usually involves more than one gene; large blocks of genes (representing large portions of the chromosome) usually are exchanged. Although the point at which the block separates from another occurs randomly, the closer together two genes are on the same chromosome, the greater the chance is that they will be passed on together to the offspring. When two inherited traits occur together at a rate significantly greater than would occur by chance, they are said to be *linked*.

Several methods take advantage of the crossing over and recombination of genes to map a particular gene. In one method, any gene that is already assigned to a chromosome can be used as a marker to assign other linked genes. For example, it was found that an extra long chromosome 1 and the Duffy blood group were inherited as a dominant trait, placing the position of the blood group gene close to the extra material on chromosome 1. Color blindness has been linked to classic hemophilia A (i.e., lack of factor VIII) in some pedigrees; hemophilia A has been linked to glucose-6-phosphate dehydrogenase deficiency in others; and color blindness has been linked to glucose-6-phosphate dehydrogenase deficiency in still others. Because the gene for color blindness is found on the X chromosome, all three genes must be located in a small section of the X chromosome. Linkage analysis can be used clinically to identify affected persons in a family with a known genetic defect. Males, because they have one X and one Y chromosome, are said to be hemizygous for sex-linked traits. Females can be homozygous (normal or mutant) or heterozygous for sex-linked traits. Heterozygous females are known as carriers for X-linked defects.

One autosomal recessive disorder that has been successfully diagnosed prenatally by linkage studies using amniocentesis is congenital adrenal hyperplasia (due to 21-hydroxylase deficiency), which is linked to an immune response gene (human leukocyte antigen [HLA] type). Postnatally, linkage studies have been used in diagnosing hemochromatosis, which is closely linked to another HLA type. Persons with this disorder are unable to metabolize iron, and it accumulates in the liver and other organs. It cannot be diagnosed by conventional means until irreversible damage has been done. Given a family history of the disorder, HLA typing can determine if the gene is present, and if it is present, dietary restriction of iron intake may be used to prevent organ damage.

Dosage Studies

Dosage studies involve measuring enzyme activity. Autosomal genes are normally arranged in pairs, and normally both are expressed. If both alleles are present and both are expressed, the activity of the enzyme should be 100%. If one member of the gene pair is missing, only 50% of the enzyme activity is present, reflecting the activity of the remaining normal allele.

Hybridization Studies

A recent biologic discovery revealed that two somatic cells from different species, when grown together in the same culture, occasionally fuse to form a new hybrid cell. Two types of hybridization methods are used in genomic studies: somatic cell hybridization and in situ hybridization.

Somatic cell hybridization involves the fusion of human somatic cells with those of a different species (typically, the mouse) to yield a cell containing the chromosomes of both species. Because these hybrid cells are unstable, they begin to lose chromosomes of both species during subsequent cell divisions. This makes it possible to obtain cells with different partial combinations of human chromosomes. By studying the enzymes that these cells produce, it is possible to determine that an enzyme is produced only when a certain chromosome is present; the coding for that enzyme must be located on that chromosome.

In situ hybridization involves the use of a specific sequence of DNA or RNA to locate genes that do not express themselves in cell culture. DNA and RNA can be chemically tagged with radioactive or fluorescent markers. These chemically tagged DNA or RNA sequences are used as probes to determine gene location. The probe is added to a chromosome spread after the DNA strands have been separated. If the probe matches the complementary DNA of a chromosome segment, it hybridizes and remains at the precise location (thus the term *in situ*) on a chromosome. Radioactive or fluorescent markers are used to determine the location of the probe.

Recombinant DNA Technology

During the past several decades, genetic engineering has provided the methods for manipulating nucleic acids and recombining genes (recombinant DNA) into hybrid molecules that can be inserted into unicellular organisms and reproduced many times over. Each hybrid molecule produces a genetically identical population, called a *clone*, that reflects its common ancestor.

The techniques of gene isolation and cloning rely on the fact that the genes of all organisms, from bacteria through mammals, are based on similar molecular organization. Gene cloning requires cutting a DNA molecule apart, modifying and reassembling its fragments, and producing copies of the modified DNA, its mRNA, and its gene product. The DNA molecule is cut apart by using a bacterial enzyme, called a *restriction enzyme*, that binds to DNA wherever a particular short sequence of base pairs is found and cleaves the molecule at a specific nucleotide site. In this way, a long DNA molecule can be broken into smaller, discrete fragments with the intent that one fragment contains the gene of interest. More than 100 restriction enzymes are commercially available that cut DNA at different recognition sites.

The selected gene fragment is replicated through insertion into a unicellular organism, such as a bacterium. To do this, a cloning vector such as a bacterial virus or a small DNA circle that is found in most bacteria, called a *plasmid*, is used. Viral and plasmid vectors replicate autonomously in the host bacterial cell. During gene cloning, a bacterial vector and the DNA fragment are mixed and joined by a special enzyme called a DNA ligase. The recombinant vectors formed are then introduced into a suitable culture of bacteria, and the bacteria are allowed to replicate and express the recombinant vector gene. Sometimes, mRNA taken from a tissue that expresses a high level of the gene is used to produce a complementary DNA molecule that can be used in the cloning process. Because the fragments of the entire DNA molecule are used in the cloning process, additional steps are taken to identify and separate the clone that contains the gene of interest.

In terms of biologic research and technology, cloning makes it possible to identify the DNA sequence in a gene and produce the protein product encoded by a gene. The specific nucleotide sequence of a cloned DNA fragment can often be identified by analyzing the amino acid sequence and mRNA codons of its protein product. Short sequences of base pairs can be synthesized, radioactively labeled, and subsequently used to identify their complementary sequence. In this way, identifying normal and abnormal gene structures is possible. Proteins that formerly were available only in small amounts can now be made in large quantities once their respective genes have been isolated. For example, genes encoding for insulin and growth hormone have been cloned to produce these hormones for pharmacologic use.

Gene Therapy

Although quite different from inserting genetic material into a unicellular organism such as bacteria, techniques are available for inserting genes into the genome of intact multicellular plants and animals. Promising delivery vehicles for these genes are the adenoviruses. These viruses are ideal vehicles because their DNA does not become integrated into the host genome; however, repeated inoculations are often needed because the body's immune system usually targets cells expressing adenovirus proteins. Sterically stable liposomes also show promise as DNA delivery mechanisms. This type of therapy is one of the more promising methods for the treatment of genetic disorders, certain cancers, cystic fibrosis, and many infectious diseases.

Two main approaches are used in gene therapy: transferred genes either replace defective genes or selectively inhibit deleterious genes. Cloned DNA sequences or ribosomes usually are the compounds used in gene therapy. However, the introduction of the cloned gene into the multicellular organism can influence only the few cells that get the gene. An answer to this problem would be the insertion of the gene into a sperm or ovum; after fertilization, the gene would be replicated in all of the differentiating cell types. Even so, techniques for cell insertion are limited. Not only are moral and ethical issues involved, but these techniques cannot direct the inserted DNA to attach to a particular chromosome or supplant an existing gene by knocking it out of its place.

DNA Fingerprinting

The technique of DNA fingerprinting is based in part on those techniques used in recombinant DNA technology and those originally used in medical genetics to detect slight variations in the genomes of different individuals. Using restrictive endonucleases, DNA is cleaved at specific regions. The DNA fragments are separated according to size by electrophoresis (*i.e.*, Southern blot) and transferred to a nylon membrane. The fragments are then broken apart and subsequently annealed with a series of radioactive probes specific for regions in each fragment. An autoradiograph reveals the DNA fragments on the membrane. When used in forensic pathology, this procedure is undertaken on specimens from the suspect and the forensic specimen. Banding patterns are then analyzed to see if they match. With conventional methods of analysis of blood and serum enzymes, a 1 in 100 to 1000 chance exists that the two specimens match because of chance. With DNA fingerprinting, these odds are 1 in 100,000 to 1 million.

In summary, the genome is the gene complement of an organism. Genomic mapping is a method used to assign genes to particular chromosomes or parts of a chromosome. The most important ones used are family linkage studies, gene dosage methods, and hybridization studies. Often the specific assignment of a gene is determined by using information from several mapping techniques. Linkage studies assign a chromosome location to genes based on their close association with other genes of known location. Recombinant DNA studies involve the extraction of specific types of messenger RNA used in synthesis of complementary DNA strands. The complementary DNA strands, labeled with a radioisotope, bind with the genes for which they are complementary and are used as gene probes. Now underway is an international project to identify and localize all 35,000 to 140,000 genes in the human genome. Genetic engineering has provided the methods for manipulating nucleic acids and recombining genes (recombinant DNA) into hybrid molecules that can be inserted into unicellular organisms and reproduced many times over. As a result, proteins that formerly were available only in small amounts can now be made in large quantities once their respective genes have been isolated. DNA fingerprinting, which relies on recombinant DNA technologies and those of genetic mapping, is often used in forensic investigations.

REVIEW QUESTIONS

- Explain the mechanisms by which genes control cell function and the characteristics of the next generation.
- Define gene locus and allele.
- Explain the difference between a person's genotype and phenotype.
- Describe the concepts of *induction* and *repression* as they apply to gene function.
- Describe the pathogenesis of gene mutation.

Explain how gene expressivity and penetrance determine the effects of a mutant gene that codes for the production of an essential enzyme.

Differentiate between autosomes and sex chromosomes and between meiosis and mitosis.

Explain the significance of the Barr body.

Construct a hypothetical pedigree for a recessive and dominant trait according to Mendel's law.

CHAPTER

Genetic and congenital defects are important at all levels of health care because they affect all age groups and can involve almost any of the body tissues and organs. Congenital defects, sometimes called *birth defects*, develop during prenatal life and usually are apparent at birth or shortly thereafter. Spina bifida and cleft lip, for example, are apparent at birth, but other malformations, such as kidney and heart defects, may be present at birth but may not become apparent until they begin to produce symptoms. Not all genetic disorders are congenital, and many are not apparent until later in life.

Birth defects, which affect more than 150,000 infants each year, are the leading cause of infant death.¹ Birth defects may be caused by genetic factors (*i.e.*, single-gene or multifactorial inheritance or chromosomal aberrations), or they may be caused by environmental factors that occurred during embryonic or fetal development (*i.e.*, maternal disease, infections, or drugs taken during pregnancy). In rare cases, congenital defects may be the result of intrauterine factors such as fetal crowding, positioning, or entanglement of fetal parts with the amnion. This chapter provides an overview of genetic and congenital disorders and is divided into three parts: (1) genetic and chromosomal disorders, (2) disorders caused by environmental agents, and (3) diagnosis and counseling.

GENETIC AND CHROMOSOMAL DISORDERS

Genetic disorders involve a permanent change (or mutation) in the genome. A genetic disorder can involve a single-gene trait, multifactorial inheritance, or a chromosome disorder.

Single-Gene Disorders

Single-gene disorders are caused by a single defective or mutant gene. The defective gene may be present on an autosome or the X chromosome and it may affect only one member of an autosomal gene pair (matched with a normal gene) or both members of the pair. Single-gene defects follow the mendelian patterns of inheritance (see Chapter 3) and are often called

KEY CONCEPTS

GENETIC AND CHROMOSOMAL DISORDERS

- Genetic disorders are inherited as autosomal dominant disorders, in which each child has a 50% chance of inheriting the disorder, and as autosomal recessive disorders, in which each child has a 25% chance of being affected, a 50% chance of being a carrier, and a 25% chance of being unaffected.
- Sex-linked disorders almost always are associated with the X chromosome and are predominantly recessive.
- Chromosomal disorders reflect events that occur at the time of meiosis and result from defective movement of an entire chromosome or from breakage of a chromosome with loss or translocation of genetic material.

mendelian disorders. At last count, there were more than 8000 single-gene disorders, many of which have been mapped to a specific chromosome.²

The genes on each chromosome are arranged in pairs and in strict order, with each gene occupying a specific location or locus. The two members of a gene pair, one inherited from the mother and the other from the father, are called *alleles*. If the members of a gene pair are identical (*i.e.*, code the exact same gene product), the person is *homozygous*, and if the two members are different, the person is *heterozygous*. The genetic composition of a person is called a *genotype*, whereas the *phenotype* is the observable expression of a genotype in terms of morphologic, biochemical, or molecular traits. If the trait is expressed in the heterozygote (one member of the gene pair codes for the trait), it is said to be *dominant*; if it is expressed only in the homozygote (both members of the gene pair code for the trait), it is *recessive*.

Although gene expression usually follows a dominant or recessive pattern, it is possible for both alleles (members) of a gene pair to be fully expressed in the heterozygote, a condition called *codominance*. Many genes have only one normal version, called a *wild-type* allele. Other genes have more than one normal allele (alternate forms) at the same locus. This is called *polymorphism*. Blood group inheritance (*e.g.*, AO, BO, AB) is an example of codominance and polymorphism.

A single mutant gene may be expressed in many different parts of the body. Marfan's syndrome is a defect in connective tissue that has widespread effects involving skeletal, eye, and cardiovascular structures. In other single-gene disorders, the same defect can be caused by mutations at several different loci. Childhood deafness can result from 16 different types of autosomal recessive mutations.

Single-gene disorders are characterized by their patterns of transmission, which usually are obtained through a family genetic history. The patterns of inheritance depend on whether the phenotype is dominant or recessive, and whether the gene is located on an autosomal or sex chromosome (see Chapter 3). Disorders of autosomal inheritance include autosomal dominant and autosomal recessive traits. Among the approximate 8000 single-gene disorders, more than half are autosomal dominant. Autosomal recessive phenotypes are less common, accounting for approximately one third of single-gene disorders.3 Currently, all sex-linked genetic disorders are thought to be X-linked, and most are recessive. The only mutations affecting the Y-linked genes are involved in spermatogenesis and male fertility and thus are not transmitted. A few additional genes with homologs on the X chromosome have been mapped to the Y chromosome, but to date, no disorders resulting from mutations in these genes have been described.

Virtually all single-gene disorders lead to formation of an abnormal protein or decreased production of a gene product. The defect can result in defective or decreased amounts of an enzyme, defects in receptor proteins and their function, alterations in nonenzyme proteins, or mutations resulting in unusual reactions to drugs. Table 4-1 lists some of the common single-gene disorders and their manifestations.

Autosomal Dominant Disorders

In autosomal dominant disorders, a single mutant allele from an affected parent is transmitted to an offspring regardless of sex. The affected parent has a 50% chance of transmitting the disorder to each offspring (Fig. 4-1). The unaffected relatives of the parent or unaffected siblings of the offspring do not transmit the disorder. In many conditions, the age of onset is delayed, and the signs and symptoms of the disorder do not appear until later in life, as in Huntington's chorea (see Chapter 37).

Autosomal dominant disorders also may manifest as a new mutation. Whether the mutation is passed on to the next generation depends on the affected person's reproductive capacity. Many new autosomal dominant mutations are accompanied by reduced reproductive capacity; therefore, the defect is not perpetuated in future generations. If an autosomal defect is accompanied by a total inability to reproduce, essentially all new cases of the disorder will be due to new mutations. If the defect does not affect reproductive capacity, it is more likely to be inherited.

Although there is a 50% chance of inheriting a dominant genetic disorder from an affected parent, there can be wide variation in gene penetration and expression. When a person inherits a dominant mutant gene but fails to express it, the trait is described as having *reduced penetrance*. Penetrance is expressed in mathematical terms; a 50% penetrance indicates that a person who inherits the defective gene has a 50% chance of expressing the disorder. The person who has a mutant gene but does not express it is an important exception to the rule that unaffected persons do not transmit an autosomal dominant trait. These persons can transmit the gene to their descendants and so produce a skipped generation. Autosomal dominant disorders also can display variable expressivity, meaning that they can be expressed differently among individuals. For example, polydactyly or the presence of more than the usual number of digits may be expressed in the fingers or the toes.

The gene products of autosomal dominant disorders usually are regulatory proteins involved in rate-limiting components of complex metabolic pathways or key components of structural proteins such as collagen.^{4,5} Two disorders of autosomal inheritance, Marfan's syndrome and neurofibromatosis (NF), are described in this chapter.

Marfan's Syndrome. Marfan's syndrome is a connective tissue disorder that is manifested by changes in the skeleton, eves, and cardiovascular system. There is a wide range of variation in expression of the disorder. Persons may have abnormalities of one or all three systems. The skeletal deformities, which are the most obvious features of the disorder, include a long, thin body with exceptionally long extremities and long, tapering fingers, sometimes called arachnodactyly or spider fingers (Fig. 4-2), hyperextensible joints, and a variety of spinal deformities including kyphoscoliosis. Chest deformity, pectus excavatum (*i.e.*, deeply depressed sternum), or pigeon chest deformity, often is present. The most common eve disorder is bilateral dislocation of the lens caused by weakness of the suspensory ligaments. Myopia and predisposition to retinal detachment also are common, the result of increased optic globe length due to altered connective tissue support of ocular structures. However, the most life-threatening aspects of the disorder are the cardiovascular defects, which include mitral valve prolapse, progressive dilation of the aortic valve ring, and weakness of the aorta and other arteries. Dissection and rupture of the aorta often lead to premature death. The average age of death in persons with Marfan's syndrome is 30 to 40 years.⁴

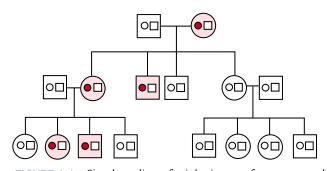

TABLE 4-1

Some Disorders of Mendelian or Single-Gene Inheritance

and Their Significance

Disorder	Significance
Autosomal Dominant	
Achondroplasia	Short-limb dwarfism
Adult polycystic kidney disease	Kidney failure
Huntington's chorea	Neurodegenerative disorder
Familial hypercholesterolemia	Premature atherosclerosis
Marfan's syndrome	Connective tissue disorder with abnormalities in skeletal, ocular, cardiovascular systems
Neurofibromatosis (NF)	Neurogenic tumors: fibromatous skin tumors, pigmented skin lesions, and ocular nodules in NF-1; bilateral acoustic neuromas in NF-2
Osteogenesis imperfecta	Molecular defects of collagen
Spherocytosis	Disorder of red blood cells
von Willebrand's disease	Bleeding disorder
Autosomal Recessive	
Color blindness	Color blindness
Cystic fibrosis	Disorder of membrane transport of ions in exocrine glands causing lung and pancreatic disease
Glycogen storage diseases	Excess accumulation of glycogen in the liver and hypoglycemia (von Gierke's disease); glycogen accumulation in striated muscle in myopathic forms
Oculocutaneous albinism	Hypopigmentation of skin, hair, eyes as result of inability to synthesize melanin
Phenylketonuria (PKU)	Lack of phenylalanine hydroxylase with hyperphenylalaninemia and impaired brain development
Sickle cell disease	Red blood cell defect
Tay-Sachs disease	Deficiency of hexosaminidase A; severe mental and physical deterioration beginning in infancy
X-Linked Recessive	
Bruton-type hypogammaglobulinemia	Immunodeficiency
Hemophilia A	Bleeding disorder
Duchenne dystrophy	Muscular dystrophy
Fragile X syndrome	Mental retardation

Neurofibromatosis. Neurofibromatosis is a condition involving neurogenic tumors that arise from Schwann cells and other elements of the peripheral nervous system.^{4,5} There are at least two genetically and clinically distinct forms of the disorder: type 1 NF (NF-1), also known as von Recklinghausen's disease, and type 2 bilateral acoustic NF (NF-2). Both of these disorders result from a genetic defect in a protein that regulates cell growth. The gene for NF-1 has been mapped to chromosome 17, and the gene for NF-2 has been mapped to chromosome 22.

■ FIGURE 4-1 ■ Simple pedigree for inheritance of an autosomal dominant trait. The small, colored circle represents the mutant gene. An affected parent with an autosomal dominant trait has a 50% chance of passing the mutant gene on to each child regardless of sex.

NF-1 is a relatively common disorder with a frequency of 1 in 3000.5 Approximately 50% of cases have a family history of autosomal dominant transmission, and the remaining 50% appear to represent a new mutation. In more than 90% of persons with NF-1, cutaneous and subcutaneous neurofibromas

■ FIGURE 4-2 ■ Long, slender fingers (arachnodactyly) in a patient with Marfan's syndrome. (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 242]. Philadelphia: Lippincott Williams & Wilkins)

develop in late childhood or adolescence. The cutaneous neurofibromas, which vary in number from a few to many hundreds, manifest as soft, pedunculated lesions that project from the skin. They are the most common type of lesion, often are not apparent until puberty, and are present in greatest density over the trunk (Fig. 4-3). The subcutaneous lesions grow just below the skin; they are firm and round, and may be painful. Plexiform neurofibromas involve the larger peripheral nerves. They tend to form large tumors that cause severe disfigurement of the face or an extremity. Pigmented nodules of the iris (Lisch nodules), which are specific for NF-1, usually are present after 6 years of age. They do not present any clinical problem but are useful in establishing a diagnosis.

A second major component of NF-1 is the presence of large (usually \geq 15 mm in diameter), flat cutaneous pigmentations, known as *café-au-lait spots*. They are usually a uniform light brown in whites and darker brown in African Americans and have sharply demarcated edges (Fig. 4-4). Although small single lesions may be found in normal children, larger lesions of six or more spots larger than 1.5 cm in diameter suggest NF-1. The skin pigmentations become more evident with age as the melanosomes in the epidermal cells accumulate melanin.

In addition to neurofibromatoses, persons with NF-1 have a variety of other associated lesions, the most common being skeletal lesions such as scoliosis and erosive bone defects. Persons with NF-1 also are at increased risk for development of other nervous system tumors such as meningiomas, optic gliomas, and pheochromocytomas.

NF-2 is characterized by tumors of the acoustic nerve. Most often, the disorder is asymptomatic through the first 15 years of life. The most frequently reported symptoms are headaches, hearing loss, and tinnitus (*i.e.*, ringing in the ears). There may be associated intracranial and spinal meningiomas. The condition is made worse by pregnancy, and oral contraceptives may increase the growth and symptoms of tumors. Persons with the disorder should be warned that severe disorientation may occur during diving or swimming underwater, and drowning may result. Surgery may be indicated for debulking or removal of the tumors.

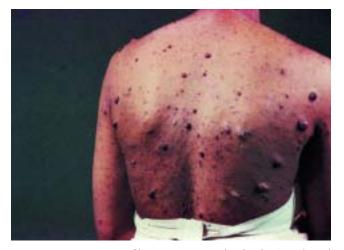

■ FIGURE 4-4 ■ Neurofibromatosis with early café-au-lait spots in a 5-year-old child. (Owen Laboratories, Inc.) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases*. Philadelphia: Lippincott-Raven)

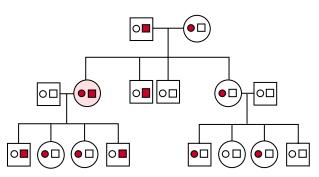

Autosomal Recessive Disorders

Autosomal recessive disorders are manifested only when both members of the gene pair are affected. In this case, both parents may be unaffected but are carriers of the defective gene. Autosomal recessive disorders affect both sexes. The occurrence risk in each pregnancy is one in four for an affected child, two in four for a carrier child, and one in four for a normal (noncarrier, unaffected) homozygous child (Fig. 4-5).

With autosomal recessive disorders, the age of onset is frequently early in life; the symptomatology tends to be more uniform than with autosomal dominant disorders; and the disorders are characteristically caused by deficiencies in enzymes, rather than abnormalities in structural proteins. In the case of a heterozygous carrier, the presence of a mutant gene usually does not produce symptoms because equal amounts of normal and defective enzymes are synthesized. The "margin of safety" ensures that cells with half their usual amount of enzyme function normally. By contrast, the inactivation of both alleles in a

■ FIGURE 4-3 ■ Neurofibromatosis on the back. (Reed and Carnick Pharmaceuticals) (Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases*. Philadelphia: Lippincott-Raven)

■ FIGURE 4-5 ■ Simple pedigree for inheritance of an autosomal recessive trait. The small, colored circle and square represent a mutant gene. When both parents are carriers of a mutant gene, there is a 25% chance of having an affected child, a 50% chance of a carrier child, and a 25% chance of a nonaffected or noncarrier child, regardless of sex. All children (100%) of an affected parent are carriers.

homozygote results in complete loss of enzyme activity. Autosomal recessive disorders include almost all inborn errors of metabolism. Enzyme disorders that impair catabolic pathways result in an accumulation of dietary substances (*e.g.*, phenylketonuria [PKU]) or cellular constituents (*e.g.*, lysosomal storage diseases). Other disorders result from a defect in the enzymemediated synthesis of an essential protein (*e.g.*, the cystic fibrosis transmembrane conductance regulator in cystic fibrosis). Two examples of autosomal recessive disorders that are not covered elsewhere in this book are PKU and Tay-Sachs disease.

Phenylketonuria. Phenylketonuria is a genetically inherited enzyme defect. It is characterized by a deficiency of phenylalanine hydroxylase, the enzyme needed for conversion of phenylalanine to tyrosine. As a result of this deficiency, toxic levels of phenylalanine accumulate in the blood. Like other inborn errors of metabolism, PKU is inherited as a recessive trait and is manifested only in the homozygote. Untreated, PKU results in severe mental retardation.

PKU occurs once in approximately 10,000 births, and damage to the developing brain almost always results when high concentrations of phenylalanine and other metabolites persist in the blood.⁴ Because the symptoms of untreated PKU develop gradually and would often go undetected until irreversible mental retardation had occurred, newborn infants are routinely screened for abnormal levels of serum phenylalanine. It is important that blood samples for PKU screening be obtained at least 12 hours after birth to ensure accuracy.⁶ It also is possible to identify carriers of the trait by subjecting them to a phenylalanine test, in which a large dose of phenylalanine is administered orally and the rate at which it disappears from the bloodstream is measured.

Infants with the disorder are treated with a special diet that restricts phenylalanine intake. Dietary treatment must be started early in neonatal life to prevent brain damage. The results of dietary therapy of children with PKU have been impressive. The diet can prevent mental retardation as well as other neurodegenerative effects of untreated PKU.

Tay-Sachs Disease. Tay-Sachs disease is a variant of a class of lysosomal storage diseases, known as gangliosidoses, in which substances (gangliosides) found in membranes of nervous tissue are deposited in neurons of the central nervous system and retina because of a failure of lysosomal degradation.^{4,5} The disease is particularly prevalent among eastern European (Ashkenazi) Jews. Infants with Tay-Sachs disease appear normal at birth but begin to manifest progressive weakness, muscle flaccidity, and decreased attentiveness at approximately 6 to 10 months of age. This is followed by rapid deterioration of motor and mental function, often with development of generalized seizures. Retinal involvement leads to visual impairment and eventual blindness. Death usually occurs before 4 years of age. Although there is no cure for the disease, analysis of the blood serum for a deficiency of the lysosomal enzyme, hexosaminidase A, which is deficient in Tay-Sachs disease, allows for accurate identification of the genetic carriers for the disease.

X-Linked Disorders

Sex-linked disorders are almost always associated with the X, or female, chromosome, and the inheritance pattern is predominantly recessive. Because of a normal paired gene, female heterozygotes rarely experience the effects of a defective gene. The common pattern of inheritance is one in which an unaffected mother carries one normal and one mutant allele on the X chromosome. This means that she has a 50% chance of transmitting the defective gene to her sons, and her daughters have a 50% chance of being carriers of the mutant gene. When the affected son procreates, he transmits the defective gene to all of his daughters, who become carriers of the mutant gene. Because the genes of the Y chromosome are unaffected, the affected male does not transmit the defect to any of his sons, and they will not be carriers or transmit the disorder to their children. X-linked recessive disorders include the fragile X syndrome, glucose-6-phosphate dehydrogenase deficiency (see Chapter 13), hemophilia A (see Chapter 12), and X-linked agammaglobulinemia (see Chapter 10).

Fragile X Syndrome. Fragile X syndrome is an X-linked disorder associated with a fragile site on the X chromosome where the chromatin fails to condense during mitosis. As with other X-linked disorders, fragile X syndrome affects males more often than females. The disorder, which affects approximately 1 in 1000 male infants, is the second most common cause of mental retardation, after Down syndrome.⁷

Affected males are mentally retarded and share a common physical phenotype that includes a long face with large mandible; large, everted ears; and large testicles (macroorchidism). Hyperextensible joints, a high-arched palate, and mitral valve prolapse, which is observed in some cases, mimic a connective tissue disorder. Some physical abnormalities may be subtle or absent. The most distinctive feature, which is present in 90% of prepubertal males, is macroorchidism.^{5,8}

In 1991, the fragile X syndrome was mapped to a small area on the X chromosome (Xq27), now designated FMR-1 (fragile X, mental retardation 1) site.⁷ The mechanism by which the normal FMR-1 gene is converted to an altered, or mutant, gene capable of producing disease symptoms involves an increase in the length of the gene. A small region of the gene that contains the CCG triplet code undergoes repeated duplication, resulting in a longer gene. The longer gene is susceptible to methylation, a chemical process that results in inactivation of the gene. When the number of repeats is small (<200), the person often has few or no manifestations of the disorder, compared with those evidenced in persons with a larger number of repeats.

In fragile X families, the probability of being affected with the disorder is related to the position in the pedigree. Later generations are more likely to be affected than earlier generations. For example, brothers of transmitting males are at a 9% risk of having mental retardation, whereas grandsons of transmitting males are at a 40% risk.⁵ Approximately 20% of males who have been shown to carry the fragile X mutation are clinically and cytogenetically normal. Because male carriers transmit the trait through all their daughters (who are phenotypically normal) to affected grandchildren, they are called *transmitting males*. Approximately 50% of female carriers are affected (mentally retarded), a proportion that is higher than with other Xlinked disorders.⁵

Multifactorial Inheritance Disorders

Multifactorial inheritance disorders are caused by multiple genes and, in many cases, environmental factors. The exact number of genes contributing to multifactorial traits is not known, and these traits do not follow a clear-cut pattern of inheritance, as do single-gene disorders. Multifactorial inheritance has been described as a threshold phenomenon in which the factors contributing to the trait might be compared with water filling a glass.9 Using this analogy, one might say that expression of the disorder occurs when the glass overflows. Disorders of multifactorial inheritance can be expressed during fetal life and be present at birth, or they may be expressed later in life. Congenital disorders that are thought to arise through multifactorial inheritance include cleft lip or palate, clubfoot, congenital dislocation of the hip, congenital heart disease, pyloric stenosis, and urinary tract malformation. Environmental factors are thought to play a significant role in disorders of multifactorial inheritance that develop in adult life, such as coronary artery disease, diabetes mellitus, hypertension, cancer, and common psychiatric disorders such as manic-depressive psychoses and schizophrenia.

Although multifactorial traits cannot be predicted with the same degree of accuracy as the mendelian single-gene mutations, characteristic patterns exist. First, multifactorial congenital malformations tend to involve a single organ or tissue derived from the same embryonic developmental field. Second, the risk of recurrence in future pregnancies is for the same or a similar defect. This means that parents of a child with a cleft palate defect have an increased risk of having another child with a cleft palate, but not with spina bifida. Third, the increased risk (compared with the general population) among first-degree relatives of the affected person is 2% to 7%, and among second-degree relatives, it is approximately one-half that amount.5 The risk increases with increasing incidence of the defect among relatives. This means that the risk is greatly increased when a second child with the defect is born to a couple. The risk also increases with severity of the disorder and when the defect occurs in the sex not usually affected by the disorder.

Chromosomal Disorders

Chromosomal disorders form a major category of genetic disease, accounting for a large proportion of reproductive wastage (early gestational abortions), congenital malformations, and mental retardation. Specific chromosomal abnormalities can be linked to more than 60 identifiable syndromes that are present in 0.7% of all live births, 2% of all pregnancies in women older than 35 years of age, and 50% of all firstterm abortions.³

During cell division (*i.e.*, mitosis) in nongerm cells, the chromosomes replicate so that each cell receives a full diploid number. In germ cells, a different form of division (*i.e.*, meiosis) takes place. During meiosis, the double sets of 22 autosomes and the 2 sex chromosomes (normal diploid number) are reduced to single sets (haploid number) in each gamete. At the time of conception, the haploid number in the ovum and that in the sperm join and restore the diploid number of chromosomes. Chromosomal defects usually develop because of defective movement during meiosis or because of breakage of a chromosome with loss or translocation of genetic material.

Chromosome abnormalities are commonly described according to the shorthand description of the karyotype. In this system, the total number of chromosomes is given first, followed by the sex chromosome complement, and then the description of any abnormality. For example, a male with trisomy 21 is designated 47,XY,+21.

Alterations in Chromosome Duplication

Mosaicism is the presence in one individual of two or more cell lines characterized by distinctive karyotypes. This defect results from an accident during chromosomal duplication. Sometimes, mosaicism consists of an abnormal karyotype and a normal one, in which case the physical deformities caused by the abnormal cell line usually are less severe.

Alterations in Chromosome Number

A change in chromosome number is called *aneuploidy*. Among the causes of aneuploidy is failure of the chromosomes to separate during oogenesis or spermatogenesis. This can occur in the autosomes or the sex chromosomes and is called nondisjunction. Nondisjunction gives rise to germ cells that have an even number of chromosomes (22 or 24). The products of conception formed from this even number of chromosomes have an uneven number of chromosomes, 45 or 47. Monosomy refers to the presence of only one member of a chromosome pair. The defects associated with monosomy of the autosomes are severe and usually cause abortion. Monosomy of the X chromosome (45,X/O), or Turner's syndrome, causes less severe defects. Polysomy, or the presence of more than two chromosomes to a set, occurs when a germ cell containing more than 23 chromosomes is involved in conception. This defect has been described for the autosomes and the sex chromosomes. Trisomies of chromosomes 8, 13, 18, and 21 are the more common forms of polysomy of the autosomes. There are several forms of polysomy of the sex chromosomes in which extra X or Y chromosomes are present.

Trisomy 21. First described in 1866 by John Langon Down, trisomy 21, or Down syndrome, causes a combination of birth defects, including characteristic facial features, some degree of mental retardation, and other health problems. According to the National Down Syndrome Association, it is the most common chromosomal disorder, occurring approximately once in every 800 to 1000 births. Currently, there are approximately 350,000 people in the United States with Down syndrome.¹⁰

Approximately 95% of cases of Down syndrome are caused by nondisjunction or an error in cell division during meiosis, resulting in a trisomy of chromosome 21. Most of the remaining cases are due to a translocation in which part of chromosome 21 breaks off and attaches to another chromosome (usually chromosome 14). Although there still are only 46 chromosomes in the cell, the presence of the extra part of chromosome 21 causes the features of Down syndrome.

The risk of having a child with Down syndrome increases with maternal age: it is 1/1300 at 25 years of age, 1/365 at 35 years, and 1/30 at 45 years of age.¹¹ The reason for the correlation between maternal age and nondisjunction is unknown, but is thought to reflect some aspect of aging of the oocyte. Although males continue to produce sperm throughout their reproductive life, females are born with all the oocytes they ever will have. These oocytes may change as a result of the aging process. With increasing age, there is a greater chance of a woman having been exposed to damaging environmental agents such as drugs, chemicals, and radiation.

56 Unit One: Mechanisms of Disease

The physical features of a child with Down syndrome are distinctive, and therefore the condition usually is apparent at birth. These features include a small and rather square head. There is upward slanting of the eyes; small, low-set, and malformed ears; a fat pad at the back of the neck; an open mouth; and a large, protruding tongue (Fig. 4-6). The child's hands usually are short and stubby, with fingers that curl inward, and there usually is only a single palmar (*i.e.*, simian) crease. Hypotonia and joint laxity also are present in infants and young children. There often are accompanying congenital heart defects and an increased risk of gastrointestinal malformations. Approximately 1% of persons with trisomy 21 Down syndrome have mosaicism (i.e., cell populations with the normal chromosome number and trisomy 21); these persons may be less severely affected. Of particular concern is the much greater risk of development of acute leukemia among children with Down syndrome-10 to 20 times greater than that of other children.5 With increased life expectancy due to improved health care, it has been found that there is an increased risk of Alzheimer's disease among older persons with Down syndrome.

There are several prenatal screening tests that can be done to determine the risk of having a child with Down syndrome. The most commonly used test is the triple screen— α -fetoprotein (AFP), human chorionic gonadotropin (HCG), and unconjugated estriol. The results of these tests, which usually are done between 15 and 20 weeks of gestation, together with the woman's age often are used to determine the probability of a pregnant woman having a child with Down syndrome. These tests are able to accurately detect only approximately 60% of fetuses with Down syndrome. Some women are given falsepositive readings, and some are given false-negative readings. In 1992, fetal nuchal (back of neck) translucency, as measured by ultrasonography in the first trimester, was proposed as another screening measure; the nucha was found to be thicker in fetuses with Down syndrome.12 This test, which must be done by a highly trained professional, continues to be investigated as a screening method. The only way to accurately determine

■ **FIGURE 4-6** ■ A child with Down syndrome. (Courtesy of March of Dimes Birth Defects Foundation, White Plains, NY)

the presence of Down syndrome in the fetus is through chromosome analysis using chorionic villus sampling, amniocentesis, or percutaneous umbilical blood sampling.

Monosomy X. Monosomy X, or Turner's syndrome, describes a monosomy of the X chromosome (45,X/0) with gonadal agenesis, or absence of the ovaries. This disorder affects approximately 1 of every 2500 live births, and it has been estimated that more than 99% of fetuses with the 45,X/0 karyotype are spontaneously aborted during the first trimester.¹³ There are variations in the syndrome, with abnormalities ranging from essentially none to webbing of the neck with redundant skin folds, nonpitting lymphedema of the hands and feet, and congenital heart defects, particularly coarctation of the aorta. There also may be abnormalities in kidney development (*i.e.*, abnormal location, abnormal vascular supply, or double collecting system). There may be other abnormalities, such as changes in nail growth, high-arched palate, short fourth metacarpal, and strabismus.

Characteristically, the female with Turner's syndrome is short in stature, but her body proportions are normal. She does not menstruate and shows no signs of secondary sex characteristics. When a mosaic cell line (*i.e.*, 45,X/0 and 46,X/X or 45,X/0 and 46,X/Y) is present, the manifestations associated with the chromosomal defect tend to be less severe.

Administration of female sex hormones (*i.e.*, estrogens) is used to promote development of secondary sexual characteristics and produce additional skeletal growth in women with Turner's syndrome. Growth hormone also may be used to increase skeletal growth.¹⁴

The diagnosis of Turner's syndrome often is delayed until late childhood or early adolescence in girls who do not present with the classic features of the syndrome.¹⁵ Early diagnosis is an important aspect of treatment for Turner's syndrome. It allows for counseling about the phenotypic characteristics of the disorder; screening for cardiac, renal, thyroid, and other abnormalities; provision of emotional support for the girl and her family; and planning for growth hormone therapy, if appropriate.13 Because of the potential for delay in diagnosis, it has been recommended that girls with unexplained short stature (height below the fifth percentile), webbed neck, peripheral lymphedema, coarctation of the aorta, or delayed puberty have chromosome studies done. In addition, chromosome analysis should be considered for girls who remain above the fifth percentile but have two or more features of Turner's syndrome, including high palate, nail deformities, short fourth metacarpal, and strabismus.15

Polysomy X. Polysomy X, or Klinefelter's syndrome, is a condition of testicular dysgenesis accompanied by the presence of one or more extra X chromosomes in excess of the normal male XY complement. Most males with Klinefelter's syndrome have one extra X chromosome (XXY). In rare cases, there may be more than one extra X chromosome (XXYY). The syndrome is characterized by enlarged breasts, sparse facial and body hair, small testes, and the inability to produce sperm.¹⁵ Regardless of the number of X chromosomes present, the male phenotype is retained. Based on studies conducted in the 1970s, including one sponsored by the National Institutes of Health and Human Development that checked the chromosomes of more than 40,000 infants, it has been estimated that

Chapter 4: Genetic and Congenital Disorders

57

the XXY syndrome is one of the most common genetic abnormalities known, occurring as frequently as 1 in 500 to 1 in 1000 male births.¹⁶ Although the presence of the extra chromosome is fairly common, the syndrome with its accompanying signs and symptoms that may result from the extra chromosome is uncommon. Many men live their lives without being aware that they have an additional chromosome. For this reason, it has been suggested that the term *Klinefelter's syndrome* be replaced with XXY male.

The condition often goes undetected at birth. The infant usually has normal male genitalia, with a small penis and small, firm testicles. At puberty, the intrinsically abnormal testes do not respond to stimulation from the gonadotropins and undergo degeneration. This leads to a tall stature with abnormal body proportions in which the lower part of the body is longer than the upper part. Later in life, the body build may become heavy, with a female distribution of subcutaneous fat and variable degrees of breast enlargement. There may be deficient secondary male sex characteristics, such as a voice that remains feminine in pitch and sparse beard and pubic hair. There may be sexual dysfunction along with the complete infertility that occurs owing to the inability to produce sperm. Regular administration of testosterone, beginning at puberty, can promote more normal growth and development of secondary sexual characteristics. Although the intellect usually is normal, most XXY males have some degree of language impairment. They often learn to talk later than do other children and often have trouble with learning to read and write.

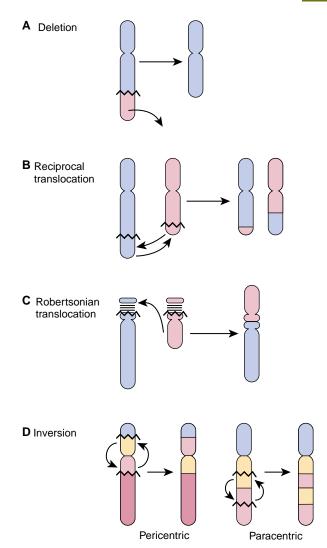

The presence of the extra X chromosome in the XXY male results from nondisjunction during meiotic division in one of the parents. The additional X chromosome (or chromosomes) is of maternal origin in approximately two thirds of cases and of paternal origin in the remaining one third.⁴ The cause of the nondisjunction is unknown. Advanced maternal age increases the risk, but only slightly.

Alterations in Chromosome Structure

Aberrations in chromosome structure occur when there is a break in one or more of the chromosomes followed by rearrangement or deletion of the chromosome parts. Among the factors believed to cause chromosome breakage are exposure to radiation sources, such as x-rays; influence of certain chemicals; extreme changes in the cellular environment; and viral infections.

Several patterns of chromosome breakage and rearrangement can occur (Fig. 4-7). There can be a *deletion* of the broken portion of the chromosome. When one chromosome is involved, the broken parts may be *inverted*. *Isochromosome formation* occurs when the centromere, or central portion, of the chromosome separates horizontally instead of vertically. *Ring formation* results when deletion is followed by uniting of the chromatids to form a ring. *Translocation* occurs when there are simultaneous breaks in two chromosomes from different pairs, with exchange of chromosome parts. With a balanced reciprocal translocation, no genetic information is lost; therefore, persons with translocations usually are normal. However, these persons are translocation carriers and may have normal and abnormal children.

A special form of translocation called a *centric fusion* or *Robertsonian translocation* involves two acrocentric chromosomes in which the centromere is near the end. Typically, the

■ FIGURE 4-7 ■ Examples of structural abnormalities of human chromosomes: (A) deletion of part of a chromosome leads to loss of genetic material and shortening of the chromosome; (B) a reciprocal translocation involves breaks in two nonhomologous chromosomes, with exchange of the acentric segment; (C) robertsonian translocation in which two nonhomologous chromosomes break near their centromeres, after which the long arms fuse to form one large metacentric chromosome; (D) inversion, which requires two breaks in a single chromosome with inversion to the opposite side of the centromere (pericentric), or paracentric if the breaks are on the same arm. (Adapted from Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 225]. Philadelphia: Lippincott Williams & Wilkins)

break occurs near the centromere affecting the short arm in one chromosome and the long arm in the other. Transfer of the chromosome fragments leads to one long and one extremely short chromosome. The short fragments commonly are lost. In this case, the person has only 45 chromosomes, but the amount of genetic material that is lost is so small that it often goes unnoticed. However, difficulty arises during meiosis; the result is gametes with an unbalanced number of chromosomes.

A rare form of Down syndrome can occur in the offspring of persons in whom there has been a translocation involving the long arm of chromosome 21q and the long arm of one of the acrocentric chromosomes (most often 14 or 22). The translocation adds to the normal long arm of chromosome 21; therefore, the person with this type of Down syndrome has 46 chromosomes, but essentially a trisomy of 21q.³

The manifestations of aberrations in chromosome structure depend to a great extent on the amount of genetic material that is lost. Many cells sustaining unrestored breaks are eliminated within the next few mitoses because of deficiencies that may in themselves be fatal. This is beneficial because it prevents the damaged cells from becoming a permanent part of the organism or, if it occurs in the gametes, from giving rise to grossly defective zygotes. Some altered chromosomes, such as those that occur with translocations, are passed on to the next generation.

In summary, genetic disorders can affect a single gene (mendelian inheritance) or several genes (polygenic inheritance). Single-gene disorders may be present on an autosome or on the X chromosome and they may be expressed as a dominant or recessive trait. In autosomal dominant disorders, a single mutant allele from an affected parent is transmitted to an offspring regardless of sex. The affected parent has a 50% chance of transmitting the disorder to each offspring. Autosomal recessive disorders are manifested only when both members of the gene pair are affected. Usually, both parents are unaffected but are carriers of the defective gene. Their chances of having an affected child are one in four; of having a carrier child, two in four; and of having a noncarrier unaffected child, one in four. Sex-linked disorders, which are associated with the X chromosome, are those in which an unaffected mother carries one normal and one mutant allele on the X chromosome. She has a 50% chance of transmitting the defective gene to her sons, and her daughters have a 50% chance of being carriers of the mutant gene. Because of a normal paired gene, female heterozygotes rarely experience the effects of a defective gene. Multifactorial inheritance disorders are caused by multiple genes and, in many cases, environmental factors.

Chromosomal disorders result from a change in chromosome number or structure. A change in chromosome number is called *aneuploidy*. *Monosomy* involves the presence of only one member of a chromosome pair; it is seen in Turner's syndrome, in which there is monosomy of the X chromosome. *Polysomy* refers to the presence of more than two chromosomes in a set. Klinefelter's syndrome involves polysomy of the X chromosome. Trisomy 21 (*i.e.*, Down syndrome) is the most common form of chromosome disorder. Alterations in chromosome structure involve deletion or addition of genetic material, which may involve a translocation of genetic material from one chromosome pair to another.

DISORDERS DUE TO ENVIRONMENTAL INFLUENCES

The developing embryo is subject to many nongenetic influences. After conception, development is influenced by the environmental factors that the embryo shares with the mother. The physiologic status of the mother—her hormone balance, her general state of health, her nutritional status, and the drugs she takes—undoubtedly influences the development of the unborn child. For example, diabetes mellitus is associated with increased risk of congenital anomalies. Smoking is associated with lower than normal neonatal weight. Alcohol, in the context of chronic alcoholism, is known to cause fetal abnormalities. Some agents cause early abortion. Measles and other infectious agents cause congenital malformations. Other agents, such as radiation, can cause chromosomal and genetic defects and produce developmental disorders.

Period of Vulnerability

The embryo's development is most easily disturbed during the period when differentiation and development of the organs are taking place. This time interval, which is often referred to as the period of *organogenesis*, extends from day 15 to day 60 after conception. Environmental influences during the first 2 weeks after fertilization may interfere with implantation and result in abortion or early resorption of the products of conception. Each organ has a critical period during which it is highly susceptible to environmental derangements (Fig. 4-8). Often, the effect is expressed at the biochemical level just before the organ begins to develop. The same agent may affect different organ systems that are developing at the same time.

Teratogenic Agents

A teratogenic agent is an environmental agent that produces abnormalities during embryonic or fetal development. It is important to remember that, in this case, the environment is that of the embryo and fetus. Maternal disease or altered metabolic state also can affect the environment of the embryo or fetus. For discussion purposes, teratogenic agents have been divided into three groups: radiation, drugs and chemical substances, and infectious agents. Chart 4-1 lists commonly identified agents in each of these groups. Theoretically, environmental agents can cause birth defects in three ways: by direct exposure of the pregnant woman and the embryo or fetus to the agent; through exposure of the soon-to-be-pregnant woman with an agent that has a slow clearance rate such that a teratogenic dose is retained during early pregnancy; or as a result of mutagenic effects of an environmental agent that occur before pregnancy, causing permanent damage to a woman's (or a man's) reproductive cells.

Radiation

Heavy doses of ionizing radiation have been shown to cause microcephaly, skeletal malformations, and mental retardation. There is no evidence that diagnostic levels of radiation cause congenital abnormalities. However, because the question of safety remains many agencies require that the day of a woman's last menstrual period be noted on all radiologic requisitions. Other institutions may require a pregnancy test before any extensive diagnostic x-ray studies are performed. Radiation is teratogenic and mutagenic, and there is the possibility of effecting inheritable changes in genetic materials. Administration of therapeutic doses of radioactive iodine (¹³¹I) during the 13th week of gestation, the time when the fetal thyroid is beginning to concentrate iodine, has been shown to interfere with thyroid development.

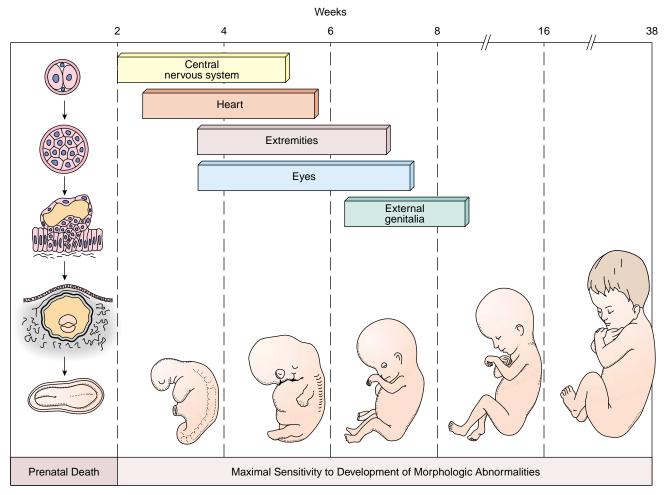

FIGURE 4-8 Sensitivity of specific organs to teratogenic agents at critical periods in embryogenesis. Exposure of adverse influences in the preimplantation and early postimplantation stages of development (*far left*) leads to prenatal death. Periods of maximal sensitivity to teratogens (*horizontal bars*) vary for different organ systems but overall are limited to the first 8 weeks of pregnancy. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 216]. Philadelphia: Lippincott Williams & Wilkins)

Chemicals and Drugs

Environmental chemicals and drugs can cross the placenta and cause damage to the developing embryo and fetus. It has been estimated that only 2% to 3% of developmental defects have a known drug or environmental origin. Some of the best-

KEY CONCEPTS

TERATOGENIC AGENTS

- Teratogenic agents such as radiation, chemicals and drugs, and infectious organisms are agents that produce abnormalities in the developing embryo.
- The stage of development of the embryo determines the susceptibility to teratogens. The period during which the embryo is most susceptible to teratogenic agents is the time during which rapid differentiation and development of body organs and tissues are taking place, usually from days 15 to 60 postconception.

documented environmental teratogens are the organic mercurials, which cause neurologic deficits and blindness. Sources of exposure to mercury include contaminated food (fish) and water.¹⁷ The precise mechanism by which chemicals and drugs exert their teratogenic effects is largely unknown. They may produce cytotoxic (cell-killing), antimetabolic, or growthinhibiting properties. Often their effects depend on the time of exposure (in terms of embryonic and fetal development) and extent of exposure (dosage).

Drugs top the list of chemical teratogens, probably because they are regularly used at elevated doses. Most drugs can cross the placenta and expose the fetus to both the pharmacologic and teratogenic effects. Factors that affect placental drug transfer and drug effects on the fetus include the rate at which the drug crosses the placenta, the duration of exposure, and the stage of placental and fetal development at the time of exposure.¹⁸ Lipid-soluble drugs tend to cross the placenta more readily and enter the fetal circulation. The molecular weight of a drug also influences the rate of transfer and the amount of drug transferred across the placenta. Drugs with a molecular weight less than 500 can cross the placenta easily, depending on lipid solubility and degree of ionization; those with a

molecular weight of 500 to 1000 cross the placenta with more difficulty; and those with molecular weights greater than 1000 cross very poorly.¹⁸

A number of drugs are suspected of being teratogens, but only a few have been identified with certainty.¹⁹ Perhaps the best known of these drugs is thalidomide, which has been shown to give rise to a full range of malformations, including phocomelia (i.e., short, flipper-like appendages) of all four extremities. Other drugs known to cause fetal abnormalities are the antimetabolites that are used in the treatment of cancer, the anticoagulant drug warfarin, several of the anticonvulsant drugs, ethyl alcohol, and cocaine. Some drugs affect a single developing structure; for example, propylthiouracil can impair thyroid development and tetracycline can interfere with the mineralization phase of tooth development. More recently, vitamin A and its derivatives (the retinoids) have been targeted for concern because of their teratogenic potential. Concern over the teratogenic effects of vitamin A derivatives became evident with the introduction of the acne drug isotretinoin (Accutane). Fetal abnormalities such as cleft palate, heart defects, retinal and optic nerve abnormalities, and central nervous system malformations were observed in women ingesting therapeutic doses of the drug during the first trimester of pregnancy.²⁰ There also is concern about the teratogenic effects when a woman consumes high doses of vitamin A, such as those contained in some dietary supplements or vitamin pills. It is currently recommended that doses greater than 10,000 IU should be avoided.21

In 1983, the U.S. Food and Drug Administration established a system for classifying drugs according to probable risks to the fetus. According to this system, drugs are put into five categories: A, B, C, D, and X. Drugs in category A are the least dangerous, and categories B, C, and D are increasingly more dangerous. Those in category X are contraindicated during pregnancy because of proven teratogenicity.²² The law does not require classification of drugs that were in use before 1983.

Because many drugs are suspected of causing fetal abnormalities, and even those that were once thought to be safe are now being viewed critically, it is recommended that women in their childbearing years avoid unnecessary use of drugs. This pertains to nonpregnant women as well as pregnant women because many developmental defects occur early in pregnancy. As happened with thalidomide, the damage to the embryo may occur before pregnancy is suspected or confirmed. Two drugs of particular importance are alcohol and cocaine.

Fetal Alcohol Syndrome. The term *fetal alcohol syndrome* (FAS) refers to a constellation of physical, behavioral, and cognitive abnormalities resulting from maternal alcohol consumption. It has been reported that 1 in 1000 infants born in the United States manifests some characteristics of the syndrome.²³ Alcohol, which is lipid soluble and has a molecular weight between 600 and 1000, passes freely across the placental barrier; concentrations of alcohol in the fetus are at least as high as in the mother. Unlike other teratogens, the harmful effects of alcohol are not restricted to the sensitive period of early gestation but extend throughout pregnancy.

Alcohol has widely variable effects on fetal development, ranging from minor abnormalities to FAS. Criteria for defining FAS were standardized by the Fetal Alcohol Study Group of the Research Society on Alcoholism in 1980,24 and modifications were proposed in 1989 by Sokol and Clarren.²⁵ The proposed criteria are prenatal or postnatal growth retardation (i.e., weight or length below the 10th percentile); central nervous system involvement, including neurologic abnormalities, developmental delays, behavioral dysfunction, intellectual impairment, and skull and brain malformation; and a characteristic face with short palpebral fissures (*i.e.*, eve openings), a thin upper lip, and an elongated, flattened midface and philtrum (*i.e.*, the groove in the middle of the upper lip). The facial features of FAS may not be as apparent in the newborn but become more prominent as the infant develops. As the children grow into adulthood, the facial features become more subtle, making diagnosis of FAS in older individuals more difficult.²⁶ Each of these defects can vary in severity, probably reflecting the timing of alcohol consumption in terms of the period of fetal development, amount of alcohol consumed, and hereditary and environmental influences. Because of problems with terminology and the diagnostic criteria, the Institute of Medicine in 1996 proposed the terms alcohol-related neurodevelopmental disorder (ARND) and alcoholrelated birth defects (ARBD) to describe conditions in which there is a history of maternal alcohol consumption.²⁷ This new terminology uses pathophysiologic diagnostic categories to describe the conditions resulting from confirmed alcohol exposure. For example, facial abnormalities, growth retardation, and central nervous system abnormalities would be classified as FAS; central nervous system and cognitive abnormalities would be classified as ARND; and birth defects as ARBD.²⁸

The mechanisms whereby alcohol exerts its teratogenic effects are unclear. Evidence suggests that the effects of alcohol observed in children with FAS are related to the timing of alcohol consumption and peak alcohol dose.

The amount of alcohol that can be safely consumed during pregnancy also is unknown. Animal studies suggest that the fetotoxic effects of alcohol are dose dependent, rather than threshold dependent. Studies suggest that even three drinks per day may be associated with a lower IQ at 4 years of age.²⁹ However, it may be that the time during which alcohol is consumed is equally important. Even small amounts of alcohol consumed during critical periods of fetal development may be teratogenic. For example, if alcohol is consumed during the period of organogenesis, a variety of skeletal and organ defects may result. When alcohol is consumed later in gestation, when the brain is undergoing rapid development, there may be behavioral and cognitive disorders in the absence of physical abnormalities. Chronic alcohol consumption throughout pregnancy may result in a variety of effects, ranging from physical abnormalities to growth retardation and compromised central nervous system functioning. Evidence suggests that short-lived high concentrations of alcohol such as those that occur with binge drinking may be particularly significant, with abnormalities being unique to the period of exposure. The recommendation of the U.S. Surgeon General is that women abstain from alcohol during pregnancy.30

Cocaine Babies. Of concern is the increasing use of cocaine by pregnant women. In 1992, approximately 45,000 women in this country used cocaine during their pregnancy.³¹ Determining exposure of infants to maternal cocaine use often is difficult. In utero exposure often is ascertained by testing maternal urine for cocaine and its metabolites and by interviewing the mother. Urine testing provides evidence only of recent cocaine use, and information from an interview may be inaccurate. Urine testing of infants provides evidence only of recent exposure to cocaine.

Among the effects of cocaine use during pregnancy is a decrease in uteroplacental blood flow, maternal hypertension, stimulation of uterine contractions, and fetal vasoconstriction. The decrease in uteroplacental blood flow is associated with an increase in preterm births, intrauterine growth retardation, microcephaly, and neurologic abnormalities.^{32,33} Furthermore, there appears to be a dose-related relationship between increasing levels of chronic cocaine abuse and impaired fetal growth and neurologic function.33 Maternal hypertension may increase the risk of abruptio placentae, particularly if it is accompanied by a decrease in uteroplacental blood flow.³¹ Fetal vasoconstriction has been suggested as the cause of fetal anomalies, particularly limb reduction defects and urogenital tract defects such as hydronephrosis, hypospadias, and undescended testicles, as well as ambiguous genitalia.^{34,35} Exposure of the fetus to cocaine also may lead to destructive lesions of the brain, including cerebral infarction and intracranial hemorrhage. Sudden infant death syndrome (SIDS) also has been more common in infants of mothers who have used cocaine during their pregnancy.36

Although the immediate effects of maternal cocaine use on infant behavior are being reported, the long-term effects are

largely unknown. Unfortunately, cocaine addiction often affects the behavior of the pregnant woman to the extent that the need to procure larger amounts of the drug overwhelms all other considerations of maternal and fetal well-being; other factors such as malnutrition, use of other drugs and teratogens, and lack of prenatal care also may contribute to fetal disorders.

Folic Acid Deficiency. Although most birth defects are related to exposure to a teratogenic agent, deficiencies of nutrients and vitamins also may be a factor. Folic acid deficiency has been implicated in the development of neural tube defects (e.g., anencephaly, spina bifida, encephalocele). Studies have shown a reduction in neural tube defects when folic acid was taken before conception and continued during the first trimester of pregnancy.^{37,38} The Public Health Service recommends that all women of childbearing age should take 400 micrograms (μg) of folic acid daily. It has been suggested that this recommendation may help to prevent as many as 50% of neural tube defects.³⁹ The Institute of Medicine Panel for Folate and Other B Vitamins and Choline has recently revised the Recommended Dietary Allowance for pregnant women to 600 µg.40 These recommendations are particularly important for women who have previously had an affected pregnancy, for couples with a close relative with the disorder, and for women with diabetes mellitus and those taking anticonvulsant drugs who are at increased risk for having infants with birth defects.

Since 1998, all enriched cereal grain products in the United States have been fortified with folic acid. To achieve an adequate intake of folic acid, pregnant women should couple a diet that contains folate-rich foods (*e.g.*, orange juice, dark, leafy green vegetables, and legumes) with sources of synthetic folic acid, such as fortified food products.⁴⁰

Infectious Agents

Many microorganisms cross the placenta and enter the fetal circulation, often producing multiple malformations. The acronym TORCH stands for toxoplasmosis, other, rubella (*i.e.*, German measles), cytomegalovirus, and herpes, which are the agents most frequently implicated in fetal anomalies.³ Other infections include varicella-zoster virus infection, listeriosis, leptospirosis, Epstein-Barr virus infection, tuberculosis, and syphilis. The TORCH screening test examines the infant's serum for the presence of antibodies to these agents. These infections tend to cause similar clinical manifestations, including microcephaly, hydrocephalus, defects of the eye, and hearing problems.

Toxoplasmosis is a protozoal infection that can be contracted by eating raw or poorly cooked meat. The domestic cat also seems to carry the organism, excreting the protozoa in its stools. It has been suggested that pregnant women should avoid contact with excrement from the family cat. The introduction of the rubella vaccine in the United States has virtually eliminated congenital rubella. The epidemiology of cytomegalovirus infection is largely unknown. Some infants are severely affected at birth, and others, although having evidence of the infection, have no symptoms. In some symptomfree infants, brain damage becomes evident over a span of several years. There also is evidence that some infants contract the infection during the first year of life, and in some of them the infection leads to retardation a year or two later. Herpes simplex type 2 infection is considered to be a genital infection and usually is transmitted through sexual contact. The infant acquires this infection in utero or in passage through the birth canal.

In summary, a teratogenic agent is one that produces abnormalities during embryonic or fetal life. It is during the early part of pregnancy (15 to 60 days after conception) that environmental agents are most apt to produce their deleterious effects on the developing embryo. A number of environmental agents can be damaging to the unborn child, including radiation, drugs and chemicals, and infectious agents. FAS is a risk for infants of women who regularly consume alcohol during pregnancy. Of recent concern is the use of cocaine by pregnant women. Because many drugs have the potential for causing fetal abnormalities, often at an early stage of pregnancy, it is recommended that women of childbearing age avoid unnecessary use of drugs. It also has been shown that folic acid deficiency can contribute to neural tube defects. The acronym TORCH stands for toxoplasmosis, other, rubella, cytomegalovirus, and herpes, which are the infectious agents most frequently implicated in fetal anomalies.

REVIEW QUESTIONS

Explain the difference between a hereditary and congenital defect.

Contrast disorders attributable to multifactorial inheritance with those caused by single-gene inheritance.

Describe two chromosomal abnormalities that demonstrate aneuploidy.

Relate maternal age and the occurrence of Down syndrome.

Cite the most susceptible period of intrauterine life for development of defects caused by environmental agents.

State the cautions that should be observed when considering the use of drugs during pregnancy.

Describe the effects of alcohol and cocaine abuse on fetal development and birth outcomes.

List four infectious agents that cause congenital defects.

ancer is the second leading cause of death in the United States after cardiovascular disease. The disease affects all age groups, causing more death in children 3 to 15 years of age than any other disease. The American Cancer Society estimates that 1.3 million Americans will develop cancer in 2003, and that one in two males and one in three females will have cancer during their lifetime. It also is estimated that approximately 556,500 Americans will die in the year from neoplastic diseases.¹ As age-adjusted cancer mortality rates increase and heart disease mortality decreases, it is predicted that cancer will become the leading cause of death in a few decades.² Trends in cancer survival demonstrate that relative 5-year survival rates have improved since the early 1960s. It is estimated that approximately 59% of people who develop cancer each year will be alive 5 years later.

CONCEPTS OF CELL GROWTH

Cancers result from a process of altered cell differentiation and growth. The resulting tissue is called *neoplasia*. The term *neoplasm* comes from a Greek word meaning *new formation*. Unlike the tissue growth that occurs with hypertrophy and hyperplasia, the growth of a neoplasm is uncoordinated and relatively autonomous in that it lacks normal regulatory controls over cell growth and division. Neoplasms tend to increase in size and continue to grow after the stimulus has ceased or the needs of the organism have been met.

Cancer is not a single disease. The term describes almost all forms of malignant neoplasia. Cancer can originate in almost any organ, with the prostate being the most common site in men and the breast in women. The ability of cancer to be cured varies considerably and depends on the type of cancer and the extent of the disease at diagnosis. Cancers such as acute lymphocytic leukemia, Hodgkin's disease, testicular cancer, and osteosarcoma, which only a few decades ago had poor prognoses, are today cured in many cases. However, lung cancer, which is the leading cause of death in men and women in the United States, is resistant to therapy, and although some progress has been made in its treatment, mortality rates remain high.

Tissue renewal and repair involves cell proliferation and differentiation. *Proliferation*, or the process of cell division, is an inherent adaptive mechanism for replacing body cells when old cells die or additional cells are needed. *Differentiation* is the process of specialization whereby new cells acquire the structure and function of the cells they replace. In adult tissues, the size of a population of cells is determined by the rates of cell proliferation, differentiation, and death by apoptosis.³ Apoptosis, which is discussed in Chapter 2, is a form of programmed cell death designed to eliminate senescent cells or unwanted cells. A balance of cellular signals that regulate cell proliferation, differentiation, and apoptosis regulates the size of cell populations.

The Cell Cycle

The cell cycle is the interval between each cell division. It regulates the duplication of genetic information and appropriately aligns the duplicated chromosomes to be received by the daughter cells. In addition, pauses or checkpoints in the cell cycle determine the accuracy with which deoxyribonucleic acid (DNA) is duplicated. These checkpoints allow for any defects to be edited and repaired, thereby assuring that the daughter cells receive the full complement of genetic information, identical to that of the parent cell.³

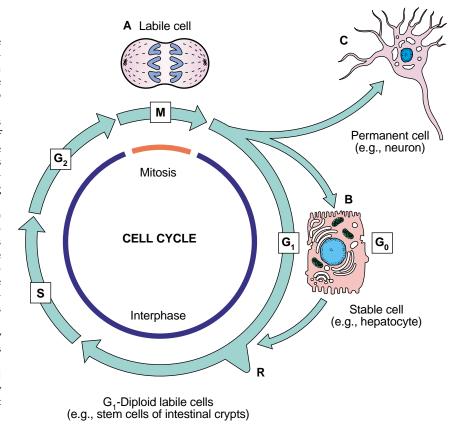

The cell cycle is divided into four distinct phases referred to as G_1 , S, G_2 , and M (Fig. 5-1). G_1 (*gap 1*), is the postmitotic phase during which DNA synthesis ceases while ribonucleic acid (RNA) and protein synthesis and cell growth take place. This is the phase during which cells pursue their own specialized type of function. Some cells such as neurons become terminally differentiated after mitosis and remain in G_1 . Continually dividing cells, such as the crypt cells in the intestinal mucosa, pass through restriction point (R) in G_1 that commits them to progression to the synthesis (S) phase and a new round of cell division. During the S phase, DNA synthesis occurs, giving rise to two separate sets of chromosomes, one for each daughter cell. G_2 (*gap 2*) is the premitotic gap and is similar to G_1 in that DNA synthesis ceases while RNA and protein synthesis continues. The *M phase* is the phase of cellular division or mitosis. Stable cells, such as hepatocytes, enter a quiescent period in the cell cycle, the G_0 gap. These quiescent cells reenter the cell cycle in response to extracellular nutrients, growth factors, hormones, and other signals, such as blood loss or tissue injury, that signal for cell renewal.^{4,5}

The duration of the phases of the cell cycle vary depending on the cell type, the frequency with which the cells divide, and host characteristics, such as the presence of appropriate growth factors. Very rapidly dividing cells can complete the cell cycle in less than 8 hours, whereas others can take longer than 1 year. Most of this variability occurs in the G_0 and G_1 phases. The duration of the S phase (10 to 20 hours), the G_2 phase (2 to 10 hours), and the M phase (0.5 to 1 hour) appears to be relatively constant.⁵

Cell Proliferation

Cell proliferation is the process by which cells divide and reproduce. Cell division provides the body with the means for replacing cells that have a limited life span such as skin and blood cells, increasing tissue mass during periods of growth, and providing for tissue repair and wound healing. In normal

■ FIGURE 5-1 ■ The cell cycle. (A) Labile cells (e.g., intestinal crypt cells) undergo continuous replication and the interval between two consecutive mitoses is designated the cell cycle. After division, the cells enter a gap (G_1) during which DNA synthesis ceases and RNA and protein synthesis takes place as the cell develops its own specialized type of function. Cells that continue in the cell cycle pass the restriction point (R), which commits them to a new round of cell division and continuation to the synthesis (S) phase during which all the chromosomes are replicated. The S phase is followed by the short gap (G_2) during which DNA synthesis ceases and protein synthesis continues. The M phase is the period of mitosis. After each cycle, one daughter cell will become committed to differentiation and the other will continue cycling. (B) Some cell types, such as hepatocytes, are stable. After cell mitosis, the cells take up their specialized functions (G₀) and not reenter the cell cycle unless stimulated by the loss of other cells. (C) Permanent cells (neurons) become terminally differentiated after mitosis and cannot reenter the cell cycle. (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 85]. Philadelphia: Lippincott Williams & Wilkins)

tissue, cell proliferation is regulated so that the number of cells actively dividing is equivalent to the number dying or being shed.

In terms of cell proliferation, the 200 or more cell types of the body can be divided into 3 large groups: the welldifferentiated neurons and cells of skeletal and cardiac muscle that are unable to divide and reproduce; the parent, or progenitor cells, that continue to divide and reproduce, such as blood cells, skin cells, and liver cells; and the undifferentiated stem cells that can be triggered to enter the cell cycle and produce large numbers of progenitor cells when the need arises. The rates of reproduction of these cells vary greatly. White blood cells and cells that line the gastrointestinal tract live several days and must be replaced constantly. In most tissues, the rate of cell reproduction is greatly increased when tissue is injured or lost. For example, bleeding stimulates the rapid reproduction of the blood-forming cells of the bone marrow. In some types of tissue, the genetic program for cell replication normally is repressed but can be resumed under certain conditions. For example, the liver has extensive regenerative capabilities under certain conditions.

Cell Differentiation

Cell differentiation is the process whereby proliferating cells are transformed into different and more specialized cell types. This process leads to a fully differentiated, adult cell that has achieved its specific set of structural, functional, and life expectancy characteristics. For example, a red blood cell is programmed to develop into a concave disk that functions as a vehicle for oxygen transport and lives approximately 120 days.

All of the different cell types of the body originate from a single cell—the fertilized ovum. As the embryonic cells increase in number, they engage in an orderly process of differentiation that is necessary for the development of all the various organs of the body. The process of differentiation is regulated by a combination of internal programming that in-

KEY CONCEPTS

CELL PROLIFERATION AND GROWTH

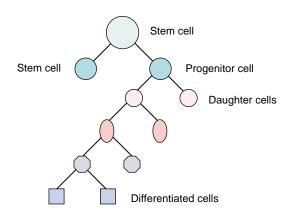

- Tissue growth and repair involve cell proliferation and differentiation.
- Cell proliferation is the process whereby tissues acquire new or replacement cells through cell division.
- Cell differentiation is the orderly process in which proliferating cells are transformed into different and more specialized types. It determines the microscopic characteristics of the cell, how the cell functions, and how long it will live.
- Cells that are fully differentiated are no longer capable of cell division.

volves the expression of specific genes and external stimuli provided by neighboring cells, exposure to substances in the maternal circulation, and a variety of growth factors, nutrients, oxygen, and ions.⁶ What makes the cells of one organ different from those of another organ is the type of gene that is expressed. Although all cells have the same complement of genes, only a small number of these genes are expressed in postnatal life. When cells, such as those of the developing embryo, differentiate and give rise to committed cells of a particular tissue type, the appropriate genes are maintained in an active state while the remainder are inactive. Normally, the rate of cell reproduction and the process of cell differentiation are precisely controlled in prenatal and postnatal life so that both of these mechanisms cease once the appropriate numbers and types of cells are formed.

The process of differentiation occurs in orderly steps; with each progressive step, increased specialization is exchanged for a loss of ability to develop different cell characteristics and different cell lines. The more highly specialized a cell becomes, the more likely it is to lose its ability to undergo mitosis. Neurons, which are the most highly specialized cells in the body, lose their ability to divide and reproduce once development of the nervous system is complete. More important, there are no reserve or parent cells to direct their replacement. However, appropriate numbers of these cell types are generated in the embryo such that loss of a certain percentage of cells does not affect the total cell population. Although these cells never divide and are not replaced if lost, they exist in sufficient numbers to carry out their specific functions. In other, less specialized tissues, such as the skin and mucosal lining, cell renewal continues throughout life.

Even in the continuously renewing cell populations, highly specialized cells are similarly unable to divide. An alternative mechanism provides for their replacement. There are progenitor cells of the same lineage that have not yet differentiated to the extent that they have lost their ability to divide. These cells are sufficiently differentiated that their daughter cells are limited to the same cell line, but they are insufficiently differentiated to preclude the potential for active proliferation. As a result, these parent or progenitor cells are able to provide large numbers of replacement cells. However, the progenitor cells have limited capacity for self-renewal and they become restricted to producing a single type of cell.

Another type of cell, called a stem cell, remains incompletely differentiated throughout life. Stem cells are reserve cells that remain quiescent until there is a need for cell replenishment, in which case they divide, thereby producing other stem cells and cells that can carry out the functions of the differentiated cell (Fig. 5-2). There are several types of stem cells, some of which include the muscle satellite cell, the epidermal stem cell, the spermatogonium, and the basal cell of the olfactory epithelium. These stem cells are unipotent in that they give rise to only one type of differentiated cell. Oligopotent stem cells can produce a small number of cells, and pluripotent stem cells, such as those involved in hematopoiesis, give rise to numerous cell types.⁴ Stem cells are the primary cellular component of bone marrow transplantation, in which the stem cells in the transplanted marrow re-establish the recipient's blood production and immune system. Peripheral blood stem cell transplantation is a transplantation procedure that by-

■ FIGURE 5-2 ■ Mechanism of stem cell-mediated cell replacement. Division of a stem cell with an unlimited potential for proliferation results in one daughter cell, which retains the characteristics of a stem cell, and a second daughter cell, which differentiates into a progenitor or parent cell, with a limited potential for differentiation and proliferation. As the daughter cells of the progenitor cell proliferate, they become more differentiated, until reaching the stage where they are fully differentiated and no longer able to divide.

passes the need for bone marrow infusion by infusing stem cells that have been separated and removed from the donor blood.

In summary, the term *neoplasm* refers to an abnormal mass of tissue in which the growth exceeds and is uncoordinated with that of the normal tissues. Unlike normal cellular adaptive processes such as hypertrophy and hyperplasia, neoplasms do not obey the laws of normal cell growth. They serve no useful purpose, they do not occur in response to an appropriate stimulus, and they continue to grow at the expense of the host.

Cell proliferation is the process whereby cells divide and bear offspring; it normally is regulated so that the number of cells that are actively dividing is equal to the number dying or being shed. The process of cell growth and division is called the *cell cycle*. It is divided into four phases: G_1 , the postmitotic phase, during which DNA synthesis ceases while RNA and protein synthesis and cell growth take place; S, the phase during which DNA synthesis occurs, giving rise to two separate sets of chromosomes; G_2 , the premitotic phase, during which RNA and protein synthesis continues; and M, the phase of cell mitosis or cell division. The G_0 phase is a resting or quiescent phase in which nondividing cells reside.

Cell differentiation is the process whereby cells are transformed into different and more specialized cell types as they proliferate. It determines the structure, function, and life span of a cell. There are three types of cells: well-differentiated cells that are no longer able to divide, progenitor or parent cells that continue to divide and bear offspring, and undifferentiated stem cells that can be recruited to become progenitor cells when the need arises. As a cell line becomes more differentiated, it becomes more highly specialized in its function and less able to divide.

CHARACTERISTICS OF BENIGN AND MALIGNANT NEOPLASMS

Neoplasms are composed of two types of tissue: parenchymal tissue and the stroma or supporting tissue. The *parenchymal cells* represent the functional components of an organ. The *supporting tissue* consists of the connective tissue, blood vessels, and lymph structure. The parenchymal cells of a tumor determine its behavior and are the component for which a tumor is named. The supporting tissue carries the blood vessels and provides support for tumor survival and growth.

Terminology

By definition, a *tumor* is a swelling that can be caused by a number of conditions, including inflammation and trauma. Although they are not synonymous, the terms *tumor* and *neoplasm* often are used interchangeably. Neoplasms usually are classified as benign or malignant. Neoplasms that contain well-differentiated cells that are clustered together in a single mass are considered to be *benign*. These tumors usually do not cause death unless their location or size interferes with vital functions. In contrast, malignant neoplasms are less well differentiated and have the ability to break loose, enter the circulatory or lymphatic systems, and form secondary malignant tumors at other sites. *Malignant neoplasms* usually cause suffering and death if untreated or uncontrolled.

Tumors usually are named by adding the suffix *-oma* to the parenchymal tissue type from which the growth originated. Thus, a benign tumor of glandular epithelial tissue is called an *adenoma*, and a benign tumor of bone tissue is called an *osteoma*. The term *carcinoma* is used to designate a malignant tumor of epithelial tissue origin. In the case of a malignant adenoma, the term *adenocarcinoma* is used. Malignant tumors of mesenchymal origin are called *sarcomas* (*e.g.*, osteosarcoma). *Papillomas* are benign microscopic or macroscopic fingerlike projections that grow on any surface. A *polyp* is a growth that projects from a mucosal surface, such as the intestine. Although the term usually implies a benign neoplasm, some malignant tumors also appear as polyps.³ Oncology is the study of tumors and their treatment. Table 5-1 lists the names of selected benign and malignant tumors according to tissue types.

Benign and malignant neoplasms usually are differentiated by their (1) cell characteristics, (2) manner of growth, (3) rate of growth, (4) potential for metastasizing or spreading to other parts of the body, (5) ability to produce generalized effects, (6) tendency to cause tissue destruction, and (7) capacity to cause death. The characteristics of benign and malignant neoplasms are summarized in Table 5-2.

Benign Neoplasms

Benign tumors are characterized by a slow, progressive rate of growth that may come to a standstill or regress, an expansive manner of growth, the presence of a well-defined fibrous capsule, and failure to metastasize to distant sites. Benign tumors are composed of well-differentiated cells that resemble the cells of the tissue of origin. For example, the cells of a uterine

Characteristics of Benign and Malignant Neoplasms TABLE 5-2

Characteristics	Benign	Malignant
Cell characteristics	Well-differentiated cells that resemble normal cells of the tissue from which the tumor originated	Cells are undifferentiated and often bear little resemblance to the normal cells of the tissue from which they arose
Mode of growth	Tumor grows by expansion and does not infiltrate the surrounding tissues; usually encapsulated	Grows at the periphery and sends out processes that infil- trate and destroy the surrounding tissues
Rate of growth	Rate of growth usually is slow	Rate of growth is variable and depends on level of differ- entiation; the more anaplastic the tumor, the more rapid the rate of growth
Metastasis	Does not spread by metastasis	Gains access to the blood and lymph channels and metas- tasizes to other areas of the body
General effects	Usually is a localized phenomenon that does not cause generalized effects unless its location interferes with vital functions	Often causes generalized effects such as anemia, weak- ness, and weight loss
Tissue destruction	Usually does not cause tissue damage unless its location interferes with blood flow	Often causes extensive tissue damage as the tumor out- grows its blood supply or encroaches on blood flow to the area; also may produce substances that cause cell damage
Ability to cause death	Usually does not cause death unless its location interferes with vital functions	Usually causes death unless growth can be controlled

leiomyoma resemble uterine smooth muscle cells. For unknown reasons, benign tumors seem to have lost the ability to suppress the genetic program for cell replication but retain the program for normal cell differentiation. Benign tumors grow by expansion and are enclosed in a fibrous capsule. This is in sharp contrast to malignant neoplasms, which grow by infiltrating the surrounding tissue (Fig. 5-3). The capsule is responsible for a sharp line of demarcation between the benign tumor and the adjacent tissues, a factor that facilitates surgical removal. The formation of the capsule is thought to represent the reaction of the surrounding tissues to the tumor.⁶

Benign tumors do not undergo degenerative changes as readily as malignant tumors, and they usually do not cause death unless they interfere with vital functions because of their location. For instance, a benign tumor growing in the cranial cavity can eventually cause death by compressing brain structures. Benign tumors also can cause disturbances in the function of adjacent or distant structures by producing pressure on tissues, blood vessels, or nerves. Some benign tumors are also known for their ability to cause alterations in body function through abnormal elaboration of hormones.

KEY CONCEPTS

BENIGN AND MALIGNANT NEOPLASMS

- A tumor is a new growth or neoplasm.
- Benign neoplasms are well-differentiated tumors that resemble the tissues of origin but have lost the ability to control cell proliferation. They grow by expansion, are enclosed in a fibrous capsule, and do not cause death unless their location is such that it interrupts vital body functions.
- Malignant neoplasms are less well-differentiated tumors that have lost the ability to control both cell proliferation and differentiation. They grow in a crablike manner to invade surrounding tissues, have cells that break loose and travel to distant sites to form metastases, and inevitably cause suffering and death unless their growth can be controlled through treatment.

■ FIGURE 5-3 ■ Photographs of a benign encapsulated fibroadenoma of the breast (top) and a bronchogenic carcinoma of the lung (bottom). The fibroadenoma has sharply defined edges, but the bronchogenic carcinoma is diffuse and infiltrates the surrounding tissues.

Malignant Neoplasms

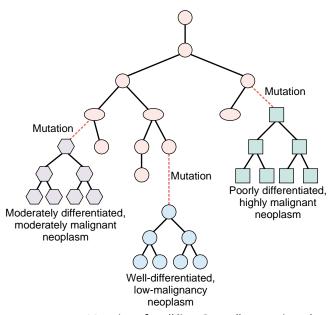

Malignant neoplasms tend to grow rapidly, spread widely, and kill regardless of their original location. Because of their rapid rate of growth, malignant tumors tend to compress blood vessels and outgrow their blood supply, causing ischemia and tissue necrosis; rob normal tissues of essential nutrients; and liberate enzymes and toxins that destroy tumor tissue and normal tissue. The destructive nature of malignant tumors is related to their lack of cell differentiation, cell characteristics, rate of growth, and ability to spread and metastasize.

There are two categories of cancer—solid tumors and hematologic cancers. Solid tumors initially are confined to a specific tissue or organ. As the growth of a solid tumor progresses, cells are shed from the original tumor mass and travel through the blood and lymph system to produce metastasis in distant sites. Hematologic cancers involve the blood-forming cells that naturally migrate to the blood and lymph systems, thereby making them disseminated diseases from the beginning.

Cancer Cell Characteristics

Cancer cells, unlike normal cells, fail to undergo normal cell proliferation and differentiation. It is thought that cancer cells develop from mutations that occur during the differentiation process (Fig. 5-4). When the mutation occurs early in the process, the resulting tumor is poorly differentiated and highly malignant; when it occurs later in the process, better differentiated and less malignant tumors result.

The term *anaplasia* is used to describe the lack of cell differentiation in cancerous tissue. Undifferentiated cancer cells are altered in appearance and nuclear size and shape from the cells in the tissue from which the cancer originated. In descending the scale of differentiation, enzymes and specialized pathways of metabolism are lost and cells undergo functional simplification.³ Highly anaplastic cancer cells, whatever their tissue of origin, begin to resemble each other more than they do their tissue of origin. For example, when examined under the

■ FIGURE 5-4 ■ Mutation of a cell line. Generally, mutations that occur early in the differentiation process result in poorly differentiated neoplasms and those that appear late in the differentiation process result in relatively well-differentiated neoplasms.

microscope, cancerous tissue that originates in the liver does not have the appearance of normal liver tissue. Some cancers display only slight anaplasia, and others display marked anaplasia.

Because cancer cells lack differentiation, they do not function properly, nor do they die in the time frame of normal cells. For example, in some types of leukemia the lymphocytes do not follow the normal developmental process. They do not differentiate fully, acquire the ability to destroy bacteria, or die on schedule. Instead, these long-lived, defective cells continue to grow, crowding the normal developing blood cells, thereby affecting the development of other cell lineages, such as the erythrocytes, platelets, and other white blood cells. This results in reduced numbers of mature, effectively functioning cells, producing white blood cells that cannot effectively fight infection, erythrocytes that cannot effectively transport oxygen to tissues, or platelets that cannot participate in the clotting system.

Alterations in cell differentiation also are accompanied by changes in cell characteristics and cell function that distinguish cancer cells from their fully differentiated normal counterparts. These changes include (1) alterations in contact inhibition, (2) loss of cohesiveness and adhesion, (3) impaired cell-to-cell communication, (4) expression of altered tissue antigens, and (5) elaboration of degradative enzymes that participate in invasion and metastatic spread.

Contact inhibition is the cessation of growth after a cell comes in contact with another cell. Contact inhibition usually switches off cell growth by blocking the synthesis of DNA, RNA, and protein. In wound healing, contact inhibition causes fibrous tissue growth to cease at the point where the edges of the wound come together. However, cancer cells tend to grow rampantly without regard for other tissue. The reduced tendency of cancer cells to stick together (*i.e., cohesiveness* and *adhesiveness*) permits shedding of the tumor's surface cells; these cells appear in the surrounding body fluids or secretions and can often be detected using the *Papanicolaou* (Pap) test.

Chemical messengers carry out cell-to-cell communication. These messengers bind to specific cell surface receptors and serve to control cell growth and modulate cell behavior. Impaired cell-to-cell communication may interfere with the formation of intercellular connections and responsiveness to membrane-derived signals.

Cancer cells express a number of cell surface molecules or antigens that are immunologically identified as foreign. These *tissue antigens* are coded by the genes of a cell. Many transformed cancer cells revert to earlier stages of gene expression and produce antigens that are immunologically distinct from the antigens that are expressed by cells of the well-differentiated tissue from which the cancer originated. Some cancers express fetal antigens that are not produced by comparable cells in the adult. Tumor antigens may be used clinically as markers to indicate the presence or progressive growth of a cancer.

Most cancers synthesize and secrete enzymes (*i.e.*, proteases and glycosidases) that break down proteins involved in ensuring intracellular organization and cell-to-cell cohesion. The degradation of the extracellular matrix by these enzymes facilitates invasiveness of the tumor. The production of degradative enzymes, such as fibrinolysins, contributes to the breakdown of the intercellular matrix, which leads to changes in the organization of the cell's cytoskeleton and affects cell-to-cell adhesion, cellular migration, and cellular communication. Cancers of nonendocrine tissues may assume hormone synthesis to produce so-called *ectopic hormones* (discussed with paraneoplastic syndromes in the section on general effects).

Invasion and Metastasis

Unlike benign tumors, which grow by expansion and usually are surrounded by a capsule, malignant tumors grow by extensive infiltration and invasion of the surrounding tissues. The word *cancer* is derived from the Latin word meaning *crablike* because cancerous growth spreads by sending crablike projections into the surrounding tissues. The lack of a sharp line of demarcation separating them from the surrounding tissue makes the complete surgical removal of malignant tumors more difficult than removal of benign tumors. *Seeding* of cancer cells into body cavities occurs when a tumor erodes into these spaces. Most often, the peritoneal cavity is involved, but other spaces such as the pleural cavity, pericardial cavity, and joint spaces may be involved. Seeding into the peritoneal cavity is particularly common with ovarian cancers.

The term *metastasis* is used to describe the development of a secondary tumor in a location distant from the primary tumor. Metastatic tumors retain many of the characteristics of the primary tumor from which they were derived. Because of this, it usually is possible to determine the site of the primary tumor from the cellular characteristics of the metastatic tumor. Some tumors tend to metastasize early in their developmental course, but others do not metastasize until later. Occasionally, the metastatic tumor is far advanced before the primary tumor becomes clinically detectable. For example, malignant tumors of the kidney may go undetected and be asymptomatic, even when a metastatic lesion is found in the lung.

Metastasis occurs by way of the lymph channels (*i.e.*, lymphatic spread) and the blood vessels (*i.e.*, hematogenic spread).^{3,7} In many types of cancer, the first evidence of disseminated disease is the presence of tumor cells in the lymph nodes that drain the tumor area. When metastasis occurs by way of the lymphatic channels, the tumor cells lodge first in the regional lymph nodes that received drainage from the tumor site. Once in the lymph node, the cells may die because of the lack of a proper environment, grow into a discernible mass, or remain dormant for unknown reasons. Because the lymphatic channels empty into the venous system, cancer cells that survive may eventually break loose and gain access to the venous system.

With hematologic spread, the blood-borne cancer cells typically follow the venous flow that drains the site of the neoplasm. Before entering the general circulation, venous blood from the gastrointestinal tract, pancreas, and spleen is routed through the portal vein to the liver. Thus, the liver is a common site for metastatic spread for cancers that originate in these organs. Although the site of hematologic spread is generally related to vascular drainage of the primary tumor, some tumors metastasize to distant and unrelated sites. One explanation is that cells of different tumors tend to metastasize to specific target organs that provide substances such as hormones or growth factors that are needed for their survival. For example, prostatic cancer preferentially spreads to bone, bronchiogenic cancer spreads to the adrenal glands and brain, and neuroblastoma spreads to the liver and bones.

The selective nature of hematologic spread indicates that metastasis is a finely orchestrated, multistep process, and only a small, select clone of cancer cells has the right combination of gene products to perform all of the steps needed for establishment of a secondary tumor. It has been estimated that fewer than 1 in 10,000 tumor cells that leave a primary tumor survives to start a secondary tumor.⁸ To metastasize, a cancer cell must be able to break loose from the primary tumor, invade the surrounding extracellular matrix, gain access to a blood vessel, survive its passage in the bloodstream, emerge from the bloodstream at a favorable location, invade the surrounding tissue, and begin to grow (Fig. 5-5).

Considerable evidence suggests that cancer cells capable of metastasis secrete enzymes that break down the surrounding extracellular matrix, allowing them to move through the degraded matrix and gain access to a blood vessel. Once in the circulation, the tumor cells are vulnerable to destruction by host immune cells. Some tumor cells gain protection from the antitumor host cells by aggregating and adhering to circulating blood components, particularly platelets, to form tumor emboli. Tumor cells that survive their travel in the circulation must be able to halt their passage by adhering to the vessel wall. After that, they must be able to exit the vessel, move through the extracellular matrix of the target tissue, and subsequently establish growth of a secondary tumor.

Once in the target tissue, the process of tumor development depends on the establishment of blood vessels and specific growth factors that promote proliferation of the tumor cells. Tumor cells secrete tumor angiogenesis factor, which enables the development of new blood vessels in the tumor.⁷ The presence of stimulatory or inhibitor growth factors correlates with the site-specific pattern of metastasis. For example, a potent growth-stimulating factor has been isolated from lung tissue,

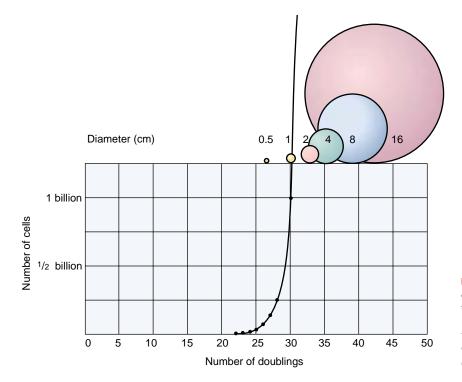

and stromal cells in bone have been shown to produce a factor that stimulates growth of prostatic cancer cells.⁷

Tumor Growth

The rate of tissue growth in normal and cancerous tissue depends on three factors: (1) the number of cells that are actively dividing or moving through the cell cycle, (2) the duration of the cell cycle, and (3) the number of cells that are being lost compared with the number of new cells being produced. One of the reasons cancerous tumors often seem to grow so rapidly relates to the size of the cell pool that is actively engaged in cycling. It has been shown that the cell cycle time of cancerous tissue cells is not necessarily shorter than that of normal cells; rather, cancer cells do not die on schedule. Also, the growth factors that allow cells to enter the resting or G_0 phase when they are not needed for cell replacement are lacking. Thus, a greater percentage of cells are actively engaged in moving through the cell cycle than occurs in normal tissue.

The ratio of dividing cells to resting cells in a tissue mass is called the *growth fraction*. The doubling time is the length of time it takes for the total mass of cells in a tumor to double. As the growth fraction increases, the doubling time decreases. When normal tissues reach their adult size, an equilibrium between cell birth and cell death is reached. However, cancer cells continue to divide until limitations in blood supply and nutrients inhibit their growth. As this happens, the doubling time for cancer cells decreases. If tumor growth is plotted against time on a semilogarithmic scale, the initial growth rate is exponential and then tends to decrease or flatten with time. This characterization of tumor growth is called the *Gompertzian model*.⁵

A tumor usually is undetectable until it has doubled 30 times and contains more than 1 billion (10⁹) cells. At this

■ FIGURE 5-6 ■ Growth curve of a hypothetical tumor on arithmetic coordinates. Notice the number of doubling times before the tumor reaches an appreciable size. (Adapted from Collins V.P., et al. [1956]. Observations of growth rates of human tumors. *Am J Roent Rad Ther Nuclear Med* 76, 988.)

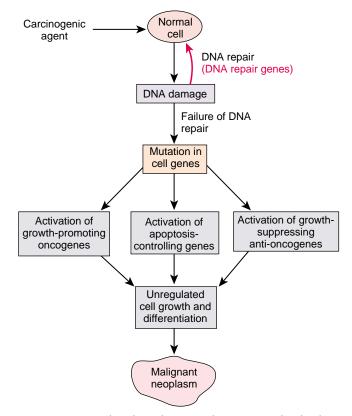

point, it is approximately 1 cm in size (Fig. 5-6). After 35 doublings, the mass contains more than 1 trillion (10^{12}) cells, which is a sufficient number to kill the host.

CARCINOGENESIS AND CAUSES OF CANCER

Carcinogenesis, or the development of cancer, is a multistep process that involves both the molecular aspects of cell transformation and the overall growth and spread of the tumor mass. Because cancer is not a single disease, it is reasonable to assume that it does not have a single cause. More likely, cancer occurs because of interactions between multiple risk factors or repeated exposure to a single carcinogenic (cancer-producing) agent. Among the risk factors that have been linked to cancer are heredity, chemical and environmental carcinogens, cancercausing viruses, and immunologic defects.

Oncogenesis: The Molecular Basis of Cancer

The term *oncogenesis* refers to a genetic mechanism whereby normal cells are transformed into cancer cells. There are three kinds of genes that control cell growth and replication: *protooncogenes, anti-oncogenes,* and genes that control programmed cell death or *apoptosis.*³ In addition to these three classes of genes, a fourth category of genes, those that regulate repair of damaged DNA, is implicated in the process of oncogenesis (Fig. 5-7). The DNA repair genes affect cell proliferation and survival indirectly through their ability to repair nonlethal damage in other genes, including proto-oncogenes, anti-oncogenes, and the genes that control apoptosis.³ These

■ FIGURE 5-7 ■ Flowchart depicting the stages in the development of a malignant neoplasm resulting from exposure to an oncogenic agent that produces DNA damage. When DNA repair genes are present (red arrow), the DNA is repaired and gene mutation does not occur.

Chapter 5: Alterations in Cell Growth and Replication: Neoplasia

genes have been implicated as the principal targets of genetic damage occurring during the development of cancer cells.^{9,10} Such genetic damage may be acquired by the action of chemicals, radiation, or viruses, or it may be inherited in the germ line. Significantly, it appears that the acquisition of a single gene mutation is not sufficient to transform normal cells into cancer cells. Instead, cancerous transformation appears to require the activation of many independently mutated genes.

Proto-oncogenes have essential roles in regulating the growth and proliferation of normal cells. Proto-oncogene products may act as growth factors, as receptors for growth factors, or as second messengers that transmit growth factor signals. The involvement of these genes in the cancer process is attributable to a somatic mutation that takes place in a specific target tissue, converting its proto-oncogenes into oncogenes.

Cancer suppressor genes, or anti-oncogenes, inhibit the proliferation of cells in a tumor. When this type of gene is inactivated, a genetic signal that normally inhibits proliferation is removed, thereby causing the cell to begin unregulated growth. Several human tumor suppressor genes have been identified.³ Of particular interest in this group is the p53 gene, located on the short arm of chromosome 17, that codes for a protein that is pivotal in growth regulation and functions as a suppressor of tumor growth. Mutation of the p53 gene has been implicated in the development of lung, breast, and colon cancer—the three leading causes of cancer death.³ The p53 gene also appears to initiate apoptosis of radiation- and chemotherapydamaged tumor cells. Thus, tumors that retain normal p53 function are more likely to respond to such therapy than are tumors that carry a defective p53 gene.³

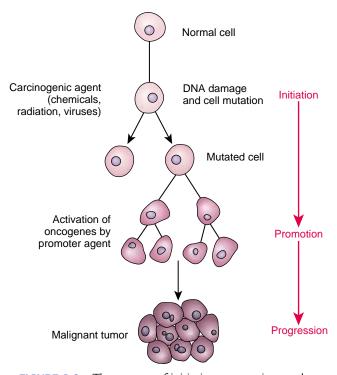

Tumor Cell Transformation

The transformation of normal cells to cancer cells by carcinogenic agents is a multistep process that can be divided into three stages: (1) initiation, (2) promotion, and (3) progression³ (Fig. 5-8). *Initiation* involves the exposure of cells to appropriate doses of a carcinogenic agent that makes them sus-

KEY CONCEPTS

ONCOGENESIS

- Normal cell growth is controlled by growthpromoting proto-oncogenes and growth-suppressing anti-oncogenes. Normally, cell growth is genetically controlled so that potentially malignant cells are targeted for elimination by tumor-suppressing genes.
- Oncogenesis is a genetic process whereby normal cells are transformed into cancer cells. It involves mutations in the normal growth-regulating genes.
- The transformation of normal cells into cancer cells is multifactorial, involving the inheritance of cancer susceptibility genes and environmental factors such as chemicals, radiation, and viruses.

■ FIGURE 5-8 ■ The process of initiation, promotion, and progression in the clonal evolution of malignant tumors. Initiation involves the exposure of cells to appropriate doses of a carcinogenic agent; promotion, the unregulated and accelerated growth of the mutated cells; and progression, the acquisition of malignant characteristics by the tumor cells.

ceptible to malignant transformation. The carcinogenic agents can be chemical, physical, or biologic, and produce irreversible changes in the genome of a previously normal cell. Because the effects of initiating agents are irreversible, multiple divided doses may achieve the same effects as single exposures of the same comparable dose or small amounts of highly carcinogenic substances. The most susceptible cells for mutagenic alterations in the genome are the cells that are actively synthesizing DNA.¹¹

Promotion involves the induction of unregulated accelerated growth in already initiated cells by various chemicals and growth factors. Promotion is reversible if the promoter substance is removed. Cells that have been irreversibly initiated may be promoted even after long latency periods. The latency period varies with the type of agent, the dosage, and the characteristics of the target cells. Many chemical carcinogens are called *complete carcinogens* because they can initiate and promote neoplastic transformation. *Progression* is the process whereby tumor cells acquire malignant phenotypic changes that promote invasiveness, metastatic competence, a tendency for autonomous growth, and increased karyotypic instability.¹¹

Heredity

A hereditary predisposition has been observed in approximately 50 types of cancer. For example, breast cancer occurs more frequently in women whose grandmothers, mothers, aunts, and sisters also have experienced a breast malignancy.

74 Unit One: Mechanisms of Disease

The genetic predisposition for development of cancer has been documented for a number of cancerous and precancerous lesions that follow mendelian inheritance patterns. Cancer is found in approximately 10% of persons having one affected first-degree relative, in approximately 15% of persons having two affected family members, and in 30% of persons having three affected family members. The risk increases to approximately 50% in women 65 years of age who have multiple family members with breast cancer. Two oncogenes, called BRAC1 (breast carcinoma 1) and BRAC2 (breast carcinoma 2), have been implicated in a genetic susceptibility to breast cancer.⁶

Several cancers exhibit an autosomal dominant inheritance pattern. In approximately 40% of cases, retinoblastoma (a malignant eye tumor that occurs in children) is inherited as an autosomal dominant trait; the remaining cases are nonhereditary. The penetrance of the genetic trait is high; in carriers of the dominant retinoblastoma gene, the penetrance for this gene is 95% for at least one tumor, and the affected person may be unilaterally or bilaterally affected.¹² Familial adenomatous polyposis of the colon also follows an autosomal dominant inheritance pattern. In people who inherit this gene, hundreds of adenomatous polyps may develop, some of which inevitably become malignant.³

Carcinogenic Agents

A carcinogen is an agent capable of causing cancer. The role of environmental agents in causation of cancer was first noted in 1775 by Sir Percivall Pott, who related the high incidence of scrotal cancer in chimney sweeps to their exposure to coal soot.¹³ In 1915, a group of Japanese investigators conducted the first experiments in which a chemical agent was used to produce cancer.¹³ These investigators found that a cancerous growth developed when they painted a rabbit's ear with coal tar. Coal tar has since been found to contain potent polycyclic aromatic hydrocarbons. Since then, many carcinogenic agents have been identified (Chart 5-1).

Chemical Carcinogens

More than six million chemicals have been identified. It is estimated that less than 1000 of these have been extensively examined for their carcinogenic potential.¹⁴ Some have been found to cause cancers in animals, and others are known to cause cancers in humans. These agents include both natural (*e.g.*, aflatoxin B₁) and artificial products (*e.g.*, vinyl chloride).

Chemical carcinogens can be divided into two groups: direct-reacting agents, which do not require activation in the body to become carcinogenic, and indirect-reacting agents, called *procarcinogens* or *initiators*, which become active only after metabolic conversion. Direct- and indirect-acting initiators form highly reactive species (*i.e.*, electrophiles and free radicals) that bind with the nucleophilic residues on DNA, RNA, or cellular proteins. The action of these reactive species tends to cause cell mutation or alteration in synthesis of cell enzymes and structural proteins in a manner that alters cell replication and interferes with cell regulatory controls. The carcinogenicity of some chemicals, called *promoters*, is augmented by agents that by themselves have little or no cancercausing ability. It is believed that promoters exert their effect by changing the expression of genetic material in a cell, in-

creasing DNA synthesis, enhancing gene amplification (*i.e.*, number of gene copies that are made), and altering intercellular communication.

The exposure to many chemical carcinogens is associated with lifestyle risk factors, such as smoking, dietary factors, and alcohol consumption. Cigarette smoke contains both procarcinogens and promoters. It is directly associated with lung and laryngeal cancer¹⁵ and has been linked with cancers of the esophagus, pancreas, kidney, uterine cervix, and bladder. Chewing tobacco or tobacco products increases the risk of cancers of the oral cavity and esophagus. It has been estimated that 30% of current cancer deaths in the United States are related to tobacco. Not only is the smoker at risk, but others passively exposed to cigarette smoke are at risk. Environmental tobacco smoke has been classified as a "group A" carcinogen based on the U.S. Environmental Protection Agency's system of carcinogen classification. It also is estimated that between 20% and 60% of the deaths that occur each year from nonsmokingrelated lung cancers may be caused by environmental tobacco smoke.16

There is strong evidence that certain elements in the diet contain chemicals that contribute to cancer risk. For example, benzo[a]pyrene and other polycyclic hydrocarbons are converted to carcinogens when foods are fried in fat that has been reused multiple times. Nitrosamines, which are powerful carcinogens, may be formed from nitrites that are derived from nitrates added to vegetables and foods as a preservative. Among the most potent of the procarcinogens are the polycyclic hydrocarbons. The polycyclic hydrocarbons are of particular interest because they are produced in the combustion of tobacco and are present in cigarette smoke. They also are produced from animal fat in the process of broiling meats and are present in smoked meats and fish. Formation of these nitrosamines may be inhibited by the presence of antioxidants such as vitamin C in the stomach. Cancer of the colon has been associated with high dietary intake of fat, protein, and beef and low intake of dietary fiber. The carcinogenic factors associated with a high-fat diet have yet to be confirmed. However, some studies have shown a relationship between high levels of fecally excreted bile acids and colon cancer. A high-fat diet increases the flow of primary bile acids. These acids are converted to secondary bile acids in the presence of anaerobic bacteria in the colon. These acids are thought to be tumor promoters, rather than initiators.⁷

Alcohol modifies the metabolism of carcinogens in the liver and esophagus.¹⁷ It is believed to influence the transport of carcinogens, increasing the contact between an externally induced carcinogen and the stem cells that line the upper oral cavity and esophagus. The carcinogenic effect of cigarette smoke can be enhanced by concomitant consumption of alcohol; persons who smoke and drink considerable amounts of alcohol are at increased risk for the development of cancer of the oral cavity and esophagus.

The effects of carcinogenic agents usually are dose dependent—the larger the dose or the longer the duration of exposure, the greater the risk that cancer will develop. Some chemical carcinogens may act in concert with other carcinogenic influences, such as viruses or radiation, to induce neoplasia. There usually is a time delay ranging from 5 to 30 years from the time of chemical carcinogen exposure to the development of overt cancer. This is unfortunate because many people may have been exposed to the agent and its carcinogenic effects before the association was recognized. This occurred with the use of diethylstilbestrol, which was widely used in the United States from the mid-1940s to 1970 to prevent miscarriages. But it was not until the late 1960s that many cases of vaginal adenosis and adenocarcinoma in young women were found to be the result of their exposure in utero to diethylstilbestrol.¹⁸

Radiation Oncogenesis

The effects of *ionizing radiation* in carcinogenesis have been well documented in atomic bomb survivors, in patients diagnostically exposed, and in industrial workers, scientists, and physicians who were exposed during employment. Malignant epitheliomas of the skin and leukemia were significantly elevated in these populations.⁶ Between 1950 and 1970, the death rate from leukemia alone in the most heavily exposed population groups of the atomic bomb survivors in Hiroshima and Nagasaki was 147 per 100,000 persons, 30 times the expected rate.¹⁹

The type of cancer that developed depended on the dose of radiation, the gender of the person, and the age at which exposure occurred. For instance, approximately 25 to 30 years after total body or trunk irradiation, there were increased incidences of leukemia and cancers of the breast, lung, stomach, thyroid, salivary gland, gastrointestinal system, and lymphoid tissues. The length of time between exposure and the onset of cancer is related to the age of the individual. For example, children exposed to ionizing radiation in utero have an increased risk for developing leukemias and childhood tumors, particularly 2 to 3 years after birth. This latency period for leukemia extends to 5 to 10 years if the child was exposed after birth and to 20 years for certain solid tumors.⁶ As another example, the latency period for the development of thyroid cancer in infants and small children who received radiation to the head and neck to decrease the size of the tonsils or thymus was as long as 35 years after exposure.

The association between sunlight and the development of skin cancer has been reported for more than 100 years. *Ultraviolet radiation* emits relatively low-energy rays that do not deeply penetrate the skin (see Chapter 44). As with other carcinogens, the effects of ultraviolet radiation usually are additive, and there usually is a long delay between the time of exposure and the time that cancer can be detected.

Oncogenic Viruses

An oncogenic virus is one that can induce cancer. Viruses, which are small particles containing genetic (DNA or RNA) material, enter a host cell and become incorporated into its chromosomal DNA or take control of the cell's machinery for the purpose of producing viral proteins. A large number of DNA and RNA viruses (*i.e.*, retroviruses) have been shown to be oncogenic in animals. However, only a few viruses have been linked to cancer in humans.³ Among the recognized oncogenic viruses in humans are the human papilloma virus (HPV), Epstein-Barr virus (EBV), hepatitis B virus (HBV), and human T-cell leukemia virus-1 (HTLV-1).⁶ Herpes simplex type 2 also has been associated with cervical cancer, but the evidence supporting its role as a carcinogenic influence is less clear.

Three DNA viruses have been implicated in human cancers: HPV, EBV, and HBV. The transforming DNA viruses form stable associations with the human genome using genes that allow them to complete their replication cycle and be expressed in transformed cells. There is strong evidence to suggest that the DNA viruses act in concert with other factors to cause cancer.

There are more than 60 genetically different types of HPV. Some types (*i.e.*, types 1, 2, 4, 7) have been shown to cause benign squamous papillomas (*i.e.*, warts). HPVs also have been implicated in squamous cell carcinoma of the cervix and anogenital region. HPV types 16 and 18 and, less commonly, types 31, 33, 35, and 51, have been found in approximately 85% of squamous cell carcinomas of the cervix and presumed precursors (*i.e.*, severe cervical dysplasia and carcinoma in situ).³

EBV is a member of the herpesvirus family. It has been implicated in the pathogenesis of four human cancers: Burkitt's lymphoma, nasopharyngeal cancer, B-cell lymphomas in immunosuppressed individuals such as those with acquired immunodeficiency syndrome (AIDS), and in some cases of Hodgkin's lymphoma. Burkitt's lymphoma, a tumor of B lymphocytes, is endemic in parts of East Africa and occurs sporadically in other areas worldwide. In persons with normal immune function, the EBV-driven, B-cell proliferation is readily controlled, and the person becomes asymptomatic or experiences a self-limited episode of infectious mononucleosis (see Chapter 11). In regions of the world where Burkitt's lymphoma is endemic, concurrent malaria or other infections cause impaired immune function, allowing sustained B-lymphocyte proliferation. The incidence of nasopharyngeal cancer is high in some areas of China, particularly southern China, and in the Cantonese population in Singapore.

HBV is the etiologic agent in the development of hepatitis B, cirrhosis, and hepatocellular carcinoma. There is a significant correlation between elevated rates of hepatocellular carcinoma worldwide and the prevalence of HBV carriers. Other etiologic factors also may contribute to the development of liver cancer. Ingestion of aflatoxin and infection with HCV, the hepatitis C virus, have been implicated. The precise mechanism by which HBV induces hepatocellular cancer has not been determined, although it has been suggested that it may be the result of prolonged HBV-induced liver damage and regeneration.

HTLV-1, a retrovirus, is associated with a form of T-cell leukemia that is endemic in certain parts of Japan and some areas of the Caribbean and Africa and is found sporadically elsewhere, including the United States and Europe.³ Similar to the AIDS virus, HTLV-1 is attracted to the CD4⁺T cells, and this subset of T cells is therefore the major target for cancerous transformation. The virus requires transmission of infected T cells by way of sexual intercourse, infected blood, or breast milk. A second type of HTLV virus, HTLV-2, has been isolated from individuals with an unusual form of hairy cell leukemia. Hairy cell leukemia is usually the result of an alteration in the B-lymphocyte lineage.²⁰

Immunologic Defects

There is growing evidence for the immune system's participation in resistance against the progression and spread of cancer. The central concept, known as the *immune surveillance hypothesis*, which was first proposed by Paul Ehrlich in 1909, postulates that the immune system plays a central role in resistance against the development of tumors.²¹ In addition to cancer-host interactions as a mechanism of cancer development, immunologic mechanisms provide a means for the detection, classification, and prognostic evaluation of cancers and as a potential method of treatment. *Immunotherapy* (discussed later in this chapter) is a cancer treatment modality designed to heighten the patient's general immune responses to increase tumor destruction.

It has been suggested that the development of cancer might be associated with impairment or decline in the surveillance capacity of the immune system. For example, increases in cancer incidence have been observed in people with immunodeficiency diseases and in those with organ transplants who are receiving immunosuppressant drugs. The incidence of cancer also is increased in the elderly, in whom there is a known decrease in immune activity. The association of Kaposi's sarcoma with AIDS further emphasizes the role of the immune system in preventing malignant cell proliferation.¹³

It has been shown that most tumor cells have molecular configurations that can be specifically recognized by immune T cells or by antibodies and thus are termed tumor antigens. The most relevant tumor antigens fall into two categories: unique tumor-specific antigens found only on tumor cells, and tumor-associated antigens found on tumor cells and on normal cells. Quantitative and qualitative differences permit the use of these tumor-associated antigens to distinguish cancer cells from normal cells.²²

Virtually all of the components of the immune system have the potential for eradicating cancer cells, including T lymphocytes, B lymphocytes, antibodies, macrophages, and natural killer (NK) cells (see Chapter 9). The T-cell response is undoubtedly one of the most important host responses for controlling the growth of antigenic tumor cells; it is responsible for the direct killing of tumor cells and for activation of other components of the immune system. The T-cell response to cancer cells reflects the function of two subsets of T cells: the CD4⁺ helper T cells and CD8⁺ cytotoxic T cells. The finding of tumor-reactive antibodies in the serum of people with cancer supports the role of the B cell as a member of the immune surveillance team. Antibodies can destroy cancer cells through complement-mediated mechanisms or through antibodydependent cellular cytotoxicity, in which the antibody binds the cancer cell to another effector cell, such as the NK cell, that does the actual killing of the cancer cell. NK cells do not require antigen recognition and can lyse a wide variety of target cells. The cytotoxic activity of NK cells can be augmented by the lymphokines, IL-2, and interferon, and NK activity can be amplified by immune T-cell responses.²³ Macrophages are important in tumor immunity as antigen-presenting cells to initiate the immune response and as potential effector cells to participate in tumor cell lysis.

In summary, neoplasms may be benign or malignant. Benign and malignant tumors differ in terms of cell characteristics, manner of growth, rate of growth, potential for metastasis, ability to produce generalized effects, tendency to cause tissue destruction, and capacity to cause death. The growth of a benign tumor is restricted to the site of origin, and the tumor usually does not cause death unless it interferes with vital functions. However, cancers or malignant neoplasms grow wildly and without organization, spread to distant parts of the body, and cause death unless their growth is inhibited or stopped by treatment.

There are two types of cancer: solid tumors and hematologic tumors. Solid tumors initially are confined to a specific organ or tissue, but hematologic cancers are disseminated from the onset. Cancer is a disorder of cell proliferation and differentiation. Cancer cells often are poorly differentiated compared with normal cells, and they display abnormal membrane characteristics, have abnormal antigens, produce abnormal biochemical products, and have abnormal karyotypes. All cancers result from nonlethal genetic changes that transform a normal cell into a cancer cell. The spread of cancer occurs through three pathways: direct invasion and extension, seeding of cancer cells in body cavities, and metastatic spread through vascular or lymphatic pathways. Only a proportionately small clone of cancer cells is capable of metastasis. To metastasize, a cancer cell must be able to break loose from the primary tumor, invade the surrounding extracellular matrix, gain access to a blood vessel, survive its passage in the bloodstream, emerge from the bloodstream at a favorable location, invade the surrounding tissue, and begin to grow.

Because cancer is not a single disease, it is reasonable to assume that it does not have a single cause. Multiple factors probably interact at the genetic level to transform normal cells into cancer cells. This transformation process is called *oncogenesis*. Four kinds of genes control normal cell growth and replication: growth-promoting regulatory genes (*i.e.*, proto-oncogenes) and growth-inhibiting regulatory genes (*i.e.*, anti-oncogenes), genes that control apoptosis, and gene-repair genes. These genes are implicated as principal targets of the genetic damage that occurs during the development of a cancer cell. Such genetic damage may be acquired by the action of chemicals (*i.e.*, chemical carcinogens), radiation, or viruses, or it may be inherited in the cell line.

CLINICAL FEATURES

TABLE 5-3

There probably is no single body function left unaffected by the presence of cancer (Table 5-3). Because tumor cells replace normally functioning parenchymal tissue, the initial manifestations of cancer usually reflect the primary site of involvement. For example, cancer of the lung initially produces impairment of respiratory function; as the tumor grows and metastasizes, other body structures become affected.

Cancer disrupts tissue integrity. As cancers grow, they compress and erode blood vessels, causing ulceration and necrosis along with frank bleeding and sometimes hemorrhage. One of the early warning signals of colorectal cancer is blood in the stool. Cancer cells also may produce enzymes and metabolic toxins that are destructive to the surrounding tissues. Usually, tissue damaged by cancerous growth does not heal normally. Instead, the damaged area persists and often continues to grow; a sore that does not heal is another warning signal of cancer. Cancer has no regard for normal anatomic boundaries; as it grows, it invades and compresses adjacent structures. For example, abdominal cancer often compresses the viscera and causes bowel obstruction. Cancer may obstruct lymph flow and penetrate serous cavities, causing pleural effusion and ascites. In its late stages, cancer often causes pain (see Chapter 39). Pain is probably one of the most dreaded aspects of cancer, and pain management is one of the major treatment concerns for persons with incurable cancers.

Abnormalities in energy, carbohydrate, lipid, and protein regulation are common manifestations during progressive tumor growth. Many cancers are associated with weight loss and wasting of body fat and lean protein, a condition called cancer cachexia. Although anorexia, reduced food intake, and abnormalities of taste are common in people with cancer and often are accentuated by treatment methods, the extent of weight loss and protein wasting cannot be explained in terms of diminished food intake alone. There also is a disparity between the size of the tumor and the severity of cachexia, which supports the existence of other mediators in the development of cachexia. Cachexia is thought to be the result of tumor-derived or host-derived factors that cause anorexia directly by acting on satiety centers in the hypothalamus or indirectly by injuring tissues that subsequently release anorexigenic substances.

Cachectin was the first identified cytokine associated with wasting. Cachectin was later found to be identical to tumor necrosis factor (TNF), a cytokine secreted primarily from macrophages in response to tumor cell growth or gram-negative bacterial infections.²⁴ TNF causes anorexia by suppressing satiety centers and by suppressing the synthesis of lipoprotein lipase, an enzyme that facilitates the release of fatty acids from lipoproteins so they can be used by tissues. TNF is an endogenous pyrogen that induces fever by its actions on cells in the hypothalamic regulatory regions of the brain. TNF also induces a number of inflammatory responses, activates the coagulation system, suppresses bone marrow stem cell division, acts on hepatocytes to increase the synthesis of specific serum proteins in response to inflammatory stimuli, and mediates endotoxic shock secondary to trauma, burns, and sepsis.²⁵ The role of TNF and its full impact on cancer cachexia are uncertain. It has been suggested by some that the cytokine may be an endogenous antineoplastic agent. Interleukin (IL)-1, another cytokine secreted from macrophages, shares with TNF the ability to initiate cachexia.

	1
Overall Effect	Related Tumor Action
Altered function of the involved tissue	Destruction and replacement of parenchymal tissue by neoplastic growth
Bleeding and hemorrhage	Compression of blood vessels, with ischemia and necrosis of tissue; or tumor may outgrow its blood supply
Ulceration, necrosis, and infection of tumor area	Ischemia associated with rapid growth, with subsequent bacterial invasion
Obstruction of hollow viscera or communication pathways	Expansive growth of tumor with compression and invasion of tissues
Effusion in serous cavities	Impaired lymph flow from the serous cavity or erosion of tumor into the cavity
Increased risk of vascular thrombosis	Abnormal production of coagulation factors by the tumor, obstruction of venous channels, and immobility
Anemia	Bleeding and depression of red blood cell production
Bone destruction	Metastatic invasion of bony structures
Hypercalcemia	Destruction of bone due to metastasis or production by the tumor of parathyroid-like hormone
Pain	Liberation of pain mediators by the tumor, compression, or ischemia of structures
Cachexia, weakness, wasting of tissues	Catabolic effect of the tumor on body metabolism along with selective trapping of nutrients by rapidly growing tumor cells
Inappropriate hormone production	Production by the tumor of hormones or hormone-like substances that are not
(e.g., ADH or ACTH secretion by cancers such	regulated by normal feedback mechanisms
as bronchogenic carcinoma)	

General Effects on Body Function Associated With Cancer Growth

Unit One: Mechanisms of Disease

In addition to signs and symptoms at the sites of primary and metastatic disease, cancer can produce manifestations in sites that are not directly affected by the disease. Such manifestations are collectively referred to as *paraneoplastic syndromes*. Some of these manifestations are caused by the elaboration of hormones by cancer cells, and others result from the production of circulating factors that produce nonmetastatic hematopoietic, neurologic, and dermatologic syndromes. For example, cancers may produce procoagulation factors that contribute to an increased risk of venous thrombosis. It is estimated that approximately 10% of persons with cancer are affected by these syndromes.3 The three most common endocrine syndromes associated with cancer are the syndrome of inappropriate antidiuretic hormone secretion (see Chapter 6), Cushing's syndrome caused by ectopic adrenocorticotropic hormone (now called *corticotropin*) production (see Chapter 31), and hypercalcemia (see Chapter 6). Hypercalcemia of malignancy does not appear to be related to parathyroid hormone (PTH) but to PTH-related protein, which shares several biologic actions with PTH. It also can be caused by osteolytic processes induced by cancer such as multiple myeloma or bony metastases from other cancers. The paraneoplastic syndromes may be the earliest indication that a person has cancer; they also may signal early recurrence of the disease in previously treated patients.

Diagnosis and Staging

The methods used in the diagnosis and staging of cancer are determined largely by the location and type of cancer suspected. A number of procedures are used in the diagnosis of cancer, including x-ray studies, endoscopic examinations, urine and stool tests, blood tests for tumor markers, bone marrow aspirations, ultrasound imaging, magnetic resonance imaging (MRI), and computed tomography (CT) scan.

The Pap Smear

The Pap smear is an example of the type of test called exfoliative cytology. It consists of a microscopic examination of a properly prepared slide by a cytotechnologist or pathologist for the purpose of detecting the presence of abnormal cells. The usefulness of exfoliative cytology relies on the fact that the cancer cells lack the cohesive properties and intercellular junctions that are characteristic of normal tissue; without these characteristics, cancer cells tend to exfoliate and become mixed with secretions surrounding the tumor growth. The American Cancer Society recommends that the test be done annually to detect cervical cancer in women who are or have been sexually active and who have reached 18 years of age. After three consecutive normal findings, the test may be performed less frequently at the discretion of the physician.²⁶ Exfoliative cytology also can be performed on other body secretions, including nipple drainage, pleural or peritoneal fluid, and gastric washings.

Biopsy

Tissue biopsy is the removal of a tissue specimen for microscopic study. Biopsies are obtained in a number of ways, including needle aspiration (*i.e.*, fine, percutaneous, or core needle); by endoscopic methods, such as bronchoscopy or cystoscopy, which involve the passage of an endoscope through an orifice and into the involved structure; or by laparoscopic methods. In some instances, a surgical incision is made from which biopsy specimens are obtained. Excisional biopsies are those in which all of the tumor is removed. The tumors usually are small, solid, palpable masses. If the tumor is too large to be completely removed, a wedge of tissue from the mass can be excised for examination. Tissue diagnosis is of critical importance in designing the treatment plan should cancer cells be found.27

Tumor Markers

Tumor markers are antigens that are expressed on the surface of tumor cells or substances released from normal cells in response to the presence of tumor. Some substances, such as hormones and enzymes, are produced normally by the tissue involved but become overexpressed as a result of cancer. Other tumor markers, such as oncofetal proteins, are produced during fetal development and are induced to re-appear later in life as a result of benign and malignant neoplasms. Tumor markers are used for screening, diagnosis, establishing prognosis, monitoring treatment, and detecting recurrent disease.

As diagnostic tools, tumor markers have limitations. The value of a marker depends on its sensitivity, specificity, proportionality, and feasibility.²⁸ Sensitivity implies that the marker is apparent early in the development of the tumor and has few false-negative results. Specificity indicates that the marker is specific for the specific cancer and is not elevated in other disease conditions (i.e., has few false-positive results). Proportionality means that the level of marker accurately reflects the growth of the tumor, such that higher levels reflect a larger growth. Feasibility implies that the methods are readily available, easy to use, and that the cost is not prohibitive. Nearly all markers can be elevated in benign conditions, and most are not elevated in the early stages of malignancy. Thus, tumor markers have limited value as screening tests. Extremely elevated levels of a tumor marker can indicate a poor prognosis or the need for more aggressive treatment. Perhaps the greatest value of tumor markers is in monitoring therapy in people with widespread cancer. Nearly all markers show an association with the clinical course of the disease. The levels of most markers decline with successful treatment and increase with recurrence of the tumor.

The markers that have been most useful in practice have been human chorionic gonadotropin (hCG), CA 125, prostatespecific antigen (PSA), prostatic acid phosphatase (PAP), α -fetoprotein (AFP), and carcinoembryonic antigen (CEA). HCG is a hormone normally produced by the placenta. It is used as a marker for diagnosing, prescribing treatment, and following the disease course in persons with high-risk gestational trophoblastic tumors. PSA and PAP are used as markers in prostate cancer, and CA 125 is used as a marker in ovarian cancer.

Some cancers express oncofetal antigens, which are differentiation antigens normally present only during embryonal development.³ The two that have proven the most useful as tumor markers are AFP and CEA. AFP is synthesized by the fetal liver, yolk sac, and gastrointestinal tract and is the major serum protein in the fetus. Elevated levels are encountered in people with primary liver cancers and have also been observed in some testicular, ovarian, pancreatic, and stomach cancers. CEA normally is produced by embryonic tissue in the gut, pancreas, and liver and is elaborated by a number of different cancers. Depending on the serum level adopted for significant elevation, CEA is elevated in approximately 60% to 90% of colorectal carcinomas, 50% to 80% of pancreatic cancers, and 25% to 50% of gastric and breast tumors.³ As with most other tumor markers, elevated levels of CEA and AFP are found in other, noncancerous conditions, and elevated levels of both depend on tumor size so that neither is useful as an early test for cancer.

Staging and Grading of Tumors

The two basic methods for classifying cancers are grading according to the histologic or cellular characteristics of the tumor and staging according to the clinical spread of the disease. Both methods are used to determine the course of the disease and aid in selecting an appropriate treatment or management plan. Grading of tumors involves the microscopic examination of cancer cells to determine their level of differentiation and the number of mitoses. Cancers are classified as grades I, II, III, and IV with increasing anaplasia or lack of differentiation. Staging of cancers uses methods to determine the progress and spread of the disease. Surgery may be used to determine tumor size and lymph node involvement.

The clinical staging of cancer is intended to provide a means by which information related to the progress of the disease, the methods and success of treatment modalities, and the prognosis can be communicated to others. The TNM system, which has evolved from the work of the International Union Against Cancer (IUAC) and the American Joint Committee on Cancer Staging and End Stage Reporting (AJCCS), is used by many cancer facilities. This system, which is briefly described in Chart 5-2, classifies the disease into stages using three tumor components: T stands for the extent of the primary tumor, N refers to the involvement of the regional lymph nodes, and M describes the extent of the metastatic involvement. The time of staging is indicated as cTNM, clinical-diagnostic staging; pTNM, postsurgical resection-pathologic staging; sTNM, surgical-evaluative staging; rTNM, retreatment staging; and aTNM, autopsy staging.29

CHART	5-2 TNM Classification System
T (tumo	or)
Tx T0 Tis T1-4	Tumor cannot be adequately assessed No evidence of primary tumor Carcinoma in situ Progressive increase in tumor size or involvement
N (nod	es)
Nx N0 N 1–3	Regional lymph nodes cannot be assessed No evidence of regional node metastasis Increasing involvement of regional lymph nodes
M (met	astasis)
Mx M0 M1	Not assessed No distant metastasis Distant metastasis present, specify sites

Cancer Treatment

The goals of cancer treatment methods fall into three categories: curative, controlling, and palliative. The most common modalities are surgery, radiation, chemotherapy, hormonal therapy, and biotherapy. The treatment of cancer involves the use of a carefully planned program that combines the benefits of multiple treatment modalities and the expertise of an interdisciplinary team of specialists including medical, surgical, and radiation oncologists; clinical nurse specialists; nurse practitioners; pharmacists; and a variety of ancillary personnel.

Surgery

Surgery is used for diagnosis, the staging of cancer, tumor removal, and palliation (*i.e.*, relief of symptoms) when a cure cannot be achieved. The type of surgery to be used is determined by the extent of the disease, the location and structures involved, the tumor growth rate and invasiveness, the surgical risk to the patient, and the quality of life the patient will experience after the surgery. If the tumor is small and has welldefined margins, the entire tumor often can be removed. However, if the tumor is large or involves vital tissues, surgical removal may be difficult if not impossible.

Surgical techniques have expanded to include electrosurgery, cryosurgery, chemosurgery, cytoreductive surgery, and laser surgery. Electrosurgery uses the cutting and coagulating effects of high-frequency current applied by needle, blade, or electrodes. Once considered a palliative procedure, it now is being used as an alternative treatment for certain cancers of the skin, oral cavity, and rectum. Cryosurgery involves the instillation of liquid nitrogen into the tumor through a probe. It is used in treating cancers of the oral cavity, brain, and prostate. Chemosurgery is used in skin cancers. It involves the use of a corrosive paste in combination with multiple frozen sections to ensure complete removal of the tumor. Laser surgery uses a laser beam to resect a tumor. It has been used effectively in retinal and vocal cord surgery.

Radiation Therapy

Radiation can be used singly as the primary method of treatment, as preoperative or postoperative treatment, with chemotherapy, or with chemotherapy and surgery. It can also be used as a palliative treatment to reduce symptoms in persons with advanced cancers. It is effective in reducing the pain associated with bone metastasis and, in some cases, improves mobility. Radiation also is used to treat several oncologic emergencies such as superior vena cava syndrome, spinal cord compression, bronchial obstruction, and hemorrhage.³⁰

Radiation therapy exerts its effects by direct or indirect ionization. Indirect ionization produced by x-rays or gamma rays causes cellular damage when these rays are absorbed into tissue and give up their energy by producing fast-moving electrons. These electrons interact with free or loosely bonded electrons of the absorber cells and subsequently produce free radicals that interact with critical cell components (see Chapter 3). It can immediately kill cells, delay or halt cell cycle progression, or at dose levels commonly used in radiation therapy, cause damage to the cell nucleus that results in cell death after replication. Cell damage can be sublethal, in which case a single break in the strand can repair itself before the next radiation insult. Double-stranded breaks in DNA are generally 80

believed to be the primary damage that leads to radiation death of cells. The result of unrepaired DNA is that cells may continue to function until they undergo cell mitosis, at which time the genetic damage from the irradiation may result in death of the cell. The clinical significance is that the rapidly proliferating and poorly differentiated cells of a cancerous tumor are more likely to be injured by radiation therapy than are the slower proliferating cells of normal tissue. However, to some extent radiation is injurious to all rapidly proliferating cells, including those of the bone marrow and the mucosal lining of the gastrointestinal tract. This results in many of the common adverse effects of radiation therapy, including infection, bleeding, and anemia due to loss of blood cells and nausea and vomiting due to loss of gastrointestinal cells. In addition to its lethal effects, radiation also produces sublethal injury. Recovery from sublethal doses of radiation occurs in the interval between the first dose of radiation and subsequent doses. This is why large total doses of radiation can be tolerated when they are divided into multiple smaller fractionated doses. Normal tissue is usually able to recover from radiation damage more readily than is cancerous tissue.

Systemic Cancer Therapy

The use of chemotherapy drugs, hormones, antihormones, and biotherapy has become a highly specialized and increasingly effective means of treating cancers. The therapies rely on systemic agents that are distributed throughout the body. Gene therapy, although investigational, may provide a foundation for the development of more effective treatments in the future.

Bone marrow transplantation and peripheral blood stem cell transplantation are two treatment approaches for leukemias, certain solid tumors, and other cancers previously thought to be incurable.

Chemotherapy. Since the early 1960s, cancer chemotherapy has evolved as a major treatment modality. More than 30 different chemotherapeutic drugs are used alone or in various combinations. Administering higher doses of multiple drugs may be used as a strategy to achieve cure or optimal palliation; however, the adverse drug interactions and side effects can be unpredictable and intense. Chemotherapeutic drugs may be the primary form of treatment, or they may be used as adjuncts to other treatments. Chemotherapy is the primary treatment for most hematologic and some solid tumors, including choriocarcinoma, testicular cancer, acute and chronic leukemia, Burkitt's lymphoma, Hodgkin's disease, and multiple myeloma.

Cancer chemotherapeutic drugs exert their effects through several mechanisms. At the cellular level, they exert their lethal action by creating adverse conditions that prevent cell growth and replication. These mechanisms include disrupting production of essential enzymes; inhibiting DNA, RNA, and protein synthesis; and preventing cell mitosis.^{6,31}

For most chemotherapy drugs, the relationship between tumor cell survival and drug dose is exponential, with the number of cells surviving being proportional to drug dose, and the number of cells at risk for exposure being proportional to the destructive action of the drug. Chemotherapeutic drugs are most effective in treating tumors that have a high growth fraction because of their ability to kill rapidly dividing cells. Exponential killing implies that a proportion or percentage of tumor cells are killed, rather than an absolute number. This proportion is a constant percentage of the total number of cells. For this reason, multiple courses of treatment are needed if the tumor is to be eradicated.⁵

The anticancer drugs may be classified as either cell cycle specific or cell cycle nonspecific. Drugs are cell cycle specific if they exert their action during a specific phase of the cell cycle. For example, methotrexate, an antimetabolite, acts by interfering with DNA synthesis and thereby interrupts the S phase of the cell cycle. Drugs that are cell cycle nonspecific affect cancer cells through all the phases of the cell cycle. The alkylating agents, which are cell cycle nonspecific, act by disrupting DNA when the cells are in the resting state and when they are dividing. The site of action of various cancer drugs varies. Chemotherapeutic drugs that have similar structures and effects on cell function usually are grouped together, and these drugs usually have similar toxic and side effects. Because they differ in their mechanisms of action, combinations of cell cycle-specific and cell cycle-nonspecific agents often are used to treat cancer.

Combination chemotherapy has been found to be more effective than treatment with a single drug. With this method, several drugs with different mechanisms of action, metabolic pathways, times of onset of action and recovery, side effects, and onset of side effects are used. Drugs used in combinations are individually effective against the tumor and synergistic with each other. The regimens for combination therapy often are referred to by acronyms. Two well-known combinations are CHOP (cyclophosphamide, doxorubicin, Oncovin [vincristine], and prednisone), used in the treatment of Hodgkin's disease, and CMF (cyclophosphamide, methotrexate, and 5-fluorouracil), used in the treatment of breast cancer. The maximum possible drug doses usually are used to ensure the maximum cell killing. Routes of administration and dosage schedules are carefully designed to ensure optimal delivery of the active forms of the drugs to a tumor during the sensitive phase of the cell cycle.

Hormone and Antihormone Therapy. Hormone therapy consists of administration of hormones or hormone-blocking drugs. It is used for cancers that are responsive to or dependent on hormones for growth. The actions of hormones depend on the presence of specific receptors in the tumor. Among the tumors known to be responsive to hormonal manipulations are those of the breast, prostate, adrenal gland, and uterine endometrium. Hormones commonly used for cancer treatment include estrogens (e.g., diethylstilbestrol, estradiol), androgens (*e.g.*, testosterone), and progestins (*e.g.*, hydroxyprogesterone). Hormone therapy also involves use of the adrenal corticosteroid hormones such as prednisone, dexamethasone, and methylprednisolone. These compounds inhibit mitosis and are cytotoxic to cells of lymphocytic origin. Hormones are cell cycle nonspecific and are thought to alter the synthesis of RNA and proteins by binding to receptor sites. The side effects of hormonal treatment are directly related to the normal action of the hormones. Because dosages of these drugs are usually higher than those that normally occur in the body, the normal actions of the hormone are accentuated.³¹

Hormone-blocking drugs include the antiestrogen drugs tamoxifen and leuprolide (*i.e.*, a gonadotropin-releasing hormone analog that blocks both estrogens and androgens) and the antiadrenal drug aminoglutethimide. **Biotherapy**. Biotherapy involves the use of biologic response modifiers (BRMs) that change the person's own biologic response to cancer. The BRMs are products normally produced in the body that serve as regulators and messengers of normal cellular function. Although biotherapy relies heavily on immune mechanisms, it is not limited to them. Three major mechanisms by which biotherapy exerts its effects are: (1) modification of host responses, (2) direct destruction of cancer cells by suppressing tumor growth or killing the tumor cell, and (3) modification of tumor cell biology.

Immunotherapy techniques include active and passive immunotherapy. Active immunotherapy involves nonspecific techniques, such as bacille Calmette-Guérin (BCG) and levamisole, and specific techniques, such as purified or recombinant antigens. Passive immunotherapy is divided into nonspecific techniques such as lymphokine-activated killer (LAK) cells and cytokine therapy, specific techniques such as antibody therapy, and combined techniques that include LAK cells and antibodies. Active immunotherapy focuses on stimulating immune response. BCG is an attenuated strain of the bacterium that causes bovine tuberculosis. BCG acts as a nonspecific stimulant of the immune system. A second method involves the use of vaccines made from the patient's own tumor (autologous) or from pooled tumor-associated antigens (allogeneic) that have been obtained from a number of tumors. Active immunotherapy has been studied as treatment for melanoma, renal cell carcinoma, and leukemia.32

Adoptive immunotherapy is a technique that uses lymphokine-activated NK cells or tumor-specific T-cell immunity as a means of eradicating cancer cells. Originally, only LAK cells were used. These NK cells are grown in culture supported by IL-2. Because NK cells are nonspecific in their function, LAK cells attack both normal and tumor cells. The technique of adoptive therapy has been expanded to the production of tumor-specific T cells. These cells are derived from a person's own *tumor-infiltrating lymphocytes* (TILs) that have been expanded in the laboratory so that a large amount of cells are available for reinfusion. Because the TILs are tumor specific, they do not attack normal host cells.

Four types of biologic response modifiers are being used or investigated: interferon therapy, interleukin therapy, monoclonal antibodies, and hematopoietic growth factors. Some agents, such as the interferons, have more than one biologic action, including antiviral, immunomodulatory, and antiproliferative actions. The *interferons* are endogenous polypeptides that are synthesized by a number of cells in response to a variety of cellular or viral stimuli. The three major types of interferons are alpha (α), beta (β) and gamma (γ), each group differing in terms of their cell surface receptors. The exact physiologic roles of each of the interferons remain unclear. They appear to inhibit viral replication and also may be involved in inhibiting tumor protein synthesis and in prolonging the cell cycle and increasing the percentage of cells in the G₀ phase. Interferons stimulate NK cells and T-lymphocyte killer cells. Although 17 interleukins have been identified, only one, IL-2, has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of metastatic renal cell carcinoma. IL-2 has been found to reduce tumor size in a minority of patients with metastatic renal cancer and melanoma.32

Monoclonal antibodies (MoAbs) are highly specific antibodies derived from cloned cells or hybridomas. Scientists were able to produce large quantities of these MoAbs that were specific for tumor cells. Several MoAbs have been approved: muromonab-CD3 (OKT-3), which targets the CD3 receptor of human T cells, for the treatment of acute allograft rejection in renal transplant recipients; satumomab pendetide, used in the detection of colorectal and ovarian cancers,³³ and rituximab, an anti-CD20 MoAb used in the treatment of B-cell malignant lymphomas.³⁴

Hematopoietic growth factors are growth and maturation factors that include the colony-stimulating factors (CSFs). The CSFs are factors that control the production of neutrophils and monocytes/macrophages, erythropoietin, and thrombopoietin (see Chapter 11).³⁴

In summary, cancer compresses and erodes blood vessels; obstructs lymph flow; penetrates serous cavities; and compresses visceral structures. It produces chemical mediators, such as TNF, that produce pain, sap energy reserves, and cause weight loss and tissue wasting. Paraneoplastic syndromes arise from the ability of cancers to elaborate hormones and other chemical messengers that produce nonmetastatic endocrine, hematopoietic, neurologic, and dermatologic syndromes.

The methods used in the diagnosis of cancer vary with the type of cancer and its location. Because many cancers are curable if diagnosed early, health care practices designed to promote early detection are important. Pap smears, tissue biopsies, and tumor markers are used to detect the presence of cancer cells and in diagnosis. There are two basic methods of classifying tumors: (1) grading according to the histologic or tissue characteristics, and (2) clinical staging according to spread of the disease. Histologic studies are done in the laboratory using cells or tissue specimens. The TNM system for clinical staging of cancer uses tumor size, lymph node involvement, and presence of metastasis.

Treatment plans that use more than one type of therapy, often in combination, are providing cures for a number of cancers that a few decades ago had a poor prognosis and are increasing the life expectancy in other types of cancer. Surgical procedures are more precise as a result of improved diagnostic equipment and new techniques, such as laser surgery. Radiation equipment and radioactive sources permit greater and more controlled destruction of cancer cells while causing less damage to normal tissues. Chemotherapy involves the use of drugs that exert their effects at the cellular level to prevent cell replication. Successes with immunotherapy techniques offer hope that the body's own defenses can be used in fighting cancer.

CHILDHOOD CANCERS

In the United States, cancer is the second leading cause of death in children 1 to 14 years of age.¹ Between 1974 and 1991, children younger than 14 years of age exhibited a 1% average yearly increase in the incidence of all malignant neoplasms, with a 1.6% average increase in the incidence of acute lymphocytic leukemia and a greater than 2% increase for astroglial tumors, rhabdomyosarcomas, germ cell tumors, and

osteosarcomas.³⁵ The spectrum of cancers that affect children differs markedly from those that affect adults. Although most adult cancers are of epithelial cell origin (*e.g.*, lung cancer, breast cancer, colorectal cancers), childhood cancers usually involve the hematopoietic system, nervous system, or connective tissue. Chart 5-3 lists the most common forms of solid childhood cancers.

As with adult cancers, there probably is no one cause of childhood cancer. However, many forms of childhood cancer repeat in families and may result from polygenic or single-gene inheritance, chromosomal aberrations (*e.g.*, translocations, deletions, insertions, inversions, duplications), exposure to mutagenic environmental agents, or a combination of these factors (see Chapter 4). If cancer develops in one child, the risk of cancer in siblings is approximately twice that of the general population, and if the disease develops in two children, the risk is even greater.

Heritable forms of cancer tend to have an earlier age of onset, a higher frequency of multifocal lesions in a single organ, and bilateral involvement of paired organs or multiple primary tumors. The two-hit hypothesis has been used as one explanation of heritable cancers.³ The first "hit" or mutation occurs prezygotically (*i.e.*, in germ cells before conception) and is present in the genetic material of all somatic cells. Cancer subsequently develops in one or several somatic cell lines that undergo a second mutation.

Children with heritable disorders are at increased risk for developing certain forms of cancer. For example, Down syndrome is associated with increased risk of leukemia; primary immunodeficiency disorders (see Chapter 10) are associated with lymphoma, leukemia, and brain cancer; and xeroderma pigmentosum is associated with basal and squamous cell carcinoma and melanoma.

Diagnosis and Treatment

The early diagnosis of childhood cancers often is overlooked because the signs and symptoms often are similar to those of common childhood diseases and because cancer occurs less frequently in children than in adults.³⁶ Symptoms of prolonged fever, unexplained weight loss, and growing masses (especially in association with weight loss) should be viewed as warning signs of cancer in children. Diagnosis of childhood cancers involves many of the same methods that are used in adults. Accurate disease staging is especially beneficial in childhood cancers, in which the potential benefits of treatment must be carefully weighed against potential long-term effects.

CHART 5-3 Common Solid Tumors of Childhood

Brain and nervous system tumors Medulloblastoma Glioma Neuroblastoma Wilms' tumor Rhabdomyosarcoma and embryonal sarcoma Retinoblastoma Osteosarcoma Ewing's sarcoma

Adult Survivors of Childhood Cancer

With improvement in treatment methods, the number of children who survive childhood cancer is continuing to increase.³⁷ Unfortunately, therapy may produce late sequelae, such as impaired growth, neurologic dysfunction, hormonal dysfunction, cardiomyopathy, pulmonary fibrosis, and risk of second malignancies. Although cures for large numbers of children have been possible only since the 1970s, much already is known about the potential for delayed effects.

Children reaching adulthood after cancer therapy may have reduced physical stature because of the therapy they received, particularly radiation, which retards the growth of normal tissues along with cancer tissue. The younger the age and the higher the radiation dose, the greater the deviation from normal growth. There also is concern that central nervous system radiation as a prophylactic measure in childhood leukemia has an effect on cognition and learning. Children younger than 6 years of age at the time of radiation and those receiving the highest radiation doses are most likely to have subsequent cognitive difficulties.

Delayed sexual maturation in both boys and girls can result from irradiation of the gonads. Delayed sexual maturation also is related to the treatment of children with alkylating agents. Cranial irradiation may result in premature menarche in girls, with subsequent early closure of the epiphysis and a reduction in final growth achieved. Data related to fertility and health of the offspring of childhood cancer survivors are just becoming available.

Vital organs such as the heart and lungs may be affected by cancer treatment. Children who received anthracyclines (*i.e.*, doxorubicin or daunorubicin) may be at risk for cardiomyopathy and congestive heart failure developing. Pulmonary irradiation may cause lung dysfunction and restrictive lung disease. Drugs such as bleomycin, methotrexate, and busulfan also can cause lung disease.

For survivors of childhood cancers, the risk of second cancers is reported to range from 3% to 12%. There is a special risk of second cancers in children with the retinoblastoma gene. Because of this risk, children who have been treated for cancer should be followed up routinely.

In summary, although most adult cancers are of epithelial cell origin, most childhood cancers usually involve the hematopoietic system, nervous system, or connective tissue. Heritable forms of cancer tend to have an earlier age of onset, a higher frequency of multifocal lesions in a single organ, and bilateral involvement of paired organs or multiple primary tumors. The early diagnosis of childhood cancers often is overlooked because the signs and symptoms often are similar to those of other childhood diseases. With improvement in treatment methods, the number of children who survive childhood cancer is continuing to increase. As these children approach adulthood, there is continued concern that the life-saving therapy they received during childhood may produce late sequelae, such as impaired growth, neurologic dysfunction, hormonal dysfunction, cardiomyopathy, pulmonary fibrosis, and risk of second malignancies.

REVIEW QUESTIONS

Use the cell cycle to explain the difference in regenerative capabilities of cells in self-renewing tissues such as the skin, stable cells such as liver cells, and permanent cells such as neurons.

Define *neoplasm* and explain how neoplastic growth differs from the normal adaptive changes seen in atrophy, hypertrophy, and hyperplasia.

Relate the properties of cell differentiation to the development of a cancer cell line and the behavior of the tumor.

Trace the pathway for hematologic spread of a metastatic cancer cell and explain why some cancers preferentially metastasize to certain tissues in the body.

Use the concepts of growth fraction and doubling time to explain the number of cancer cells that would be present in a breast cancer lesion at the time it can be detected by breast self exam.

Describe the role of proto-oncogenes and anti-oncogenes in the transformation of a normal cell line to a cancer cell line.

- Compare methods used in histological grading of tumors and clinical staging of cancers.
- Cite the early warning signs of cancer in children.

Fluids and electrolytes are present in body cells, in the tissue spaces between the cells, and in the blood that fills the vascular compartment. Body fluids serve to transport gases, nutrients, and wastes; help to generate the electrical activity needed to power body functions; take part in the transforming of food into energy; and otherwise maintain the overall function of the body. Although fluid volume and composition remain relatively constant in the presence of a wide range of changes in intake and output, conditions such as environmental stresses and disease can increase fluid loss, impair its intake, and otherwise interfere with mechanisms that regulate fluid volume, composition, and distribution.

COMPOSITION AND COMPARTMENTAL DISTRIBUTION OF BODY FLUIDS

Body fluids are distributed between the intracellular fluid (ICF) and extracellular fluid (ECF) compartments. The ICF compartment consists of fluid contained within all of the billions of cells in the body. It is the larger of the two compartments, containing approximately two thirds of the body water in healthy adults. The remaining one third of body water is in the ECF compartment, which contains all the fluids outside the cells, including that in the interstitial or tissue spaces and blood vessels (Fig. 6-1). The ECF, including the plasma and interstitial fluids,

■ FIGURE 6-1 ■ Distribution of body water. The extracellular space includes the vascular compartment (plasma water) and the interstitial spaces.

contain large amounts of sodium and chloride, moderate amounts of bicarbonate, but only small quantities of potassium. In contrast to the ECF fluid, the ICF contains small amounts of sodium, chloride, and bicarbonate and large amounts of potassium (Table 6-1). It is the ECF levels of electrolytes in the blood or blood serum that are measured clinically. Although blood levels usually are representative of the total body levels of an electrolyte, this is not always the case, particularly with potassium, which is approximately 28 times more concentrated inside the cell than outside.

The cell membrane serves as the primary barrier to the movement of substances between the ECF and ICF compartments. Lipid-soluble substances such as gases (*i.e.*, oxygen and carbon dioxide), which dissolve in the lipid bilayer of the cell membrane, pass directly through the membrane. Many ions, such as sodium (Na⁺) and potassium (K⁺), rely on transport

TABLE 6-1Concentrations ofExtracellular and IntracellularElectrolytes in Adults		
Electrolyte	Extracellular Concentration*	Intracellular Concentration*
Sodium	135–145 mEq/L	10–14 mEq/L
Potassium	3.5–5.0 mEq/L	140–150 mEq/L
Chloride	98–106 mEq/L	3–4 mEq/L
Bicarbonate	24–31 mEq/L	7–10 mEq/L
Calcium	8.5–10.5 mg/dL	<1 mEq/L
Phosphate/ phosphorus	2.5–4.5 mg/dL	4 mEq/kg [†]
Magnesium	1.8–3.0 mg/dL	40 mEq/kg†

*Values may vary among laboratories, depending on the method of analysis used.

*Values vary among various tissues and with nutritional status.

mechanisms such as the Na⁺/K⁺-ATPase pump that is located in the cell membrane for movement across the membrane (see Chapter 1). Water crosses the cell membrane by osmosis using special protein channels.

Introductory Concepts

The electrolytes in body fluids are substances that dissociate in solution to form charged particles, or *ions*. For example, a sodium chloride (NaCl) molecule dissociates to form a positively charged Na⁺ ion and a negatively charged Cl⁻ ion. Because of their attraction forces, positively charged cations are always accompanied by negatively charged anions. The distribution of electrolytes between body compartments is influenced by their electrical charge. However, one cation may be exchanged for another, providing it carries the same charge. For example, a positively charged H⁺ ion may be exchanged for a positively charged K⁺ and a negatively charged HCO₃⁻ ion may be exchanged for a negatively charged Cl⁻ anion.

Diffusion and Osmosis

Diffusion is the movement of charged or uncharged particles along a concentration gradient. All molecules and ions, including water and dissolved molecules, are in constant random motion. It is the motion of these particles, each colliding with one another, that supplies the energy for diffusion. Because there are more molecules in constant motion in a concentrated solution, particles move from an area of higher concentration to one of lower concentration.

Osmosis is the movement of water across a semipermeable membrane (*i.e.*, one that is permeable to water but impermeable to most solutes). As with solute particles, water diffuses down its concentration gradient, moving from the side of the membrane with the lesser number of particles and greater concentration of water to the side with the greater number of particles and lesser concentration of water (Fig. 6-2). As water moves across the semipermeable membrane, it generates a pressure, called the *osmotic pressure*. The osmotic pressure represents the pressure (measured in millimeters of mercury [mm Hg]) needed to oppose the movement of water across the membrane.

The osmotic activity that nondiffusible particles exert in pulling water from one side of the semipermeable membrane to the other is measured by a unit called an *osmole*. The osmole is derived from the gram molecular weight of a substance (*i.e.*, 1 gram molecular weight of a nondiffusible and nonionizable substance is equal to 1 osmole). In the clinical setting, osmotic activity usually is expressed in milliosmoles (one thousandth of an osmole) per liter. Each nondiffusible particle, large or small, is equally effective in its ability to pull water through a semipermeable membrane. Thus, it is the number, rather than the size, of the nondiffusible particles that determines the osmotic activity of a solution.

The osmotic activity of a solution may be expressed in terms of either its osmolarity or osmolality. *Osmolarity* refers to the osmolar concentration in 1 L of solution (mOsm/L) and *osmolality* to the osmolar concentration in 1 kg of water (mOsm/kg of H_2O). Osmolarity is usually used when referring to fluids outside the body and osmolality for describing fluids inside the body. Because 1 L of water weighs 1 kg, the terms *osmolarity* and *osmolality* are often used interchangeably.

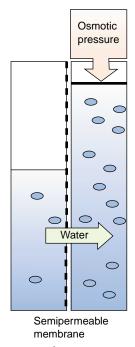

FIGURE 6-2 Movement of water across a semipermeable membrane. Water moves from the side that has fewer nondiffusible particles to the side that has more. The osmotic pressure is equal to the hydrostatic pressure needed to oppose water movement across the membrane.

Serum osmolality, which is largely determined by sodium and its attendant anions (chloride and bicarbonate), normally ranges between 275 and 295 mOsm/kg. Blood urea nitrogen (BUN) and glucose, which also are osmotically active, account for less than 5% of the total osmotic pressure in the ECF compartment. However, this can change, such as when blood glucose levels are elevated in persons with diabetes mellitus or when BUN levels change rapidly in persons with renal failure.

Tonicity. A change in water content causes cells to swell or shrink. The term *tonicity* refers to the tension or effect that the effective osmotic pressure of a solution with impermeable solutes exerts on cell size because of water movement across the cell membrane. An effective osmole is one that exerts an osmotic force and cannot permeate the cell membrane, whereas an ineffective osmole is one that exerts an osmotic force but crosses the cell membrane. Tonicity is determined solely by effective solutes such as glucose that cannot penetrate the cell membrane, thereby producing an osmotic force that pulls water into or out of the cell and causing it to change size.

Solutions to which body cells are exposed can be classified as isotonic, hypotonic, or hypertonic, depending on whether they cause cells to swell or shrink (Fig. 6-3). Cells placed in an isotonic solution, which has the same effective osmolality as the ICF (*i.e.*, 280 mOsm/L), neither shrink nor swell. An example of an isotonic solution is 0.9% sodium chloride. When cells are placed in a hypotonic solution, which has a lower effective osmolality than the ICF, they swell as water moves into the cell; when they are placed in a hypertonic solution, which has a greater effective osmolality than ICF, they shrink as water is pulled out of the cell.

Measurement Units

Laboratory measurements of electrolytes in body fluids are expressed as a concentration or amount of solute in a given volume of fluid, such as milligrams per deciliter (mg/dL), milliequivalents per liter (mEq/L), or millimoles per liter (mmol/L).

The use of *milligrams (mg) per deciliter* expresses the weight of the solute in one tenth of a liter (dL). The concentration of electrolytes, such as calcium, phosphate, and magnesium, is often expressed in mg/dL.

The *milliequivalent* is used to express the charge equivalency for a given weight of an electrolyte: 1 mEq of sodium has the same number of charges as 1 mEq of chloride, regardless of molecular weight. The number of milliequivalents of an electrolyte in a liter of solution can be derived from the following equation:

mEq =
$$\frac{\text{mg}/100 \text{ mL} \times 10 \times \text{valence}}{\text{atomic weight}}$$

The Système Internationale (SI) units express electrolyte concentration in *millimoles per liter* (mmol/L). A millimole is one thousandth of a mole, or the molecular weight of a substance expressed in milligrams. The number of millimoles of an electrolyte in a liter of solution can be calculated using the following equation:

$$mmol/L = \frac{mEq/L}{valence}$$

Compartmental Distribution of Body Fluids

Body water is distributed between the ICF and ECF compartments. In the adult, the fluid in the ICF compartment constitutes approximately 40% of body weight.¹ The fluid in the ECF compartment is further divided into two major subdivisions: the plasma compartment, which constitutes approximately 4%

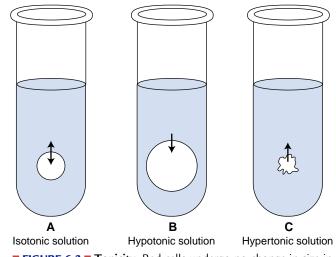

FIGURE 6-3 Tonicity. Red cells undergo no change in size in isotonic solutions (**A**). They increase in size in hypotonic solutions (**B**) and decrease in size in hypertonic solutions (**C**).

of body weight, and the interstitial fluid compartment, which constitutes approximately 15% of body weight (Fig. 6-4).

A third, usually minor, subdivision of the ECF compartment is the transcellular compartment. It includes the cerebrospinal fluid and fluid contained in the various body spaces, such as the peritoneal, pleural, and pericardial cavities; the joint spaces; and the gastrointestinal tract. Normally, only approximately 1% of ECF is in the transcellular space. This amount can increase considerably in conditions such as ascites, in which large amounts of fluid are sequestered in the peritoneal cavity. When the transcellular fluid compartment becomes considerably enlarged, it is referred to as a *third space*, because this fluid is not readily available for exchange with the rest of the ECF.

Intracellular Fluid Volume

The intracellular fluid volume is regulated by proteins and organic compounds in the ICF and by solutes that move between the ECF and ICF. The membrane in most cells is freely permeable to water; therefore, water moves between the ECF and ICF as a result of osmosis. In contrast, osmotically active proteins and other organic compounds cannot pass through the membrane. Water entry into the cell is regulated by these osmotically active substances as well as by solutes such as sodium and potassium that pass through the cell membrane. Many of the intracellular proteins are negatively charged and attract positively charged ions such as the K⁺ ion, accounting for its higher concentration in the ICF. The Na⁺ ion, which has a greater concentration in the ECF, tends to enter the cell by diffusion. The Na⁺ ion is osmotically active, and its entry would, if left unchecked, pull water into the cell until it ruptured. The reason this does not occur is because the Na⁺/K⁺-ATPase membrane pump continuously removes three Na⁺ ions from the cell for every two K⁺ ions that are moved back into the cell (see Chapter 1). Situations that impair the function of the Na⁺/K⁺-ATPase pump, such as hypoxia, cause cells to swell because of an accumulation of Na+ ions.

Intracellular volume is also affected by the concentration of osmotically active substances in the extracellular fluid that cannot cross the cell membrane. In diabetes mellitus, for example, glucose cannot enter the cell and its increased concentration in the ECF pulls water out of the cell.

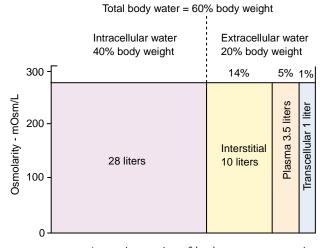

FIGURE 6-4 Approximate size of body compartments in a 70-kg adult.

Extracellular Fluid Volume

The ECF is divided between the vascular and interstitial fluid compartments. The vascular compartment contains blood, which is essential to the transport of substances such as electrolytes, gases, nutrients, and waste products throughout the body. The fluid in the interstitial compartment acts as a transport vehicle for gases, nutrients, wastes, and other materials that move between the vascular compartment and body cells. The interstitial fluid compartment also provides a reservoir from which vascular volume can be maintained during periods of hemorrhage or loss of vascular volume. A tissue gel, which is a spongelike material composed of large quantities of mucopolysaccharides, fills the tissue spaces and aids in even distribution of interstitial fluid. Normally, most of the fluid in the interstitium is in gel form. The tissue gel is supported by collagen fibers that hold the gel in place. The tissue gel, which has a firmer consistency than water, opposes the outflow of water from the capillaries and prevents the accumulation of free water in the interstitial spaces.

Capillary/Interstitial Fluid Exchange

The transfer of water between the vascular and interstitial compartments occurs at the capillary level. Four forces control the movement of water between the capillary and interstitial spaces: (1) the capillary filtration pressure, which pushes water out of the capillary into the interstitial spaces; (2) the capillary colloidal osmotic pressure, which pulls water back into the capillary; (3) the interstitial hydrostatic pressure, which opposes the movement of water out of the capillary; and (4) the tissue colloidal osmotic pressure, which pulls water out of the capillary into the interstitial spaces (Fig. 6-5). Normally, the combination of these four forces is such that only a small excess of fluid remains in the interstitial compartment. This excess fluid is removed from the interstitium by the lymphatic system and returned to the systemic circulation.

Capillary filtration refers to the movement of water through capillary pores because of a mechanical, rather than an osmotic, force. The capillary filtration pressure, sometimes called the *capillary hydrostatic pressure*, is the pressure pushing water out of the capillary into the interstitial spaces. It reflects the

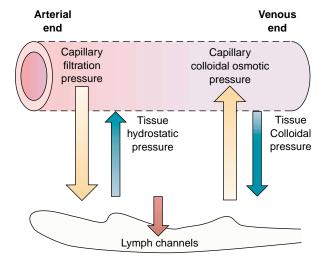

FIGURE 6-5 Exchange of fluid at the capillary level.

Unit One: Mechanisms of Disease

arterial and venous pressures, the precapillary (arterioles) and postcapillary (venules) resistances, and the force of gravity.² A rise in arterial or venous pressure increases capillary pressure. A decrease in arterial resistance or increase in venous resistance increases capillary pressure, and an increase in arterial resistance or decrease in venous resistance decreases capillary pressure. The force of gravity increases capillary pressure in the dependent parts of the body. In a person who is standing absolutely still, the weight of blood in the vascular column causes an increase of 1 mm Hg in pressure for every 13.6 mm of distance from the heart.² This pressure results from the weight of water and is therefore called *hydrostatic pressure*. In the adult who is standing absolutely still, the pressure in the veins of feet can reach 90 mm Hg. This pressure is then transmitted to the capillaries.

The *capillary colloidal osmotic pressure* is the osmotic pressure generated by the plasma proteins that are too large to pass through the pores of the capillary wall. The term *colloidal osmotic pressure* differentiates this type of osmotic pressure from the osmotic pressure that develops at the cell membrane from the presence of electrolytes and nonelectrolytes. Because plasma proteins do not normally penetrate the capillary pores and because their concentration is greater in the plasma than in the interstitial fluids, it is capillary colloidal osmotic pressure that pulls fluids back into the capillary.

The interstitial fluid pressure and the tissue colloidal osmotic pressure contribute to movement of water into and out of the interstitial spaces. The interstitial fluid pressure opposes the outward movement of water from the capillary into the interstitial spaces. The tissue colloidal osmotic pressure pulls water out of the capillary into the tissue spaces. It reflects the small amount of plasma proteins that normally escape from the capillary to enter the interstitial spaces.

Edema

Edema can be defined as palpable swelling produced by expansion of the interstitial fluid volume. Edema does not become evident until the interstitial fluid volume has been increased by 2.5 to 3 L.³

The physiologic mechanisms that contribute to edema formation include factors that: (1) increase the capillary filtration pressure, (2) decrease the capillary colloidal osmotic pressure, (3) increase capillary permeability, or (4) produce obstruction to lymph flow. The causes of edema are summarized in Chart 6-1.

Increased Capillary Filtration Pressure. As the capillary filtration pressure rises, the movement of vascular fluid into the interstitial spaces increases. Among the factors that increase capillary pressure are: (1) a decrease in the resistance to flow through the precapillary sphincters; (2) an increase in venous pressure or resistance to outflow at the postcapillary sphincters, and (3) capillary distention caused by increased vascular volume.

Edema can be either localized or generalized. The localized edema that occurs with urticaria (*i.e.*, hives) or other allergic or inflammatory conditions results from the release of histamine and other inflammatory mediators that cause dilation of the precapillary sphincters and arterioles that supply the swollen lesions. Thrombophlebitis obstructs venous flow, producing an elevation of venous pressure and edema of the affected part, usually one of the lower extremities.

CHART 6-1 Causes of Edema

Increased Capillary Pressure

Increased Capillary Pressure
Increased vascular volume
Heart failure
Kidney disease
Premenstrual sodium retention
Pregnancy Environmental heat stress
Venous obstruction
Liver disease with portal vein obstruction
Acute pulmonary edema
Venous thrombosis (thrombophlebitis)
Decreased arteriolar resistance
Calcium channel-blocking drug responses
Decreased Colloidal Osmotic Pressure
Increased loss of plasma proteins Protein-losing kidney diseases Extensive burns Decreased production of plasma proteins Liver disease
Starvation, malnutrition
Increased Capillary Permeability
Inflammation Allergic reactions (<i>e.g.,</i> hives, angioneurotic edema) Malignancy (<i>e.g.,</i> ascites, pleural effusion) Tissue injury and burns
Obstruction of Lymphatic Flow

Malignant obstruction of lymphatic structures Surgical removal of lymph nodes

Generalized edema is common in conditions such as congestive heart failure that produce fluid retention and venous congestion. In right-sided heart failure, blood dams up throughout the entire venous system, causing organ congestion and edema of the dependent extremities. Decreased sodium and water excretion by the kidneys leads to an increase in ECF volume with an increase in capillary volume and pressure with subsequent movement of fluid into the tissue spaces. The swelling of hands and feet that occurs in healthy persons during hot weather results from vasodilation of superficial blood vessels along with sodium and water retention.

Because of the effects of gravity, edema resulting from increased capillary pressure commonly causes fluid to accumulate in the dependent parts of the body, a condition referred to as *dependent edema*. For example, edema of the ankles and feet becomes more pronounced during prolonged periods of standing.

Decreased Capillary Colloidal Osmotic Pressure. Plasma proteins exert the osmotic force needed to pull fluid back into the capillary from the tissue spaces. The plasma proteins constitute a mixture of proteins, including albumin, globulins, and fibrinogen. Albumin, the smallest of the plasma proteins, has a molecular weight of 69,000; globulins have molecular weights of approximately 140,000; and fibrinogen has a molecular weight of 400,000.² Because of its lower molecular weight, 1 g of albumin has approximately twice as many osmotically active molecules as 1 g of globulin and almost six times as many osmotically active molecules as 1 g of fibrinogen. In addition, the concentration of albumin (approximately 4.5 g/dL) is greater than that of the globulins (2.5 g/dL) and fibrinogen (0.3 mg/dL).

Edema caused by decreased capillary colloidal osmotic pressure usually is the result of inadequate production or abnormal loss of plasma proteins, mainly albumin. The plasma proteins are synthesized in the liver. In persons with severe liver failure, impaired synthesis of albumin results in a decrease in colloidal osmotic pressure. In starvation and malnutrition, edema develops because there is a lack of the amino acids needed in plasma protein synthesis.

The most common site of plasma protein loss is the kidney. In kidney diseases such as nephrosis, the glomerular capillaries become permeable to the plasma proteins, particularly albumin, which is the smallest of the proteins. When this happens, large amounts of albumin are filtered out of the blood and lost in the urine. An excessive loss of plasma proteins also occurs when large areas of skin are injured or destroyed. Edema is a common problem during the early stages of a burn, resulting from capillary injury and loss of plasma proteins.

Because the plasma proteins are evenly distributed throughout the body and are not affected by the force of gravity, edema caused by decreased capillary colloidal osmotic pressure tends to affect tissues in nondependent as well as dependent parts of the body. There is swelling of the face as well as the legs and feet.

Increased Capillary Permeability. When the capillary pores become enlarged or the integrity of the capillary wall is damaged, capillary permeability is increased. When this happens, plasma proteins and other osmotically active particles leak into the interstitial spaces, increasing the tissue colloidal osmotic pressure and thereby contributing to the accumulation of interstitial fluid. Among the conditions that increase capillary permeability are burn injury, capillary congestion, inflammation, and immune responses.

Obstruction of Lymph Flow. Osmotically active plasma proteins and other large particles that cannot be reabsorbed through the pores in the capillary membrane rely on the lymphatic system for movement back into the circulatory system. Edema caused by impaired lymph flow is commonly referred to as *lymphedema*. Malignant involvement of lymph structures and removal of lymph nodes at the time of cancer surgery are common causes of lymphedema. Another cause of lymphedema is infection involving the lymphatic channels and lymph nodes.

Manifestations. The effects of edema are determined largely by its location. Edema of the brain, larynx, or lungs is an acute, life-threatening condition. Although not life threatening, edema may interfere with movement by limiting joint motion. Swelling of the ankles and feet often is insidious in onset and may or may not be associated with disease. At the tissue level, edema increases the distance for diffusion of oxygen, nutrients, and wastes. Edematous tissues usually are more susceptible to

injury and the development of ischemic tissue damage, including pressure ulcers. Edema can also compress blood vessels. For example, the skin of a severely swollen finger can act as a tourniquet, shutting off the blood flow to the finger. Edema can also be disfiguring, causing psychological effects and disturbances in self-concept.

Assessment and Treatment. Methods for assessing edema include daily weight, visual assessment, measurement of the affected part, and application of finger pressure to assess for pitting edema. Daily weight performed at the same time each day with the same amount of clothing provides a useful index of water gain (1 L of water weighs 2.2 pounds) attributable to edema. Visual inspection and measurement of the circumference of an extremity can also be used to assess the degree of swelling. This is particularly useful when swelling is caused by thrombophlebitis. Pitting edema occurs when the accumulation of interstitial fluid exceeds the absorptive capacity of the tissue gel. In this form of edema, the tissue water becomes mobile and can be translocated with pressure exerted by a finger. Finger pressure can be used to assess the degree of pitting edema. If an indentation remains after the finger has been removed, pitting edema is identified. It is evaluated on a scale of +1 (minimal) to +4 (severe) (Fig. 6-6).

Treatment of edema usually is directed toward maintaining life when the swelling involves vital structures, correcting or controlling the cause, and preventing tissue injury. Diuretic therapy commonly is used to treat edema. Edema of the lower extremities may respond to simple measures such as elevating the feet.

Elastic support stockings and sleeves increase interstitial fluid pressure and resistance to outward movement of fluid from the capillary into the tissue spaces. These support devices typically are prescribed for patients with conditions such as lymphatic or venous obstruction and are most efficient if applied before the tissue spaces have filled with fluid, such as in the morning, before the effects of gravity have caused fluid to move into the ankles.

Third-Space Accumulation

Third spacing represents the loss or trapping of ECF in the transcellular space. The serous cavities are part of the transcellular compartment (i.e., third space) located in strategic body areas where there is continual movement of body structures-the pericardial sac, the peritoneal cavity, and the pleural cavity. The exchange of ECF among the capillaries, the interstitial spaces, and the transcellular space of the serous cavity uses the same mechanisms as capillaries elsewhere in the body. The serous cavities are closely linked with lymphatic drainage systems. The milking action of the moving structures, such as the lungs, continually forces fluid and plasma proteins back into the circulation, keeping these cavities empty. Any obstruction to lymph flow causes fluid accumulation in the serous cavities. As with edema fluid, third-space fluids represent an accumulation or trapping of body fluids that contribute to body weight but not to fluid reserve or function.

The prefix *hydro-* may be used to indicate the presence of excessive fluid, as in *hydrothorax*, which means excessive fluid in the pleural cavity. The accumulation of fluid in the peritoneal cavity is called *ascites*. The transudation of fluid into the serous cavities is also referred to as *effusion*. Effusion can contain blood, plasma proteins, inflammatory cells (*i.e.*, pus), and ECF.

In summary, body fluids are distributed between the ICF and ECF compartments of the body. Two thirds of body fluids are contained in the body cells of the ICF compartment, and one third is contained in the vascular compartment, interstitial spaces, and third-space areas of the ECF compartment. Electrolytes and nonelectrolytes move by diffusion across cell membranes that separate the ICF and ECF compartments. Water moves by osmosis across semipermeable membranes, moving from the side of the membrane that has the lesser number of particles and greater concentration of water to the side that has the greater number of particles and lesser concentration of water. The osmotic tension or effect that a solution exerts on cell volume in terms of causing the cell to swell or shrink is called *tonicity*.

Intracellular volume is regulated by the large numbers of proteins and other inorganic solutes that cannot cross the cell's membrane and solutes such as sodium, potassium, and glucose that selectively move between the ICF and ECF dependent upon concentration gradients and transport mechanisms. ECF volume, which is distributed between the vascular and interstitial compartments, is regulated by the elimination of sodium and water by the kidney.

Edema represents an increase in interstitial fluid volume. The physiologic mechanisms that predispose to edema formation are increased capillary filtration pressure, decreased capillary colloidal osmotic pressure, increased capillary permeability, and obstruction of lymphatic flow. The effect that edema exerts on body function is determined by its location; cerebral edema can be a life-threatening situation, but swollen feet can be a normal discomfort that accompanies hot weather. Fluid can also accumulate in the transcellular compartment—the joint spaces, pericardial sac, the peritoneal cavity, and the pleural cavity. Because this fluid is not easily exchanged with the rest of the ECF, it is often referred to as third-space fluid.

SODIUM AND WATER BALANCE

The movement of body fluids between the ICF and ECF compartments occurs at the cell membrane and depends on regulation of ECF water and sodium. Water provides approximately 90% to 93% of the volume of body fluids and sodium salts approximately 90% to 95% of the ECF solutes. Normally, equivalent changes in sodium and water are such that the volume and osmolality of the ECF is maintained within a normal range. Because it is the concentration of sodium (in milligrams per liter) that controls ECF osmolality, changes in sodium are usually accompanied by proportionate changes in water volume.

Alterations of sodium and water balance can be divided into two main categories: (1) isotonic contraction or expansion of ECF volume and (2) hypotonic dilution (hyponatremia) or hypertonic concentration (hypernatremia) of sodium brought about by changes in extracellular water (Fig. 6-7). Isotonic disorders usually are confined to the ECF compartment producing a contraction (fluid volume deficit) or expansion (fluid volume excess) of the interstitial and vascular fluids. Disorders of sodium concentration produce a change in the osmolality of the ECF with movement of water from the ECF compartment into the ICF compartment (hyponatremia) or from the ICF compartment into the ECF compartment (hypernatremia) (Fig. 6-8).

Regulation of Sodium and Water Balance

Regulation of Sodium Balance

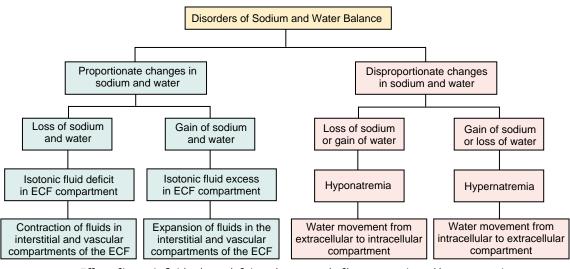

Sodium is the most abundant cation in the body, averaging approximately 60 mEq/kg of body weight.² Most of the body's sodium is in the ECF compartment (135 to 145 mEq/L), with only a small amount (10 to 14 mEq/L) located in the ICF compartment.

Sodium functions mainly in regulating extracellular fluid volume, including that in the vascular compartment. As the major cation in the ECF compartment, Na⁺ and its attendant anions (Cl⁻ and HCO₃⁻) account for most of the osmotic activity in the ECF. Because sodium is part of the sodium bicarbonate molecule, it is important in regulating acid-base balance. As a current-carrying ion, sodium contributes to the function of the nervous system and other excitable tissue.

Gains and Losses. Sodium normally enters the body through the gastrointestinal tract. Sodium intake normally is derived from dietary sources. Other sources of sodium are intravenous saline infusions and medications that contain sodium.

Sodium leaves the body through the kidney, gastrointestinal tract, and skin. Most sodium losses occur through the kidney. The kidneys are extremely efficient in regulating sodium output, and when sodium intake is limited or conservation of sodium is needed, the kidneys are able to reabsorb almost all the sodium that has been filtered by the glomerulus. This results in an essentially sodium-free urine. Conversely, urinary losses of sodium increase as intake increases.

Usually less than 10% of sodium intake is lost through the gastrointestinal tract and skin. Sodium losses increase with conditions such as vomiting, diarrhea, fistula drainage, and

■ FIGURE 6-7 ■ Effect of isotonic fluid volume deficit and excess and of hyponatremia and hypernatremia on ECF and ICF volume.

gastrointestinal suction that remove sodium from the upper gastrointestinal tract. Irrigation of gastrointestinal tubes with distilled water removes sodium from the gastrointestinal tract, as do repeated tap water enemas. Sweat losses, which usually are negligible, can increase greatly during exercise and periods of exposure to a hot environment. Loss of skin integrity, such as occurs in extensive burns, also leads to excessive skin losses of sodium. **Mechanisms of Sodium Regulation.** The kidney is the main regulator of sodium. The kidney monitors arterial pressure and retains sodium when the arterial pressure is decreased and eliminates it when the arterial pressure is increased. The rate at which the kidney excretes or conserves sodium is coordinated by the sympathetic nervous system and the renin-angiotensin-aldosterone system. The sympathetic nervous system responds to changes in arterial pressure and blood volume by adjusting

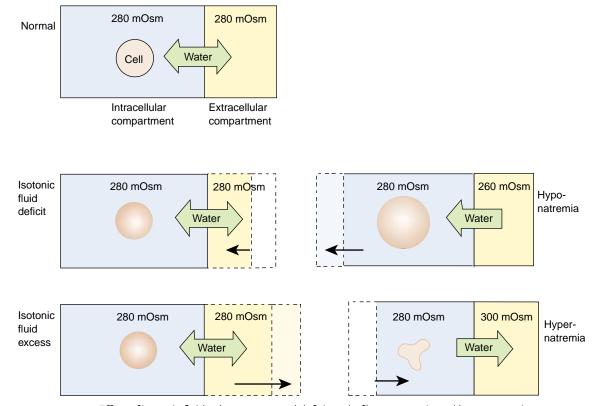

FIGURE 6-8 Effect of isotonic fluid volume excess and deficit and of hyponatremia and hypernatremia on extracellular and intracellular fluid volume.

the glomerular filtration rate and the rate at which sodium is filtered from the blood. Sympathetic activity also regulates tubular reabsorption of sodium and renin release. The reninangiotensin-aldosterone system exerts its action through angiotensin II and aldosterone (see Chapter 16). Angiotensin II acts directly on the renal tubules to increase sodium reabsorption. It also acts to constrict renal blood vessels, thereby decreasing the glomerular filtration rate and slowing renal blood flow so that less sodium is filtered and more is reabsorbed. Angiotensin II is also a powerful regulator of aldosterone, a hormone secreted by the adrenal cortex. Aldosterone acts at the level of the cortical collecting tubules of the kidneys to increase sodium reabsorption while increasing potassium elimination.

Regulation of Water Balance

Total body water (TBW) varies with gender and weight. These differences can be explained by differences in body fat, which is essentially water free. In men, body water approximates 60% of body weight during young adulthood and decreases to approximately 50% in old age. In young women, it is approximately 50% and in elderly women, approximately 40%.³ Obesity produces further decreases in body water, sometimes reducing these levels to values as low as 30% to 40% of body weight in adults (Fig. 6-9).

Infants have a high TBW content. TBW constitutes approximately 75% to 80% of body weight in full-term infants and is even greater in premature infants. In addition to having proportionately more body water than adults, infants have relatively more water in their ECF compartment. Infants have more than half of their TBW in the ECF compartment, whereas adults have only approximately a third.⁴ The greater extracellular water content of an infant can be explained in terms of its higher metabolic rate, larger surface area in relation to its body mass, and its inability to concentrate its urine because of immature

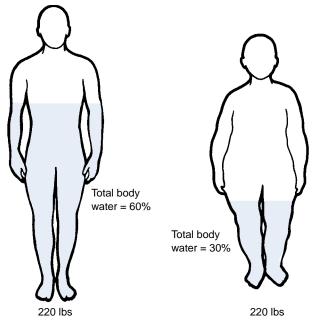

FIGURE 6-9 Body composition of a lean and an obese individual. (Adapted with permission from Statland H. [1963]. *Fluids and electrolytes in practice*. [3rd ed.]. Philadelphia: J.B. Lippincott)

kidney structures. Because ECF is more easily lost from the body, infants are more vulnerable to fluid deficit than are older children and adults. As an infant grows older, TBW decreases, and by the second year of life, the percentages and distribution of body water approach those of an adult.⁵

Gains and Losses. Regardless of age, all healthy persons require approximately 100 mL of water per 100 calories metabolized for dissolving and eliminating metabolic wastes. This means that a person who expends 1800 calories for energy requires approximately 1800 mL of water for metabolic purposes. The metabolic rate increases with fever; it rises approximately 12% for every 1°C (7% for every 1°F) increase in body temperature.² Fever also increases the respiratory rate, resulting in additional loss of water vapor through the lungs.

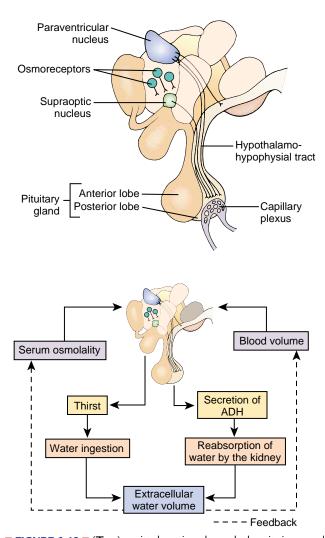

The main source of water gain is through oral intake and metabolism of nutrients. Water, including that obtained from liquids and solid foods, is absorbed from the gastrointestinal tract. Metabolic processes also generate a small amount of water. The amount of water gained from these processes varies from 150 to 300 mL/day, depending on metabolic rate.

Normally, the largest loss of water occurs through the kidneys, with lesser amounts being lost through the skin, lungs, and gastrointestinal tract. Even when oral or parenteral fluids are withheld, the kidneys continue to produce urine as a means of ridding the body of metabolic wastes. The urine output that is required to eliminate these wastes is called the *obligatory urine output*. The obligatory urine loss is approximately 300 to 500 mL/day. Water losses that occur through the skin and lungs are referred to as *insensible water losses* because they occur without a person's awareness. The gains and losses of body water are summarized in Table 6-2.

Mechanisms of Regulation. There are two main physiologic mechanisms that assist in regulating body water: thirst and antidiuretic hormone (ADH). Thirst is primarily a regulator of water intake and ADH a regulator of water output. Both mechanisms respond to changes in extracellular osmolality and volume (Fig. 6-10).

Thirst. Thirst is controlled by the thirst center in the hypothalamus. There are two stimuli for true thirst based on water need: (1) cellular dehydration caused by an increase in extracellular osmolality and (2) a decrease in blood volume, which may or may not be associated with a decrease in serum osmolality. Sensory neurons, called *osmoreceptors*, which are located in or

TABLE 6-2 Sources of Body Water Gains and Losses in the Adult			
Gains		Losses	
Oral intake		Urine	1500 mL
As water In food	1000 mL 1300 mL	Insensible losses Lungs	300 mL

■ FIGURE 6-10 ■ (Top) sagittal section through the pituitary and anterior hypothalamus. Antidiuretic hormone (ADH) is formed primarily in the supraoptic nucleus and to a lesser extent in the paraventricular nucleus of the hypothalamus. It is then transported down the hypothalamohypophysial tract and stored in secretory granules in the posterior pituitary, where it can be released into the blood. (**Bottom**) pathways for regulation of extracellular water volume by thirst and antidiuretic hormone.

near the thirst center in the hypothalamus, respond to changes in extracellular osmolality by stimulating the sensation of thirst (Fig. 6-10). Thirst normally develops when there is as little as a 1% to 2% change in serum osmolality.⁶ Stretch receptors in the vascular system that are sensitive to changes in arterial blood pressure and central blood volume also aid in the regulation of thirst. A third important stimulus for thirst is angiotensin II, which becomes increased in response to low blood volume and low blood pressure.

Dryness of the mouth produces a sensation of thirst that is not necessarily associated with the body's hydration status. Thirst sensation also occurs in those who breathe through their mouths, such as smokers and persons with chronic respiratory disease or hyperventilation syndrome.

Hypodipsia represents a decrease in the ability to sense thirst. There is evidence that thirst is decreased and water in-

take reduced in elderly persons, despite higher serum sodium and osmolality levels.^{7,8} The inability to perceive and respond to thirst is compounded in elderly persons who have had a stroke and may be further influenced by confusion and sensory disturbances.

Polydipsia, or excessive thirst, can be classified into three categories: (1) symptomatic or true thirst, (2) inappropriate or false thirst that occurs despite normal levels of body water and serum osmolality, and (3) compulsive water drinking. Symptomatic thirst develops when there is a loss of body water and resolves after the loss has been replaced. Among the most common causes of symptomatic thirst are water losses associated with diarrhea, vomiting, diabetes mellitus, and diabetes insipidus. Inappropriate or excessive thirst may persist despite adequate hydration. It is a common complaint in persons with renal failure and congestive heart failure. Although the cause of thirst in these persons is unclear, it may result from increased angiotensin levels. Thirst is also a common complaint in persons with dry mouth caused by decreased salivary function or treatment with drugs with an anticholinergic action (e.g., antihistamines, atropine) that lead to decreased salivary flow.

Psychogenic polydipsia involves compulsive water drinking and is usually seen in persons with psychiatric disorders, most commonly schizophrenia. Persons with the disorder drink large amounts of water and excrete large amounts of urine. The cause of excessive water drinking in these persons is uncertain. It has been suggested that the compulsive water drinking may share the same pathology as the psychosis because persons with the disorder often increase their water drinking during periods of exacerbation of their psychotic symptoms.⁹ The condition may be compounded by antipsychotic medications that increase ADH levels and interfere with water excretion by the kidneys. Cigarette smoking, which is common among persons with psychiatric disorders, also stimulates ADH secretion. Excessive water ingestion coupled with impaired water excretion (or rapid ingestion at a rate that exceeds renal excretion) in persons with psychogenic polydipsia can lead to water intoxication (see Hyponatremia). Treatment consists of water restriction and behavioral measures aimed at decreasing water consumption.10

Antidiuretic Hormone. The reabsorption of water by the kidneys is regulated by ADH, also known as vasopressin. ADH is synthesized by cells in the supraoptic and paraventricular nuclei of the hypothalamus; transported along a neural pathway (*i.e.*, hypothalamohypophysial tract) to the neurohypophysis (*i.e.*, posterior pituitary); and then released into the circulation (see Fig. 6-10).¹¹

As with thirst, ADH levels are controlled by extracellular volume and osmolality. Osmoreceptors in the hypothalamus sense changes in extracellular osmolality and stimulate the production and release of ADH. A small increase in serum osmolality of 1% is sufficient to cause ADH release. Likewise, stretch receptors (baroreceptors) that are sensitive to changes in blood pressure and central blood volume aid in the regulation of ADH release. A blood volume decrease of 5% to 10% produces a maximal increase in ADH levels.¹² As with many other homeostatic mechanisms, acute conditions produce greater changes in ADH levels than do chronic conditions; long-term changes in blood volume or blood pressure may exist without affecting ADH levels. An abnormal increase in ADH synthesis and release occurs in a number of stress situations. Severe pain, nausea, trauma, surgery, certain anesthetic agents, and some narcotics (*e.g.*, morphine and meperidine) increase ADH levels. Nausea is a potent stimulus of ADH secretion; it can increase ADH levels 10 to 1000 times those required for maximal diuresis.¹³ Among the drugs that affect ADH are nicotine, which stimulates its release, and alcohol, which inhibits it. Two important conditions alter ADH levels: diabetes insipidus and inappropriate secretion of ADH.

Diabetes insipidus (DI) is caused by a deficiency of or a decreased response to ADH. Persons with DI are unable to concentrate their urine during periods of water restriction; they excrete large volumes of urine, usually 3 to 20 L/day, depending on the degree of ADH deficiency or renal insensitivity to ADH. This large urine output is accompanied by excessive thirst. As long as the thirst mechanism is normal and fluid is readily available, there is little or no alteration in the fluid levels of persons with DI. The danger arises when the condition develops in someone who is unable to communicate the need for water or is unable to secure the needed water. In such cases, inadequate fluid intake rapidly leads to hypertonic dehydration and increased serum osmolality.

There are two types of DI: central or neurogenic and nephrogenic DI. Neurogenic DI occurs because of a defect in the synthesis or release of ADH and nephrogenic DI occurs because the kidneys do not respond to ADH.¹⁴ In neurogenic DI, loss of 75% to 80% of ADH-secretory neurons is necessary before polyuria becomes evident. Most persons with neurogenic DI have an incomplete form of the disorder and retain some ability to concentrate their urine. Temporary neurogenic DI may follow head injury or surgery near the hypophysial tract. Nephrogenic DI is characterized by impairment of the urineconcentrating ability of the kidney and free-water conservation. It may occur as a genetic trait that affects the ADH receptors in the kidney, as a side effect of drugs such as lithium,¹⁵ or as the result of electrolyte disorders such as potassium depletion or chronic hypercalcemia.

The syndrome of inappropriate ADH (SIADH) results from a failure of the negative feedback system that regulates the release and inhibition of ADH.¹⁶ In persons with this syndrome, ADH secretion continues even when serum osmolality is decreased, causing marked water retention and dilutional hyponatremia.

SIADH may occur as a transient condition, such as in a stress situation, or as a chronic condition, resulting from disorders such as a lung tumor. Stimuli, such as surgery, pain, stress, and temperature changes, are capable of stimulating ADH release through the central nervous system (CNS). Drugs induce SIADH in different ways; some drugs are thought to increase hypothalamic production and release of ADH, and others are believed to act directly on the renal tubules to enhance the action of ADH. More chronic forms of SIADH may be the result of lung tumors, chest lesions, and CNS disorders. Tumors, particularly bronchogenic carcinoma and cancers of the lymphoid tissues, prostate, and pancreas, are known to produce and release ADH independent of normal hypothalamic control mechanisms. Other intrathoracic conditions, such as advanced tuberculosis, severe pneumonia, and positive-pressure breathing, can also cause SIADH. The suggested mechanism for SIADH in positive-pressure ventilation is activation of baroreceptors (e.g., aortic baroreceptors, cardiopulmonary receptors) that respond to marked changes in intrathoracic pressure. Human immunodeficiency virus (HIV) infection is emerging as a new cause of SIADH. It has been reported that as many as 35% of persons with acquired immunodeficiency syndrome (AIDS) who are admitted to the acute care setting will have SIADH related to *Pneumocystis carinii* pneumonia, central nervous system infections, or malignancies.¹⁷

The manifestations of SIADH are those of dilutional hyponatremia. Urine output decreases despite adequate or increased fluid intake. Urine osmolality is high, and serum osmolality is low. Hematocrit and the serum sodium and BUN levels are all decreased because of the expansion of the ECF volume. The severity of symptoms usually is proportional to the extent of sodium depletion and water intoxication.

Alterations in Isotonic Fluid Volume

Isotonic fluid volume disorders represent an expansion or contraction of the ECF brought about by proportionate changes in both sodium and water.

Isotonic Fluid Volume Deficit

Fluid volume deficit is characterized by a decrease in ECF, including circulating blood volume. The term *isotonic fluid volume deficit* is used to differentiate fluid deficit in which there are proportionate losses in sodium and water from water deficit and the hyperosmolar state associated with hypernatremia. Unless other fluid and electrolyte imbalances are present, the concentration of serum electrolytes remains essentially unchanged. When the effective circulating blood volume is compromised, the condition is often referred to as *hypovolemia*.

Causes. Isotonic fluid volume deficit results when water and electrolytes are lost in isotonic proportions. It is almost always caused by a loss of body fluids and is often accompanied by a

KEY CONCEPTS

SODIUM AND WATER BALANCE

- It is the amount of water and its effect on sodium concentration in the ECF that serves to regulate the distribution of fluid between the ICF and the ECF compartments.
- Isotonic changes in body fluids that result from proportionate gains or losses of sodium and water are largely confined to the ECF compartment. Many of the manifestations of isotonic fluid deficit or excess reflect changes in vascular and interstitial fluid volume.
- Hyponatremia or hypernatremia brought about by disproportionate losses or gains in sodium or water exert their effects on the ICF compartment, causing water to move in or out of body cells. Many of the manifestations of changes in sodium concentration reflect changes in the intracellular volume of cells, particularly those in the nervous system.

decrease in fluid intake. It can occur because of a loss of gastrointestinal fluids, polyuria, or sweating caused by fever and exercise. Third-space losses cause sequestering of ECF in the serous cavities, extracellular spaces in injured tissues, or lumen of the gut.

In a single day, 8 to 10 L of ECF is secreted into the gastrointestinal tract. Most of it is reabsorbed in the ileum and proximal colon, and only about 150 to 200 mL per day is eliminated in the feces. Vomiting and diarrhea interrupt the reabsorption process and, in some situations, lead to increased secretion of fluid into the intestinal tract. Gastrointestinal suction, fistulas, and drainage tubes can remove large amounts of fluid from the gastrointestinal tract.

Excess sodium and water losses can also occur through the kidney. Certain forms of kidney disease are characterized by salt wasting caused by impaired sodium reabsorption. Fluid volume deficit also can result from osmotic diuresis or injudicious use of diuretic therapy. Glucose in the urine filtrate prevents reabsorption of water by the renal tubules, causing a loss of sodium and water. In Addison's disease, a condition of chronic adrenocortical insufficiency, there is unregulated loss of sodium in the urine with a resultant loss of ECF volume (see Chapter 31).

The skin acts as an exchange surface for heat and as a vapor barrier to prevent water from leaving the body. Body surface losses of sodium and water increase when there is excessive sweating or when large areas of skin have been damaged. Hot weather and fever increase sweating. The respiratory rate and sweating usually are increased as body temperature rises. Burns are another cause of excess fluid loss.

Manifestations. The manifestations of fluid volume deficit reflect a decrease in ECF volume. They include thirst, signs of water conservation by the kidney, loss of body weight, im-

paired temperature regulation, and signs of reduced interstitial and vascular volume (Table 6-3).

Thirst is a common symptom of fluid deficit, although it is not always present during early stages of isotonic fluid deficit. It develops as the effective circulating volume decreases to a point sufficient to stimulate the thirst mechanism. Urine output decreases and urine osmolality and specific gravity increase as ADH levels rise because of a decrease in vascular volume. Although there is an isotonic loss of sodium and water from the vascular compartment, other substances such as hematocrit and BUN become more concentrated.

A loss in fluid volume is accompanied by a decrease in body weight. One liter of water weighs 1 kg (2.2 lb). A mild ECF deficit exists when weight loss equals 2% of body weight.⁵ In a person who weighs 68 kg (150 lb.), this percentage of weight loss equals 1.4 L of water. A moderate deficit equates to a 5% loss in weight and a severe deficit to an 8% or greater loss in weight.⁵ To be accurate, weight must be measured at the same time each day with the person wearing the same amount of clothing. Because the fluid is trapped within the body in persons with third-space losses, their body weight may not decrease.

The fluid content of body tissues decreases as fluid is removed from the interstitial spaces. The eyes assume a sunken appearance and feel softer than normal as the fluid content in the anterior chamber of the eye is decreased. Fluids add resiliency to the skin and underlying tissues that is referred to as *skin* or *tissue turgor*.⁵ Pinching a fold of skin between the thumb and forefinger provides a means for assessing tissue turgor. The skin should immediately return to its original configuration when the fingers are released. A loss of 3% to 5% of body water in children causes the resiliency of the skin to be lost. Decreased tissue turgor is less predictive of fluid deficit in older persons (>65 years) because of the loss of tissue elasticity. In

TABLE 6-3 Manifestations of Isotonic Fluid Volume Deficit and Excess		
Fluid Volume Deficit	Fluid Volume Excess	
Acute Weight Loss (% body weight) Mild fluid volume deficit: 2% Moderate fluid volume deficit: 5% Severe fluid volume deficit: >8%	Acute Weight Gain (% body weight) Mild fluid volume excess: 2% Moderate fluid volume excess: 5% Severe fluid volume excess: >8%	
Signs of Compensatory Mechanisms Increased thirst Increased ADH: oliguria and high urine-specific gravity		
Decreased Interstitial Fluid Volume Decreased skin and tissue turgor Dry mucous membranes Sunken and soft eyeballs Depressed fontanel in infants	Increased Interstitial Fluid Volume Dependent and generalized edema	
Decreased Vascular Volume Postural hypotension Weak rapid pulse Decreased vein filling Hypotension and shock (severe deficit)	Increased Vascular Volume Full and bounding pulse Venous distention Pulmonary edema (severe excess) Shortness of breath Crackle Dyspnea Cough	

infants fluid deficit may be evidenced by depression of the anterior fontanel because of a decrease in cerebrospinal fluid.

Arterial and venous volumes decline during periods of fluid deficit, as does filling of the capillary circulation. As the volume in the arterial system declines, the blood pressure decreases, the heart rate increases, and the pulse becomes weak and thready. Postural hypotension (a drop in blood pressure upon standing) is an early sign of fluid deficit. On the venous side of the circulation, the veins become less prominent, and venous refill time increases. Body temperature may be subnormal because of decreased metabolism.⁵ When volume depletion becomes severe, signs of hypovolemic shock and vascular collapse appear (see Chapter 18).

Diagnosis and Treatment. Treatment of fluid volume deficit consists of fluid replacement and measures to correct the underlying cause. Usually, isotonic electrolyte solutions are used for fluid replacement. Acute hypovolemia and hypovolemic shock can cause renal damage; therefore, prompt assessment of the degree of fluid deficit and adequate measures to resolve the deficit and treat the underlying cause are essential.

Isotonic Fluid Volume Excess

Fluid volume excess represents an isotonic expansion of the ECF compartment with increases in both interstitial and vascular volumes. Although increased fluid volume is usually the result of a disease condition, this is not always true. For example, a compensatory isotonic expansion of body fluids can occur in healthy persons during hot weather as a mechanism for increasing body heat loss.

Causes. Isotonic fluid volume excess almost always results from an increase in total body sodium that is accompanied by a proportionate increase in body water. Although it can occur as the result of excessive sodium intake, it is most commonly caused by a decrease in sodium and water elimination by the kidney. Among the causes of decreased sodium and water elimination are disorders of renal function, heart failure, liver failure, and corticosteroid excess.

Heart failure produces a decrease in renal blood flow and a compensatory increase in sodium and water retention (Chapter 18). Persons with severe congestive heart failure maintain a precarious balance between sodium and water intake and output. Even small increases in sodium intake can precipitate a state of fluid volume excess and a worsening of heart failure. Liver failure impairs aldosterone metabolism and alters renal perfusion, leading to increased salt and water retention. Corticosteroid hormones increase sodium reabsorption by the kidney. Persons taking corticosteroid medications and those with Cushing's syndrome (see Chapter 31) often have problems with sodium retention.

Manifestations. Isotonic fluid volume excess is characterized by an increase in interstitial and vascular fluids. It is manifested by weight gain over a short period of time. A mild fluid volume excess represents a 2% weight gain; moderate fluid volume excess, a 5% weight gain; and severe fluid volume excess, a weight gain of 8% or more (Table 6-3).⁵ The presence of edema is characteristic of isotonic fluid volume excess. When the excess fluid accumulates gradually, as often happens in debilitating diseases and starvation, edema fluid may mask the loss of tissue

mass. As the vascular volume increases, the neck veins become distended, the pulse becomes full and bounding, and the central venous pressure becomes elevated. The BUN and hematocrit may be decreased as a result of the expanded plasma volume. When excess fluid accumulates in the lungs (*i.e.*, pulmonary edema), there is shortness of breath, complaints of difficult breathing, respiratory crackles, and a productive cough (see Chapter 18). Ascites and pleural effusion may occur with severe fluid volume excess.

Diagnosis and Treatment. The treatment of fluid volume excess focuses on providing a more favorable balance between sodium intake and output. A sodium-restricted diet is often prescribed. Diuretic therapy may be used to increase sodium elimination.

Alterations in Sodium Concentration

The normal serum sodium ranges from 135 to 145 mEq/L (135 to 145 mmol/L). Serum sodium values, expressed in mEq/L, reflect the concentration or dilution of sodium by water, rather than its absolute value. Because sodium and its attendant anions account for 90% to 95% of the osmolality of the ECF (normal range, 275 to 295 mOsm/kg), changes in serum sodium generally are accompanied by changes in serum osmolality.

Hyponatremia

Hyponatremia represents a serum sodium concentration below 135 mEq/L (135 mmol/L). Because of the effects of other osmotically active particles in the ECF, such as glucose, hyponatremia may be associated with high or low tonicity.¹⁷⁻¹⁹

Hypertonic (translocational) hyponatremia results from an osmotic shift of water from ICF to the ECF, such as occurs with hyperglycemia. In this case, the sodium in the ECF becomes diluted as water moves out of cells in response to the osmotic effects of the elevated blood glucose level.

Hypotonic (dilutional) is by far the most common form of hyponatremia. It is caused by water retention and characterized by a decrease in serum osmolality. Dilutional hyponatremia can present as a hypervolemic, euvolemic, or hypovolemic condition. Hypervolemic hyponatremia involves an increase in ECF volume and is seen when hyponatremic conditions are accompanied by edema-forming disorders such as congestive heart failure, cirrhosis, and advanced kidney disease.

Euvolemic hyponatremia represents a retention of water with dilution of sodium while maintaining the ECF volume within a normal range. It is usually the result of inappropriate thirst or SIADH. Hypovolemic hyponatremia occurs when water is lost along with sodium but to a lesser extent. It occurs with diuretic use, excessive sweating in hot weather, and vomiting and diarrhea.

Causes. The most common causes of acute dilutional hyponatremia in adults are drug therapy (diuretics and drugs that increase ADH levels), inappropriate fluid replacement during heat exposure or after heavy exercise, SIADH, and polydipsia in persons with psychotic disorder.

Among the causes of hypovolemic hyponatremia are excessive sweating in hot weather, particularly during heavy exercise, which leads to loss of salt and water; hyponatremia develops when water, rather than electrolyte-containing liquids, is used to replace fluids lost in sweating. Another potential cause of hypovolemic hyponatremia is the loss of sodium from the gastrointestinal tract caused by repeated tap water enemas or frequent gastrointestinal irrigations with distilled water. Isoosmotic fluid loss, such as occurs in vomiting or diarrhea, does not usually lower serum sodium levels unless these losses are replaced with disproportionate amounts of orally ingested or parenterally administered water. Gastrointestinal fluid loss and ingestion of excessively diluted formula are common causes of acute hyponatremia in infants and children.

Hypovolemic hyponatremia is a common complication of adrenal insufficiency and is attributable to the effects of aldosterone and cortisol deficiency (see Chapter 31). A lack of aldosterone increases renal losses of sodium, and a cortisol deficiency leads to increased release of ADH with water retention.

The risk of euvolemic hyponatremia is increased during the postoperative period. During this time ADH levels are often high, producing an increase in water reabsorption by the kidney (see SIADH). Although these elevated levels usually resolve in about 72 hours, they can persist for as long as 5 days. The hyponatremia becomes exaggerated when electrolyte-free fluids (*e.g.*, 5% glucose in water) are used for fluid replacement. *Manifestations.* The manifestations of hyponatremia will vary dependent upon the serum osmolality, the ECF fluid volume status, the rapidity of onset, and the severity of the sodium dilution (Table 6-4). The signs and symptoms may be acute, as in severe water intoxication, or more insidious in onset and less severe, as in chronic hyponatremia. Because of water movement, hypotonic hyponatremia causes intracellular hypoosmolality, which is responsible for many of the clinical manifestations of the disorder.¹⁹ Fingerprint edema is a sign of excess intracellular water. This phenomenon is demonstrated by pressing the finger firmly over the bony surface of the sternum for 15 to 30 seconds. When excess intracellular water is present, a fingerprint similar to that observed when pressing on a piece of modeling clay is seen.

Muscle cramps, weakness, and fatigue reflect the hypoosmolality of skeletal muscle cells and are often early signs of hyponatremia. These effects commonly are observed in persons with hyponatremia that occurs during heavy exercise in hot weather. Gastrointestinal manifestations such as nausea and vomiting, abdominal cramps, and diarrhea may develop.

The brain and nervous system are the most seriously affected by pronounced increases in intracellular water. Symptoms include apathy, lethargy, and headache, which can progress to disorientation, confusion, gross motor weakness, depression of

TABLE 6-4 Manifestations of Hyponatremia and Hypernatremia

	Decreased Vascular Volume Weak rapid pulse Possible impaired temperature regulation with fever Decreased blood pressure Vascular collapse (severe)	

deep tendon reflexes. Seizures and coma occur when serum sodium levels reach extremely low levels. These severe effects, which are caused by brain swelling, may be irreversible.¹⁹ If the condition develops slowly, signs and symptoms do not develop until serum sodium levels approach 125 mEq/L. The term "water intoxication" is often used to describe the neurologic effects of acute hypotonic hyponatremia.

Treatment. The treatment of hyponatremia with water excess focuses on the underlying cause. When hyponatremia is caused by water intoxication, limiting water intake or discontinuing medications that contribute to SIADH may be sufficient. The administration of saline solution orally or intravenously may be needed in severe hyponatremia caused by sodium deficiency.

Hypernatremia

Hypernatremia implies a serum sodium level above 145 mEq/L and a serum osmolality greater than 295 mOsm/kg. Because sodium is functionally an impermeable solute, it contributes to the tonicity and movement of water across cell membranes. Hypernatremia is characterized by hypertonicity of the ECF and almost always causes cellular dehydration.²⁰

Causes. Hypernatremia represents a deficit of water in relation to the body's sodium levels. It can be caused by net gain of sodium or net loss of water. Rapid ingestion or infusion of sodium with insufficient time or opportunity for water ingestion can produce a disproportionate gain in sodium. A defect in thirst or inability to obtain or drink water can interfere with water replacement.

Hypernatremia also occurs when there is an excess loss of body fluids that have a lower than normal concentration of sodium so that water is lost in excess of sodium. This can result from increased losses from the respiratory tract during fever or strenuous exercise, from watery diarrhea, or when osmotically active tube feedings are given with inadequate amounts of water. With pure water loss, each body fluid compartment loses an equal percentage of its volume. Because approximately one third of the water is in the ECF compartment, compared with the two thirds in the ICF compartment, more actual water volume is lost from the ICF than the ECF compartment.⁵

Normally, water deficit stimulates thirst and increases water intake. Therefore, hypernatremia is more likely to occur in infants and in persons who cannot express their thirst or obtain water to drink. With hypodipsia, or impaired thirst, the need for fluid intake does not activate the thirst response. Hypodipsia is particularly prevalent among the elderly. In persons with diabetes insipidus, hypernatremia can develop when thirst is impaired or access to water is impeded.

Manifestations. The clinical manifestations of hypernatremia caused by water loss are largely those of ECF fluid loss and cellular dehydration (Table 6-4). The severity of signs and symptoms is greatest when the increase in serum sodium is large and occurs rapidly. Body weight is decreased in proportion to the amount of water that has been lost. Because blood plasma is roughly 90% to 93% water, the concentrations of blood cells, hematocrit, BUN, and other solutes increase as ECF water decreases.

Thirst is an early symptom of water deficit, occurring when water losses are equal to 0.5% of body water. Urine output is decreased and urine osmolality increased because of renal water-conserving mechanisms. Body temperature frequently is elevated, and the skin becomes warm and flushed. As the vascular volume decreases, the pulse becomes rapid and thready, and the blood pressure drops. Hypernatremia produces an increase in serum osmolality and results in water being pulled out of body cells. As a result, the skin and mucous membranes become dry, and salivation and tearing of the eyes are decreased. The mouth becomes dry and sticky, and the tongue becomes rough and fissured. Swallowing is difficult. The subcutaneous tissues assume a firm, rubbery texture. Most significantly, water is pulled out of the cells in the CNS, causing decreased reflexes, agitation, headache, and restlessness. Coma and seizures may develop as hypernatremia progresses.

Treatment. The treatment of hypernatremia includes measures to treat the underlying cause of the disorder and fluid replacement therapy to treat the accompanying dehydration. Replacement fluids can be given orally or intravenously. The oral route is preferable. Oral glucose–electrolyte replacement solutions are available for the treatment of infants with diarrhea.²¹ Until recently, these solutions were used only early in diarrheal illness or as a first step in re-establishing oral intake after parenteral replacement therapy. These solutions are now widely available in grocery stores and pharmacies for use in the treatment of diarrhea and other dehydrating disorders in infants and young children.

In summary, body fluids are distributed between the ICF and ECF compartments. Regulation of fluid volume, solute concentration, and distribution between the two compartments depends on water and sodium balance. Water provides approximately 90% to 93% of fluid volume and sodium salts, approximately 90% to 95% of extracellular solutes. Body water is regulated by thirst, which controls water intake, and ADH, which controls urine concentration and renal output. Sodium is ingested in the diet and eliminated by the kidneys under the influence of the sympathetic nervous system and the renin-angiotensin-aldosterone system.

Isotonic fluid disorders result from contraction or expansion of ECF volume brought about by proportionate losses of sodium and water. *Isotonic fluid volume deficit* is characterized by a decrease in ECF volume. It causes thirst, decreased vascular volume and circulatory function, decreased urine output, and increased urine specific gravity. *Isotonic fluid volume excess* is characterized by an increase in ECF volume. It is manifested by signs of increased vascular volume and edema.

Alterations in extracellular sodium concentration are brought about by a disproportionate gain (hyponatremia) or loss (hypernatremia) of water. As the major cation in the ECF compartment, sodium controls the ECF osmolality and its effect on cell volume. Hypotonic hyponatremia is characterized by water being pulled into the cell from the extracellular compartment, causing cells to swell. It is manifested by muscle cramps and weakness; nausea, vomiting, abdominal cramps, and diarrhea; and CNS signs such as lethargy, headache, depression of deep tendon reflexes, and in severe cases seizure and coma. Hypernatremia is characterized by intracellular water being pulled into the extracellular compartment, causing cells to shrink. It is manifested by thirst and decreased urine output; dry mouth and decreased tissue turgor; signs of decreased vascular volume (tachycardia, weak and thready pulse); and CNS signs, such as decreased reflexes, agitation, headache, and in severe cases seizures and coma.

POTASSIUM BALANCE

Potassium is the second most abundant cation in the body and the major cation in the ICF compartment. Approximately 98% of body potassium is contained within body cells, with an intracellular concentration of 140 to 150 mEq/L.²² The potassium content of ECF (3.5 to 5.0 mEq/L) is considerably less. Because potassium is an intracellular ion, total body stores of potassium are related to body size and muscle mass. Approximately 65% to 75% of potassium is in muscle.²³ Thus, total body potassium declines with age, mainly as a result of a decrease in muscle mass.

As the major intracellular cation, potassium is critical to many body functions. It is involved in a wide range of body functions, including the maintenance of the osmotic integrity of cells, acid-base balance, and the kidney's ability to concentrate urine. Potassium is necessary for growth, and it contributes to the intricate chemical reactions that transform carbohydrates into energy, change glucose into glycogen, and convert amino acids to proteins.

Potassium also plays a critical role in conducting nerve impulses and the excitability of skeletal, cardiac, and smooth muscle (see Chapter 1). It does this by regulating: (1) the rest-

KEY CONCEPTS

POTASSIUM BALANCE

- Most of the body's potassium is contained in the ICF, with only a small, but vital, amount being present in the ECF.
- Two major mechanisms function in the control of serum potassium: (1) renal mechanisms that conserve or eliminate potassium, and (2) transcellular buffer systems that remove potassium from and release it into the serum as needed.
- The distribution of potassium between the ICF and ECF compartments regulates electrical membrane potentials controlling the excitability of nerve and muscle cells as well as contractility of skeletal, cardiac, and smooth muscle tissue. Many of the manifestations of potassium deficit or excess are related to potassium's effect on membrane potentials in cardiac, skeletal, and smooth muscle in the gastrointestinal tract.

ing membrane potential, (2) the opening of the sodium channels that control the flow of current during the action potential, and (3) the rate of repolarization. Changes in nerve and muscle excitability are particularly important in the heart, where alterations in serum potassium can produce serious dysrhythmias and conduction defects. Changes in serum potassium also affect skeletal muscles and the smooth muscle in blood vessels and the gastrointestinal tract.

The resting membrane potential is determined by the ratio of intracellular to extracellular potassium. A decrease in serum potassium causes the resting membrane potential to become more negative (hyperpolarization), moving further from the threshold for excitation (Fig. 6-11). Thus, it takes a greater stimulus to reach threshold and open the sodium channels that are responsible for the action potential. An increase in serum potassium has the opposite effect; it causes the resting membrane potential to become more positive (hypopolarized), moving closer to threshold. This produces an initial increase in excitability. Activation and opening of the sodium channels that control the flow of current during an action potential are also affected by potassium levels. With severe hyperkalemia, the sodium channels become inactivated, producing a net decrease in excitability. The rate of repolarization also varies with serum potassium levels.¹¹ It is more rapid in hyperkalemia and delayed in hypokalemia. The rate of repolarization is important clinically because it predisposes to conduction defects and dysrhythmias in the heart.

Regulation of Potassium Balance

Potassium intake is normally derived from dietary sources. In healthy persons, potassium balance usually can be maintained by a daily dietary intake of 50 to 100 mEq. Additional amounts of potassium are needed during periods of trauma and stress. The kidneys are the main source of potassium loss. Approximately 80% to 90% of potassium losses occur in the urine, with the remainder being lost in stools or sweat.

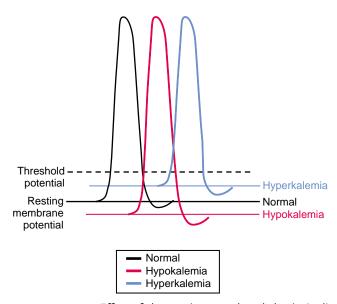

FIGURE 6-11 Effect of changes in serum hypokalemia (red) and hyperkalemia (blue) on the resting membrane potential.

Mechanisms of Regulation. Normally, the ECF concentration of potassium is precisely regulated at about 4.2 mEq/ml. The precise control is necessary because many cell functions are sensitive to even small changes in ECF potassium levels. An increase in serum potassium levels of only maybe 0.3 to 0.4 mEq/L can cause serious cardiac dysrhythmias and even death.

Serum potassium levels are largely regulated through two mechanisms: (1) renal mechanisms that conserve or eliminate potassium, and (2) a transcellular shift of potassium between the ICF and ECF compartments. Normally, it takes 6 to 8 hours to eliminate 50% of potassium intake.³ To avoid an increase in extracellular potassium levels during this time, excess potassium is temporarily shifted into red blood cells and other cells such as those of muscle, liver, and bone.

Renal Regulation. The kidney provides the major route for potassium elimination. Potassium is filtered in the glomerulus, reabsorbed along with sodium and water in the proximal tubule and with sodium and chloride in the thick ascending loop of Henle, and then secreted into the late distal and cortical collecting tubules for elimination in the urine. The latter mechanism serves to "fine-tune" the concentration of potassium in the ECF.

Aldosterone plays an essential role in regulating potassium elimination by the kidney (see Chapter 22). In the presence of aldosterone, sodium is transported back into the blood and potassium is secreted into the tubular filtrate for elimination in the urine. There is also a potassium-hydrogen exchange system in the collecting tubules of the kidney. When serum potassium levels are increased, potassium is secreted into the urine and hydrogen is reabsorbed into the blood, producing a decrease in pH and metabolic acidosis. Conversely, when potassium levels are low, potassium is reabsorbed and hydrogen is secreted into the urine, leading to metabolic alkalosis.

Extracellular-Intracellular Shifts. The movement of potassium between the ECF and ICF allows potassium to move into body cells when serum levels are high and move out when serum levels are low. Among the factors that alter potassium distribution between the ECF and ICF are insulin, β -adrenergic stimulation, serum osmolality, and acid-base disorders. Both insulin and the β -adrenergic catecholamines (*e.g.*, epinephrine) increase cellular uptake of potassium. Insulin increases the cellular uptake of potassium after a meal. The potassium content of a single meal is often as high as 50 mEq; the actions of insulin prevent a rise in serum potassium to life-threatening levels. The catecholamines, particularly epinephrine, facilitate the movement of potassium into muscle tissue during periods of physiologic stress.

Extracellular osmolality and pH also influence the movement of potassium between the ICF and ECF. Acute increases in serum osmolality cause potassium to move out of cells. When serum osmolality is increased because of the presence of impermeable solutes such as glucose (without insulin), water leaves the cell. The loss of cell water produces an increase in intracellular potassium, causing it to move out of the cell into the ECF. Acid-base disorders are often accompanied by a change in serum potassium. Both the hydrogen and potassium ions are positively charged, and both ions move freely between the ICF and ECF compartments. In metabolic acidosis, hydrogen ions move into body cells for buffering; this causes potassium to leave the cells and move into the ECF. Metabolic alkalosis has the opposite effect.

Exercise can also produce compartmental shifts in potassium. Repeated muscle contraction releases potassium into the ECF. Although the increase usually is small with modest exercise, it can be considerable during exhaustive exercise. Even the repeated clenching and unclenching of the fist during a blood draw can cause potassium to move out of cells and artificially elevate serum potassium levels.

Hypokalemia

Hypokalemia refers to a serum potassium level below 3.5 mEq/L (3.5 mmol/L). Because of transcellular shifts, temporary changes in serum K⁺ may occur as the result of movement between the ICF and ECF compartments.

Causes. The causes of potassium deficit can be grouped into three categories: (1) inadequate intake; (2) excessive losses through the kidney, skin, and gastrointestinal tract; and (3) redistribution between the ICF and ECF compartments.

Inadequate intake is a frequent cause of hypokalemia. A potassium intake of at least 10 to 30 mEq/day is needed to compensate for obligatory urine losses.^{4,23} A person on a potassium-free diet continues to lose approximately 5 to 15 mEq of potassium daily. Insufficient dietary intake may result from the inability to obtain or ingest food or from a diet that is low in potassium-containing foods.

Excessive renal losses can occur with diuretic use, metabolic alkalosis, magnesium depletion, trauma and stress, and increased levels of aldosterone. Diuretic therapy, with the exception of potassium-sparing diuretics, is the most common cause of hypokalemia. Both thiazide and loop diuretics increase the loss of potassium in the urine. The degree of hypokalemia is directly related to diuretic dose and is greater when sodium intake is higher.²³ Magnesium depletion causes renal potassium wasting. Magnesium deficiency often coexists with potassium depletion because of diuretic therapy or disease processes such as diarrhea. Importantly, the ability to correct potassium deficiency is impaired when magnesium deficiency is present.

The kidneys do not have the homeostatic mechanisms needed to conserve potassium during periods of stress or insufficient intake. After trauma and in stress situations, urinary losses of potassium are greatly increased, sometimes approaching levels of 150 to 200 mEq/L.²⁴ Renal losses of potassium are accentuated by aldosterone and cortisol. Trauma and surgery produce a stress-related increase in these hormones. Primary aldosteronism, caused by an aldosterone-secreting tumor of the adrenal cortex, can produce severe urinary losses of potassium. Cortisol binds to aldosterone receptors and exerts aldosterone-like effects on potassium elimination.

Although potassium losses from the gastrointestinal tract and the skin usually are minimal, these losses can become excessive under certain conditions. The gastrointestinal tract is one of the most common sites for acute potassium losses. Vomiting and gastrointestinal suction lead to hypokalemia, partly because of actual potassium losses and because of renal losses associated with metabolic alkalosis (see section on metabolic alkalosis under acid-base balance). Because intestinal secretions are high in potassium content, diarrhea and intestinal suction can also cause large losses of potassium. Excessive skin losses occur with loss of the protective skin surface and sweating. Burns and other types of skin injury increase the loss of potassium through wound drainage. Losses caused by sweating increase in persons who are acclimating to a hot climate, partly because increased secretion of aldosterone during heat acclimatization increases the loss of potassium in urine and sweat.

Because of the high ratio of intracellular to extracellular potassium, a redistribution of potassium from the ECF to the ICF compartment can produce a marked decrease in the serum concentration. One cause of potassium redistribution is insulin. Because insulin increases the movement of glucose and potassium into cells, potassium deficit often develops during treatment of diabetic ketoacidosis. β -adrenergic agonist drugs, such as pseudoephedrine and albuterol, can have a similar effect on potassium distribution.

Manifestations. The manifestations of hypokalemia include the effect of altered membrane potentials on cardiovascular, neuromuscular and gastrointestinal function (see Table 6-5). The signs and symptoms of potassium deficit seldom develop until the serum potassium level has fallen to less than 3.0 mEq/L. They are typically gradual in onset, so the disorder may go undetected for some time.

The most serious effects of hypokalemia are those affecting cardiovascular function. Postural hypotension is common. Most persons with a serum potassium level of less than 3.0 mEq/L demonstrate electrocardiographic (ECG) changes typical of hypokalemia. These changes include prolongation of the PR interval, depression of the ST segment, flattening of the T wave, and appearance of a prominent U wave (Fig. 6-12). Although these ECG changes usually are not serious, they may predispose to sinus bradycardia and ectopic ventricular dysrhythmias (see Chapter 17). Digitalis toxicity can be provoked in persons treated with this drug, and there is an increased risk of ventricular dysrhythmias, particularly in persons with underlying heart disease. Potassium and digitalis compounds compete for binding to sites on the Na⁺/K⁺-ATPase membrane pump. In hypokalemia, more sites are available for digitalis to bind to and exert its action. The dangers associated with digitalis toxicity are compounded in persons who are receiving diuretics that increase urinary losses of potassium.

Complaints of weakness, fatigue, and muscle cramps, particularly during exercise, are common in moderate hypokalemia (serum potassium 3.0 to 2.5 mEq/L). Muscle paralysis with life-threatening respiratory insufficiency can occur with severe hypokalemia (serum potassium <2.5 mEq/L). Leg muscles, particularly the quadriceps, are most prominently affected. Some persons report muscle tenderness and paresthesias, rather than weakness. In chronic potassium deficiency, muscle atrophy may contribute to muscle weakness.

There are numerous signs and symptoms associated with altered gastrointestinal function, including anorexia, nausea, and vomiting. Atony of the gastrointestinal smooth muscle can cause constipation, abdominal distention, and, in severe hypokalemia, paralytic ileus. When gastrointestinal symptoms occur

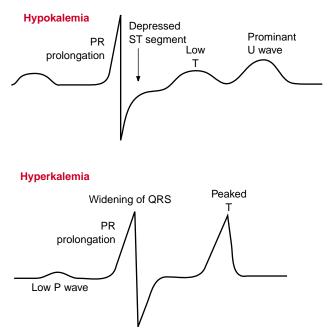

FIGURE 6-12 Electrocardiographic changes with hyperkalemia and hypokalemia.

gradually and are not severe, they often impair potassium intake and exaggerate the condition.

The renal processes that conserve potassium during hypokalemia interfere with the kidney's ability to concentrate urine. As a result, urine output and serum osmolality are increased, urine specific gravity is decreased, and polyuria, nocturia, and thirst are common. Metabolic alkalosis and renal chloride wasting are signs of severe hypokalemia.

Treatment. When possible, hypokalemia caused by potassium deficit is treated by increasing the intake of foods high in potassium content. Oral potassium supplements are prescribed for persons whose intake of potassium is insufficient in relation to losses. This is particularly true of persons who are receiving diuretic therapy and those who are taking digitalis.

Potassium may be given intravenously when the oral route is not tolerated or when rapid replacement is needed. Magnesium deficiency may impair potassium correction; in such cases, magnesium replacement is indicated.²⁵ The rapid infusion of a concentrated potassium solution can cause death from cardiac arrest. Health personnel who assume responsibility for administering potassium-containing intravenous solutions should be fully aware of all the precautions pertaining to potassium dilution and flow rate.

Hyperkalemia

Hyperkalemia refers to an increase in serum levels of potassium in excess of 5.0 mEq/L (5.0 mmol/L). It seldom occurs in healthy persons because the body is extremely effective in preventing excess potassium accumulation in the ECF.

Causes. The three major causes of potassium excess are (1) decreased renal elimination, (2) excessively rapid administration, and (3) movement of potassium from the ICF to ECF compartment.

The most common cause of hyperkalemia is decreased renal function. Chronic hyperkalemia is almost always associated with renal failure. Usually, the glomerular filtration rate must decline to less than 10 mL/minute before hyperkalemia develops. Some renal disorders, such as sickle cell nephropathy, lead nephropathy, and systemic lupus nephritis, can selectively impair tubular secretion of potassium without causing renal failure. As discussed previously, acidosis diminishes potassium elimination by the kidney. Persons with acute renal failure accompanied by lactic acidosis or ketoacidosis are at increased risk for the development of hyperkalemia. Correcting the acidosis usually helps to correct the hyperkalemia.²⁶

Aldosterone acts at the level of the distal tubular sodium/ potassium exchange system to increase potassium excretion while facilitating sodium reabsorption. A decrease in aldosterone-mediated potassium elimination can result from adrenal insufficiency (*i.e.*, Addison's disease), depression of aldosterone release caused by a decrease in renin or angiotensin II, or impaired ability of the kidneys to respond to aldosterone. Potassium-sparing diuretics (*e.g.*, spironolactone, amiloride, triamterene) can produce hyperkalemia by means of the latter mechanism. Because of their ability to decrease aldosterone levels, angiotensin-converting enzyme inhibitors also can produce an increase in serum potassium levels.

Potassium excess can result from excessive oral ingestion or intravenous administration of potassium. It is difficult to increase potassium intake to the point of causing hyperkalemia when renal function is adequate and the aldosterone sodium/ potassium exchange system is functioning. An exception to this rule is the intravenous route of administration. In some cases, severe and fatal incidents of hyperkalemia have occurred when intravenous potassium solutions were infused too rapidly. Because the kidneys control potassium elimination, the administration of potassium-containing intravenous solutions should not be initiated until urine output has been assessed and renal function has been deemed to be adequate.

The movement of potassium out of body cells into the ECF also can lead to elevated serum potassium levels. Tissue injury, such as that caused by burns and crushing injuries, causes release of intracellular potassium into the ECF compartment. The same injuries often diminish renal function, which contributes to the development of hyperkalemia. Transient hyperkalemia may be induced during extreme exercise or seizures, when muscle cells are permeable to potassium.

Manifestations. The signs and symptoms of potassium excess are closely related to the alterations in neuromuscular excitability (see Table 6-5). The neuromuscular manifestations of potassium excess usually are absent until the serum concentration exceeds 6 mEq/L. The first symptom associated with hyperkalemia typically is paresthesia. There may be complaints of generalized muscle weakness or dyspnea secondary to respiratory muscle weakness.

The most serious effect of hyperkalemia is on the heart. As potassium levels increase, disturbances in cardiac conduction occur. The earliest changes are peaked, narrow T waves and widening of the QRS complex. If serum levels continue to rise, the PR interval becomes prolonged and is followed by the disappearance of P waves (see Fig. 6-12). The heart rate may be slow. Ventricular fibrillation and cardiac arrest are terminal events. Detrimental effects of hyperkalemia on the heart

are most pronounced when the serum potassium level rises rapidly.

Treatment. The treatment of potassium excess varies with the severity of the disturbance and focuses on decreasing or curtailing intake or absorption, increasing renal excretion, and increasing cellular uptake. Decreased intake can be achieved by restricting dietary sources of potassium. The major ingredient in most salt substitutes is potassium chloride, and such substitutes should not be given to patients with renal problems.

Increasing potassium output often is more difficult. People with renal failure may require hemodialysis or peritoneal dialysis to reduce serum potassium levels. Most emergency methods focus on measures that cause serum potassium to move into the ICF compartment. An intravenous infusion of insulin and glucose is often used for this purpose.

In summary, potassium, which is the major intracellular cation, contributes to the maintenance of intracellular osmolality, is necessary for normal neuromuscular function, and influences acid-base balance. Potassium levels are influenced by dietary intake and elimination by the kidney. A transcellular shift can produce a redistribution of potassium between the ECF and ICF compartments, causing blood levels to increase or decrease.

Hypokalemia represents a serum potassium level below 3.5 mEq/L. It can result from inadequate intake, excessive losses, or redistribution between the ICF and ECF compartments. The manifestations of potassium deficit include alterations in renal, skeletal muscle, gastrointestinal, and cardiovascular function, reflecting the crucial role of potassium in cell metabolism and neuromuscular function. *Hyperkalemia* represents an increase in serum potassium in excess of 5.0 mEq/L. It seldom occurs in healthy persons because the body is extremely effective in preventing excess potassium accumulation in the ECF. The major causes of potassium excess are decreased renal elimination of potassium, excessively rapid intravenous administration of potassium, and a transcellular shift of potassium out of the cell to the ECF compartment. The most serious effect of hyperkalemia is cardiac arrest.

CALCIUM AND MAGNESIUM BALANCE

Calcium Balance

Calcium is one of the major divalent cations in the body. Approximately 99% of body calcium is found in bone, where it provides the strength and stability for the skeletal system and serves as an exchangeable source to maintain extracellular calcium levels. Most of the remaining calcium (approximately 1%) is located inside cells, and only 0.1%–0.2% is present in the ECF.

Serum calcium exists in three forms: (1) protein bound, (2) complexed, and (3) ionized. Approximately 40% of serum calcium is bound to plasma proteins, mostly albumin, and cannot diffuse or pass through the capillary wall to leave the vascular compartment (Fig. 6-13). Another 10% is complexed (*i.e.*, chelated) with substances such as citrate, phosphate, and

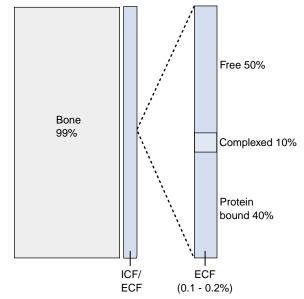

KEY CONCEPTS

CALCIUM BALANCE

- About 99% of body calcium is stored in bone; 1% is located inside cells; and 0.1% is found in the ECF.
- ECF calcium levels are made up of free (ionized), complexed, and protein-bound fractions. Only the ionized calcium ions play an essential role in neuromuscular and cardiac excitability.
- Serum calcium levels are regulated by parathyroid hormone and by renal mechanisms in which serum levels of calcium and phosphate are reciprocally regulated to prevent the damaging deposition of calcium phosphate crystals in the soft tissues of the body.

sulfate. This form is not ionized. The remaining 50% of serum calcium is present in the ionized form. It is the ionized form of calcium that is free to leave the vascular compartment and participate in cellular functions. The total serum calcium level fluctuates with changes in serum albumin and pH.

Ionized calcium serves a number of functions. It participates in many enzyme reactions; exerts an important effect on membrane potentials and neuronal excitability; is necessary for contraction in skeletal, cardiac, and smooth muscle; participates in the release of hormones, neurotransmitters, and other chemical messengers; influences cardiac contractility and automaticity by way of slow calcium channels; and is essential for blood clotting. The use of calcium channel-blocking drugs in circulatory disorders demonstrates the importance of the calcium ion

■ FIGURE 6-13 ■ Distribution of body calcium between the bone and the intracellular and extracellular fluids. The percentages of free, complexed, and protein-bound calcium in extracellular fluids are indicated.

in the normal function of the heart and blood vessels. Calcium is required for all but the first two steps of the intrinsic pathway for blood coagulation. Because of its ability to bind calcium, citrate often is used to prevent clotting in blood that is to be used for transfusions.

Regulation of Serum Calcium

Calcium enters the body through the gastrointestinal tract, is absorbed from the intestine under the influence of vitamin D, is stored in bone, and is excreted by the kidney. The major sources of calcium are milk and milk products. Only 30% to 50% of dietary calcium is absorbed from the duodenum and upper jejunum; the remainder is eliminated in the stool.

Calcium is filtered in the glomerulus of the kidney and then selectively reabsorbed back into the blood. Approximately 60% to 65% of filtered calcium is passively reabsorbed in the proximal tubule, driven by the reabsorption of sodium chloride; 15% to 20% is reabsorbed in the thick ascending loop of Henle, driven by the Na⁺/K⁺/ 2Cl⁻ cotransport system; and 5% to 10% is reabsorbed in the distal convoluted tubule (see Chapter 22). The distal convoluted tubule is an important regulatory site for controlling the amount of calcium that enters the urine. PTH and possibly vitamin D stimulate calcium reabsorption in this segment of the nephron. Other factors that may influence calcium reabsorption in the distal convoluted tubule are phosphate levels and glucose and insulin levels. Thiazide diuretics, which exert their effects in the distal convoluted tubule, enhance calcium reabsorption.

Serum calcium, which is responsible for the physiologic functions of calcium, is directly or indirectly regulated by parathyroid hormone (PTH) and vitamin D. Calcitonin, a hormone produced by C cells in the thyroid, is thought to act on the kidney and bone to remove calcium from the circulation. The regulation of serum calcium is also strongly influenced by serum phosphate levels. The role of PTH, calcitonin, and vitamin D on skeletal function is discussed in Chapter 44.

Parathyroid hormone, a major regulator of serum calcium and phosphate, is secreted by the parathyroid glands. The response to a decrease in serum calcium is prompt, occurring within seconds. The main function of PTH is to maintain the calcium concentration of the ECF (Fig. 6-14). It performs this function by promoting the release of calcium from bone, increasing the activation of vitamin D as a means of enhancing intestinal absorption of calcium, and stimulating calcium conservation by the kidney while increasing phosphate excretion (see Chapter 31).

Vitamin D, although classified as a vitamin, functions as a hormone. Vitamin D_3 , the precursor of the active form of vitamin D, is synthesized in the skin or obtained from foods in the diet, many of which are fortified with vitamin D. Vitamin D_3 is hydroxylated in the liver and is transformed to its active form in the kidney. The major action of the activated form of vitamin D is to increase the absorption of calcium from the intestine.

The extracellular concentrations of calcium and phosphate are reciprocally regulated such that calcium levels fall when phosphate levels are high and vice versa. Normal serum levels of calcium (8.5 to 10.5 mg/dL in adults) and phosphate (2.5 to 4.5 mg/dL in adults) are regulated so that the product of the two concentrations ($[Ca^{2+}] \times [PO_4^{2-}]$) is normally maintained at less than 70.²⁷ Maintenance of the calcium-phosphate prod-

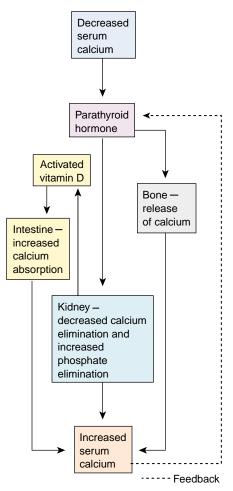

FIGURE 6-14 Regulation of serum calcium concentration by parathyroid hormone.

uct within this range is important in preventing the deposition of CaPO₄ salts in soft tissue, damaging the kidneys, blood vessels, and lungs.

Hypocalcemia

Hypocalcemia represents a serum calcium level of less than 8.5 mg/dL. Hypocalcemia occurs in many forms of critical illness and has affected as many as 70% to 90% of patients in intensive care units.²⁷

Causes. The causes of hypocalcemia can be divided into three categories: (1) impaired ability to mobilize calcium bone stores, (2) abnormal losses of calcium from the kidney, and (3) increased protein binding or chelation such that greater proportions of calcium are in the nonionized form. A pseudo-hypocalcemia is caused by hypoalbuminemia. It results in a decrease in protein-bound, rather than ionized, calcium and usually is asymptomatic.²⁸ Calcium deficit caused by dietary deficiency exerts its effects on bone stores, rather than extracellular calcium levels.

Serum calcium exists in a dynamic equilibrium with calcium in bone. The ability to mobilize calcium from bone depends on adequate levels of PTH. Decreased levels of PTH may result from primary or secondary forms of hypoparathyroidism (see Chapter 31). Suppression of PTH release may also occur when vitamin D levels are elevated. Magnesium deficiency inhibits PTH release and impairs the action of PTH on bone resorption. This form of hypocalcemia is difficult to treat with calcium supplementation alone and requires correction of the magnesium deficiency.

Phosphate elimination is impaired in renal failure. Because of the inverse relation between calcium and phosphate, serum calcium levels fall as phosphate levels rise in renal failure. Hypocalcemia and hyperphosphatemia occur when the glomerular filtration rate falls to less than 25 to 30 mL/minute (normal is 100 to 120 mL/minute).

Only the ionized form of calcium is able to leave the capillary and participate in body functions. A change in pH alters the proportion of calcium that is in the bound and ionized forms. An acid pH decreases binding of calcium to protein, causing a proportionate increase in ionized calcium, whereas total serum calcium remains unchanged. An alkaline pH has the opposite effect. As an example, hyperventilation sufficient to cause respiratory alkalosis can produce tetany because of increased protein binding of calcium. Free fatty acids increase binding of calcium to albumin, causing a reduction in ionized calcium. Elevations in free fatty acids sufficient to alter calcium binding may occur during stressful situations that cause elevations of epinephrine, glucagon, growth hormone, and adrenocorticotropin levels.

Hypocalcemia is a common finding in a patient with acute pancreatitis. Inflammation of the pancreas causes release of proteolytic and lipolytic enzymes. It is thought that the calcium ion combines with free fatty acids released by lipolysis in the pancreas, forming soaps and removing calcium from the circulation.

Manifestations. Hypocalcemia can manifest as an acute or chronic condition. The manifestations of acute hypocalcemia reflect the increased neuromuscular excitability and cardiovascular effects of a decrease in ionized calcium (see Table 6-6). Ionized calcium stabilizes neuromuscular excitability, thereby making nerve cells less sensitive to stimuli. Nerves exposed to low ionized calcium levels show decreased thresholds for excitation, repetitive responses to a single stimulus, and, in extreme cases, continuous activity. The severity of the manifestations depends on the underlying cause, rapidity of onset, accompanying electrolyte disorders, and extracellular pH. Increased neuromuscular excitability can manifest as paresthesias (i.e., tingling around the mouth and in the hands and feet) and tetany (i.e., muscle spasms of the muscles of the face, hands, and feet). Severe hypocalcemia can lead to laryngeal spasm, seizures, and even death.

The cardiovascular effects of acute hypocalcemia include hypotension, cardiac insufficiency, cardiac dysrhythmias (particularly heart block and ventricular fibrillation), and failure to have a response to drugs such as digitalis, norepinephrine, and dopamine that act through calcium-mediated mechanisms.

Chronic hypocalcemia is often accompanied by skeletal manifestations and skin changes. There may be bone pain, fragility, deformities, and fractures. The skin may be dry and

Hypocalcemia	Hypercalcemia
Laboratory Serum calcium <8.5 mg/dL	Laboratory Serum calcium >10.5 mg/dL
	Inability to Concentrate Urine and Exposure of Kidney to Increased Concentration of Calcium Polyuria Increased thirst Flank pain Signs of acute renal insufficiency Signs of kidney stones
Neural and Muscle Effects (Increased Excitability) Paresthesias, especially numbness and tingling Skeletal muscle cramps Abdominal muscle spasms and cramps Hyperactive reflexes Carpopedal spasm Tetany Laryngeal spasm	Neural and Muscle Effects (Decreased Excitability) Muscle weakness Ataxia, loss of muscle tone Lethargy Personality and behavioral changes Stupor and coma
Cardiovascular Effects Hypotension Signs of cardiac insufficiency Decreased response to drugs that act by calcium-mediated mechanisms Prolongation of the QT interval predisposes to ventricular dysrhythmias	Cardiovascular Effects Hypertension Shortening of the QT interval Atrioventricular block
Skeletal Effects (Chronic Deficiency) Osteomalacia Bone pain	Gastrointestinal Effects Anorexia Nausea, vomiting Constipation

scaling, the nails brittle, and hair dry. The development of cataracts is common. A person with chronic hypocalcemia may also present with mild diffuse brain disease mimicking depression, dementia, or psychoses.

Diagnosis and Treatment. Chvostek's and Trousseau's tests can be used to assess for an increase in neuromuscular excitability and tetany.⁵ *Chvostek's sign* is elicited by tapping the face just below the temple at the point where the facial nerve emerges. Tapping the face over the facial nerve causes spasm of the lip, nose, or face when the test result is positive. An inflated blood pressure cuff is used to test for *Trousseau's sign*. The cuff is inflated above systolic blood pressure for 3 minutes. Contraction of the fingers and hands (*i.e.*, carpopedal spasm) indicates the presence of tetany.

Acute hypocalcemia is an emergency situation, requiring prompt treatment. An intravenous infusion containing calcium is used when tetany or acute symptoms are present or anticipated because of a decrease in the serum calcium level.

Chronic hypocalcemia is treated with oral intake of calcium. One glass of milk contains approximately 300 mg of calcium. Oral calcium supplements may be used. In some cases, long-term treatment may require the use of vitamin D preparations. The active form of vitamin D is administered when the liver or kidney mechanisms needed for hormone activation are impaired.

Hypercalcemia

Hypercalcemia represents a total serum calcium concentration greater than 10.5 mg/dL. Falsely elevated levels of calcium can result from prolonged drawing of blood with an excessively tight tourniquet. Increased plasma proteins (*e.g.*, hyperalbuminemia, hyperglobulinemia) may elevate the total serum calcium but not affect the ionized calcium concentration

Causes. A serum calcium excess (*i.e.*, hypercalcemia) results when calcium movement into the circulation overwhelms the calcium regulatory hormones or the ability of the kidney to remove excess calcium ions. The most common causes of hypercalcemia are increased bone resorption caused by neoplasms or hyperparathyroidism. Hypercalcemia is a common complication of cancer, occurring in approximately 10% to 20% of persons with advanced disease.²⁹ A number of malignant tumors, including carcinoma of the lungs, have been associated with hypercalcemia. Some tumors destroy the bone, but others produce humoral agents that stimulate osteoclastic activity, increase bone resorption, or inhibit bone formation.

Less common causes of hypercalcemia are prolonged immobilization, increased intestinal absorption of calcium, and excessive doses of vitamin D. Prolonged immobilization and lack of weight bearing cause demineralization of bone and release of calcium into the bloodstream. Intestinal absorption of calcium can be increased by excessive doses of vitamin D or as a result of a condition called the *milk-alkali syndrome*. The milkalkali syndrome is caused by excessive ingestion of calcium (often in the form of milk) and absorbable antacids. Because of the advent of nonabsorbable antacids, the condition is seen less frequently than in the past, but it may occur in women who are overzealous in taking calcium preparations for osteoporosis prevention.

A variety of drugs elevate calcium levels. The use of lithium to treat bipolar disorders has caused hypercalcemia and hyperparathyroidism. The thiazide diuretics increase calcium reabsorption in the distal convoluted tubule of the kidney. Although the thiazide diuretics seldom cause hypercalcemia, they can unmask hypercalcemia from other causes such as underlying bone disorders and conditions that increase bone resorption.

Manifestations. The signs and symptoms associated with calcium excess originate from three sources: (1) changes in neural excitability, (2) alterations in smooth and cardiac muscle function, and (3) exposure of the kidneys to high concentrations of calcium (see Table 6-6).

Neural excitability is decreased in patients with hypercalcemia. There may be a dulling of consciousness, stupor, weakness, and muscle flaccidity. Behavioral changes may range from subtle alterations in personality to acute psychoses.

The heart responds to elevated levels of calcium with increased contractility and ventricular dysrhythmias. Digitalis accentuates these responses. Gastrointestinal symptoms reflect a decrease in smooth muscle activity and include constipation, anorexia, nausea, and vomiting. Pancreatitis is another potential complication of hypercalcemia and is probably related to stones in the pancreatic ducts.

High calcium concentrations in the urine impair the ability of the kidneys to concentrate urine by interfering with the action of ADH. This causes salt and water diuresis and an increased sensation of thirst. Hypercalciuria also predisposes to the development of renal calculi.

Hypercalcemic crisis describes an acute increase in the serum calcium level.²⁹ Malignant disease and hyperparathyroidism are major causes of hypercalcemic crisis. In hypercalcemic crisis, polyuria, excessive thirst, volume depletion, fever, altered levels of consciousness, azotemia (*i.e.*, nitrogenous wastes in the blood), and a disturbed mental state accompany other signs of calcium excess. Symptomatic hypercalcemia is associated with a high mortality rate; death often is caused by cardiac arrest.

Treatment. The treatment of calcium excess usually is directed toward rehydration and measures to increase urinary excretion of calcium and inhibit release of calcium from bone. Fluid replacement is needed in situations of volume depletion. The excretion of sodium is accompanied by calcium excretion. Diuretics and sodium chloride can be administered to increase urinary elimination of calcium after the ECF volume has been restored. Loop diuretics commonly are used, rather than thiazide diuretics, which increase calcium reabsorption.

The initial lowering of calcium levels is followed by measures to inhibit bone reabsorption. Drugs that are used to inhibit calcium mobilization include bisphosphonates, calcitonin, and the glucocorticosteroids. The bisphosphonates are a relatively new group of drugs that act mainly by inhibiting osteoclastic activity. Calcitonin inhibits osteoclastic activity, thereby decreasing resorption. The glucocorticosteroids inhibit bone resorption and are used to treat hypercalcemia associated with cancer.

Magnesium Balance

Magnesium is the second most abundant intracellular cation. The average adult has approximately 24 g of magnesium distributed throughout the body.³⁰ Of the total magnesium content, approximately 50% to 60% is stored in bone, 39% to 49% is contained in the body cells, and the remaining 1% is dis-

persed in the ECF.³¹ Approximately 20% to 30% of the extracellular magnesium is protein bound, and only a small fraction of intracellular magnesium (15% to 30%) is exchangeable with the ECF. The normal serum concentration of magnesium is 1.8 to 2.7 mg/dL.

Only recently has the importance of magnesium to the overall function of the body been recognized.³¹ Magnesium acts as a cofactor in many intracellular enzyme reactions, including those related to transfer of phosphate groups. It is essential to all reactions that require ATP, for every step related to replication and transcription of DNA, and for the translation of messenger RNA. It is required for cellular energy metabolism, functioning of the sodium-potassium membrane pump, membrane stabilization, nerve conduction, ion transport, and calcium channel activity. Magnesium binds to calcium receptors, and it has been suggested that alterations in magnesium levels may exert their effects through calciummediated mechanisms. Magnesium may bind competitively to calcium binding sites, producing the appropriate response; it may compete with calcium for a binding site but not exert an effect; or it may alter the distribution of calcium by interfering with its movement across the cell membrane.

Regulation of Magnesium

Magnesium is ingested in the diet, absorbed from the intestine, and excreted by the kidneys. Intestinal absorption is not closely regulated, and approximately 25% to 65% of dietary magnesium is absorbed. Magnesium is contained in all green vegetables, grains, nuts, meats, and seafood. Magnesium is also present in much of the groundwater in North America.

The kidney is the principal organ of magnesium regulation. Magnesium is a unique electrolyte in that only approximately 30% to 40% of the filtered amount is reabsorbed in the proximal tubule. The greatest quantity, approximately 50% to 70%, is reabsorbed in the thick ascending loop of Henle. The distal tubule, which reabsorbs a small amount of magnesium, is the major site of magnesium regulation. Magnesium reabsorption is decreased in the presence of increased serum levels, stimulated by PTH, and inhibited by increased calcium levels. The major driving force for magnesium absorption in the thick ascending loop of Henle is the Na⁺/K⁺/2Cl⁻ cotransport system (see Chapter 22). Inhibition of this transport system by loop diuretics lowers magnesium reabsorption.

Hypomagnesemia

Hypomagnesemia represents a serum magnesium concentration of less than 1.8 mg/dL (Table 6-7).³² It is seen in conditions that limit intake or increase intestinal or renal losses, and it is a common finding in emergency department and critical care patients.

Causes. Magnesium deficiency can result from insufficient intake, excessive losses, or movement between the ECF and ICF compartments. It can result from conditions that directly limit intake, such as malnutrition, starvation, or prolonged maintenance of magnesium-free parenteral nutrition. Other conditions, such as diarrhea, malabsorption syndromes, prolonged nasogastric suction, or laxative abuse can serve to decrease intestinal absorption. Excessive calcium intake impairs intestinal absorption of magnesium by competing for the same transport site. Another common cause of magnesium deficiency is chronic alcoholism. There are many factors that contribute to hypomagnesemia in alcoholism, including low intake and gastrointestinal losses from diarrhea.

Although the kidneys are able to defend against hypermagnesemia, they are less able to conserve magnesium and prevent hypomagnesemia. Urine losses are increased in diabetic ketoacidosis, hyperparathyroidism, and hyperaldosteronism. Some drugs increase renal losses of magnesium, including diuretics (particularly loop diuretics) and nephrotoxic drugs such as aminoglycoside antibiotics, cyclosporine, cisplatin, and amphotericin B.

A relative hypomagnesemia may also develop in conditions that promote movement of magnesium between the ECF and ICF compartments, including rapid administration of glucose, insulin-containing parenteral solutions, and alkalosis. Although transient, these conditions can cause serious alterations in body function.

Manifestations. Signs of magnesium deficiency are not usually apparent until the serum magnesium is less than 1 mEq/dL. Hypomagnesemia is characterized by an increase in neuro-muscular excitability as evidenced by muscle weakness and tremors. Other manifestations may include hyperactive deep tendon reflexes, paresthesias (*e.g.*, numbness, pricking, tingling sensation), muscle fasciculations, and tetanic muscle contractions. A positive Chvostek's or Trousseau's may be present,

TABLE 6-7 Manifestations of Hypomagnesemia and Hypermagnesemia		
Hypomagnesemia	Hypermagnesemia	
Laboratory Values	Laboratory Values	
Serum magnesium <1.8 mg/dL	Serum magnesium >2.7 mg/dL

Tachycardia	Hypotension	
Hypertension	Cardiac dysrhythmias	
Cardiac dysrhythmias	Cardiac arrest	

particularly if hypocalcemia is present. Because decreased serum magnesium increases irritability in nervous tissue, seizures may occur. Other manifestations may include ataxia, vertigo, disorientation, depression, and psychotic symptoms.

Cardiovascular manifestations include tachycardia, hypertension, and ventricular dysrhythmias. There may be ECG changes such as widening of the QRS complex, appearance of peak T waves, prolongation of the PR interval, T-wave inversion, and appearance of U waves. Ventricular dysrhythmias, particularly in the presence of digitalis, may be difficult to treat unless magnesium levels are normalized.

Magnesium deficiency often occurs in conjunction with hypocalcemia and hypokalemia, producing a number of related neurologic and cardiovascular manifestations. Hypocalcemia is typical of severe hypomagnesemia. Most persons with hypomagnesemia-related hypocalcemia have decreased PTH levels, probably as a result of impaired magnesiumdependent mechanisms that control PTH release and synthesis. Hypokalemia also is a typical feature of hypomagnesemia. It leads to a reduction in intracellular potassium and impairs the ability of the kidney to conserve potassium. When hypomagnesemia is present, hypokalemia is unresponsive to potassium replacement therapy.

Treatment. Hypomagnesemia is treated with magnesium replacement. The route of administration depends on the severity of the condition. Symptomatic, moderate to severe magnesium deficiency is treated by parenteral administration. Treatment must be continued for several days to replace stored and serum levels. In conditions of chronic intestinal or renal loss, maintenance support with oral magnesium may be required. Patients with any degree of renal failure must be carefully monitored to prevent magnesium excess. Magnesium often is used therapeutically to treat cardiac arrhythmia, myocardial infarct, angina, and pregnancy complicated by preeclampsia or eclampsia. Caution to prevent hypermagnesemia is essential.

Hypermagnesemia

Hypermagnesemia represents a serum magnesium concentration in excess of 2.7 mg/dL. Because of the ability of the normal kidney to excrete magnesium, hypermagnesemia is rare.

When hypermagnesemia does occur, it usually is related to renal insufficiency and the injudicious use of magnesiumcontaining medications such as antacids, mineral supplements, or laxatives. The elderly are particularly at risk because they have age-related reductions in renal function and tend to consume more magnesium-containing medications. Magnesium sulfate is used to treat toxemia of pregnancy and premature labor; in these cases, careful monitoring for signs of hypermagnesemia is essential.

Hypermagnesemia affects neuromuscular and cardiovascular function (see Table 6-7). The signs and symptoms occur only when serum magnesium levels exceed 4.9 mg/dL.³²

Hypermagnesemia diminishes neuromuscular transmission, causing hyporeflexia, muscle weakness, and confusion. Magnesium decreases acetylcholine release at the myoneural junction and may cause neuromuscular blockade and respiratory paralysis. Cardiovascular effects are related to the calcium channelblocking effects of magnesium. Blood pressure is decreased, and the ECG shows an increase in the PR interval, a shortening of the QT interval, T-wave abnormalities, and prolongation of the QRS and PR intervals. Hypotension caused by vasodilation and cardiac dysrhythmias can occur with moderate hypermagnesemia (\geq 5 to 10 mg/dL), and confusion and coma can occur with severe hypermagnesemia (\geq 10 mg/dL). Very severe hypermagnesemia (\geq 15 mg/dL) may cause cardiac arrest.

The treatment of hypermagnesemia includes cessation of magnesium administration. Calcium is a direct antagonist of magnesium, and intravenous administration of calcium may be used. Peritoneal dialysis or hemodialysis may be required.

In summary, calcium is one of the major divalent ions in the body. Approximately 99% of body calcium is found in bone; about 1% is in the ICF and 0.1% to 0.2% is in the ECF. The calcium in bone is in dynamic equilibrium with extracellular calcium. Of the three forms of ECF calcium (*i.e.*, protein bound, complexed, and ionized), only the ionized form can cross the cell membrane and contribute to cellular function. Ionized calcium has a number of functions. It contributes to neuromuscular function, plays a vital role in the blood clotting process, and participates in a number of enzyme reactions. Alterations in ionized calcium levels produce neural effects; neural excitability is increased in hypocalcemia and decreased in hypercalcemia.

Magnesium is the second most abundant intracellular cation. It acts as a cofactor in many enzyme reactions and affects neuromuscular function in the same manner as the calcium ion. Magnesium deficiency can result from insufficient intake, excessive losses, or movement between the ECF and ICF compartments. The manifestations of hypomagnesemia are characterized by a decrease in neuromuscular excitability as evidenced by paresthesias and hyperactive reflexes. Cardiovascular effects include tachycardia, hypertension, and ventricular dysrhythmias. Hypermagnesemia usually is related to renal insufficiency and the injudicious use of magnesiumcontaining medications such as antacids, mineral supplements, or laxatives. It diminishes neuromuscular transmission leading to hyporeflexia, muscle weakness, and confusion.

ACID-BASE BALANCE

Metabolic activities of the body require the precise regulation of acid-base balance, which is reflected by the pH of ECF. Membrane excitability, enzyme systems, and chemical reactions depend on pH being regulated within a narrow physiologic range. Many conditions, pathologic or otherwise, can alter body pH.

Introductory Concepts

Normally, the concentration of body acids and bases is regulated so that the pH of extracellular body fluids is maintained within a very narrow range of 7.35 to 7.45. This balance is maintained through mechanisms that generate, buffer, and eliminate acids and bases.

Acid-Base Chemistry

An *acid* is a molecule that can release a hydrogen ion (H^+) , and a *base* is a molecule that can accept or combine with an H^+ ion. Most of the body's acids and bases are weak acids and

bases; the most important are *carbonic acid* (H_2CO_3), which is a weak acid derived from carbon dioxide (CO_2), and *bicarbonate* (HCO_3^-), which is a weak base.

The concentration of H⁺ ions in body fluids is low compared with other ions. For example, the Na⁺ ion is present at a concentration approximately 1 million times that of the H⁺ ion. Because of its low concentration in body fluids, the H⁺ ion concentration is commonly expressed in terms of pH. Specifically, *pH* represents the negative logarithm (p) of the H⁺ ion concentration in mEq/L. A pH value of 7.0 implies a H⁺ ion concentration of 10⁻⁷ (0.0000001 mEq/L). Because the pH is inversely related to the H⁺ ion concentration, a low pH indicates a high concentration of H⁺ ions and a high pH, a low concentration.²

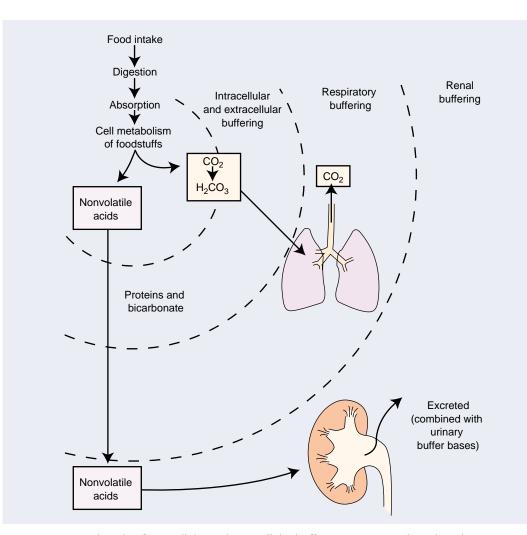

Metabolic Acid and Bicarbonate Production

Acids are continuously generated as by-products of metabolic processes. Physiologically, these acids fall into two groups: the volatile acid carbonic acid and all other nonvolatile or fixed acids (Fig. 6-15).

KEY CONCEPTS

MECHANISMS OF ACID-BASE BALANCE

- The pH is determined by the ratio of the HCO₃[−] base to CO₂ (H₂CO₃). At a pH of 7.4, the ratio is normally 20 to 1.
- The HCO₃⁻ part of the pH equation reflects the generation of nonvolatile metabolic acids that are buffered in intracellular and extracellular buffers and eliminated by the kidney.
- The H_2CO_3 or volatile acid part of the equation represents the level of dissolved CO_2 ($H_2O + CO_2 \leftrightarrow H_2CO_3$) in the blood. It is regulated by the elimination of CO_2 by the lungs.

■ FIGURE 6-15 ■ The role of intracellular and extracellular buffer, respiratory, and renal mechanisms in maintaining normal blood pH. (Rhoades R.A., Tanner G.A. [1996]. *Medical physiology* [p. 468]. Boston: Little, Brown)

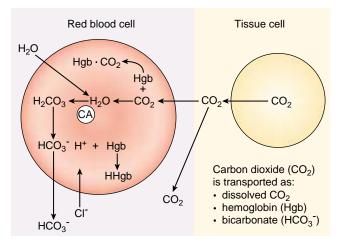

110 Unit One: Mechanisms of Disease

The difference between the two types of acids arises because H_2CO_3 is in equilibrium with the volatile CO_2 , which leaves the body by way of the lungs. Therefore, the H_2CO_3 concentration is determined by the lungs and their respiratory capacity. The *noncarbonic acids* (*e.g.*, sulfuric, hydrochloric, phosphoric) are *nonvolatile* and are not eliminated by the lungs. Instead, they are buffered by body proteins or extracellular buffers, such as HCO_3^- , and then excreted by the kidney.

Carbon Dioxide and Bicarbonate Production. Body metabolism results in the production of approximately 15,000 mmol of CO₂ each day.³³ Carbon dioxide is transported in the circulation in three forms: (1) attached to hemoglobin, (2) as dissolved CO₂ (*i.e.*, PCO₂), and as (3) HCO₃⁻ (Fig. 6-16). Collectively, dissolved CO₂ and HCO₃⁻ constitute approximately 77% of the CO₂ that is transported in the ECF; the remaining CO₂ travels attached to hemoglobin. Although CO₂ is not an acid, a small percentage of the gas combines with water in the blood-stream to form H₂CO₃ (CO₂ + H₂O \leftrightarrow H₂CO₃). The reaction between CO₂ and water is catalyzed by an enzyme, called *carbonic anhydrase*, which is present in large quantities in red blood cells, renal tubular cells, and other tissues in the body.

Because it is almost impossible to measure H_2CO_3 , dissolved CO_2 measurements are commonly substituted when calculating pH. The H_2CO_3 content of the blood can be calculated by multiplying the partial pressure of the CO_2 in the blood by its solubility coefficient, which is 0.03. This means that the concentration of H_2CO_3 in venous blood, which normally has a PCO₂ of approximately 45 mm Hg, is 1.35 mEq/L ($45 \times 0.03 = 1.35$).

Production of Metabolic Acids. The metabolism of dietary proteins is the major source of strong *inorganic acids*—sulfuric acid, hydrochloric acid, and phosphoric acid.^{33, 34} Oxidation of the sulfur-containing amino acids (*e.g.*, methionine, cysteine, cystine) results in the production of sulfuric acid. Oxidation of arginine and lysine produces hydrochloric acid, and oxidation of phosphorus-containing nucleic acids yields phosphoric acid. Incomplete oxidation of glucose results in the formation of lactic acid, and incomplete oxidation of fats results in the production of ketoacids. The major source of base is the metabolism of amino acids such as aspartate and glutamate and the

■ FIGURE 6-16 ■ Mechanisms of carbon dioxide transport.

metabolism of certain organic anions (*e.g.*, citrate, lactate, acetate). Acid production normally exceeds base production, with the net effect being the addition of approximately 1 mmol/kg body weight of nonvolatile acid to the body each day.³³ A vegetarian diet, which contains large amounts of organic anions, results in the net production of base.

Calculation of pH. The pH is calculated with the *Henderson-Hasselbalch equation* using the dissociation constant for the bicarbonate buffer system (6.1) and the HCO₃⁻ to H₂CO₃ ratio.

$$pH = 6.1 + \log \frac{HCO_3}{H_2CO_3}$$

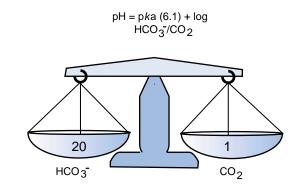

The log of 20 is 1.3. Thus, when the ratio is 20 to 1, the pH is within the normal range at 7.4 (Fig. 6-17). Because the ratio is used, a change in HCO_3^- will have little or no effect on pH, as long as there are accompanying changes in H_2CO_3 . The generation of metabolic acids and the availability of bicarbonate to buffer these acids control the HCO_3^- part of the equation. The H_2CO_3 part of the equation is regulated by the lungs and their ability to eliminate CO_2 . The kidney functions in the generation and reabsorption of HCO_3^- and contributes to control of the metabolic part of the equation.

Regulation of pH

The pH of body fluids is regulated by three major mechanisms: (1) ICF and ECF buffering systems, (2) the lungs, which control the elimination of CO_2 , and (3) the kidneys, which eliminate H⁺ and regulate the elimination of HCO_3^- .

Intracellular and Extracellular Buffer Systems. The momentby-moment regulation of pH depends on the ICF and ECF buffer systems. A *buffer system* consists of a weak acid and the base salt of that acid or of a weak base and its acid salt. In the process of preventing large changes in pH, the system trades a strong acid for a weak acid or a strong base for a weak base.

The three major buffer systems that protect the pH of body fluids are (1) proteins, (2) the HCO_3^- buffer system, and (3) the transcellular H⁺/K⁺ exchange system.² These buffer systems are immediately available to combine with excess acids or bases and prevent large changes in pH from occurring during the time it takes for the respiratory and renal mechanisms to become effective. Bone also represents an important site for the buffering of acids and bases.³³ The role of bone buffers is even greater in chronic acid-base disorders. One consequence of

■ FIGURE 6-17 ■ The Henderson-Hasselbalch equation expressed as a simple scale.

bone buffering is the release of calcium from bone and increased renal excretion of calcium. In addition to causing demineralization of bone, it also predisposes to kidney stones.

Proteins are the largest buffer system in the body. Proteins are *amphoteric*, meaning that they can function as either acids or bases. They contain many ionizable groups that can release or bind H⁺. The protein buffers are largely located within cells, and H⁺ ions and CO₂ diffuse across cell membranes for buffering by intracellular proteins. Albumin and plasma globulins are the major protein buffers in the vascular compartment.

The bicarbonate buffer system uses H_2CO_3 as its weak acid and HCO_3^- as its weak base. It substitutes the weak H_2CO_3 for a strong acid such as hydrochloric acid or the weak HCO_3^- base for a strong base such as sodium hydroxide. The HCO_3^-/H_2CO_3 buffer system is a particularly efficient system because the buffer components can be readily added or removed from the body.³⁴ Metabolism provides an ample supply of CO_2 , which can replace any H_2CO_3 that is lost when excess base is added, and CO_2 can be readily eliminated when excess acid is added. Likewise, the kidney can form new HCO_3^- when excess base is added.

The transcompartmental exchange of the K⁺ and H⁺ ions is important in the regulation of acid-base balance. Both ions are positively charged, and both ions move freely between the ICF and ECF compartments. When excess H⁺ is present in the ECF, it moves into the body cells in exchange for K⁺. Likewise, when excess K⁺ is present in the ECF, it moves into the cell in exchange for H⁺. On the average, serum K⁺ rises by approximately 0.6 mEq/L for every 0.1 unit fall in pH.33 Thus, alterations in K⁺ levels can affect acid-base balance, and changes in acid-base balance can influence K⁺ levels. Potassium shifts tend to be more pronounced in acidemia than alkalemia and are greater in metabolic acidosis than respiratory acidosis.⁵ Metabolic acidosis caused by an accumulation of nonorganic acids (e.g., hydrochloric acid that occurs in diarrhea, phosphoric acid that occurs in renal failure) produces a greater increase in K⁺ than does acidosis caused by an accumulation of organic acids (e.g., lactic acid, ketoacids).

An important implication of the K⁺ and H⁺ transcompartmental exchange is its effect on the resting membrane potential of neurons and other excitable tissue. In acidosis, increased levels of serum K⁺ cause the resting membrane potential to become less negative and in alkalosis, decreased levels cause the resting membrane potential to become more negative. Changes in neural excitability are further influenced by alterations in ionized calcium. In acidosis, the ionized portion of the extracellular calcium is increased, making neurons less excitable, and in alkalosis, the amount of ionized calcium is reduced, making neurons more excitable.

Respiratory Control Mechanisms. The respiratory system provides for the elimination of CO_2 into the air and plays a major role in acid-base regulation. The respiratory control of pH is rapid, occurring within minutes, and is maximal within 12 to 24 hours.³³ However, it does not return the pH to normal.

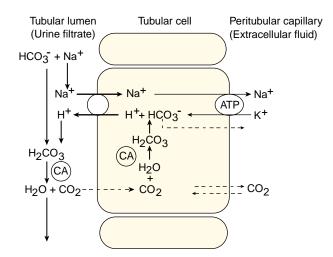

Renal Control Mechanisms. The kidneys regulate acid-base balance by excreting acidic or alkaline urine. Excreting an acidic urine reduces the amount of acid in the ECF, and excreting an alkaline urine removes base from the ECF. The renal mechanisms for regulating acid-base balance cannot adjust the pH

within minutes, as respiratory mechanisms can, but they continue to function for days until the pH has returned to normal or near-normal range.

The kidneys filter HCO_3^- in the glomerulus and then reabsorb it in the tubules as a means of maintaining ECF levels. Bicarbonate ions do not readily cross the membranes of renal tubular cells; therefore, HCO_3^- that has been filtered in the glomerulus cannot be directly reabsorbed. Instead, the $HCO_3^$ ions are reabsorbed in a special process in which they first combine with H⁺ ions that have been secreted into the tubular fluid to form H_2CO_3 , which is converted to CO_2 and water (Fig. 6-18). The resulting CO_2 can readily cross the tubular membrane and enter the tubular cell, where it combines with water, under the influence of carbonic anhydrase, to generate a new H_2CO_3 molecule. The newly formed H_2CO_3 , in turn, dissociates to form a HCO_3^- and a H⁺ ion. The HCO_3^- that is formed moves out of the tubular cell into the bloodstream and the H⁺ is secreted into the tubular fluid.

The HCO_3^- reabsorption system serves a dual purpose—it buffers the H⁺ ions that have been secreted from the blood into the tubular fluid, and it conserves the HCO_3^- ions that have been filtered from the blood into the tubular fluid. Normally, only a few of the secreted H⁺ ions remain in the tubular fluid because the secretion of H⁺ ions is roughly equivalent to the number of HCO_3^- ions that are filtered in the glomerulus. When the number of H⁺ ions secreted into the tubular fluid exceeds the amount of filtered HCO_3^- ions, the urine filtrate becomes acidic.

The elimination of H^+ is accomplished through secretion into the urine filtrate by the cells in the renal tubules. Because extremely acidic urine would be damaging to structures in the urinary tract, the pH of the urine is maintained within a range from 4.5 to 8.0. This limits the number of unbuffered H^+ ions that can be excreted by the kidney. When the number of free H^+ ions secreted into the tubular fluid threatens to cause the urine to become too acidic, the H^+ ions must be carried in

■ FIGURE 6-18 ■ Hydrogen ion (H⁺) secretion and bicarbonate ion (HCO₃⁻) reabsorption in a renal tubular cell. Carbon dioxide (CO₂) diffuses from the blood or urine filtrate into the tubular cell, where it combines with water in a carbonic anhydrase-catalyzed reaction that yields carbonic acid (H₂CO₃). The H₂CO₃ dissociates to form H⁺ and HCO₃⁻. The H⁺ is secreted into the tubular fluid in exchange for Na⁺. The Na⁺ and HCO₃⁻ enter the extracellular fluid.

some other form. This is accomplished by combining the H⁺ ions with intratubular buffers before being excreted in the urine. There are two important intratubular buffer systems: the phosphate buffer system and the ammonia buffer system.

The phosphate buffer system uses HPO_4^{2-} and $H_2PO_4^{-}$ that are present in the tubular filtrate to buffer H⁺. The combination of H⁺ with HPO_4^{2-} to form $H_2PO_4^{-}$ allows the kidneys to increase their secretion of H⁺ ions. Because they are poorly reabsorbed, the phosphates become more concentrated as they move through the tubules. This system works best when the renal tubular fluid contains a high concentration of H⁺ ions.

Another important but more complex buffer system is the *ammonia buffer system*. Renal tubular cells are able to use the amino acid glutamine to synthesize ammonia (NH₃) and secrete it into the tubular fluid. The H⁺ ions then combine with the NH₃ to form an ammonium ion (NH₄⁺). The NH₄⁺ ions combine with Cl⁻ ions (Cl⁻), which are present in the tubular fluid, to form ammonium Cl⁻ (NH₄Cl), which is then excreted in the urine.

Plasma potassium levels influence renal elimination of H^+ ions and vice versa. When plasma potassium levels fall, there is movement of K^+ ions from tubular cells into the plasma and a reciprocal movement of H^+ ions from the plasma into tubular cells. Potassium depletion also produces a reduction in Cl^- reabsorption in the distal tubule. The result is increased reabsorption of the filtered bicarbonate and development of metabolic alkalosis. An elevation in serum potassium has the opposite effect.

Aldosterone also influences H⁺ ion elimination by the kidney. It acts in the collecting duct to indirectly stimulate H⁺ ion secretion, while increasing Na⁺ ion reabsorption and K⁺ secretion. Hyperaldosteronism tends to lead to a decrease in serum K⁺ levels and increased pH and alkalosis caused by increased H⁺ ion secretion. Hypoaldosteronism has the opposite effect. It leads to increased K⁺ levels, decreased H⁺ ion secretion, and acidosis.

One of the mechanisms that the kidneys use in regulating the pH of the ECF is the conservation or elimination of $HCO_3^$ ions; in the process, it often is necessary to shuffle anions. Chloride is the most abundant anion in the ECF and can substitute for HCO_3^- when an anion shift is needed. As an example, serum HCO_3^- levels normally increase as hydrochloric acid (HCl) is secreted into the stomach after a heavy meal, causing what is called the *postprandial alkaline tide*. Later, as the Cl⁻ ion is reabsorbed in the small intestine, the pH returns to normal. *Hypochloremic alkalosis* refers to an increase in pH that is induced by a decrease in serum Cl⁻ levels and *hyperchloremic acidosis* to a decrease in pH that occurs when excess levels of Cl⁻ are present.

Laboratory Tests

Laboratory tests that are used in assessing acid-base balance include arterial blood gas measurements, carbon dioxide content and bicarbonate levels, base excess or deficit, and the anion gap.

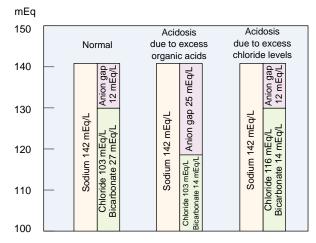

Arterial blood gases provide a means of assessing the respiratory component of acid-base balance. H_2CO_3 levels are determined from arterial CO_2 levels and the solubility coefficient for CO_2 (normal arterial PCO₂ is 38 to 42 mm Hg). Arterial blood gases are used because *venous blood gases* are highly variable, depending on metabolic demands of the various tissues that empty into the vein from where the sample is being drawn. Laboratory measurements of electrolytes include the CO_2 content and bicarbonate levels. The CO_2 content refers to the total CO_2 content of blood, including that contained in bicarbonate. It is determined by adding a strong acid to a plasma sample and measuring the amount of CO_2 generated. More than 70% of the CO_2 in the blood is in the form of bicarbonate.² The serum *bicarbonate* is then determined from the total CO_2 content of the blood.

Base excess or *deficit* is a measurement of bicarbonate excess or deficit. It describes the amount of a fixed acid or base that must be added to a blood sample to achieve a pH of 7.4 (normal \pm 3.0 mEq/L).³³ A base excess indicates metabolic alkalosis, and a base deficit indicates metabolic acidosis.

The *anion gap* describes the difference between the plasma concentration of the major measured cation (Na⁺) and the sum of the measured anions (Cl⁻ and HCO₃⁻). This difference represents the concentration of unmeasured anions, such as phosphates, sulfates, organic acids, and proteins (Fig. 6-19). Normally, the anion gap ranges between 8 and 12 mEq/L (a value of 16 mEq is normal if Na⁺ and K⁺ concentrations are used in the calculation). The anion gap is increased in conditions such as lactic acidosis and ketoacidosis that result from elevated levels of metabolic acids. A low anion gap is found in conditions that produce a fall in unmeasured anions (primarily albumin) or rise in unmeasured cations. An increase in unmeasured anions can occur in hyperkalemia, hypercalcemia, hypermagnesemia, lithium intoxication, or multiple myeloma, in which an abnormal immunoglobulin is produced.³⁴

Alterations in Acid-Base Balance

The terms *acidosis* and *alkalosis* describe the clinical conditions that arise as a result of changes in dissolved CO_2 and HCO_3^- concentrations. An alkali represents a combination of one or more alkali metals such as sodium or potassium with a highly basic ion such as a hydroxyl ion (OH⁻). Sodium bicarbonate (NaHCO₃) is the main alkali in the ECF. Although the definitions differ somewhat, the terms *alkali* and *base* are often used

■ FIGURE 6-19 ■ The anion gap in acidosis due to excess metabolic acids and excess serum chloride levels. Unmeasured anions such as phosphates, sulfates, and organic acids increase the anion gap because they replace bicarbonate. This assumes there is no change in sodium content.

KEY CONCEPTS

ACID-BASE DISORDERS

- The manifestations of acid-base disorders can be divided into three groups: (1) those due to the primary cause of the imbalance, (2) those due to the changed pH, and (3) those due to the elicited compensatory mechanisms.
- Metabolic acidosis represents a decrease in HCO₃⁻ that is caused by an excess of nonvolatile acids or loss of bicarbonate, and metabolic alkalosis represents an increase in HCO₃⁻ caused by a decrease in nonvolatile acids or increase in HCO₃⁻ intake or generation.
- Respiratory acidosis represents an increase in H₂CO₃ that is caused by respiratory conditions that interfere with the elimination of CO₂, and respiratory alkalosis represents a decrease in H₂CO₃ that is caused by excess elimination of CO₂.

interchangeably. Thus, the term *alkalosis* has come to mean the opposite of *acidosis*.

Metabolic Versus Respiratory Acid-Base Disorders

There are two types of acid-base disorders: metabolic and respiratory. Metabolic disorders produce an alteration in bicarbonate concentration and result from the addition or loss of nonvolatile acid or alkali to or from the ECF. A decrease in pH caused by a decrease in bicarbonate is called *metabolic acidosis*, and an elevated pH caused by increased bicarbonate levels is called *metabolic alkalosis*. Respiratory disorders involve changes in the CO₂, reflecting an increase or decrease in alveolar ventilation. *Respiratory acidosis* is characterized by a decrease in pH, reflecting a decrease in ventilation and an increase in CO₂. *Respiratory alkalosis* involves an increase in pH, resulting from an increase in alveolar ventilation and a decrease in CO₂.

Primary Versus Compensatory Mechanisms

Acidosis and alkalosis typically involve a *primary* or *initiating event* and a *compensatory state* that results from homeostatic mechanisms that attempt to correct or prevent large changes in pH. For example, a person may have a primary metabolic acidosis as a result of overproduction of ketoacids and respiratory alkalosis because of a compensatory increase in ventilation (see Table 6-8).

Compensatory mechanisms adjust the pH toward a more normal level without correcting the underlying cause of the disorder. Often, compensatory mechanisms are interim measures that permit survival while the body attempts to correct the primary disorder. Compensation requires the use of mechanisms that are different from those that caused the primary disorder. In other words, the lungs cannot compensate for respiratory acidosis that is caused by lung disease, nor can the kidneys compensate for metabolic acidosis that occurs because of renal failure. Compensatory mechanisms often become more effective with time; thus, there are differences between the level of pH change that occurs with acute and chronic acidbase disorders.

Metabolic Acidosis

Metabolic acidosis involves a primary deficit in base bicarbonate along with a decrease in plasma pH. In metabolic acidosis, the body compensates for the decrease in pH by increasing the respiratory rate in an effort to decrease CO₂ and H₂CO₃ levels.

Causes. Metabolic acidosis can be caused by one of four mechanisms: (1) increased production of nonvolatile metabolic acids, (2) decreased acid secretion by the kidney, (3) excessive loss of bicarbonate, or (4) an increase in chloride. Metabolic acids increase when there is an accumulation of lactic acid, overproduction of ketoacids, or ingestion of drugs (e.g., aspirin and salicylates) or chemicals (e.g., methanol or ethylene glycol) that results in production of metabolic acids or an inability of the kidneys to excrete metabolic acids or conserve bicarbonate. The anion gap is often useful in determining the cause of the metabolic acidosis (Chart 6-2). The presence of excess metabolic acids produces an increase in the anion gap as sodium bicarbonate is replaced by the sodium salt of the offending acid (e.g., sodium lactate). When acidosis results from increased chloride levels (e.g., hyperchloremic acidosis), the anion gap remains within normal levels.

Acute lactic acidosis is one of the most common types of metabolic acidosis. Lactic acid is produced by the anaerobic metabolism of glucose. Lactic acidosis develops when there is excess production of lactic acid or diminished lactic acid removal from the blood. Most cases of lactic acidosis are caused by inadequate oxygen delivery, as in shock or cardiac arrest. These conditions

TABLE 6-8S	Summary of Acid-Base Imbalances		
Acid-Base Imbala	nce Primary Disturbance	Respiratory Compensation	Renal Compensation
Metabolic acidosis	Decrease in bicarbonate	Hyperventilation to decrease PCO ₂	If no renal disease, increased H ⁺ excretion and increased HCO3 ⁻ reabsorption
Metabolic alkalosis	Increase in bicarbonate	Hypoventilation to increase PCO ₂	If no renal disease, decreased H ⁺ excretion and decreased HCO ₃ ⁻ reabsorption
Respiratory acidosis	Increase in PCO ₂	None	Increased H ⁺ excretion and increased HCO ₃ ⁻ reabsorption
Respiratory alkalosis	Decrease in PCO ₂	None	Decreased H ⁺ excretion and decreased HCO ₃ ⁻ reabsorption

CHART 6-2 The Anion Gap in Differential Diagnosis of Metabolic Acidosis

Decreased Anion Gap (<8 mEq/L)

Hypoalbuminemia (decrease in unmeasured anions) Multiple myeloma (increase in unmeasured cationic IgG paraproteins)

Increased unmeasured cations (hyperkalemia, hypercalcemia, hypermagnesemia, lithium intoxication)

Increased Anion Gap (>12 mEq/L)

Presence of unmeasured metabolic anion Diabetic ketoacidosis Alcoholic ketoacidosis Lactic acidosis Starvation Renal insufficiency Presence of drug or chemical anion Salicylate poisoning Methanol poisoning Ethylene glycol poisoning Normal Anion Gap (8–12 mEq/L)

Loss of bicarbonate Diarrhea Pancreatic fluid loss Ileostomy (unadapted) Chloride retention Renal tubular acidosis Ileal loop bladder Parenteral nutrition (arginine and lysine)

increase lactic acid production, and they impair lactic acid clearance because of poor liver perfusion. Excess lactate also is produced with vigorous exercise or grand mal seizures (*i.e.*, convulsions), during which there is a local disproportion between oxygen supply and demand in the contracting muscles.

Lactic acidosis is also associated with disorders in which tissue hypoxia does not appear to be present. It has been reported in patients with leukemia, lymphomas, or other cancers and in patients with severe liver failure. The mechanisms causing lactic acidosis in these conditions are poorly understood. Some conditions such as neoplasms may produce local increases in tissue metabolism and lactate production or may interfere with blood flow delivery to noncancerous cells.

Ketoacids (i.e., acetoacetic and β -hydroxybutyric acid), produced in the liver from fatty acids, are the source of fuel for many body tissues. An overproduction of ketoacids occurs when carbohydrate stores are inadequate or when the body cannot use available carbohydrates as a fuel. Under these conditions, fatty acids are mobilized from adipose tissue and delivered to the liver, where they are converted to ketones. Ketoacidosis develops when ketone production exceeds tissue use.

The most common cause of ketoacidosis is uncontrolled diabetes mellitus, in which an insulin deficiency leads to the release of fatty acids from adipose cells with subsequent production of excess ketoacids (see Chapter 32). Ketoacidosis may also develop as the result of fasting or food deprivation, during which the lack of carbohydrates produces a self-limited state of ketoacidosis (self-limited because the resultant decrease in insulin release suppresses the release of fatty acids for fat cells). Ketones are also formed during the oxidation of alcohol, a process that occurs in the liver. A condition called *alcoholic ketoacidosis* can develop in persons who engage in excess alcohol consumption.³⁵ It usually follows prolonged alcohol ingestion, particularly if accompanied by decreased food intake and vomiting that results in using fatty acids as an energy source.

Kidney failure is the most common cause of chronic metabolic acidosis. The kidneys normally conserve HCO_3^- and secrete H⁺ ions into the urine as a means of regulating acid-base balance. In renal failure, there is loss of glomerular and tubular function, with retention of nitrogenous wastes and metabolic acids. In a condition called *renal tubular acidosis*, glomerular function is normal, but the tubular secretion of H⁺ or reabsorption of HCO_3^- is abnormal.

Increased HCO₃⁻ losses occur with the loss of bicarbonaterich body fluids or with impaired conservation of HCO₃⁻ by the kidney. Intestinal secretions have a high HCO₃⁻ concentration. Consequently, excessive losses of HCO₃⁻ ions occur with severe diarrhea; small bowel, pancreatic, or biliary fistula drainage; ileostomy drainage; and intestinal suction. In diarrhea of microbial origin, HCO₃⁻ is secreted into the bowel to neutralize the metabolic acids produced by the microorganisms causing the diarrhea.

Hyperchloremic acidosis occurs when serum Cl⁻ ion levels are increased. Because Cl⁻ and HCO₃⁻ are anions, the serum HCO₃⁻ ion concentration decreases when there is an increase in Cl⁻ ions. Hyperchloremic acidosis can occur as the result of abnormal absorption of chloride by the kidneys or as a result of treatment with chloride-containing medications (*i.e.*, sodium chloride, amino acid-chloride hyperalimentation solutions, and ammonium chloride). The administration of intravenous sodium chloride or parenteral hyperalimentation solutions that contain an amino acid-chloride combination can cause acidosis in a similar manner.³⁶ With hyperchloremic acidosis, the anion gap is within the normal range, but the chloride levels are increased and bicarbonate levels are decreased.

Manifestations. Metabolic acidosis is characterized by a decrease in pH (<7.35) and a decrease in serum HCO_3^- levels (<24 mEq/L). Acidosis typically produces a compensatory increase in respiratory rate with a decrease in PCO_2 and H_2CO_3 (see Table 6-9).

The manifestations of metabolic acidosis fall into three categories: (1) signs and symptoms of the disorder causing the acidosis, (2) alterations in function resulting from the decreased pH, and (3) changes in body function related to recruitment of compensatory mechanisms. The signs and symptoms of metabolic acidosis usually begin to appear when the plasma $HCO_3^$ concentration falls to 20 mEq/L or less. Metabolic acidosis is seldom a primary disorder; the manifestations of the disorder are frequently superimposed on the symptoms of the contributing health problem. With diabetic ketoacidosis, which is a common cause of metabolic acidosis, there is an increase in blood and urine glucose and a characteristic smell of ketones to the breath. In metabolic acidosis that accompanies renal failure, blood urea nitrogen levels are elevated, and tests of renal function yield abnormal results.

Changes in pH have a direct effect on body function that can produce signs and symptoms common to most types of meta-

TABLE 6-9 Manifestations of Metabolic Acidosis and Alkalosis

Skeletal System Effects Bone disease (chronic acidosis)		

bolic acidosis, regardless of cause. A person with metabolic acidosis often reports weakness, fatigue, general malaise, and a dull headache. Anorexia, nausea, vomiting, and abdominal pain also may be reported. The skin is warm and flushed, and there is a decrease in tissue turgor when fluid deficit accompanies acidosis. In persons with undiagnosed diabetes mellitus, the nausea, vomiting, and abdominal symptoms may be misinterpreted as being caused by gastrointestinal flu or other abdominal disease, such as appendicitis.

Neural activity becomes depressed as body pH declines. Acidosis directly depresses membrane excitability, and it decreases binding of calcium to plasma proteins so that more free calcium is available to decrease neural activity. As acidosis progresses, the level of consciousness declines, and stupor and coma develop. The skin becomes warm and flushed as the cutaneous blood vessels become less responsive to sympathetic stimulation and lose tone.

When the pH falls to 7.0, cardiac contractility and cardiac output decrease, the heart becomes less responsive to catecholamines (*i.e.*, epinephrine and norepinephrine), and dysrhythmias, including fatal ventricular dysrhythmias, can develop.

Metabolic acidosis also is accompanied by signs and symptoms related to the recruitment of compensatory mechanisms. In situations of acute metabolic acidosis, the respiratory system compensates for a decrease in pH by increasing ventilation to reduce PCO₂; this is accomplished through deep and rapid respirations. There may be complaints of dyspnea with exertion; with severe acidosis, dyspnea may be present even at rest.

When kidney function is normal, net acid excretion increases promptly in response to acidosis, and the urine becomes more acid. Most of the initial acid secretion into the urine is facilitated through use of the phosphate buffer system. Over several days, ammonia production by the kidney increases and becomes the most important mechanism for excreting excess H⁺ ions.

Chronic acidemia, as in renal failure, can lead to a variety of skeletal problems, some of which result from the release of calcium and phosphate during bone buffering of excess H⁺ ions.³⁷ Of particular importance is impaired growth in children. In infants and children, acidemia may be associated with a variety of nonspecific symptoms such as anorexia, weight loss, muscle weakness, and listlessness.^{33,37}

Treatment. The treatment of metabolic acidosis focuses on correcting the condition that caused the disorder and restoring the fluids and electrolytes that have been lost from the body. The treatment of diabetic ketoacidosis is discussed in Chapter 32.

Metabolic Alkalosis

Metabolic alkalosis involves a primary excess of base bicarbonate along with an increased plasma pH. It can be caused by a gain in HCO_3^- or loss of H⁺ ions. The body compensates for the increase in pH by decreasing the respiratory rate as a means of increasing PCO₂ and H₂CO₃ levels.

Causes. Metabolic alkalosis can occur because of (1) ingestion or administration of excess NaHCO₃ or other alkali, (2) excess H^+ , Cl^- , and K^+ loss, or (3) ECF volume contraction.

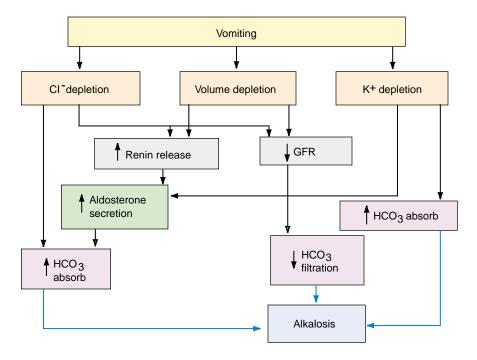

Excessive alkali ingestion, as in the use of bicarbonatecontaining antacids or sodium bicarbonate administration during cardiopulmonary resuscitation, can cause metabolic alkalosis. Other sources of alkali intake are acetate in hyperalimentation solutions and lactate in parenteral solutions such as Ringer's lactate. A condition called the milk-alkali syndrome may develop in persons who consume excessive amounts of milk (Ca⁺⁺ source) along with alkaline antacids. In this case metabolic alkalosis develops as a consequence of vomiting (volume depletion and K⁺ loss), hypercalcemia (increased HCO_3^- reabsorption), and reduced glomerular filtration rate (increased HCO_3^- reabsorption).^{34,38}

Vomiting, removal of gastric secretion through use of nasogastric suction, and low serum potassium levels resulting from hyperaldosteronism or diuretic therapy are the most common causes of metabolic alkalosis in hospitalized patients. The binge-purge syndrome, or self-induced vomiting, is also associated with metabolic alkalosis.³⁸ Gastric secretions contain high concentrations of HCl and lesser concentrations of K⁺. As Cl⁻ is taken from the blood and secreted into the stomach with H⁺, it is replaced by HCO₃⁻. Normally, the increase in serum HCO₃⁻ concentration is only transient because the entry of acid into the duodenum stimulates an equal secretion of pancreatic HCO₃⁻. However, the continued loss of H⁺ and Cl⁻ ions from the stomach because of vomiting or gastric suction stimulates continued production of gastric acid and thus the addition of more bicarbonate into the blood. Metabolic alkalosis can also result from the use of diuretics (*e.g.*, loop and thiazide diuretics) and other conditions that cause excessive loss of potassium in the urine. Hypokalemia produces a compensatory increase in K⁺ reabsorption and H⁺ secretion by the kidney, along with a simultaneous increase in HCO_3^- reabsorption.³⁴ The adrenocorticosteroid hormone, aldosterone, increases H⁺ ion secretion as it increases Na⁺ and HCO_3^- ion reabsorption. In hyperaldosteronism, the concurrent loss of K⁺ in the urine serves to perpetuate the alkalosis.

Chronic respiratory acidosis produces a compensatory loss of H⁺ and Cl⁻ ions in the urine along with HCO_3^- retention. When respiratory acidosis is corrected abruptly, as with mechanical ventilation, a "posthypercapnic" metabolic alkalosis may develop because of a rapid drop in PCO₂, while the HCO_3^- concentration, which requires renal elimination, remains elevated.

Vomiting results in the loss of water, Na⁺, Cl⁻, and K⁺. The resultant volume depletion, hypochloremia, and hypokalemia produce a metabolic alkalosis by increasing renal reabsorption of HCO_3^- (Fig. 6-20). Volume depletion and hypokalemia also increase the activity of the renin-angiotensin-aldosterone system, with increased Na⁺ reabsorption. Na⁺ reabsorption requires a concomitant anion reabsorption. Because of a Cl⁻ deficit, HCO_3^- is reabsorbed along with Na⁺, contributing to the development of metabolic alkalosis.

Manifestations. Metabolic alkalosis is characterized by a plasma pH greater than 7.45, plasma HCO_3^- level greater than 29 mEq/L, and base excess greater than 3.0 mEq/L (Table 6-9). Persons with metabolic alkalosis often have no symptoms or have signs related to volume depletion or hypokalemia. The neurologic signs (*e.g.*, hyperexcitability) occur less frequently with metabolic alkalosis than with other acid-base disorders because the HCO_3^- ion enters the cerebrospinal fluid more slowly than does CO_2 . When neurologic manifestations occur, as in acute and severe metabolic alkalosis, they include mental confusion, hyperactive reflexes, tetany, and carpopedal spasm. Metabolic alkalosis also leads to a compensatory hypoventila-

■ FIGURE 6-20 ■ The mechanisms by which vomiting maintains metabolic alkalosis. See text for explanation. (Adapted from Galla J.H., Luke R.G. [1987]. Pathophysiology of metabolic alkalosis. *Hospital Practice* 22 [10], 130)

tion, with the development of various degrees of hypoxemia and respiratory acidosis. Significant morbidity occurs with severe metabolic alkalosis (pH >7.55), including respiratory failure, dysrhythmias, seizures, and coma.

Treatment. The treatment of metabolic alkalosis usually is directed toward correcting the cause of the condition. A chloride deficit requires correction. Potassium chloride usually is the treatment of choice for metabolic alkalosis when there is an accompanying potassium deficit. When potassium chloride is used as a therapy, the chloride anion replaces the bicarbonate anion, and the administration of potassium corrects the potassium deficit and allows the kidneys to conserve H+ while eliminating the K⁺. Fluid replacement with normal saline or onehalf normal saline often is used in the treatment of patients with volume contraction alkalosis.

Respiratory Acidosis

Respiratory acidosis involves an increase in PCO₂ and H₂CO₃ along with a decrease in pH. Acute respiratory failure is associated with severe acidosis and only a small change in serum bicarbonate levels. Within a day or so, renal compensatory mechanisms begin to conserve and generate HCO₃⁻ ions. In chronic respiratory acidosis, there is a compensatory increase in bicarbonate levels.39

Causes. Respiratory acidosis occurs in conditions that impair alveolar ventilation and cause an increase in PCO2. It can occur as an acute or chronic disorder. Because renal compensatory mechanisms take time to exert their effects, blood pH tends to drop sharply in persons with acute respiratory acidosis.

Acute respiratory acidosis can be caused by impaired function of the respiratory center in the medulla (as in narcotic overdose), lung disease, chest injury, weakness of the respiratory muscles, or airway obstruction. Acute respiratory acidosis can also result from breathing air with a high CO₂ content. Almost all persons with acute respiratory acidosis are hypoxemic if they are breathing room air. In many cases, signs of hypoxemia develop before those of respiratory acidosis because CO₂ diffuses across the alveolar capillary membrane 20 times more rapidly than does oxygen.^{33,34}

Chronic respiratory acidosis is associated with chronic lung diseases such as chronic bronchitis and emphysema (see Chapter 21). In people with these disorders, the persistent elevation of PCO₂ stimulates renal H⁺ ion secretion and HCO₃⁻ reabsorption. The effectiveness of these compensatory mechanisms can often return the pH to near-normal values as long as oxygen levels are maintained within a range that does not unduly suppress the chemoreceptor-mediated control of ventilation.

An acute episode of respiratory acidosis can develop in persons with chronic lung disease who receive oxygen therapy at a flow-rate sufficient to raise the PO₂ to a level that produces a decrease in ventilation. In these persons, the respiratory center has become adapted to the elevated levels of CO₂ and no longer responds to increases in PCO₂. Instead, the oxygen content of their blood becomes the major stimulus for respiration. If oxygen is administered at a flow rate that is sufficient to suppress this stimulus, the rate and depth of respiration decrease, and the CO₂ content of the blood increases.

Manifestations. Respiratory acidosis is associated with a plasma pH less than 7.35 and an arterial PCO₂ greater than 50 mm Hg (Table 6-10). The signs and symptoms of respiratory acidosis depend on the rapidity of onset and whether the condition is acute or chronic. Because respiratory acidosis often

is accompanied by hypoxemia, the manifestations of respiratory acidosis often are intermixed with those of oxygen deficit.

Sudden elevations in arterial CO_2 can cause headache, blurred vision, an increase in heart rate and blood pressure, warm and flushed skin, irritability, muscle twitching, and psychological disturbances. Carbon dioxide readily crosses the blood-brain barrier, exerting its effects by changing the pH of brain fluids. Elevated levels of CO_2 produce vasodilation of cerebral blood vessels. If the condition is severe and prolonged, it can cause an increase in cerebrospinal fluid pressure and papilledema. Impaired consciousness, ranging from lethargy to coma, develops as the PCO₂ rises. Paralysis of extremities may occur, and there may be respiratory depression.

Treatment. The treatment of acute and chronic respiratory acidosis is directed toward improving ventilation (see Chapter 21). In severe cases, mechanical ventilation may be necessary.

Respiratory Alkalosis

Respiratory alkalosis involves a decrease in PCO_2 and a primary deficit in carbonic acid (H_2CO_3) along with an increase in pH. Because respiratory alkalosis can occur suddenly, a compensatory decrease in HCO_3^- may not occur before respiratory correction has been accomplished. The increase in pH is less in chronic compensated respiratory alkalosis, and the fall in HCO_3^- is greater.

Causes. Respiratory alkalosis is caused by hyperventilation or a respiratory rate in excess of that needed to maintain normal PCO_2 levels. One of the most common causes of respiratory alkalosis is the hyperventilation syndrome, which is characterized by recurring episodes of overbreathing often associated with anxiety. Persons experiencing panic attacks frequently present in the emergency room with acute respiratory alkalosis. Other causes of hyperventilation are fever, hypoxemia, early salicylate toxicity, and encephalitis. Hyperventilation can also occur during anesthesia or with use of mechanical ventilatory devices. Hypoxemia exerts its effect through stimulation of the peripheral chemoreceptors. Salicylate toxicity and encephalitis produce hyperventilation by directly stimulating the respiratory center in the brain stem.

Manifestations. Respiratory alkalosis is characterized by a pH greater than 7.45, arterial PCO₂ less than 35 mm Hg, and serum HCO₃⁻ levels less than 24 mEq/L (Table 6-10). The signs and symptoms of respiratory alkalosis are mainly associated with hyperexcitability of the nervous system and a decrease in cerebral blood flow. Alkalosis increases protein binding of serum calcium. This reduces ionized serum calcium levels, causing an increase in neuromuscular excitability. A decrease in the CO₂ content of the blood causes constriction of cerebral blood vessels. Because CO₂ crosses the blood-brain barrier rather quickly, the manifestations of acute respiratory alkalosis often are of sudden onset. The person often experiences light-headedness, dizziness, tingling, and numbness of the fingers and toes. These manifestations may be accompanied by sweating, palpitations, panic, air hunger, and dyspnea. Chvostek's and Trousseau's signs may be positive, and tetany and convulsions may occur. Because CO₂ provides the stimulus for short-term regulation of respiration, short periods of apnea may occur in persons with acute episodes of hyperventilation.

Treatment. The treatment of respiratory alkalosis focuses on measures to increase the PCO₂. Attention is directed toward correcting the disorder that caused the overbreathing. Rebreathing of small amounts of expired air (breathing into a paper bag) may prove useful in restoring PCO₂ levels in persons with anxiety-produced respiratory alkalosis.

In summary, normal body function depends on the precise regulation of acid-base balance to maintain a pH within the narrow physiologic range of 7.35 to 7.45. Metabolic processes produce volatile and nonvolatile metabolic acids that must be buffered and eliminated from the body. The volatile acid H₂CO₃ is in equilibrium with dissolved CO₂, which is eliminated through the lungs. The nonvolatile metabolic acids, most of which are excreted by the kidneys, are derived mainly from protein metabolism and incomplete carbohydrate and fat metabolism. It is the ratio of the bicarbonate ion concentration to dissolved CO₂ (carbonic acid concentration) that determines body pH. When this ratio is 20:1, the pH is 7.4. The ability of the body to maintain pH within the normal physiologic range depends on respiratory and renal mechanisms and on intracellular and extracellular buffers; the most important of these is the bicarbonate buffer system. The respiratory regulation of pH is rapid but does not return pH completely to normal. The kidney aids in regulation of pH by eliminating H⁺ ions or conserving HCO₃⁻ ions. In the process of eliminating H⁺ ions, it uses the phosphate and ammonia buffer systems. Body pH is also affected by the distribution of exchangeable cations (K^+ and H^+) and anions (Cl^- and HCO_3^-). Metabolic acidosis is defined as a decrease in HCO₃⁻, and metabolic alkalosis as an increase in HCO₃⁻. Metabolic acidosis is caused by an excessive production and accumulation of metabolic acids or an excessive loss of HCO₃⁻.

Metabolic alkalosis is caused by an increase in HCO_3^- or from a decrease in H^+ or CI^- , with a resultant increase in renal reabsorption of HCO_3^- . Respiratory acidosis reflects a decrease in pH that is caused by conditions that produce hypoventilation, with a resultant increase in PCO_2 levels. Respiratory alkalosis reflects an increase in pH that is caused by conditions that produce hyperventilation, with a resultant decrease in PCO_2 levels.

The signs and symptoms of acidosis and alkalosis reflect alterations in body function associated with the disorder causing the acid-base disturbance, the effect of the change of pH on body function, and the body's attempt to correct and maintain the pH within a normal physiologic range. In general, neuromuscular excitability is decreased in acidosis and increased in alkalosis.

REVIEW QUESTIONS

Describe factors that control fluid exchange between the vascular and interstitial fluid compartments and relate them to the development of edema and third spacing of extracellular fluids.

Compare and contrast the causes, manifestations, and treatment of isotonic fluid volume deficit, isotonic fluid volume excess, hyponatremia with water excess, and hypernatremia with water deficit.

Characterize the distribution of potassium in the body and explain how extracellular potassium levels are regulated in relation to body gains and losses.

Persons with severe hyperkalemia are at risk for cardiac arrest. Explain the effects of potassium on membrane potentials that are responsible for this risk.

A person may have hypocalcemia according to laboratory reports but have no clinical signs of the disorder. Explain.

Persons with renal failure experience both hyperphosphatemia and hypocalcemia. Explain.

Describe the three forms of carbon dioxide transport and their contribution to acid-base balance.

Use the Henderson-Hasselbalch equation to calculate pH and compare compensatory mechanisms for regulating pH.

Describe a clinical situation involving an acid-base disorder in which primary and compensatory mechanisms might be active.

Define metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis.

Explain the use of the plasma anion gap in differentiating types of metabolic acidosis.

Constancy of the Internal Environment Control Systems Feedback Systems Stress

The Stress Response Neuroendocrine-Immune Interactions Neuroendocrine Responses Immune Responses Coping and Adaptation to Stress Adaptation Factors Affecting the Ability to Adapt Disorders of the Stress Response Effects of Acute Stress Effects of Chronic Stress Post-traumatic Stress Disorder Treatment of Stress Disorders

Stress has become an increasingly discussed topic in today's world. The concept is discussed extensively in the health care fields, and it is found as well in economics, political science, business, and education. At the level of the popular press, the term is exploited with messages about how stress can be prevented, managed, and even eliminated.

Whether stress is more prevalent today than it was in centuries past is uncertain. Certainly, the pressures that existed were equally challenging, although of a different type. Social psychologists Richard Lazarus and Susan Folkman related that as early as the 14th century the term was used to indicate hardship, straits, adversity, or affliction.¹ In the 17th century, *stress* and related terms appeared in the context of physical sciences: *load* was defined as an external force, *stress* as the ratio of internal force created by the load to the area over which the force acted, and *strain* was the deformation or distortion of the object.¹ These concepts are still used in engineering today.

The concepts of stress and strain survived, and throughout the 19th and early 20th centuries, stress and strain were thought to be the cause of "ill health" and "mental disease."² By the 20th century, stress had drawn considerable attention both as a health concern and as a research focus. In 1910, when Sir William Osler delivered his Lumleian Lectures on "angina pectoris," he described the relationship of stress and strain to angina pectoris.³ Approximately 15 years later, Walter Cannon, well known for his work in physiology, began to use the word *stress* in relation to his laboratory experiments on the "fight-orflight" response. It seems possible that the term emerged from his work with the homeostatic features of living organisms and their tendency to "bound back" and "resist disruption" when acted on by an "external force."⁴ At about the same time, Hans Selye, who became known for his research and publications on stress, began using the term *stress* in a very special way to mean an orchestrated set of bodily responses to any form of noxious stimulus.⁵

The content in this chapter has been organized into three sections: homeostasis, the stress response and adaptation to stress, and the acute and chronic effects of stress.

HOMEOSTASIS

The concepts of stress and adaptation have their origin in the complexity of the human body and the interactions between the body's cells and its many organ systems. The body requires that a level of homeostasis or constancy be maintained during the many changes that occur in the internal and external environments. Stress and adaptation involve feedback control systems that regulate cellular function and integrate the function of the different body systems.

Constancy of the Internal Environment

The environment in which body cells live is not the external environment that surrounds the organism, but rather the local fluid environment that surrounds each cell. Claude Bernard, a 19th century physiologist, was the first to describe clearly the central importance of a stable internal environment, which he termed the milieu intèrieur. Bernard recognized that body fluids surrounding the cells and the various organ systems provide the means for exchange between the external and the internal environments. It is from this internal environment that body cells receive their nourishment, and it is into this fluid that they secrete their wastes. Even the contents of the gastrointestinal tract and lungs do not become part of the internal environment until they have been absorbed into the extracellular fluid. A multicellular organism is able to survive only as long as the composition of the internal environment is compatible with the survival needs of the individual cells. For example, even a small change in the pH of the body fluids can disrupt the metabolic processes of individual cells.

The concept of a stable internal environment was supported by Walter B. Cannon. He proposed that this kind of stability, which he called *homeostasis*, was achieved through a system of carefully coordinated physiologic processes that oppose change.⁶ Cannon pointed out that these processes were largely automatic and emphasized that homeostasis involves resistance to both internal and external disturbances.

In his book *The Wisdom of the Body*, published in 1939, Cannon presented four tentative propositions to describe the general features of homeostasis.⁶ With this set of propositions, Cannon emphasized that when a factor is known to shift homeostasis in one direction, it is reasonable to expect the existence of mechanisms that have the opposite effect. For example, in the homeostatic regulation of blood sugar, mechanisms that both raise and lower blood sugar levels would be expected to play a part. As long as the mechanism responding to the initiating disturbance can recover homeostasis, the integrity of the body and the status of normality are retained.

KEY CONCEPTS

HOMEOSTASIS

- Homeostasis is the purposeful maintenance of a stable internal environment maintained by coordinated physiologic processes that oppose change.
- The physiologic control systems that oppose change operate by negative feedback mechanisms that are composed of a sensor that detects a change, an integrator/comparator that sums and compares incoming data with a set point, and an effector system that returns the sensed function to within the range of the set point.

Control Systems

The ability of the body to function and maintain homeostasis under conditions of change in the internal and external environment depends on the thousands of physiologic *control systems* that regulate body function. A homeostatic control system is a collection of interconnected components that function to keep a physical or chemical parameter of the body relatively constant. The body's control systems regulate cellular function, control life processes, and integrate functions of the different organ systems.

Of recent interest have been the neuroendocrine control systems that influence behavior. Biochemical messengers that exist in our brain control nerve activity, information flow, and ultimately, behavior.⁷ These control systems function in producing the emotional reactions to stressors. In persons with mental health disorders, they can interact in the production of

Constancy of the Internal Environment

- Constancy in an open system, such as our bodies represent, requires mechanisms that act to maintain this constancy. Cannon based this proposition on insights into the ways by which steady states such as glucose concentrations, body temperature, and acid-base balance were regulated.
- Steady-state conditions require that any tendency toward change automatically meet with factors that resist change. An increase in blood sugar results in thirst as the body attempts to dilute the concentration of sugar in the extracellular fluid.
- 3. The regulating system that determines the homeostatic state consists of a number of cooperating mechanisms acting simultaneously or successively. Blood sugar is regulated by insulin, glucagon, and other hormones that control its release from the liver or its uptake by the tissues.
- Homeostasis does not occur by chance, but is the result of organized self-government.
- (Cannon W.B. [1932]. *The wisdom of the body* (pp. 299–300). New York: W.W. Norton)

symptoms associated with the disorder. The field of neuropharmacology has focused on the modulation of the endogenous messengers and signaling systems that control behavior in the treatment of mental disorders such as anxiety disorders, depression, and schizophrenia.

Feedback Systems

Most control systems in the body operate by *negative feedback mechanisms*, which function in a manner similar to the thermostat on a heating system. When the monitored function or value decreases below the set point of the system, the feedback mechanism causes the function or value to increase, and when the function or value is increased above the set point, the feedback mechanism causes it to decrease (Fig. 7-1). For example, in the negative feedback mechanism that controls blood glucose levels, an increase in blood glucose stimulates an increase in insulin, which enhances the removal of glucose from the blood. When sufficient glucose has left the bloodstream to cause blood glucose levels to fall, insulin secretion is inhibited and glucagon and other counter regulatory mechanisms stimulate the release of glucose from the liver, which causes the blood glucose level to return to normal.

The reason most physiologic control systems function under negative rather than *positive feedback mechanisms* is that a positive feedback mechanism interjects instability rather than stability into a system. It produces a cycle in which the initiating stimulus produces more of the same. For example, in a positive feedback system, exposure to an increase in environmental temperature would invoke compensatory mechanisms designed to increase, rather than decrease, body temperature.

In summary, physiologic and psychological adaptation involves the ability to maintain the constancy of the internal environment (homeostasis) and behavior in the face of a wide range of changes in the internal and external environments. It involves negative feedback control systems that regulate cellular function, control life's processes, regulate behavior, and integrate the function of the different body systems.

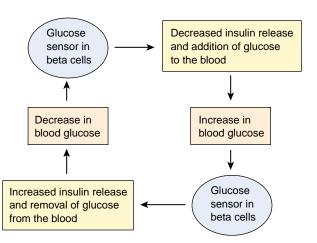

FIGURE 7-1 Illustration of negative feedback control mechanisms using blood glucose as an example.

STRESS

The increased focus on health promotion has heightened interest in the roles of stress and biobehavioral stress responses in the development of disease.⁸ Stress may contribute directly to the production or exacerbation of a disease, or it may contribute to the development of behaviors such as smoking, overeating, and drug abuse that increase the risk of disease.⁹

The Stress Response

In the early 1930s, the world-renowned endocrinologist Hans Selve was the first to describe a group of specific anatomic changes that occurred in rats that were exposed to a variety of different experimental stimuli. He came to an understanding that these changes were manifestations of the body's attempt to adapt to stimuli. Selve described stress as "a state manifested by a specific syndrome of the body developed in response to any stimuli that made an intense systemic demand on it."¹⁰ As a young medical student, Selve noticed that patients with diverse disease conditions had many signs and symptoms in common. He observed that "whether a man suffers from a loss of blood, an infectious disease, or advanced cancer, he loses his appetite, his muscular strength, and his ambition to accomplish anything; usually the patient also loses weight and even his facial expression betrays that he is ill."¹¹ Selve referred to this as the "syndrome of just being sick."

In his early career as an experimental scientist, Selye noted a triad of adrenal enlargement, thymic atrophy, and gastric ulcer appeared in rats he was using for his studies. These same three changes developed in response to many different or nonspecific experimental challenges. He assumed that the hypothalamic-pituitary-adrenal (HPA) axis played a pivotal role in the development of this response. To Selye, the response to stressors was a process that enabled the rats to resist the experimental challenge by using the function of the system best able to respond to it. He labeled the response the general adaptation syndrome (GAS): general because the effect was a general systemic reaction, adaptive because the response was in reaction to a stressor, and syndrome because the physical manifestations were coordinated and dependent on each other.¹⁰

According to Selve, the GAS involves three stages: the alarm stage, the stage of resistance, and the stage of exhaustion. The *alarm stage* is characterized by a generalized stimulation of the sympathetic nervous system and the HPA axis, resulting in the release of catecholamines and cortisol. During the resistance stage, the body selects the most effective and economic channels of defense. During this stage, the increased cortisol levels present during the first stage drop because they are no longer needed. If the stressor is prolonged or overwhelms the ability of the body to defend itself, the stage of exhaustion ensues, during which resources are depleted and signs of "wear and tear" or systemic damage appear.12 Selve contended that many ailments, such as various emotional disturbances, mildly annoying headaches, insomnia, upset stomach, gastric and duodenal ulcers, certain types of rheumatic disorders, and cardiovascular and kidney diseases appear to be initiated or encouraged by the "body itself because of its faulty adaptive reactions to potentially injurious agents."11

124 Unit Two: Alterations in Body Defenses

The events or environmental agents responsible for initiating the stress response were called stressors. According to Selye, stressors could be endogenous, arising from within the body, or exogenous, arising from outside the body.¹¹ In explaining the stress response, Selve proposed that two factors determine the nature of the stress response: the properties of the stressor and the conditioning of the person being stressed. Selve indicated that not all stress was detrimental; thus, he coined the terms eustress and distress.12 He suggested that mild, brief, and controllable periods of stress could be perceived as positive stimuli to emotional and intellectual growth and development. It is the severe, protracted, and uncontrolled situations of psychological and physical distress that are disruptive of health.¹¹ For example, the joy of becoming a new parent and the sorrow of losing a parent are completely different experiences, yet their stressor effect-the nonspecific demand for adjustment to a new situation-can be similar.

Stressors tend to produce different responses in different persons or in the same person at different times, indicating the influence of the adaptive capacity of the person, or what Selye called *conditioning factors*. These conditioning factors may be internal (*e.g.*, genetic predisposition, age, gender) or external (*e.g.*, exposure to environmental agents, life experiences, dietary factors, level of social support).¹¹ The relative risk for development of a stress-related pathologic process seems, at least in part, to depend on these factors.

Neuroendocrine-Immune Interactions

The manifestations of the stress response are strongly influenced by both the nervous and endocrine systems. The neuroendocrine systems integrate signals received along neurosensory pathways and from circulating mediators that are carried in the bloodstream. In addition, the immune system both affects and is affected by the stress response. The stress response is meant to protect the person against acute threats to homeostasis and is normally time limited. Therefore, under normal circumstances, the neural responses and the hormones that are released during the response are not around long enough to cause damage to vital tissues. However, in situations in which the stress response is hyperactive or becomes habituated, the physiologic and behavioral changes (*e.g.*, immunosuppression, sympathetic system activation) induced by the response can themselves become a threat to homeostasis. If the stress response is hypoactive, the person may be more susceptible to diseases associated with overactivity of the immune response.⁹

Neuroendocrine Responses

The integration of the stress responses, which occurs at the level of the central nervous system (CNS), is complex and not completely understood. It relies on communication along neuronal pathways of the cerebral cortex, the limbic system, the thalamus, the hypothalamus, the pituitary gland, and the reticular activating system (RAS) (Fig. 7-2). The cerebral cortex is involved with vigilance, cognition, and focused attention, and the limbic system with emotional components (e.g., fear, excitement, rage, anger) of the stress response. The thalamus functions as the relay center and is important in receiving, sorting out, and distributing sensory input. The hypothalamus coordinates the responses of the endocrine and autonomic nervous systems (ANS). The RAS modulates mental alertness, ANS activity, and skeletal muscle tone, using input from other neural structures. The musculoskeletal tension that occurs during the stress response reflects the increased activity of the RAS and its influence on the reflex circuits that control muscle tone.

Locus Ceruleus. Central to the neural component of the neuroendocrine response to the stress is an area in the brain stem

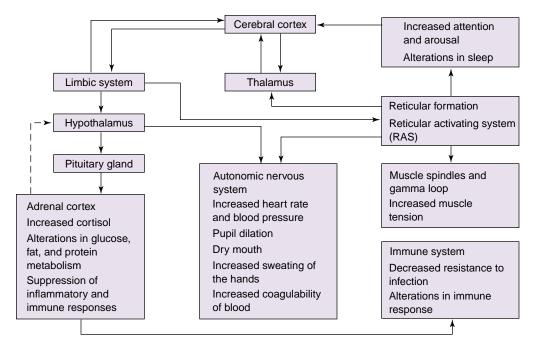

FIGURE 7-2 Stress pathways. The broken line represents negative feedback.

called the locus ceruleus (LC).¹³ The locus ceruleus is densely populated with neurons that produce norepinephrine (NE) and is thought to be the central integrating site for the ANS response to stressful stimuli (Fig. 7-3). The LC-NE system has afferent pathways to the hypothalamus, the limbic system, the hippocampus, and the cerebral cortex.

The LC-NE system confers an adaptive advantage during a stressful situation. The sympathetic nervous system manifestation of the stress reaction has been called the *fight-or-flight response*. This is the most rapid of the stress responses and represents the basic survival response of our primitive ancestors when confronted with the perils of the wilderness and its inhabitants. The increase in sympathetic activity in the brain increases attention and arousal and thus probably intensifies memory. The heart and respiratory rates increase, the hands and feet become moist, the pupils dilate, the mouth becomes dry, and the activity of the gastrointestinal tract decreases.

The Corticotropin-Releasing Factor. The corticotropinreleasing factor (CRF) is central to the endocrine component of the neuroendocrine response to stress (Fig. 7-3). CRF is a small peptide hormone found in both the hypothalamus and in extrahypothalamic structures, such as the limbic system and the brain stem. It is both an important endocrine regulator of pituitary and adrenal activity and a neurotransmitter involved in autonomic nervous system activity, metabolism, and behavior.^{9,14,15} Receptors for CRF are distributed throughout the brain as well as many peripheral sites. CRF from the hypothalamus induces the secretion of the adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. ACTH, in turn, stimulates the adrenal gland to synthesize and secrete the glucocorticoid hormones (*e.g.*, cortisol).

The glucocorticoid hormones have a number of direct or indirect physiologic effects that mediate the stress response, enhance the action of other stress hormones, or suppress other components of the stress system. In this regard, cortisol acts both as a mediator of the stress response and an inhibitor of the stress response such that overactivation does not occur.¹⁶ Cortisol maintains blood glucose levels by antagonizing the effects of insulin and enhances the effect of catecholamines on the cardiovascular system. It also suppresses osteoblast activity, hematopoiesis, protein and collagen synthesis, and immune responses. All of these functions are meant to protect the organism against the effects of a stressor and to focus energy on regaining balance in the face of an acute challenge to homeostasis.

Other Hormones. A wide variety of other hormones, including growth hormones, thyroid hormone, and the reproductive hormones, also are responsive to stressful situations. Systems responsible for reproduction, growth, and immunity are directly linked to the stress system, and the hormonal effects of the stress response profoundly influence these systems.

Although growth hormone is initially elevated at the onset of stress, the prolonged presence of cortisol leads to suppression of growth hormone, somatomedin C, and other growth factors, exerting a chronically inhibitory effect on growth. In addition, CRF directly increases somatostatin, which in turn inhibits growth hormone secretion. Although the connection is speculative, the effects of stress on growth hormone may provide one of the vital links to understanding failure to thrive in children.

Stress-induced cortisol secretion also is associated with decreased levels of thyroid-stimulating hormone and inhibition of conversion of thyroxine to the more biologically active triiodothyronine in peripheral tissues. Both changes may serve as a means to conserve energy at times of stress.

Antidiuretic hormone (ADH) also is involved in the stress response, particularly in hypotensive stress or stress caused by

fluid volume loss. ADH, also known as vasopressin, increases water retention by the kidneys, produces vasoconstriction of blood vessels, and appears to synergize CRF's capacity to increase the release of ACTH.

The reproductive hormones are inhibited by CRF at the hypophyseal level and by cortisol at the pituitary, gonadal, and target tissue level.¹¹ Sepsis and severe trauma can induce anovulation and amenorrhea in women and decreased spermatogenesis and decreased levels of testosterone in men.

Immune Responses

The hallmark of the stress response, as first described by Selve, is the endocrine-immune interactions (i.e., increased corticosteroid production and atrophy of the thymus) that are known to suppress the immune response. In concert, these two components of the stress system, through endocrine and neurotransmitter pathways, produce the physical and behavioral changes designed to adapt to acute stress. Much of the literature regarding stress and the immune response focuses on the causal role of stress in immune-related diseases. It has also been suggested that the reverse may occur; emotional and psychological manifestations of the stress response may be a reflection of alterations in the CNS resulting from the immune response (Fig. 7-3). Immune cells such as monocytes and lymphocytes can penetrate the blood-brain barrier and take up residence in the brain, where they secrete cytokines and other inflammatory mediators that influence the stress response. In the case of cancer, this could mean that the subjective feelings of helplessness and hopelessness that have been repeatedly related to the onset and progression of cancers may arise secondary to the CNS effects of products released by immune cells during the early stage of the disease.¹⁷

The exact mechanism by which stress produces its effect on the immune response is unknown and probably varies from person to person, depending on genetic endowment and environmental factors. The most significant arguments for interactions between the neuroendocrine and immune systems derive from evidence that the immune and neuroendocrine systems share common signal pathways (i.e., messenger molecules and receptors), that hormones and neuropeptides can alter the function of immune cells, and that the immune system and its mediators can modulate neuroendocrine function.¹⁸ Receptors for a number of CNS-controlled hormones and neuromediators reportedly have been found on lymphocytes. Among these are receptors for glucocorticoids, insulin, testosterone, prolactin, catecholamines, estrogens, acetylcholine, and growth hormone, suggesting that these hormones influence lymphocyte function. For example, cortisol is known to suppress immune function, and pharmacologic doses of cortisol are used clinically to suppress the immune response. There is evidence that the immune system, in turn, influences neuroendocrine function.¹⁹ It has been observed that the HPA axis is activated by cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor that are released from immune cells (see Chapter 8).

A second possible route for neuroendocrine regulation of immune function is through the sympathetic nervous system and the release of catecholamines. The lymph nodes, thymus, and spleen are supplied with ANS nerve fibers. Centrally acting CRF activates the ANS through multisynaptic descending pathways, and circulating epinephrine acts synergistically with CRF and cortisol to inhibit the function of the immune system.

Not only is the quantity of immune expression changed because of stress, but the quality of the response is changed. Stress hormones differentially stimulate the proliferation of subtypes of T lymphocyte helper cells. Because these T helper cell subtypes secrete different cytokines, they stimulate different aspects of the immune response. One subtype tends to stimulate the cellular-mediated immune response; whereas, a second type tends to activate B lymphocytes and humoral-mediated immune response.⁷

Coping and Adaptation to Stress

The ability to adapt to a wide range of environments and stressors is not peculiar to humans. According to René Dubos (a microbiologist noted for his study of human responses to the total environment), "adaptability is found throughout life and is perhaps the one attribute that distinguishes most clearly the world of life from the world of inanimate matter."20 Living organisms, no matter how primitive, do not submit passively to the impact of environmental forces. They attempt to respond adaptively, each in its own unique and most suitable manner. The higher the organism on the evolutionary scale, the larger its repertoire of adaptive mechanisms and its ability to select and limit aspects of the environment to which it responds. The most fully evolved mechanisms are the social responses through which individuals or groups modify their environments, their habits, or both to achieve a way of life that is best suited to their needs.

Adaptation

Human beings, because of their highly developed nervous system and intellect, usually have alternative mechanisms for adapting and have the ability to control many aspects of their environment. Air conditioning and central heating limit the need to adapt to extreme changes in environmental temperature. The availability of antiseptic agents, immunizations, and antibiotics eliminates the need to respond to common infectious agents. At the same time, modern technology creates new challenges for adaptation and provides new sources of stress, such as increased noise, air pollution, exposure to harmful chemicals, and changes in biologic rhythms imposed by shift work and transcontinental air travel.

Of particular interest are the differences in the body's response to events that threaten the integrity of the body's physiologic environment and those that threaten the integrity of the person's psychosocial environment. Many of the body's responses to physiologic disturbances are controlled on a moment-by-moment basis by feedback mechanisms that limit their application and duration of action. For example, the baroreflex-mediated rise in heart rate that occurs when a person moves from the recumbent to the standing position is almost instantaneous and subsides within seconds. Furthermore, the response to physiologic disturbances that threaten the integrity of the internal environment is specific to the threat; the body usually does not raise the body temperature when an increase in heart rate is needed. In contrast, the response to psychological disturbances is not regulated with the same degree of specificity and feedback control; instead, the effect may be inappropriate and sustained.

KEY CONCEPTS

STRESS AND ADAPTATION

- Stress is a state manifested by symptoms that arise from the coordinated activation of the neuroendocrine and immune systems, which Selye called the general adaptation syndrome.
- The hormones and neurotransmitters (catecholamines and cortisol) that are released during the stress response function to alert the individual to a threat or challenge to homeostasis, to enhance cardiovascular and metabolic activity in order to manage the stressor, and to focus the energy of the body by suppressing the activity of other systems that are not immediately needed.
- Adaptation is the ability to respond to challenges of physical or psychological homeostasis and to return to a balanced state.
- The ability to adapt is influenced by previous learning, physiologic reserve, time, genetic endowment, age, health status and nutrition, sleep-wake cycles, and psychosocial factors.

Factors Affecting the Ability to Adapt

Adaptation implies that an individual has successfully created a new balance between the stressor and the ability to deal with it. The means used to attain this balance are called *coping strategies* or *coping mechanisms*. Coping mechanisms are the emotional and behavioral responses used to manage threats to our physiologic and psychological homeostasis. According to Lazarus, how we cope with stressful events depends on how we perceive and interpret the event.²¹ Is the event perceived as a threat of harm or loss? And, is the event perceived as a challenge rather than a threat? Physiologic reserve, time, genetic endowment and age, health status, nutrition, sleep-wake cycles, hardiness, and psychosocial factors influence a person's appraisal of a stressor and the coping mechanisms used to adapt to the new situation (Fig. 7-4).

Physiologic and Anatomic Reserve. The trained athlete is able to increase cardiac output sixfold to sevenfold during exercise. The safety margin for adaptation of most body systems is considerably greater than that needed for normal activities. The red blood cells carry more oxygen than the tissues can use, the liver and fat cells store excess nutrients, and bone tissue stores calcium in excess of that needed for normal neuromuscular function. The ability of body systems to increase their function given the need to adapt is known as the *physiologic reserve*. Many of the body organs, such as the lungs, kidneys, and adrenals, are paired to provide anatomic reserve as well. Both organs are not needed to ensure the continued existence and maintenance of the internal environment. Many persons function normally with only one lung or one kidney. For example, in kidney disease signs of renal failure do not occur

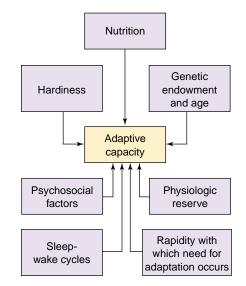

FIGURE 7-4 Factors affecting adaptation.

until approximately 90% of the functioning nephrons have been destroyed.

Time. Adaptation is most efficient when changes occur gradually, rather than suddenly. For instance, it is possible to lose a liter or more of blood through chronic gastrointestinal bleeding during the period of a week without manifesting signs of shock. However, a sudden hemorrhage that causes rapid loss of an equal amount of blood is likely to cause hypotension and shock.

Genetic Endowment. Adaptation is further affected by the availability of adaptive responses and flexibility in selecting the most appropriate and economical response. The greater the number of available responses, the more effective is the capacity to adapt.

Genetic endowment can ensure that the systems that are essential to adaptation function adequately. Even a gene that has deleterious effects may prove adaptive in some environments. In Africa, the gene for sickle cell anemia persists in some populations because it provides some resistance to infection with the parasite that causes malaria.

Age. The capacity to adapt is decreased at the extremes of age. The ability to adapt is impaired by the immaturity of an infant, much as it is by the decline in functional reserve that occurs with age. For example, the infant has difficulty concentrating urine because of immature renal structures and therefore is less able than an adult to cope with decreased water intake or exaggerated water losses. A similar situation, caused by age-related changes in renal function, exists in the elderly.

Health Status. Physical and mental health status determines physiologic and psychological reserves and is a strong determinant of the ability to adapt. For example, persons with heart disease are less able to adjust to stresses that require the recruitment of cardiovascular responses. Severe emotional stress often produces disruption of physiologic function and limits

the ability to make appropriate choices related to long-term adaptive needs. Those who have worked with acutely ill persons know that the will to live often has a profound influence on survival during life-threatening illnesses.

Nutrition. There are 50 to 60 essential nutrients, including minerals, lipids, certain fatty acids, vitamins, and specific amino acids. Deficiencies or excesses of any of these nutrients can alter a person's health status and impair the ability to adapt. The importance of nutrition to enzyme function, immune response, and wound healing is well known. On a worldwide basis, malnutrition may be one of the most common causes of immunodeficiency.

Among the problems associated with dietary excess are obesity and alcohol abuse. Obesity is a common problem. It predisposes to a number of health problems, including atherosclerosis and hypertension. Alcohol is commonly used in excess. It acutely affects brain function and, with long-term use, can seriously impair the function of the liver, brain, and other vital structures.

Sleep-Wake Cycles. Sleep is considered to be a restorative function in which energy is restored and tissues are regenerated.²² Sleep occurs in a cyclic manner, alternating with periods of wakefulness and increased energy use. Biologic rhythms play an important role in adaptation to stress, development of illness, and response to medical treatment. Many rhythms, such as rest and activity, work and leisure, and eating and drinking, oscillate with a frequency similar to that of the 24-hour light-dark solar day. The term *circadian*, from the Latin *circa* ("about") and *dies* ("day"), is used to describe these 24-hour diurnal rhythms.

Sleep disorders and alterations in the sleep-wake cycle have been shown to alter immune function, the normal circadian pattern of hormone secretion, and physical and psychological functioning.²³ The two most common manifestations of an alteration in the sleep-wake cycle are insomnia and sleep deprivation or increased somnolence. In some persons, stress may produce sleep disorders, and in others, sleep disorders may lead to stress. Acute stress and environmental disturbances, loss of a loved one, recovery from surgery, and pain are common causes of transient and short-term insomnia. Air travel and jet lag constitute additional causes of altered sleep-wake cycles, as does shift work. In persons with chronic insomnia, the bed often acquires many unpleasant secondary associations and becomes a place of stress and worry, rather than a place of rest.²⁴

Hardiness. Studies by social psychologists have focused on individuals' emotional reactions to stressful situations and their coping mechanisms to determine those characteristics that help some people remain healthy despite being challenged by high levels of stressors. For example, the concept of *hardiness* describes a personality characteristic that includes a sense of having control over the environment, a sense of having a purpose in life, and an ability to conceptualize stressors as a challenge, rather than a threat.²⁵ Many studies by nurses and social psychologists suggest that hardiness is correlated with positive health outcomes.²⁵

Psychosocial Factors. Several studies have related social factors and life events to illness. Scientific interest in the social en-

vironment as a cause of stress has gradually broadened to include the social environment as a resource that modulates the relation between stress and health. Presumably, persons who can mobilize strong supportive resources from within their social relationships are better able to withstand the negative effects of stress on their health. Studies suggest that social support has direct and indirect positive effects on health status and serves as a buffer or modifier of the physical and psychosocial effects of stress.²⁶

Social networks contribute in a number of ways to a person's psychosocial and physical integrity. The configuration of significant others that constitutes this network functions to mobilize the resources of the person; these friends, colleagues, and family members share the person's tasks and provide monetary support, materials and tools, and guidance in improving problem-solving capabilities.²⁶ Persons with ample social networks are not as likely to experience many types of stress, such as being homeless or being lonely.⁹ There is also evidence that persons who have social supports or social assets may live longer and have a lower incidence of somatic illness.²⁷

Social support has been viewed in terms of the number of relationships a person has and the person's perception of these relationships.²⁸ Close relationships with others can involve positive effects as well as the potential for conflict and may, in some situations, leave the person less able to cope with life stressors.

In summary, the stress response is an activation of several physiologic systems (sympathetic nervous system, the HPA axis, and the immune system) that work in a coordinated fashion to protect the body against damage from the intense demands made on it. Selye called this response the *general adaptation syndrome*. The stress response is divided into three stages: the *alarm stage*, with activation of the sympathetic nervous system and the HPA axis; the *resistance stage*, during which the body selects the most effective defenses; and the *stage of exhaustion*, during which physiologic resources are depleted and signs of systemic damage appear.

The activation and control of the stress response are mediated by the combined efforts of the nervous and endocrine systems. The neuroendocrine systems integrate signals received along neurosensory pathways and from circulating mediators that are carried in the bloodstream. In addition, the immune system both affects and is affected by the stress response.

Adaptation is affected by a number of factors, including experience and previous learning, the rapidity with which the need to adapt occurs, genetic endowment and age, health status, nutrition, sleep-wake cycles, hardiness, and psychosocial factors.

DISORDERS OF THE STRESS RESPONSE

For the most part, the stress response is meant to be acute and time limited. The time-limited nature of the process renders the accompanying catabolic and immunosuppressive effects advantageous. It is the chronicity of the response that is thought to be disruptive to physical and mental health. Stressors can assume a number of patterns in relation to time. They may be classified as acute time-limited, chronic intermittent, or chronic sustained. An acute time-limited stressor is one that occurs over a short time and does not recur; a chronic intermittent stressor is one to which a person is chronically exposed. The frequency or chronicity of circumstances to which the body is asked to respond often determines the availability and efficiency of the stress responses. For example, the response of the immune system is more rapid and efficient on second exposure to a pathogen than it is on first exposure, but chronic exposure to a stressor can fatigue the system and impair its effectiveness.

Effects of Acute Stress

The reactions to acute stress are those associated with the autonomic nervous system, the fight-or-flight response. The manifestations of the stress response—a pounding headache, cold moist skin, a stiff neck—are all part of the acute stress response. Centrally, there is facilitation of neural pathways mediating arousal, alertness, vigilance, cognition, and focused attention, as well as appropriate aggression. The acute stress response can result from either psychologically or physiologically threatening events. In situations of life-threatening trauma, these acute responses may be lifesaving in that they divert blood from less essential to more essential body functions. Increased alertness and cognitive functioning enables rapid processing of information and arrival at the most appropriate solution to the threatening situation.

However, for persons with limited coping abilities, either because of physical or mental health, the acute stress response may be detrimental. This is true of persons with pre-existing heart disease in whom the overwhelming sympathetic behaviors associated with the stress response can lead to dysrhythmias. For people with other chronic health problems, such as headache disorder, acute stress may precipitate a recurrence. In healthy individuals, the acute stress response can redirect attention from behaviors that promote health, such as attention to proper meals and getting adequate sleep. For those with health problems, it can interrupt compliance with medication regimens and exercise programs. In some situations, the acute arousal state actually can be life threatening, physically immobilizing the person when movement would avert catastrophe (*e.g.*, moving out of the way of a speeding car).

Effects of Chronic Stress

The stress response is designed to be an acute self-limited response in which activation of the ANS and the HPA axis is controlled in a negative feedback manner. As with all negative feedback systems, including the stress response system, pathophysiologic changes can occur. Function can be altered in several ways, including when a component of the system fails; when the neural and hormonal connections among the components of the system are dysfunctional; and when the original stimulus for the activation of the system is prolonged or of such magnitude that it overwhelms the ability of the system to respond appropriately. In these cases, the system may become overactive or underactive.

Chronicity and excessive activation of the stress response can result from chronic illnesses as well as contribute to the development of long-term health problems. Chronic activation of the stress response is an important public health issue from both a health and a cost perspective. The National Institute for Occupational Safety and Health declared stress a hazard of the workplace.²⁹ It is linked to a myriad of health disorders, such as diseases of the cardiovascular, gastrointestinal, immune, and neurologic systems, as well as depression, chronic alcoholism and drug abuse, eating disorders, accidents, and suicide.

Occurrence of the oral disease acute necrotizing gingivitis, in which the normal bacterial flora of the mouth become invasive, is known by dentists to be associated with acute stress, such as final examinations.³⁰ Similarly, herpes simplex type 1 infection (*i.e.*, cold sores) often develops during periods of inadequate rest, fever, ultraviolet radiation, and emotional upset. The resident herpesvirus is kept in check by body defenses, probably T lymphocytes, until a stressful event occurs that causes suppression of the immune system. Psychological stress is associated in a dose-response manner with an increased risk for development of the common cold, and this risk is attributable to increased rates of infection, rather than frequency of symptoms after infection.³¹

In a study in which participants were infected with the influenza virus, persons who reported the greatest amount of premorbid stress reported the most intense influenza symptoms and had a statistically greater production of interleukin-6, a cytokine that acts as a chemotactic agent for immune cells.³² Elderly caregivers of a spouse with dementia had a significantly higher score for emotional distress and higher salivary cortisol than did matched control subjects. The higher stress was correlated with a decreased immune response to the influenza vaccine.³⁴ The experience of stress also has been associated with delays in wound healing.

Post-traumatic Stress Disorder

The post-traumatic stress disorder (PTSD) is an example of chronic activation of the stress response as a result of experiencing a potentially life-threatening event. It was formerly called *battle fatigue* or *shell shock* because it was first characterized in men and women returning from combat. Although war is still a significant cause of PTSD, other major catastrophic events, such as major weather-related disasters, airplane crashes, terrorist bombings, and rape or child abuse, also may result in the development of the disorder. The terrorist attacks on the World Trade Center and Pentagon on September 11, 2001, represented an amalgam of interpersonal violence, loss, and threat to tens of thousands of people.35 These events have influenced and will continue to influence the development of PTSD in a substantial number of people. On the basis of data obtained after the 1995 bombing of the Murrah Federal Building in Oklahoma City, it is predicted that PTSD will develop in approximately 35% of those who were directly exposed to the September 11 attacks.36

PTSD is characterized by a constellation of symptoms that are experienced as states of intrusion, avoidance, and hyperarousal. *Intrusion* refers to the occurrence of "flashbacks" during waking hours or nightmares in which the past traumatic event is relived, often in vivid and frightening detail. *Avoidance* refers to the emotional numbing that accompanies this disorder and disrupts important personal relationships. Because a

130 Unit Two: Alterations in Body Defenses

person with PTSD has not been able to resolve the painful feelings associated with the trauma, depression is commonly a part of the clinical picture. Survivor guilt also may be a product of traumatic situations in which the person survived the disaster but loved ones did not. *Hyperarousal* refers to the presence of increased irritability and exaggerated startle reflex. In addition, memory problems, sleep disturbances, and anxiety are commonly experienced by persons with PTSD.

Although the pathophysiology of PTSD is not completely understood, the elucidation of physiologic changes related to the disorder has shed light on why some people recover from the disorder but others do not. It has been hypothesized that the intrusive symptoms of PTSD may arise from exaggerated sympathetic nervous system activation in response to the traumatic event. Persons with chronic PTSD have been shown to have increased levels of norepinephrine and increased activity of α_2 -adrenergic receptors.³⁵ The increase in catecholamines, in tandem with increased thyroid levels in persons with PTSD, is thought to explain some of the intrusive and somatic symptoms of the disorder.^{35,37}

Recent neuroanatomic studies have identified alterations in two brain structures—the amygdala and hippocampus. Positron-emission tomography and functional magnetic resonance imaging (MRI) have shown increased reactivity of the amygdala and hippocampus and decreased reactivity of the anterior cingulate and orbitofrontal areas. These areas of the brain are involved in fear responses. The hippocampus also functions in memory processes. Differences in hippocampal function and memory processes suggest a neuroanatomic basis for the intrusive recollections and other cognitive problems that characterize PTSD.³⁵

Despite the observed neuroanatomical changes, persons with PTSD do not uniformly undergo the biological responses associated with other types of stress.³⁸ For example, persons with PTSD demonstrate decreased cortisol levels, increased sensitivity of cortisol receptors, and an enhanced negative feedback inhibition of cortisol release with the dexamethasone suppression test. Dexamethasone is a synthetic glucocorticoid that mimics the effects of cortisol and directly inhibits the action of CRF and ACTH. This is in contrast to patients with major depression, who have a decreased sensitivity of glucocorticoid receptors, a high plasma level of cortisol, and a decreased dexamethasone suppression.³⁸ The hypersuppression of cortisol observed with the dexamethasone test suggests that persons with PTSD do not exhibit a classic stress response as described by Selye. Because this hypersuppression has not been described in other psychiatric disorders, it may serve as a relatively specific marker for PTSD.

Little is known about the risk factors that predispose people to the development of PTSD. It is important to note that less than half of all people who are exposed to a traumatic event experience PTSD. For example, only 15% to 30% of soldiers exposed to combat experience the disorder.³⁹ It also has been found that children exposed to violent events but who have strong family relationships rarely experience PTSD.⁴⁰ Statistics indicate there is a need for studies to determine risk factors for PTSD as a means of targeting individuals who may need intensive therapeutic measures after a life-threatening event. Research also is needed to determine the mechanisms by which the disorder develops so that it can be prevented, or if that is not possible, so that treatment methods can be created to decrease the devastating effects that this disorder has on affected individuals and their families.³⁷

Health care professionals need to be aware that clients who present with symptoms of depression, anxiety, and alcohol or drug abuse may in fact be experiencing PTSD. The client history should include questions concerning the occurrence of violence, major loss, or traumatic events in the person's life. Debriefing, or talking about the traumatic event at the time it happens, often is an effective therapeutic tool. Crisis teams are among the first people to attend to the emotional needs of those caught in catastrophic events. Some people may need continued individual or group therapy. Often concurrent pharmacotherapy, such as antidepressants and antianxiety agents, is useful and helps the individual participate more fully in therapy.

Most important, the person with PTSD must not be made to feel responsible for the disorder or that it is evidence of a character flaw. It is not uncommon for persons with this disorder to be told to "get over it" or "just get on with it, because others have." There is ample evidence to suggest that there is a biologic basis for the individual differences in responses to traumatic events, and these differences need to be taken into account.

Treatment of Stress Disorders

The treatment of stress should be directed toward helping people avoid coping behaviors that impose a risk to their health and providing them with alternative stress-reducing strategies. Purposeful priority setting and problem solving can be used by persons who are overwhelmed by the number of life stresses to which they have been exposed. Other nonpharmacologic methods used for stress reduction are relaxation techniques, guided imagery, music therapy, massage, and biofeedback.

Relaxation

Practices for evoking the relaxation response are numerous. They are found in virtually every culture and are credited with producing a generalized decrease in sympathetic system activity and musculoskeletal tension. According to Herbert Benson, a physician who worked in developing the technique, four elements are integral to the various relaxation techniques: a repetitive mental device, a passive attitude, decreased mental tonus, and a quiet environment.⁴¹ Benson developed a noncultural method that is commonly used for achieving relaxation (see accompanying box).

Progressive muscle relaxation, originally developed by Edmund Jacobson, who did extensive research on the muscle correlates of anxiety and tension, is another method of relieving tension. He observed that tension can be defined physiologically as the inappropriate contraction of muscle fibers. His procedure, which has been modified by a number of therapists, consists of systematic contraction and relaxation of major muscle groups.⁴² As the person learns to relax, the various muscle groups are combined. Eventually, the person learns to relax individual muscle groups without first contracting them.

Imagery

Guided imagery is another technique that can be used to achieve relaxation. One method is scene visualization, in which the person is asked to sit back, close the eyes, and con-

- Sit quietly in a comfortable position.
- Deeply relax all your muscles, beginning at your feet and progressing up to your face.
- Breathe through your nose. Become aware of your breathing. As you breathe out, say the word "one" silently to yourself. Continue for 20 minutes. When you have finished, sit quietly for several minutes, first with your eyes closed and then with them open.
- Do not worry about whether you are successful in achieving a deep level of relaxation. Maintain a positive attitude and permit the relaxation to occur at its own rate. Expect distracting thoughts, ignore them, and continue repeating "one" as you breathe out.
- (Modified from Benson H. [1977]. Systemic hypertension and the relaxation response. New England Journal of Medicine 296, 1152)

centrate on a scene narrated by the therapist. Whenever possible, all five senses are involved: the person attempts to see, feel, hear, and taste aspects of the visual experience. Other types of imagery involve imagining the appearance of each of the major muscle groups and how they feel during tension and relaxation.

Music Therapy

Music therapy is used for both its physiologic and psychological effects. It involves listening to selected pieces of music as a means of ameliorating anxiety or stress, reducing pain, decreasing feelings of loneliness and isolation, buffering noise, and facilitating expression of emotion. Music is defined as having three components: rhythm, melody, and harmony.43,44 Rhythm is the order in the movement of the music. Rhythm is the most dynamic aspect of music, and particular pieces of music often are selected because they harmonize with body rhythms, such as heart rhythm, respiratory rhythm, or gait. The melody is created by the musical pitch and distance (or interval) between the musical tone. The melody contributes to the listener's emotional response to the music. The harmony results from the way pitches are blended together, with the combination of sounds described as consonant or dissonant by the listener. Music usually is selected based on a person's musical preference and past experiences with music. Depending on the setting, headphones may be used to screen distracting noises. Radio and television music is inappropriate for music therapy because of the inability to control the selection of pieces that are played, the interruptions that occur (e.g., commercials and announcements), and the quality of the reception.

Massage Therapies

Massage is the manipulation of the soft tissues of the body to promote relaxation and relief of muscle tension. The technique that is used may involve a gentle stroking along the length of a muscle (effleurage), application of pressure across the width of a muscle (pétrissage), deep massage movements applied by a circular motion of the thumbs or fingertips (friction), squeezing across the width of a muscle (kneading), or use of light slaps or chopping actions (hacking).⁴⁵ Massage may be administered by practitioners who have received special training in its use or by less prepared persons, such as parents of small children^{46,47} or caregivers of confused elders.⁴⁸ It often is used as a means of physiologic relaxation and stress relief in critically ill patients.49

Biofeedback

Biofeedback is a technique in which an individual learns to control physiologic functioning. It involves electronic monitoring of one or more physiologic responses to stress with immediate feedback of the specific response to the person undergoing treatment. Several types of responses are used: electromyographic (EMG), electrothermal, and electrodermal (EDR).⁵⁰ The EMG response involves the measurement of electrical potentials from muscles, usually the forearm extensor or frontalis. This is used to gain control over the contraction of skeletal muscles that occurs with anxiety and tension. The electrodermal sensors monitor skin temperature in the fingers or toes. The sympathetic nervous system exerts significant control over blood flow in the distal parts of the body such as the digits of the hands and feet. Consequently, anxiety often is manifested by a decrease in skin temperature in the fingers and toes. EDR sensors measure conductivity of skin (usually the hands) in response to anxiety. Fearful and anxious people often have cold and clammy hands, which leads to a decrease in conductivity.

In summary, stress is neither negative nor deleterious to health. The stress response is designed to be time limited and protective, but in situations of prolonged activation of the response because of overwhelming or chronic stressors, it could be damaging to health. PTSD is an example of chronic activation of the stress response as a result of experiencing a severe trauma. In this disorder, memory of the traumatic event seems to be enhanced. Flashbacks of the event are accompanied by intense activation of the neuroendocrine system.

Treatment of stress should be aimed at helping people avoid coping behaviors that can adversely affect their health and providing them with other ways to reduce stress. Nonpharmacologic methods used in the treatment of stress include relaxation techniques, guided imagery, music therapy, massage techniques, and biofeedback.

REVIEW QUESTIONS

Describe the concept of homeostasis as it relates to a specific body function.

State Selve's definition of stress.

Relate Selve's description of the general adaptation syndrome to the signs and symptoms experienced by a person with a condition such as hemorrhagic shock.

Describe the contributions of the autonomic nervous system, endocrine system, and the immune system to the stress response.

List at least six factors that influence a person's adaptive apacity.

132 Unit Two: Alterations in Body Defenses

Describe the physiologic and psychological effects of a chronic stress response.

Describe the three states characteristic of post-traumatic stress disorder.

Describe at least five nonpharmacologic methods of treating stress.

he immune system is clearly essential for survival. It constantly defends the body against bacteria, viruses, and other foreign substances it encounters. It also detects and responds to abnormal cells and molecules that periodically develop in the body so that diseases such as cancers do not occur. An essential aspect of the immune response is the ability to recognize almost limitless numbers of foreign cells and nonself substances, distinguishing them from self molecules that are native to the body.

The major focus of this chapter is to present an overview of the immune cells, molecules, and tissues and to describe the normal mechanisms used to protect the body against foreign invaders.

THE IMMUNE SYSTEM

The *immune system* consists of the central and peripheral lymphoid tissues and the immune cells that protect the body against a myriad of microbes and foreign substances. The individual components of the substance that the immune system recognizes as foreign are called *antigens*. The interaction of the collective and coordinated components of the immune system and the antigens of a foreign agent is called the *immune response*.

Fundamental to the appropriate functioning of the immune system is the ability to regulate the recognition, amplification, and the response of the immune cells to a foreign agent. The immune system must recognize and differentiate one foreign pathogen from another, while simultaneously distinguishing these foreign molecules from normal cells and proteins in the body.

Properties of the Immune System

The body protects again bacteria, viruses, and other foreign substances by many different mechanisms. These include physical barriers, phagocytic cells in the blood and tissues, a class of lymphocytes called natural killer cells, and various bloodborne molecules that protect individuals from a potentially harmful environment. These mechanisms can be divided into two cooperative defense systems: the nonspecific or innate defense system and the specific or acquired immune system.

As a first line of defense system, the nonspecific immune system distinguishes self from non-self but does not distinguish one type of pathogen from another. Nonspecific resistance to microbe invasion results from two general lines of defense. Microorganisms encounter the first line of resistance on exposure to the epithelial layers of our skin and mucous membranes that line our respiratory, gastrointestinal, and urogenital tracts. The second line of nonspecific defense involves chemical signals, antimicrobial substances, phagocytic and natural killer cells, and fever associated with the inflammatory response. These two lines of nonspecific defense mechanisms are important for excluding pathogens from our body and removing them if they enter. They also aid in proper signaling of the second defense system—specific immunity.

Specific Immunity

Specific or acquired immunity develops during an individual's lifetime, distinguishes self from nonself, and responds specifically to different pathogens and foreign molecules. White blood cells called *lymphocytes* are key players in the specific or acquired immune response. These cells include the T lymphocytes (also called T cells), which participate in cell-mediated immunity, and the B lymphocytes (also called B cells), which participate in humoral immunity. Cell-mediated immunity involves the production of cytotoxic T cells, which have the ability to destroy antigen-bearing cells. Humoral immunity is characterized by the transformation of B cells into plasma cells, which secrete immunoglobulins (antibodies) that have specific activity against the inciting antigen.

Specificity, Diversity, Memory, Self-limitation, and Self-nonself Recognition

A cardinal feature of the specific immunity provided by the T and B lymphocytes is that of specificity, diversity, memory, selflimitation, and self-nonself recognition. These cells can exactly recognize a particular microorganism or foreign molecule. Each lymphocyte targets a specific antigen and distinguishes subtle differences between distinct antigens. The approximately 10¹² lymphocytes in the body have tremendous diversity. They can respond to the millions of different kinds of antigens encountered daily. This diversity occurs because an enormous variety of lymphocyte populations have been programmed during development, each to respond to a particular antigen.

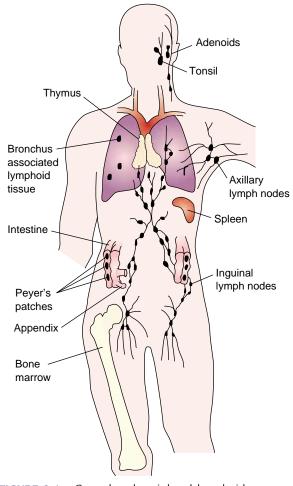

An evolutionary adaptation that is unique to the immune system is a memory response—the ability to recall and quickly produce a heightened immune response on subsequent exposure to the same foreign agent. After lymphocytes are stimulated by an antigen, they acquire a memory response. The memory T and B lymphocytes that are generated remain in the body for a long time and can respond more rapidly on repeat exposure than can naive cells. Because of this heightened state of immune reactivity, the immune system usually can respond to commonly encountered microorganisms so quickly and efficiently that one is unaware of the response.

Self-limitation refers to the ability of the stimulated lymphocytes to perform their functions for a brief period of time, sufficient to destroy the invading pathogen, and then die or differentiate into functionally quiescent memory cells. Selflimitation allows the immune system to return to a state of rest after it eliminates each antigen, thus enabling it to respond optimally to other antigens that an individual encounters.

Discrimination of self from nonself is one of the most important properties of the immune system. Immunologic unresponsiveness to self antigens, or self-tolerance, is essential for preventing reactions against one's own cells and tissues while maintaining a diverse repertoire of lymphocytes specific for foreign antigens.

Lymphoid Organs

The lymphoid organs are at the center of the immune response. These organs and tissues are widely distributed in the body and provide different, but often overlapping, functions (Fig. 8-1). The central lymphoid organs, the bone marrow and the thymus, provide the environment for immune cell production and maturation. The peripheral lymphoid organs function to trap and process antigen and promote its interaction with mature immune cells. Lymph nodes, spleen, tonsils, appendix, Peyer's patches in the intestine, and mucosa-associated lymphoid tissues in the respiratory, gastrointestinal, and reproductive systems comprise the peripheral lymphoid organs. Networks of lymph channels, blood vessels, and capillaries connect the lymphoid organs. The immune cells continuously circulate through

■ FIGURE 8-1 ■ Central and peripheral lymphoid organs and tissues.

KEY CONCEPTS

COMPONENTS OF THE IMMUNE SYSTEM

- The immune system consists of immune cells; the central immune structures (the bone marrow and thymus), where immune cells are produced and mature; and the peripheral immune structures (lymph nodes, spleen, and other accessory structures), where the immune cells interact with antigen.
- The immune cells consist of the lymphocytes (T and B lymphocytes), which are the primary cells of the immune system, and the accessory cells such as the macrophages, which aid in processing and presentation of antigens to the lymphocytes.
- Cytokines are molecules that form a communication link between immune cells and other tissues and organs of the body.
- Recognition of self from nonself by the immune cells depends on a system of MHC membrane molecules that differentiate viral-infected and abnormal cells from normal cells (MHC I) and identify immune cells from other types of cells (MHC II).

the various tissues and organs to seek out and destroy foreign material.

Thymus

The thymus is an elongated, bilobed structure that is located in the neck region above the heart. The function of the thymus is central to the development of the immune system because it generates mature immunocompetent T lymphocytes. The thymus is a fully developed organ at birth, weighing approximately 15 to 20 g. At puberty, when the immune cells are well established in peripheral lymphoid tissues, the thymus begins regressing and is replaced by adipose tissue. Nevertheless, some thymus tissue persists into old age. Precursor T (pre-T) cells enter the thymus as functionally and phenotypically immature T cells. They progressively differentiate into mature T cells under the influence of the thymic hormones and cytokines. As the T cells multiple and mature, they acquire T cell receptors, surface markers that distinguish among the different types of T cells, and antigens that distinguish self from nonself. More than 95% of the thymocytes die in the thymus because they do not produce the appropriate type of self-antigens. Only those T cells able to recognize foreign antigen and not react to selfantigens are allowed to mature. This process is called *thymic* selection. Mature immunocompetent T cells leave the thymus in 2 to 3 days and enter the peripheral lymphoid tissues through the bloodstream.

Lymph Nodes

Lymph nodes are small aggregates of lymphoid tissue located along lymphatic vessels throughout the body. Each lymph node processes lymph from a discrete, adjacent anatomic site. Many lymph nodes are in the axillae, groin, and along the great vessels of the neck, thorax, and abdomen. These tissues are located along the lymph ducts, which lead from the tissues to the thoracic duct. Lymph nodes have two functions: removal of foreign material from lymph before it enters the bloodstream and serving as centers for proliferation of immune cells.

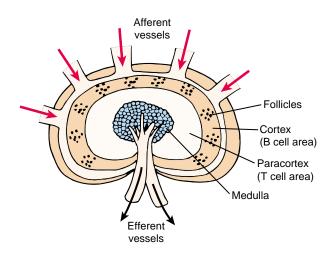

A lymph node is a bean-shaped tissue surrounded by a connective tissue capsule. Lymph enters the node through afferent channels that penetrate the capsule, and the lymph leaves through the efferent lymph vessels located in the deep indentation of the hilus (Fig. 8-2). Lymphocytes and macrophages flow slowly through the node, which allows trapping and interaction of antigen and immune cells. The reticular meshwork serves as a surface on which macrophages can more easily phagocytize antigens. Dendritic cells, which also permeate the lymph node, aid antigen presentation.

Spleen

The spleen is a large, ovoid organ located high in the left abdominal cavity. The spleen filters antigens from the blood and is important in response to systemic infections. The spleen is composed of red and white pulp. The red pulp is well supplied with arteries and is the area where senescent and injured red blood cells are destroyed. The white pulp contains concentrated areas of B and T lymphocytes permeated by macrophages and dendritic cells.

Other Secondary Lymphoid Tissues

Other secondary lymphoid tissues include the *mucosa-associated lymphoid tissues*. These nonencapsulated clusters of lymphoid tissues are located around membranes lining the respiratory, digestive, and urogenital tract. These gateways into the body contain the immune cells needed to respond to a large and diverse population of microorganisms. In some tissues, the lymphocytes are organized in loose clusters, but in other tissues such as the tonsils, Peyer's patches in the intestine, and the appendix, organized structures are evident. These tissues contain all the necessary cell components (*i.e.*, T cells, B cells, macrophages, and dendritic cells) for an immune response.

Immunity at the mucosal layers helps to protect the vulnerable internal organs.

Antigens

Before discussing the cells and responses inherent to immunity, it is important to understand the substances that elicit a response from the host. Antigens or immunogens are substances foreign to the host that can stimulate an immune response. These foreign molecules are recognized by receptors on immune cells and by proteins, called antibodies or immunoglobulins, that are generated in response to the antigen. Antigens include bacteria, fungi, viruses, protozoans, and parasitic worms. Antigens also can include substances such as pollen, poison ivy plant resin, insect venom, and transplanted organs. Most antigens are macromolecules such as proteins and polysaccharides, although lipids and nucleic acids occasionally can serve as antigens. Chemically complex molecules tend to be good stimulators of immunity.

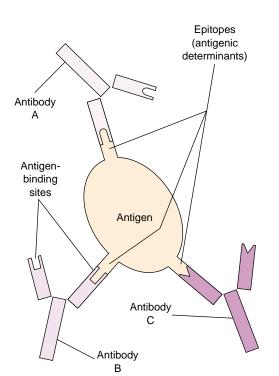

Antigens, which in general are large and complex, are biologically degraded into smaller chemical units or peptides. These discrete, immunologically active sites on antigens are called antigenic determinants or epitopes (Fig. 8-3). It is the unique molecular shape of an epitope that is recognized by a specific receptor found on the surface of the lymphocyte or by the antigen-binding site of an antibody. A single antigen may contain several antigenic determinants; each can stimulate a distinct clone of lymphocytes to respond. For example, different proteins that comprise a virus may function as unique antigens, each of which contains several antigenic determinants. Hundreds of antigenic determinants are found on complex structures such as the bacterial cell wall.

Smaller substances (molecular masses <10,000 daltons) usually are unable to stimulate an adequate immune response by themselves. When these low-molecular-weight compounds, known as haptens, combine with larger protein molecules, they function as antigens. The proteins act as carrier molecules for the haptens to form antigenic hapten-carrier complexes. An allergic response to the antibiotic penicillin is an example of a hapten-carrier complex that has medical importance. Penicillin (molecular mass of approximately 350 daltons) is incapable of causing an immune response by itself. However, penicillin can chemically combine with body proteins to form larger complexes that can then generate in some individuals an immune response to the penicillin epitope.

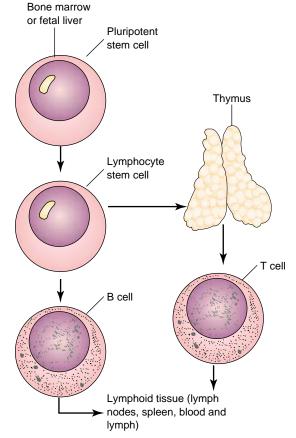

Immune Cells

The primary cells of the specific immune system are the lymphocytes. However, the recognition and activation of the specific immune responses depend on non-lymphoid cells, called accessory cells, which are not specific for different antigens. The accessory cells include the mononuclear phagocytes, dendritic cells, and other specialized antigen-presenting cells (APCs).

Lymphocytes represent 25% to 35% of blood leukocytes. Like other blood cells, lymphocytes are generated from stem cells in the bone marrow (Fig. 8-4). These undifferentiated cells congregate in the central lymphoid tissues, where they mature into distinct types of lymphocytes. One class of lymphocyte, the B lymphocytes (B cells), matures in the bone marrow and is essential for humoral or antibody-mediated immunity. The other class of lymphocytes, the T lymphocytes

■ FIGURE 8-3 ■ Multiple epitopes on a complex antigen being recognized by their respective (A, B, C) antibodies.

■ FIGURE 8-4 ■ Pathway for T- and B-cell differentiation.

138 Unit Two: Alterations in Body Defenses

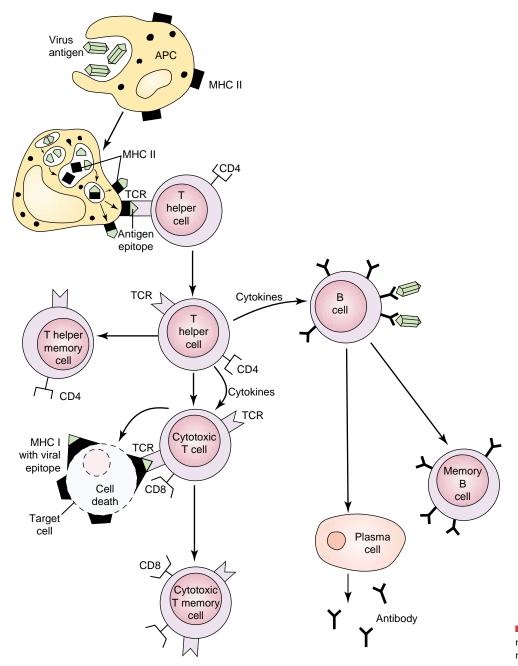

(T cells), complete their maturation in the thymus and are essential for cell-mediated immunity, as well as aiding with antibody production. Approximately 60% to 70% of blood lymphocytes are T cells, and 10% to 20% are B cells. The various types of lymphocytes are distinguished by their function and response to antigen, their cell membrane molecules and receptors, their types of secreted proteins, and their tissue location.

Activation of the lymphocytes is dependent upon the appropriate processing and presentation of antigen to the T lymphocytes by APCs such as macrophages (Fig. 8-5). On recognition of antigen and after additional stimulation by various secreted signaling molecules called *cytokines*, the T and B lymphocytes divide several times to form populations or clones of

cells that continue to differentiate into effector cells that destroy the antigen and memory cells that retain the information needed for future encounters with the antigen.

Clusters of Differentiation

Mature T and B cells display surface molecules called *clusters of differentiation* (CD). These molecules serve to define functionally distinct T-cell subsets such as CD4⁺ T helper cells and CD8⁺ T cytotoxic cells. The many cell surface CD molecules detected on immune cells have allowed scientists to study the normal and abnormal processes displayed by these cells. In cell-mediated immunity, regulatory CD4⁺ helper T cells enhance the response of other T and B cells, and effector cytotoxic T cells

■ **FIGURE 8-5** ■ Pathway for immune cell participation in an immune response.

(CD8⁺) kill virus-infected cells and tumor cells. The human immunodeficiency virus (HIV) that causes acquired immunodeficiency syndrome (AIDS) infects and destroys the CD4⁺ helper T cell (see Chapter 10).

Major Histocompatibility Complex Molecules

An essential feature of specific immunity is the ability to discriminate between the body's own molecules and foreign antigens. Failure to distinguish self from nonself can lead to conditions such as autoimmune disease where the immune system destroys the body's own cells. Key recognition molecules essential for distinguishing self from nonself are the cell surface MHC antigens. These molecules, which in humans are coded by closely linked genes on chromosome 6, were first identified because of their role in organ and tissue transplantation. When cells are transplanted between individuals who are not identical for their MHC molecules, the immune system produces a vigorous immune response, leading to rejection of the transferred cells or organs. MHC molecules did not evolve to reject transplanted tissues, a situation not encountered in nature. Rather, these molecules are essential for correct cell-to-cell interactions among immune and body cells.

The MHC molecules involved in self-recognition and cell-tocell communication fall into two classes, class I and class II (Fig. 8-6). Class I MHC molecules are cell surface glycoproteins that interact with antigen receptors and the CD8 molecule on T cytotoxic lymphocytes. They are found on nearly all nucleated cells in the body and thus are capable of alerting the immune system of any cell changes caused by viruses or products of mutated genes in cancer cells. In viral infected cells, viral protein antigens become associated with class I MHC molecules. As the virus multiplies, small peptides from degraded viral proteins

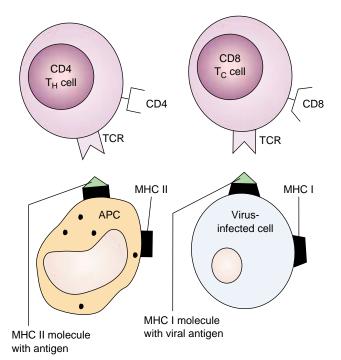

FIGURE 8-6 Interaction of a T-cell receptor (TCR) on a CD4 helper T (T_H) cell with class II MHC molecule on an antigenpresenting (APC) cell and CD8 cytotoxic (T_c) T cell with class I MHC molecule on a virus-infected cell.

complex with class I MHC molecules and are then transported to the infected cell membrane. This antigen-MHC I complex communicates to the T cytotoxic cell that the cell must be destroved for the overall survival of the host. Class II MHC molecules, which are found primarily on APCs such as macrophages, dendritic cells, and B lymphocytes, communicate with an antigen receptor and a CD4 molecule on T helper lymphocytes. Class II MHC molecules bind to a fragment of antigen from pathogens that have been engulfed and digested during the process of phagocytosis. The engulfed pathogen is degraded in cytoplasmic vesicles and its peptide components complexed with class II MHC molecules. Thelper cells recognize these complexes on the surface of APCs and become activated. These activated T cells multiply quickly and direct the immune response to the invading pathogen.

Each individual has a unique collection of several MHC proteins, and a variety of MHC molecules can exist in a population. Because of the number of MHC genes and the possibility of several alleles for each gene, it is almost impossible for any two individuals to be identical, unless they are identical twins. The uniqueness of these genes is essential for the immune system to distinguish self from nonself. In contrast to the receptors on T and B lymphocytes that bind a unique antigen molecule, each MHC protein can bind a broad spectrum of antigen peptides. Incorporation of the MHC molecules into the antigen presentation process allow for self/nonself recognition in establishing an appropriate immune response.

Human MHC proteins are called human leukocyte antigens (HLA) because they were first detected on white blood cells. Because these molecules play a role in transplant rejection and are detected by immunologic tests, they are commonly called antigens. The human class I MHC molecules are divided into types called HLA-A, HLA-B, and HLA-C, and the class II MHC molecules are identified as HLA-DR, HLA-DP, and HLA-DQ (Table 8-1). Additional, less well-defined class I and II MHC genes also have been described. Each of the gene loci that describes an HLA molecule can be occupied by multiple alleles or alternate genes. For example, there are more than 120 possible genes for the A locus and 250 genes for the B locus. Each of the gene products or antigens is designated by a number, such as HLA-B27.

Because the class I and II MHC genes are closely linked on one chromosome, the combination of HLA genes usually is inherited as a unit, called a haplotype. Each person inherits a chromosome from each parent and therefore has two HLA haplotypes. The identification or typing of HLA molecules is important in tissue or organ transplantation, forensics, and paternity evaluations. In organ or tissue transplantation, the closer the matching of HLA types, the greater is the probability of identical antigens and the lower the chance of rejection.

Monocytes, Macrophages, and Dendritic Cells

Monocytes and tissue macrophages are a part of the mononuclear phagocyte system, which in turn is part of the reticuloendothelial system. All of the cells of the mononuclear phagocytic system arise from common precursors in the bone marrow that produce the blood monocytes (see Chapter 11). The monocytes migrate to various tissues where they mature into macrophages. Macrophages are characterized as large cells with extensive cytoplasm and numerous vacuoles. The tissue macrophages are scattered in connective tissue or clustered in

TABLE 8-1	Properties of MHC Class I and MHC Class II Molecules

organs such as the lung (*i.e.*, alveolar macrophages), liver (*i.e.*, Kupffer's cells), spleen, lymph nodes, peritoneum, central nervous system (*i.e.*, microglial cells), and other areas.

Macrophages have important functions in both innate and antigen-specific immune responses. As phagocytic cells with antigen nonspecific activity, they help to contain infectious agents until specific immunity can be marshaled. In addition, early in the host response, the macrophage functions as an accessory cell to ensure amplification of the inflammatory response and initiation of specific immunity. Macrophages are activated by the presence of antigen to engulf and digest foreign particles (Fig. 8-7). Activated macrophages act as APCs that break down complex antigens into peptide fragments that can associate with class II MHC molecules. Macrophages can then

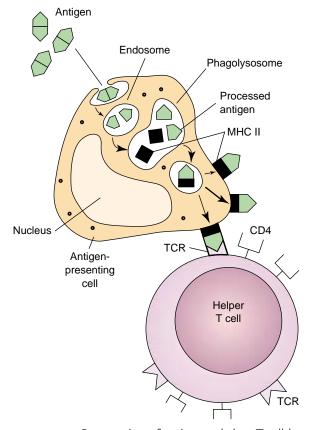

FIGURE 8-7 Presentation of antigen to helper T cell by an antigen-presenting cell (APC).

present these complexes to the helper T cell so that nonself-self recognition and activation of the immune response can occur. Macrophages also secrete cytokines that produce fever and prime T and B lymphocytes that have recognized antigen.

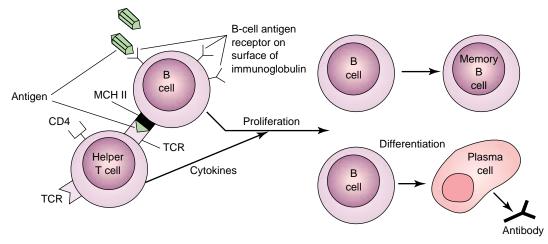

As the general scavenger cell of the body, the macrophage can be fixed in a tissue or can be free to migrate from an organ to lymphoid tissues. Macrophages also can serve as phagocytic effector cells in humoral and cell-mediated immune responses. They can remove antigen–antibody aggregates or, under the influence of T-cell cytokines, they can destroy virus-infected cells or tumor cells.

Dendritic cells share with the macrophage the important task of presenting antigen to T lymphocytes. These distinctive, star-shaped cells with long extensions of their cytoplasmic membrane provide an extensive surface rich in class II MHC molecules, which is essential for initiation of an acquired immune response. Dendritic cells are found in lymphoid tissues and other body areas where antigen enters the body. In these different environments, dendritic cells can acquire specialized functions and appearances, as do macrophages. Langerhans' cells are specialized dendritic cells in the skin, whereas follicular dendritic cells are found in the lymph nodes. Langerhans' cells are constantly surveying the skin for antigen and can transport foreign material to a nearby lymph node. Skin dendritic cells and macrophages also are involved in cell-mediated immune reactions of the skin, such as delayed allergic contact hypersensitivity.

B Lymphocytes

B lymphocytes can be identified by the presence of surface immunoglobulin that functions as the antigen receptor, class II MHC proteins, complement receptors, and specific CD molecules. During the maturation of B cells, which occurs in the bone marrow, stem cells change into immature precursor (pre-B) cells (Fig. 8-8). This B cell then acquires a unique surface receptor and a specific type of effector antibody (*e.g.*, immunoglobulin M [IgM] or IgD). This stage of maturation is programmed into the B cells and does not require antigen for its stimulation. CD molecules also change as the B cell matures. The CD surface markers are useful for defining immature and undifferentiated cells in B-cell malignancies. The mature B cell leaves the bone marrow, enters the circulation, and migrates to the various peripheral lymphoid tissues, where it is stimulated to respond to a specific antigen.

The commitment of a B-cell line to a specific antigen is evident by the expression of the surface immunoglobulin receptors. B cells that encounter antigen complementary to their sur-

■ FIGURE 8-8 ■ Pathway for B-cell differentiation.

face immunoglobulin receptor and receive T-cell help undergo a series of changes that transform them into antibody-secreting plasma cells or into memory B cells (Fig. 8-8). The activated B cell that divides and maturates into a plasma cell can produce thousands of antibody molecules per second. The antibodies are released into the blood and lymph, where they bind and remove their unique antigen with the help of other immune cells and molecules. Longer-lived memory B cells are generated and distributed into the peripheral tissues in preparation for subsequent antigen exposure.

Immunoglobulins. Antibodies comprise a class of proteins called immunoglobulins. The immunoglobulins have been divided into five classes: IgG, IgA, IgM, IgD, and IgE (Table 8-2), each with a different role in the immune defense strategy. Immunoglobulins have a characteristic four-polypeptide structure consisting of at least two identical antigen-binding sites (Fig. 8-9). Each immunoglobulin is composed of two identical light (L) chains and two identical heavy (H) chains to form a Y-shaped molecule. The two forked ends of the immunoglobulin molecule bind antigen and are called Fab (i.e., antigenbinding) fragments, and the tail of the molecule, which is called the *Fc* fragment, determines the biologic properties that are characteristic of a particular class of immunoglobulins. The amino acid sequence of the heavy and light chains shows constant (C) regions and variable (V) regions. The constant regions have sequences of amino acids that vary little among the antibodies of a particular class of immunoglobulin. The constant region allows for separation of immunoglobulins into classes (e.g., IgM, IgG) and it allows each class of antibody to interact with certain effector cells and molecules. For example, IgG can tag an antigen for recognition and destruction by phagocytes. The variable regions contain the antigen-binding sites of the molecule. The wide variation in the amino acid sequence of the variable regions seen from antibody to antibody allows this region to serve as the antigen-binding site. A unique amino acid sequence in this region determines a distinctive three-dimensional pocket that is complementary to the antigen, allowing recognition and binding of the antigen. Each B-cell clone produces antibody with one specific antigen-binding variable region or domain. During the course of the immune response, class

switching (*e.g.*, from IgM to IgG) can occur, causing the B-cell clone to produce any of the following antibody types.

IgG (gamma globulin) is the most abundant of the circulating immunoglobulins. It is present in body fluids and readily enters the tissues. IgG is the only immunoglobulin that crosses the placenta and can transfer immunity from the mother to the fetus. This class of immunoglobulin protects against bacteria, toxins, and viruses in body fluids and activates the complement system. There are four subsets of IgG (*i.e.*, IgG1, IgG2, IgG3, and IgG4) that have some restrictions in their response to certain types of antigens. For example, IgG2 appears to be responsive to bacteria that are encapsulated with a polysaccharide

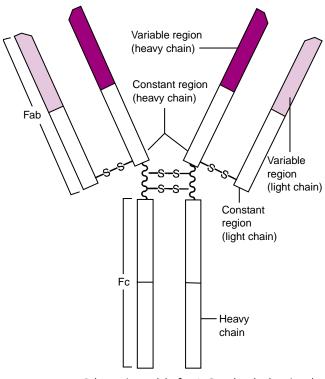

FIGURE 8-9 Schematic model of an IgG molecule showing the constant and variable regions of the light and dark chains.

TABLE 8-2	Classes and Characteristics of Immunoglobulins			
Figure	Class	Percentage of Total	Characteristics	
	lgG	75.0	Displays antiviral, antitoxin, and antibacterial properties; only lg that crosses the placenta; responsible for protection of new- born; activates complement and binds to macrophages	
	IgA	15.0	Predominant Ig in body secretions, such as saliva, nasal and respiratory secretions, and breast milk; protects mucous membranes	
	IgM	10.0	Forms the natural antibodies such as those for ABO blood antigens; prominent in early immune responses; activates complement	
\ <u></u> //	, IgD	0.2	Found on B lymphocytes; needed for maturation of B cells	
	IgE	0.004	Binds to mast cells and basophils; involved in parasitic infections, allergic and hypersensitivity reactions	

covering, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*.

IgA is the second most abundant of the immunoglobulins. It is a secretory immunoglobulin found in saliva, tears, colostrum (*i.e.*, first milk of a nursing mother), and in bronchial, gastrointestinal, prostatic, and vaginal secretions. IgA prevents the attachment of viruses and bacteria to epithelial cells and is considered a primary defense against local infections in mucosal tissues.

IgM is a macromolecule that forms a polymer of five basic immunoglobulin units. It cannot cross the placenta and does not transfer maternal immunity. It is the first circulating immunoglobulin to appear in response to an antigen and is the first antibody type made by a newborn. This is diagnostically useful because the presence of IgM suggests a current infection by a specific pathogen. The identification of newborn IgM, rather than maternally transferred IgG, to a specific pathogen is indicative of an in utero or newborn infection. *IgD* is found primarily on the cell membranes of B lymphocytes. It serves as an antigen receptor for initiating the differentiation of B cells.

IgE is involved in inflammation, allergic responses, and combating parasitic infections. It binds to mast cells and basophils. The binding of antigen to mast cell- or basophil-bound IgE triggers these cells to release histamine and other mediators important in inflammation and allergies.

T Lymphocytes

T lymphocytes function in the activation of other T cells and B cells, in the control of viral infections, in the rejection of foreign tissue grafts, and in delayed hypersensitivity reactions (see Chapter 10). Collectively, these immune responses are called *cell-mediated* or *cellular immunity*. Besides the ability to respond to cell-associated antigens, the T cell is integral to immunity because it regulates self-recognition and amplifies the response of B and T lymphocytes.

T lymphocytes arise from bone marrow stem cells, but unlike B cells, pre-T cells migrate to the thymus for their maturation. There, the immature T lymphocyte acquires a T-cell receptor (TCR). The TCR for antigen is composed of membrane proteins expressed only on the T lymphocytes and binds specifically to antigen-peptide-MHC complexes on the surface of APCs or target cells. As with the variable proteins on the immunoglobulin molecule, the TCR proteins differ among T cells with different antigen specificity.

Maturation of subpopulations of T cells (*i.e.*, CD4⁺ and CD8⁺) also occurs in the thymus. Mature T cells migrate to the peripheral lymphoid tissues and, on encountering antigen, multiply and differentiate into memory T cells and various effector T cells.

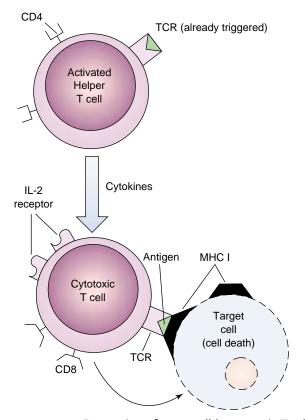

The CD4⁺ helper T cell (T_H) serves as a master switch for the immune system. Activation of helper T cells depends on the recognition of antigen in association with class II MHC molecules. Activated helper T cells secrete cytokines that influence the function of nearly all other cells of the immune system. These cytokines activate and regulate B cells, cytotoxic T cells, natural killer (NK) cells, macrophages, and other immune cells. Distinct subpopulations of helper T cells (*i.e.*, T_H1 and T_H2) have been identified and shown to secrete different patterns of cytokines. The pattern of cytokine production determines whether an antibody- or cell-mediated immune response develops. This differential expression of cytokines can influence expressions of some diseases (*i.e.*, lepromatous and tuberculoid leprosy).

The cytotoxic CD8⁺ T cells become activated after recognition of class I MHC-antigen complexes on target cell surfaces such as body cells infected by viruses or transformed by cancer (Fig. 8-10). The recognition of class I MHC-antigen complexes on infected target cells ensures that neighboring uninfected host cells, which express class I MHC molecules alone or with self-peptide, are not indiscriminately destroyed. The CD8⁺ T cells destroy target cells by releasing cytolytic enzymes, toxic cytokines, and pore-forming molecules (*i.e.*, perforins) or by triggering programmed cell death (apoptosis) in the target cell. The perforin proteins produce pores in the target cell membrane, allowing entry of toxic molecules and loss of cell constituents. The CD8⁺ T cells are especially important in controlling replicating viruses and intracellular bacteria because antibody cannot penetrate living cells.

Natural Killer Cells

Natural killer cells are lymphocytes that are functionally, genotypically, and phenotypically distinct from T cells, B cells, and monocyte-macrophages. The NK cell is a nonspecific effector cell that can kill tumor cells and virus-infected cells. They are called *natural killer cells* because, unlike T cytotoxic cells, they do not need to recognize a specific antigen before being activated. Both NK cells and T cytotoxic cells kill after contact with a target cell. The NK cell is programmed automatically to kill foreign cells, in contrast with the CD8⁺ T cells, which need to be activated to become cytotoxic. However, programmed killing is inhibited if the NK cell membrane molecules contact MHC self-molecules on normal host cells.

The mechanism of NK cytotoxicity is similar to T-cell cytotoxicity in that it depends on production of pore-forming proteins (*i.e.*, NK perforins), enzymes, and toxic cytokines. NK cell activity can be enhanced in vitro on exposure to

■ **FIGURE 8-10** Destruction of target cell by cytotoxic T cell. Cytokines released from the activated helper T cell enhance final destruction of the target cell by the cytotoxic T cell.

interleukin-2 (IL-2), a phenomenon called *lymphokine-activated killer* activity. These activated NK cells are used in the treatment of cancer. NK cells also participate in *antibody-dependent cellular cytotoxicity*, a mechanism by which a cytotoxic effector cell can kill an antibody-coated target cell. The role of NK cells probably is one of immune surveillance for cancerous or virally infected cells.

Cytokines and the Immune Response

Cytokines are low-molecular-weight regulatory proteins that are produced during all phases of an immune response. Cytokines are made primarily by and act predominantly on immune cells. These intercellular signal molecules are very potent, act at very low concentrations, and usually regulate neighboring cells. Cytokines modulate reactions of the host to foreign antigens or injurious agents by regulating the movement, proliferation, and differentiation of leukocytes and other cells (Table 8-3). Cytokines are synthesized by many cell types but are made primarily by activated T helper cells and macrophages.

These regulator molecules can be named for the general cell type that produces them (*e.g.*, lymphokines, monokines). More specifically, they are named by an international nomenclature (*i.e.*, interleukins 1 through 18) for the biologic property that was first ascribed to them. For example, *interferons* (IFNs) were named because they interfered with virus multiplication. Cytokines commonly affect more than one cell type

Characteristic Biologic Properties of Human Cytokin

TARI F 8-3

TABLE 6-5 Characteristic Biologic Properties of Human Cytokines				
Cytokine	Biologic Activity			
Interleukin-1 (alpha and beta)	Activates resting T cells; is cofactor for hematopoietic growth factor; induces fever, sleep, adreno- corticotropic hormone release, neutropenia, and other systemic acute-phase responses; stimu- lates synthesis of cytokines, collagen, and collegenases; activates endothelial and macrophagic cells; mediates inflammation, catabolic processes, and nonspecific resistance to infection			
Interleukin-2	Growth factor for activated T cells; induces synthesis of other cytokines, activates cytotoxic lymphocytes			
Interleukin-3	Support growth of pluripotent (multilineage) bone marrow stem cells; is growth factor for mast cells			
Interleukin-4	Growth factor for activated B cells, resting T cells, and mast cells; induces MHC class I antigen ex- pression on B cells; enhances cytotoxic T cells; activates macrophages			
Interleukin-5	B-cell differentiating and growth factor; promotes differentiation of eosinophils; promotes antibody production (IgA)			
Interleukin-6	Acts as cofactor for immunoglobulin production by B cells; stimulates hepatocytes to produce acute-phase proteins			
Interleukin-7	Stimulates pre-B cells and thymocytes; stimulates myeloid precursors and megakaryocytes			
Interleukin-8	Chemoattracts neutrophils and T lymphocytes; regulates lymphocyte homing and neutrophil infiltration			
Interleukin-10	Suppresses cytokine production by T helper cells; inhibits antigen presentation			
Interleukin-12	Enhances activation of cytotoxic T, NK, and macrophages; acts opposite to IL-10			
Interferon-gamma (γ)	Induces MHC class I, class II, and other surface antigens on a variety of cells; activates			
	macrophages and endothelial cells; augments or inhibits other cytokine activities; augments NK cell activity; exerts antiviral activity			
Interferon (alpha and beta) (α and β)	Exerts antiviral activity; induces class I antigen expression; augments NK cell activity; has fever- inducing and antiproliferative properties			
Tumor necrosis factor (alpha) (α)	Direct cytotoxin for some tumor cells; induces fever, sleep, and other acute-phase responses; stim- ulates the synthesis of other cytokines, collagen, and collagenases; activates endothelial and macrophagic cells; mediates inflammation, catabolic processes, and septic shock			
Colony-stimulating factor (CSF) Granulocyte-macrophage CSF	Promotes neutrophilic, eosinophilic, and macrophagic bone marrow colonies; activates mature granulocytes			
Granulocyte CSF	Promotes neutrophilic colonies			
Macrophage CSF	Promotes macrophagic colonies			

MHC, major histocompatibility complex; NK, natural killer.

and have more than one biologic effect. For example, IFN- γ inhibits virus replication and is a potent activator of macrophages and NK cells. Specific cytokines can have biologic activities that overlap. Maximization of the immune response and protection against detrimental mutations in a single cytokine are possible benefits of redundancy.

The production of cytokines often occurs in a cascade, in which one cytokine affects the production of subsequent cytokines or cytokine receptors. Some cytokines function as antagonists to inhibit the biologic effects of earlier cytokines. This pattern of expression and feedback ensures appropriate control of cytokine synthesis and subsequently of the immune response. Excessive cytokine production can have serious adverse effects, including those associated with septic shock, food poisoning, and types of cancer.

Cytokines generate their responses by binding to specific receptors on their target cells. Many cytokine receptors share a common structural shape and a cytoplasmic tail that interacts with a family of cytoplasmic signaling proteins responsible for the induction of the genes for cell responses. Most cytokines are released at cell-to-cell interfaces, where they bind to receptors on nearby cells. The short half-life of cytokines ensures that excessive immune responses and systemic activation do not occur.

The biologic properties of cytokines fall into several major groups. One group of cytokines (e.g., IL-1, IL-6, TNF) mediates

inflammation by producing fever and the acute-phase response and by attracting and activating phagocytes (*e.g.*, IL-8, IFN- γ). Other cytokines are maturation factors for the hematopoiesis of white or red blood cells (*e.g.*, IL-3, granulocyte-macrophage colony-stimulating factor [GM-CSF]). Recombinant CSF molecules are being used to increase the success rates of bone marrow transplantations. Most of the interleukin cytokines function as cell communication molecules among T cells, B cells, macrophages, and other immune cells. The availability of recombinant cytokines offers the possibility of several clinical therapies for which stimulation or inhibition of the immune response is desirable.

Interleukin 1 and 2

The major function of IL-1 is as a mediator of the inflammatory response. In concert with IL-6 and TNF- α , IL-1 can stimulate the production of an acute-phase response, mobilize neutrophils, produce a fever, and activate the vascular epithelium. IL-1 also can serve as a priming signal in the activation of CD4⁺ T cells and the growth and differentiation of B cells. The major source of IL-1 is the macrophage, although it also is produced by keratinocytes, Langerhans' cells, normal B cells, cultured T cells, fibroblasts, neutrophils, and smooth muscle cells.

The presence of IL-2, formerly known as *T-cell growth factor*, is necessary for the proliferation and function of helper T, cyto-

toxic T, B, and NK cells. IL-2 interacts with T lymphocytes by binding to specific membrane receptors that are present on activated T cells but not on resting T cells. The expression of highaffinity IL-2 receptors can be triggered by specific antigen and other stimulatory signals. Sustained T-cell proliferation relies on the presence of IL-2 and IL-2 receptors; if either is missing, cell proliferation ceases, and the cell dies. This cytokine ensures maximum amplification of immune responses if antigen is present. The drugs cyclosporine and tacrolimus, which are used to prevent rejection of heart, kidney, and liver transplants, function primarily by inhibiting the synthesis of IL-2.

Interferons

The IFNs are a family of cytokines that protect neighboring cells from invasion by intracellular parasites, including viruses, rickettsiae, malarial parasites, and other organisms. Bacterial toxins, complex polysaccharides, and several other chemical substances can induce IFN production. Not all the substances that induce IFN are antigenic.

There are three types of IFN: IFN- α , produced by leukocytes; IFN- β , produced by fibroblasts; and IFN- γ , produced by T and NK cells. IFN- α and IFN- β are grouped as type I IFNs to distinguish them from IFN- γ (type II). Type I-secreted IFNs interact with receptors on neighboring cells to stimulate the translation of an antiviral protein that affects viral synthesis and its spread to uninfected cells. The actions of IFNs are not pathogen specific; they are effective against different types of viruses and intracellular parasites. However, they are species specific. Animal IFNs do not provide protection in humans. The IFN produced during immune reactions is primarily IFN- γ . IFN- γ functions to activate macrophages, generate cytotoxic lymphocytes, and enhance NK cell activity.

Tumor Necrosis Factor

Like IL-1, TNF-α is a cytokine with multiple immunologic and inflammatory effects. It was first described as an activity in serum that induced hemorrhagic necrosis in certain tumors, and can function as a circulating mediator of wasting disease. TNF is produced by activated macrophages and other activated cells, such as T cells. Besides functioning as a major chemical mediator in the inflammatory response and indirectly affecting the fever response, TNF may function as a costimulator of T cells. This cytokine is an especially potent stimulator of IL-1, IL-6, and IL-8. In bacterial sepsis, high serum levels of TNF may mediate endotoxic shock. TNF is primarily responsible for the tissue wasting seen in cases of chronic inflammation.

Hematopoietic Colony-Stimulating Factors

Colony-stimulating factors are cytokines that stimulate bone marrow pluripotent stem and progenitor or precursor cells to produce large numbers of platelets, erythrocytes, neutrophils, monocytes, eosinophils, and basophils (see Chapter 11). The CSFs were named according to the type of target cell on which they act (see Table 8-3). GM-CSF acts on the granulocyte– monocyte progenitor cells to produce monocytes, neutrophils, and dendritic cells; G-CSF more specifically induces neutrophil proliferation; and M-CSF specifically directs the mononuclear phagocyte progenitor. Other cytokines, including IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, and IL-11, also may influence hematopoiesis.

Mechanisms of the Immune Response

The immune response is a complex series of interactions among the components of the immune system and the antigens of infectious agents and other pathogens. It consists of active or passive immunity and involves humoral and cellmediated immune mechanisms. The complement system links the humoral immune response with the inflammatory response and the lysis and phagocytosis of pathogens.

Active Versus Passive Immunity

Active or acquired immunity can be achieved through exposure to a specific antigen or through transfer of protective antibodies to an antigen. It is acquired through immunization or actually having a disease. Active immunity, although long lasting once established, requires a few days to weeks after a first exposure to become sufficiently developed to contribute to the destruction of the pathogen. However, on subsequent exposure to the same agent, the immune system usually is able to react within hours because of the presence of memory B and T lymphocytes.

Passive immunity is immunity transferred from one source to another source. An infant receives passive immunity naturally from the transfer of antibodies from its mother in utero and through a mother's breast milk. Normally, an infant has few infectious diseases during the first 3 to 6 months because of the protection provided by the mother's antibodies. Passive immunity also can be artificially provided by the transfer of antibodies produced by other people or animals. Some protection against infectious disease can be provided by the injection of hyperimmune serum, which contains high concentrations of antibodies for a specific disease, or immune serum or gamma globulin, which contains a pool of antibodies for many infectious agents. Passive immunity produces only short-term protection that lasts weeks to months.

KEY CONCEPTS

THE IMMUNE RESPONSE

- The immune response involves a complex series of interactions between components of the immune system and the antigens of a foreign pathogen.
- Passive immunity represents a temporary type of immunity that is transferred from another source (in utero transfer of antibodies from mother to infant).
- Active immunity depends on a response by the person's immune system and is acquired through immunization or actually having a disease.
- Humoral immunity consists of protection provided by the B lymphocyte-derived plasma cells, which produce antibodies that travel in the blood and interact with circulating and cell surface antigens.
- Cell-mediated immunity consists of protection provided by cytotoxic T lymphocytes, which protect against virus-infected or cancer cells.

Humoral Immunity

Humoral, or antibody-mediated immunity, relies on the presence of antibodies in the blood or body fluids. The combination of antigen with antibody can result in several effector responses, such as precipitation of antigen–antibody complexes, agglutination or clumping of cells, neutralization of bacterial toxins and viruses, lysis and destruction of pathogens or cells, adherence of antigen to immune cells, complement activation, and facilitation of phagocytosis. Phagocytic cells can more effectively bind, engulf, and digest antigen–antibody aggregates or immune complexes than they can antigen alone. Antibody can also neutralize a virus by blocking the sites on the virus that it uses to bind to the host cell, thereby negating its ability to infect the cell.

Two types of responses occur in the development of humoral immunity: a primary and a secondary response (Fig. 8-11). A primary immune response occurs when the antigen is first introduced into the body. During this primary response, there is a latent period or lag before the antibody can be detected in the serum. During this latent period, B cells are activated to proliferate and differentiate into antibody-secreting plasma cells. Recovery from many infectious diseases occurs at the time during the primary response when the antibody concentration is reaching its peak. The secondary or memory response occurs on second or subsequent exposures to the antigen. During the secondary response, the rise in antibody occurs sooner and reaches a higher level because of the available memory cells. The booster immunization given for some infectious diseases, such as tetanus, makes use of the secondary or memory response. For a person who has been previously immunized, administration of a booster shot causes an almost immediate rise in antibody to a level sufficient to prevent development of the disease.

Cell-mediated Immunity

Cell-mediated immunity provides protection against viruses, intracellular bacteria, and cancer cells. In cell-mediated immunity, the actions of T lymphocytes and macrophages predominate. The most aggressive phagocyte, the macrophage, becomes activated after exposure to T-cell cytokines, espe-

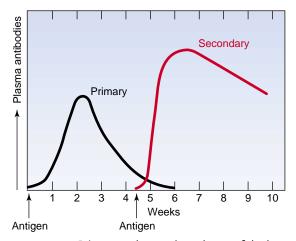

FIGURE 8-11 Primary and secondary phases of the humoral immune response to the same antigen.

cially IFN- γ . As in humoral immunity, the initial stages of cellmediated immunity are directed by an APC displaying the antigen peptide–class II MHC complex to the helper T cell. Helper T cells become activated after recognition by the TCR of the antigen–MHC complex and by priming with IL-1. The activated helper T cell then synthesizes IL-2 and the IL-2 receptor. These molecules drive the multiplication of clones of helper T cells, which amplify the response. Further differentiation of the helper T cells leads to production of additional cytokines (*e.g.*, IFN- γ , TNF, IL-12), which enhance the activity of cytotoxic T cells and effector macrophages. A cell-mediated immune response usually occurs through the cytotoxic activity of cytotoxic T cells and the enhanced engulfment and killing by macrophages.

The Complement System

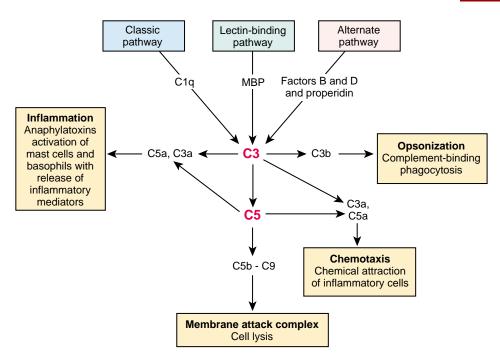

The complement system is a primary mediator of the humoral immune response that enables the body to produce an inflammatory response, lyse foreign cells, and increase phagocytosis. The complement system, like the blood coagulation system, consists of a group of proteins that normally are present in the circulation as functionally inactive precursors. These proteins make up 10% to 15% of the plasma protein fraction. For a complement reaction to occur, the complement components must be activated in the proper sequence. Uncontrolled activation of the complement system is prevented by inhibitor proteins and the instability of the activated complement proteins at each step of the process. There are three parallel but independent mechanisms for recognizing microorganisms that result in the activation of the complement system: the classic, the alternate, and the lectin-mediated pathways. All three pathways of activation generate a series of enzymatic reactions that proteolytically cleave successive complement proteins in the pathway. The consequence is the deposition of some complement protein fragments on the pathogen surface, thereby producing tags for better recognition by the phagocytic cells. Other complement fragments that are released into the tissue fluids further stimulate the inflammatory response.

The classic pathway of complement activation is initiated by antibody bound to antigens on the surface of microbes or through soluble immune complexes (Fig. 8-12). The alternate and the lectin pathways do not use antibodies and are part of the innate immune defenses. The alternate pathway of complement activation is initiated by the interaction with certain polysaccharide molecules characteristic of bacterial surfaces. The lectin-mediated pathway is initiated following the binding of a mannose-binding protein to mannose-containing molecules commonly present on the surface of bacteria and yeast.

The activation of the three pathways produces similar effects on C3 and subsequent complement proteins. The classic pathway of complement activation was the first discovered and is the best studied. The major proteins of the classic system are designated by a numbering system from C1 to C9. The classic pathway is triggered when complement-fixing antibodies, such as IgG or IgM, bind to antigens. The immune complexes trigger a series of enzyme reactions that act in a cascade fashion. Modified or split complement proteins (*e.g.*, C3b, C3a, C5a) released during activation function in the next step of the pathway or are released into the tissue fluid to produce biologic effects important in inflammation. C3 has a central role in the

Chapter 8: The Immune Response

147

■ FIGURE 8-12 ■ Classic, lectin, and alternative complement pathways.

complement pathway because it is integral to all three pathways. The triggering of C3 initiates several mechanisms for microbial destruction. One result of activation of C3 is the formation of the membrane attack complex formed by C5 to C9. Several structurally modulated complement proteins bind to form pores in the membrane of foreign cells that lead to eventual cell lysis.

The alternate and lectin pathways are activated by microbial surface molecules and substitute other molecules for the proteins in the first two steps of the classic complement pathway. The *alternate pathway* uses protein factors B, D, and properdin for activation, whereas the *lectin pathway* uses mannosebinding protein (MBP) and accessory proteins. Both pathways require the presence of C3b and subsequent complement proteins to generate biologic effects similar to those of the classic complement pathway. Whatever the mechanism of activation of the complement system, the effects produced range from lysis of a variety of different cells to direct mediation of the inflammatory process.

The activation of complement can result in formation of products that produce opsonization, chemotaxis, anaphylaxis, and cell membrane attack (Fig. 8-12). A major biologic function of complement activation is opsonization—the coating of antigen–antibody complexes such that antigens are engulfed and cleared more efficiently by macrophages. Chemotactic complement products (C3a and C5a) can trigger an influx of leukocytes. These white blood cells remain fixed in the area of complement activation through attachment to specific sites on C3b and C4b molecules. Anaphylatoxins (C3a and C5a) lead to activation of basophils and mast cells and release of inflammatory mediators that produce smooth muscle contract and increased vascular permeability. The late phase of the complement cascade involves the mediation of the membrane attack complex (MAC) that leads to the lytic destruction of many kinds of cells, including red blood cells, platelets, bacteria, and lymphocytes.

Regulation of the Immune Response

Self-regulation is an essential property of the immune system. An inadequate immune response may lead to immunodeficiency, but an inappropriate or excessive response may lead to conditions varying from allergic reactions to autoimmune diseases. This regulation is not well understood and involves all aspects of the immune response—antigen, antibody, cytokines, regulatory T cells, and the neuroendocrine system.

With each exposure to antigen, the immune system must determine the branch of the immune system to be activated and the extent and duration of the immune response. After exposure to an antigen, the immune response to that antigen develops after a brief lag, reaches a peak, and then recedes. Normal immune responses are self-limited because the response eliminates the antigen, and the products of the response, such as cytokines and antibodies, have a short or limited life span and are secreted only for brief periods after antigen recognition. Evidence suggests that cytokine feedback from the helper T cell controls several aspects of the immune response.

Another facet of immune self-regulation is inhibition of immune responses by tolerance. The term *tolerance* is used to define the ability of the immune system to be nonreactive to self-antigens while producing immunity to foreign agents. Tolerance to self-antigens protects an individual from harmful autoimmune reactions. Exposure of an individual to foreign antigens may lead to tolerance and the inability to respond to potential pathogens that cause infection. Tolerance exists not only to self-tissues, but to maternal-fetal tissues. Special regulation of the immune system also is evident in defined privileged sites, such as the brain, testes, ovaries, and eyes. Immune damage in these areas could result in serious consequences to the individual and the species.

In summary, immunity is the resistance to a disease that is provided by the immune system. It can be acquired actively through immunization or by having a disease, or passively by receiving antibodies or immune cells from another source. Antigens have antigenic determinant sites or epitopes, which the immune system recognizes with specific receptors that distinguish the antigens as nonself and as unique foreign molecules. Immune mechanisms can be classified into two types: specific or acquired and nonspecific or innate immunity. Specific or acquired immunity involves humoral and cellular mechanisms whereby the immune cells differentiate self from nonself and recognize and respond to a unique antigen. The humoral immune response involves antibodies produced by activated B lymphocytes. Cell-mediated immunity depends on T-cell responses to cellular antigens. Nonspecific immune mechanisms can distinguish between self and nonself but cannot differentiate among antigens. They include the complement system, cytokines, and the phagocytic activities of neutrophils and macrophages. The cytokines, produced largely by T cells, function as intercellular signals that regulate immune and inflammatory responses.

DEVELOPMENTAL ASPECTS OF THE IMMUNE SYSTEM

Embryologically, the immune system develops in several stages, beginning at 5 to 6 weeks as the fetal liver becomes active in hematopoiesis. Development of the primary lymphoid organs (*i.e.*, thymus and bone marrow) begins during the middle of the first trimester and proceeds rapidly. Secondary lymphoid organs (*i.e.*, spleen, lymph nodes, and tonsils) develop soon after. These secondary lymphoid organs are rather small but well developed at birth and mature rapidly during the postnatal period. The thymus at birth is the largest lymphoid tissue relative to body size and normally is approximately two thirds its mature weight, which it achieves during the first year of life.

Transfer of Immunity From Mother to Infant

Protection of a newborn against antigens occurs through transfer of maternal antibodies. Maternal IgG antibodies cross the placenta during fetal development and remain functional in the newborn for the first months of life (Fig. 8-13). IgG is the only class of immunoglobulins to cross the placenta. Levels of maternal IgG decrease significantly during the first 3 to 6 months of life while infant synthesis of immunoglobulins increases. Maternally transmitted IgG is effective against most microorganisms and viruses. The largest amount of IgG crosses the placenta during the last weeks of pregnancy and is stored in fetal tissues, and infants born prematurely have deficient amounts. Because of the transfer of IgG antibodies to the fetus, an infant born to a mother infected with HIV has a positive HIV antibody test result, although he or she may not be infected with the virus. Cord blood does not normally contain IgM or IgA. If present, these antibodies are of fetal origin and represent exposure to intrauterine infection. The infant begins producing IgM antibodies within a few months after birth in response to the immense antigenic stimulation of his or her new environment. Premature infants appear to be able to produce IgM as well as do term infants. At approximately 6 days of age, the neonate's IgM rises sharply, and this rise continues until approximately 1 year of age, when the adult level is achieved.

Serum IgA normally is first detected at approximately 13 days after birth. The level increases during early childhood until adult levels are reached between the sixth and seventh year. Maternal IgA also is transferred to the infant in colostrum or milk by breast-feeding. These antibodies provide local immunity for the intestinal system and have been shown to decrease diarrheal infections in underdeveloped countries. These evolutionary adaptations of the immune system have increased the survival of our species and optimized the development of other important organs in the early months of life.

Immune Response in the Elderly

Aging is characterized by a declining ability to adapt to environmental stresses. One of the factors thought to contribute to this problem is a decline in immune responsiveness. This includes changes in cell-mediated and antibody-mediated immune responses. Elderly persons tend to be more susceptible to infections, have more evidence of autoimmune and immune complex disorders than do younger persons, and have a higher incidence of cancer. Experimental evidence suggests that vaccination is less successful in inducing immunization in older persons than in younger adults. However, the effect of altered immune function on the health of elderly persons is clouded by the fact that age-related changes or disease may affect the immune response.

The alterations in immune function that occur with advanced age are not fully understood. There is a decrease in the size of the thymus gland, which is thought to affect T-cell function. The size of the gland begins to decline shortly after sexual maturity, and by 50 years of age, it usually has diminished to 15% or less of its maximum size. A common finding is a slight decrease in the proportion of T cells to other lymphocytes and a decrease in CD4⁺ and CD8⁺ cells.

More evident are altered responses of the immune cells to antigen stimulation, increasing the proportion of lymphocytes that become unresponsive, while the remainder continue to function relatively normally. T and B cells show deficiencies in activation. In the T-cell types, the CD4⁺ subset is most severely affected. Evidence indicates that aged T cells have a decreased rate of synthesis of the cytokines that drive the proliferation of lymphocytes and a diminished expression of the receptors that interact with those cytokines. For example, it has been shown that IL-2 synthesis decreases markedly with aging. Although Bcell function is compromised with age, the range of antigens that can be recognized is not diminished. If anything, the repertoire is increased to the extent that B cells begin to recognize some self-antigens as foreign antigens. This may be the basis for the increased incidence of autoimmune disease in the elderly.

In summary, a newborn is protected against antigens in early life by passive transfer of maternal antibodies through the placenta (IgG) and in colostrum (IgA) through breastfeeding. Some changes are seen with aging, including an increase in autoimmune diseases. The impact of alterations in immune function that occur with aging is not fully understood.

REVIEW QUESTIONS

Compare the properties of innate or nonspecific and specific or acquired immunity.

Differentiate between the central and peripheral lymphoid structures in terms of generation of immune cells and interaction with antigens.

Characterize the significance and function of major histocompatibility complex molecules in terms of recognizing self from nonself and distinguishing between body cells and immune cells.

Describe the phagocytic and antigen presenting functions of the macrophage as they relate to the immune response.

Explain why destruction of the CD4⁺ helper T cells by the human immunodeficiency virus has such a devastating effect on the immune system.

Explain the body's rationale for using natural killer (NK) cells, rather than B lymphocytes, to destroy mutant cells with the potential for development into cancer cells.

State the function of the five classes of immunoglobulins.

Describe the properties of cytokines and their functions in terms of the immune response and production of symptoms such as fever and malaise that accompany an acute infectious process.

Characterize the role of the complement system in mediation of the immune response.

Explain the transfer of passive immunity from mother to fetus and explain why infants who have high circulating levels of IgM at birth are thought to have contracted the infection in utero.

CHAPTER

The ability of the body to sustain injury, resist attack by microbial agents, and repair damaged tissue is dependent upon the inflammatory reaction, the immune system response, and tissue repair and wound healing. Although the effects of inflammation are often viewed as undesirable because they are unpleasant and cause discomfort, the process is essentially a beneficial one that allows a person to live with the effects of everyday stress. Without the inflammatory response, wounds would not heal, and minor infections would become overwhelming. Inflammation also produces undesirable effects. For example, the crippling effects of rheumatoid arthritis result from chronic inflammation.

This chapter focuses on the manifestations of acute and chronic inflammation, tissue repair and wound healing, and temperature regulation and fever. The immune response is discussed in Chapter 8.

THE INFLAMMATORY RESPONSE

Inflammation is the reaction of vascularized tissue to local injury. The causes of inflammation are many and varied. Inflammation commonly results because of an immune response to infectious microorganisms. Other causes of inflammation are trauma, surgery, caustic chemicals, extremes of heat and cold, and ischemic damage to body tissues.

Inflammatory conditions are named by adding the suffix *-itis* to the affected organ or system. For example, *appendicitis* refers to inflammation of the appendix, *pericarditis* to inflammation of the pericardium, and *neuritis* to inflammation of a nerve. More descriptive expressions of the inflammatory process might indicate whether the process was acute or chronic and what type of exudate was formed (*e.g.*, acute fibrinous pericarditis).

Acute Inflammation

Acute inflammation is the early (almost immediate) response to injury. It is nonspecific and may be evoked by any injury short of one that is immediately fatal. It is usually of short duration and typically occurs before the immune response becomes established and is aimed primarily at removing the injurious agent and limiting the extent of tissue damage.

Cardinal Signs

The classic description of acute inflammation has been handed down through the ages. In the first century AD, the Roman physician Celsus described the local reaction of injury in terms that have come to be known as the *cardinal signs* of inflammation. These signs are *rubor* (redness), *tumor* (swelling), *calor* (heat), and *dolor* (pain). In the second century AD, the Greek physician Galen added a fifth cardinal sign, *functio laesa*, or loss of function. These signs and symptoms, which are apparent when inflammation occurs on the surface of body, may not be present when internal organs are involved. For example, inflammation of the lung does not usually cause pain unless the pleura, where pain receptors are located, is affected. In addition, an increase in heat is uncommon in inflammation involving internal organs, where tissues are normally maintained at core temperature.

In addition to the cardinal signs that appear at the site of injury, systemic manifestations (*e.g.*, fever) may occur as chemical mediators produced at the site of inflammation gain entrance to the circulatory system. The constellation of systemic manifestations that may occur during an acute inflammatory response is known as the *acute-phase response* (to be discussed).

The manifestation of acute inflammation can be divided into two categories: vascular and cellular responses.^{1,2,3} At the biochemical level, many of the responses that occur during acute inflammation are associated with the release of chemical mediators.

The Vascular Response

The vascular, or hemodynamic, changes that occur with inflammation begin almost immediately after injury and are initiated by a momentary constriction of small blood vessels in the area. This vasoconstriction is followed rapidly by vasodilation of the arterioles and venules that supply the area (Fig. 9-1). As a result, the area becomes congested, causing the

KEY CONCEPTS

THE INFLAMMATORY RESPONSE

- Inflammation represents the response of body tissue to immune reactions, injury, or ischemic damage.
- The classic response to inflammation includes redness, swelling, heat, pain or discomfort, and loss of function.
- The manifestations of an acute inflammatory response can be attributed to the immediate vascular changes that occur (vasodilation and increased capillary permeability), the influx of inflammatory cells such as neutrophils, and, in some cases, the widespread effects of inflammatory mediators, which produce fever and other systemic signs and symptoms.
- The manifestations of chronic inflammation are due to infiltration with macrophages, lymphocytes, and fibroblasts, leading to persistent inflammation, fibroblast proliferation, and scar formation.

redness (erythema) and warmth associated with acute inflammation. Accompanying this hyperemic vascular response is an increase in capillary permeability, which causes fluid to move into the tissues and cause swelling, pain, and impaired function. The exudation or movement of the fluid out of the capillaries and into the tissue spaces dilutes the offending agent. As fluid moves out of the capillaries, stagnation of flow and clotting of blood in the small capillaries occurs at the site of injury. This aids in localizing the spread of infectious microorganisms.

Depending on the severity of injury, the vascular changes that occur with inflammation follow one of three patterns of response.³ The first is an immediate transient response, which occurs with minor injury. The second is an immediate sustained response, which occurs with more serious injury and continues for several days and damages the vessels in the area. The third type of response is a delayed hemodynamic response, which involves an increase in capillary permeability that occurs 4 to 24 hours after injury. A delayed response often accompanies radiation types of injuries, such as sunburn.

The Cellular Stage

The cellular stage of acute inflammation is marked by movement of phagocytic white blood cells (leukocytes) into the area of injury. Two types of leukocytes participate in the acute inflammatory response—the granulocytes and monocytes.

Granulocytes. Granulocytes are identifiable because of their characteristic cytoplasmic granules. These white blood cells have distinctive multilobed nuclei. The granulocytes are divided into three types (*i.e.*, neutrophils, eosinophils, and basophils) according to the staining properties of the granules (Fig. 9-2).

The neutrophil is the primary phagocyte that arrives early at the site of inflammation, usually within 90 minutes of injury. The neutrophils' cytoplasmic granules contain enzymes and other antibacterial substances that are used in destroying and degrading the engulfed particles. They also have oxygendependent metabolic pathways that generate toxic oxygen (e.g., hydrogen peroxide) and nitrogen (e.g., nitric oxide) products. Because these white blood cells have nuclei that are divided into three to five lobes, they often are called *polymor*phonuclear neutrophils (PMNs) or segmented neutrophils (segs). The neutrophil count in the blood often increases greatly during the inflammatory process, especially with bacterial infections. After being released from the bone marrow, circulating neutrophils have a life span of only approximately 10 hours and therefore must be constantly replaced if their numbers are to remain adequate. This requires an increase in circulating white blood cells, a condition called leukocytosis. With excessive demand for phagocytes, immature forms of neutrophils are released from the bone marrow. These immature cells often are called *bands* because of the horseshoe shape of their nuclei.

The cytoplasmic granules of the *eosinophils* stain red with the acid dye eosin. These granulocytes increase in the blood during allergic reactions and parasitic infections. The granules of eosinophils contain a protein that is highly toxic to large parasitic worms that cannot be phagocytized. They also regulate inflammation and allergic reactions by controlling the release of specific chemical mediators during these processes.

The granules of the *basophils* stain blue with a basic dye. The granules of these granulocytes contain histamine and other

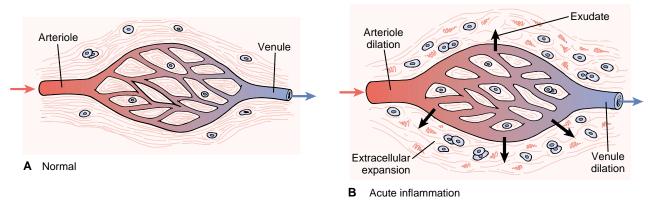

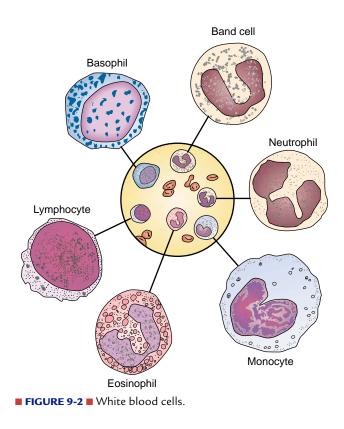

FIGURE 9-1 Vascular phase of acute inflammation. (A) Normal capillary bed. (B) Acute inflammation with vascular dilation causing increased redness (erythema) and heat (calor), movement of fluid into the interstitial spaces (swelling), extravasation of plasma proteins into the extracellular spaces (exudate), and emigration of leukocytes.

bioactive mediators of inflammation. The basophils are involved in producing the symptoms associated with inflammation and allergic reactions. The mast cell, which is widely distributed in connective tissues throughout the body, is very similar in many of its properties to the basophil. It can participate in acute and chronic inflammatory responses.² Sensitized mast cells, which are "armed" with IgE, play a central role in allergic and hypersensitivity responses (see Chapter 10). They also may play a role in parasitic infections. Mast cells can also elaborate tumor necrosis factor (TNF), thereby participating in chronic inflammatory responses.

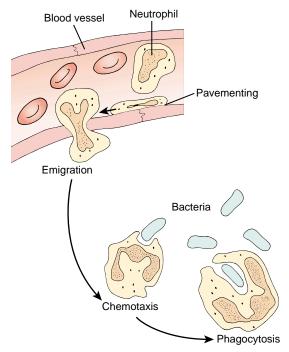

Mononuclear Phagocytes. The monocytes are the largest of the white blood cells and constitute 3% to 8% of the total blood leukocytes. The circulating life span of the monocyte is three to four times longer than that of the granulocytes, and these cells survive for a longer time in the tissues. These longer-lived phagocytes help to destroy the causative agent, aid in the signaling processes of specific immunity, and serve to resolve the inflammatory process.

The monocytes, which migrate in increased numbers into the tissues in response to inflammatory stimuli, mature into macrophages. Within 24 hours, mononuclear cells arrive at the inflammatory site, and by 48 hours, monocytes and macrophages are the predominant cell types. The macrophages engulf larger and greater quantities of foreign material than do the neutrophils. They also migrate to the local lymph nodes to prime specific immunity. These leukocytes play an important role in chronic inflammation, where they can surround and wall off foreign material that cannot be digested.

Cellular Response. The sequence of events in the cellular response to inflammation includes: (1) pavementing, (2) emigration, (3) chemotaxis, and (4) phagocytosis (Fig. 9-3). During the early stages of the inflammatory response, fluid leaves the capillaries, causing blood viscosity to increase. The release of chemical mediators (*i.e.*, histamine, leukotrienes, and kinins) and cytokines affects the endothelial cells of the capillaries and causes the leukocytes to increase their expression of adhesion molecules. As this occurs, the leukocytes slow their migration and begin to marginate, or move to and along the periphery of the blood vessels.

Emigration is a mechanism by which the leukocytes extend pseudopodia, pass through the capillary walls by ameboid movement, and migrate into the tissue spaces. The emigration of leukocytes also may be accompanied by an escape of red blood cells. Once they have exited the capillary, the leukocytes wander through the tissue guided by secreted cytokines (chemokines; interleukin [IL]-8), bacterial and cellular debris, and complement fragments (C3a, C5a). The process by which leukocytes migrate in response to a chemical signal is called *chemotaxis*. The positive movement up the

■ FIGURE 9-3 ■ Cellular phase of acute inflammation. Neutrophil margination, pavementing, chemotaxis, and phagocytosis.

concentration gradient of chemical mediators to the site of injury increases the probability of a sufficiently localized cellular response.

During the next and final stage of the cellular response, the neutrophils and macrophages engulf and degrade the bacteria and cellular debris in a process called *phagocytosis*. Phagocytosis involves three distinct steps: (1) adherence plus opsonization, (2) engulfment, and (3) intracellular killing (see Fig. 9-4). Contact of the bacteria or antigen with the phagocyte cell membrane is essential for trapping the agent and triggering the final steps of phagocytosis. If the antigen is coated with antibody or

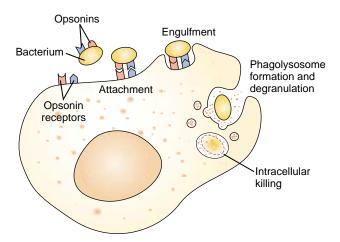

FIGURE 9-4 Phagocytosis of a particle (*e.g.*, bacterium): opsonization, attachment, engulfment, and intracellular killing.

Chapter 9: Inflammation, Tissue Repair, and Fever

complement, its adherence is increased because of binding to complement. This process of enhanced binding of an antigen caused by antibody or complement is called *opsonization* (Chapter 8). Engulfment follows the recognition of the agent as foreign. Cytoplasmic extensions (pseudopods) surround and enclose the particle in a membrane-bounded phagocytic vesicle or phagosome. In the cell cytoplasm, the phagosome merges with a lysosome containing antibacterial molecules and enzymes that can digest the microbe.

Intracellular killing of pathogens is accomplished through several mechanisms, including enzymes, defensins, and toxic oxygen and nitrogen products produced by oxygen-dependent metabolic pathways. The metabolic burst pathways that generate toxic oxygen and nitrogen products (*i.e.*, nitric oxide, peroxyonitrites, hydrogen peroxide, and hypochlorous acid) require oxygen and metabolic enzymes such as myeloperoxidase, NADPH oxidase, and nitric oxide synthetase. Individuals born with genetic defects in some of these enzymes have immunodeficiency conditions that make them susceptible to repeated bacterial infection.

Inflammatory Mediators

Although inflammation is precipitated by injury, its signs and symptoms are produced by chemical mediators. Mediators can be classified by function: those with vasoactive and smooth muscle-constricting properties such as histamine, prostaglandins, leukotrienes, and platelet-activating factor; chemotactic factors such as complement fragments and cytokines; plasma proteases that can activate complement and components of the clotting system; and reactive molecules and cytokines liberated from leukocytes, which when released into the extracellular environment can damage the surrounding tissue. Table 9-1 describes some chemical mediators and their major impact on inflammation.

Histamine. Histamine is widely distributed throughout the body. It is found in high concentration in platelets, basophils, and mast cells. Histamine causes dilation and increased permeability of capillaries. It is one of the first mediators of an inflammatory response. Antihistamine drugs inhibit this immediate, transient response.

Plasma Proteases. The plasma proteases consist of the kinins, activated complement proteins, and clotting factors. One kinin, bradykinin, causes increased capillary permeability and pain. The clotting system (see Chapter 12) contributes to the vascular phase of inflammation, mainly through fibrinopeptides that are formed during the final steps of the clotting process.

Prostaglandins. The prostaglandins are ubiquitous, lipidsoluble molecules derived from arachidonic acid, a fatty acid liberated from cell membrane phospholipids. Several prostaglandins are synthesized from arachidonic acid through the cyclooxygenase metabolic pathway (Fig. 9-5). Prostaglandins contribute to vasodilation, capillary permeability, and the pain and fever that accompany inflammation. The stable prostaglandins (PGE₁ and PGE₂) induce inflammation and potentiate the effects of histamine and other inflammatory mediators. The prostaglandin thromboxane A₂ promotes platelet aggregation and vasoconstriction. Aspirin and the nonsteroidal

anti-inflammatory drugs (NSAIDs) reduce inflammation by inactivating the first enzyme in the cyclooxygenase pathway for prostaglandin synthesis.

Leukotrienes. Like the prostaglandins, the leukotrienes are formed from arachidonic acid, but through the lipoxygenase pathway (see Fig. 9-5). Histamine and leukotrienes are complementary in action in that they have similar functions. Histamine is produced rapidly and transiently while the more potent leukotrienes are being synthesized. Leukotrienes C4 and D4 are recognized as the primary components of the *slowreacting substance of anaphylaxis* (SRS-A) that causes slow and sustained constriction of the bronchioles and is an important inflammatory mediator in bronchial asthma and anaphylaxis. The leukotrienes also have been reported to affect the permeability of the postcapillary venules, the adhesion properties of endothelial cells, and the chemotaxis and extravascularization of neutrophils, eosinophils, and monocytes.

Platelet-Activating Factor. Platelet-activating factor (PAF), which is generated from a complex lipid stored in cell membranes, affects a variety of cell types and induces platelet aggregation. It activates neutrophils and is a potent eosinophil chemoattractant. When injected into the skin, PAF causes a

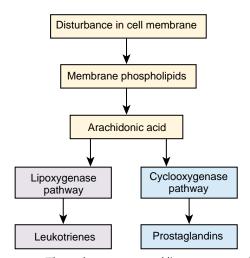

FIGURE 9-5 The cyclooxygenase and lipoxygenase pathways.

wheal-and-flare reaction and the leukocyte infiltrate characteristic of immediate hypersensitivity reactions. When inhaled, PAF causes bronchospasm, eosinophil infiltration, and nonspecific bronchial hyperreactivity.

Chronic Inflammation

Acute infections usually are self-limiting and rapidly controlled by the host defenses. In contrast, chronic inflammation is selfperpetuating and may last for weeks, months, or even years. It may develop during a recurrent or progressive acute inflammatory process or from low-grade, smoldering responses that fail to evoke an acute response.

Characteristic of chronic inflammation is an infiltration by mononuclear cells (macrophages) and lymphocytes, instead of the influx of neutrophils commonly seen in acute inflammation. Chronic inflammation also involves the proliferation of fibroblasts instead of exudates. As a result, the risk of scarring and deformity usually is considered greater than in acute inflammation. Agents that evoke chronic inflammation typically are low-grade, persistent irritants that are unable to penetrate deeply or spread rapidly. Among the causes of chronic inflammation are foreign bodies such as talc, silica, asbestos, and surgical suture materials. Many viruses provoke chronic inflammatory responses, as do certain bacteria, fungi, and larger parasites of moderate to low virulence. Examples are the tubercle bacillus, the treponema of syphilis, and the actinomyces. The presence of injured tissue such as that surrounding a healing fracture also may incite chronic inflammation. Immunologic mechanisms are thought to play an important role in chronic inflammation. The two patterns of chronic inflammation are a nonspecific chronic inflammation and granulomatous inflammation.

Nonspecific Chronic Inflammation

Nonspecific chronic inflammation involves a diffuse accumulation of macrophages and lymphocytes at the site of injury. Ongoing chemotaxis causes macrophages to infiltrate the inflamed site, where they accumulate because of prolonged survival and immobilization. These mechanisms lead to fibroblast proliferation, with subsequent scar formation that in many cases replaces the normal connective tissue or the functional parenchymal tissues of the involved structures. For example, scar tissue resulting from chronic inflammation of the bowel causes narrowing of the bowel lumen.

Granulomatous Lesions

A granulomatous lesion results from chronic inflammation. A granuloma typically is a small, 1- to 2-mm lesion in which there is a massing of macrophages surrounded by lymphocytes. These modified macrophages resemble epithelial cells and sometimes are called epithelioid cells. Like other macrophages, these epithelioid cells are derived originally from blood monocytes. Granulomatous inflammation is associated with foreign bodies such as splinters, sutures, silica, and asbestos and with microorganisms that cause tuberculosis, syphilis, sarcoidosis, deep fungal infections, and brucellosis. These types of agents have one thing in common: they are poorly digested and usually are not easily controlled by other inflammatory mechanisms. The epithelioid cells in granulomatous inflammation may clump in a mass (granuloma) or coalesce, forming a large, multinucleated giant cell that attempts to surround the foreign agent (Fig. 9-6). A dense membrane of connective tissue eventually encapsulates the lesion and isolates it.

A *tubercle* is a granulomatous inflammatory response to *Mycobacterium tuberculosis* infection. Peculiar to the tuberculosis granuloma is the presence of a caseous (cheesy) necrotic center.

Local Manifestations of Inflammation

The local manifestations of acute and chronic inflammation are dependent upon its cause and the particular tissue involved. These manifestations can range from swelling and the formation of exudates to abscess formation or ulceration.

Characteristically, the acute inflammatory response involves production of exudates. These exudates vary in terms of fluid, plasma proteins, and cell count. Acute inflammation can produce serous, hemorrhagic, fibrinous, membranous, or purulent exudates. Inflammatory exudates often are composed of a combination of these types. *Serous exudates* are watery fluids low in protein content that result from plasma entering the inflammatory site. *Hemorrhagic exudates* occur when there is severe tissue injury that causes damage to blood vessels or when there is significant leakage of red cells from the capillaries. *Fibrinous exudates* contain large amounts of fibrinogen and form a thick and sticky meshwork, much like the fibers of a

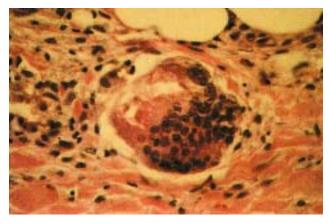

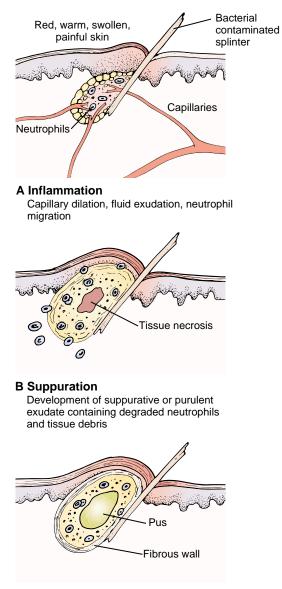

FIGURE 9-6 Foreign body giant cell. The numerous nuclei are randomly arranged in the cytoplasm. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p 40]. Philadelphia: Lippincott-Raven)

blood clot. *Membranous* or *pseudomembranous exudates* develop on mucous membrane surfaces and are composed of necrotic cells enmeshed in a fibropurulent exudate.

A purulent or suppurative exudate contains pus, which is composed of degraded white blood cells, proteins, and tissue debris (Fig. 9-7). An abscess is a localized area of inflammation containing a purulent exudate. Certain microorganisms (*e.g.*, staphylococcus) are more likely to induce localized suppurative inflammation and are referred to as *pyogenic*. Abscesses typically have a central necrotic core containing purulent

C Abscess formation Walling off of the area of purulent (pus) exudate to form an abscess

FIGURE 9-7 Abscess formation. (**A**) Bacterial invasion and development of inflammation. (**C**) Walling off of the inflamed area with its purulent exudate to form an abscess.

exudates surrounded by a layer of neutrophils.² Fibroblasts may eventually enter the area and wall of the abscess. Because antimicrobial agents cannot penetrate the abscess wall, surgical incision and drainage may be required to effect a cure.

An *ulceration* refers to a site of inflammation where an epithelial surface (*e.g.*, skin or gastrointestinal epithelium) has become necrotic and eroded, often with associated subepithelial inflammation. Ulceration may occur as the result of traumatic injury to the epithelial surface (*e.g.*, peptic ulcer) or because of vascular compromise (foot ulcers associated with diabetes). In chronic lesions where there is repeated insult, the area surrounding the ulcer develops fibroblastic proliferation, scarring, and accumulation of chronic inflammatory cells.²

Systemic Manifestations of Inflammation

Under optimal conditions, the inflammatory response remains confined to a localized area. However, in some cases local injury can result in prominent systemic manifestations as inflammatory mediators are released into the circulation. The most prominent systemic manifestations of inflammation are the acute phase response, alterations in white blood cell count (leukocytosis or leukopenia), and fever. Sepsis and septic shock, also called the *systemic inflammatory response*, represent the severe systemic manifestations of inflammation (see Chapter 18).

Acute-Phase Response

Along with the cellular responses that occur during the inflammatory response, a constellation of systemic effects called the acute-phase response occurs. The acute-phase response, which usually begins within hours or days of the onset of inflammation or infection, includes changes in the concentrations of plasma proteins, increased erythrocyte sedimentation rate (ESR), fever, increased numbers of leukocytes, skeletal muscle catabolism, and negative nitrogen balance. These responses are generated after the release of the cytokines, IL-1, IL-6, and TNF- α . These cytokines affect the thermoregulatory center in the hypothalamus to produce fever, the most obvious sign of the acute-phase response. IL-1 and other cytokines induce an increase in the number and immaturity of circulating neutrophils by stimulating their production in the bone marrow. Lethargy, a common feature of the acute-phase response, results from the effects of IL-1 and TNF- α on the central nervous system.

During the acute-phase response, the liver dramatically increases the synthesis of acute-phase proteins such as fibrinogen and C-reactive protein that serve several different nonspecific host defense functions. The change in the types of plasma proteins contributes to the increased ESR. The metabolic changes, including skeletal muscle catabolism, provide amino acids that can be used in the immune response and for tissue repair. The total systemic process coordinates various activities in the body to enable an optimum host response.

White Blood Cell Response (Leukocytosis and Leukopenia)

Leukocytosis is common feature of the inflammatory response, especially those caused by bacterial infection. The white blood cell count usually increases to 15,000 to 20,000 cells/ μ L (normal 4000 to 10,000 cells/ μ L). After being released from the

bone marrow, circulating neutrophils have a life span of only about 10 hours and therefore must be constantly replaced if their numbers are to be adequate. With excessive demand for phagocytes, immature forms of neutrophils (bands) are released from the bone marrow. The phase, which is referred to as a "shift to the left" in a white blood cell differential count, refers to the increase in immature neutrophils seen in severe infections.

Bacterial infections produce a relatively selective increase in neutrophils (neutrophilia), whereas parasitic and allergic responses induce eosinophilia. Viral infections tend to produce neutropenia (decreased numbers of neutrophils) and lymphocytosis.³ Leukopenia is also encountered in infections that overwhelm persons with other debilitating diseases such as cancer.

Lymphadenitis

Localized acute and chronic inflammation may lead to a reaction in the lymph nodes that drain the affected area. This response represents a nonspecific response to mediators released from the injured tissue or an immunologic response to a specific antigen. Painful palpable nodes are more commonly associated with inflammatory processes, whereas nonpainful lymph nodes are more characteristic of neoplasms.¹

In summary, inflammation describes a local response to tissue injury and can present as an acute or chronic condition. The classic signs of inflammation are redness, swelling, local heat, pain, and loss of function. It involves a hemodynamic phase during which blood flow and capillary permeability are increased, and a cellular phase during which phagocytic white blood cells move into the area to engulf and degrade the inciting agent. The inflammatory response is orchestrated by chemical mediators such as histamine, prostaglandins, PAF, complement fragments, and reactive molecules that are liberated by leukocytes.

In contrast to acute inflammation, which is self-limiting, chronic inflammation is prolonged and usually is caused by persistent irritants, most of which are insoluble and resistant to phagocytosis and other inflammatory mechanisms. Chronic inflammation involves the presence of mononuclear cells (lymphocytes and macrophages), rather than granulocytes.

The local manifestations of acute and chronic inflammation depend upon the agent and extent of injury. Acute inflammation may involve the production of exudates containing serous fluid (serous exudate), red blood cells (hemorrhagic exudate), fibrinogen (fibrinous exudate), or tissue debris and white blood cell breakdown products (purulent exudate). *Ulceration* occurs at the site of inflammation where an epithelial surface (skin or mucous membranes) has become necrotic and eroded. In chronic lesions where there is repeated insult, the area surrounding the ulcer develops fibroblastic proliferation, scarring, and the accumulation of chronic inflammatory cells.

The systemic manifestations of inflammation include an increased ESR, fever, and leukocytosis (or in some cases, leukopenia). These responses are mediated by release of the cytokines, IL-1, TNF- α , and IL-6. Localized acute and chronic inflammation may lead to a reaction in the lymph nodes and enlargement of the lymph nodes that drain the affected area.

Body organs and structures contain two types of tissues: parenchymal and stromal. The parenchymal tissues contain the functioning cells of an organ or body part (*e.g.*, hepatocytes, renal tubular cells). The stromal tissues consist of the supporting connective tissues, blood vessels, and nerve fibers.

Injured tissues are repaired by regeneration of parenchymal cells or by connective tissue repair in which scar tissue is substituted for the parenchymal cells of the injured tissue. The primary objective of the healing process is to fill the gap created by tissue destruction and to restore the structural continuity of the injured part. When regeneration cannot occur, healing by replacement with connective scar tissue provides the means for maintaining this continuity. Although scar tissue fills the gap created by tissue death, it does not repair the structure with functioning parenchymal cells. Because the regenerative capabilities of most tissues are limited, wound healing usually involves some connective tissue repair.

Considerable research has contributed to the understanding of chemical mediators and growth factors that orchestrate the healing process.^{4,5} These chemical mediators and growth factors are released in an orderly manner from many of the cells that participate in the healing process. Some growth factors act as chemoattractants, enhancing the migration of white blood cells and fibroblasts to the wound site, and others act as mitogens, causing increased proliferation of cells that participate in the healing process.⁶ For example, platelet-derived growth factor, which is released from activated platelets, attracts white blood cells and acts as a growth factor for blood vessels and fibroblasts. Many of the cytokines discussed in Chapter 8 function as growth factors that are involved in wound healing.

Regeneration

Regeneration involves replacement of the injured tissue with cells of the same parenchymal type, leaving little or no evidence of the previous injury. The ability to regenerate varies with the tissue and cell type. Body cells are divided into three types according to their ability to undergo regeneration: labile, stable, or permanent cells.⁴

Labile cells are those that continue to divide and replicate throughout life, replacing cells that are continually being destroyed. Labile cells can be found in tissues that have a daily turnover of cells. They include the surface epithelial cells of the skin, the oral cavity, vagina, and cervix; the columnar epithelium of the gastrointestinal tract, uterus, and fallopian tubes; the transitional epithelium of the urinary tract; and bone marrow cells.

Stable cells are those that normally stop dividing when growth ceases. However, these cells are capable of undergoing regeneration when confronted with an appropriate stimulus. For stable cells to regenerate and restore tissues to their original state, the supporting stromal framework must be present. When this framework has been destroyed, the replacement of tissues is haphazard. The hepatocytes of the liver are one form of stable cell, and the importance of the supporting framework to regeneration is evidenced by two forms of liver disease. For example, in some types of viral hepatitis there is selective destruction of the parenchymal liver cells, while the cells of the

supporting tissue remain unharmed. After the disease has subsided, the injured cells regenerate, and liver function returns to normal. In cirrhosis of the liver, fibrous bands of tissue form and replace the normal supporting tissues of the liver, causing disordered replacement of liver cells and disturbance of hepatic blood flow and liver function.

Permanent or fixed cells cannot undergo mitotic division. The fixed cells include nerve cells, skeletal muscle cells, and cardiac muscle cells. These cells cannot regenerate; once destroyed, they are replaced with fibrous scar tissue that lacks the functional characteristics of the destroyed tissue. For example, the scar tissue that develops in the heart after a heart attack (Fig. 9-8) cannot conduct impulses or contract to pump blood.

Connective Tissue Repair

Connective tissue replacement is an important process in the repair of tissue. It allows replacement of nonregenerated parenchymal cells by a connective tissue scar. Depending on the extent of tissue loss, wound closure and healing occur by *primary* or *secondary* intention. A sutured surgical incision is an example of healing by primary intention. Larger wounds (*e.g.*, burns and large surface wounds) that have a greater loss of tissue and contamination, heal by secondary intention. Healing by secondary intention is slower than healing by primary intention of larger amounts of scar tissue. A wound that might otherwise have healed by primary intention.

Wound healing is commonly divided into three phases: the inflammatory phase, the proliferative phase, and the maturational or remodeling phase (Fig. 9-9).^{6,7} In wounds healing by primary intention, the duration of the phases is fairly predictable. In wounds healing by secondary intention, the process depends on the extent of injury and the healing environment.

Inflammatory Phase

The inflammatory phase of wound healing begins at the time of injury and is a critical period because it prepares the wound environment for healing. It includes hemostasis and the

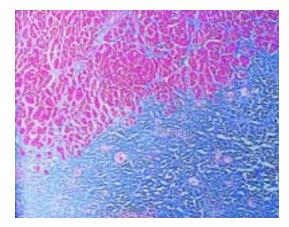

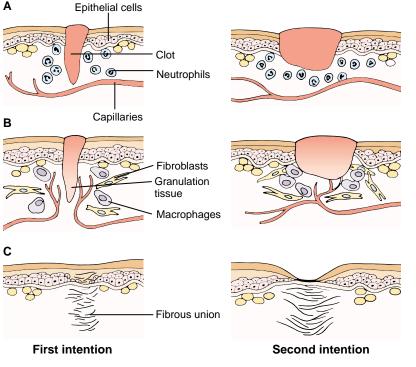

FIGURE 9-8 Healed myocardial infarct. Tissues with permanent cells are replaced with scar tissue only. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 102]. Philadelphia: Lippincott Williams & Wilkins)

■ FIGURE 9-9 ■ Healing of a skin wound by primary and secondary intention. (A) The inflammatory phase with formation of a blood clot and migration of neutrophils. (B) The proliferative phase with migration of macrophages and fibroblasts, proliferation of vascular endothelial cells, and development of granulation tissue. (C) Remodeling stage with development of the fibrous scar, disappearance of increased vascularity, and exit of inflammatory cells.

vascular and cellular phases of inflammation. Hemostatic processes are activated immediately at the time of injury. There is constriction of injured blood vessels and initiation of blood clotting by way of platelet activation and aggregation (see Chapter 12). After a brief period of constriction, these same vessels dilate and capillaries increase their permeability, allowing plasma and blood components to leak into the injured area. In small surface wounds, the clot loses fluid and becomes a hard, desiccated scab that protects the area.

The cellular phase of inflammation follows and is evidenced by the migration of phagocytic white blood cells that digest and remove invading organisms, fibrin, extracellular debris, and other foreign matter. The neutrophils or PMNs are the first cells to arrive and are usually gone by day 3 or 4. They ingest bacteria and cellular debris. Approximately 24 hours after the arrival of the PMNs, a larger and less specific phagocytic cell, the macrophage, which is an essential cell in the healing process, enters the wound area and remains for an extended period. Its functions include phagocytosis and release of growth factors that stimulate epithelial cell growth, angiogenesis (i.e., growth of new blood vessels), and attraction of fibroblasts. When a large defect occurs in deeper tissues, PMNs and macrophages are required to remove the debris and facilitate wound closure. Although a wound may heal in the absence of PMNs, it cannot heal in the absence of macrophages.

Proliferative Phase

The proliferative phase of healing usually begins within 2 to 3 days of injury and may last as long as 3 weeks in wounds healing by primary intention. The primary processes during this time focus on the building of new tissue to fill the wound space. The key cell during this phase is the *fibroblast*. The fibroblast is a connective tissue cell that synthesizes and secretes

collagen and other intercellular elements needed for wound healing. Fibroblasts also produce a family of growth factors that induce the growth of blood vessels (angiogenesis) and endothelial cell proliferation and migration.

As early as 24 to 48 hours after injury, fibroblasts and vascular endothelial cells begin proliferating to form a specialized type of soft, pink granular tissue, called *granulation tissue*, that

KEY CONCEPTS

TISSUE REPAIR AND WOUND HEALING

- Injured tissues can be repaired by regeneration of the injured tissue cells with cells of the same tissue or parenchymal type, or by connective repair processes in which scar tissue is used to effect healing.
- Regeneration is limited to tissues with cells that are able to undergo mitosis.
- Connective tissue repair occurs by primary or secondary intention and involves the inflammatory phase, the proliferative phase, and remodeling phases of the wound healing process.
- Wound healing is impaired by conditions that diminish blood flow and oxygen delivery, restrict nutrients and other materials needed for healing, and depress the inflammatory and immune responses; and by infection, wound separation, and the presence of foreign bodies.

serves as the foundation for scar tissue development. This tissue is fragile and bleeds easily because of the numerous, newly developed capillary buds. Wounds that heal by secondary intention have more necrotic debris and exudate that must be removed, and they involve larger amounts of granulation tissue. The newly formed blood vessels are leaky and allow plasma proteins and white blood cells to leak into the tissues. At approximately the same time, epithelial cells at the margin of the wound begin to regenerate and move toward the center of the wound, forming a new surface layer that is similar to that destroyed by the injury. In wounds that heal by primary intention, these epidermal cells proliferate and seal the wound within 24 to 48 hours.8 When a scab has formed on the wound, the epithelial cells migrate between it and the underlying viable tissue; when a significant portion of the wound has been covered with epithelial tissue, the scab can be easily removed. At times, excessive granulation tissue, sometimes referred to as proud flesh, may form and extend above the edges of wound, preventing re-epithelialization. Surgical removal or chemical cauterization of the defect allows healing to proceed.

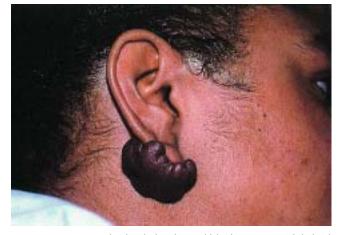

As the proliferative phase progresses, there is continued accumulation of collagen and proliferation of fibroblasts. Collagen synthesis reaches a peak within 5 to 7 days and continues for several weeks, depending on wound size. By the second week, the white blood cells have largely left the area, the edema has diminished, and the wound begins to blanch as the small blood vessels become thrombosed and degenerate.

Remodeling Phase

The third or remodeling phase of wound healing begins approximately 3 weeks after injury and can continue for 6 months or longer, depending on the extent of the wound. As the term implies, there is continued remodeling of scar tissue by simultaneous synthesis of collagen by fibroblasts and lysis by collagenase enzymes. As a result of these two processes, the architecture of the scar becomes reoriented to increase the tensile strength of the wound.

Most wounds do not regain the full tensile strength of unwounded skin after healing is completed. Carefully sutured wounds immediately after surgery have approximately 70% of the strength of unwounded skin, largely because of the placement of the sutures. This allows persons to move about freely after surgery without fear of wound separation. When the sutures are removed, usually at the end of the first week, wound strength is approximately 10%. It increases rapidly during the next 4 weeks and then slows, reaching a plateau of approximately 70% to 80% of the tensile strength of unwounded skin at the end of 3 months.⁵ An injury that heals by secondary intention undergoes wound contraction during the proliferative and remodeling phases. As a result, the scar that forms is considerably smaller than the original wound. Cosmetically, this may be desirable because it reduces the size of the visible defect. However, contraction of scar tissue over joints and other body structures tends to limit movement and cause deformities. As a result of loss of elasticity, scar tissue that is stretched fails to return to its original length.

An abnormality in healing by scar tissue repair is *keloid* formation (Fig. 9-10). Keloids are tumorlike masses caused by excess production of scar tissue. The tendency toward development of keloids is more common in African Americans and seems to have a genetic basis.

■ FIGURE 9-10 ■ Keloid. A light-skinned black woman with keloid that developed following ear piercing. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 90]. Philadelphia: Lippincott Williams & Wilkins)

Factors That Affect Wound Healing

Many local and systemic factors influence wound healing. Although there are many factors that impair healing, science has found a few ways to hasten the normal process of wound repair. Among the causes of impaired wound healing are malnutrition; impaired blood flow and oxygen delivery; impaired inflammatory and immune responses; infection, wound separation, and foreign bodies; and age effects.

Malnutrition

Successful wound healing depends in part on adequate stores of proteins, carbohydrates, fats, vitamins, and minerals. It is well recognized that malnutrition slows the healing process, causing wounds to heal inadequately or incompletely.⁹ Protein deficiencies prolong the inflammatory phase of healing and impair fibroblast proliferation, collagen and protein matrix synthesis, angiogenesis, and wound remodeling. Carbohydrates are needed as an energy source for white blood cells. Carbohydrates also have a protein-sparing effect and help to prevent the use of amino acids for fuel when they are needed for the healing process. Fats are essential constituents of cell membranes and are needed for the synthesis of new cells.

Although most vitamins are essential cofactors for the daily functions of the body, only vitamins A and C have been shown to play an essential role in the healing process. Vitamin C is needed for collagen synthesis. In vitamin C deficiency, improper sequencing of amino acids occurs, proper linking of amino acids does not take place, the by-products of collagen synthesis are not removed from the cell, and new wounds do not heal properly. Vitamin A functions in stimulating and supporting epithelialization, capillary formation, and collagen synthesis. The B vitamins are important cofactors in enzymatic reactions that contribute to the wound-healing process. All are water soluble, and with the exception of vitamin B_{12} , which is stored in the liver, almost all must be replaced daily. Vitamin K plays an indirect role in wound healing by preventing bleeding disorders that contribute to hematoma formation and subsequent infection.

The role of minerals in wound healing is less clearly defined. The macrominerals, including sodium, potassium, calcium, and phosphorus, as well as the microminerals, such as copper and zinc, must be present for normal cell function. Zinc is a cofactor in a variety of enzyme systems responsible for cell proliferation. In animal studies, zinc has been found to aid in re-epithelialization.

Blood Flow and Oxygen Delivery

For healing to occur, wounds must have adequate blood flow to supply the necessary nutrients and to remove the resulting waste, local toxins, bacteria, and other debris. Impaired wound healing caused by poor blood flow may occur as a result of wound conditions (*e.g.*, swelling) or pre-existing health problems. Arterial disease and venous pathology are well-documented causes of impaired wound healing. In situations of trauma, a decrease in blood volume may cause a reduction in blood flow to injured tissues.

Molecular oxygen is required for collagen synthesis. It has been shown that even a temporary lack of oxygen can result in the formation of less stable collagen.¹⁰ Wounds in ischemic tissue become infected more frequently than do wounds in well-vascularized tissue. PMNs and macrophages require oxygen for destruction of microorganisms that have invaded the area. Although these cells can accomplish phagocytosis in a relatively anoxic environment, they cannot digest bacteria.

Impaired Inflammatory and Immune Responses

Inflammatory and immune mechanisms function in wound healing. Inflammation is essential to the first phase of wound healing, and immune mechanisms prevent infections that impair wound healing. Among the conditions that impair inflammation and immune function are disorders of phagocytic function, diabetes mellitus, and therapeutic administration of corticosteroid drugs.

Phagocytic disorders may be divided into extrinsic and intrinsic defects. Extrinsic disorders are those that impair attraction of phagocytic cells to the wound site, prevent engulfment of bacteria and foreign agents by the phagocytic cells (*i.e.*, opsonization), or cause suppression of the total number of phagocytic cells (*e.g.*, immunosuppressive agents). Intrinsic phagocytic disorders are the result of enzymatic deficiencies in the metabolic pathway for destroying the ingested bacteria by the phagocytic cell (see Chapter 10).

Wound healing is a problem in persons with diabetes mellitus, particularly those who have poorly controlled blood glucose levels. Studies have shown delayed wound healing, poor collagen formation, and poor tensile strength in diabetic animals. Of particular importance is the effect of hyperglycemia on the phagocytic function of white blood cells. For example, neutrophils have diminished chemotactic and phagocytic function, including engulfment and intracellular killing of bacteria, when exposed to elevated glucose levels. Small blood vessel disease is also common among persons with diabetes, impairing the delivery of inflammatory cells, oxygen, and nutrients to the wound site.¹¹

The therapeutic administration of corticosteroid drugs decreases the inflammatory process and may delay the healing process. These hormones decrease capillary permeability during the early stages of inflammation, impair the phagocytic property of the leukocytes, and inhibit fibroblast proliferation and function.

Infection, Wound Separation, and Foreign Bodies

Wound contamination, wound separation, and foreign bodies delay wound healing. Infection impairs all dimensions of wound healing. It prolongs the inflammatory phase, impairs the formation of granulation tissue, and inhibits proliferation of fibroblasts and deposition of collagen fibers. All wounds are contaminated at the time of injury. Although body defenses can handle the invasion of microorganisms at the time of wounding, badly contaminated wounds can overwhelm host defenses. Trauma and existing impairment of host defenses also can contribute to the development of wound infections.

Approximation of the wound edges (*i.e.*, suturing of an incision type of wound) greatly enhances healing and prevents infection. Epithelialization of a wound with closely approximated edges occurs within 1 to 2 days. Large, gaping wounds tend to heal more slowly because it is often impossible to effect wound closure with this type of wound. Foreign bodies tend to invite bacterial contamination and delay healing. Fragments of wood, steel, glass, and other compounds may have entered the wound at the site of injury and can be difficult to locate when the wound is treated. Sutures are also foreign bodies, and although needed for the closure of surgical wounds, they are an impediment to healing. This is why sutures are removed as soon as possible after surgery. Wound infections are of special concern in persons with implantation of foreign bodies such as orthopedic devices (e.g., pins, stabilization devices), cardiac pacemakers, and shunt catheters. These infections are difficult to treat and may require removal of the device.

In summary, the ability of tissues to repair damage caused by injury depends on the body's ability to replace the parenchymal cells and to organize them as they were originally. Regeneration describes the process by which tissue is replaced with cells of a similar type and function. Healing by regeneration is limited to tissue with cells that are able to divide and replace the injured cells. Body cells are divided into types according to their ability to regenerate: labile cells, such as the epithelial cells of the skin and gastrointestinal tract, which continue to regenerate throughout life; stable cells, such as those in the liver, which normally do not divide but are capable of regeneration when confronted with an appropriate stimulus; and permanent or fixed cells, such as nerve cells, which are unable to regenerate. Scar tissue repair involves the substitution of fibrous connective tissue for injured tissue that cannot be repaired by regeneration.

Wound healing occurs by primary and secondary intention and is commonly divided into three phases: the inflammatory phase, the proliferative phase, and the maturational or remodeling phase. In wounds healing by primary intention, the duration of the phases is fairly predictable. In wounds healing by secondary intention, the process depends on the extent of injury and the healing environment. Wound healing can be impaired or complicated by factors such as malnutrition; restricted blood flow and oxygen delivery; diminished inflammatory and immune responses; and infection, wound separation, and the presence of foreign bodies.

TEMPERATURE REGULATION AND FEVER

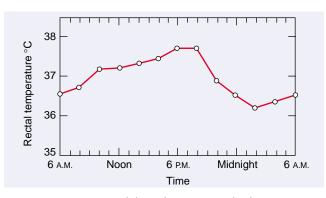

Fever is a clinical hallmark of infection and inflammation. This section of the chapter focuses on regulation of body temperature and fever caused by infectious and noninfectious conditions.

Body Temperature Regulation

The temperature within the deep tissues of the body (core temperature) is normally maintained within a range of 36.0°C to 37.5°C (97.0°F to 99.5°F).¹² Within this range, there are individual differences and diurnal variations; internal core temperatures reach their highest point in late afternoon and evening and their lowest point in the early morning hours (Fig. 9-11). Virtually all biochemical processes in the body are affected by changes in temperature. Metabolic processes speed up or slow down, depending on whether body temperature is rising or falling.

Body temperature reflects the difference between heat production and heat loss. Body heat is generated in the tissues of the body, transferred to the skin surface by the blood, and then released into the environment surrounding the body. The thermoregulatory center in the hypothalamus functions to modify heat production and heat losses as a means of regulating body temperature.

It is the core body temperature, rather than the surface temperature, that is regulated by the thermoregulatory center in the hypothalamus. This center integrates input from cold and warm thermal receptors located throughout the body and generates output responses that conserve body heat or increase its dissipation. The thermostatic set point of the thermoregulatory center is set so that the core temperature is regulated within the normal range. When body temperature begins to rise above the normal range, heat-dissipating behaviors are initiated; when the temperature falls below the normal range, heat production is increased. A core temperature greater than 41°C (105.8°F) or less than 34°C (93.2°F) usually indicates that the body's ability to thermoregulate is impaired (Fig. 9-12). Body responses that produce, conserve, and dissipate heat are described in Table 9-2. Spinal cord injuries that transect the cord at T6 or above can seriously impair temperature regulation because

■ FIGURE 9-11 ■ Normal diurnal variations in body temperature.

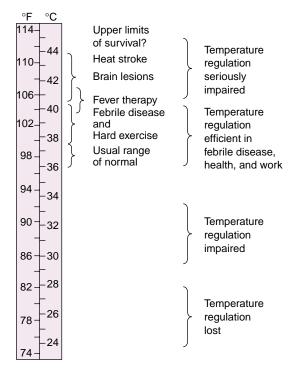

KEY CONCEPTS

FEVER

- Fever represents an increase in body temperature due to resetting of the hypothalamic thermoregulatory set point as the result of endogenous pyrogens released from host macrophages or endothelial cells.
- In response to the increase in set point, the hypothalamus initiates physiologic responses to increase core temperature to match the new set point.
- Fever is an adaptive response to bacterial and viral infections or to tissue injury. The growth rate of microorganisms is inhibited, and immune function is enhanced.

the hypothalamus can no longer control skin blood flow or sweating.

In addition to physiological thermoregulatory mechanisms, humans engage in voluntary behaviors to help regulate body temperature. These behaviors include the selection of proper clothing and regulation of environmental temperature through heating systems and air conditioning. Body positions that hold the extremities close to the body (*e.g.*, huddling or holding the extremities close to the body) prevent heat loss and are commonly assumed in cold weather.

TABLE 9-2

Heat Gain and Heat Loss Responses Used in Regulation

of Body Temperatur

Hea	at Gain	Heat Loss		
Body Response	Mechanism of Action	Body Response	Mechanism of Action	
Vasoconstriction of the superficial blood vessels	Confines blood flow to the inner core of the body, with the skin and sub- cutaneous tissues acting as insula- tion to prevent loss of core heat	Dilatation of the super- ficial blood vessels	Delivers blood containing core heat to the periphery where it is dissipated through radiation, conduction, and convection	
Contraction of the pilomotor mus- cles that surround the hairs on the skin	Reduces the heat loss surface of the skin	Sweating	Increases heat loss through evaporation	
Assumption of the huddle position with the extremities held close to the body	Reduces the area for heat loss			
Shivering	Increases heat production by the muscles			
Increased production of epinephrine	Increases the heat production associ- ated with metabolism			
Increased production of thyroid hormone	Is a long-term mechanism that in- creases metabolism and heat production			

Mechanisms of Heat Production

Metabolism is the body's main source of heat production. The sympathetic neurotransmitters, epinephrine and norepinephrine, which are released when an increase in body temperature is needed, act at the cellular level to shift metabolism so energy production is reduced and heat production is increased. This may be one of the reasons fever tends to produce feelings of weakness and fatigue. Thyroid hormone increases cellular metabolism, but this response usually requires several weeks to reach maximal effectiveness.

Fine involuntary actions such as shivering and chattering of the teeth can produce a threefold to fivefold increase in body temperature. *Shivering* is initiated by impulses from the hypothalamus. The first muscle change that occurs with shivering is a general increase in muscle tone, followed by an oscillating rhythmic tremor involving the spinal-level reflex that controls muscle tone. Because no external work is performed, all of the energy liberated by the metabolic processes from shivering is in the form of heat.

Physical exertion increases body temperature. With strenuous exercise, more than three quarters of the increased metabolism resulting from muscle activity appears as heat within the body, and the remainder appears as external work.

Mechanisms of Heat Loss

Most of the body's heat is produced by the deeper core tissues (*i.e.*, muscles and viscera), which are insulated from the environment and protected against heat loss by the subcutaneous tissues. Adipose tissue is a particularly good insulator, conducting heat only one third as effectively as other tissues.

Heat is lost from the body through radiation and conduction from the skin surface; through the evaporation of sweat and insensible perspiration; through the exhalation of air that has been warmed and humidified; and through heat lost in urine and feces. Contraction of the *pilomotor muscles* of the skin, which raises the skin hair and produces goose bumps, reduces the surface area available for heat loss. Of these mechanisms, only heat losses that occur at the skin surface are directly under hypothalamic control.

Most of the body's heat losses occur at the skin surface as heat from the blood moves to the skin and from there into the surrounding environment. There are numerous *arteriovenous* (*AV*) *shunts* under the skin surface that allow blood to move directly from the arterial to the venous system (Fig. 9-13). These AV shunts are much like the radiators in a heating system. When the shunts are open, body heat is freely dissipated to the skin and surrounding environment; when the shunts are closed, heat is retained in the body. The blood flow in the AV shunts is controlled almost exclusively by the sympathetic ner-

vous system in response to changes in core temperature and environmental temperature. The transfer of heat from the skin to the environment occurs by means of radiation, conduction, convection, and evaporation.

Radiation. Radiation involves the transfer of heat through the air or a vacuum. Heat from the sun is carried by radiation. The human body radiates heat in all directions. The ability to dissipate body heat by radiation depends on the temperature of the environment. Environmental temperature must be less than that of the body for heat loss to occur.

Conduction. Conduction involves the direct transfer of heat from one molecule to another. Blood carries, or conducts, heat from the inner core of the body to the skin surface. Normally, only a small amount of body heat is lost through conduction to a cooler surface. However, loss of heat by conduction to air represents a sizable proportion of the body's heat loss.

The conduction of heat to the body's surface is influenced by blood volume. In hot weather, the body compensates by increasing blood volume as a means of dissipating heat. Exposure to cold produces a cold diuresis and a reduction in blood volume as a means of controlling the transfer of heat to the body's surface.

Convection. Convection refers to heat transfer through the circulation of air currents. Normally, a layer of warm air tends to remain near the body's surface; convection causes continual removal of the warm layer and replacement with air from the surrounding environment. The wind-chill factor that often is included in the weather report combines the effect of convection caused by wind with the still-air temperature.

Evaporation. Evaporation involves the use of body heat to convert water on the skin to water vapor. Water that diffuses through the skin independent of sweating is called *insensible perspiration*. Insensible perspiration losses are greatest in a dry

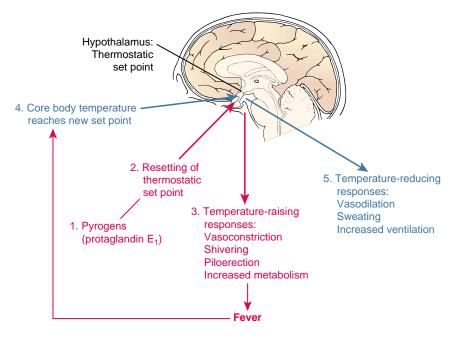

environment. Sweating occurs through the sweat glands and is controlled by the sympathetic nervous system. In contrast to other sympathetically mediated functions, sweating relies on acetylcholine, rather that the catecholamines, as a neurotransmitter. This means that anticholinergic drugs, such as atropine, can interfere with heat loss by interrupting sweating.

Evaporative heat losses involve insensible perspiration and sweating, with 0.58 calories being lost for each gram of water that is evaporated.¹² As long as body temperature is greater than the atmospheric temperature, heat is lost through radiation. However, when the temperature of the surrounding environment becomes greater than skin temperature, evaporation is the only way the body can rid itself of heat. Any condition that prevents evaporative heat losses causes the body temperature to rise.

Fever

Fever, or *pyrexia*, describes an elevation in body temperature that is caused by a cytokine-induced upward displacement of the set point of the hypothalamic thermoregulatory center. Fever is resolved or "broken" when the factor that caused the increase in the set point is removed. Fevers that are regulated by the hypothalamus usually do not rise above 41°C (105.8°F), suggesting a built-in thermostatic safety mechanism. Temperatures above that level are usually the result of superimposed activity, such as convulsions, hyperthermic states, or direct impairment of the temperature control center.

Fever can be caused by a number of microorganisms and substances that are collectively called pyrogens (Fig. 9-14). Many proteins, breakdown products of proteins, and certain other substances, including lipopolysaccharide toxins released from bacterial cell membranes, can cause the set point of the hypothalamic thermostat to increase. Some pyrogens can act directly and immediately on the hypothalamic thermoregulatory center to increase its set point. Other pyrogens, sometimes called *exogenous pyrogens*, act indirectly and may require several hours to produce their effect.¹²

■ FIGURE 9-14 ■ Mechanisms of fever. (1) Release of endogenous pyrogen from inflammatory cells, (2) resetting of hypothalamus thermostatic set point to a higher level (prodrome), (3) generation of hypothalamicmediated responses that raise body temperature (chill), (4) development of fever with elevation of body to new thermostatic set point, and (5) production of temperaturelowering responses (flush and defervescence) and return of body temperature to a lower level.

164 Unit Two: Alterations in Body Defenses

Exogenous pyrogens induce host cells, such as blood leukocytes and tissue macrophages, to produce fever-producing mediators called *endogenous pyrogens* (e.g., interleukin-1). For example, the phagocytosis of bacteria and breakdown products of bacteria that are present in the blood lead to the release of endogenous pyrogens into the circulation. The endogenous pyrogens are thought to increase the set point of the hypothalamic thermoregulatory center through the action of prostaglandin E2.12 In response to the sudden increase in set point, the hypothalamus initiates heat production behaviors (shivering and vasoconstriction) that increase the core body temperature to the new set point, and fever is established. In addition to their fever-producing actions, the endogenous pyrogens mediate a number of other responses. For example, interleukin-1 is an inflammatory mediator that produces other signs of inflammation, such as leukocytosis, anorexia, and malaise.

Many noninfectious disorders, such as myocardial infarction, pulmonary emboli, and neoplasms, produce fever. In these conditions, the injured or abnormal cells incite the production of pyrogen. For example, trauma and surgery can be associated with several days of fever. Some malignant cells, such as those of leukemia and Hodgkin's disease, secrete pyrogen.

A fever that has its origin in the central nervous system is sometimes referred to as a *neurogenic fever*.¹³ It usually is caused by damage to the hypothalamus caused by central nervous system trauma, intracerebral bleeding, or an increase in intracranial pressure. Neurogenic fevers are characterized by a high temperature that is resistant to antipyretic therapy and is not associated with sweating.

The purpose of fever is not completely understood. However, from a purely practical standpoint, fever is a valuable index to health status. For many, fever signals the presence of an infection and may legitimize the need for medical treatment. In ancient times, fever was thought to "cook" the poisons that caused the illness. With the availability of antipyretic drugs in the late 19th century, the belief that fever was useful began to wane, probably because most antipyretic drugs also had analgesic effects.

There is little research to support the belief that fever is harmful unless the temperature is greater than 40°C (104°F). Animal studies have demonstrated a clear survival advantage in infected members with fever compared with animals that were unable to produce a fever.¹⁴ It has been shown that small elevations in temperature, such as those that occur with fever, enhance immune function. There is increased motility and activity of the white blood cells, stimulation of interferon production, and activation of T cells.^{15,16} Many of the microbial agents that cause infection grow best at normal body temperatures, and their growth is inhibited by temperatures in the fever range. For example, the rhinoviruses responsible for the common cold are cultured best at 33°C (91.4°F), which is close to the temperature in the nasopharynx. Temperaturesensitive mutants of the virus that cannot grow at temperatures greater than 37.5°C (99.5°F), produce fewer signs and symptoms.17

Patterns

The patterns of temperature change in persons with fever vary and may provide information about the nature of the causative agent.¹⁸ These patterns can be described as intermittent, remittent, sustained, or relapsing. An *intermittent fever* is one in which temperature returns to normal at least once every 24 hours. Intermittent fevers are commonly associated with conditions such as gram-negative/positive sepsis, abscesses, and acute bacterial endocarditis. In a *remittent fever*, the temperature does not return to normal and varies a few degrees in either direction. It is associated with viral upper respiratory tract, legionella, and mycoplasma infections. In a *sustained* or *continuous* fever, the temperature remains above normal with minimal variations (usually less than 0.55°C or 1°F). Sustained fevers are seen in persons with drug fever. A *recurrent* or *relapsing fever* is one in which there is one or more episodes of fever, each as long as several days, with one or more days of normal temperature between episodes. Relapsing fevers may be caused by a variety of infectious diseases, including tuberculosis, fungal infections, Lyme disease, and malaria.

Critical to the analysis of a fever pattern is the relation of heart rate to the level of temperature elevation. Normally, a 1°C rise in temperature produces a 15-bpm (beats per minute) increase in heart rate (1°F, 10 bpm).¹⁹ Most persons respond to an increase in temperature with an appropriate increase in heart rate. The observation that a rise in temperature is not accompanied by the anticipated change in heart rate can provide useful information about the cause of the fever. For example, a heart rate that is slower than would be anticipated can occur with Legionnaires' disease and drug fever, and a heart rate that is more rapid than anticipated can be symptomatic of hyperthyroidism and pulmonary emboli.

Manifestations

The physiologic behaviors that occur during the development of fever can be divided into four successive stages: a prodrome; a chill, during which the temperature rises; a flush; and defervescence. During the first or prodromal period, there are nonspecific complaints, such as mild headache and fatigue, general malaise, and fleeting aches and pains. During the second stage or chill, there is the uncomfortable sensation of being chilled and the onset of generalized shaking, although the temperature is rising. Vasoconstriction and piloerection usually precede the onset of shivering. At this point the skin is pale and covered with goose flesh. There is a feeling of being cold and an urge to put on more clothing or covering and to curl up in a position that conserves body heat. When the shivering has caused the body temperature to reach the new set point of the temperature control center, the shivering ceases, and a sensation of warmth develops. At this point, the *third stage* or *flush* begins, during which cutaneous vasodilation occurs and the skin becomes warm and flushed. The fourth, or defervescence, stage of the febrile response is marked by the initiation of sweating. Not all persons proceed through the four stages of fever development. Sweating may be absent, and fever may develop gradually, with no indication of a chill or shivering.

Common manifestations of fever are anorexia, myalgia, arthralgia, and fatigue. These discomforts are worse when the temperature rises rapidly or exceeds 39.5°C (103.1°F). Respiration is increased, and the heart rate usually is elevated. Dehydration occurs because of sweating and the increased vapor losses caused by the rapid respiratory rate. The occurrence of chills commonly coincides with the introduction of pyrogen into the circulation. This is one of the reasons that blood cultures to identify the organism causing the fever are usually drawn during the first signs of a chill.

Chapter 9: Inflammation, Tissue Repair, and Fever

Many of the manifestations of fever are related to the increases in the metabolic rate, increased need for oxygen, and use of body proteins as an energy source. During fever, the body switches from using glucose (an excellent medium for bacterial growth) to metabolism based on protein and fat breakdown. With prolonged fever, there is increased breakdown of endogenous fat stores. If fat breakdown is rapid, metabolic acidosis may result (see Chapter 6).

Headache is a common accompaniment of fever and is thought to result from the vasodilation of cerebral vessels occurring with fever. Delirium is possible when the temperature exceeds 40°C (104°F). In the elderly, confusion and delirium may follow moderate elevations in temperature. Because of the increasingly poor oxygen uptake by the aging lung, pulmonary function may prove to be a limiting factor in the hypermetabolism that accompanies fever in older persons. Confusion, incoordination, and agitation commonly reflect cerebral hypoxemia. Febrile seizures can occur in some children.²⁰ They usually occur with rapidly rising temperatures or at a threshold temperature that differs with each child.

The herpetic lesions, or fever blisters, that develop in some persons during fever are caused by a separate infection by the type 1 herpes simplex virus that established latency in the regional ganglia and is reactivated by a rise in body temperature.

Diagnosis and Treatment

Fever usually is a manifestation of a disease state, and as such, determining the cause of a fever is an important aspect of its treatment. For example, fevers caused by infectious diseases usually are treated with antibiotics, whereas other fevers, such as those resulting from a noninfectious inflammatory condition, may be treated symptomatically.

Sometimes it is difficult to establish the cause of a fever. A prolonged fever for which the cause is difficult to ascertain is often referred to as fever of unknown origin (FUO). FUO is defined as a temperature elevation of 38.3°C (101°F) or higher that is present for 3 weeks or longer.²¹ Among the causes of FUO are malignancies (i.e., lymphomas, metastases to the liver and central nervous system); infections such as human immunodeficiency virus or tuberculosis, or abscessed infections; and drug fever. Malignancies, particularly non-Hodgkin's lymphoma, are important causes of FUO in the elderly. Cirrhosis of the liver is another cause of FUO.

The methods of fever treatment focus on modifications of the external environment intended to increase heat transfer from the internal to the external environment, support of the hypermetabolic state that accompanies fever, protection of vulnerable body organs and systems, and treatment of the infection or condition causing the fever. Because fever is a disease symptom, its manifestation suggests the need for treatment of the primary cause.

Modification of the environment ensures that the environmental temperature facilitates heat transfer away from the body. Sponge baths with cool water or an alcohol solution can be used to increase evaporative heat losses. More profound cooling can be accomplished through the use of a cooling mattress, which facilitates the conduction of heat from the body into the coolant solution that circulates through the mattress. Care must be taken so that cooling methods do not produce vasoconstriction and shivering that decrease heat loss and increase heat production.

Adequate fluids and sufficient amounts of simple carbohydrates are needed to support the hypermetabolic state and prevent the tissue breakdown that is characteristic of fever. Additional fluids are needed for sweating and to balance the insensible water losses from the lungs that accompany an increase in respiratory rate. Fluids also are needed to maintain an adequate vascular volume for heat transport to the skin surface.

Antipyretic drugs, such as aspirin and acetaminophen, often are used to alleviate the discomforts of fever and protect vulnerable organs, such as the brain, from extreme elevations in body temperature. These drugs act by resetting the hypothalamic temperature control center to a lower level, presumably by blocking the activity of cyclooxygenase, an enzyme that is required for the conversion of arachidonic acid to prostaglandin E2.22

Fever in Children

The mechanisms for controlling temperature are not well developed in the infant. In infants younger than 3 months, a mild elevation in temperature (i.e., rectal temperature of 38°C [100.4°F]) can indicate serious infection that requires immediate medical attention.^{23,24} Fever without a source occurs frequently in infants and children and is a common reason for visits to the clinic or emergency department.

Both minor and life-threatening infections are common in the infant to 3-year age group.^{23,24} The most common causes of fever in children are minor or more serious infections of the respiratory system, urinary system, gastrointestinal tract, or central nervous system. Occult bacteremia and meningitis also occur in this age group and should be excluded as diagnoses. The Agency for Health Care Policy and Research Expert Panel has developed clinical guidelines for use in the treatment of infants and children 0 to 36 months of age with fever without a source.²⁵ The guidelines define fever in this age group as a rectal temperature of at least 38°C (100.4°F). The guidelines also point out that fever may result from overbundling or a vaccine reaction. When overbundling is suspected, it is suggested that the infant be unbundled and the temperature retaken after 15 to 30 minutes.

Fever in infants and children can be classified as low risk or high risk, depending on the probability of the infection progressing to bacteremia or meningitis. Infants usually are considered at low risk if they were delivered at term and sent home with their mother without complications and have been healthy with no previous hospitalizations or previous antimicrobial therapy. A white blood cell count and urinalysis are recommended as a means of confirming low-risk status. Signs of toxicity (and high risk) include lethargy, poor feeding, hypoventilation, poor tissue oxygenation, and cyanosis. Blood and urine cultures, chest radiographs, and lumbar puncture usually are done in high-risk infants and children to determine the cause of fever.

Infants with fever who are considered to be at low risk usually are managed on an outpatient basis providing the parents or caregivers are deemed reliable. Older children with fever without source also may be treated on an outpatient basis. Parents or caregivers require full instructions, preferably in writing, regarding assessment of the febrile child. They should be instructed to contact their health care provider should their child show signs suggesting sepsis. Infants younger than 3 months are evaluated carefully. Infants and children with signs of toxicity and/or petechiae (a sign of meningitis) usually are hospitalized for evaluation and treatment.²⁶ Parenteral antimicrobial therapy usually is initiated after samples for blood, urine, and spinal fluid cultures have been taken.

Fever in the Elderly

In the elderly, even slight elevations in temperature may indicate serious infection or disease. This is because the elderly often have a lower baseline temperature, and although they increase their temperature during an infection, it may fail to reach a level that is equated with significant fever.^{27,28}

Normal body temperature and the circadian pattern of temperature variation often are altered in the elderly. Elderly persons are reported to have a lower basal temperature (36.4°C [97.6°F] in one study) than do younger persons.²⁹ It has been recommended that the definition of fever in the elderly be expanded to include an elevation of temperature of at least 1.1°C (2°F) above baseline values.²⁸

It has been suggested that 20% to 30% of elders with serious infections present with an absent or blunted febrile response.²⁸ When fever is present in the elderly, it usually indicates the presence of serious infection, most often caused by bacteria. The absence of fever may delay diagnosis and initiation of antimicrobial treatment. Unexplained changes in functional capacity, worsening of mental status, weakness and fatigue, and weight loss are signs of infection in the elderly. They should be viewed as possible signs of infection and sepsis when fever is absent. The probable mechanisms for the blunted fever response include a disturbance in sensing of temperature by the thermoregulatory center in the hypothalamus, alterations in release of endogenous pyrogens, and the failure to elicit responses such as vasoconstriction of skin vessels, increased heat production, and shivering that increase body temperature during a febrile response.

Another factor that may delay recognition of fever in the elderly is the method of temperature measurement. Oral temperature remains the most commonly used method for measuring temperature in the elderly. It has been suggested that rectal and tympanic membrane methods are more effective in detecting fever in the elderly. This is because conditions such as mouth breathing, tongue tremors, and agitation often make it difficult to obtain accurate oral temperatures in the elderly.

In summary, body temperature is normally maintained within a range of 36.0°C to 37.4°C. Body heat is produced by metabolic processes that occur within deeper core structures of the body and is lost at the body's surface when core heat is transported to the skin by the circulating blood. The transfer of heat from the skin to the environment occurs through radiation, conduction, convection, and evaporation. The thermoregulatory center in the hypothalamus functions to modify heat production and heat losses as a means of regulating body temperature.

Fever represents an increase in body temperature outside the normal range. Fever can be caused by a number of factors, including microorganisms, trauma, and drugs or chemicals, all of which incite the release of endogenous pyrogens and subsequent resetting of the hypothalamic thermoregulatory center. The reactions that occur during fever consist of four stages: a prodrome, a chill, a flush, and defervescence. Many of the manifestations of fever are related to the increases in the metabolic rate, increased need for oxygen, and use of body proteins as an energy source.

Fever in infants and children can be classified as low risk or high risk, depending upon the probability of the infection progressing to bacteremia or meningitis. Infants younger than 28 days and those at high risk usually are hospitalized for evaluation of their fever and treatment. In the elderly, even slight elevations in temperature may indicate serious infection or disease. The elderly often have a lower baseline temperature, so serious infections may go unrecognized because of the perceived lack of a significant fever.

REVIEW QUESTIONS

State the five cardinal signs of acute inflammation and describe the physiologic mechanisms and mediators involved in production of these signs.

Describe the systemic manifestations associated with an acute inflammatory response.

Compare the etiology and pathogenesis of acute and chronic inflammation.

- Trace the wound-healing process through the inflammatory, proliferative, and remodeling phases.
- Explain the effect of malnutrition; ischemia and oxygen deprivation; impaired immune and inflammatory responses; and infection, wound separation, and foreign bodies on wound healing.
- Apply the physiologic mechanisms involved in body temperature regulation to describe the four stages of fever.
- Describe the criteria used when determining the seriousness of fever without source in children younger than 36 months.
- State the definition for fever in the elderly and cite possible mechanisms for altered febrile responses in the elderly.

Under normal conditions, the immune response deters or prevents disease. However, occasionally the inadequate, inappropriate, or misdirected activation of the immune system can lead to debilitating or life-threatening illnesses, typified by allergic or hypersensitivity reactions, transplantation immunopathology, autoimmune disorders, and immunodeficiency states.

ALLERGIC AND HYPERSENSITIVITY DISORDERS

Hypersensitivity is defined as an exaggerated immune response to a foreign agent resulting in injury to the host.^{1,2} Allergic or hypersensitivity disorders are caused by immune responses to environmental antigens that produce inflammation and cause tissue injury. In the context of an allergic response, these antigens usually are referred to as allergens. Allergens are any foreign substances capable of inducing an immune response. Many different chemicals of natural and synthetic origin are known allergens. Complex natural organic chemicals, especially proteins, are more likely to cause an immediate hypersensitivity response, whereas simple organic compounds, inorganic chemicals, and metals more commonly cause delayed hypersensitivity reactions. Exposure to the allergen can be through inhalation, ingestion, injection, or skin contact. Sensitization of a specific individual to a specific allergen is the result of a particular interplay between the chemical or physical properties of the allergen, the mode and quantity of exposure, and the unique genetic makeup of the person.

The manifestations of allergic responses reflect the effect of an immunologically induced inflammatory response in the organ or tissue involved. These manifestations usually are independent of the agent involved. For example, the symptoms of hay fever are the same whether the allergy is caused by ragweed pollen or mold spores. The diversity of allergic responses derives from the different immunologic effector pathways that are involved (*e.g.*, hay fever vs. allergic dermatitis).

Historically, hypersensitivity disorders have been categorized as four types: type I, IgE-mediated disorders; type II,

ALLERGIC AND HYPERSENSITIVITY DISORDERS

- Allergic and hypersensitivity disorders result from immune responses to exogenous and endogenous antigens that produce inflammation and cause tissue damage.
- Type I hypersensitivity is an IgE-mediated immune response that leads to the release of inflammatory mediators for sensitized mast cells.
- Type II disorders involve humoral antibodies that participate directly in injuring cells by predisposing them to phagocytosis or lysis.
- Type III disorders result in generation of immune complexes in which humoral antibodies bind antigen and activate complement. The fractions of complement attract inflammatory cells that release tissue-damaging products.
- Type IV disorders involve tissue damage in which cell-mediated immune responses with sensitized T lymphocytes cause cell and tissue injury.

antibody-mediated (cytotoxic) disorders; type III, immune complex-mediated disorders; and type IV, cell-mediated hypersensitivity reactions (Table 10-1). Latex allergy is a newly emerging disorder that can result from an IgE-mediated or T-cell-mediated hypersensitivity response.

Type I, IgE-Mediated Disorders

Type I reactions are immediate-type hypersensitivity reactions that are triggered by binding of an allergen to a specific IgE that is found on the surface of mast cells or basophils. In addition to its role in allergic responses, IgE is involved in acquired immunity to parasitic infections.

The mast cells, which are tissue cells, and basophils, which are blood cells, are derived from hematopoietic (blood) precursor cells. Mast cells normally are distributed throughout connective tissue, especially in areas beneath the skin and mucous membranes of the respiratory, gastrointestinal, and genitourinary tracts, and adjacent to blood and lymph vessels.³ This location places mast cells near surfaces that are exposed to environmental antigens and parasites. Mast cells and basophils have granules that contain potent mediators of allergic reactions. These mediators are preformed in the cell or activated through enzymatic processing. During the sensitization or priming stage, the allergen-specific IgE antibodies attach to receptors on the surface of mast cells and basophils. With subsequent exposure, the sensitizing allergen binds to the cellassociated IgE and triggers a series of events that ultimately lead to degranulation of the sensitized mast cells or basophils, causing release of their allergy-producing mediators (Fig. 10-1).

The primary (preformed) mediators of allergic reactions include histamine, acetylcholine, adenosine, chemotactic mediators, and neutral proteases that are released from mast cells. Histamine, the most important of these preformed mediators, is a potent vasodilator that increases the permeability of capillaries and venules, and causes bronchoconstriction and increased secretion of mucus. Acetylcholine produces bronchial smooth muscle contraction and dilation of small blood vessels. The proteases generate kinins and cleave complement components to produce additional chemotactic and inflammatory mediators. Secondary mediators include leukotrienes and prostaglandins that are generated from arachidonic acid in the mast cell membrane (see Chapter 9). The leukotrienes and prostaglandins produce responses similar to those of histamine and acetylcholine, although their effects are delayed and prolonged by comparison. Platelet-activating factor is another secondary mediator, resulting in platelet aggregation, histamine release, and bronchospasm. It also acts as a chemotactic factor for neutrophils and eosinophils. Mast cells also produce a number of cytokines that play a role in type I hypersensitivity responses through their ability to recruit and activate a variety of inflammatory cells.

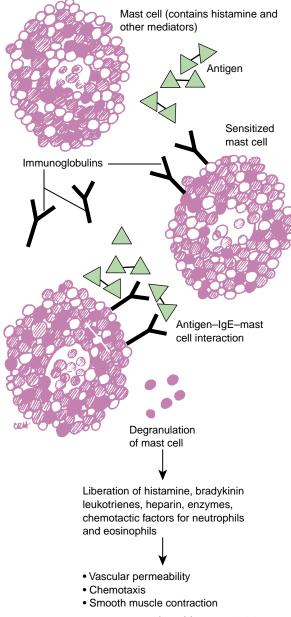

Type I hypersensitivity reactions may present as a systemic disorder (anaphylaxis) or a localized reaction (atopy).²

Systemic Anaphylactic Reactions

Systemic anaphylactic disorders often result from injected allergens (*e.g.*, penicillin, radiographic contrast dyes, bee or wasp stings). More rarely, they may result from ingested allergens (seafood, nuts, legumes). In sensitized individuals, only a small amount of the allergen may be required to produce a

IV— Cell-mediate hypersensitiv		Sensitized T lymphocytes release cytokines and produce T-cell-mediated cytotoxicity.	Tuberculosis, contact dermatitis, transplant rejection	

170 Unit Two: Alterations in Body Defenses

■ FIGURE 10-1 ■ Type I, IgE-mediated hypersensitivity reaction. Exposure to the antigen causes sensitization of the mast cell; subsequent binding of the antigen to the sensitized degranulation of mast cell with release of potent inflammatory mediators, such as histamine, that are responsible for the hypersensitivity reactions.

reaction. Anaphylaxis has a rapid onset, often within minutes, of itching, urticaria (hives), gastrointestinal cramps, and difficulty breathing caused by bronchospasm. Angioedema (swelling of face and throat) may develop, causing upper airway obstruction. Massive vasodilation may lead to peripheral pooling of blood, a profound drop in blood pressure, and life-threatening circulatory shock (see Chapter 18).

Localized Atopic Disorders

Localized reactions generally occur when the antigen is confined to a particular site, usually related to the route of exposure. Localized type I hypersensitivity reactions appear to be genetically determined and the term *atopy* is often used to imply a hereditary predisposition to such reactions. Persons with atopic disorders commonly are allergic to more than one, and often many, environmental allergens. They tend to have high serum levels of IgE and increased numbers of basophils and mast cells. Although the IgE-triggered response is likely to be a key factor in the pathophysiology of the disorders, it is not the only factor. It is possible that persons with atopic disorders are exquisitely responsive to the chemical mediators of allergic reactions, rather than having a hyperactive IgE immune response.

Atopic disorders include food allergies, allergic rhinitis (hay fever), allergic dermatitis, and certain forms of bronchial asthma. The discussion in this section focuses on allergic rhinitis and food allergy. Allergic asthma is discussed in Chapter 21 and atopic dermatitis in Chapter 44.

Allergic Rhinitis. Allergic rhinitis (i.e., allergic rhinoconjunctivitis) is characterized by symptoms of sneezing, itching, and watery discharge from the eyes and nose. Allergic rhinitis not only produces nasal symptoms but also frequently is associated with other chronic airway disorders, such as sinusitis and bronchial asthma.⁴ Severe attacks may be accompanied by systemic malaise, fatigue, and muscle soreness from sneezing. Fever is absent. Sinus obstruction may cause headache. Typical allergens include pollens from ragweed, grasses, trees, and weeds; fungal spores; house dust mites; animal dander; and feathers. Allergic rhinitis can be divided into perennial and seasonal allergic rhinitis, depending on the chronology of symptoms. Persons with the perennial type of allergic rhinitis experience symptoms throughout the year, but those with seasonal allergic rhinitis (i.e., hay fever) are plagued with intense symptoms in conjunction with periods of high allergen (e.g., pollens, fungal spores) exposure. Symptoms that become worse at night suggest a household allergen, and symptoms that disappear on weekends suggest occupational exposure.

Diagnosis depends on a careful history and physical examination, microscopic identification of nasal eosinophilia, and skin testing to identify the offending allergens.

Treatment is symptomatic in most cases and includes the use of oral antihistamines and decongestants.⁴ Intranasal corticosteroids often are effective when used appropriately. Intranasal cromolyn, a drug that stabilizes mast cells and prevents their degranulation, may be useful, especially when administered before expected contact with an offending allergen. The anticholinergic agent ipratropium, which is available as a nasal spray, also may be used. When possible, avoidance of the offending allergen is recommended.

Food Allergies. Virtually any food can produce atopic allergies. The primary target of food allergy may be the skin, the gastrointestinal tract, or the respiratory system. The foods most commonly causing these reactions in children are milk, eggs, peanuts, soy, tree nuts, fish, and shellfish foods (*i.e.*, crustaceans and mollusks).⁵ In adults, such foods are peanuts, shellfish, and fish. The allergenicity of a food may be changed by heating or cooking. A person may be allergic to drinking milk but may not have symptoms when milk is included in cooked foods. Both acute reactions (*e.g.*, anaphylaxis) and chronic reactions (*e.g.*, asthma, atopic dermatitis, and gastrointestinal disorders) can occur. Anaphylaxis is a serious and sometimes fatal systemic reaction. The foods most responsible for anaphylaxis are peanuts, tree nuts (*e.g.*, walnuts, almonds, pecans, cashews, hazelnuts), and shellfish.

Although food allergies can occur at any age, they tend to manifest during childhood. The allergic response is thought to occur after contact between specific food allergens and IgEsensitized mast cells found in the intestinal mucosa causes local and systemic release of histamine and other mediators of the allergic response. In this disorder, allergens usually are food proteins and partially digested food products. Carbohydrates, lipids, or food additives, such as preservatives, colorings, or flavorings, also are potential allergens. Closely related food groups can contain common cross-reacting allergens. For example, some persons are allergic to all legumes (*i.e.*, beans, peas, and peanuts).

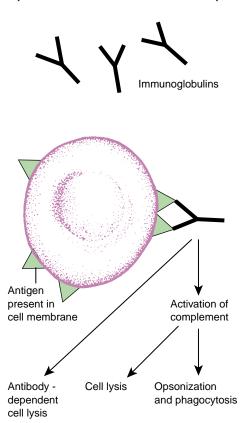

Diagnosis of food allergies usually is based on careful food history and provocative diet testing. Provocative testing involves careful elimination of a suspected allergen from the diet for a period of time to see if the symptoms disappear and reintroducing the food to see if the symptoms reappear. Only one food should be tested at a time. Treatment focuses on avoidance of the food or foods responsible for the allergy. However, avoidance may be difficult for persons who are exquisitely sensitive to a particular food protein because foods may be contaminated with the protein during processing or handling of the food. For example, contamination may occur when chocolate candies without peanuts are processed with the same equipment used for making candies with peanuts. In predisposed persons, even using the same spatula to serve cookies with and without peanuts can cause enough contamination to produce a severe anaphylactic reaction.

Type II, Antibody-Mediated Cytotoxic Disorders

Type II (cytotoxic) hypersensitivity reactions are the end result of direct interaction between IgG and IgM class antibodies and tissue or cell surface antigens, with subsequent activation of complement- or antibody-dependent cell-mediated cytotoxicity (Fig. 10-2). Examples of type II reactions include mismatched blood transfusions, hemolytic disease of the newborn caused by ABO or Rh incompatibility, and certain drug reactions. In the latter, the binding of certain drugs to the surface of red or white blood cells elicits an antibody and complement response that lyses the drug-coated cell. Lytic drug reactions can produce transient anemia, leukopenia, or thrombocytopenia, which are corrected by the removal of the offending drug.

Type III, Immune-Complex Disorders

Immune complex disorders are mediated by the formation of insoluble antigen-antibody complexes that activate complement (Fig. 10-3). Activation of complement by the immune complex generates chemotactic and vasoactive mediators that cause tissue damage by a variety of mechanisms, including alterations in blood flow, increased vascular permeability, and the destructive action of inflammatory cells. The reaction occurs when the antigen combines with antibody, whether in the

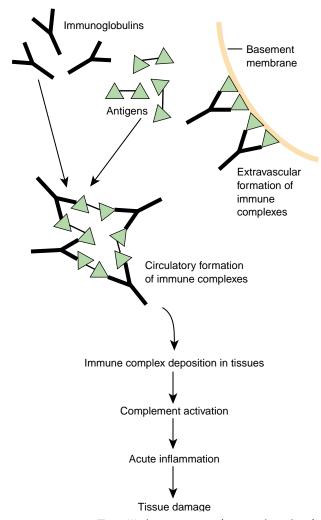

■ FIGURE 10-2 ■ Type II, cytotoxic hypersensitivity reactions involve formation of immunoglobulins (IgG and IgM) against cell surface antigens. The antigen-antibody response leads to (1) complement-mediated mechanisms of cell injury or to (2) antibody cytotoxicity that does not require the complement system.

circulation (circulating immune complexes) or at extravascular sites where antigen may have been deposited. Immune complexes formed in the circulation produce damage when they come in contact with the vessel lining or are deposited in tissues, including the renal glomerulus, skin venules, the lung, and joint synovium. Once deposited, the immune complexes elicit an inflammatory response by activating complement, thereby leading to chemotactic recruitment of neutrophils and other inflammatory cells.

There are two general types of antigens that cause immunecomplex mediated injury: (1) exogenous antigens such as viral and bacterial proteins and (2) endogenous antigens such as self-antigens associated with autoimmune disorders. Type III reactions are responsible for the acute glomerulonephritis that follows a streptococcal infection and the manifestations of autoimmune disorders such as systemic lupus erythematosus (SLE). Unlike type II reactions, in which the damage is caused by binding of antibody to body cells, the harmful effects of type III reactions are indirect (*i.e.*, secondary to the inflammatory response induced by activated complement).

Acute serum sickness is the prototype of a systemic immune complex disease. The term *serum sickness* was originally coined to describe a syndrome consisting of rash, lymphadenopathy, arthralgias, and occasionally neurologic disorders that appeared 7 or more days after injections of horse antisera for prevention of tetanus. Although this therapy is not used

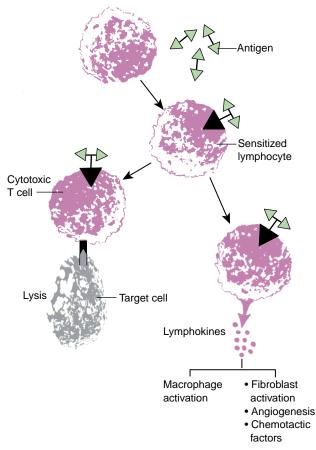

■ FIGURE 10-3 ■ Type III, immune complex reactions involve complement-activating IgG and IgM immunoglobulins with formation of blood-borne immune complexes that are eventually deposited in tissues. Complement activation at the site of immune complex deposition leads to recruitment of leukocytes, which are eventually responsible for tissue injury.

today, the name remains. The most common contemporary causes of this allergic disorder include antibiotics (especially penicillin), various foods, drugs, and insect venoms. Serum sickness is triggered by the deposition of insoluble antigenantibody (IgM and IgG) complexes in blood vessels, joints, heart, and kidney tissue. The deposited complexes activate complement, increase vascular permeability, and recruit phagocytic cells, all of which can promote focal tissue damage and edema. The signs and symptoms include urticaria, patchy or generalized rash, extensive edema (usually of the face, neck, and joints), and fever. In most cases, the damage is temporary, and symptoms resolve within a few days. However, a prolonged and continuous exposure to the sensitizing antigen can lead to irreversible damage. In previously sensitized persons, severe and even fatal forms of serum sickness may occur immediately or within several days after the sensitizing drug or serum is administered.

Type IV, Cell-Mediated Hypersensitivity Disorders

Unlike other hypersensitivity reactions, type IV, delayed hypersensitivity, is mediated by cells, not antibodies. Type IV hypersensitivity reactions usually occur 24 to 72 hours after exposure of a sensitized individual to the offending antigen. They are mediated by T lymphocytes that are directly cytotoxic (CD8⁺ T cells) or that secrete inflammatory mediators (CD4⁺ T cells) that cause tissue changes (Fig. 10-4). The reaction is initiated by antigen-specific CD4⁺ helper T cells, which release numerous immunoregulatory and proinflammatory cytokines into the surrounding tissue. These substances attract antigenspecific and antigen-nonspecific T or B lymphocytes as well as monocytes, neutrophils, eosinophils, and basophils. Some of the cytokines promote differentiation and activation of macrophages that function as phagocytic and antigen-presenting cells (APCs). Activation of the coagulation cascade leads to formation and deposition of fibrin.

The best-known type of delayed hypersensitivity response is the reaction to the tuberculin test, in which inactivated tuberculin or purified protein derivative is injected under the skin. In a previously sensitized person, redness and induration of the area develop within 8 to 12 hours, reaching a peak in

■ FIGURE 10-4 ■ Type IV, cell-mediated or delayed-type hypersensitivity reactions involve sensitization of T lymphocytes with the subsequent formation of cytotoxic T cells that lyse target cells or T cells that release cell-damaging lymphokines.

24 to 72 hours. A positive tuberculin test indicates that a person has had sufficient exposure to the *M. tuberculosis* organism to incite a hypersensitivity reaction; it does not mean that the person has tuberculosis. Certain types of antigens induce cellmediated immunity with an especially pronounced macrophage response. This type of delayed hypersensitivity commonly develops in response to particulate antigens that are large, insoluble, and difficult to eliminate. The accumulated macrophages are often transformed into so-called *epithelioid cells* because they resemble epithelium. A microscopic aggregation of epithelioid cells, which usually are surrounded by a layer of lymphocytes, is called a *granuloma*. Inflammation that is characterized by this type of type IV hypersensitivity is called *granulomatous inflammation* (see Chapter 9).

Direct T-cell-mediated cytotoxicity, which causes necrosis of antigen-bearing cells, is believed to be important in the eradication of virus-infected cells, autoimmune diseases such as Hashimoto's thyroiditis, and host-versus-graft or graft-versushost transplant rejection. Allergic contact dermatitis and hypersensitivity pneumonitis are presented as examples of cellmediated hypersensitivity reactions.

Allergic Contact Dermatitis

Allergic contact dermatitis denotes an inflammatory response confined to the skin that is initiated by re-exposure to an allergen to which a person had previously become sensitized (*e.g.*, cosmetics, hair dyes, metals, topical drugs). Contact dermatitis usually consists of erythematous macules, papules, and vesicles (*i.e.*, blisters). The affected area often becomes swollen and warm, with exudation, crusting, and development of a secondary infection. The location of the lesions often provides a clue about the nature of the antigen causing the disorder. The most common form of this condition is the dermatitis that follows an intimate encounter with poison ivy or poison oak antigens, although many other substances can trigger a reaction.

The mechanism of events leading to prior sensitization to an antigen is not completely understood. It is likely that sensitization follows transdermal transport of an antigen, with subsequent presentation to T lymphocytes. Subpopulations of sensitized lymphocytes are distributed throughout the body so that subsequent cutaneous exposure to the offending antigen promotes a localized reaction regardless of the initial site of contact. The severity of the reaction associated with contact dermatitis ranges from mild to intense, depending on the person and the allergen. Because this condition follows the time course of a delayed hypersensitivity response, the reaction does not become apparent for at least 12 hours and usually more than 24 hours after exposure. Depending on the antigen and the duration of exposure, the reaction may last from days to weeks and is typified by erythematous, vesicular, or papular lesions associated with intense pruritus and weeping.

Diagnosis of contact dermatitis is made by observing the distribution of lesions on the skin surface and associating a particular pattern with exposure to possible allergens. If a particular allergen is suspected, a patch test can be used to confirm the suspicion. Treatment usually is limited to removal of the irritant and application of topical preparations (*e.g.*, ointments, corticosteroid creams) to relieve symptomatic skin lesions and prevent secondary bacterial infections. Severe reactions may require systemic corticosteroid therapy.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis or allergic alveolitis is associated with exposure to inhaled organic dusts or related occupational antigens. The disorder is thought to involve a susceptible host and activation of pulmonary T cells, followed by the release of cytokine mediators of inflammation.6 The inflammatory response that ensues (usually several hours after exposure) produces labored breathing, dry cough, chills and fever, headache, and malaise. The symptoms usually subside within hours after the sensitizing antigens are removed. A primary example of hypersensitivity pneumonitis is "farmer's lung," a condition resulting from exposure to moldy hay. Other sensitizing antigens include tree bark, sawdust, animal danders, and Actinomycetes bacteria that are occasionally found in humidifiers, hot tubs, and swimming pools. Exposure to small amounts of antigen for a long period may lead to chronic lung disease with minimal reversibility. This can happen to persons exposed to avian or animal antigens or a contaminated home air humidifier.6

The most important element in the diagnosis of hypersensitivity pneumonitis is to obtain a good history (occupational and otherwise) of exposure to possible antigens. Skin tests, when available, and serum tests for precipitating antibody can be done. Occasionally, direct observation of the person's work and other environments may help to establish a diagnosis. Treatment consists of identifying and avoiding the offending antigens. Severe forms of the disorder may be treated with systemic corticosteroid therapy.

Latex Allergy

With the advent of the human immunodeficiency virus (HIV) and other blood-borne pathogens, the use of natural latex gloves has spiraled. Along with the expanded use of latex gloves have come increased reports of latex allergy among health care workers. Other persons at high risk of sensitization are those with prolonged exposure to latex, including persons who have undergone repeated surgeries. Exposure to latex may occur by cutaneous, mucous membrane, inhalation, internal tissue, or intravascular routes. Most severe reactions have resulted from latex proteins coming in contact with the mucous membranes of the mouth, vagina, urethra, or rectum. Children with meningomyelocele (spina bifida) who undergo frequent examinations and treatments involving the mucosal surface of the bladder or rectum are at particular risk for the development of latex allergy.^{7,8} A large number of latex products are used in dentistry, and oral mucosal contact is common during dental procedures. Anaphylactic reactions have been caused by exposure of the internal organs to the surgeon's gloves during surgery.

Allergic reactions to latex products can be triggered by the latex proteins or by the additives used in the manufacturing process. Natural rubber latex is derived from the milky sap of the *Hevea brasiliensis* plant or rubber tree. Various accelerants, curing agents, antioxidants, and stabilizers are added to the liquid latex during the manufacturing process. Cornstarch powder is applied to the gloves during the manufacturing process to prevent stickiness and give the gloves a smooth feel. The cornstarch glove powder has an important role in the allergic response. Latex proteins are readily absorbed by glove powder and become airborne during removal of the gloves. Operating rooms and other high exposure areas where powdered gloves are used contain sufficiently high levels of aerosolized latex to produce symptoms in sensitized persons.

Latex allergy can involve a type I, IgE-mediated hypersensitivity reaction, or a type IV, cell-mediated response. The distinction between the type I and type IV reactions to latex products is not always clear. Affected individuals may experience both types of reactions. Persons with latex allergy commonly show cross-sensitivity to bananas, avocado, kiwi, tomatoes, and chestnuts, probably because latex proteins are similar to the proteins in these foods.^{7,8} These foods have been responsible for anaphylactic reactions in latex-sensitive persons.

The most common type of allergic reaction to latex gloves is a contact dermatitis caused by a type IV, delayed hypersensitivity reaction to rubber additives. It usually develops 48 to 96 hours after direct contact with latex additives. It often affects the dorsum of the hands and is characterized by a vesicular rash. When latex contact is continued, the area becomes crusted and thickened. The type I, IgE-mediated hypersensitivity reactions that occur in response to the latex proteins are less common but far more serious. They may manifest as urticaria, rhinoconjunctivitis, asthma, or anaphylaxis.

Diagnosis of latex allergy often is based on careful history and evidence of skin reactions caused by latex exposure. Symptoms after use of a rubber condom or diaphragm should raise suspicion of latex allergy. Because many of the reported reactions to latex gloves have been the result of a nonimmunologic dermatitis, it is important to differentiate between nonallergic and allergic types of dermatitis.

Treatment of latex allergy consists of avoiding latex exposure. Use of powder-free gloves can reduce the amount of airborne latex particles. Health care workers with severe and lifethreatening allergy may be forced to change employment. Patients at high risk for latex allergy (*e.g.*, children with spina bifida, health care workers with atopic disorders) should be offered clinical testing for latex allergy before undergoing procedures that expose them to natural rubber latex. All surgical or other procedures on persons with latex allergy should be done in a latex-free environment.

In summary, hypersensitivity and allergic disorders are responses to environmental, food, or drug antigens that would not affect most of the population. There are four basic categories of hypersensitivity responses: type I responses such as allergic rhinitis, bronchial asthma, and food allergies, which are mediated by IgE-class immunoglobulins; type II cytotoxic reactions such as blood transfusion reactions, which result from immunoglobulin (IgG and IgM) activation of complement; type III reactions, which result from the formation of insoluble antigen-antibody complexes that become deposited in blood vessels or in the kidney and cause localized tissue injury; and type IV, cell-mediated responses which cause conditions such as allergic dermatitis and hypersensitivity pneumonitis. Latex allergy, which is becoming more common with the spiraling use of latex gloves to prevent transmission of blood-borne diseases, can involve a type I, IgE-mediated anaphylactic reaction or a type IV, T-cell-mediated contact dermatitis.

TRANSPLANTATION IMMUNOPATHOLOGY

Not long ago, transplantation of solid organs (*e.g.*, liver, kidney, heart) and bone marrow was considered experimental and reserved for persons for whom alternative methods of therapy were exhausted and survival was unlikely. However, with a greater understanding of humoral and cellular immune regulation, the development of immunosuppressive drugs such as cyclosporine, and an appreciation of the role of the major histocompatibility complex (MHC) antigens, transplantation has become nearly routine, and the subsequent success rate has been greatly enhanced.

The cell surface antigens that determine whether transplanted tissue is recognized as foreign are the MHC or human leukocyte antigen (HLA) (see Chapter 8). Transplanted tissue can be categorized as *allogeneic* if the donor and recipient are related or unrelated but share similar HLA types, syngeneic if the donor and recipient are identical twins, and autologous if donor and recipient are the same person. Donors of solid organ transplants can be living or dead (cadaver) and related or nonrelated (heterologous). When tissues bearing foreign MHC antigens are transplanted, the recipient's immune system attempts to eliminate the donor cells, a process referred to as host-versusgraft disease (HVGD). Conversely, the cellular immune system of the transplanted tissues can attack unrelated recipient tissue, causing a graft-versus-host disease (GVHD). The likelihood of rejection varies indirectly with the degree of HLA or MCH relatedness between donor and recipient.

Host-Versus-Graft Disease

In HVGD, the immune cells of the transplant recipient attack the donor cells of the transplanted organ. HVGD usually is limited to allogeneic organ transplants, although even HLAidentical siblings may differ in some minor HLA loci, which can evoke slow rejection. Rejection caused by HVGD is a complex process that involves cell-mediated and circulating antibodies. Although many cells may participate in the process of acute transplant rejection, only the T lymphocytes seem to be absolutely required.² The activation of CD8⁺ cytotoxic T cells and CD4⁺ helper T cells is triggered in response to the donor's HLA antigens. Activation of CD4⁺ helper cells leads to proliferation of B-cell-mediated antibody production and a delayed-type hypersensitivity reaction. The initial target of the recipient antibodies is graft vasculature. The antibodies can produce injury to the transplanted organ by complementmediated cytotoxicity, generation of antigen-antibody complexes, or through antibody-mediated cytolysis.²

There are three basic patterns of transplant rejection: hyperacute, acute, and chronic.² A hyperacute reaction occurs almost immediately after transplantation; in kidney transplants, it can often be seen at the time of surgery. As soon as blood flow from the recipient to the donor organ begins, it takes on a cyanotic, mottled appearance. Sometimes, the reaction takes hours to days to develop. The hyperacute response is produced by existing recipient antibodies to graft antigens that initiate a type III immune-complex reaction in the blood vessels of the graft. These antibodies usually have developed in response to pre-

Chapter 10: Alterations in the Immune Response

vious blood transfusions, pregnancies in which the mother makes antibodies to fetal antigens, or infections with bacteria or viruses possessing antigens that mimic MHC antigens.

Acute rejection usually occurs within the first few months after transplantation. It also may occur suddenly months or even years later, after immunosuppression has been used and terminated. In the person with an organ transplant, acute rejection is evidenced by signs of organ failure. Acute rejection often involves both humoral and cell-mediated immune responses. Histologically, humoral rejection is associated with vasculitis, whereas a cell-mediated rejection response is marked by interstitial infiltration by mononuclear cells. Acute rejection vasculitis is mediated primarily by antidonor antibodies and is characterized by lesions that lead to arterial narrowing or obliteration.

Chronic HVGD occurs over a prolonged period. It is manifest by dense fibrosis of the intimal layer of blood vessels in the transplanted organ. In renal transplantation, it is characterized by a gradual rise in serum creatinine during a period of 4 to 6 months. The actual mechanism of this type of response is unclear but may include release of inflammatory mediators such as interleukin-1 and platelet-derived growth factor.

Graft-Versus-Host Disease

GVHD occurs mainly in patients who undergo bone marrow transplant and in severely immunocompromised patients who have received blood products containing HLA-incompatible lymphocytes.1 Although GVHD occurs mainly in patients who undergo bone marrow transplant, it may also occur after transplantation of solid organs rich in lymphoid cells (e.g., the liver) or transfusion of nonirradiated blood.² Three basic requirements are necessary for GVHD to develop: (1) the donor bone marrow must have a functional cellular immune component; (2) the recipient's tissue must bear antigens foreign to the donor tissue; and (3) the recipient's immunity must be compromised to the point that it cannot destroy the transplanted cells. The primary agents of GVHD are the donor T cells, and the antigens they recognize and attack are the host HLA. The greater the difference in tissue antigens between the donor and recipient, the greater is the likelihood of GVHD. Recipients of bone marrow transplants are usually immunodeficient, either because of the primary disease or prior treatment with immunosuppressant drugs or irradiation. When such recipients receive normal bone marrow cells from allogenic donors, the immunocompetent T cells derived from the donor recognize the recipient's HLA antigens as foreign and react against them.

If GVHD occurs, the primary targets of the acute illness are the skin, liver, intestine, and cells of the immune system. Acute GVHD is characterized by a pruritic, maculopapular rash, which begins on the palms and soles and frequently extends over the entire body, with subsequent desquamation. The epithelial layer is the primary site of injury. When the intestine is involved, symptoms include nausea, bloody diarrhea, and abdominal pain. GVHD of the liver can lead to bleeding disorders and coma. GVHD is considered chronic if symptoms persist or begin 100 days or more after transplantation. Chronic GVHD is characterized by abnormal humoral and cellular immunity, severe skin disorders, and liver disease. Another type of GVHD has been recognized after the transplantation of genetically identical tissue (*i.e.*, syngeneic or autologous [from self]). This variety of GVHD stems from the pretreatment conditioning regimen (*e.g.*, total-body irradiation) or treatment with cytotoxic drugs. The conditioning therapy disrupts the normal immune surveillance system and allows "rogue" autoreactive T cells to proliferate and attack native tissue. This type of GVHD usually is self-limited and not severe.

GVHD can often be prevented by selectively blocking the mechanisms responsible for the rejection process. For example, donor T cells can be selectively removed from the transplanted tissue or destroyed using various treatments such as monoclonal antibodies with attached toxins, equivalent to heat-seeking missiles. Alternatively, immunosuppressive or anti-inflammatory drugs such as cyclosporine and tacrolimus or glucocorticoids can be used to block T-cell activation and the action of cytokines.

In summary, organ and bone marrow transplantation has been enhanced by a greater understanding of humoral and cellular immune regulation, the development of immunosuppressive drugs such as cyclosporine, and an appreciation of the role of the MHC antigens in transplant rejection. The likelihood of rejection varies with the degree of HLA (or MHC) relatedness between donor and recipient. A rejection can involve an attempt by the recipient's immune system to eliminate the donor cells, as in HVGD, or an attack by the cellular immunity of the transplanted tissue on the unrelated recipient tissue, as in GVHD.

AUTOIMMUNE DISORDERS

Autoimmune diseases represent a group of disorders that are caused by a breakdown in the ability of the immune system to differentiate between self- and nonself antigens. To function properly, the immune system must be able to differentiate foreign antigens from self-antigens. Normally, there is a high degree of immunologic tolerance to self-antigens, which prevents the immune system from destroying the host.

Autoimmune diseases can affect almost any cell or tissue in the body. Some autoimmune disorders, such as Hashimoto's thyroiditis, are tissue specific; others, such as SLE, affect multiple organs and systems. Chart 10-1 lists some of the probable autoimmune diseases. Many of these disorders are discussed elsewhere in this book.

Immunologic Tolerance

The ability of the immune system to differentiate self from nonself is called *self-tolerance*. It is the HLA antigens encoded by MHC genes that serve as recognition markers of self and nonself for the immune system (see Chapter 8). To elicit an immune response, an antigen must first be processed by an antigen-presenting cell (APC), such as a macrophage, which then presents the antigenic determinants along with an MHC II molecule to a CD4⁺ helper T cell for binding to its T-cell receptor (TCR). It is the dual recognition of the MHC-antigen

*Examples are not inclusive.

complex by the TCR that acts as a security check that affects all T cells, including CD4⁺ helper T cells, which orchestrate T- and B-cell immune responses, and cytotoxic T cells, which act directly to destroy target cells. A number of chemical messengers (*e.g.*, interleukins) and costimulatory signals are essential to the activation of immune responses and the preservation of self-tolerance.

Several mechanisms have been postulated to explain the tolerant state, including central tolerance and peripheral tolerance.⁹ Central tolerance refers to the elimination of self-reactive T cells in the thymus and B cells in the bone marrow. Peripheral tolerance refers to the deletion or inactivation of autoreactive T cells or B cells that escaped elimination in the central lymphoid organs. Autoreactive B cells are deleted in the spleen and lymph nodes. Autoreactive T cells may undergo activation-induced cell death, be rendered inactive to the extent that they cannot recognize self antigens, or their activity may be suppressed by other regulatory T cells.²

Mechanisms of Autoimmune Disease

There are multiple explanations for the loss of self-tolerance and formation of autoantibodies or failure to recognize host antigens as self. Among the possible mechanisms responsible for development of autoimmune disease are aberrations in immune cell function or antigen structure. Heredity and gender may play a role in the development of autoimmunity. Because

KEY CONCEPTS

IMMUNOLOGIC TOLERANCE AND AUTOIMMUNE DISEASE

- Immunologic tolerance is the ability of the immune system to differentiate self from nonself.
- Central tolerance involves the elimination of selfreactive T and B cells in the central lymphoid organs. Self-reactive T cells are deleted in the thymus and self-reactive B cells in the bone marrow.
- Peripheral tolerance derives from the deletion or inactivation of self-reactive T and B cells that escaped deletion in the central lymphoid organs.
- Autoimmune disorders result from the breakdown in the integrity of immune tolerance such that a humoral or cellular immune response can be mounted against host tissue or antigens, leading to localized or systemic injury.

of the complexity of the immune system, it seems unlikely that autoimmune disorders arise from a single defect.

Heredity and Gender

Genetic factors can increase the incidence and severity of autoimmune diseases, ¹⁰ as shown by the familial clustering of several autoimmune diseases and the observation that certain inherited HLA types occur more frequently in persons with a variety of immunologic and lymphoproliferative disorders. For example, 90% of persons with ankylosing spondylitis carry the HLA-B27 antigen. Other HLA-associated diseases are Reiter's syndrome and HLA-B27, rheumatoid arthritis and HLA-DR4, and systemic lupus erythematosus (SLE) and HLA-DR3 (see Chapter 44). The molecular basis for these associations is unknown. Because autoimmunity does not develop in all persons with genetic predisposition, it appears that other factors, such as a "trigger event," interact to precipitate the altered immune state. The event or events that trigger the development of an autoimmune response are unknown. It has been suggested that the trigger may be a virus or other microorganism, a chemical substance, or a self-antigen from a body tissue that has been hidden from the immune system during development.

A number of autoimmune disorders such as SLE occur more commonly in women than men, suggesting that estrogens may play a role in the development of autoimmune disease. Evidence suggests that estrogens stimulate and androgens suppress the immune response.¹¹ For example, estrogen stimulates a DNA sequence that promotes the production of interferon- γ , which is thought to assist in the induction of an autoimmune response.

Failure of Self-tolerance

Autoimmune disorders can result from one or more mechanisms of self-tolerance. Immunologic cells are undoubtedly involved in the tissue injury that results, but the precise mechanisms involved in initiating the response are largely unknown. More than one defect might be present in each disease, and each mechanism may be involved in more than one disease. Among the proposed mechanisms involved in loss of selftolerance are: failure of T-cell-mediated suppression, breakdown of T-cell anergy, disorders of MHC-antigen receptor/ complex interactions, release of sequestered antigens, molecular mimicry, and superantigens.

Failure of T-cell–Mediated Suppression. Disorders of immune regulatory or surveillance function can result from failure to delete autoreactive immune cells or suppress the immune response.² Because T cells regulate the immune response, an increasing ratio of helper T to suppressor T cells may lead to the development of autoimmune disorders.

Breakdown in T-cell Anergy. Anergy involves the prolonged or irreversible inactivation of T cells under certain conditions. Activation of antigen-specific CD4+ T cells requires two signals: recognition of the antigen in association with class II MHC molecules on the surface of the APCs and a set of costimulatory signals provided by the APCs. If the second costimulatory signal is not delivered, the T cell becomes anergic. Most normal tissues do not express the costimulatory molecules and thus are protected from autoreactive T cells. This protection can be broken if the normal cells that do not normally express the costimulatory molecules are induced to do so. Some inductions can occur after an infection, or in situations where there is tissue necrosis and local inflammation. For example, up-regulation of the costimulator molecule B7-1 has been observed in the central nervous system of persons with multiple sclerosis, in the synovium of persons with rheumatoid arthritis, and in the skin of persons with psoriasis.2

Disorders in MHC-Antigen Complex/Receptor Interactions.

The immune system recognizes antigen in the context of MHC-antigen complex and TCR interactions. Aberrations in any of these three stages of the immune response—antigen structure, TCR recognition of antigen, or MHC antigen presentation—have the potential for initiating an autoimmune response.

There are many ways in which chemical or microbial antigens can be modified to evoke an altered immune response, leading to an autoimmune disorder. Autoantigenic drugs and viruses can be complexed to a carrier that is recognized by nontolerant CD4⁺ helper T cells as foreign. Virus-encoded antigens expressed on the cell surface can serve as carriers for selfantigens. In this case, the self-antigen would appear as a hapten for which an immune response could be induced.

Partial degradation of self-antigens also may occur. For example, partially degraded collagen or enzymatically altered thyroglobulin or gamma globulin may be sufficiently foreign to promote an autoimmune response.

Release of Sequestered Antigens. Normally the body does not produce antibodies against self-antigens. Thus, any self-antigen that was completely sequestered during development and then reintroduced to the immune system is likely to be regarded as foreign. Among the sequestered tissues that could be regarded as foreign are spermatozoa and ocular antigens such as those

found in uveal tissue. Post-traumatic uveitis and orchiditis after vasectomy may fall into this category.

Molecular Mimicry. It is possible that certain autoimmune disorders are caused by molecular mimicry, in which a foreign antigen so closely resembles a self-antigen that antibodies produced against the former react with the latter.^{12,13} A humoral or cellular response can be mounted against antigenically altered or injured tissue, creating an immune process. For example, in rheumatic fever and acute glomerulonephritis, a protein in the cell wall of group A β-hemolytic streptococci has considerable similarity with antigens in heart and kidney tissue, respectively. After infection, antibodies directed against the microorganism cause a classic case of mistaken identity, which leads to inflammation of the heart or kidney. Certain drugs, when bound to host proteins or glycoproteins, form a complex to which a humoral response is directed with substantial cross-reactivity to the original self-protein. The antihypertensive agent methyldopa can bind to surface antigens on red cells to induce an antibody-mediated hemolytic anemia.

Not everyone exposed to group A β -hemolytic streptococci has an autoimmune reaction. The reason that only certain persons are targeted for autoimmune reactions to a particular selfmimicry molecule may be determined by differences in HLA types. The HLA type determines exactly which fragments of a pathogen are displayed on the cell surface for presentation to T cells. One individual's HLA may bind self-mimicry molecules for presentation to T cells, and another's HLA type may not. In the spondyloarthropathies, particularly Reiter's syndrome and reactive arthritis, there is a clear relationship between arthritis and a prior bacterial infection, combined with the inherited HLA-B27 antigens.¹³

Superantigens. Superantigens are a family of related substances, including staphylococcal and streptococcal exotoxins, that can short-circuit the normal sequence of events in an immune response, leading to inappropriate activation of CD4⁺ helper T cells. Superantigens do not require processing and presentation of antigen by APCs to induce a T-cell response.¹⁴ Instead, they are able to interact with a TCR outside the normal antigenbinding site. Normally, only a small percentage (0.01%) of the T-cell population is stimulated by the presence of processed antigens on the surface of macrophages; however, superantigens can interact with 5% to 30% of T cells.14 Superantigens directly link the MHC II complex molecules of APCs such as macrophages to TCRs, causing a massive release of T-cell inflammatory cytokines, primarily interleukin-2 and tumor necrosis factor, and an uncontrolled proliferation of T cells. At least one disease in adults, toxic shock syndrome, is mediated by superantigens (see Chapter 18). Kawasaki's disease in children (see Chapter 17) probably has a similar cause.

Diagnosis and Treatment

Suggested criteria for determining that a disorder is an autoimmune disorder are evidence of an autoimmune reaction, determination that the immunologic findings are not secondary to another condition, and the lack of other identifiable causes for the disorder. Currently, the diagnosis of autoimmune disease is based primarily on clinical findings and serologic testing. The basis for most serologic assays is the demonstration of antibodies directed against tissue antigens or cellular components. For example, a serological assay for antinuclear antibodies is used in the diagnosis of SLE.

Treatment of autoimmune disease is based on the tissue or organ that is involved, the effector mechanism involved, and the magnitude and chronicity of the effector processes. Ideally, treatment should focus on the mechanism underlying the autoimmune disorder.

In summary, autoimmune diseases represent a disruption in self-tolerance that results in damage to body tissues by the immune system. Autoimmune diseases can affect almost any cell or tissue of the body. The ability of the immune system to differentiate self from nonself is called *self-tolerance*. Normally, self-tolerance is maintained through central and peripheral mechanisms that delete autoreactive B or T cells or otherwise suppress or inactivate immune responses that would be destructive to host tissues. Defects in any of these mechanisms could impair self-tolerance and predispose to development of autoimmune disease.

The ability of the immune system to differentiate foreign from self-antigens is the responsibility of HLA encoded by MHC genes. Antigen is presented to receptors of T cells in combination with MHC molecules. Among the possible mechanisms responsible for the development of autoimmune disease are failure of T-cell-mediated immune suppression; aberrations in MHC-antigen-TCR interactions; molecular mimicry; and superantigens.

Suggested criteria for determining that a disorder results from an autoimmune disorder are evidence of an autoimmune reaction, determination that the immunologic findings are not secondary to another condition, and the lack of other identifiable causes for the disorder.

IMMUNODEFICIENCY DISORDERS

Immunodeficiency can be defined as an abnormality in one or more branches of the immune system that renders a person susceptible to diseases normally prevented by an intact immune system. Two major categories of immune mechanisms defend the body against infectious or neoplastic disease: humoral or antibody-mediated immunity (*i.e.*, B lymphocytes) and cell-mediated immunity (*i.e.*, T lymphocytes and lymphokines).

Abnormalities of the immune system can be classified as primary (*i.e.*, congenital or inherited) or secondary if the immunodeficiency is acquired later in life. Secondary immunodeficiencies are more common than primary disorders of genetic origin. Secondary deficiencies in humoral immunity can develop as a consequence of selective loss of immunoglobulins through the gastrointestinal or genitourinary tracts. Secondary deficiencies of T-cell function have been described in conjunction with acute viral infections (*e.g.*, measles virus, cytomegalovirus) and with certain malignancies (*e.g.*, Hodgkin's disease and other lymphomas). HIV/AIDS (to be discussed) is the most devastating example of a secondary immunodeficiency. Regardless of the cause, primary and secondary deficiencies can produce the same spectrum of disease. The severity and symptomatology of the various immunodeficiencies depend on the disorder and extent of immune system involvement.

Primary Immunodeficiency Disorders

Until recently, little was known about the causes of primary immunodeficiency diseases. As a result of recent advances in mapping the human genome, the genetic origin of many of the defects has been identified.¹⁵ In addition, previous classifications of the disorders were based on specific clinical manifestations and alterations in immune function. Advances in molecular genetics now allow many of these disorders to be grouped according to the types of genetically altered molecules that are involved. Although genes essential to immune function are located throughout the genome, a large number are located on the X chromosome. Thus, there is a clear dominance of X-linked immunodeficiencies in males who have only one X chromosome and a single copy of these genes.¹⁵ In addition, spontaneous mutations in these X-linked genes are relatively common.

Humoral (B-Cell) Immunodeficiencies

Humoral immunodeficiency can range from a transient decrease in immunoglobulin levels during early infancy to inherited disorders that interrupt the production of one or all of the immunoglobulins. During the first few months of life, infants are protected from infection by immunoglobulin G (IgG) class

KEY CONCEPTS

PRIMARY IMMUNODEFICIENCY DISORDERS

- Primary immunodeficiency disorders are congenital or inherited abnormalities of immune function that render a person susceptible to diseases normally prevented by an intact immune system.
- Disorders of B-cell function impair the ability to produce antibodies and defend against microorganisms and toxins that circulate in body fluids (IgM and IgG) or enter the body through the mucosal surface of the respiratory or gastrointestinal tract (IgA). Persons with primary B-cell immunodeficiency are particularly prone to infections due to encapsulated organisms.
- Disorders of T-cell function impair the ability to orchestrate the immune response (CD4+ helper T cells) and to protect against fungal, protozoan, viral, and intracellular bacterial infections (CD8+ cytotoxic T cells).
- Combined T-cell and B-cell immunodeficiency states affect all aspects of immune function. Severe combined immunodeficiency represents a lifethreatening absence of immune function that requires bone marrow transplantation for survival.

Chapter 10: Alterations in the Immune Response 179

antibodies that have been transferred from the maternal circulation during fetal life. IgA, IgM, IgD, and IgE do not normally cross the placenta (see Chapter 9). An infant's level of maternal IgG gradually declines during a period of approximately 6 months. Concomitant with the loss of maternal antibody, the infant's immature humoral immune system begins to function, and between the ages of 1 and 2 years, the child's antibody production reaches that of adult levels.

Any abnormality that blocks or prevents the maturation of B-lymphocyte stem cells can produce a state of immunodeficiency. For example, certain infants experience a delay in the maturation process of B cells that leads to a prolonged deficiency in IgG levels (IgM and IgA levels are normal) beyond 6 months of age. The total number and antigenic response of circulating B cells is normal, but the chemical communication between B and T cells that leads to clonal proliferation of antibody-producing plasma cells seems to be reduced.¹⁶ This condition is referred to as *transient hypogammaglobulinemia of infancy*. The result of this condition usually is limited to repeated bouts of upper respiratory and middle ear infections. This condition usually resolves by the time the child is 2 to 4 years of age.

Primary B-cell immunodeficiencies are genetic disorders of B lymphocyte maturation. They account for 70% of primary immunodeficiencies and are manifested by decreased IgG production.¹⁷ Antibody production depends on the differentiation of B-lymphocyte stem cells in the bone marrow to mature, immunoglobulin-producing plasma cells. This maturation cycle initially involves the production of surface IgM, migration from the marrow to the peripheral lymphoid tissue, and switching to the specialized production of IgG, IgA, IgD, IgE, or IgM antibodies after antigenic stimulation (Fig. 10-5). Defects in B-cell function increase the risk of recurrent pyogenic infections, including those caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*, and by gram-negative organisms such as *Pseudomonas* species. Humoral immunity usually is not as important in defending against intracellular bacteria (mycobacteria), fungi, and protozoa. Viruses usually are handled normally, except for the enteroviruses that cause gastrointestinal infections.

X-linked Agammaglobulinemia. *X-linked* or *Bruton's agammaglobulinemia* is a recessive trait that affects only males.^{15–18} As the name implies, persons with this disorder have essentially undetectable levels of all serum immunoglobulins. Therefore, they are susceptible to meningitis and recurrent otitis media and to sinus and pulmonary infections with encapsulated organisms such as *S. pneumoniae*, *H. influenzae* type b, *S. aureus*, and *Neisseria meningitidis*.¹⁵ Many boys with this disorder have severe tooth decay.

The central defect in this syndrome is a genetic mutation that blocks the differentiation of pre-B cells, creating an absence of mature circulating B cells and plasma cells. However, T lymphocytes are normal in number and function. Symptoms of the disorder usually coincide with the loss of maternal antibodies at about 6 months of age. A clue to the presence of the disorder is failure of an infection to respond completely and promptly to antibiotic therapy. Diagnosis is based on demonstration of low or absent serum immunoglobulins. Therapy consists of prophylaxis with intravenous immunoglobulin and prompt antimicrobial therapy for suspected infections. The prognosis of this condition depends on the prompt recognition and treatment of infections. Chronic pulmonary disease is an ever-present danger.

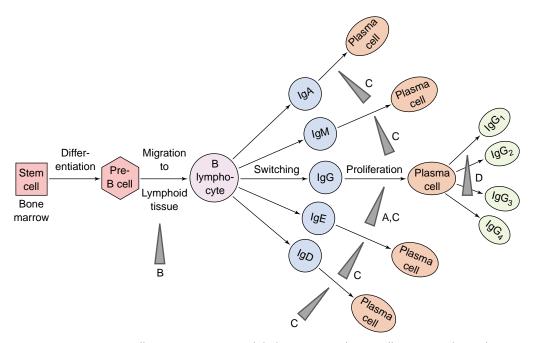

FIGURE 10-5 Stem cells to mature immunoglobulin-secreting plasma cells. *Arrows* indicate the stage of the maturation process that is interrupted in (**A**) transient hypoglobulinemia, (**B**) X-linked hypogammaglobulinemia, (**C**) common variable immunodeficiency, and (**D**) IgG subclass deficiency.

180 Unit Two: Alterations in Body Defenses

Common Variable Immunodeficiency. Another disorder of B-cell maturation, which is similar to X-linked agammaglobulinemia, is a condition called *common variable immunodeficiency*. In this syndrome, the terminal differentiation of mature B cells to plasma cells is blocked. The result is markedly reduced serum immunoglobulin levels, normal numbers of circulating B lymphocytes, and a complete absence of germinal centers and plasma cells in lymph nodes and the spleen.

The symptomatology of common variable immunodeficiency is similar to that of X-linked agammaglobulinemia (*i.e.*, recurrent otitis media and sinus and pulmonary infections with encapsulated organisms), but the onset of symptoms occurs much later, usually between the ages of 15 and 35 years, and distribution of disease between the sexes is equal. Persons with late-onset hypogammaglobulinemia also have an increased tendency toward development of chronic lung disease, autoimmune disorders, hepatitis, gastric carcinoma, and chronic diarrhea with associated intestinal malabsorption. Approximately one half of persons with the disorder have evidence of abnormal T-cell immunity, suggesting that this syndrome is a complex immunodeficiency. Treatment methods for late-onset hypogammaglobulinemia are similar to those used for X-linked hypogammaglobulinemia.

Selective Immunoglobulin A Deficiency. Selective IgA deficiency is the most common type of immunoglobulin deficiency, affecting 1 in 400 to 1 in 1000 persons.¹⁵ The syndrome is characterized by moderate to marked reduction in levels of serum and secretory IgA. It is likely that the cause of this deficiency is a block in the pathway that promotes terminal differentiation of mature B cells to IgA-secreting plasma cells.

Approximately two thirds of persons with selective IgA deficiency have no overt symptoms, presumably because IgG and IgM levels are normal and compensate for the defect. At least 50% of affected children overcome the deficiency by the age of 14 years. Persons with markedly reduced levels of IgA often experience repeated upper respiratory and gastrointestinal infections and have increased incidence of allergies such as asthma and autoimmune disorders. It has been estimated that as many as 50% of persons with selective IgA deficiency have some form of allergy.¹⁹ It has been suggested that the lack of IgA allows inhaled and ingested antigens to cross the mucosal epithelium and elicit antibody responses in the gastrointestinal and bronchial lymphoid tissues. Persons with IgA deficiency also can develop antibodies against IgA, which can lead to an anaphylactic response when blood components containing IgA are given.18

There is no treatment available for selective IgA deficiency unless there is a concomitant reduction in IgG levels. Administration of IgA is of little benefit because it has a short halflife and is not secreted across the mucosa. There also is the risk associated with IgA antibodies.

Immunoglobulin G Subclass Deficiency. An IgG subclass deficiency can affect one or more of IgG subtypes, despite normal levels or elevated serum concentrations of IgG. As discussed in Chapter 9, IgG immunoglobulins can be divided into four subclasses (IgG1 through IgG4) based on structure and function. Most circulating IgG belongs to the IgG1 (70%) and IgG2 (20%) subclasses. In general, antibodies directed against protein antigens belong to the IgG1 and IgG3 sub-

classes, and antibodies directed against carbohydrate and polysaccharide antigens are primarily IgG2 subclass. As a result, persons who are deficient in IgG2 subclass antibodies can be at greater risk for development of sinusitis, otitis media, and pneumonia caused by polysaccharide-encapsulated microorganisms such as *S. pneumoniae*, *H. influenzae* type b, and *N. meningitidis*. Children with mild forms of the deficiency can be treated with prophylactic antibiotics to prevent repeated infections. Intravenous immune globulin can be given to children with severe manifestations of this deficiency. The use of polysaccharide vaccines conjugated to protein carriers can provide protection against some of these infections because protein conjugated to protein carriers stimulates an IgG1 response.

Cellular (T-Cell) Immunodeficiencies

There are few primary forms of T-cell immunodeficiency, probably because persons with defects in this branch of the immune response rarely survive beyond infancy or childhood. However, exceptions are being recognized as newer T-cell defects, such as X-linked immunodeficiency with hyper IgM and CD2, are being identified. Other primary T-cell immunodeficiency disorders result from defective expression of the T-cell receptor complex, defective cytokine production, and defects in T-cell activation.

Unlike the B-cell lineage, in which a well-defined series of differentiation steps ultimately leads to the production of immunoglobulins, mature T lymphocytes are composed of distinct subpopulations whose immunologic assignments are diverse. T cells can be functionally divided into helper and cytotoxic subtypes and a population of T cells that promote delayed hypersensitivity reactions. Collectively, T lymphocytes protect against fungal, protozoan, viral, and intracellular bacterial infections; control malignant cell proliferation; and are responsible for coordinating the overall immune response.

DiGeorge Syndrome. DiGeorge syndrome stems from a developmental defect that occurs during the time (*i.e.*, before the 12th week of gestation) when the thymus gland, parathyroid gland, and parts of the head, neck, and heart are developing. The disorder affects both sexes. Formerly thought to be caused by a variety of factors, including extrinsic teratogens, this defect has been traced to a gene on chromosome 22 (22q11).¹⁸⁻²⁰

Infants born with this defect have partial or complete failure of development of the thymus and parathyroid glands and have congenital defects of the head, neck, and heart. The extent of immune and parathyroid abnormalities is highly variable, as are the other defects. Occasionally, a child has no heart defect. In some children, the thymus is not absent but is in an abnormal location and is extremely small. These infants can have partial DiGeorge syndrome, in which hypertrophy of the thymus occurs with development of normal immune function. The facial disorders can include hypertelorism (i.e., increased distance between the eyes); micrognathia (i.e., fish mouth); low-set, posteriorly angulated ears; split uvula; and high-arched palate. Urinary tract abnormalities also are common. The most common presenting sign is hypocalcemia and tetany that develops during the first 24 hours of life. It is caused by the absence of the parathyroid gland and is resistant to standard therapy.

Children who survive the immediate neonatal period may have recurrent or chronic infections because of impaired T-cell immunity. Children also may have an absence of immunoglobulin production, caused by a lack of helper T-cell function. For children who do require treatment, thymus transplantation can be performed to reconstitute T-cell immunity. Bone marrow transplantation also has been successfully used to restore normal T-cell populations. If blood transfusions are needed, as during corrective heart surgery, special processing is required to prevent graft-versus-host disease.

X-Linked Immunodeficiency With Hyper-IgM. The X-linked immunodeficiency of hyper-IgM, also known as the *hyper-IgM syndrome*, is characterized by low IgG and IgA levels with normal or, more frequently, high IgM concentrations. Being X-linked, the disorder is confined to males. Formerly classified as a B-cell defect, it now has been traced to a T-cell defect. The disorder results from the inability of T cells to signal B cells to undergo isotype switching to IgG and IgA; thus, they produce only IgM.¹⁸

Like boys with X-linked agammaglobulinemia, affected boys become symptomatic during the first and second years of life. They have recurrent pyogenic infections, including otitis media, sinusitis, tonsillitis, and pneumonia. They are also more susceptible to *Pneumocystis carinii* infection. Thymicdependent lymphoid tissues and T-cell function usually are normal, as are B-cell counts. Hemolytic anemia and thrombocytopenia may occur, and transient, persistent, or cyclic neutropenia is a common feature. The occurrence of concomitant autoimmune disorders is higher than with other immunoglobulin deficiency disorders.¹⁸

Combined T-Cell and B-Cell Immunodeficiencies

Disorders of the immune response that have elements of T-cell and B-cell dysfunction fall under the broad classification of combined immunodeficiency syndrome (CIDS) and include a spectrum of inherited (autosomal recessive and X-linked) conditions. A single mutation in any one of the many genes that influence lymphocyte development or response, including lymphocyte receptors, cytokines, or major histocompatibility antigens, could lead to combined immunodeficiency. Regardless of the affected gene, the net result is a disruption in the normal communication system of T and B lymphocytes and deregulation of the immune response. The spectrum of disease resulting from CIDS ranges from mild to severe to ultimately fatal forms.

Severe Combined Immunodeficiency. The most severe form of T- and B-cell deficiency often is referred to as *severe combined immunodeficiency syndrome* (SCIDS). SCIDS is caused by diverse genetic mutations that lead to absence of all immune function.^{18,19} A family history of similarly affected relatives occurs in approximately 50% of cases.¹⁹ Both autosomal recessive and X-linked inheritance are involved. Infants with SCIDS have a disease course that resembles acquired immunodeficiency syndrome (AIDS), with failure to thrive, chronic diarrhea, and opportunistic infections that usually lead to death by the age of 2 years. If recognized at birth or within the first 3 months of life, 95% of infants can be successfully treated with human leukocyte antigen (HLA)-identical or T-cell-depleted bone marrow stem cell transplantation.¹⁸

Approximately 50% of persons with the autosomal recessive form of SCIDS have an associated deficiency in the enzyme adenosine deaminase (ADA).¹⁶ Absence of this enzyme leads to accumulation of toxic metabolites that kill dividing and resting T cells. Bone marrow and stem cell transplantation has been successful in treating children with ADA-negative SCIDS.^{18,21} Enzyme replacement therapy also may be used in the care of persons with this form of SCIDS.²¹

Acquired Immunodeficiency Syndrome

AIDS is an infectious disease of the immune system caused by the HIV retrovirus. First described in June 1981, the disease is prevalent worldwide and is one of the leading causes of death among young adults in the United States. At the end of 2000, nearly 36.1 million people worldwide were living with HIV/AIDS, 22 million had died of the infection, and 5.3 million people had become newly infected during the year.²² Most of the new infections are in people younger than 25 years who live in developing countries. Sub-Saharan Africa has been hardest hit by HIV, with close to 70% of the world's infections, although it is home to only 10% of the world's population.²²

The virus responsible for most HIV infection worldwide is called *HIV type 1*. A second type of human immunodeficiency, *HIV type 2* (HIV-2) is endemic in many countries in West Africa but generally much more rare in other parts of the world.²³ HIV-2 appears to be transmitted in the same manner as HIV-1. HIV-2 can also cause immunodeficiency evidenced by a reduction in the number of CD4⁺ T cells and the development of AIDS. Although the spectrum of disease for HIV-2 is similar to that of HIV-1, it spreads more slowly and causes disease more slowly than HIV-1.²³ Long-term consequences of HIV-2 will depend on its spread in the population.

KEY CONCEPTS

ACQUIRED IMMUNODEFICIENCY SYNDROME

- AIDS is a secondary immunodeficiency disorder that results from HIV infection, which is transmitted from one person to another through blood, semen, or vaginal fluids.
- The main effect of HIV infection is the destruction of CD4⁺ T cells, which constitutes an attack on the entire immune system, because this subset of T cells exerts critical regulatory and effector functions involving both cellular and humoral immunity.
- The three phases of HIV are primary HIV, latency, and overt AIDS. The classification of HIV/AIDS is based on laboratory counts of CD4⁺ T cells and the manifestations of the immunodeficiency state (development of opportunistic infections, neoplasms, and other related problems).

Transmission of HIV Infection

Human immunodeficiency virus is transmitted from one person to another through sexual contact, blood, or perinatally. Transmission can occur when infected blood, semen, or vaginal secretions from one person are deposited onto a mucous membrane or into the bloodstream of another person.

HIV is transmitted most frequently via sexual contact. Worldwide, 75% to 85% of HIV infections are transmitted through unprotected sex.24 HIV is present in semen and vaginal fluids. There is risk of transmitting HIV when these fluids come in contact with a part of the body that lets them enter the bloodstream. This can include the vaginal mucosa, anal mucosa, and wounds or a sore on the skin.²⁴ Contact with semen occurs during vaginal and anal sexual intercourse, oral sex (*i.e.*, fellatio), and donor insemination. Exposure to vaginal or cervical secretions occurs during vaginal intercourse and oral sex (i.e., cunnilingus). Condoms are highly effective in preventing transmission of HIV. Evidence increasingly shows that people with other sexually transmitted diseases (STDs) are at increased risk for HIV infection. The risk of HIV transmission is further increased in the presence of STDs with genital ulcerations (i.e., syphilis, herpes simplex virus infection, and chancroid) as well as nonulcerative STDs (i.e., gonorrhea, chlamydial infection, and trichomoniasis).

Because HIV is found in blood, the use of needles, syringes, and other drug injection paraphernalia is a direct route for transmission. HIV-infected injecting drug users can pass the virus to their needle-sharing and sex partners and, in the case of pregnant women, to their offspring. Although alcohol, cocaine, and other noninjected drugs do not directly transmit infection, their use alters perception of risk and reduces inhibitions about engaging in behaviors that pose a high risk of transmitting HIV infection.

Transfusions of whole blood, plasma, platelets, or blood cells before 1985 resulted in the transmission of HIV. Since 1985, all blood donations in the United States have been screened for HIV so the risk of transmission has virtually been eliminated. The clotting factor used by persons with hemophilia is derived from the pooled plasma of hundreds of donors. Before HIV testing of plasma donors was implemented in 1985, the virus was transmitted to persons with hemophilia through infusions of these clotting factors.

HIV may be transmitted from infected women to their offspring in utero, during labor and delivery, or through breastfeeding. Transmission from mother to infant is the most common way that children become infected with HIV. Ninety percent of infected children acquired the virus from their mother. The risk of transmission of HIV from mother to infant is approximately 25%, with estimates ranging from 15% to 45%, depending on the country in which they reside.²⁵

Occupational HIV infection among health care workers is uncommon.²⁶ Universal Blood and Body Fluid Precautions should be used in encounters with all patients in the health care setting because HIV status is not always known. The occupational risk of infection for health care workers most often is associated with percutaneous inoculation (*i.e.*, needle stick) of blood from a patient with HIV.

The HIV-infected person can transmit the virus even when no symptoms are present and the antibody test is negative. The point at which an infected person converts from being negative for the presence of HIV antibodies in the blood to being positive is called *seroconversion*. Seroconversion typically occurs within 1 to 3 months after exposure to HIV but can take up to 6 months.²⁷ The time after infection and before seroconversion is known as the *window period*. During the window period, an HIV-infected person could transmit the virus through the blood. Blood collection centers have implemented more stringent processes to avoid HIV transmission from a donor who has not seroconverted. Potential donors are now screened through interviews designed to identify risk behaviors for HIV infection, and blood is tested for the HIV antibody as well as viral nucleic acid.

Pathophysiology of AIDS

HIV belongs to a class of viruses called retroviruses, which carry their genetic information in ribonucleic acid (RNA), rather than deoxyribonucleic acid (DNA). HIV infects a limited number of cell types in the body, including a subset of lymphocytes called *CD4*⁺ T helper cells and macrophages. The CD4⁺ T cells are necessary for normal immune function (see Chapter 8). Among other functions, the CD4⁺ T cell recognizes foreign antigens and infected cells and helps activate antibody-producing B lymphocytes. The CD4⁺ T cells also orchestrate cell-mediated immunity, in which cytotoxic CD8⁺ T cells and natural killer cells directly destroy viral infected cells and foreign antigens. Phagocytic monocytes and macrophages are also activated by CD4⁺ T cells.

Viral Replication. Replication of HIV has been divided into eight steps (Fig. 10-6). Each of these steps provides insights into the development of methods for preventing and treating HIV infection. The first step involves the binding of the virus to the CD4⁺ T cell. Once the HIV has entered the bloodstream, it attaches to the surface of a CD4⁺ T cell by binding to the CD4 molecule and a chemokine coreceptor.² This is known as attachment. The second step allows for the internalization of the virus. Binding to the coreceptor allows the virus to be internalized into the cell, where it releases its coat along with two single strands of viral RNA that carry the instructions for producing more HIV. This is called *uncoating*. The *third step* consists of DNA synthesis. In order for the HIV to reproduce, it must change its RNA into DNA. It does this by using an enzyme called *reverse transcriptase*. Reverse transcriptase makes a copy of the viral RNA, and then in reverse order makes another mirror image copy. The result is double-stranded DNA. The fourth step is called integration. It involves the entry of the double stranded viral DNA into the nucleus of the CD4⁺ T cell and, with the help of the enzyme *integrase*, insertion of the HIV DNA into the cell's original DNA. The fifth step involves transcription of the double stranded viral DNA to form a single stranded messenger RNA (mRNA) with the instructions for building new viruses. Transcription involves activation of the T cell and induction of host cell transcription factors. The sixth step includes the translation of mRNA. During translation, the ribosomal RNA (rRNA) uses the instructions in viral mRNA to create a chain of proteins and enzymes called a *polyprotein*. These polyproteins are the components for the new viruses that are formed. The seventh step is called cleavage. During the cleavage stage, protease, one of the enzymes in the polypeptide chain, cuts the chain into individual proteins, which will make up the

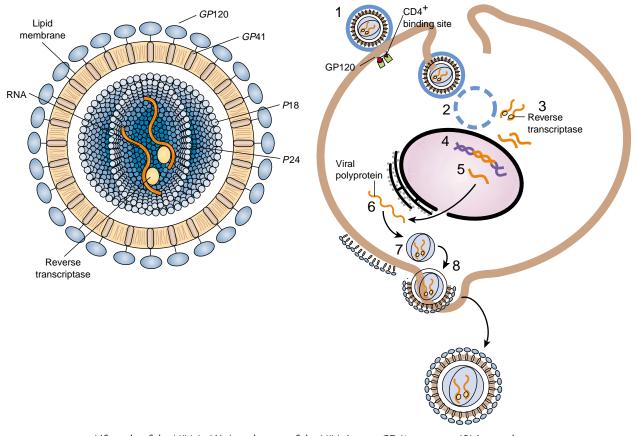

FIGURE 10-6 Life cycle of the HIV-1: (1) Attachment of the HIV virus to CD4⁺ receptor; (2) internalization and uncoating of the virus with viral RNA and reverse transcriptase; (3) reverse transcription, which produces a mirror image of the viral RNA and double-stranded DNA molecule; (4) integration of viral DNA into host DNA using the integrase enzyme; (5) transcription of the inserted viral DNA to produce viral messenger RNA; (6) translation of viral messenger RNA to create viral polyprotein; (7) cleavage of viral polyprotein into individual viral proteins that make up the new virus; and (8) assembly and release of the new virus from the host cell.

new HIV viruses. Finally, during the *eighth step*, the proteins and the new RNA are assembled into new HIV viruses and released from the cell.

Viral Latency and Activation. In some CD4⁺ T cells, the infection enters a latent phase that serves as a reservoir from which the virus can continue to be released for several years. In other CD4⁺ T cells, the virus replicates, killing the cell and releasing copies of HIV into the bloodstream. These viral particles, or virions, invade other CD4+ T cells, allowing the infection to progress. Initially, the infected cells are replaced and the viral particles destroyed. However, with time the CD4+ T-cell count gradually decreases and the viral count detected in the blood increases. The initiation of viral replication in latent HIV infection is critically dependent on host proteins and transcription factors that are present during T-cell activation. These factors may be activated by proteins produced by other viruses known to affect persons with AIDS, such as herpes viruses, Epstein-Barr virus, adenovirus, and cytomegalovirus.² Thus, activation of the immune system by a variety of infectious agents may promote HIV replication.

Until the CD4⁺ T-cell count falls to a very low level, infected persons can remain symptom free, although there is active viral replication, and serologic tests can identify antibodies to HIV. Unfortunately, these antibodies do not convey protection against the virus. Although symptoms are not evident, the infection proceeds on a microbiologic level, including the invasion and selective destruction of CD4⁺ T cells. The continual decline of CD4⁺ T cells, which are pivotal cells in the immune response, strips the person with AIDS of protection against common organisms and cancerous cells.

Diagnosis and Classification

Diagnosis. The most accurate and inexpensive method for identifying HIV is the HIV antibody test. The first commercial assays for HIV were introduced in 1985 to screen donated blood. Since then, the use of antibody detection tests has been expanded to include evaluating persons at increased risk for HIV infection. The HIV antibody test procedure consists of screening with an *enzyme immunoassay* (*EIA*), also known as *enzyme-linked immunosorbent assay* (*ELISA*), followed by a confirmatory test, the *Western blot* assay, which is performed if the

EIA is positive.²⁸ The EIA is based on the reaction of antibodies to HIV in the blood sample with viral proteins in the test material. The Western blot is a more sensitive assay that looks for the presence of antibodies to specific viral antigens.

Polymerase chain reaction (PCR) is a technique for detecting HIV DNA. PCR detects the presence of the virus, rather than the antibody to the virus, which the EIA and Western blot tests detect.¹⁷ PCR is useful in diagnosing HIV infection in infants born to infected mothers because these infants have their mothers' HIV antibody, regardless of whether the children are infected.

Classification. Effective January 1, 1993, the United States Centers for Disease Control implemented a new classification system for HIV infection identifying two categories: one based on laboratory tests and the other on clinical manifestations²⁹ (Fig. 10-7). The classification system defines three laboratory test categories that correspond to CD4⁺ cell counts per micro-liter (μ L) of blood: *category 1:* >500 cells/ μ L, *category 2:* 200 to 499 cells/ μ L, and *category 3:* <200 cells/ μ L.

The clinical manifestations are also divided into three categories. *Clinical category A* includes persons who have no symptoms or have persistent generalized lymphadenopathy or symptoms of primary HIV infection (*i.e.*, acute seroconversion illness). *Clinical category B* includes persons with symptoms of immune deficiency not serious enough to be AIDS defining. *Clinical category C* includes AIDS-defining illnesses that are listed in the AIDS surveillance case definition shown in Chart 10-2. Each HIV-infected person has a CD4⁺ T-cell category and a clinical category. The combination of laboratory and clinical categorizations can guide clinical and therapeutic actions in the management of HIV infection. According to the 1993 case definition, persons in laboratory category 3 or clinical category C are considered to have AIDS.

Clinical Course

The typical course of HIV is defined by three phases, which usually occur during a period of 8 to 12 years. The three stages are the primary infection or the acute clinical syndrome,

AIDS-defining clinical category	Category A No AIDS- defining symptoms			
	Category B Symptoms not severe enough to be AIDS defining			
	Category C AIDS-defining illnesses present			
		Category 1 >500 cells u/L	Category 2 200–499 cells u/L	Category 3 <200 cells u/L

CD4⁺ count category

■ FIGURE 10-7 ■ CD4⁺ category and clinical category.

CHART 10-2 Conditions Included in the 1993 AIDS Surveillance Case Definition

Candidiasis of bronchi, trachea, or lungs
Candidiasis, esophageal
Cervical cancer, invasive*
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV-related
Herpes simplex: chronic ulcer(s) (>1 month's duration) or
bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi's sarcoma
Lymphoma, Burkitt's (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium-intracellulare complex or M. kansasii,
disseminated or extrapulmonary
Mycobacterium tuberculosis, any site (pulmonary* or
extrapulmonary)
Mycobacterium, other species or unidentified species,
disseminated or extrapulmonary
Pneumocystis carinii pneumonia
Pneumonia, recurrent*
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome due to HIV
*Added to the 1993 expansion of the AIDS surveillance case definition.

chronic asymptomatic phase or latency, and overt AIDS³⁰ (Fig. 10-8).

Many persons, when they are initially infected with HIV, have an acute mononucleosis-like syndrome known as primary infection. This acute phase may include fever, fatigue, myalgias, sore throat, night sweats, gastrointestinal problems, lymphadenopathy, maculopapular rash, and headache³⁰ (Chart 10-3). During this time, there is an increase in viral replication, which leads to very high viral loads, sometime greater than 1,000,000 copies/mL, and a decrease in the CD4⁺ count. The signs and symptoms of primary HIV infection usually appear 2 to 4 weeks after exposure to HIV and last for a few days to 2 weeks.³⁰ After several weeks, the immune system acts to control viral replication and reduces it to a lower level, where it remains for several years.

The primary phase is followed by a latent period during which the person has no signs or symptoms of illness. The median time of the latent period is 10 years. During this time, the CD4⁺ count falls gradually from the normal range (800 to 1000 cells/ μ L) to 200 cells/ μ L or lower.³⁰ Lymphadenopathy

develops in some persons with HIV infection during this phase. Persistent generalized lymphadenopathy usually is defined as lymph nodes that are chronically swollen for more than 3 months in at least two locations, not including the groin. The lymph nodes may be sore or visible externally.

The third phase, overt AIDS, occurs when a person has a CD4⁺ count of less than 200 cells/ μ L or an AIDS-defining illness. Without antiretroviral therapy, this phase leads to death within 2 to 3 years. The risk of death and opportunistic infection increases significantly when the CD4⁺ count reaches this level.³⁰

The clinical course of HIV varies from person to person. Most (60% to 70%) of those infected with HIV acquire AIDS 10 to 11 years after infection. These people are the *typical progressors*.³⁰ Another 10% to 20% of those infected experience more rapid progression. They acquire AIDS in less than 5 years and are called *rapid progressors*. The final 5% to 15% are *slow progressors*, who do not experience progression to AIDS for more than 15 years. There is a subset of slow progressors, called *longterm nonprogressors*, who account for 1% of all HIV infections. These people have been infected for at least 8 years, are anti-

retroviral naive, have high CD4⁺ counts, and usually have very low viral loads. $^{\rm 30}$

Opportunistic Infections

When the immune system becomes severely compromised, an opportunistic infection or malignancy may occur. The number of CD4⁺ T cells directly correlates with the risk of developing opportunistic infections. The risk of opportunistic infections increases greatly once the CD4⁺ count drops to less than 200 cells/ μ L.³¹ Opportunistic infections involve common organisms that normally do not produce infection unless there is impaired immune function. Although a person with AIDS may live for many years after the first serious illness, as the immune system fails, these opportunistic illnesses become progressively more severe and difficult to treat.

In the United States, the most common opportunistic infections are *Pneumocystis carinii* pneumonia (PCP), oropharyngeal or esophageal candidiasis (thrush), cytomegalovirus (CMV), and respiratory infections caused by *Mycobacterium avium-intracellulare complex* (MAC).³¹

Respiratory Infections. The most common causes of respiratory disease in persons with HIV infection are PCP and pulmonary tuberculosis (TB). Other organisms that cause opportunistic pulmonary infections in persons with AIDS include CMV, MAC, *Toxoplasma gondii*, and *Cryptococcus neoformans*. Pneumonia also may occur because of more common pulmonary pathogens, including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Legionella pneumophila*. Some persons may be infected with multiple organisms. Kaposi's sarcoma (KS) also can occur in the lungs.

P. carinii pneumonia was the most common presenting manifestation of AIDS during the first decade of the epidemic. Since highly active antiretroviral therapy (HAART) and prophylaxis for PCP were instituted, the incidence has decreased.³² PCP still is common in people who do not know their HIV status, those who choose not to treat their HIV, and in those with poor access to health care. The best predictor of PCP is a CD4⁺ T-cell count of less than 200 cells/µL, and it is at this point that prophylaxis with trimethoprim-sulfamethoxazole

186 Unit Two: Alterations in Body Defenses

is started. PCP is caused by *P. carinii*, an organism that is common in soil, houses, and many other places in the environment. Although *P. carinii* does not cause infection in persons with healthy immune systems, it can multiply quickly in the lungs of persons with AIDS and cause pneumonia. The symptoms of PCP may be acute or gradually progressive. The person may present with mild cough, fever, shortness of breath, and weight loss. Physical examination may demonstrate only fever and tachypnea, and breath sounds may be normal. As the disease progresses, the alveoli become filled with foamy protein-rich fluid, causing impairment of gas exchange (Fig. 10-9). Diagnosis of PCP is made on recognition of the organism in pulmonary secretions. This can be done through examination of induced sputum, bronchoalveolar lavage, occasionally bronchoscopy, and rarely, lung biopsy.

Tuberculosis is the leading cause of death for people with HIV worldwide. There are more than 80,000 people coinfected with HIV and TB in North America and another 5 million in the rest of the world.³³

Although the lungs are the most common site of *M. tuber-culosis* infection, extrapulmonary infections of the kidney, bone marrow, and other organs also occur in people with HIV. Whether a person has pulmonary or extrapulmonary TB, most patients present with fever, night sweats, cough, and weight loss.³³ Persons infected with *M. tuberculosis* (*i.e.*, those with positive tuberculin skin tests) are more likely to have reactivated TB develop if they become infected with HIV; if they are coinfected, they are more likely to have a rapidly progressive form of TB.³³ Equally important, HIV-infected persons with TB coinfection usually have an increase in viral load, which decreases the success of TB therapy. They also have an increased number of other opportunistic infections and an increased mortality rate.³³

Since the late 1960s, most persons with TB have experienced good response to therapy. However, in 1991, there were outbreaks of multidrug-resistant (MDR) TB. Many cases of drug-resistant TB occur in HIV-infected persons.

Gastrointestinal Infections. Infections of the gastrointestinal tract are some of the most common complications of HIV and

AIDS. Esophageal candidiasis (thrush), CMV infection, and herpes simplex virus infection are common opportunistic infections that cause esophagitis in people with HIV. Persons experiencing these infections usually report painful swallowing or retrosternal pain. The clinical presentation can range from no symptoms to a complete inability to swallow and dehydration.

Diarrhea or gastroenteritis is common in persons with HIV. The most common protozoal infection that causes diarrhea is *Cryptosporidium parvum*. The clinical features of cryptosporidiosis can range from mild diarrhea to severe, watery diarrhea with a loss of as much as several liters of water per day. The most severe form usually occurs in persons with a CD4⁺ count of less than 50 cells/µL, and also can include malabsorption, electrolyte disturbances, dehydration, and weight loss.³⁴ Other organisms that cause gastroenteritis and diarrhea are *Salmonella*, CMV, *Clostridium difficile*, *Escherichia coli*, *Shigella*, *Giardia*, and Microsporida.

Nervous System Manifestations. HIV infection, particularly in its late stages of severe immunocompromise, leaves the nervous system vulnerable to an array of neurologic disorders, including AIDS dementia complex (ADC), toxoplasmosis, and progressive multifocal leukoencephalopathy (PML). These disorders can affect the peripheral (PNS) or central nervous system (CNS) and contribute to the morbidity and mortality of persons with HIV.³⁵

AIDS dementia complex is a syndrome of cognitive and motor dysfunction. ADC is caused by HIV itself, rather than an opportunistic infection, and usually is a late complication of HIV. The clinical features of ADC are impairment of attention and concentration, slowing of mental speed and agility, slowing of motor speed, and apathetic behavior. The diagnosis of ADC can be based on these clinical findings.

Toxoplasmosis is a common opportunistic infection in persons with AIDS. The organism responsible, *T. gondii*, is a parasite that most often affects the CNS. Toxoplasmosis usually is a reactivation of a latent *T. gondii* infection that has been dormant in the CNS.³⁶ The typical presentation includes fever, headaches, and neurologic dysfunction, including confusion

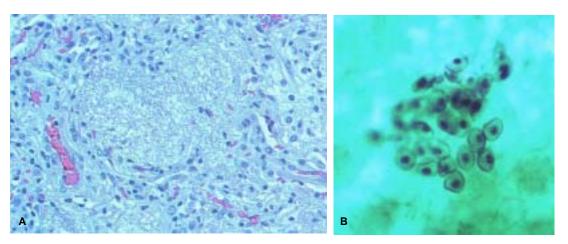

FIGURE 10-9 *Pneumocystis carinii* pneumonia. (**A**) The alveoli are filled with a foamy exudate, and the interstitium is thickened and contains a chronic inflammatory infiltrate. (**B**) A centrifuged bronchoalveolar lavage specimen impregnated with silver shows a cluster of *Pneumocystis carinii* cysts. (From Rubin E., Farber J.L. [1994]. *Pathology* [2nd ed.]. Philadelphia: J.B. Lippincott)

and lethargy, visual disturbances, and seizures. Computed tomography scans or magnetic resonance imaging (MRI) should be performed immediately to detect the presence of neurologic lesions. Prophylactic treatment with trimethoprimsulfamethoxazole is effective against *T. gondii* when the CD4⁺ T-cell count decreases to less than 200 cells/µL.

Progressive multifocal leukoencephalopathy is a demyelinating disease of the white matter of the brain caused by the JC virus, a DNA papovavirus that attacks the oligodendrocytes. PML advances slowly, and it can be weeks to months before the person seeks medical care.³⁷ It is characterized by progressive limb weakness, sensory loss, difficulty controlling the digits, visual disturbances, subtle alterations in mental status, hemiparesis, ataxia, diplopia, and seizures. Diagnosis is based on clinical findings and an MRI, and confirmed by the presence of the JC virus. The mortality rate is high, and the average survival time is 2 to 4 months.³⁷

Cancers and Malignancies

Persons with AIDS have a high incidence of certain malignancies, especially Kaposi's sarcoma (KS), non-Hodgkin's lymphoma, and noninvasive cervical carcinoma. The increased incidence of malignancies probably is a function of impaired cell-mediated immunity. Non-Hodgkin's lymphoma develops in 3% to 4% of people with HIV infection (see Chapter 11). Women with HIV infection experience a higher incidence of *cervical dysplasia* than do women without HIV infection.³⁸ Cervical dysplasia, which usually results from infection with a human papillomavirus, is a slowly developing precursor to cervical carcinoma (see Chapter 34). In women with HIV infection this progression is much more rapid.³⁸

Kaposi's Sarcoma. Kaposi's sarcoma is a malignancy of endothelial cells that line small blood vessels. An opportunistic cancer, KS occurs in immunosuppressed persons (e.g., transplant recipients or persons with AIDS). KS was one of the first opportunistic cancers associated with AIDS and still is the malignancy most frequently related to HIV.³⁹

The lesions of KS can be found on the skin and in the oral cavity, gastrointestinal tract, and lungs. More than 50% of people with skin lesions also have gastrointestinal lesions. The disease usually begins as one or more macules, papules, or violet skin lesions that enlarge and become darker (Fig. 10-10). They may enlarge to form raised plaques or tumors. These irregularly shaped tumors can be from one eighth of an inch to silver dollar size. Tumor nodules frequently are located on the head, neck, and trunk. They usually are painless in the early stages, but discomfort may develop as the tumor ages. Invasion to the internal organs, including the lungs, gastrointestinal tract, and lymphatic system, commonly occurs. Gastrointestinal tract KS often is asymptomatic but can cause pain, bleeding, or obstruction. Pulmonary KS usually is a late development of the disease. Pulmonary KS causes dyspnea, cough, and hemoptysis. The progression of KS may be slow or rapid.

A presumptive diagnosis of KS usually is made based on visual identification of red or violet skin or oral lesions. Biopsy of at least one lesion must be done to establish the diagnosis and to distinguish the KS from other skin lesions that may resemble it. Effective HAART, local therapy with liquid nitrogen or vinblastine, chemotherapy, radiation, and interferon injections are the most common therapies. These therapies are largely palliative and are not a cure.

■ FIGURE 10-10 ■ Disseminated Kaposi's sarcoma. Multiple red to brown papules distributed along the skin lines in a man with AIDS. (Hall J.C. [2000] *Sauer's manual of skin* [p.197]. Philadelphia: Lippincott Williams & Wilkins.)

There is recent evidence linking KS to a herpesvirus (herpesvirus 8, also called KS-associated herpesvirus [KSHV]).⁴⁰ More than 95% of KS lesions, regardless of the source or clinical subtype, have reportedly been found to be infected with KSHV. The virus is readily transmitted through homosexual and heterosexual activities. Maternal–infant transmission also occurs. The virus has been detected in saliva from infected persons, and other modes of transmission are suspected.

Wasting Syndrome

In 1997, wasting became an AIDS-defining illness. The syndrome is common in persons with HIV infection or AIDS. Wasting is characterized by involuntary weight loss of at least 10% of baseline body weight in the presence of diarrhea, more than two stools per day, or chronic weakness and a fever. This diagnosis is made when no other opportunistic infections or neoplasms can be identified as causing these symptoms. Factors that contribute to wasting are anorexia, metabolic abnormalities, endocrine dysfunction, malabsorption, and cytokine dysregulation. Treatment for wasting includes nutritional interventions such as oral supplements, or enteral or parenteral nutrition. There also are numerous pharmacologic agents used to treat wasting, including appetite stimulants, cannabinoids, and megestrol acetate.⁴¹

Metabolic Disorders

A wide range of metabolic disorders is associated with HIV infection, including lipodystrophy and mitochondrial disorders.

Lipodystrophy. A metabolic disorder called *lipodystrophy* is one of the newest group of problems for those infected with HIV. The symptoms of HIV-associated lipodystrophy fall into two categories: changes in body appearance and metabolic changes. The alterations in body appearance include an increase in abdominal girth, abnormal distribution of fat in the supraclavicular area (*i.e., buffalo hump*), wasting of fat from the face and

extremities, and breast enlargement in men and women. The metabolic changes include elevated serum cholesterol and triglyceride levels and insulin resistance. Originally attributed to the use of protease inhibitors, the pathogenesis of lipodystrophy still is not understood. It may be caused by protease inhibitor therapy or nucleoside reverse transcriptase inhibitor therapy, or may arise simply because people are living longer with HIV.

The diagnosis of lipodystrophy is based on appearance changes, elevated serum levels of triglycerides and cholesterol, and observed changes in body shape (measured changes in waist and hip girth).⁴² The management of lipodystrophy is a matter of controversy because the etiology is unknown. Some authorities recommend switching to a nonprotease inhibitor-based HAART regimen. The problem with this approach is that, although serum levels of triglycerides and cholesterol decrease and there may be some resolution of the fat redistribution, the viral load often increases and becomes detectable.⁴³

Mitochondrial Disorders. Mitochondrial disorders are metabolic disorders caused by antiretroviral therapy, in particular, the nucleoside reverse transcriptase inhibitors.⁴² The mitochondria control many of the oxidative chemical reactions that release energy from glucose and other organic molecules. In the absence of normal mitochondrial function, cells revert to anaerobic metabolism with generation of lactic acid. Patients often present with nonspecific gastrointestinal symptoms, including nausea, vomiting, and abdominal pain. On examination, they can have hepatomegaly with normal liver function tests. The only laboratory abnormality may be lactic acidosis.⁴² Mitochondrial dysfunction is the most feared complication of antiretroviral therapy. This fear is caused by the condition's unpredictability, its fatality in half the presenting patients, the nonspecific presenting symptoms, and the prevalence of elevated lactate levels in 8% to 22% of patients who have no symptoms.⁴²

Treatment

There is no cure for AIDS. Although many companies are working on a vaccine to prevent HIV infection, none has been approved. There currently are three different types of HIV antiretroviral medications: nucleoside reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, and protease inhibitors.⁴⁴ Each type of agent attempts to interrupt viral replication at a different point.

Reverse transcriptase inhibitors inhibit HIV replication by acting on the enzyme reverse transcriptase. There are two types of HIV medications that work on this enzyme: nucleoside reverse transcriptase inhibitors and non-nucleoside reverse transcriptase inhibitors. *Nucleoside reverse transcriptase inhibitors* act by blocking the elongation of the DNA chain by stopping more nucleosides from being added. *Non-nucleoside reverse transcriptase inhibitors* work by binding to the reverse transcriptase enzyme so it cannot copy the virus's RNA into DNA. *Protease inhibitors* bind to the protease enzyme and inhibit its action. This inhibition prevents the cleavage of the polyprotein chain into individual proteins, which would be used to construct the new virus. Because the information inside the nucleus is not put together properly, the new viruses that are released into the body are immature and noninfectious.

The treatment of HIV is one of the most rapidly evolving fields in medicine. Optimal treatment of HIV includes a com-

bination of drugs because different drugs act on different stages of the replication cycle. The goal of HAART, using a combination of antiviral drugs, is a sustained suppression of HIV replication, resulting in an undetectable viral load and an increasing CD4⁺ count. In general, antiviral therapies are prescribed to improve the overall survival time of persons with HIV infection and to slow the progression to AIDS.

Drugs and vaccines commonly are used for the prevention and treatment of opportunistic infections and conditions, including PCP, toxoplasmosis, MAC, candidiasis, CMV infection, influenza, hepatitis B, and *S. pneumoniae* infections. Prophylactic medications are used once an individual's CD4⁺ count has dropped below a certain level that indicates his or her immune system is no longer able to fight off the opportunistic infections.

Persons with HIV should be advised to avoid infections as much as possible and seek evaluation promptly when they occur. Immunization is important because persons infected with HIV are at risk for contracting many infectious diseases. Some of these diseases can be avoided by vaccination while the immune system's responsiveness is relatively intact.

Infection in Pregnancy and in Infants and Children

Early in the epidemic, children who contracted HIV could have become infected through blood products or perinatally. Now, almost all of the children who become infected with HIV at a young age in the United States get HIV perinatally. Infected women may transmit the virus to their offspring in utero, during labor and delivery, or through breast milk.⁴⁵ The risk of transmission is increased if the mother has advanced HIV disease as evidenced by low CD4⁺ counts, high levels of HIV in the blood (high viral load); if the time from the rupture of membranes to delivery is prolonged; if there is increased exposure of the fetus to maternal blood; or if the mother breast-feeds the child.²⁵

Diagnosis of HIV infection in children born to HIVinfected mothers is complicated by the presence of maternal HIV IgG antibody, which crosses the placenta to the fetus. Consequently, infants born to HIV-infected women can be HIV antibody positive by ELISA for as long as 18 months, even though they are not HIV infected.²⁵ PCR testing for HIV DNA is used most often to diagnose HIV in infants younger than 18 months. Two positive PCR tests for HIV DNA are needed to diagnose HIV in a child. Children born to mothers with HIV infection are considered uninfected if they become HIV antibody negative after 6 months of age, have no other laboratory evidence of HIV infection, and have not met the surveillance case definition criteria for AIDS in children.²⁵

Perinatal transmission can be lowered by approximately two thirds by administering zidovudine to the mother during pregnancy and labor and delivery and to the infant when it is born.⁴⁵ Thus, the U.S. Public Health Service recommends that HIV counseling and testing should be offered to all pregnant women and women of childbearing age in the United States.⁴⁵ The recommendations also stress that women who test positive for HIV antibodies should be informed of the perinatal prevention benefits of zidovudine therapy and offered treatment that includes zidovudine alone, or HAART therapy. The benefits of voluntary testing for mothers and newborns include reduced morbidity because of intensive treatment and supportive health care, the opportunity for early antiviral therapy for mother and child, and information regarding the risk of transmission from breast milk.45

Because pregnant women in less developed countries do not always have access to zidovudine, studies are being conducted in Africa to determine if any other simple and less expensive antiretroviral regimen can be used to decrease the transmission from mother to infant.

Children have a very different pattern of HIV infection than do adults. Failure to thrive, CNS abnormalities, and developmental delays are the most prominent primary manifestations of HIV infection in children.²⁸ Children born infected with HIV usually weigh less and are shorter than noninfected infants. A major cause of early mortality for HIV-infected children is PCP. As opposed to adults, in whom PCP occurs in the late stages, children experience PCP early, with the peak age of onset at 3 to 6 months. For this reason, prophylaxis with trimethoprimsulfamethoxazole is started by 4 to 6 weeks for all infants born to HIV-infected mothers, regardless of their CD4+ count or infection status.46

In summary, an immunodeficiency is defined as an absolute or partial loss of the normal immune response, which places a person in a state of compromise and increases the risk for development of infections or malignant complications. Any components of the immune response, including antibody or humoral (B-cell) immunity or cellular or T-cell immunity, may contribute to immunodeficiencies. The variety of defects known to involve the immune response can be classified as primary (i.e., endogenous or inherited) or secondary (*i.e.*, caused by exogenous factors such as drugs or infection).

Most primary immunodeficiency states are inherited and are either present at birth or become apparent shortly after birth. Primary immunodeficiencies can be categorized into three types: humoral (B-cell) immunodeficiencies, cellular (T-cell) immunodeficiencies, and combined (B-cell and T-cell) immunodeficiencies. B-cell immunodeficiencies can selectively affect a single type of immunoglobulin (e.g., IgA immunodeficiency) or all of the immunoglobulins. Defects in B-cell function increase the risk of recurrent pyogenic infections, including those caused by Streptococcus pneumoniae, Haemophilus influenzae, and Staphylococcus aureus, and by gram-negative organisms such as Pseudomonas species. There are few primary forms of T-cell immunodeficiency, probably because persons with defects in this branch of the immune response rarely survive beyond infancy or childhood. Combined immunodeficiency disorders involve both B-cell and T-cell dysfunction and include a spectrum of inherited (autosomal recessive and X-linked) conditions. The spectrum of disease resulting from combined immunodeficiency ranges from mild to severe to ultimately fatal forms.

AIDS is the most common type of secondary immunodeficiency. AIDS is an infectious disease of the immune system caused by the retrovirus HIV. The disease is prevalent worldwide and is one of the leading causes of death among young adults in the United States. HIV is transmitted from one person to another through sexual contact, through blood exchange, or perinatally. HIV is a retrovirus that infects the

body's CD4⁺ T cells and macrophages. The destruction of CD4⁺ T cells by HIV constitutes an attack on the entire immune system because this subset of lymphocytes exerts critical regulatory and effector functions that involve both humoral and cellular immunity.

Manifestations of infection, such as acute mononucleosislike symptoms, may occur shortly after infection, and this is followed by a latent phase that may last for many years. The end of the latent period is characterized by the marked decrease in CD4⁺ T cells and the development of opportunistic infections, cancers, and other disorders as the person moves toward an AIDS diagnosis. The complications of these infections, manifested throughout the respiratory, gastrointestinal, and nervous systems, include pneumonia, esophagitis, diarrhea, gastroenteritis, tumors, wasting syndrome, altered mental status, seizures, motor deficits, and metabolic disorders. There is no cure for AIDS. Treatment largely involves the use of drugs that interrupt the replication of the HIV virus and prevention or treatment of complications such as opportunistic infections.

Infected women may transmit the virus to their offspring in utero, during labor and delivery, or through breast milk. Diagnosis of HIV infection in children born to HIV-infected mothers is complicated by the presence of maternal HIV antibody, which crosses the placenta to the fetus. This antibody usually disappears within 18 months in uninfected children. The administration of zidovudine to the mother during pregnancy and labor and delivery and to the infant after birth can decrease perinatal transmission.

REVIEW QUESTIONS

Describe the immune mechanisms involved in a type I, type II, type III, and type IV hypersensitivity reaction and use these mechanisms to describe the pathogenesis of allergic rhinitis, food allergy, serum sickness, contact dermatitis, and hypersensitivity pneumonitis.

Compare the immune mechanisms involved in host-versusgraft and graft-versus-host transplant rejection.

Relate the mechanisms of self-tolerance to the possible explanations for development of autoimmune disease.

Describe three or more postulated mechanisms underlying autoimmune disease.

Compare and contrast immunodeficiency disorders caused by B-cell, T-cell, and combined B- and T-cell disorders.

Explain why the attack by the HIV virus on the CD4⁺ cell is so devastating in terms of the function of the immune system.

Explain why it is not possible to state with certainty that a person with a positive ELISA antibody test for HIV does in fact have the disease and needs to be retested using the Western blot test.

Relate the altered immune function in persons with HIV infection and AIDS to the development of opportunistic infections.

Discuss the vertical transmission of HIV from mother to child and explain why the HIV test might be positive even the infant does not have the virus.

he white blood cells and lymphoid tissues where these cells originate and mature function to protect the body against invasion by foreign agents. Disorders of the white blood cells include a deficiency of leukocytes (leukopenia) or increased numbers as occurs with proliferative disorders. The proliferative disorders may be reactive, such as occurs with infection, or neoplastic, such as occurs with leukemias and lymphomas.

HEMATOPOIETIC AND LYMPHOID TISSUE

Blood consists of blood cells (*i.e.*, white blood cells, thrombocytes or platelets [see Chapter 12], and red blood cells [see Chapter 13]) and the plasma in which the cells are suspended. The generation of blood cells takes place in the *hematopoietic* (from the Greek *haima* for "blood" and *poiesis* for "making") system.¹ The hematopoietic system encompasses all of the blood cells and their precursors, the bone marrow where blood cells have their origin, and the lymphoid tissues where some blood cells circulate as they develop and mature.

Leukocytes (White Blood Cells)

The leukocytes, or white blood cells, constitute only 1% of the total blood volume. They originate in the bone marrow and circulate throughout the lymphoid tissues of the body. There they function in the inflammatory and immune processes. They include the granulocytes, the lymphocytes, and the monocytes (Fig. 11-1).

Granulocytes

192

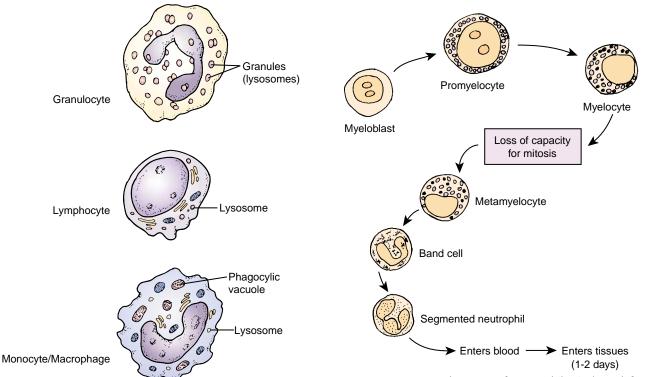

The granulocytes are all phagocytic cells and are identifiable because of their cytoplasmic granules. These white blood cells are spherical and have distinctive multilobar nuclei. The granulocytes are divided into three types (neutrophils, eosinophils, and basophils) according to the staining properties of the granules.

Neutrophils. The neutrophils, which constitute 55% to 65% of the total number of white blood cells, have granules that are neutral and thus do not stain with an acidic or a basic dye. Because their nuclei are divided into three to five lobes, they are often called polymorphonuclear leukocytes (PMNs).

The neutrophils are primarily responsible for maintaining normal host defenses against invading bacteria, fungi, products of cell destruction, and a variety of foreign substances. The cytoplasm of mature neutrophils contains fine granules. These granules contain degrading enzymes that are used in destroying foreign substances and correspond to lysosomes found in other cells. Enzymes and oxidizing agents associated with these granules are capable of degrading a variety of natural and synthetic substances, including complex polysaccharides, proteins, and lipids. The degradative functions of the neutrophil are important in maintaining normal host defenses and in mediating the inflammatory response (see Chapter 9).

The neutrophils have their origin in the myeloblasts that are found in the bone marrow (Fig. 11-2). The myeloblasts are the committed precursors of the granulocyte pathway and do not normally appear in the peripheral circulation. When they are present, it suggests a disorder of blood cell proliferation and differentiation. The myeloblasts differentiate into promyelocytes and then myelocytes. Generally, a cell is not called a myelocyte until it has at least 12 granules. The myelocytes mature to become metamyelocytes (Greek meta for "beyond"), at which point they lose their capacity for mitosis. Subsequent development of the neutrophil involves reduction in size, with transformation from an indented to an oval to a horseshoeshaped nucleus (i.e., band cell) and then to a mature cell with a segmented nucleus. Mature neutrophils are often referred to as segs because of their segmented nucleus. The development from stem cell to mature neutrophil takes about 2 weeks. It is at this point that the neutrophil enters the bloodstream.

After release from the marrow, the neutrophils spend only about 4 to 8 hours in the circulation before moving into the tissues.² Their survival in the tissues lasts about 4 to 5 days. They die in the tissues while discharging their phagocytic function or die of senescence. The pool of circulating neutrophils (*i.e.*, those that appear in the blood count) is in rapid equilibrium with a similar-sized pool of cells marginating along the

■ **FIGURE 11-1** White blood cells—granulocyte, lymphocyte, and monocyte.

■ FIGURE 11-2 ■ Development of neutrophils. (Adapted from Cormack D.H. [1993]. *Ham's histology* [9th ed.]. Philadelphia: J.B. Lippincott)

walls of small blood vessels. These are the neutrophils that respond to chemotactic factors and migrate into the tissues toward the offending agent during an inflammatory response. Epinephrine, exercise, stress, and corticosteroid drug therapy can cause rapid increases in the circulating neutrophil count by shifting cells from the marginating to the circulating pool. Endotoxins or microbes may have the opposite effect, by attracting neutrophils to move out of the circulation and into the tissues.

Eosinophils. The cytoplasmic granules of the eosinophils stain red with the acidic dye eosin. These leukocytes constitute 1% to 3% of the total number of white blood cells and increase in number during allergic reactions. They are thought to release enzymes or chemical mediators that detoxify agents associated with allergic reactions. Eosinophils are also involved in parasitic infections. Although most parasites are too large to be phagocytized by eosinophils, the eosinophils attach themselves to the parasite by special surface molecules and release hydrolytic enzymes and other substances from their granules that kill the parasite.

Basophils. The granules of the basophils stain blue with a basic dye. These cells constitute only about 0.3% to 0.5% of the white blood cells. The basophils in the circulating blood are similar to the large mast cells located immediately outside the capillaries in body tissues. Both the basophils and mast cells release heparin, an anticoagulant, into the blood. The mast cells and basophils also release histamine, a vasodilator, and other inflammatory mediators. The mast cells and basophils play an exceedingly important role in allergic reactions (see Chapter 10).

Lymphocytes

The lymphocytes have their origin in the lymphoid stem cells that are found in the bone marrow. The lymphocytes constitute 20% to 30% of the white blood cell count. They have no identifiable granules in the cytoplasm and are sometimes referred to as *agranulocytes*. They move between blood and lymphoid tissues, where they may be stored for hours or years. Their function in the lymph nodes or spleen is to defend against foreign microbes in the immune response (see Chapter 8). There are two types of lymphocytes: B lymphocytes and T lymphocytes. The lymphocytes play an important role in the immune response. The B lymphocytes differentiate to form antibodyproducing plasma cells and are involved in humoral-mediated immunity. The T lymphocytes are responsible for orchestrating the immune response (CD4⁺ T cells) and effecting cellmediated immunity (CD8⁺ T cells).

Monocytes and Macrophages

Monocytes are the largest of the white blood cells and constitute about 3% to 8% of the total leukocyte count. They have abundant cytoplasm and a darkly stained nucleus, which has a distinctive U or kidney shape. The circulating life span of the monocyte is about 1 to 3 days, three to four times longer than that of the granulocytes. These cells survive for months to years in the tissues. The monocytes, which are phagocytic cells, are often referred to as *macrophages* when they enter the tissues. The monocytes engulf larger and greater quantities of foreign material than do the neutrophils. These leukocytes play an important role in chronic inflammation and are also involved in the immune response by activating lymphocytes and by presenting antigen to T cells. When the monocyte leaves the vascular system and enters the tissues, it functions as a macrophage with specific activity. The macrophages are known as histiocytes in loose connective tissue, *microglial cells* in the brain, and *Kupffer's cells* in the liver.

The Bone Marrow and Hematopoiesis

The blood-forming population of bone marrow is made up of three types of cells: self-renewing stem cells, differentiated progenitor (parent) cells, and functional mature blood cells. All of the blood cell precursors of the erythrocyte (*i.e.*, red cell), myelocyte (*i.e.*, granulocyte or monocyte), lymphocyte (*i.e.*, platelet) series are derived from a small population of primitive cells called the pluripotent stem cells (Fig. 11-3). Their lifelong potential for proliferation and self-renewal makes them an indispensable and lifesaving source of reserve cells for the entire hematopoietic system.

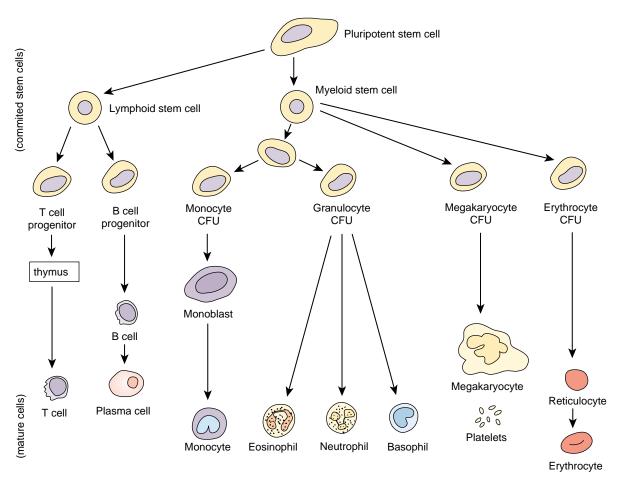

Several levels of differentiation lead to the development of committed stem cells, which are the progenitor for each of the blood cell types. A committed stem cell that forms a specific type of blood cell is called a *colony-forming unit* (CFU). Under normal conditions, the numbers and total mass for each type of circulating blood cell remain relatively constant. The blood cells are produced in different numbers according to needs and regulatory factors. This regulation of blood cells is controlled by a group of short-acting soluble mediators, called *cytokines*, that stimulate the proliferation, differentiation, and functional activation of the various blood cell precursors in bone marrow.³ The cytokines that stimulate hematopoiesis are called colony-stimulating factors (CSFs), based on their ability to promote the growth of the hematopoietic cell colonies from bone marrow precursors. Lineage-specific CSFs that act on committed progenitor cells include: erythropoietin (EPO), granulocyte-monocyte colony-stimulating factor (GM-CSF), and thrombopoietin (TPO). The major sources of the CSFs are lymphocytes and stromal cells of the bone marrow. Other cytokines, such as the interleukins, support the development of lymphocytes and act synergistically to aid the functions of the CSFs (see Chapter 8).

Lymphoid Tissues

The lymphoid tissues represent the structures where lymphocytes originate, mature, and interact with antigens. Lymphoid tissues can be classified into two groups: the central or generative organs and peripheral lymphoid organs (see Chapter 8). The central lymphoid structures consist of the bone marrow, where all lymphocytes arise, and the thymus, where T cells mature and reach a stage of functional competence. The thymus is also the site where self-reactive T cells are eliminated.

The peripheral lymphoid organs are the sites where mature lymphocytes respond to foreign antigens. They include the lymph nodes, the spleen, mucosa-associated lymphoid tissues, and the cutaneous immune system. In addition, poorly defined aggregates of lymphocytes are found in connective tissues and virtually all organs of the body.

194 Unit Three: Alterations in the Hematologic System

■ FIGURE 11-3 ■ Major maturational stages of blood cells. CFU, colony-forming units.

KEY CONCEPTS

HEMATOPOIESIS

- White blood cells are formed partially in the bone marrow (granulocytes, monocytes, and some lymphocytes) and partially in the lymph system (lymphocytes and plasma cells).
- They are formed from hematopoietic stem cells that differentiate into committed progenitor cells that in turn develop into the myelogenous and lymphocytic lineages needed for the formation of the different types of white blood cell.
- The growth and reproduction of the different stem cells is controlled by CSFs and other cytokines and chemical mediators.
- The life span of white blood cells is relatively short so that constant renewal is necessary to maintain normal blood levels. Any conditions that decrease the availability of stem cells or hematopoietic growth factors produce a decrease in white blood cells.

In summary, the hematopoietic system consists of a number of cells derived from the pluripotent stem cells originating in the bone marrow. These cells differentiate into committed cell lines that mature in red blood cells, platelets, and a variety of white blood cells. The development of the different types of blood cells is supported by chemical messengers called colony-stimulating factors. The lymphoid tissues are found in the central lymphoid structures (bone marrow and thymus) where lymphocytes arise, mature, and where self-reactive lymphocytes are eliminated and the peripheral lymphoid structures (lymph nodes, spleen, mucosalassociated lymphoid tissue, and the cutaneous immune system) where lymphocytes respond to foreign antigens.

NON-NEOPLASTIC DISORDERS OF WHITE BLOOD CELLS

The number of leukocytes, or white blood cells, in the peripheral circulation normally ranges from 5000 to $10,000/\mu$ L of blood. The term *leukopenia* describes an absolute decrease in white blood cell numbers. The disorder may affect any of the

specific types of white blood cells, but most often it affects the neutrophils, which are the predominant type of granulocyte.

Neutropenia (Agranulocytosis)

Neutropenia refers specifically to a decrease in neutrophils. It commonly is defined as a circulating neutrophil count of less than 1500 cells/µL. Agranulocytosis, which denotes a severe neutropenia, is characterized by a circulating neutrophil count of less than 200 cells/µL.4

The reduction in granulocytes can occur because there is reduced or ineffective production of neutrophils or because there is excessive removal of neutrophils from the blood. The causes of neutropenia are summarized in Table 11-1.

Acquired Neutropenia

Granulopoiesis may be impaired by a variety of bone marrow disorders, such as aplastic anemia or bone marrow depression caused by cancer chemotherapy and irradiation, that interfere with the formation of all blood cells. Overgrowth of neoplastic cells in cases of nonmyelogenous leukemia and lymphoma also may suppress the function of neutrophil precursors. Infections by viruses or bacteria may drain neutrophils from the blood faster than they can be replaced, thereby depleting the neutrophil storage pool in the bone marrow.⁴ Because of the neutrophil's short life span of less than 1 day in the peripheral blood, neutropenia occurs rapidly when granulopoiesis is impaired. Under these conditions, neutropenia usually is accompanied by thrombocytopenia (*i.e.*, platelet deficiency).

In aplastic anemia, all of the myeloid stem cells are affected, resulting in anemia, thrombocytopenia, and agranulocytosis. Autoimmune disorders or idiosyncratic drug reactions may cause increased and premature destruction of neutrophils. In splenomegaly, neutrophils may be trapped in the spleen along with other blood cells. In Felty's syndrome, a variant of rheumatoid arthritis, there is increased destruction of neutrophils in the spleen.

Most cases of neutropenia are drug related. Chemotherapeutic drugs used in the treatment of cancer (e.g., alkylating agents, antimetabolites) cause predictable dose-dependent suppression of bone marrow function. The term idiosyncratic is used to describe drug reactions that are different from the effects obtained in most persons and that cannot be explained in terms of allergy. A number of drugs, such as chloramphenicol (an antibiotic), phenothiazine tranquilizers, sulfonamides, propylthiouracil (used in the treatment of hyperthyroidism), and phenylbutazone (used in the treatment of arthritis), may cause idiosyncratic depression of bone marrow function. Some drugs, such as hydantoin derivatives and primidone (used in the treatment of seizure disorders), can cause intramedullary destruction of granulocytes and thereby impair production. Many idiosyncratic cases of drug-induced neutropenia are thought to be caused by immunologic mechanisms, with the drug or its metabolites acting as antigens (i.e., haptens) to incite the production of antibodies reactive against the neutrophils. Neutrophils possess human leukocyte antigens (HLA) and other antigens specific to a given leukocyte line. Antibodies to these specific antigens have been identified in some cases of drug-induced neutropenia.4

8 **Congenital Neutropenia**

A decreased production of granulocytes is a feature of a group of hereditary hematologic disorders, including cyclic neutropenia and Kostmann's syndrome. Periodic or cyclic neutropenia is an autosomal dominant disorder with variable expression that begins in infancy and persists for decades. It is characterized by periodic neutropenia that develops every 21 to 30 days and lasts approximately 3 to 6 days. Although the cause is undetermined, it is thought to result from impaired feedback regulation of granulocyte production and release. Kostmann's syndrome, which occurs sporadically or as an autosomal recessive disorder, causes severe neutropenia while preserving the erythroid and megakaryocyte cell lineages that result in red blood cell and platelet production. The total white blood cell count may be within normal limits, but the neutrophil count is less than 200/µL. Monocyte and eosinophil levels may be elevated.

A transient neutropenia may occur in neonates whose mothers have hypertension. It usually lasts from 1 to 60 hours

TABLE 11-1 Causes of Neutropenia	
Cause	Mechanism
Accelerated removal (<i>e.g.,</i> inflammation and infection) Drug-induced granulocytopenia Defective production	Removal of neutrophils from the circulation exceeds production
Cytotoxic drugs used in cancer therapy Phenothiazine, thiouracil, chloramphenicol, phenylbutazone, and others	Predictable damage to precursor cells, usually dose dependent Idiosyncratic depression of bone marrow function
Hydantoinates, primidone, and others Immune destruction Aminopyrine and others	Intramedullary destruction of granulocytes Immunologic mechanisms with cytolysis or leukoagglutination
Periodic or cyclic neutropenia (occurs during infancy and later)	Unknown
Neoplasms involving bone marrow (e.g., leukemias and lymphomas)	Overgrowth of neoplastic cells, which crowd out granulopoietic precursors
Idiopathic neutropenia that occurs in the absence of other disease or provoking influence	Autoimmune reaction
Felty's syndrome	Intrasplenic destruction of neutrophils

but can persist for 3 to 30 days. This type of neutropenia, which is associated with increased risk of nosocomial infection, is thought to result from transiently reduced neutrophil production.⁴

Clinical Course

The clinical features of neutropenia usually depend on the severity of neutropenia and the cause of the disorder. Because the neutrophil is essential to the cellular phase of inflammation, infections are common in persons with neutropenia, and extreme caution is needed to protect them from exposure to infectious organisms. Infections that may go unnoticed in a person with a normal neutrophil count could prove fatal in a person with neutropenia. These infections commonly are caused by organisms that normally colonize the skin, vagina, and the gastrointestinal tract.

The signs and symptoms of neutropenia initially are those of bacterial or fungal infections. They include malaise, chills, and fever, followed by extreme weakness and fatigue. The white blood cell count often is reduced to $1000/\mu$ L and, in certain cases, may fall to 200 to $300/\mu$ L. The most frequent site of serious infection is the respiratory tract, a result of bacteria, fungi, and protozoa that frequently colonize the airways. Ulcerative necrotizing lesions of the mouth are common in neutropenia. Ulcerations of the skin, vagina, and gastrointestinal tract also may occur.⁴

Antibiotics are used to treat infections in those situations in which neutrophil destruction can be controlled or the neutropoietic function of the bone marrow can be recovered. Hematopoietic growth factors such as GM-CSF are being used more commonly to stimulate the maturation and differentiation of the polymorphonuclear cell lineage. Treatment with these biologic response modifiers has reduced the period of neutropenia and the risk for development of potentially fatal septicemia.^{4,5}

Infectious Mononucleosis

Infectious mononucleosis is a self-limiting lymphoproliferative disorder caused by the Epstein-Barr virus (EBV), a member of the herpesvirus family.^{6,7} EBV is commonly present in all human populations. Infectious mononucleosis is most prevalent in adolescents and young adults in the upper socioeconomic classes in developed countries. This is probably because the disease, which is relatively asymptomatic when it occurs during childhood, confers complete immunity to the virus. In families from upper socioeconomic classes, exposure to the virus may be delayed until late adolescence or early adulthood. In such persons, the mode of infection, size of the viral pool, and physiologic and immunologic condition of the host may determine whether the infection occurs.

Pathogenesis

Infectious mononucleosis is largely transmitted through oral contact with EBV-contaminated saliva. The virus initially penetrates the nasopharyngeal, oropharyngeal, and salivary epithelial cells. It then spreads to the underlying oropharyngeal lymphoid tissue, and more specifically, to B lymphocytes, all of which have receptors for EBV. Infection of the B cells may take one of two forms—it may kill the infected B cell or it may become incorporated into its genome. A small number of infected B cells are killed and in the process release the virions. However, in most cells the virus associates with the B-cell genome. The B cells that harbor the EBV genome proliferate in the circulation and produce the well known *heterophil* antibodies that are used for the diagnosis of infectious mono-nucleosis.⁷ A heterophil antibody is an immunoglobulin that reacts with antigens from another species—in this case, sheep red blood cells.

The normal immune response is important in controlling the proliferation of the EBV-infected B cells and cell-free virus. Most important in controlling the proliferation of EBV-infected B cells are the cytotoxic CD8⁺ T cells and natural killer (NK) cells. The virus-specific T cells appear as large atypical lymphocytes that are characteristic of the infection.⁷ In otherwise healthy persons, the humoral and cellular immune responses control viral shedding by limiting the number of infected B cells, rather than eliminating them.

Although infectious B cells and free virions disappear from the blood after recovery from the disease, the virus remains in a few transformed B cells in the oropharyngeal region and is shed in the saliva. Once infected with the virus, persons have asymptomatic infection for life, and a few intermittently shed EBV. Immunosuppressed persons shed the virus more frequently. Asymptomatic shedding of EBV by healthy persons accounts for most of the spread of infectious mononucleosis, despite the fact that it is not a highly contagious disease.

Clinical Course

The onset of infectious mononucleosis usually is insidious. The incubation period lasts 4 to 8 weeks.⁸ A prodromal period, which lasts for several days, follows and is characterized by malaise, anorexia, and chills. The prodromal period precedes the onset of fever, pharyngitis, and lymphadenopathy. Occasionally, the disorder comes on abruptly with a high fever. Most persons seek medical attention for severe pharyngitis, which usually is most severe on days 5 to 7 and persists for 7 to 14 days. Rarely severe toxic pharyngotonsillitis may cause airway obstruction.

The lymph nodes are typically enlarged throughout the body, particularly in the cervical, axillary, and groin areas. Hepatitis and splenomegaly are common manifestations of the disease and are thought to be immune mediated. Hepatitis is characterized by hepatomegaly, nausea, anorexia, and jaundice. Although discomforting, it usually is a benign condition that resolves without causing permanent liver damage. The spleen may be enlarged two to three times its normal size, and rupture of the spleen is an infrequent complication. A rash that resembles rubella develops in 10% to 15% of cases.⁷ In less than 1% of cases, mostly in the adult age group, complications of the central nervous system (CNS) develop. These complications include cranial nerve palsies, encephalitis, meningitis, transverse myelitis, and Guillain-Barré syndrome.

The peripheral blood usually shows an increase in the number of leukocytes, with a white blood cell count between 12,000 and 18,000/ μ L, 95% of which are lymphocytes.⁷ The rise in white blood cells begins during the first week and continues during the second week of the infection; the white blood cell count returns to normal around the fourth week. Although leukocytosis is common, leukopenia may be seen in some persons during the first 3 days of the illness. Atypical lymphocytes are common, constituting more than 20% of the total lymphocyte count. Heterophil antibodies usually appear during the second or third week and decline after the acute illness has subsided. However, they may be detectable for as long as 9 months after onset of the disease.

Most persons with infectious mononucleosis recover without incident. The acute phase of the illness usually lasts 2 to 3 weeks, after which recovery occurs rapidly. Some degree of debility and lethargy may persist for 2 to 3 months. Treatment is primarily symptomatic and supportive. It includes bed rest and analgesics such as aspirin to relieve the fever, headache, and sore throat.8

In summary, neutropenia, a marked reduction in the number of circulating neutrophils, is one of the major disorders of the white blood cells. It can be acquired or congenital and can result from a combination of mechanisms. Severe neutropenia can occur as a complication of lymphoproliferative diseases, in which neoplastic cells crowd out neutrophil precursor cells, or of radiation therapy or treatment with cytotoxic drugs, which destroy neutrophil precursor cells. Neutropenia also may be encountered as an idiosyncratic reaction to various drugs. Because the neutrophil is essential to the cellular stage of inflammation, severe and often lifethreatening infections are common in persons with neutropenia.

Infectious mononucleosis is a self-limited lymphoproliferative disorder caused by EBV, a member of the herpesvirus family. The highest incidence of infectious mononucleosis is found in adolescents and young adults, and it is seen more frequently in the upper socioeconomic classes of developed countries. The virus is usually transmitted in the saliva. The disease is characterized by fever, generalized lymphadenopathy, sore throat, and the appearance in the blood of atypical lymphocytes and several antibodies, including the well-known heterophil antibodies that are used in the diagnosis of infectious mononucleosis. Most persons with infectious mononucleosis recover without incident. Treatment is largely symptomatic and supportive.

NEOPLASTIC DISORDERS OF HEMATOPOIETIC AND LYMPHOID ORIGIN

The neoplastic disorders of hematopoietic and lymphoid origin represent the most important of the white blood cell disorders. They include three somewhat overlapping categories: the lymphomas (Hodgkin's disease and non-Hodgkin's lymphoma), the leukemias, and plasma cell dyscrasias (multiple myeloma).

Malignant Lymphomas

The lymphomas, Hodgkin's disease and non-Hodgkin's lymphoma, represent solid tumors derived from neoplastic lymphoid tissue cells (i.e., lymphocytes or histiocytes) and their precursors or derivatives. The seventh most common cancer in the United States, the lymphomas are among the most studied human tumors and among the most curable.

KEY CONCEPTS

MALIGNANT LYMPHOMAS

- The lymphoma represent malignancies of cells derived from lymphoid cells and tissues.
- Hodgkin's disease is a group of cancers characterized by Reed-Sternberg cells that begins as a malignancy in a single lymph node and then spreads to contiguous lymph nodes.
- Non-Hodgkin's lymphomas represent a group of heterogeneous lymphocytic cancers that are multicentric in origin and spread to various tissues throughout the body, including the bone marrow.
- Both types of lymphomas are characterized by manifestations related to uncontrolled lymph node and lymphoid tissue growth, bone marrow involvement, and constitutional symptoms (fever, fatigue, weight loss) related to the rapid growth of abnormal lymphoid cells and tissues.

Hodgkin's Disease

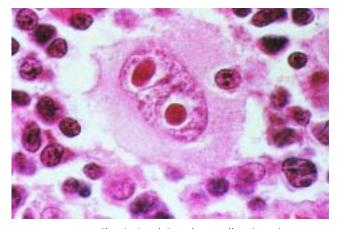

Hodgkin's disease is a specialized form of lymphoma that features the presence of an abnormal cell called a Reed-Sternberg cell.9 It was estimated that approximately 7000 new cases of Hodgkin's disease would be diagnosed in 2002, with 1400 deaths.¹⁰ Distribution of the disease is bimodal; the incidence rises sharply after 10 years of age, peaks in the early 20s, and then declines until 50 years of age. After 50 years of age, the incidence again increases steadily with age. The younger adult group consists equally of men and women, but after age 50 years, the incidence is higher among men.¹¹

The cause of Hodgkin's disease is unknown. Although exposure to carcinogens or viruses as well as genetic and immune mechanisms have been proposed as causes, none have been proven to be involved in the pathogenesis of Hodgkin's disease.

Hodgkin's disease is characterized by painless and progressive enlargement of a single node or group of nodes. It is believed to originate in one area of the lymphatic system, and if unchecked, it spreads throughout the lymphatic network. The initial lymph node involvement typically is above the level of the diaphragm. An exception is in elderly persons, in whom the subdiaphragmatic lymph nodes may be the first to be involved. Involvement of the retroperitoneal lymph nodes, liver, spleen, and bone marrow occurs after the disease becomes generalized.

A distinctive tumor cell (the Reed-Sternberg cell) is considered to be the true neoplastic element in Hodgkin's disease (Fig. 11-4).^{9,12} These malignant proliferating cells may invade almost any area of the body and may produce a wide variety of signs and symptoms. The spleen is involved in one third of the cases at the time of diagnosis.12

Manifestations. A common finding in Hodgkin's disease is the presence of painless lymph node enlargement, involving a single lymph node or groups of lymph nodes. The cervical

■ FIGURE 11-4 ■ Classic Reed-Sternberg cell. Mirror-image nuclei contain large eosinophilic nucleoli. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1144]. Philadelphia: Lippincott Williams & Wilkins)

and mediastinal nodes are involved most frequently. Less commonly, the axillary, inguinal and retroperitoneal nodes are initially involved.¹²

Persons with Hodgkin's disease are commonly designated as stage A if they lack constitutional symptoms and stage B if significant weight loss, fever, or night sweats are present. Approximately 40% of persons with Hodgkin's disease exhibit the "B" symptoms.¹² Other symptoms such as fatigue, pruritus, and anemia are indicative of disease spread. In the advanced stages of Hodgkin's disease, the liver, lungs, digestive tract, and, occasionally, the CNS may be involved. As the disease progresses, the rapid proliferation of abnormal lymphocytes leads to an immunologic defect, particularly in cell-mediated responses, rendering the person more susceptible to viral, fungal, and protozoal infections. Anergy, or the failure to develop a positive response to skin tests, such as the tuberculin test, is common early in the course of the disease. An increased neutrophil count and mild anemia are often noted.

Diagnosis and Treatment. A definitive diagnosis of Hodgkin's disease requires that the Reed-Sternberg cell be present in a biopsy specimen of lymph node tissue.^{12,13} Computed tomographic (CT) scans of the abdomen commonly are used in screening for involvement of abdominal and pelvic lymph nodes. Radiologic visualization of the abdominal and pelvic lymph structures can be achieved through the use of bipedal lymphangiography. In this diagnostic test, radiopaque dye is injected into the lymphatic channels of the lower leg, enabling visualization of the iliac and para-aortic nodes. Nuclear studies, such as a gallium scan in which the tumor takes up the radionuclide, or a staging laparotomy to detect abdominal nodes and inspect the liver may be done.

The staging of Hodgkin's disease is of great clinical importance because the choice of treatment and the prognosis ultimately are related to the distribution of the disease. Staging is determined by the number of lymph nodes that are involved, whether the lymph nodes are on one or both sides of the diaphragm, and whether there is disseminated disease involving the bone marrow and liver. Irradiation and chemotherapy are used in treating the disease. Most people with localized disease are treated with radiation therapy. As the accuracy of staging techniques, delivery of radiation, and curative efficacy of combination chemotherapy regimens have improved, the survival of people with Hodgkin's disease also has improved. With modern treatment methods an overall cure rate of 70% can be achieved.

Non-Hodgkin's Lymphomas

The non-Hodgkin's lymphomas are a heterogeneous group of solid tumors composed of neoplastic lymphoid cells. The heterogeneity reflects the potential for malignant transformation at any stage of B- and T-lymphocyte differentiation. The non-Hodgkin's lymphomas occur three times more frequently than does Hodgkin's disease. In 2002, approximately 54,000 new cases were diagnosed in the United States, and approximately 24,400 deaths resulted from these disorders.¹⁰ Non-Hodgkin's lymphomas are the fifth most common malignancy in men and the sixth in women,¹³ and the disease's incidence and associated mortality rates have increased considerably during the last several decades.¹⁴

The etiology of most of the non-Hodgkin's lymphomas is unknown. A viral cause is suspected in at least some of the lymphomas. There is evidence of EBV infection in 95% of people with Burkitt's lymphoma, which is endemic to some parts of Africa.9,12 By contrast, the virus is found in only a small percentage of Burkitt's lymphoma occurring in the United States and other nonendemic areas.¹² A second virus, the human T cell/lymphoma virus (HTLV-1), which is endemic in the southwestern islands of Japan, has been associated with adult T-cell leukemia/lymphoma. Evidence of infection has been demonstrated in 90% of adult T-cell leukemia/lymphoma cases in Japan.9,12 Non-Hodgkin's lymphomas also are seen with increased frequency in persons with acquired immunodeficiency syndrome, in those who have received chronic immunosuppressive therapy after kidney or liver transplantation, and in individuals with acquired or congenital immunodeficiencies.

As neoplasms of the immune system, the non-Hodgkin's lymphomas can originate in either the T cells or B cells.^{9,12} Most (80% to 85%) are of B-cell origin with the remainder being largely of T-cell origin. All of these variants have the potential to spread to various tissues throughout the body, especially the liver, spleen, and bone marrow. Non-Hodgkin's lymphomas commonly are divided into three groups, depending on the grade of the tumor: low-grade lymphomas, which are predominantly B-cell tumors; intermediate-grade lymphomas; and high-grade lymphomas, which are largely immunoblastic (B-cell), lymphoblastic (T-cell), Burkitt's, and non-Burkitt's lymphomas.¹²

Clinical Course. The clinical course of non-Hodgkin's lymphomas depends upon the lymphoma type and the stage of the disease. For example, the small lymphocyte tumors, which account for about 4% of all non-Hodgkin's lymphomas, are low-grade tumors associated with mild symptoms and prolonged survival. The diffuse large B-cell lymphomas, which account for about 20% of all non-Hodgkin's lymphomas, are particularly aggressive tumors that are rapidly fatal if not treated. However, with intensive combination chemotherapy, complete remission can be achieved in 60% to 80% of cases.

The most frequently occurring clinical manifestation in the non-Hodgkin's lymphomas is painless, superficial lymphadenopathy. There may be noncontiguous nodal spread of the disease with more frequent involvement of the gastrointestinal tract, liver, testes, and bone marrow. Frequently, there is increased susceptibility to bacterial, viral, and fungal infections associated with hypogammaglobulinemia and a poor humoral antibody response, rather than the impaired cellular immunity seen with Hodgkin's disease.

Leukemic transformation with high peripheral lymphocytic counts occurs in a small percentage of persons with non-Hodgkin's lymphoma.9

Diagnosis and Treatment. As with Hodgkin's disease, a lymph node biopsy is used to confirm the diagnosis of non-Hodgkin's lymphoma. Bone marrow biopsy, blood studies, abdominal computed tomographic scans, and nuclear medicine studies often are used to determine the stage of the disease.

For early-stage disease, radiation therapy is used as a single treatment. However, because most people present with latestage disease, combination chemotherapy, combined adjuvant radiation therapy, or both are recommended. For rapidly progressive intermediate- or high-grade lymphomas, CNS prophylaxis is achieved with high doses of chemotherapeutic agents that can cross the blood-brain barrier or cranial irradiation. Bone marrow and peripheral stem cell transplantation are being investigated as potentially curative treatment modalities for people with highly resistant forms of the disease.

Leukemias

The leukemias are malignant neoplasms of cells originally derived from hematopoietic stem cells. They are characterized by diffuse replacement of bone marrow with unregulated, proliferating, immature neoplastic cells. In most cases, the leukemic cells spill out into the blood, where they are seen in large numbers. The term leukemia (i.e., "white blood") was first used by Virchow to describe a reversal of the usual ratio of red blood cells to white blood cells. The leukemic cells may also infiltrate the liver, spleen, lymph nodes, and other tissues throughout the body, causing enlargement of these organs.

Leukemia strikes approximately 31,000 persons in the United States each year. In 2002, approximately 30,800 new cases were diagnosed, and approximately 21,700 persons died of this disease.¹⁰ More children are stricken with leukemia than with any other form of cancer, and it is the leading cause of death in children between the ages of 3 and 14 years. Although leukemia commonly is thought of as a childhood disease, it strikes more adults than children.

The causes of leukemia are unknown. The incidence of leukemia among persons who have been exposed to high levels of radiation is unusually high. The number of cases of leukemia reported in the most heavily exposed survivors of the atomic blasts at Hiroshima and Nagasaki during the 20-year period from 1950 to 1970 was nearly 30 times the expected rate.15 An increased incidence of leukemia also is associated with exposure to benzene and the use of antitumor drugs (*i.e.*, mechlorethamine, procarbazine, cyclophosphamide, chloramphenicol, and the epipodophyllotoxins).¹⁶ Leukemia may occur as a second cancer after aggressive chemotherapy for other cancers, such as Hodgkin's disease.¹⁷ The existence of a

KEY CONCEPTS

LEUKEMIAS

- Leukemias are malignant neoplasms arising from the transformation of a single blood cell line derived from hematopoietic stem cells.
- The leukemias are classified as acute and chronic lymphocytic (lymphocytes) or myelogenous (granulocytes, monocytes) leukemias, according to their cell lineage.
- Because leukemic cells are immature and poorly differentiated, they proliferate rapidly and have a long life span; they do not function normally; they interfere with the maturation of normal blood cells; and they circulate in the bloodstream, cross the bloodbrain barrier, and infiltrate many body organs.

genetic predisposition to acute leukemia is suggested by the increased leukemia incidence among a number of congenital disorders, including Down syndrome, von Recklinghausen's disease, and Fanconi's anemia. In individuals with Down syndrome, the incidence of acute leukemia is 10 times that of the general population.¹⁸ In addition, there are numerous reports of multiple cases of acute leukemia occurring within the same family.

Classification

The leukemias commonly are classified according to their predominant cell type (i.e., lymphocytic or myelogenous) and whether the condition is acute or chronic. Biphenotypic leukemias demonstrate characteristics of both lymphoid and myeloid lineages. A rudimentary classification system divides leukemia into four types: acute lymphocytic (lymphoblastic) leukemia, chronic lymphocytic leukemia, acute myelogenous (myeloblastic) leukemia, and chronic myelogenous leukemia. The lymphocytic leukemias involve immature lymphocytes and their progenitors that originate in the bone marrow but infiltrate the spleen, lymph nodes, CNS, and other tissues. The myelogenous leukemias, which involve the pluripotent myeloid stem cells in bone marrow, interfere with the maturation of all blood cells, including the granulocytes, erythrocytes, and thrombocytes.

Acute Leukemias

The acute leukemias usually have a sudden and stormy onset of signs and symptoms related to depressed bone marrow function (Table 11-2). Acute lymphocytic leukemia (ALL) is the most common leukemia in childhood, comprising 80% to 85% of leukemia cases.¹⁹ The peak incidence occurs between 2 and 4 years of age. Acute myelogenous leukemia (AML) is chiefly an adult disease; although it is also seen in children and young adults. The incidence steadily increases after middle age. AML appears to be increasing among the elderly.¹²

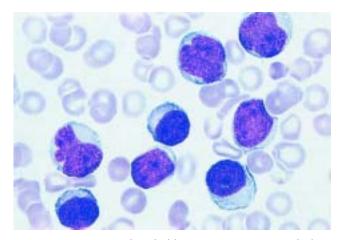

ALL encompasses a group of neoplasms composed of immature precursor B or T lymphocytes (Fig. 11-5). Most cases (about 85%) of ALL are of pre-B-cell origin.9 Approximately 90% of persons with ALL have nonrandom chromosome ab-

Clinical Manifestations	Pathologic Basis	
Bone marrow depression		
Malaise, easy fatigability	Anemia	
Fever	Infection or increased metabolism by neoplastic cells	
Bleeding	Decreased thrombocytes	
Petechiae		
Ecchymosis		
Gingival bleeding		
Epistaxis		
Bone pain and tenderness upon palpation	Subperiosteal bone infiltration, bone marrow expansion, and bone resorption	
Headache, nausea, vomiting, papilledema,	Leukemic infiltration of central nervous system	
cranial nerve palsies, seizures, coma		
Abdominal discomfort	Generalized lymphadenopathy, hepatomegaly, splenomegaly due to leukemic cell infiltration	
Increased vulnerability to infections	Immaturity of the white cells and ineffective immune function	
Hematologic abnormalities	Physical and metabolic encroachment of leukemia cells on red blood cell and thrombo	
Anemia	cyte precursors	
Thrombocytopenia		
Hyperuricemia and other metabolic disorders	Abnormal proliferation and metabolism of leukemic cells	

*Manifestations vary with the type of leukemia.

normalities. The AMLs are an extremely heterogeneous group of disorders. Some arise from the pluripotent stem cells in which myeloblasts predominate, and others arise from the monocyte-granulocyte precursor, which is the cell of origin for myelomonocytic leukemia. Of all the leukemias, AML is most strongly linked with toxins and underlying congenital and hematologic disorders. It is the type of leukemia associated with Down syndrome.

Clinical Manifestations. Although ALL and AML are distinct disorders, they typically present with similar clinical features. The warning signs and symptoms of acute leukemia are fatigue,

■ FIGURE 11-5 ■ Acute lymphoblastic anemia (L2 ALL). The lymphoblasts in the peripheral blood contain irregular and indented nuclei with prominent nucleoli and a moderate amount of cytoplasm. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1129]. Philadelphia: Lippincott-Raven)

pallor, weight loss, repeated infections, easy bruising, nosebleeds, and other types of hemorrhage. These features often appear suddenly in children.

Persons with acute leukemia usually present for medical evaluation within 3 months of the onset of symptoms. Both ALL and AML are characterized by fatigue resulting from anemia; low-grade fever, night sweats, and weight loss caused by the rapid proliferation and hypermetabolism of the leukemic cells; bleeding caused by a decreased platelet count; and bone pain and tenderness caused by bone marrow expansion.^{19,20} Infection results from neutropenia, with the risk of infection becoming high as the neutrophil count falls to less than 500 cells/µL. Generalized lymphadenopathy, splenomegaly, and hepatomegaly caused by infiltration of leukemic cells occur in all acute leukemias but are more common in ALL. In addition to the common manifestations of acute leukemia (e.g., fatigue, weight loss, fever, easy bruising), infiltration of malignant cells in the skin, gums, and other soft tissue is particularly common in the monocytic form of AML.

CNS involvement is more common in ALL than AML, and is more common in children than adults. Signs and symptoms of CNS involvement include cranial nerve palsies, headache, nausea, vomiting, papilledema, and occasionally seizures and coma.

Leukostasis is a condition in which the circulating blast count is markedly elevated (usually 100,000 cells/ μ L). The high number of circulating leukemic blasts increases blood viscosity and predisposes to the development of leukoblastic emboli with obstruction of small vessels in the pulmonary and cerebral circulations. Plugging of the pulmonary vessels leads to vessel rupture and infiltration of lung tissue, resulting in sudden shortness of breath and progressive dyspnea. Cerebral leukostasis leads to diffuse headache and lethargy, which can progress to confusion and coma. Once identified, leukostasis requires immediate and effective treatment to lower the blast count rapidly. Diagnosis and Treatment. A definitive diagnosis of acute leukemia is based on blood and bone marrow studies; it requires the demonstration of leukemic cells in the peripheral blood, bone marrow, or extramedullary tissue. Laboratory findings reveal the presence of immature (blasts) white blood cells in the circulation and bone marrow, where they may constitute 60% to 100% of the cells. As these cells proliferate and begin to crowd the bone marrow, the development of other blood cell lines in the marrow is suppressed. Consequently, there is a loss of mature myeloid cells, such as erythrocytes, granulocytes, and platelets. Anemia is almost always present, and the platelet count is decreased.

Chemotherapy and selective irradiation (e.g., CNS irradiation) are used in the treatment of acute leukemia. Remission is defined as eradication of leukemic cells as detectable by conventional technology. Chemotherapy includes induction therapy designed to elicit a remission, intensification therapy to produce a further reduction in leukemic cells after a remission is achieved, and maintenance therapy to maintain the remission. Because systemic chemotherapeutic agents cannot cross the blood-brain barrier and eradicate leukemic cells that have entered the CNS, CNS irradiation is administered concurrent with systemic chemotherapy.^{19,20} The long-term effects of treatment on childhood cancer survivors is discussed in Chapter 5.

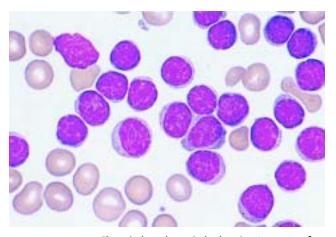

Massive destruction of malignant cells can occur during the initial phase of treatment. This phenomenon, known as tumor lysis syndrome, can lead to life-threatening metabolic disorders, including hyperkalemia, hyperphosphatemia, hyperuricemia, hypomagnesemia, hypocalcemia, and acidosis, with the potential for causing acute renal failure. Prophylactic aggressive hydration with alkaline solutions and administration of allopurinol to reduce uric acid levels is given to counteract these effects.

Bone marrow transplantation may be considered for persons with ALL and AML who experience no response to other forms of therapy. There has been recent interest in the use of stem cell transplantation in ALL²¹ and AML.²²

Chronic Leukemias

Chronic leukemias have a more insidious onset than do acute leukemias and may be discovered during a routine medical examination by a blood count. Chronic lymphocytic leukemia (CLL) is mainly a disorder of older persons; fewer than 10% of those who have the disease are younger than 50 years. Men are affected twice as frequently as women. Chronic myelogenous leukemia (CML) accounts for 15% to 20% of all leukemias in adults. It is predominantly a disorder of adults between the ages of 30 and 50 years, but it can affect children as well. The incidence is slightly higher in men than women.

CLL is a disorder characterized by the proliferation and accumulation of relatively mature lymphocytes that are immunologically incompetent (Fig. 11-6). In the United States,

■ FIGURE 11-6 ■ Chronic lymphocytic leukemia. A smear of peripheral blood shows numerous small-to-medium-sized lymphocytes. (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 1125]. Philadelphia: Lippincott Williams & Wilkins)

more than 95% of cases of CLL are of B-cell origin. The leukemic B cells fail to respond to antigenic stimulation; thus, persons with CLL have hypogammaglobulinemia. Infections remain a major cause of morbidity and mortality.

CML is a myeloproliferative disorder that involves expansion of all bone marrow elements. CML is associated in all cases with the presence of the Ph (Philadelphia) chromosome, representing a reciprocal translocation of the long arm of chromosome 22 to the long arm of chromosome 9.9,23 In about 95% of persons with CML, the Ph chromosome can be identified in granulocytic, erythroid, and megakaryocytic precursors, as well as B cells, and in some cases, T cells.9 Although CML originates in the pluripotent stem cells, granulocyte precursors remain the dominant cell type.

Clinical Course. Both CLL and CML have an insidious onset. However, the two types of chronic leukemias differ in their manifestations and clinical course.

CLL typically follows a slow, chronic course. The clinical signs and symptoms are largely related to the progressive infiltration of neoplastic lymphocytes in the bone marrow and extramedullary tissue and to secondary immunologic defects. Affected persons often have no symptoms at the time of diagnosis, and lymphocytosis is noted on a complete blood count obtained for another, unrelated disorder. Fatigue, reduced exercise tolerance, enlargement of superficial lymph nodes, or splenomegaly usually reflect a more advanced stage. As the disease progresses, lymph nodes gradually increase in size and new nodes are involved, sometimes in unusual areas such as the scalp, orbit, pharynx, pleura, gastrointestinal tract, liver, prostate, and gonads. Severe fatigue, recurrent or persistent infections, pallor, edema, thrombophlebitis, and pain are also experienced. As the malignant cell population increases, the proportion of normal marrow precursors is reduced until only lymphocytes remain in the marrow.²⁰

Typically CML follows a triphasic course: a chronic phase of variable length, a short accelerated phase, and a terminal blast crisis phase. The onset of the chronic phase is usually slow with nonspecific symptoms such as weakness and weight loss. The most characteristic laboratory finding at the time of

202 Unit Three: Alterations in the Hematologic System

presentation is leukocytosis with immature granulocyte cell types in the peripheral blood. Anemia and, eventually, thrombocytopenia develop. Anemia causes weakness, easy fatigability, and exertional dyspnea. Splenomegaly is often present at the time of diagnosis; hepatomegaly is less common; and lymphadenopathy is relatively uncommon. Although persons in the early chronic phase of CML generally have no symptoms, without effective treatment most will enter the accelerated phase within 3 to 5 years.

The accelerated phase is characterized by enlargement of the spleen and progressive symptoms. Splenomegaly often causes a feeling of abdominal fullness and discomfort. An increase in basophil count and more immature cells in the blood or bone marrow confirm transformation to the accelerated phase. During this phase, constitutional symptoms such as low-grade fever, night sweats, bone pain, and weight loss develop because of rapid proliferation and hypermetabolism of the leukemic cells. Bleeding and easy bruising may arise from dysfunctional platelets. Generally the accelerated phase is short (6 to 12 months).¹⁸

The terminal or blast crisis phase represents evolution to acute leukemia and is characterized by an increasing number of myeloid precursors, especially blast cells. Constitutional symptoms become more pronounced during this period, and splenomegaly may increase significantly. Isolated infiltrates of leukemic cells can involve the skin, lymph nodes, bones, and CNS. With very high blast counts (100,000/ μ L), symptoms of leukostasis may occur. The prognosis for patients who are in the blast crisis phase is poor, with survival rates averaging 2 to 4 months.

Diagnosis and Treatment. The diagnosis of chronic leukemia is based on blood and bone marrow studies. The treatment varies with the type of leukemic cell, the stage of the disease, other health problems, and the person's age. Most early cases of CLL require no specific treatment. Reassurance that persons with the disorder can live a normal life for many years is important. Indications for chemotherapy include progressive fatigue, troublesome lymphadenopathy, anemia, and thrombocytopenia. Complications such as autoimmune hemolytic anemia or thrombocytopenia may require treatment with corticosteroids or splenectomy. Unlike CML, transformation to acute leukemia with blast crisis is rare, and many persons live longer than 10 years and die of unrelated causes.

The treatment of CML is often palliative. The median survival is 5 to 7 years, with fewer than 50% of persons alive at 5 years.¹⁸ Standard treatment includes the use of single-agent chemotherapy to control the disease in persons in the chronic phase of the disease. Interferon- α induces clinical remission in 70% to 80% of persons treated during the early chronic phase of the disease. During the blast crisis phase, combination therapy is administered, although response rates are low (20% to 30%) and remissions vary from 2 to 12 months. Allogeneic bone marrow or stem cell transplantation provides the only cure for CML.

Multiple Myeloma

Multiple myeloma is a plasma cell cancer of the osseous tissue and accounts for 10% to 15% of all hematologic malignancies.²⁴ In the course of its dissemination, it also may involve nonosseous sites. It is characterized by the uncontrolled proliferation of an abnormal clone of plasma cells, which secrete primarily IgG or IgA. Fewer than 3% of cases occur before the age of 40 years, with the median age of patients with multiple myeloma being 65 years.

The cause of multiple myeloma is unknown. It does not appear to be caused by previous exposure to toxic agents (*e.g.*, solvents such as benzene, paints, pesticides). Interestingly, an association with human herpesvirus 8 has been described, but the role of this virus in the pathogenesis of the disease remains to be established.²⁴

In multiple myeloma, there is an atypical proliferation of one of the immunoglobulins, called the M protein, a monoclonal antibody.²⁵ Although multiple myeloma is characterized by excessive production of monoclonal immunoglobulin, levels of normal immunoglobulins are usually depressed. This contributes a general susceptibility to bacterial infections. Cytokines are important in the pathogenesis of the disorder. The multiple myeloma plasma cell has a surface-membrane receptor for interleukin-6, which is known to be a growth factor for the disorder. Another important growth factor for the myeloma cell is interleukin-1, which has important osteoclast activity.²⁶

The main sites involved in multiple myeloma are the bones and bone marrow. In addition to the abnormal proliferation of marrow plasma cells, there is proliferation and activation of osteoclasts that leads to bone resorption and destruction (Fig. 11-7). This increased bone resorption predisposes the individual to pathologic fractures and hypercalcemia. Paraproteins secreted by the plasma cells may cause a hyperviscosity of body fluids and may break down into amyloid, a proteinaceous substance deposited between cells, causing heart failure and neuropathy.

FIGURE 11-7 Multiple myeloma. Multiple lytic lesions of the vertebrae are present. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1148]. Philadelphia: Lippincott Williams & Wilkins)

In some forms of multiple myeloma, the plasma cells produce only Bence Jones proteins, abnormal proteins that consist of the light chains of the immunoglobulin molecule. Because of their low molecular weight, Bence Jones proteins are partially excreted in the urine. Many of these abnormal proteins are directly toxic to renal tubular structures, which may lead to tubular destruction and, eventually, to renal failure.

The malignant plasma cells also can form plasmacytomas (plasma cell tumors) in bone and soft tissue sites. The most common site of soft tissue plasmacytomas is the gastrointestinal tract. The development of plasmacytomas in bone tissue is associated with bone destruction and localized pain. Occasionally, the lesions may affect the spinal column, causing vertebral collapse and spinal cord compression.²⁴

Manifestations. Bone pain is one of the first symptoms to occur and one of the most common, occurring in approximately 80% of all individuals with diagnoses of multiple myeloma. Bone destruction also impairs the production of erythrocytes and leukocytes and predisposes the patient to anemia and recurrent infections. Many patients experience weight loss and weakness. Renal insufficiency occurs in 50% of patients. Neurologic manifestations caused by neuropathy or spinal cord compression also may be present.

Diagnosis and Treatment. Diagnosis is based on clinical manifestations, blood tests, and bone marrow examination. The hallmark of myeloma is the finding of paraproteins on serum protein electrophoresis. Bone radiographs are important in establishing the presence of bone lesions.

Although numerous treatments for multiple myeloma have been attempted since the early 1970s, the results have been disappointing. With standard chemotherapy, the median survival may reach 2 to 3 years. Multiple myeloma is a radiosensitive disease, but most radiation therapy is used primarily for palliation, specifically to treat lytic bone lesions and compression fractures and to decrease pain. Recently, thalidomide has been shown to induce responses in persons whose myeloma was refractory to conventional therapies.²⁴

In summary, the lymphomas (Hodgkin's disease and non-Hodgkin's lymphoma) represent malignant neoplasms of cells native to lymphoid tissue (*i.e.*, lymphocytes and histiocytes) and their precursors or derivatives. Hodgkin's disease is characterized by painless and progressive enlargement of a single node or group of nodes. It is believed to originate in one area of the lymphatic system and, if unchecked, spreads throughout the lymphatic network. Non-Hodgkin's lymphomas are multicentric in origin and spread early to various tissues throughout the body, especially the liver, spleen, and bone marrow.

Leukemias are malignant neoplasms of the hematopoietic stem cells with diffuse replacement of bone marrow. Leukemias are classified according to cell type (*i.e.*, lymphocytic or myelogenous) and whether the disease is acute or chronic. The lymphocytic leukemias involve immature lymphocytes and their progenitors that originate in the bone marrow but infiltrate the spleen, lymph nodes, CNS, and other tissues. The myelogenous leukemias involve the pluripotent myeloid stem cells in bone marrow and interfere with the maturation of all blood cells, including the granulocytes, erythrocytes, and thrombocytes. The acute leukemias (*i.e.*, ALL, which primarily affects children, and AML, which primarily affects adults) have a sudden and stormy onset, with symptoms of depressed bone marrow function (anemia, fatigue, bleeding, and infections); bone pain; and generalized lymphadenopathy, splenomegaly, and hepatomegaly. The chronic leukemias, which largely affect adults, have a more insidious onset. CLL often has the most favorable clinical course, with many persons living long enough to die of unrelated causes. The course of CML is slow and progressive, with transformation to a course resembling that of AML.

Multiple myeloma results in the uncontrolled proliferation of immunoglobulin-secreting plasma cells, usually a single clone of IgG- or IgA-producing cells, that results in increased bone resorption, leading to pathologic bone lesions.

REVIEW QUESTIONS

■ Trace the development of the different blood cells from their origin in the pluripotent bone marrow stem cell to their circulation in the bloodstream.

Explain the signs and symptoms of neutropenia in terms of the function of the neutrophil.

Explain the manifestations of infectious mononucleosis in terms of the immune systems response to infection by the Epstein-Barr virus.

Contrast the signs and symptoms of Hodgkin's and non-Hodgkin's lymphoma based on the differences in involvement of lymphoid tissues and immune cells.

One of the manifestations of Hodgkin's disease is the inability of persons with tuberculosis to display a positive response to the tuberculin skin test. Explain.

Relate the constitutional symptoms of lymphomas (*e.g.,* fever, general malaise, and fatigue) to the pathophysiology of Hodgkin's disease and non-Hodgkin's lymphoma.

Explain the manifestations of leukemia in terms of altered cell differentiation.

Describe the pathophysiologic basis for the following complications of leukemia: leukostasis, tumor lysis syndrome, hyperuricemia, and blast crisis.

Relate abnormal proliferation of an abnormal plasma cell clone to the manifestations of multiple myeloma.

CHAPTER

he term *hemostasis* refers to the stoppage of blood flow. The normal process of hemostasis is regulated by a complex array of activators and inhibitors that maintain blood fluidity and prevent blood from leaving the vascular compartment. Hemostasis is normal when it seals a blood vessel to prevent blood loss and hemorrhage. It is abnormal when it causes inappropriate blood clotting or when clotting is insufficient to stop the flow of blood from the vascular compartment. Disorders of hemostasis fall into two main categories: the inappropriate formation of clots within the vascular system (*i.e.*, thrombosis) and the failure of blood to clot in response to an appropriate stimulus (*i.e.*, bleeding).

MECHANISMS OF HEMOSTASIS

Hemostasis is divided into five stages: vessel spasm, formation of the platelet plug, blood coagulation or development of an insoluble fibrin clot, clot retraction, and clot dissolution (Fig. 12-1).

Vessel Spasm

Vessel spasm is initiated by endothelial injury and caused by local and humoral mechanisms. A spasm constricts the vessel and reduces blood flow. It is a transient event that usually lasts less than 1 minute. Thromboxane A_2 (TXA₂), a prostaglandin released from the platelets, contributes to the vasoconstriction. A second prostaglandin, prostacyclin, released from the vessel endothelium, produces vasodilation and inhibits platelet aggregation.

Formation of the Platelet Plug

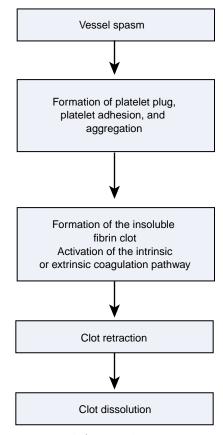

The platelet plug, the second line of defense, is initiated as platelets come in contact with the vessel wall. Small breaks in the vessel wall are often sealed with a platelet plug and do not require the development of a blood clot.

Platelets, also called *thrombocytes*, are large fragments from the cytoplasm of bone marrow cells called *megakaryocytes*. They are enclosed in a membrane but have no nucleus and cannot reproduce. Their cytoplasmic granules release mediators for hemostasis. Although they lack a nucleus, they have many of the characteristics of a whole cell. They have mitochondria and enzyme systems for producing adenosine triphosphate (ATP) and adenosine diphosphate (ADP), and they have the enzymes needed for synthesis of prostaglandins, which are required for their function in hemostasis. Platelets also produce a growth factor that causes vascular endothelial cells, smooth muscle cells, and fibroblasts to proliferate and grow.

The life span of a platelet is only 8 to 9 days. A protein called *thrombopoietin* causes proliferation and maturation of megakaryocytes.¹ The sources of thrombopoietin include the liver, kidney, smooth muscle, and bone marrow, which controls platelet production. Its production and release are regulated by the number of platelets in the circulation. The newly formed

■ FIGURE 12-1 ■ Steps in hemostasis.

platelets that are released from the bone marrow spend as long as 8 hours in the spleen before they are released into the blood.

The cell membrane of the platelet is important to its function. The outside of the platelet membrane is coated with glycoproteins that repulse adherence to the normal vessel endothelium, while causing adherence to injured areas of the vessel wall, particularly the subendothelial layer.² The platelet membrane also has glycoprotein receptors that bind fibrinogen and link platelets together. Glycoprotein receptor antagonists have been developed and are selectively used in the treatment

KEY CONCEPTS

HEMOSTASIS

- Hemostasis is the orderly, stepwise process for stopping bleeding that involves vasospasm, formation of a platelet plug, and the development of a fibrin clot.
- The blood clotting process requires the presence of platelets produced in the bone marrow, von Willebrand factor generated by the vessel endothelium, and clotting factors synthesized in the liver, using vitamin K.
- The final step of the process involves fibrinolysis or clot dissolution, which prevents excess clot formation.

of acute coronary myocardial infarction (see Chapter 17). In addition, the platelet membrane contains large amounts of phospholipids that play a role in activating several points in the blood-clotting process.

Platelet plug formation involves adhesion and aggregation of platelets. Platelet adhesion also requires a protein molecule called *von Willebrand factor* (vWF). vWF, which is produced by the endothelial cells of blood vessels, performs two important functions: it aids in platelet adhesion, and it circulates in the blood as a carrier protein for coagulation factor VIII.

Platelets are attracted to a damaged vessel wall, become activated, and change from smooth disks to spiny spheres, exposing receptors on their surfaces. Adhesion to the vessel subendothelial layer occurs when the platelet receptor binds to vWF at the injury site, linking the platelet to exposed collagen fibers (Fig. 12-2A). The process of adhesion is controlled by local hormones and substances released by platelet granules. As the platelets adhere to the collagen fibers on the damaged vessel wall, they begin to release large amounts of ADP and TXA₂. Platelet aggregation and formation of a loosely organized platelet plug occur as the ADP and TXA₂ cause nearby platelets to become sticky and adhere to the original platelets. Stabilization of the platelet plug occurs as the coagulation

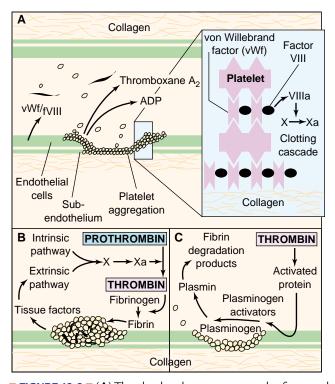

FIGURE 12-2 (A) The platelet plug occurs seconds after vessel injury. Von Willebrand's factor, released from the endothelial cells, binds to platelet receptors, causing *adhesion* of platelets to the exposed collagen. Platelet *aggregation* is induced by release of thromboxane A_2 and adenosine diphosphate. (B) Coagulation factors, activated on the platelet surface, lead to the formation of thrombin and fibrin, which stabilize the platelet plug. (C) Control of the coagulation process and clot dissolution are governed by thrombin and plasminogen activators. Thrombin activates protein C, which stimulates the release of plasminogen activators in turn promote the formation of plasmin, which digests the fibrin strands.

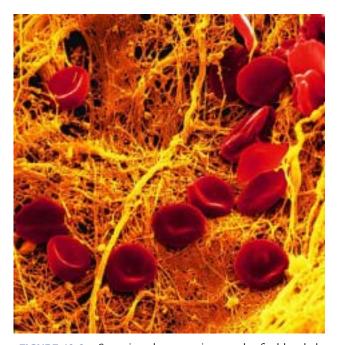

pathway is activated on the platelet surface and fibrinogen is converted to fibrin, thereby creating a fibrin meshwork that cements together the platelets and other blood components (see Fig. 12-2B).

Defective platelet plug formation causes bleeding in persons who are deficient in platelet receptor sites or vWF. In addition to sealing vascular breaks, platelets play an almost continuous role in maintaining normal vascular integrity. They may supply growth factors for the endothelial cells and arterial smooth muscle cells. Persons with platelet deficiency have increased capillary permeability and sustain small skin hemorrhages from the slightest trauma or change in blood pressure.

Blood Coagulation

Blood coagulation is controlled by many substances that promote clotting (*i.e.*, procoagulation factors) or inhibit it (*i.e.*, anticoagulation factors). Each of the procoagulation factors, identified by Roman numerals, performs a specific step in the coagulation process. The action of one coagulation factor or proenzyme is designed to activate the next factor in the sequence (*i.e.*, cascade effect). Because most of the inactive procoagulation factors are present in the blood at all times, the multistep process ensures that a massive episode of intravascular clotting does not occur by chance. It also means that abnormalities of the clotting process occur when one or more of the factors are deficient or when conditions lead to inappropriate activation of any of the steps.

The chemical events in the blood coagulation process involve a number of essential steps that result in the conversion of fibrinogen, a circulating plasma protein, to the fibrin strands that enmesh platelets, blood cells, and plasma to form the clot (Fig. 12-3). The initiation of the clotting process oc-

■ FIGURE 12-3 ■ Scanning electron micrograph of a blood clot (×3600). The fibrous bridges that form a meshwork between red blood cells are fibrin fibers. (© Oliver Meckes, Science Source/ Photo Researchers)

curs by way of the intrinsic or the extrinsic coagulation pathways (Fig. 12-4). The intrinsic pathway, which is a relatively slow process, begins in the blood itself. The extrinsic pathway, which is a much faster process, begins with tissue or vessel trauma and the subsequent release of a complex of several factors, called *tissue factor*, or *tissue thromboplastin*. The terminal steps in both pathways are the same: the activation of factor X, the conversion of prothrombin to thrombin, and the conversion of fibrinogen to fibrin. Prothrombin is an unstable plasma protein, which is easily split into smaller parts, one of which is thrombin. Thrombin, in turn, acts as an enzyme to convert fibrinogen to fibrin.

Both the intrinsic and extrinsic pathways are needed for normal hemostasis, and many interrelations exist between them. Each system is activated when blood passes out of the vascular system. The intrinsic system is activated as blood comes in contact with collagen in the injured vessel wall and the extrinsic system when blood is exposed to tissue extracts. Bleeding, when it occurs because of defects in the extrinsic system, usually is not as severe as that which results from defects in the intrinsic pathway.

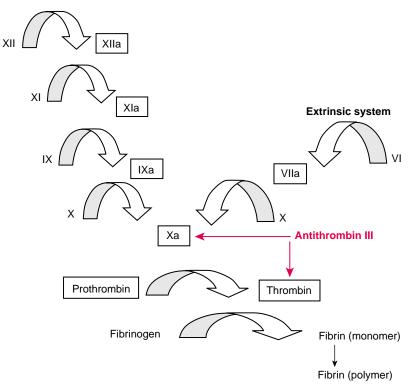

With few exceptions, almost all the blood-clotting factors are synthesized in the liver. Vitamin K is required for the synthesis of prothrombin, factors VII, IX, X, and protein C. Calcium (factor IV) is required in all but the first two steps of the clotting process. The body usually has sufficient amounts of calcium for these reactions. Inactivation of the calcium ion prevents blood from clotting when it is removed from the body. The addition of citrate to blood stored for transfusion purposes prevents clotting by chelating ionic calcium. Another chelator, EDTA, is often added to blood samples used for analysis in the clinical laboratory.

Coagulation is regulated by several natural anticoagulants. Antithrombin III inactivates coagulation factors and neutralizes thrombin, the last enzyme in the pathway for the conversion of fibrinogen to fibrin. When antithrombin III is complexed with naturally occurring heparin, its action is accelerated and provides protection against uncontrolled thrombus formation on the endothelial surface. Protein C, a plasma protein, acts as an anticoagulant by inactivating factors V and VIII. Protein S, another plasma protein, accelerates the action of protein C. Plasmin breaks down fibrin into fibrin degradation products that act as anticoagulants. It has been suggested that some of these natural anticoagulants may play a role in the bleeding that occurs with disseminated intravascular coagulation (DIC; discussed later).

The anticoagulant drugs heparin and warfarin are used to prevent venous thrombi and thromboembolic disorders, such as deep vein thrombosis and pulmonary embolism. Heparin is naturally formed by basophilic mast cells located at the precapillary junctions in tissues throughout the body. These cells continuously secrete small amounts of heparin, which is released into the circulation. Pharmacologic preparations of heparin, extracted from animal tissues, are available for treatment of coagulation disorders. Heparin binds to antithrombin III, causing a conformational change that increases the ability of antithrombin III to inactivate factor Xa, thrombin, and other clotting factors. By promoting the inactivation of clotting factors, heparin ultimately suppresses the formation of fibrin. Heparin is unable to cross the membranes of the gastrointestinal tract and must be given by injection. Warfarin acts by

208 Unit Three: Alterations in the Hematologic System

■ FIGURE 12-4 ■ Intrinsic and extrinsic coagulation pathways. The terminal steps in both pathways are the same. Calcium, factors X and V, and platelet phospholipids combine to form prothrombin activator, which then converts prothrombin to thrombin. This interaction causes conversion of fibrinogen into the fibrin strands that create the insoluble blood clot. Prothrombin and factors VII, IX, and X require vitamin K for synthesis.

decreasing prothrombin and other procoagulation factors. It alters vitamin K such that it reduces its availability to participate in synthesis of the vitamin K-dependent coagulation factors in the liver. Warfarin is readily absorbed after oral administration. Its maximum effect takes 36 to 72 hours because of the varying half-lives of preformed clotting factors that remain in the circulation.

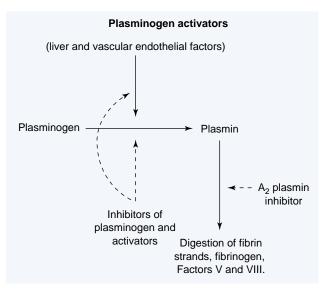

Clot Retraction

After the clot has formed, clot retraction, which requires large numbers of platelets, contributes to hemostasis by squeezing serum from the clot and joining the edges of the broken vessel.

Clot Dissolution

The dissolution of a blood clot begins shortly after its formation; this allows blood flow to be re-established and permanent tissue repair to take place (see Fig. 12-2C). The process by which a blood clot dissolves is called *fibrinolysis*. As with clot formation, clot dissolution requires a sequence of steps controlled by activators and inhibitors (Fig. 12-5). Plasminogen, the proenzyme for the fibrinolytic process, normally is present in the blood in its inactive form. It is converted to its active form, plasmin, by plasminogen activators formed in the vascular endothelium, liver, and kidneys. The plasmin formed from plasminogen digests the fibrin strands of the clot and certain clotting factors, such as fibrinogen, factor V, factor VIII, prothrombin, and factor XII. Circulating plasmin is rapidly inactivated by α_2 -plasmin inhibitor, which limits fibrinolysis to the local clot and prevents it from occurring in the entire circulation.

Two naturally occurring plasminogen activators are tissuetype plasminogen activator and urokinase-type plasminogen activator. The liver, plasma, and vascular endothelium are the major sources of physiologic activators. These activators are released in response to a number of stimuli, including vasoactive drugs, venous occlusion, elevated body temperature, and exercise. The activators are unstable and rapidly inactivated by inhibitors synthesized by the endothelium and the liver. For this reason, chronic liver disease may cause altered

■ FIGURE 12-5 ■ Fibrinolytic system and its modifiers. The *solid* lines indicate activation, and the *broken lines* indicate inactivation.

fibrinolytic activity. A major inhibitor, plasminogen activator inhibitor-1, in high concentrations has been associated with deep vein thrombosis, coronary artery disease, and myocar-dial infarction.³

In summary, hemostasis is designed to maintain the integrity of the vascular compartment. The process is divided into five phases: vessel spasm, which constricts the size of the vessel and reduces blood flow; platelet adherence and formation of the platelet plug; formation of the fibrin clot, which cements together the platelet plug; clot retraction, which pulls the edges of the injured vessel together; and clot dissolution, which involves the action of plasmin that dissolves the clot and allows blood flow to be re-established and tissue healing to take place. Blood coagulation requires the stepwise activation of coagulation factors, carefully controlled by activators and inhibitors.

HYPERCOAGULABILITY STATES

Hypercoagulability represents hemostasis in an exaggerated form and predisposes to thrombosis. Arterial thrombi caused by turbulence are composed of platelet aggregates, and venous thrombi caused by stasis of flow are largely composed of platelet aggregates and fibrin complexes that result from excess coagulation. There are two general forms of hypercoagulability states: conditions that create increased platelet function and conditions that cause accelerated activity of the coagulation system. Chart 12-1 summarizes conditions commonly associated with hypercoagulability states.

Increased Platelet Function

Increased platelet function predisposes to platelet adhesion, formation of a platelet or blood clot, and disturbance of blood flow. The causes of increased platelet function are disturbances in flow, endothelial damage, and increased sensitivity of platelets to factors that cause adhesiveness and aggregation. Athero-

CHART 12-1 Conditions Associated With Hypercoagulability States

Increased Platelet Function

Atherosclerosis Diabetes mellitus Smoking Elevated blood lipid and cholesterol levels Increased platelet levels

Accelerated Activity of the Clotting System

Pregnancy and the puerperium Use of oral contraceptives Postsurgical state Immobility Congestive heart failure Malignant diseases sclerotic plaques disturb flow, cause endothelial damage, and promote platelet adherence. Platelets that adhere to the vessel wall release growth factors that can cause proliferation of smooth muscle and thereby contribute to the development of atherosclerosis. Smoking, elevated levels of blood lipids and cholesterol, hemodynamic stress, diabetes mellitus, and immune mechanisms may cause vessel damage, platelet adherence, and, eventually, thrombosis. Some cancers and other diseases are associated with high platelet counts and the potential for thrombosis. The term *thrombocytosis* is used to describe platelet counts greater than 1,000,000/mm³. This occurs in some malignancies and inflammatory states and after splenectomy. Myeloproliferative disorders that result in excess platelet production may predispose to thrombosis or, paradoxically, bleeding when the rapidly produced platelets are defective.

Increased Clotting Activity

Increased clotting activity results from factors that increase the activation of the coagulation system, including stasis of blood flow and alterations in the coagulation components of the blood (*i.e.*, an increase in procoagulation factors or a decrease in anticoagulation factors). Stasis of blood flow causes the accumulation of activated clotting factors and platelets and prevents their interactions with inhibitors. Slow and disturbed flow is a common cause of venous thrombosis in the immobilized or postoperative patient. Heart failure also contributes to venous congestion and thrombosis. Elevated levels of estrogen tend to increase hepatic synthesis of many of the coagulation factors and decrease the synthesis of antithrombin III.⁴ The incidence of stroke, thromboemboli, and myocardial infarction is greater in women who use oral contraceptives, particularly after age 35 years, and in heavy smokers. Clotting factors are also increased during normal pregnancy. These changes, along with limited activity during the puerperium (immediate postpartum period), predispose to venous thrombosis. A hypercoagulability state is also common in cancer and sepsis. Many tumor cells are thought to release tissue factor molecules that, along with the increased immobility and sepsis seen in patients with malignant disease, contribute to increased risk of both venous and arterial thrombosis.

A reduction in anticoagulants such as antithrombin III, protein C, and protein S predisposes to venous thrombosis.⁵

KEY CONCEPTS

HYPERCOAGULABILITY STATES

- Hypercoagulability states increase the risk of clot or thrombus formation in either the arterial or venous circulations.
- Arterial thrombi are associated with conditions that produce turbulent blood flow and platelet adherence.
- Venous thrombi are associated with conditions that cause stasis of blood flow with increased concentrations of coagulation factors.

Deficiencies of these inhibitor proteins are uncommon inherited defects. It has been suggested that high circulating levels of homocysteine also predispose to venous and arterial thrombosis by activating platelets and altering antithrombotic mechanisms.⁶

Another cause of increased venous and arterial clotting is a condition known as the antiphospholipid syndrome.7 The syndrome is associated with a number of clinical manifestations, including multiple thromboses. The condition can manifest as a primary disorder in persons who exhibit only the manifestations of the hypercoagulable state or as a secondary disorder in persons with well-defined autoimmune disorders, such as systemic lupus erythematosus. Thrombosis may be precipitated by trauma, surgical conditions, use of drugs such as oral contraceptives, or abrupt withdrawal of anticoagulant drugs. Persons with the disorder have a history of having one or more of the following: deep venous thrombosis; arterial thrombosis, including stroke, myocardial infarction, or gangrene; or thrombocytopenia.7 Antiphospholipid antibody syndrome is also a cause of renal microangiopathy, resulting in renal failure caused by multiple capillary and arterial thromboses.

Women with the disorder often have a history of recurrent pregnancy losses within the fetal period (10 weeks or more gestation) because of ischemia and thrombosis of placental vessels.⁷ Pregnancies in women with antiphospholipid syndrome can also be complicated by premature delivery caused by pregnancy-associated hypertension and uteroplacental insufficiency.

In most persons with antiphospholipid syndrome, thrombotic events occur singly. However, recurrences may occur months or years after the initial event. Occasionally, someone will present with multiple almost simultaneous vascular occlusions involving different organ systems. The condition, sometimes termed *catastrophic antiphospholipid syndrome*, is a serious and sometimes fatal condition.

Exactly how antiphospholipid antibodies, which interact with cardiolipin, a mitochondrial phospholipid, produce thrombosis is unclear. Possible mechanisms include activation or injury of vascular endothelial cells, direct platelet activation, or inactivation of anticoagulation factors (*e.g.*, anti-thrombin III or protein C).

Treatment focuses on prophylaxis, treatment of acute thrombotic events, and prevention of future thrombotic events.⁷ Prophylaxis focuses on removal or reduction in factors that predispose to thrombosis, such as smoking and the use of estrogen-containing oral contraceptives by women. Treatment during a thrombotic event includes the use of anticoagulant medications (heparin and warfarin) and immune suppression in refractory cases. Aspirin and anticoagulant drugs may be used to prevent further thrombosis.

In summary, hypercoagulability causes excessive clotting and contributes to thrombus formation. It results from conditions that create increased platelet function or that cause accelerated activity of the coagulation system. Increased platelet function usually results from disorders such as atherosclerosis that damage the vessel endothelium and disturb blood flow or from conditions such as smoking that cause increased sensitivity of platelets to factors that promote adhesiveness and aggregation. Factors that cause accelerated activity of the coagulation system include blood flow stasis, resulting in an accumulation of coagulation factors, and alterations in the components of the coagulation system (*i.e.*, an increase in procoagulation factors or a decrease in anticoagulation factors). Another cause of increased venous and arterial clotting is the antiphospholipid syndrome, which can manifest as a primary disorder or as a secondary disorder in persons with autoimmune disorders, such as systemic lupus erythematosus.

BLEEDING DISORDERS

Bleeding disorders or impairment of blood coagulation can result from defects in any of the factors that contribute to hemostasis. Defects are associated with platelets, coagulation factors, and vascular integrity.

Platelet Defects

Platelets provide one of the first defenses against bleeding. Bleeding can occur as a result of a decrease in the number of circulating platelets or impaired platelet function. The depletion of platelets must be relatively severe (10,000 to 20,000/mm³, compared with the normal values of 150,000 to 400,000/mm³) before hemorrhagic tendencies or spontaneous bleeding become evident. Bleeding that results from platelet deficiency commonly occurs in small vessels and is characterized by petechiae (*i.e.*, pinpoint purplish-red spots) and purpura (*i.e.*, purple areas of bruising) on the arms and thighs. Bleeding from mucous membranes of the nose, mouth, gastrointestinal tract, and vagina is characteristic. Bleeding of the intracranial vessels is a rare danger with severe platelet depletion.

KEY CONCEPTS

BLEEDING DISORDERS

- Bleeding disorders are caused by defects associated with platelets, coagulation factors, and vessel integrity.
- Disorders of platelet plug formation include a decrease in platelet numbers due to inadequate platelet production (bone marrow dysfunction), excess platelet destruction (thrombocytopenia), abnormal platelet function (thrombocytopathia), or defects in von Willebrand factor.
- Impairment of the coagulation stage of hemostasis is caused by a deficiency in one or more of the clotting factors.
- Disorders of blood vessel integrity result from structurally weak vessels or vessel damage due to inflammation and immune mechanisms.

Thrombocytopenia

Thrombocytopenia represents a decrease in the number of circulating platelets (usually less than 100,000/mm³). It can result from decreased platelet production by the bone marrow, increased pooling of platelets in the spleen, or decreased platelet survival caused by immune or nonimmune mechanisms. Dilutional thrombocytopenia can result from massive transfusions because blood stored for more that 24 hours has virtually no platelets.

Decreased platelet production can result from suppression or failure of bone marrow function, such as occurs in aplastic anemia (see Chapter 13), or from replacement of bone marrow by malignant cells, such as occurs in leukemia (see Chapter 11). Infection with human immunodeficiency virus (HIV) suppresses the production of megakaryocytes. Radiation therapy and drugs such as those used in the treatment of cancer may suppress bone marrow function and reduce platelet production.

There may be normal production of platelets but excessive pooling of platelets in the spleen. The spleen normally sequesters approximately 30% to 40% of the platelets. However, as much as 80% of the platelets can be sequestered when the spleen is enlarged (splenomegaly). Splenomegaly occurs in cirrhosis with portal hypertension and in lymphomas.

Decreased platelet survival is an important cause of thrombocytopenia. In many cases, premature destruction of platelets is caused by antiplatelet antibodies or immune complexes. The antibodies can be directed against self-antigens (autoimmunity) or against nonself platelet antigens (from blood transfusions). Autoimmune thrombocytopenias include idiopathic thrombocytopenic purpura and HIV-associated thrombocytopenias. Decreased platelet survival may also occur as the result of mechanical injury associated with prosthetic heart valves.

Drug-Induced Thrombocytopenia. Some drugs, such as quinine, quinidine, and certain sulfa-containing antibiotics, may induce thrombocytopenia. These drugs act as a hapten (see Chapter 8) and induce antigen–antibody response and formation of immune complexes that cause platelet destruction by complement-mediated lysis. In persons with drug-associated thrombocytopenia, there is a rapid fall in platelet count within 2 to 3 days of resuming use of a drug or 7 or more days (*i.e.*, the time needed to mount an immune response) after starting use of a drug for the first time. The platelet count rises rapidly after the drug use is discontinued.

The anticoagulant drug heparin has been increasingly implicated in thrombocytopenia and, paradoxically, in thrombosis. The complications typically occur 5 days after the start of therapy and result from production of heparin-dependent antiplatelet antibodies that cause aggregation of platelets and their removal from the circulation. The antibodies often bind to vessel walls, causing injury and thrombosis. The newer, low-molecular-weight heparin has been shown to be effective in reducing the incidence of heparin-induced complications compared with the older, high-molecular-weight form of the drug.⁸

Idiopathic Thrombocytopenic Purpura. Idiopathic thrombocytopenic purpura, an autoimmune disorder, results in platelet antibody formation and excess destruction of platelets. The IgG antibody binds to two identified membrane glycoproteins while in the circulation. The platelets, which are made more susceptible to phagocytosis because of the antibody, are destroyed in the spleen.

Acute idiopathic thrombocytopenic purpura is more common in children and usually follows a viral infection. It is characterized by sudden onset of petechiae and purpura and is a self-limited disorder with no treatment. In contrast, the chronic form is usually seen in adults and seldom follows an infection. It is a disease of young people, with a peak incidence between the ages of 20 and 50 years, and is seen twice as often in women as in men. It may be associated with other immune disorders such as acquired immunodeficiency syndrome (AIDS) or systemic lupus erythematosus. The condition occasionally presents precipitously with signs of bleeding, often into the skin (i.e., purpura and petechiae) or oral mucosa. There is commonly a history of bruising, bleeding from gums, epistaxis (*i.e.*, nosebleeds), and abnormal menstrual bleeding. Because the spleen is the site of platelet destruction, splenic enlargement may occur.

Diagnosis usually is based on severe thrombocytopenia (platelet counts <20,000/mL), and exclusion of other causes. Treatment includes the initial use of corticosteroid drugs, often followed by splenectomy and the use of immunosuppressive agents.

Thrombotic Thrombocytopenic Purpura. Thrombotic thrombocytopenic purpura (TPP) is a combination of thrombocytopenia, hemolytic anemia, signs of vascular occlusion, fever, and neurologic abnormalities. The onset is abrupt, and the outcome may be fatal. Widespread vascular occlusions consist of thrombi in arterioles and capillaries of many organs, including the heart, brain, and kidneys. Erythrocytes become fragmented as they circulate through the partly occluded vessels and cause the hemolytic anemia. The clinical manifestations include purpura and petechiae and neurologic symptoms ranging from headache to seizures and altered consciousness.

Although TTP may have diverse causes, the initiating event seems to be widespread endothelial damage and activation of intravascular thrombosis. Toxins produced by certain strains of *Escherichia coli (e.g., E. coli O157:H7)* are a trigger for endothelial damage and an associated condition called the *hemolytic-uremic syndrome* (see Chapter 27).

Treatment for TTP includes *plasmapheresis*, a procedure that involves removal of plasma from withdrawn blood and replacement with fresh-frozen plasma. The treatment is continued until remission occurs. With plasmapheresis treatment, there is a complete recovery in 80% to 90% of cases.

Impaired Platelet Function

Impaired platelet function (also called *thrombocytopathia*) may result from inherited disorders of adhesion (*e.g.*, von Willebrand disease) or acquired defects caused by drugs, disease, or extracorporeal circulation. Defective platelet function is also common in uremia, presumably because of unexcreted waste products. Cardiopulmonary bypass also causes platelet defects and destruction.

Use of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) is the most common cause of impaired platelet function. Aspirin (acetylsalicylic acid) produces irreversible acetylation of platelet cyclooxygenase (COX), the enzyme required for TXA₂ synthesis. The antiplatelet effects of aspirin last

for the life of the platelet, usually approximately 8 to 9 days. Because aspirin prolongs bleeding time, it is usually recommended that aspirin use be avoided for a week before surgery. The antiplatelet effects of other NSAIDs, which do not contain the acetyl group, are reversible and last only for the duration of drug action.⁹ Because of aspirin's antiplatelet function, low doses of the drug (usually 81 mg daily) are commonly used in the prevention of heart attack and stroke.

Coagulation Defects

Impairment of blood coagulation can result from deficiencies of one or more of the known clotting factors. Deficiencies can arise because of defective synthesis, inherited defects, or increased consumption of the clotting factors. Bleeding that results from clotting factor deficiency typically occurs after injury or trauma. Large bruises, hematomas, or prolonged bleeding into the gastrointestinal or urinary tracts or joints are common.

Impaired Synthesis of Coagulation Factors

Coagulation factors V, VII, IX, X, XI, and XII; prothrombin; and fibrinogen are synthesized in the liver. In liver disease, synthesis of these clotting factors is reduced, and bleeding may result. Of the coagulation factors synthesized in the liver, factors VII, IX, and X and prothrombin require the presence of vitamin K for normal activity. In vitamin K deficiency, the liver produces the clotting factor, but in an inactive form. Vitamin K is a fatsoluble vitamin that is continuously being synthesized by intestinal bacteria. This means that a deficiency in vitamin K is not likely to occur unless intestinal synthesis is interrupted or absorption of the vitamin is impaired. Vitamin K deficiency can occur in the newborn infant before the establishment of the intestinal flora; it can also occur as a result of treatment with broad-spectrum antibiotics that destroy intestinal flora. Because vitamin K is a fat-soluble vitamin, its absorption requires bile salts. Vitamin K deficiency may result from impaired fat absorption caused by liver or gallbladder disease.

Hereditary defects have been reported for each of the clotting factors, but most are rare diseases. The bleeding disorders are hemophilia A, which affects 1 in 10,000 males, and von Willebrand disease, which occurs in 1% of the population.¹⁰ Factor IX deficiency (*i.e.*, hemophilia B) occurs in approximately 1 in 50,000 persons and is genetically and clinically similar to hemophilia A.

Circulating factor VIII is part of a complex molecule, bound to vWF. Factor VIII coagulant protein is the functional portion produced by the liver and endothelial cells. vWF, synthesized by the endothelium and megakaryocytes, binds and stabilizes factor VIII in the circulation by preventing proteolysis. It is also required for platelet adhesion to the subendothelial layer.

Hemophilia A

Hemophilia A, which is caused by a deficiency in factor VIII, is an X-linked recessive disorder that primarily affects males. Although it is a hereditary disorder, there is no family history of the disorder in approximately one third of newly diagnosed cases, suggesting that it has arisen as a new mutation in the factor VIII gene.¹⁰ Approximately 90% of persons with hemophilia produce insufficient quantities of the factor, and 10% produce a defective form. The percentage of normal factor VIII activity in the circulation depends on the genetic defect and determines the severity of hemophilia (i.e., 6% to 50% in mild hemophilia, 2% to 5% in moderate hemophilia, and 1% or less in severe forms of hemophilia).¹⁰ In mild or moderate forms of the disease, bleeding usually does not occur unless there is a local lesion or trauma such as surgery or dental procedures. The mild disorder may not be detected in childhood. In severe hemophilia, bleeding usually occurs in childhood (e.g., it may be noticed at the time of circumcision) and is spontaneous and severe. Characteristically, bleeding occurs in soft tissues, the gastrointestinal tract, and the hip, knee, elbow, and ankle joints. Joint bleeding usually begins when a child begins to walk. Often, a target joint is prone to repeated bleeding. The bleeding causes inflammation of the synovium, with acute pain and swelling. Without proper treatment, chronic bleeding and inflammation cause joint fibrosis and contractures, resulting in major disability. There is also the potential for lifethreatening intracranial hemorrhage.

Factor VIII replacement therapy is initiated when bleeding occurs or as prophylaxis with repeated bleeding episodes. The purpose is to limit the extent of tissue damage. Highly purified factor VIII concentrates prepared from human plasma are the usual replacement products for persons with severe hemophilia. Before blood was tested for infectious diseases, these products were prepared from multiple donor samples and carried a high risk of exposure to viruses for hepatitis and HIV. Donor screening and the development of effective virusinactivation procedures have effectively reduced the transmission of hepatitis viruses and HIV through clotting concentrates. Recombinant factor VIII, although expensive, is now available and should reduce the risk of transmitting HIV or other viruses. Desmopressin acetate (DDAVP, 1-desamino-8-D-arginine vasopressin) may be used to prevent bleeding in persons with mild hemophilia.¹¹ It stimulates the release of vWF (the carrier for factor VIII) from the endothelium, thus increasing factor VIII levels twofold to threefold for several hours.

The cloning of the factor VIII gene and progress in gene delivery systems have led to the hope that hemophilia A may be cured by gene therapy. Carrier detection and prenatal diagnosis can now be done by analysis of direct gene mutation or DNA linkage studies.

Von Willebrand Disease

Von Willebrand disease, which typically is diagnosed in adulthood, is the most common hereditary bleeding disorder. Transmitted as an autosomal trait, it is caused by a deficiency of or defect in vWF. This deficiency results in reduced platelet adhesion. There are many variants of the disease, and manifestations range from mild to severe. Because vWF carries factor VIII, its deficiency may also be accompanied by reduced levels of factor VIII and results in defective clot formation. Symptoms include bruising, excessive menstrual flow, and bleeding from the nose, mouth, and gastrointestinal tract. Many persons with the disorder receive a diagnosis when surgery or dental extraction results in prolonged bleeding. Most cases are mild and untreated.

In severe cases, factor VIII products that contain vWF are infused to replace the deficient clotting factors. The disorder also responds to desmopressin acetate (DDAVP), a synthetic analog of the hormone vasopressin, which stimulates the endothelial cells to release vWF and plasminogen activator. DDAVP can also be used to treat platelet dysfunction caused by uremia, heart bypass, and the effects of aspirin.¹¹

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation is a paradox in the hemostatic sequence and is characterized by widespread intravascular coagulation and bleeding. It is not a primary disease but occurs as a complication of a wide variety of conditions. DIC begins with massive activation of the coagulation sequence as a result of unregulated generation of thrombin, resulting in systemic formation of fibrin. In addition, levels of all the major anticoagulants are reduced (Fig. 12-6). The generation of microthrombi results in vessel occlusion and tissue ischemia. Multiple organ failure may ensue. Clot formation consumes all available coagulation proteins and platelets, and severe hemorrhage results.

The disorder can be initiated by activation of the intrinsic or extrinsic pathways, both of which involve the formation of thrombin (see Fig. 12-4). Initiation of DIC through the extrinsic pathway, as occurs with trauma and cancer, begins with the liberation of tissue factor. The intrinsic pathway may be activated through extensive endothelial damage caused by viruses, infections, or immune mechanisms, or stasis of blood. Obstetric disorders that involve necrotic placental or fetal tissue commonly are associated with DIC. Other inciting clinical conditions include massive trauma, burns, sepsis, shock, meningococcemia, and malignant disease. The initiating factors in these conditions are multiple and often related. For example, in infections, particularly those caused by gramnegative bacteria, endotoxins released from the bacteria activate both the intrinsic and extrinsic pathways. In addition, endotoxins inhibit the anticoagulant activity of protein C.⁵ In obstetric conditions, tissue factor released from the necrotic placental or fetal tissue may enter the circulation. At the same time, the shock, hypoxia, and acidosis that often coexist with the obstetrical condition can also cause widespread endothelial injury.⁵ Chart 12-2 summarizes the conditions associated with DIC.

There is also evidence that the fibrinolytic system may be involved in the pathogenesis of DIC. It may be suppressed and thereby contribute to the formation of microthrombi, or it may be the source of fibrin degradation products that contribute to the bleeding that occurs. Finally, regardless of the inciting event, DIC may be a systemic inflammatory disorder with release of proinflammatory cytokines that mediate the derangement of coagulation and fibrin breakdown.¹²

Although coagulation and formation of microemboli initiate the events that characterize DIC, its acute manifestations usually are more directly related to the bleeding problems that occur. The bleeding may be present as petechiae, purpura, oozing from puncture sites, or severe hemorrhage. Cardiovascular shock is a common complication. Uncontrolled postpartum bleeding may indicate DIC. Microemboli may obstruct blood

causes a fragile wall; Cushing's disease, causing protein wasting and loss of vessel tissue support because of excess cortisol; and senile purpura (*i.e.*, bruising in elderly persons) caused by the aging process. Vascular defects also occur in the course of DIC as a result of the presence of microthrombi and corticosteroid therapy.

Vascular disorders are characterized by easy bruising and the spontaneous appearance of petechiae and purpura of the skin and mucous membranes. In persons with bleeding disorders caused by vascular defects, the platelet count and results of other tests for coagulation factors are normal.

In summary, bleeding disorders or impairment of blood coagulation can result from defects in any of the factors that contribute to hemostasis: platelets, coagulation factors, or vascular integrity. The number of circulating platelets can be decreased (i.e., thrombocytopenia), or platelet function can be impaired (i.e., thrombocytopathia). Impairment of blood coagulation can result from deficiencies of one or more of the known clotting factors. Deficiencies can arise because of defective synthesis (i.e., liver disease or vitamin K deficiency), inherited diseases (i.e., hemophilia A or von Willebrand disease), or increased consumption of the clotting factors (DIC). Bleeding may also occur from structurally weak vessels that result from impaired synthesis of vessel wall components (i.e., vitamin C deficiency, excessive cortisol levels such as in Cushing's disease, or the aging process) or from damage by genetic mechanisms (i.e., hemorrhagic telangiectasia) or the presence of microthrombi.

vessels and cause tissue hypoxia and necrotic damage to organ structures, such as the kidneys, heart, lungs, and brain. As a result, common clinical signs may be caused by renal, circulatory, or respiratory failure. A form of hemolytic anemia may develop as red cells are damaged as they pass through vessels partially blocked by thrombus.

The treatment of DIC is directed toward managing the primary disease, replacing clotting components, and preventing further activation of clotting mechanisms. Transfusions of fresh-frozen plasma, platelets, or fibrinogen-containing cryoprecipitate may correct the clotting factor deficiency. Heparin may be given to decrease blood coagulation, thereby interrupting the clotting process.

Vascular Disorders

Bleeding from small blood vessels may result from vascular disorders. These disorders may occur because of structurally weak vessel walls or because of damage to vessels by inflammation or immune responses. Among the vascular disorders that cause bleeding are hemorrhagic telangiectasia, an uncommon autosomal dominant disorder characterized by thinwalled, dilated capillaries and arterioles; vitamin C deficiency (*i.e.*, scurvy), resulting in poor collagen synthesis and failure of the endothelial cells to be cemented together properly, which

REVIEW QUESTIONS

Relate the function of the platelet to platelet clot formation in myocardial infarction and thrombocytopenia.

- Explain the physiologic basis for the antiplatelet effects of low-dose aspirin.
- Explain the mechanisms whereby immobility, dehydration, oral contraceptive medications, and the antiphospholipid syndrome predispose to blood clotting.
- State the mechanisms of drug-induced thrombocytopenia and idiopathic thrombocytopenia and the differing features in terms of onset and resolution of the disorders.
- Newborn infants often receive an injection of vitamin K shortly after birth. Explain the rationale for this treatment.
- Differentiate between the mechanisms of bleeding in hemophilia A and von Willebrand disease.
- Explain why desmopressin acetate (DDAVP, 1-desamino-8-Darginine vasopressin) is sometimes used in the treatment of mild hemophilia.
- Use information related to blood coagulation to explain the differing actions of the anticoagulant drugs heparin and warfarin.
- Describe the physiologic events that occur with acute disseminated intravascular coagulation.

CHAPTER

Ithough the lungs provide the means for gas exchange between the external and internal environment, it is the hemoglobin in the red blood cells that transports oxygen to the tissues. The red blood cells also function as carriers of carbon dioxide and participate in acid-base balance. The function of the red blood cells, in terms of oxygen transport, is discussed in Chapter 19, and acid-base balance is covered in Chapter 6. This chapter focuses on the red blood cell, anemia, and polycythemia.

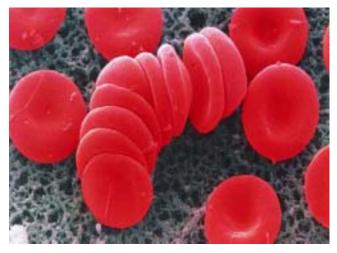

THE RED BLOOD CELL

The mature red blood cell, the erythrocyte, is a non-nucleated, biconcave disk (Fig. 13-1). This shape increases the surface area available for diffusion of oxygen and allows the cell to change in volume and shape without rupturing its membrane. A cyto-skeleton of proteins attached to the lipid bilayer provides this unique shape and flexibility. The biconcave form presents the plasma with a surface 20 to 30 times greater than if the red blood cell were an absolute sphere. The erythrocytes, 500 to 1000 times more numerous than other blood cells, are the most common type of blood cell.

The function of the red blood cell, facilitated by the hemoglobin molecule, is to transport oxygen to the tissues. Hemoglobin also binds some carbon dioxide and carries it from the tissues to the lungs. The hemoglobin molecule is composed of two pairs of structurally different polypeptide chains determined by genes (Fig. 13-2). Alterations in these genes can result in abnormal hemoglobins. Each of the four polypeptide chains is attached to a *heme* unit, which surrounds an atom of iron that binds oxygen. Thus, one molecule of hemoglobin can carry four molecules of oxygen.

The two major types of normal hemoglobin are adult hemoglobin (HbA) and fetal hemoglobin (HbF). HbA consists of a pair of α chains and a pair of β chains. HbF is the predominant hemoglobin in the fetus from the third through the ninth month of gestation. It has a pair of γ chains substituted for the β chains. Because of this chain substitution, HbF has a high affinity for oxygen. This facilitates the transfer of oxygen across the placenta. HbF is replaced within 6 months of birth with HbA.

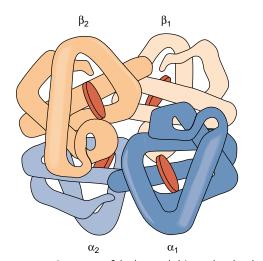

The rate at which hemoglobin is synthesized depends on the availability of iron for heme synthesis. A lack of iron results in relatively small amounts of hemoglobin in the red blood cells. The amount of iron in the body is approximately 35 to 50 mg/kg of body weight for males and less for females. Body iron is found in several compartments. Most of the functional iron (80%) is found in hemoglobin, with small amounts being found in the myoglobin of muscle, the cytochromes, and ironcontaining enzymes such as catalase. Approximately 15% to 20% is stored in the bone marrow, liver, spleen, and other organs. Iron in the hemoglobin compartment is recycled. As red

blood cells age and are destroyed in the spleen, iron from their hemoglobin is released into the circulation and transported to the bone marrow for use in production of new red cells or to the liver and other tissues for storage.

Dietary iron helps to maintain body stores. Iron, principally derived from meat, is absorbed in the small intestine, especially the duodenum (Fig. 13-3). When body stores of iron are diminished or red cell production is stimulated, absorption is increased. In iron overload, excretion of iron is accelerated. Normally, some iron is sequestered in the intestinal epithelial cells and is lost in the feces as these cells slough. The iron that is absorbed enters the circulation, where it immediately combines with a β -globulin, called *apotransferrin*, to form *transferrin*, which is then transported in the plasma. From the plasma, iron can be deposited in tissues such as the liver. There it is stored as *ferritin*, a protein–iron complex, which can easily return to the circulation. Serum

■ FIGURE 13-3 ■ Iron cycle.

ferritin levels, which can be measured in the laboratory, provide an index of body iron stores. Clinically, decreased serum ferritin levels indicate the need for prescription of iron supplements. Transferrin can also deliver iron to the developing red cell in bone marrow by binding to membrane receptors. The iron is taken up by the developing red cell, where it is used in heme synthesis.

Red Cell Production

Erythropoiesis is the production of red blood cells. After birth, red cells are produced in the red bone marrow. Until age 5 years, almost all bones produce red cells to meet growth needs. After this period, bone marrow activity gradually declines. After 20 years of age, red cell production takes place mainly in the membranous bones of the vertebrae, sternum, ribs, and pelvis. With this reduction in activity, the red bone marrow is replaced with fatty yellow bone marrow.

The red cells are derived from the erythroblasts or red cell precursors, which are continuously being formed from the pluripotent stem cells in the bone marrow (Fig. 13-4). As they develop into mature red cells, the red cell precursors move through a series of divisions, each producing a smaller cell. Hemoglobin synthesis begins at an early stage and continues until the cell becomes a mature erythrocyte. During the maturation time, the red blood cell accumulates hemoglobin as the

KEY CONCEPTS

RED BLOOD CELLS

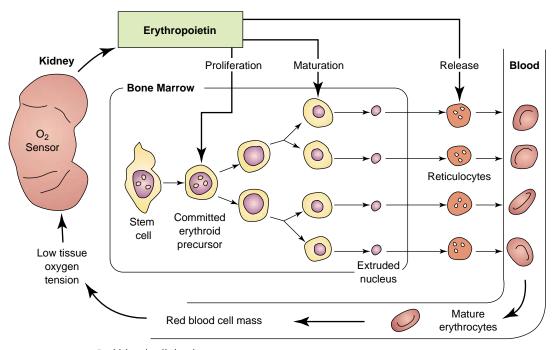

- The function of red blood cells, facilitated by the iron-containing hemoglobin molecule, is to transport oxygen from the lungs to the tissues.
- The production of red blood cells, which is regulated by erythropoietin, occurs in the bone marrow and requires iron, vitamin B₁₂, and folate.
- The red blood cell, which has a life span of approximately 120 days, is broken down in the spleen; the degradation products such as iron and amino acids are recycled.
- The heme molecule, which is released from the red blood cell during the degradation process, is converted to bilirubin and transported to the liver, where it is removed and rendered water soluble for elimination in the bile.

nucleus condenses and is finally lost. The period from stem cell to emergence of the reticulocyte in the circulation normally takes approximately 1 week. Maturation of reticulocyte to erythrocyte takes approximately 24 to 48 hours. During this process, the red cell loses its mitochondria and ribosomes, along with its ability to produce hemoglobin and engage in oxidative metabolism. Most maturing red cells enter the blood as reticulocytes. Approximately 1% of the body's total complement of red blood cells is generated from bone marrow each day, so the reticulocyte count serves as an index of the erythropoietic activity of the bone marrow.

Erythropoiesis is governed for the most part by tissue oxygen needs. Any condition that causes a decrease in the amount of oxygen that is transported in the blood produces an increase in red cell production. The oxygen content of the blood does not act directly on the bone marrow to stimulate red blood cell production. Instead, the decreased oxygen content is sensed by the kidneys, which then produce a hormone called *erythropoietin*. Normally, the kidneys produce approximately 90% of erythropoietin, with the remaining 10% being released by the liver. In the absence of erythropoietin, as in kidney failure, hypoxia has little or no effect on red blood cell production. Erythropoietin takes several days to effect a release of red blood cells from the bone marrow, and only after 5 days or more does red blood cell production reach a maximum.

Erythropoietin acts in the bone marrow by binding to receptors on committed stem cells. It functions on many levels to promote hemoglobin synthesis, increase production of membrane proteins, and cause differentiation of erythroblasts. Human erythropoietin can be produced by recombinant deoxyribonucleic acid (DNA) technology. It is used for management of anemia in cases of chronic renal failure, for treatment of chemotherapy-induced anemia in persons with malignancies, and treatment of anemia in persons with human immunodeficiency virus (HIV) infection who are being treated with zidovudine.

Because red blood cells are released into the blood as reticulocytes, the percentage of these cells is higher when there is a marked increase in red blood cell production. For example, in some severe anemias, the reticulocytes may account for as much as 30% of the total red cell count. In some situations, red cell production is so accelerated that numerous erythroblasts appear in the blood.

■ FIGURE 13-4 ■ Red blood cell development.

Red Cell Destruction

Mature red blood cells have a life span of approximately 4 months or 120 days. As the red blood cell ages, a number of changes occur. Metabolic activity in the cell decreases, and enzyme activity decreases; adenosine triphosphate (ATP) decreases, and the cell membrane becomes more fragile. Once the red cell membrane becomes fragile, the cell ruptures during passage through narrowed places in the circulation. Many of the red cells self-destruct in the small trabecular spaces in the red pulp of the spleen. The rate of red cell destruction (1% per day) normally is equal to red cell production, but in conditions such as hemolytic anemia, the cell's life span may be shorter.

The destruction of red blood cells is facilitated by a group of large phagocytic cells found in the spleen, liver, bone marrow, and lymph nodes. These phagocytic cells ingest the hemoglobin from the ruptured cells and break it down in a series of enzymatic reactions. During these reactions, the amino acids from the globulin chains and iron from the heme units are salvaged and reused (Fig. 13-5). The bulk of the heme unit is converted to bilirubin, the pigment of bile, which is insoluble in plasma and attaches to the plasma proteins for transport. Bilirubin is removed from the blood by the liver and conjugated with glucuronide to render it water soluble so that it can be excreted in the bile. The plasma-insoluble form of bilirubin is referred to as unconjugated bilirubin; the water-soluble form is referred to as conjugated bilirubin. Serum levels of conjugated and unconjugated bilirubin can be measured in the laboratory and are reported as direct and indirect, respectively. If red cell

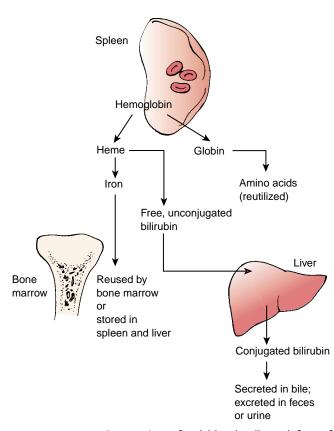

FIGURE 13-5 Destruction of red blood cells and fate of hemoglobin.

destruction and consequent bilirubin production are excessive, unconjugated bilirubin accumulates in the blood. This results in a yellow discoloration of the skin, called *jaundice*.

When red blood cell destruction takes place in the circulation, as in hemolytic anemia, the hemoglobin-binding protein called *haptoglobin*. Other plasma proteins, such as albumin, can also bind hemoglobin. With extensive intravascular destruction of red blood cells, hemoglobin levels may exceed the hemoglobin-binding capacity of haptoglobin. When this happens, free hemoglobin appears in the blood (*i.e.*, hemoglobinemia) and is excreted in the urine (*i.e.*, hemoglobinuria). Because excessive red blood cell destruction can occur in hemolytic transfusion reactions, urine samples are tested for free hemoglobin after a transfusion reaction.

Red Cell Metabolism and Hemoglobin Oxidation

The red blood cell, which lacks mitochondria, relies on glucose and the glycolytic pathway for its metabolic needs. The enzyme-mediated anaerobic metabolism of glucose generates the ATP needed for normal membrane function and ion transport. The depletion of glucose or the functional deficiency of one of the glycolytic enzymes leads to the premature death of the red blood cell. An offshoot of the glycolytic pathway is the production of 2,3-diphosphoglycerate (2,3-DPG), which binds to the hemoglobin molecule and reduces the affinity of hemoglobin for oxygen. This facilitates the release of oxygen at the tissue level. An increase in the concentration of 2,3-DPG occurs in conditions of chronic hypoxia such as chronic lung disease, anemia, and high altitudes.

The oxidation of hemoglobin—the combining of hemoglobin with oxygen-can be interrupted by certain chemicals (e.g., nitrates and sulfates) and drugs that oxidize hemoglobin to an inactive form. For example, the nitrite ion reacts with hemoglobin to produce methemoglobin, which has a low affinity for oxygen. Large doses of nitrites can result in high levels of methemoglobin, causing pseudocyanosis and tissue hypoxia. For example, sodium nitrate, which is used in curing meats, can produce methemoglobin when taken in large amounts. In nursing infants, the intestinal flora is capable of converting significant amounts of inorganic nitrate (e.g., from well water) to nitrite. A hereditary deficiency of glucose 6-phosphate dehydrogenase (G6PD; to be discussed) predisposes to oxidative denaturation of hemoglobin, with resultant red cell injury and lysis. Hemolysis occurs as the result of oxidative stress generated by either an infection or exposure to certain drugs.

Laboratory Tests

Red blood cells can be studied by means of a sample of blood (Table 13-1). In the laboratory, automated blood cell counters rapidly provide accurate measurements of red cell content and cell indices. The *red blood cell count* (RBC) measures the total number of red blood cells in 1 mm³ of blood. The *percentage of reticulocytes* (normally approximately 1%) provides an index of the rate of red cell production. The *hemoglobin* (grams per 100 mL of blood) measures the hemoglobin content of the blood. The major components of blood are the red cell mass and plasma volume. The *hematocrit* measures the volume of red

220 Unit Three: Alterations in the Hematologic System

TABLE 13-1	Standard Laboratory Values for Red Blood Cells						
Test		Normal Values	Significance				
Red blood cell count (RBC)							
Men		$4.2-5.4 imes 10^{6}/\mu L$	Number of red cells in the blood				
Women		$3.6-5.0 \times 10^{6}/\mu$ L					
Reticulocytes		1.0%–1.5% of total RBC	Rate of red cell production				
Hemoglobin							
Men		14–16.5 g/dL	Hemoglobin content of the blood				
Women		12–15 g/dL					
Hematocrit							
Men		40%–50%	Volume of cells in 100 mL of blood				
Women		37%–47%					
Mean corpuscular volume		85–100 fL/red cell	Size of the red cell				
Mean corpuscular hemoglobin concentration		31–35 g/dL	Concentration of hemoglobin in the red cell				
Mean cell hemog	obin	27–34 pg/cell	Red cell mass				

cell mass in 100 mL of plasma volume. To determine the hematocrit, a sample of blood is placed in a glass tube, which is then centrifuged to separate the cells and the plasma. The hematocrit may be deceptive because it varies with the quantity of extracellular fluid, rising with dehydration and falling with overexpansion of extracellular fluid volume.

Red cell indices are used to differentiate types of anemias by size or color of red cells. The *mean corpuscular volume* (MCV) reflects the volume or size of the red cells. The MCV falls in microcytic (small cell) anemia and rises in macrocytic (large cell) anemia. Some anemias are normocytic (*i.e.*, cells are of normal size or MCV). The *mean corpuscular hemoglobin concentration* (MCHC) is the concentration of hemoglobin in each cell. Hemoglobin accounts for the color of red blood cells. Anemias are described as *normochromic* (normal color or MCHC) or *hypochromic* (decreased color or MCHC). *Mean cell hemoglobin* (MCH) refers to the mass of the red cell and is less useful in classifying anemias.

A stained blood smear provides information about the size, color, and shape of red cells and the presence of immature or abnormal cells. If blood smear results are abnormal, examination of the bone marrow may be important. Marrow commonly is aspirated with a special needle from the posterior iliac crest or the sternum. The aspirate is stained and observed for number and maturity of cells and abnormal types.

In summary, the red blood cell provides the means for transporting oxygen from the lungs to the tissues. Red cells develop from stem cells in the bone marrow and are released as reticulocytes into the blood, where they become mature erythrocytes. Red blood cell production is regulated by the hormone erythropoietin, which is produced by the kidney in response to a decrease in oxygen levels. The life span of a red blood cell is approximately 120 days. Red cell destruction normally occurs in the spleen, liver, bone marrow, and lymph nodes. In the process of destruction, the iron from the hemoglobin is returned to the bone marrow for reuse in red cell production or taken to the liver or other tissues for storage. The heme portion of the hemoglobin molecule is converted to bilirubin. Bilirubin, which is insoluble in plasma, attaches to plasma proteins for transport in the blood. It is removed from the blood by the liver and conjugated to a water-soluble form so that it can be excreted in the bile.

The red blood cell, which lacks mitochondria, relies on glucose and the glycolytic pathway for its metabolic needs. The end-product of the glycolytic pathway, 2,3-DPG, increases the release of oxygen to the tissues during conditions of hypoxia by reducing hemoglobin's affinity for oxygen.

In the laboratory, automated blood cell counters rapidly provide accurate measurements of red cell content and cell indices. A stained blood smear provides information about the size, color, and shape of red cells and the presence of immature or abnormal cells. If blood smear results are abnormal, examination of the bone marrow may be important.

ANEMIA

Anemia is defined as an abnormally low hemoglobin level, number of circulating red blood cells, or both, resulting in diminished oxygen-carrying capacity of the blood. Anemia usually results from excessive loss (*i.e.*, bleeding) or destruction (*i.e.*, hemolysis) of red blood cells or from deficient red blood cell production because of a lack of nutritional elements or bone marrow failure.

Anemia is not a disease, but an indication of some disease process or alteration in body function. The manifestations of anemia can be grouped into three categories: (1) impaired oxygen transport and recruitment of compensatory mechanisms; (2) alterations in hemoglobin levels and red cell number and appearance; and (3) signs and symptoms associated with the pathologic process that is causing the anemia. The manifestations of anemia also depend on its severity, the rapidity of its development, and the affected person's age and health status. With rapid blood loss, circulatory shock and circulatory collapse may occur. Because the body adapts to slowly developing anemia, the amount of red cell mass lost may reach 50% without the occurrence of signs and symptoms.¹

In anemia, the oxygen-carrying capacity of hemoglobin is reduced, causing tissue hypoxia. Tissue hypoxia can give rise

KEY CONCEPTS

ANEMIA

- Anemia, which is a deficiency of red cells or hemoglobin, results from excessive loss (blood loss anemia), increased destruction (hemolytic anemia), or impaired production of red blood cells (irondeficiency, megaloblastic, and aplastic anemias).
- Blood loss anemia is characterized by loss of ironcontaining red blood cells from the body; hemolytic anemia involves destruction of red blood cells in the body with iron being retained in the body.
- Manifestations of anemia are caused by the decreased presence of hemoglobin in the blood (pallor), tissue hypoxia due to deficient oxygen transport (weakness and fatigue), and recruitment of compensatory mechanisms (tachycardia and palpitations) designed to increase oxygen delivery to the tissues.

to fatigue, weakness, dyspnea, and sometimes angina. Brain hypoxia results in headache, faintness, and dim vision. The redistribution of the blood from cutaneous tissues or a lack of hemoglobin causes pallor of the skin, mucous membranes, conjunctiva, and nail beds. Tachycardia and palpitations may occur as the body tries to compensate with an increase in cardiac output. A flow-type systolic heart murmur may result from the turbulence caused by a decrease in blood viscosity. Ventricular hypertrophy and high-output heart failure may develop in persons with severe anemia, particularly those with pre-existing heart disease. Erythropoiesis is accelerated and may be recognized by diffuse bone pain and sternal tenderness. The production of 2,3-DPG is a compensatory mechanism that reduces the hemoglobin affinity for oxygen, as evidenced by a shift to the right in the oxygen-hemoglobin saturation curve; this causes more oxygen to be released to the tissues rather than remaining bound to hemoglobin.

Blood Loss Anemia

With anemia caused by bleeding, iron and other components of the erythrocyte are lost from the body. Blood loss may be acute or chronic.

Acute blood loss is accompanied by a loss of vascular volume and carries with it a risk of hypovolemia and shock (see Chapter 18). The red cells are normal in size and color. Hemodilution caused by movement of fluid into the vascular compartment produces a fall in red blood cell count, hemoglobin, and hematocrit. The hypoxia that results from blood loss stimulates red cell production by the bone marrow. If the bleeding is controlled and sufficient iron stores are available, the red cell concentration returns to normal within 3 to 4 weeks.

Chronic blood loss does not affect blood volume but instead leads to iron-deficiency anemia when iron stores are depleted. Because of compensatory mechanisms, patients commonly have no symptoms until the hemoglobin level is less than 8 g/dL. The red cells that are produced have too little hemoglobin, giving rise to microcytic hypochromic anemia.

Hemolytic Anemia

Hemolytic anemia is characterized by the (1) premature destruction of red cells, (2) retention in the body of iron and the other products of hemoglobin destruction, and (3) marked increase in erythropoiesis within the bone marrow.² Almost all types of hemolytic anemia are distinguished by normocytic and normochromic red cells. Because of the red blood cell's shortened life span, the bone marrow usually is hyperactive, resulting in an increase in the number of reticulocytes in the circulating blood. As with other types of anemias, the person experiences easy fatigability, dyspnea, and other signs and symptoms of impaired oxygen transport. The person may also have an increase in serum bilirubin and mild jaundice.

In hemolytic anemia, red cell breakdown can occur in the vascular compartment, or it can result from phagocytosis within the reticuloendothelial system. Intravascular hemolysis occurs as a result of complement fixation in transfusion reactions, mechanical injury, or toxic factors. It is characterized by hemoglobinemia and hemoglobinuria. Extravascular hemolysis occurs when abnormal red cells are phagocytized in the spleen. A common example is sickle cell anemia.

The cause of hemolytic anemia can be intrinsic or extrinsic to the red blood cell. Intrinsic causes include defects of the red cell membrane, the various hemoglobinopathies, and inherited enzyme defects. Acquired forms of hemolytic anemia are caused by agents extrinsic to the red blood cell, such as drugs, bacterial and other toxins, antibodies, and physical trauma. Although all these factors can cause premature and accelerated destruction of red cells, they cannot all be treated in the same way. Some respond to splenectomy, others respond to treatment with corticosteroid hormones, and still others do not resolve until the primary disorder is corrected.

Inherited Disorders of the Red Cell Membrane

Hereditary spherocytosis, transmitted as an autosomal dominant trait, is the most common inherited disorder of the red cell membrane. The disorder is a deficiency of membrane proteins (*i.e.*, spectrin and ankyrin) that leads to gradual loss of the membrane surface during the life span of the red blood cell, resulting in a tight sphere instead of a concave disk. Although the spherical cell retains its ability to transport oxygen, it is poorly deformable and susceptible to destruction as it passes through the venous sinuses of the splenic circulation. Clinical signs are variable but typically include mild anemia, splenomegaly, jaundice, and bilirubin gallstones. A life-threatening aplastic crisis may occur when a sudden disruption of red cell production (in most cases from a viral infection) causes a rapid drop in hematocrit and the hemoglobin level. The disorder usually is treated with splenectomy to reduce red cell destruction.

Hemoglobinopathies

Hemoglobinopathies represent abnormalities in hemoglobin structure that can lead to accelerated red cell destruction. Two main types of hemoglobinopathies can cause red cell hemolysis: the abnormal substitution of an amino acid in the hemoglobin molecule, as in sickle cell anemia, and the defective synthesis of one of the polypeptide chains that form the globin portion of hemoglobin, as in the thalassemias.

Sickle Cell Disease (Anemia). Sickle cell disease is a chronic disorder resulting in organ failure and premature death. The disorder affects approximately 50,000 (0.1% to 0.2%) black Americans. Approximately 8% of black Americans carry the trait.²

Sickle cell disease results from a point mutation in the β chain of the hemoglobin molecule, with an abnormal substitution of a single amino acid, valine, for glutamic acid. Sickle hemoglobin (HbS) is transmitted by recessive inheritance and can manifest as sickle cell trait (*i.e.*, in heterozygotes with one HbS gene and one normal HbA gene) or sickle cell disease (*i.e.*, in homozygotes with two HbS genes). In the homozygote with sickle cell disease, almost all the hemoglobin is HbS. In the heterozygote with sickle cell trait, only approximately 40% of the hemoglobin is HbS.

In the homozygote, sickling occurs when the HbS becomes deoxygenated.³ The deoxygenated hemoglobin aggregates and polymerizes, creating a semisolid gel that changes the shape and deformability of the cell (Fig. 13-6). Sickling of red cells is initially a reversible process with oxygenation. HbS returns to its normal depolymerized state. However, with repeated episodes of deoxygenation, the cells remain permanently sickled. These sickled red cells are abnormally adhesive, attach to the vessel wall, and cause accumulation of more cells that obstruct blood flow in the microcirculation, leading to tissue hypoxia.³ Sickled cells have a rigid and nondeformable membrane, predisposing to premature destruction and hemolysis. Thus, the life span of the sickled cells is markedly reduced.

Perhaps the most important factor in promoting sickling is the amount of HbS and its interaction with other hemoglobin chains. The person with sickle cell trait who has less HbS has little tendency to sickle except during severe hypoxia and has virtually no symptoms. HbF does not interact with HbS or sickle; therefore, infants with sickle cell disease do not begin to experience the effects of the sickling until sometime

■ FIGURE 13-6 ■ Photograph of a sickled cell and a normal red blood cell. (© Dr. Gopal Murti, Science Photo Library, Science Source/Photo Researchers)

after 4 to 6 months of age, when the HbF has been replaced by HbS.

The factors associated with sickling and consequent blood vessel occlusion in persons with sickle cell disease include cold; stress; physical exertion; infection; illnesses that may cause hypoxia, acidosis, or dehydration; or even such trivial incidents as reduced oxygen tension induced by sleep. The rate of HbS polymerization is affected by the hemoglobin concentration in the cell. Thus dehydration, which increases the hemoglobin concentration, greatly facilitates sickling and vascular obstruction. Acidosis, or a fall in pH, which reduces the affinity of hemoglobin for oxygen, can increase sickling because it enhances the amount of deoxygenated HbS.

Persons with sickle cell disease experience problems associated with severe hemolytic anemia, chronic hyperbilirubinemia, and vaso-occlusion. Chronic hemolysis produces rather severe anemia, with hematocrit levels ranging from 18% to 30%.² The hyperbilirubinemia that results from the breakdown products of hemoglobin often leads to jaundice and the production of pigment stones in the gallbladder. Children with sickle cell disease may experience growth retardation and susceptibility to osteomyelitis.

Vaso-occlusion accounts for the most severe complications of sickle cell disease. An acute pain episode results from vessel occlusion and can affect almost any part of the body. Common sites obstructed by sickled cells include the abdomen, chest, bones, and joints. Multiple areas are frequently involved simultaneously, and symmetric involvement of both extremities is common. The frequency ranges from daily to yearly. Infarctions caused by sluggish blood flow can cause chronic damage to the liver, spleen, heart, kidneys, retina, and other organs. Acute chest syndrome is an atypical pneumonia resulting from pulmonary infarction. It affects approximately 40% of persons with sickle cell disease and is characterized by fever, chest pain, and cough.⁴ The syndrome can cause chronic respiratory insufficiency and is a leading cause of death in sickle cell disease. The most serious complication is stroke resulting from cerebral occlusion. Stroke associated with vessel occlusion occurs in children 1 to 15 years of age and may recur in two thirds of those afflicted.

The spleen is especially susceptible to damage by sickle cell hemoglobin. Because of the spleen's sluggish blood flow and low oxygen tension, hemoglobin is deoxygenated and causes ischemia. Splenic injury begins as early as 3 to 6 months of age with intense congestion and is usually asymptomatic.⁵ The congestion causes functional asplenia and predisposes the person to life-threatening infections by encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Klebsiella* species. Neonates and small children who have not had time to create antibodies to these organisms rely on the spleen for their removal.⁵

Most children with sickle cell disease are at risk for fulminant septicemia and death during the first 3 years of life, when bacteremia from encapsulated organisms occurs commonly even in normal children. Prophylactic penicillin should be begun as early as 2 months of age and continued until at least 5 years of age.⁶ Maintaining full immunization, including administration of *H. influenzae* and hepatitis B vaccines, is recommended. The National Institutes of Health Committee on Management of Sickle Cell Disease also recommends administration of the 7-valent pneumococcal vaccine (see Chapter 20) beginning at 2 to 6 months of age.⁶ The 7-valent vaccine should be followed by immunization with the 23-valent pneumococcal vaccine at 24 months of age or after.⁶

There is no known cure for sickle cell anemia, so treatment to reduce symptoms includes pain control, hydration, and management of complications. Persons with the disorder need to avoid situations that precipitate sickling episodes, such as infections, cold exposure, severe physical exertion, acidosis, and dehydration. Infections are aggressively treated, and blood transfusions may be warranted in a crisis or given chronically in severe disease.

In the United States, screening programs have been implemented to detect newborns with sickle cell disease and other hemoglobinopathies so that appropriate interventions can be implemented. Hydroxyurea is a promising new treatment for the prevention of complications. The drug allows synthesis of more HbF and less HbS, thereby decreasing sickling.^{4,6} Hematopoietic stem cell transplantation may offer the curative potential for sickle cell disease in the future.⁶

Thalassemias. In contrast to sickle cell anemia, the thalassemias result from absent or defective synthesis of the α or the β chains of hemoglobin. The β -thalassemias represent a defect in β -chain synthesis, and the α -thalassemias represent a defect in α -chain synthesis. The defect is inherited as a mendelian trait, and a person may be heterozygous for the trait and have a mild form of the disease or be homozygous and have the severe form of the disease. Like sickle cell anemia, the thalassemias occur with high degree of frequency in certain populations. The β -thalassemias, sometimes called *Cooley's anemia* or *Mediterranean anemia*, are most common in the Mediterranean populations of southern Italy and Greece, and the α -thalassemias are most common among Asians. Both α - and β -thalassemias are common in Africans and black Americans.

Two factors contribute to the anemia that occurs in the thalassemias: reduced hemoglobin synthesis and an imbalance in globin chain production. In α - and β -thalassemia, defective globin chain production leads to deficient hemoglobin production and the development of a hypochromic microcytic anemia. The unaffected type of chain continues to be synthesized, accumulates in the red cell, interferes with normal maturation, and contributes to red cell destruction and anemia. In the β -thalassemias, the excess α chains are denatured to form precipitates (*i.e.*, Heinz bodies) in the bone marrow red cell precursors.^{2,7} These Heinz bodies impair DNA synthesis and cause damage to the red cell membrane. Severely affected red cell precursors are destroyed in the bone marrow, and those that escape intramedullary death are at increased risk of destruction in the spleen.

The clinical manifestations of the β -thalassemias are based on the severity of the anemia. The presence of one normal gene in heterozygous persons (thalassemia minor) usually results in sufficient normal hemoglobin synthesis to prevent severe anemia.² Persons who are homozygous for the trait (thalassemia major) have severe, transfusion-dependent anemia evident at 6 to 9 months of age. Severe growth retardation affects children with the disorder. Increased hematopoiesis in response to erythropoietin causes bone marrow expansion, impairs bone growth, and causes bone abnormalities. The facial and cranial bones, in particular, tend to be enlarged and distorted.^{2,8} In addition, there is increased iron absorption, and splenomegaly and hepatomegaly resulting from increased red cell destruction.² Excess iron stores, which accumulate from increased dietary absorption and repeated transfusions, can deposit in the myocardium, liver, and pancreas and produce organ injury. Cardiac disease resulting from iron overload and secondary hemochromatosis is a frequent cause of death. Frequent transfusions prevent most of the complications, and iron chelation therapy can reduce the iron overload and extend life into the fifth decade.⁸ Bone marrow transplantation is a potential cure for some patients.

Synthesis of the α chains of the hemoglobin molecule is controlled by two pairs of genes; thus, α -thalassemia shows great variations in severity. Silent carriers who have deletion of a single α -thalassemia gene and those with deletion of two genes usually have no symptoms. The most severe form of α -thalassemia occurs in infants in whom all four α -thalassemia genes are deleted.^{8,9} Such a defect results in a hemoglobin molecule (Hb Bart's) that is formed exclusively from the chains of HbF. Hb Bart's, which has an extremely high oxygen affinity, cannot release oxygen in the tissues. Affected infants experience severe hypoxia and are stillborn or die shortly after birth unless intrauterine transfusions are given. Deletion of three of the four α -chain genes leads to unstable aggregates of β chains called hemoglobin H (HbH). The β chains are more soluble than the α chains, and their accumulation is less toxic to the red cells, so that senescent, rather than precursor, red cells are affected. Most persons with HbH have only mild to moderate hemolytic anemia, and manifestations of ineffective erythropoiesis (*i.e.*, bone marrow expansion and iron overload) are absent.

Inherited Enzyme Defects

The most common inherited enzyme defect that results in hemolytic anemia is a deficiency of G6PD. The gene that determines this enzyme is located on the X chromosome, and the defect is expressed only in males and homozygous females. There are many genetic variants of this disorder. The African variant has been found in 10% of black Americans.² The disorder makes red cells more vulnerable to oxidants and causes direct oxidation of hemoglobin to methemoglobin and the denaturing of the hemoglobin molecule to form Heinz bodies, which precipitate within the red blood cell. Hemolysis usually occurs as the damaged red blood cells move through the narrow vessels of the spleen, causing hemoglobinemia, hemoglobinuria, and jaundice. The hemolysis is short-lived, occurring 2 to 3 days after the trigger event. In blacks, the defect is mildly expressed and is not associated with chronic hemolytic anemia unless triggered by oxidant drugs, acidosis, or infection. The antimalarial drug primaquine, the sulfonamides, nitrofurantoin, aspirin, phenacetin, some chemotherapeutics, and other drugs cause hemolysis. Free radicals generated by phagocytes during infections also are possible triggers.

Acquired Hemolytic Anemias

Several acquired factors exogenous to the red blood cell produce hemolysis by direct membrane destruction or by antibodymediated lysis. Various drugs, chemicals, toxins, venoms, and infections such as malaria destroy red cell membranes. Hemolysis can also be caused by mechanical factors such as prosthetic heart valves, vasculitis, and severe burns. Obstructions in the microcirculation, as in disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and renal disease, may traumatize the red cells by producing turbulence and changing pressure gradients.

Many hemolytic anemias are immune mediated, caused by antibodies that damage the red cell membrane. Autoantibodies may be produced by a person in response to drugs and disease. Alloantibodies come from an exogenous source and are responsible for transfusion reactions and hemolytic disease of the newborn.

The autoantibodies that cause red cell destruction are of two types: warm-reacting antibodies of the immunoglobulin G (IgG) type, which are maximally active at 37°C, and coldreacting antibodies of the immunoglobulin M (IgM) type, which are optimally active at or near 4°C. The warm-reacting antibodies cause no morphologic or metabolic alteration in the red cell. Instead, they react with antigens on the red cell membrane, causing destructive changes that lead to spherocytosis, with subsequent phagocytic destruction in the spleen or reticuloendothelial system. They lack specificity for the ABO antigens but may react with the Rh antigens. The hemolytic reactions associated with the warm-reacting antibodies occur with an incidence of approximately 10 per 1 million. The reactions have a rapid onset, and persons usually have mild jaundice and manifestations of anemia. There are varied causes; approximately 50% are idiopathic, and 50% are drug induced or are related to cancers of the lymphoproliferative system (e.g., chronic lymphocytic leukemia, lymphoma) or collagen diseases (e.g., systemic lupus erythematosus).² The drug-related hemolytic anemias are usually benign conditions. The principle offenders are the antihypertensive drug α -methyldopa and the antiarrhythmic agent quinidine.8

The cold-reacting antibodies activate complement. Chronic hemolytic anemia caused by cold-reacting antibodies occurs with lymphoproliferative disorders and as an idiopathic disorder of unknown cause. The hemolytic process occurs in distal body parts, where the temperature may fall to less than 30°C. Vascular obstruction by red cells results in pallor, cyanosis of the body parts exposed to cold temperatures, and Raynaud's phenomenon (see Chapter 15). Hemolytic anemia caused by cold-reacting antibodies develops in only a few persons and is rarely severe.

The Coombs' test, or the antiglobulin test, is used to diagnose immune hemolytic anemias. It detects the presence of antibody or complement on the surface of the red cell.

Anemias of Deficient Red Cell Production

Anemia may result from the decreased production of erythrocytes by the bone marrow. A deficiency of nutrients for hemoglobin synthesis (iron) or DNA synthesis (cobalamin or folic acid) may reduce red cell production by the bone marrow. A deficiency of red cells also results when the marrow itself fails or is replaced by nonfunctional tissue.

Iron-Deficiency Anemia

Iron deficiency is a common worldwide cause of anemia affecting persons of all ages. The anemia results from dietary deficiency, loss of iron through bleeding, or increased demands. Because iron is a component of heme, a deficiency leads to decreased hemoglobin synthesis and consequent impairment of oxygen delivery. Body iron is used repeatedly. When red cells become senescent and are broken down, their iron is released and reused in the production of new red cells. Despite this efficiency, small amounts of iron are lost in the feces and need to be replaced by dietary uptake. Iron balance is maintained by the absorption of 0.5 to 1.5 mg daily to replace the 1 mg lost in the feces. The average Western diet supplies this amount. The absorbed iron is more than sufficient to supply the needs of most individuals but may be barely adequate in women and young children. Dietary deficiency of iron is uncommon in developed countries, except in certain populations. Most iron is derived from meat, and when meat is not available, as for deprived populations, or is not a dietary constituent, as for vegetarians, iron deficiency may occur.

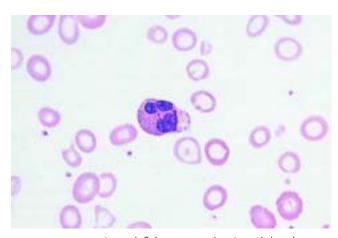

The usual reason for iron deficiency in adults is chronic blood loss because iron cannot be recycled to the pool. In men and postmenopausal women, blood loss may occur from gastrointestinal bleeding because of peptic ulcer, intestinal polyps, hemorrhoids, or cancer. Excessive aspirin intake may cause undetected gastrointestinal bleeding. In women, menstruation may account for an average of 1.5 mg of iron lost per day, causing a deficiency.¹⁰ Although cessation of menstruation removes a major source of iron loss in the pregnant woman, iron requirements increase at this time and deficiency is common. The expansion of the mother's blood volume requires approximately 500 mg of additional iron, and the growing fetus requires approximately 360 mg during pregnancy. During the postnatal period, lactation requires approximately 1.0 mg of iron daily.¹⁰

A child's growth places extra demands on the body. Blood volume increases, with a greater need for iron. Iron requirements are proportionally higher in infancy (3 to 24 months) than at any other age, although they are also increased in childhood and adolescence. In infancy, the two main causes of iron-deficiency anemia are low iron levels at birth because of maternal deficiency and a diet consisting mainly of cow's milk, which is low in absorbable iron. Adolescents are also susceptible to iron deficiency because of high requirements due to growth spurts, dietary deficiencies, and menstrual loss.¹¹

Iron deficiency anemia is characterized by low hemoglobin and hematocrit values, decreased iron stores, and low serum iron and ferritin levels. The red cells are decreased in number and are microcytic and hypochromic. Poikilocytosis (irregular shape) and anisocytosis (irregular size) are also present (Fig 13-7). The laboratory values indicate reduced MCHC and MCV. Membrane changes may predispose to hemolysis, causing further loss of red cells.

The manifestations of iron-deficiency anemia are related to lack of hemoglobin and impaired oxygen transport. Depending on the severity of the anemia, fatigability, palpitations, dyspnea, angina, and tachycardia may occur. Epithelial tissue atrophy is common and results in waxy pallor, brittle hair and nails, smooth tongue, sores in the corners of the mouth, and sometimes dysphagia and decreased acid secretion. A poorly understood symptom that sometimes is seen is pica, the bizarre compulsive eating of ice, dirt, or other abnormal substances.

The treatment of iron-deficiency anemia is directed toward controlling chronic blood loss, increasing dietary intake of iron, and administering supplemental iron. Ferrous sulfate, which is the usual oral replacement therapy, replenishes iron stores in several months. Parenteral iron (iron dextran) therapy

■ FIGURE 13-7 ■ Iron deficiency anemia. A peripheral smear shows hypochromic and microcytic erythrocytes. Poikilocytosis (irregular shape) and anisocytosis (irregular size) are often observed. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1077]. Philadelphia: Lippincott-Raven)

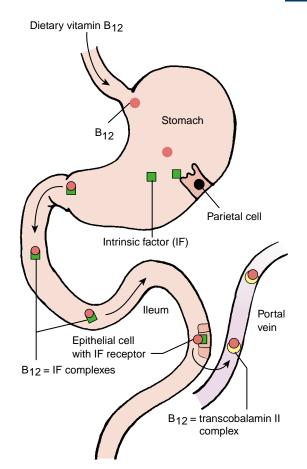

may be used when oral forms are not tolerated or are ineffective. Caution is required because of the possibility of severe hypersensitivity reactions.

Megaloblastic Anemias

Megaloblastic anemias are caused by abnormal nucleic acid synthesis that results in enlarged red cells (MCV >100 fL) and deficient nuclear maturation. Cobalamin (vitamin B_{12}) and folic acid deficiencies are the most common cause of megaloblastic anemias. Because megaloblastic anemias develop slowly, there are often few symptoms until the anemia is far advanced.

Cobalamin (Vitamin B_{12})-Deficiency Anemia. Vitamin B_{12} serves as a cofactor for two important reactions in humans. It is essential for the synthesis of DNA. When it is deficient, nuclear maturation and cell division, especially of the rapidly proliferating red cells, fail to occur. It is also involved in a reaction that prevents abnormal fatty acids from being incorporated into neuronal lipids. This abnormality may predispose to myelin breakdown and production of the neurologic complications of vitamin B_{12} deficiency.

Vitamin B₁₂ is found in all foods of animal origin. Dietary deficiency is rare and usually found only in strict vegetarians who avoid all dairy products as well as meat and fish. It is absorbed by a unique process. After release from the animal protein, vitamin B₁₂ is bound to intrinsic factor, a protein secreted by the gastric parietal cells (Fig. 13-8). The vitamin B₁₂-intrinsic factor complex travels to the ileum, where membrane receptors allow the binding of the complex and transport of B₁₂ across the membrane. From there it is bound to its carrier protein, transcobalamin II, which carries vitamin B₁₂ in the circulation to its storage and tissue sites. Any defects in this pathway may cause a deficiency. An important cause of vitamin B₁₂ deficiency is pernicious anemia, resulting from a hereditary atrophic gastritis. As discussed in Chapter 27, immunemediated chronic atrophic gastritis is a disorder that destroys the gastric mucosa, with loss of parietal cells and production of

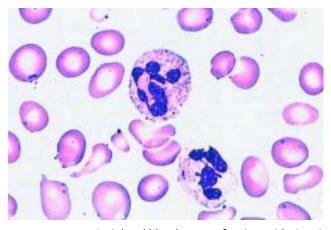

■ FIGURE 13-8 ■ Absorption of vitamin B₁₂.

antibodies that interfere with the binding of vitamin B_{12} to the intrinsic factor. Other causes of vitamin B_{12} deficiency anemia include gastrectomy, ileal resection, and malabsorption syndromes in which vitamin B_{12} and other vitamin B compounds are poorly absorbed.

The hallmark of vitamin B_{12} deficiency is megaloblastic anemia. When vitamin B_{12} is deficient, the red cells that are produced are abnormally large because of excess ribonucleic acid production of hemoglobin and structural protein (Fig. 13-9). They have flimsy membranes and are oval, rather than biconcave. These oddly shaped cells have a short life span that can be measured in weeks, rather than months. The MCV is elevated, and the MCHC is normal.

Neurologic changes that accompany the disorder are caused by deranged methylation of myelin protein. Demyelination of the dorsal and lateral columns of the spinal cord causes symmetric paresthesias of the feet and fingers, loss of vibratory and position sense, and eventual spastic ataxia. In more advanced cases, cerebral function may be altered. In some cases, dementia and other neuropsychiatric changes may precede hematologic changes.

Diagnosis of vitamin B_{12} deficiency is made by finding an abnormally low vitamin B_{12} serum level. The Schilling test, which measures the 24-hour urinary excretion of radiolabeled vitamin B_{12} administered orally, is used to document decreased absorption of vitamin B_{12} . Lifelong treatment consisting of

■ FIGURE 13-9 ■ Peripheral blood smear of patient with vitamin B₁₂ deficiency (pernicious anemia) that shows prominent megablastic anemia. The erythrocytes are large, often with oval shape, and are associated with poikilocytosis and teardrop shapes. The neutrophils are hypersegmented. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 1076]. Philadelphia: Lippincott-Raven)

intramuscular injections of vitamin B₁₂ reverses the anemia and improves the neurologic status.

Folic Acid-Deficiency Anemia. Folic acid is also required for DNA synthesis and red cell maturation, and its deficiency produces the same type of red cell changes that occur in vitamin B_{12} deficiency anemia (*i.e.*, increased MCV and normal MCHC). Symptoms are also similar, but the neurologic manifestations are not present.

Folic acid is readily absorbed from the intestine. It is found in vegetables (particularly the green leafy types), fruits, cereals, and meats. However, much of the vitamin is lost in cooking. The most common causes of folic acid deficiency are malnutrition or dietary lack, especially in the elderly or in association with alcoholism, and malabsorption syndromes such as sprue or other intestinal disorders. In neoplastic disease, tumor cells compete for folate, and deficiency is common. Some drugs used to treat seizure disorders (*e.g.*, primidone, phenytoin, phenobarbital) and triamterene, a diuretic, predispose to a deficiency by interfering with folic acid absorption. Methotrexate, a folic acid analog used in the treatment of cancer, impairs the action of folic acid by blocking its conversion to the active form.

Because pregnancy increases the need for folic acid 5- to 10-fold, a deficiency commonly occurs. Poor dietary habits, anorexia, and nausea are other reasons for folic acid deficiency during pregnancy. Studies also show an association between folate deficiency and neural tube defects.¹² The Public Health Service recommends that all women of childbearing age should take 400 micrograms (µg) of folic acid daily. It is estimated that as many as 50% of neural tube defects could be prevented.¹² The Institute of Medicine Panel on Folate and Other B Vitamins and Choline recently revised the recommended daily allowance (RDA) for pregnant women to 600 µg.¹³ To ensure adequate folate consumption, the U.S. Food and Drug Administration has issued a recommendation for the addition of folate to cereal grain products.¹⁴

Aplastic Anemia

Aplastic anemia (*i.e.*, bone marrow depression) describes a primary condition of bone marrow stem cells that results in a reduction of all three hematopoietic cell lines—red blood cells, white blood cells, and platelets—with fatty replacement of bone marrow. Pure red cell aplasia, in which only the red cells are affected, rarely occurs.

Anemia results from the failure of the marrow to replace senescent red cells that are destroyed and leave the circulation, although the cells that remain are of normal size and color. At the same time, because the leukocytes, particularly the neutrophils, and the thrombocytes have a short life span, a deficiency of these cells usually is apparent before the anemia becomes severe.

The onset of aplastic anemia may be insidious, or it may strike with suddenness and great severity. It can occur at any age. The initial presenting symptoms include weakness, fatigability, and pallor caused by anemia. Petechiae (*i.e.*, small, punctate skin hemorrhages) and ecchymoses (*i.e.*, bruises) often occur on the skin, and bleeding from the nose, gums, vagina, or gastrointestinal tract may occur because of decreased platelet levels. The decrease in the number of neutrophils increases susceptibility to infection.

Among the causes of aplastic anemia are exposure to high doses of radiation, chemicals, and toxins that suppress hematopoiesis directly, or through immune mechanisms. Chemotherapy and irradiation commonly result in bone marrow depression. Identified toxic agents include benzene, the antibiotic chloramphenicol, and the alkylating agents and antimetabolites used in the treatment of cancer (see Chapter 5). Aplastic anemia caused by exposure to chemical agents may be an idiosyncratic reaction because it affects only certain susceptible persons. It typically occurs weeks after use of a drug is initiated. Such reactions often are severe and sometimes irreversible and fatal. Aplastic anemia can develop in the course of many infections and has been reported most often as a complication of viral hepatitis, mononucleosis, and other viral illnesses, including acquired immunodeficiency syndrome (AIDS). In two thirds of cases, the cause is unknown, and these are called *idiopathic aplastic anemia.*

Therapy for aplastic anemia in the young and severely affected includes stem cell replacement by bone marrow or peripheral blood transplantation. For those who are not transplantation candidates, immunosuppressive therapy with lymphocyte immune globulin (*i.e.*, antithymocyte globulin) prevents suppression of proliferating stem cells, producing remission in as many as 50% of patients.¹⁵ Patients with aplastic anemia should avoid the offending agents and be treated with antibiotics for infection. Red cell transfusions to correct the anemia and platelets and corticosteroid therapy to minimize bleeding may also be required.

Chronic Disease Anemias

Anemia often occurs as a complication of chronic infections, inflammation, and cancer. Chronic diseases commonly associated with anemia include AIDS, osteomyelitis, rheumatoid arthritis, and Hodgkin's disease. It is theorized that the short life span, deficient red cell production, and low serum iron are caused by actions of macrophages and lymphocytes in response to cell injury. Macrophages sequester iron in the spleen and contribute to red cell destruction, and the lymphocytes release cytokines that suppress erythropoietin production and action.¹⁶ The mild to moderate anemia is usually reversed when the underlying disease is treated.

Chronic renal failure almost always results in a normocytic, normochromic anemia, primarily because of a deficiency of erythropoietin. Uremic toxins also interfere with the actions of erythropoietin and red cell production. They also cause hemolysis and bleeding tendencies, which contribute to the anemia. Until recently, dialysis and red cell transfusions constituted the only therapy. Recombinant erythropoietin injected several times each week for 10 or more weeks dramatically elevates the hemoglobin level and hematocrit to a range of 32% to 38% and eliminates the need for transfusions.¹⁷ Oral iron is usually required for a good response.

In summary, anemia is a condition of an abnormally low hemoglobin level, number of circulating red blood cells, or both. Anemia can result from excessive blood loss, red cell destruction caused by hemolysis, or deficient hemoglobin or red cell production. Blood loss anemia can be acute or chronic. With bleeding, iron and other components of the erythrocyte are lost from the body. Hemolytic anemia is characterized by the premature destruction of red cells, with retention in the body of iron and the other products of red cell destruction. Hemolytic anemia can be caused by defects in the red cell membrane, hemoglobinopathies (sickle cell anemia or thalassemia), or inherited enzyme defects (G6PD deficiency). Acquired forms of hemolytic anemia are caused by agents extrinsic to the red blood cell, such as drugs, bacterial and other toxins, antibodies, and physical trauma. Iron-deficiency anemia, which is characterized by decreased hemoglobin synthesis, can result from dietary deficiency, loss of iron through bleeding, or increased demands for red cell production. Vitamin B₁₂ and folic acid deficiency impair red cell production by interfering with DNA synthesis. Aplastic anemia is caused by bone marrow suppression and usually results in a reduction of white blood cells and platelets, as well as red blood cells.

The manifestations of anemia include those associated with impaired oxygen transport, recruitment of compensatory mechanisms, and the underlying process causing the anemia. commonly is seen in men between the ages of 40 and 60 years. In polycythemia vera, the manifestations are related to an increase in the red cell count, hemoglobin level, and hematocrit with increased blood volume and viscosity. Commonly reported symptoms include headache, dizziness, and some difficulty with hearing and vision because of decreased cerebral blood flow. Hypertension is common, the result of an increase in blood viscosity. Venous stasis gives rise to a plethoric appearance or dusky redness-even cyanosis-particularly of the lips, fingernails, and mucous membranes. Because of the increased concentration of blood cells, the person may experience itching and pain in the fingers or toes, and the hypermetabolism may induce night sweats and weight loss. Thrombosis, caused by increased blood viscosity and stagnation of blood flow, is a common complication of polycythemia vera and the major cause of morbidity and mortality.¹⁸

The goal of treatment in primary polycythemia is to reduce blood viscosity. This can be done by withdrawing blood by means of periodic phlebotomy to reduce red cell volume. Control of platelet and white cell counts is accomplished by suppressing bone marrow function with chemotherapy or radiation therapy.

Secondary polycythemia results from a physiologic increase in the level of erythropoietin, commonly as a compensatory response to hypoxia. The causes of secondary polycythemia due to hypoxia include living at high altitudes, chronic heart and lung disease, and smoking. Treatment of secondary polycythemia focuses on relieving hypoxia. For example, continuous low-flow oxygen therapy can be used to correct the severe hypoxia that occurs in some persons with chronic obstructive lung disease.

In summary, polycythemia describes a condition in which the red blood cell mass is increased. It can present as a relative, primary, or secondary disorder. Relative polycythemia results from a loss of vascular fluid and is corrected by replacing the fluid. Primary polycythemia, or polycythemia vera, is a proliferative disease of the bone marrow with an absolute increase in total red blood cell mass accompanied by elevated white cell and platelet counts. Secondary polycythemia results from increased erythropoietin levels caused by hypoxic conditions such as chronic heart and lung disease. Many of the manifestations of polycythemia are related to increased blood volume and viscosity that lead to hypertension and stagnation of blood flow.

POLYCYTHEMIA

Polycythemia is an abnormally high total red blood cell mass with a hematocrit greater than 54% in males and 51% in females.¹⁸ It is categorized as relative, primary, or secondary. In relative polycythemia, the hematocrit rises because of a loss of plasma volume without a corresponding decrease in red cells. This may occur with water deprivation, excess use of diuretics, or gastrointestinal losses. Relative polycythemia is corrected by increasing the vascular fluid volume.

Primary polycythemia, or polycythemia vera, is a proliferative disease of the pluripotent cells of the bone marrow characterized by an absolute increase in total red blood cell mass accompanied by elevated white cell and platelet counts. It most

AGE-RELATED CHANGES IN RED BLOOD CELLS

Red Cell Changes in the Neonate

At birth, changes in the red blood cell indices reflect the transition to extrauterine life and the need to transport oxygen from the lungs (Table 13-2). Hemoglobin concentrations at birth are high, reflecting the high synthetic activity in utero to provide adequate oxygen delivery.¹⁹ Toward the end of the first postnatal week, the hemoglobin concentration begins to decline, gradually falling to a minimum value at approximately age

2 months. The red cell count, hematocrit, and MCV likewise fall. The factors responsible for the decline include reduced red cell production and plasma dilution caused by increased blood volume with growth. Neonatal red cells also have a shorter life span of 50 to 70 days and are thought to be more fragile than those of older persons. During the early neonatal period, there is also a switch from HbF to HbA. The amount of HbF in term infants varies from 53% to 95% of the total hemoglobin and decreases by approximately 3% per week after birth.²⁰ In an infant 6 months of age, HbF usually accounts for less than 2% of total hemoglobin. The switch to HbA provides greater unloading of oxygen to the tissues because HbA has a lower affinity for oxygen than does HbF. Infants who are small for gestational age, those born to mothers who have diabetes or smoke, and those who experienced hypoxia in utero have higher total hemoglobin levels, higher HbF levels, and a delayed switch to HbA.

A physiologic anemia of the newborn develops at approximately 2 months of age. It seldom produces symptoms and cannot be altered by nutritional supplements. Anemia of prematurity, an exaggerated physiologic response in low–birthweight infants, is thought to result from a poor erythropoietin response. The hemoglobin level rapidly declines after birth to a low of 7 to 10 g/dL at approximately 6 weeks of age. Signs and symptoms include apnea, poor weight gain, pallor, decreased activity, and tachycardia. In infants born before 33 weeks' gestation or those with hematocrits of less than 33%, the clinical features are more evident. One study suggests that the protein content of breast milk may not be sufficient for hematopoiesis in the premature infant. Protein supplementation significantly increases the hemoglobin concentrations between the ages of 4 and 10 weeks.¹⁹

Anemia at birth, characterized by pallor, congestive heart failure, or shock, usually is caused by hemolytic disease of the newborn. Bleeding from the umbilical cord, internal hemorrhage, congenital hemolytic disease, or frequent blood sampling are other possible causes of anemia. The severity of symptoms and presence of coexisting disease may warrant red cell transfusion.

Hyperbilirubinemia in the Neonate

Hyperbilirubinemia, an increased level of serum bilirubin, is a common cause of jaundice in the neonate. A benign, selflimited condition, it most often is related to the developmental state of the neonate. Rarely, cases of hyperbilirubinemia are pathologic and may lead to kernicterus and serious brain damage.

In the first week of life, approximately 60% of term and 80% of preterm neonates have jaundice.²¹ This physiologic jaundice appears in term infants on the second or third day of life. Under normal circumstances, the indirect bilirubin in umbilical cord blood is 1 to 3 mg/dL and rises at a rate of less than 5 mg/dL/24 hours, peaking at 5 to 6 mg/dL between the second and fourth days and decreasing to less than 2 mg/dL between the fifth and seventh days of life.²¹ The increase in bilirubin is related to the increased red cell breakdown and the inability of the immature liver to conjugate bilirubin. Premature infants exhibit a similar but slower rise in serum bilirubin level, perhaps because of poor hepatic uptake and reduced albumin binding of bilirubin. This generally results in higher bilirubin levels, with peak levels of 8 to 12 mg/dL being reached on the fifth to seventh day. Most neonatal jaundice resolves within 1 week and is untreated.

A search to determine the cause of the jaundice is usually made when (1) the jaundice appears during the first 24 to 36 hours of life or persists beyond 10 to 14 days, (2) serum bilirubin rises at a rate greater than 5 mg/dL/24 hours, (3) serum bilirubin is greater than 12 mg/dL in a full term infant or 10 to 14 mg/dL in preterm infants, (4) or the directreacting bilirubin is greater than 2 mg/dL at any time.

Many factors cause elevated bilirubin levels in the neonate: breast-feeding, hemolytic disease of the newborn, hypoxia, infections, and acidosis. Bowel or biliary obstruction and liver disease are less common causes. Associated risk factors include prematurity, Asian ancestry, and maternal diabetes. Breast milk jaundice occurs in approximately 2% of breast-fed infants.²¹ These neonates accumulate significant levels of unconjugated bilirubin 7 days after birth that reach maximum levels during the third week of life. It is thought that the breast milk contains fatty acids that inhibit bilirubin conjugation in the neonatal liver. A factor in breast milk is also thought to increase the absorption of bilirubin in the duodenum. This type of jaundice disappears if breast-feeding is discontinued. Breast-feeding can be resumed in 3 to 4 days without any hyperbilirubinemia ensuing.

Hyperbilirubinemia places the neonate at risk for the development of a neurologic syndrome called kernicterus. This condition is caused by the accumulation of unconjugated bilirubin in brain cells. Unconjugated bilirubin is lipid soluble, crosses the permeable blood-brain barrier of the neonate, and is deposited in cells of the basal ganglia, causing brain damage. The precise blood level of unconjugated bilirubin or duration of exposure necessary to produce toxic effects is largely unknown. The less mature the infant, the greater the susceptibility to kernicterus. Asphyxia and hyperosmolality may damage the blood-brain barrier and increase the risk of brain damage.²¹

Symptoms may appear 2 to 5 days after birth in term infants and as late as 7 days in premature infants. Lethargy, poor feeding, and short-term behavioral changes may be evident in mildly affected infants. Severe manifestations include rigidity, tremors, ataxia, and hearing loss. Extreme cases cause seizures and death. Most survivors of severe hyperbilirubinemia are seriously damaged and by 3 years of age exhibit involuntary muscle spasm, seizures, mental retardation, and deafness.

Hyperbilirubinemia in the neonate is treated with phototherapy or exchange transfusion. Phototherapy is more commonly used to treat infants with jaundice and reduce the risk of kernicterus. Exposure to fluorescent light in the blue range of the visible spectrum (420- to 470-nm wavelength) reduces bilirubin levels. Bilirubin in the skin absorbs the light energy and is converted to a structural isomer that is more water soluble and can be excreted in the stool and urine. Exchange transfusion is considered when signs of kernicterus are evident or hyperbilirubinemia is sustained or rising and unresponsive to phototherapy.

Hemolytic Disease of the Newborn

Erythroblastosis fetalis, or hemolytic disease of the newborn, occurs in Rh-positive infants of Rh-negative mothers who have been sensitized. The mother can produce anti-Rh antibodies from pregnancies in which the infants are Rh positive or by blood transfusions of Rh-positive blood. The Rh-negative mother usually becomes sensitized during the first few days after delivery, when fetal Rh-positive red cells from the placental site are released into the maternal circulation. Because the antibodies take several weeks to develop, the first Rh-positive infant of an Rh-negative mother usually is not affected. Infants with Rh-negative blood have no antigens on their red cells to react with the maternal antibodies and are not affected.

After an Rh-negative mother has been sensitized, the Rh antibodies from her blood are transferred to subsequent infants through the placental circulation. These antibodies react with the red cell antigens of the Rh-positive infant, causing agglutination and hemolysis. This leads to severe anemia with compensatory hyperplasia and enlargement of the bloodforming organs, including the spleen and liver, in the fetus. Liver function may be impaired, with decreased production of albumin causing massive edema, called hydrops fetalis. If blood levels of unconjugated bilirubin are abnormally high because of red cell hemolysis, there is danger of kernicterus developing in the infant, resulting in severe brain damage or death.

Several advances have served to significantly decrease the threat to infants born to Rh-negative mothers: prevention of sensitization, antenatal identification of the at-risk fetus, and intrauterine transfusion to the affected fetus. The injection of Rh immune globulin (i.e., gamma-globulin-containing Rh antibody) prevents sensitization in Rh-negative mothers who have given birth to Rh-positive infants if administered at 28 weeks' gestation and within 72 hours of delivery, abortion, genetic amniocentesis, or fetal-maternal bleeding. After sensitization has developed, the immune globulin is of no value. Since 1968, the year Rh immune globulin was introduced, the incidence of sensitization of Rh-negative women has dropped dramatically. Early prenatal care and screening of maternal blood continue to be important in reducing immunization. Efforts to improve therapy are aimed at production of monoclonal anti-D, the Rh antibody.

In the past, approximately 20% of erythroblastotic fetuses died in utero. Fetal Rh phenotyping can now be performed to identify at-risk fetuses during the first trimester using fetal blood or amniotic cells.²² Hemolysis in these fetuses can be treated by intrauterine transfusions of red cells through the umbilical cord. Exchange transfusions are administered after birth by removing and replacing the infant's blood volume with type O Rh-negative blood. The exchange transfusion removes most of the hemolyzed red cells and some of the total bilirubin, treating the anemia and hyperbilirubinemia.

Red Cell Changes With Aging

Aging is associated with red cell changes. Bone marrow cellularity declines with age, from approximately 50% cellularity at age 65 years to approximately 30% at age 75 years. The decline may reflect osteoporosis, rather than a decrease in hematopoietic cells.23

Hemoglobin levels decline after middle age. In studies of men older than 60 years of age, mean hemoglobin levels ranged from 15.3 to 12.4 g/dL, with the lowest levels found in the oldest persons. The decline is less in women, with mean levels ranging from 13.8 to 11.7 mg/dL.23 In most elderly persons with no symptoms, lower hemoglobin levels result from iron deficiency and anemia of chronic disease. Orally administered iron is poorly used in older adults, despite normal iron absorption. Underlying neoplasms also may contribute to anemia in this population.

In summary, hemoglobin concentrations at birth are high, reflecting the in utero need for oxygen delivery; toward the end of the first postnatal week, these levels begin to decline, gradually falling to a minimum value at approximately 2 months of age. During the early neonatal period, there is a shift from fetal to adult hemoglobin. Many infants have physiologic jaundice because of hyperbilirubinemia during the first week of life, probably related to increased red cell breakdown and the inability of the infant's liver to conjugate bilirubin. The term kernicterus describes elevated levels of lipid-soluble, unconjugated bilirubin, which can be toxic to brain cells.

Depending on severity, the condition is treated with phototherapy or exchange transfusions (or both). Hemolytic disease of the newborn occurs in Rh-positive infants of Rh-negative mothers who have been sensitized. It involves hemolysis of infant red cells in response to maternal Rh antibodies that have crossed the placenta. Administration of Rh immune globulin to the mother within 72 hours of delivery of an Rh-positive infant, abortion, or amniocentesis prevents sensitization.

Aging is associated with red cell changes. Bone marrow cellularity decreases, and there is a decrease in hemoglobin.

REVIEW QUESTIONS

Relate the function of the red blood cell to the manifestations of anemia.

Explain why the appearance of an increased number of reticulocytes in the blood is suggestive of blood loss and why a low ferritin level suggests the need for iron replacement therapy.

Explain why infants with sickle cell anemia usually do not display evidence of the disease until their hemoglobin F has been replaced with hemoglobin A.

Explain why fever, extreme exercise, and going to high altitudes produce sickling in persons with sickle cell anemia.

What is the common reason for the development of irondeficiency anemia in infancy, adolescence, and in pregnant women?

Describe the relation between vitamin B₁₂ deficiency and megaloblastic anemia. Explain why a person with sickle cell anemia who takes folic acid may not show evidence of megaloblastic anemia on laboratory tests but may have progressive neurologic changes caused by vitamin B₁₂ deficiency.

Explain why ecchymosis, signs of platelet deficiency, and decreased resistance to infection occur before signs of a decreased red blood cell count in persons with aplastic anemia.

Explain the pathogenesis of secondary polycythemia in persons with chronic lung disease.

Describe the pathogenesis of hemolytic disease of the newborn and compare the difference between conjugated and unconjugated bilirubin in terms of causing neurologic damage.

he main function of the *circulatory system*, which consists of the heart and blood vessels, is transport. The circulatory system delivers oxygen and nutrients needed for metabolic processes to the tissues, carries waste products from cellular metabolism to the kidneys and other excretory organs for elimination, and circulates electrolytes and hormones

KEY CONCEPTS

FUNCTIONAL ORGANIZATION OF THE CIRCULATORY SYSTEM

- The circulatory system consists of the heart, which pumps blood; the arterial system, which distributes oxygenated blood to the tissues; the venous system, which collects deoxygenated blood from the tissues and returns it to the heart; and the capillaries, where exchange of gases, nutrients, and wastes occurs.
- The circulatory system is divided into two parts: the low-pressure pulmonary circulation, linking the transport function of the circulation with the gas exchange function of the lungs; and the high-pressure systemic circulation, providing oxygen and nutrients to the tissues.
- The circulation is a closed system, so the output of the right and left heart must be equal over time for effective functioning of the circulation.

needed to regulate body function. This process of nutrient delivery is carried out with exquisite precision so that the blood flow to each tissue of the body is exactly matched to tissue need.

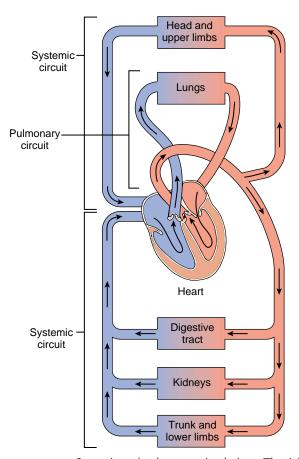

ORGANIZATION OF THE CIRCULATORY SYSTEM

Pulmonary and Systemic Circulations

The circulatory system can be divided into two parts: the *pul-monary circulation*, which moves blood through the lungs and creates a link with the gas exchange function of the respiratory system, and the *systemic circulation*, which moves blood throughout all the other tissues of the body (Fig. 14-1). The blood that is in the heart and pulmonary circulation is sometimes referred to as the *central circulation*, and that outside the central circulation.

The pulmonary circulation consists of the right heart, the pulmonary artery, the pulmonary capillaries, and the pulmonary veins. The large pulmonary vessels are unique in that the pulmonary artery is the only artery that carries deoxygenated venous blood and the pulmonary veins, the only veins that carry oxygenated arterial blood. The systemic circulation consists of the left heart, the aorta and its branches, the capillaries that supply the brain and peripheral tissues, and the systemic venous system and the vena cava. The veins from the lower portion of the body empty into the inferior vena cava and those from the head and upper extremities into the superior vena cava. Blood from both the inferior and superior vena cava empties into the right heart.

Although the pulmonary and systemic systems function similarly, they have some important differences. The pulmonary circulation is the smaller of the two and functions with a much lower pressure. Because the pulmonary circulation is located in the chest near to the heart, it functions as a low-

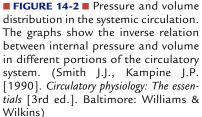

■ **FIGURE 14-1** ■ Systemic and pulmonary circulations. The right side of the heart pumps blood to the lungs, and the left side of the heart pumps blood to the systemic circulation.

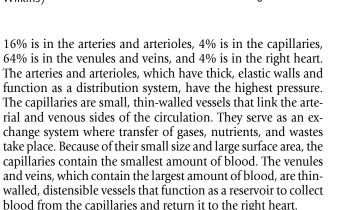

pressure system with a mean arterial pressure of approximately 12 mm Hg. The low pressure of the pulmonary circulation allows blood to move through the lungs more slowly, which is important for gas exchange. Because the systemic circulation must transport blood to distant parts of the body, often against the effects of gravity, it functions as a high-pressure system, with a mean arterial pressure of 90 to 100 mm Hg.

The heart, which propels the blood through the circulation, consists of two pumps in series—the right heart which propels blood through the lungs and the left heart which propels blood to all other tissues of the body. The effective function of the circulatory system requires that the outputs of both sides of the heart pump the same amount of blood over time. If the output of the left heart were to fall below that of the right heart, blood would accumulate in the pulmonary circulation. Likewise, if the right heart were to pump less effectively than the left heart, blood would accumulate in the systemic circulation.

Volume and Pressure Distribution

Blood flow in the circulatory system depends on a blood volume that is sufficient to fill the blood vessels and a pressure difference across the system that provides the force that is needed to move blood forward. As shown in Figure 14-2, approximately 4% of the blood at any given time is in the left heart,

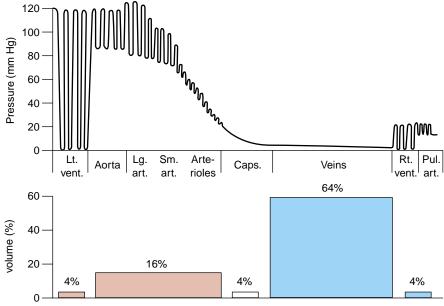

Total blood

Blood moves from the arterial to the venous side of the circulation along a pressure difference, moving from an area of higher pressure to one of lower pressure. The pressure distribution in the different parts of the circulation is almost an inverse of the volume distribution (see Fig. 14-2). The pressure in the arterial side of the circulation, which contains only approximately one sixth of the blood volume, is much greater than the pressure on the venous side of the circulation, which contains approximately two thirds of the blood. This pressure and volume distribution is due in large part to the structure and relative elasticity of the arteries and veins. It is the pressure difference between the arterial and venous sides of the circulation (approximately 84 mm Hg) that provides the driving force for flow of blood in the systemic circulation. The pulmonary circulation has a similar arterial-venous pressure difference, albeit of a lesser magnitude, that facilitates blood flow.

Because the pulmonary and systemic circulations are connected and function as a closed system, blood can be shifted from one circulation to the other. In the pulmonary circulation, the blood volume (approximately 450 mL in the adult) can vary from as low as 50% of normal to as high as 200% of normal. An increase in intrathoracic pressure, such as occurs when exhaling against a closed glottis, impedes venous return to the right heart. This can produce a transient shift from the central to the systemic circulation of as much as 250 mL of blood. Body position also affects the distribution of blood vol-

ume. In the recumbent position, approximately 25% to 30% of the total blood volume is in the central circulation. On standing, this blood is rapidly displaced to the lower part of the body because of the forces of gravity. Because the volume of the systemic circulation is approximately seven times that of the pulmonary circulation, a shift of blood from one system to the other has a much greater effect in the pulmonary than in the systemic circulation.

In summary, the circulatory system functions as a transport system that circulates nutrients and other materials to the tissues and removes waste products. The circulatory system can be divided into two parts: the systemic and the pulmonary circulation. The heart pumps blood throughout the system, and the blood vessels serve as tubes through which blood flows. The arterial system carries blood from the heart to the tissues, and the veins carry it back to the heart. The cardiovascular system is a closed system with a right and left heart connected in series. The systemic circulation, which is served by the left heart, supplies all the tissues except the lungs, which are served by the right heart and the pulmonary circulation. Blood moves throughout the circulation along a pressure gradient, moving from the high-pressure arterial system to the low-pressure venous system. In the circulatory system, pressure is inversely related to volume. The pressure on the arterial side of the circulation, which contains only approximately one sixth of the blood volume, is much greater than the pressure on the venous side of the circulation, which contains approximately two thirds of the blood.

PRINCIPLES OF BLOOD FLOW

The term *hemodynamics* describes the physical principles governing pressure, flow, and resistance as they relate to the circulatory system. The hemodynamics of the circulatory system are complex. The heart is an intermittent pump, and as a result, blood flow in the arterial circulation is pulsatile. The blood vessels are branched, distensible tubes of various dimensions. The blood is a suspension of blood cells, platelets, lipid globules, and plasma proteins. Despite this complexity, the function of the circulatory system can be explained by the principles of basic fluid mechanics that apply to nonbiologic systems, such as household plumbing systems.

Pressure, Flow, and Resistance

The most important factors governing the function of the circulatory system are *volume*, *pressure*, *resistance*, and *flow*. Optimal function requires a volume that is sufficient to fill the vascular compartment and a pressure that is sufficient to ensure blood flow to all body tissues.

Blood flow is determined by two factors: (1) a pressure difference between the two ends of a vessel or group of vessels and (2) the resistance that blood must overcome as it moves through the vessel or vessels (Fig. 14-3). The relation between pressure, resistance, and flow is expressed by the equation F = P/R, in which F is the blood flow, P is the difference in pressure between the two ends of the system, and R is the resistance to flow through the system. In the circulatory system, blood flow is represented by the cardiac output (CO).

The resistance that blood encounters as it flows through the peripheral circulation is referred to as the *peripheral vascular resistance* (PVR) or, sometimes, as the systemic vascular resistance. A helpful equation for understanding factors that affect blood flow ($F = \Delta P \times \pi \times r^4/8n \times L \times viscosity$) was derived by the French physician Poiseuille more than a century ago (see Fig. 14-3). It expands the previous equation, F = P/R, by relating flow to several determinants of resistance—radius, length, and viscosity. According to this equation, the two most important determinants of flow in the circulatory system are a difference in pressure (ΔP) and the vessel radius to the fourth power (r^4). Because flow is directly related to the fourth power of the radius, small changes in vessel radius can produce large changes in flow to an organ or tissue. For example, if the pressure remains constant, the rate of flow is 16 times greater in a

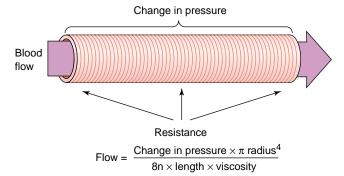

vessel with a radius of 2 mm $(2 \times 2 \times 2 \times 2)$ than in a vessel with a radius of 1 mm.

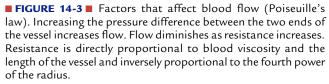

Blood flow is also affected by the viscosity of blood. Viscosity is the resistance to flow caused by the friction of molecules in a fluid. The viscosity of a fluid is largely related to its thickness. The more particles that are present in a solution, the greater the frictional forces that develop between the molecules. Unlike water that flows through plumbing pipes, blood is a nonhomogeneous liquid. It contains blood cells, platelets, fat globules, and plasma proteins that increase its viscosity. The red blood cells, which constitute 40% to 45% of the formed elements of the blood, largely determine the viscosity of the blood. Under special conditions, temperature may affect viscosity. There is a 2% rise in viscosity for each 1°C decrease in body temperature, a fact that helps explain the sluggish blood flow seen in persons with hypothermia. The length (L) of vessels does not usually change, and 8n is a constant that does not change.

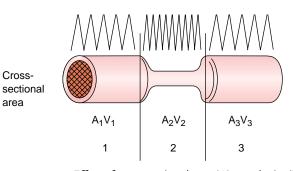

Cross-sectional Area and Velocity of Flow

Velocity is a distance measurement; it refers to the speed or linear movement with time (centimeters per second) with which blood flows through a vessel. *Flow* is a volume measurement (mL/second); it is determined by the cross-sectional area of a vessel and the velocity of flow (Fig. 14-4). When the flow through a given segment of the circulatory system is constant— as it must be for continuous flow—the velocity is inversely proportional to the cross-sectional area of the vessel (*i.e.*, the smaller the cross-sectional area, the greater the velocity of flow). This phenomenon can be compared with cars moving from a two-lane to a single-lane section of a highway. To keep traffic moving at its original pace, cars would have to double their speed in the single-lane section of the highway. So it is with flow in the circulatory system.

The linear velocity of blood flow in the circulatory system varies widely from 30 to 35 cm/second in the aorta to 0.2 to 0.3 mm/second in the capillaries. This is because even though each individual capillary is very small, the total cross-sectional area of all the systemic capillaries greatly exceeds the cross-sectional area of other parts of the circulation. As a result of this large surface area, the slower movement of blood allows ample

■ FIGURE 14-4 ■ Effect of cross-sectional area (A) on velocity (V) of flow. In section 1, velocity is low because of an increase in cross-sectional area. In section 2, velocity is increased because of a decrease in cross-sectional area. In section 3, velocity is again reduced because of an increase in cross-sectional area. Flow is assumed to be constant.

time for exchange of nutrients, gases, and metabolites between the tissues and the blood.

Laminar and Turbulent Flow

Blood flow normally is *laminar*, with the blood components arranged in layers so that the plasma is adjacent to the smooth, slippery endothelial surface of the blood vessel, and the blood cells, including the platelets, are in the center or axis of the bloodstream (Fig. 14-5). This arrangement reduces friction by allowing the blood layers to slide smoothly over one another, with the axial layer having the most rapid rate of flow.

Under certain conditions, blood flow switches from laminar to turbulent flow (see Fig. 14-5). Turbulent flow can be caused by a number of factors, including high velocity of flow, change in vessel diameter, and low blood viscosity. The tendency for turbulence to occur increases in direct proportion to the velocity of flow. Imagine the chaos as cars from a two- or three-lane highway converge on a single-lane section of the highway. The same type of thing happens in blood vessels that have been narrowed by disease processes, such as atherosclerosis. Low blood viscosity allows the blood to move faster and accounts for the transient occurrence of heart murmurs in some persons who are severely anemic. Turbulent flow may predispose to clot formation as platelets and other coagulation factors come in contact with the endothelial lining of the vessel. Turbulent flow often produces sounds that can be heard through the use of a stethoscope. For example, a heart murmur results from turbulent flow through a diseased heart valve.

Wall Tension, Radius, and Pressure

In a blood vessel, wall tension is the force in the vessel wall that opposes the distending pressure inside the vessel. The French astronomer and mathematician Pierre de Laplace described the relationship between wall tension, pressure, and the radius of a vessel or sphere more than 200 years ago. This relationship, which has come to be known as Laplace's law, can be expressed

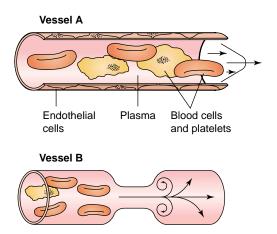

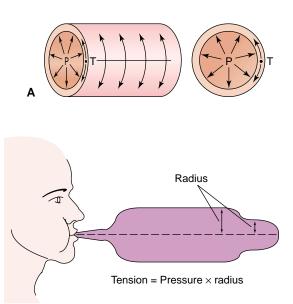

FIGURE 14-5 Laminar and turbulent flow in blood vessels. Vessel A shows streamlined or laminar flow in which the plasma layer is adjacent to the vessel endothelial layer and blood cells are in the center of the bloodstream. Vessel B shows turbulent flow in which the axial location of the platelets and other blood cells is disturbed.

by the equation, P = T/r, in which T is wall tension, P is the intraluminal pressure, and r is vessel radius (Fig. 14-6A). Accordingly, the internal pressure expands the vessel until it is exactly balanced by the tension in the vessel wall. The smaller the radius, the greater the pressure needed to balance the wall tension. Laplace's law can also be used to express the effect of the radius on wall tension (T = Pr). This correlation can be compared with a partially inflated balloon (Fig. 14-6B). Because the pressure is equal throughout, the tension in the part of the balloon with the smaller radius is less than the tension in the section with the larger radius (Fig. 14-6B). The same holds true for an arterial aneurysm in which the tension and risk of rupture increase as the aneurysm grows in size (see Chapter 16).

Laplace's law was later expanded to include wall thickness $(T = P \times r/wall thickness)$. Wall tension is inversely related to wall thickness, such that the thicker the vessel wall, the lower the tension, and vice versa. In hypertension, arterial vessel walls hypertrophy and become thicker, thereby reducing the tension and minimizing wall stress. Laplace's law can also be applied to the pressure required to maintain the patency of small blood vessels. Providing that the thickness of a vessel wall remains constant, it takes more pressure to overcome wall tension and keep a vessel open as its radius decreases in size. The critical closing pressure refers to the point at which vessels collapse so that blood can no longer flow through them. For example, in circulatory shock there is a decrease in blood volume and vessel radii, along with a drop in blood pressure. As a result, many of the small vessels collapse as blood pressure drops to the point where it can no longer overcome the wall tension. The collapse of peripheral veins often makes it difficult

■ **FIGURE 14-6** ■ Laplace's law relates pressure (P), tension (T), and radius in a cylindrical blood vessel (A). The pressure expanding the vessel is equal to the wall tension multiplied by the vessel radius. (B) Effect of the radius of a cylinder on tension. In a balloon, the tension in the wall is proportional to the radius because the pressure is the same everywhere inside the balloon. The tension is lower in the portion of the balloon with the smaller radius. (Rhoades R.A., Tanner G.A. [1996]. Medical physiology [p. 627]. Boston: Little, Brown)

R

to insert venous lines that are needed for fluid and blood replacement.

Distention and Compliance

Compliance refers to the total quantity of blood that can be stored in a given portion of the circulation for each millimeter rise in pressure. Compliance reflects the *distensibility* of the blood vessel. The distensibility of the aorta and large arteries allows them to accommodate the pulsatile output of the heart. The most distensible of all vessels are the veins, which can increase their volume with only slight changes in pressure, allowing them to function as a reservoir for storing large quantities of blood that can be returned to the circulation when it is needed. The compliance of a vein is approximately 24 times that of its corresponding artery, because it is eight times as distensible and has a volume three times as great.

In summary, blood flow is controlled by many of the same mechanisms that control fluid flow in nonbiologic systems. It is influenced by vessel length, pressure differences, vessel radius, blood viscosity, cross-sectional area, and wall tension. The rate of flow is directly related to the pressure difference between the two ends of the vessel and the vessel radius and inversely related to vessel length and blood viscosity. The cross-sectional area of a vessel influences the velocity of flow; as the cross-sectional area decreases, the velocity is increased, and vice versa. Laminar blood flow is flow in which there is layering of blood components in the center of the bloodstream. This reduces frictional forces and prevents clotting factors from coming in contact with the vessel wall. In contrast to laminar flow, turbulent flow is disordered flow, in which the blood moves crosswise and lengthwise in blood vessels. The relation between wall tension, transmural pressure, and radius is described by Laplace's law, which states the pressure needed to overcome wall tension becomes greater as the radius decreases. Wall tension is also affected by wall thickness; it increases as the wall becomes thinner and decreases as the wall becomes thicker.

THE HEART AS A PUMP

The heart is a four-chambered muscular pump approximately the size of a man's fist that beats an average of 70 times each minute, 24 hours each day, 365 days each year for a lifetime. In 1 day, this pump moves more than 1800 gallons of blood throughout the body, and the work performed by the heart over a lifetime would lift 30 tons to a height of 30,000 ft.

Functional Anatomy of the Heart

The heart is located between the lungs in the mediastinal space of the intrathoracic cavity in a loose-fitting sac called the *pericardium*. It is suspended by the great vessels, with its broader side (*i.e.*, base) facing upward and its tip (*i.e.*, apex) pointing downward, forward, and to the left (Fig.14-7).

The wall of the heart is composed of an outer epicardium, which lines the pericardial cavity; the myocardium or muscle

KEY CONCEPTS

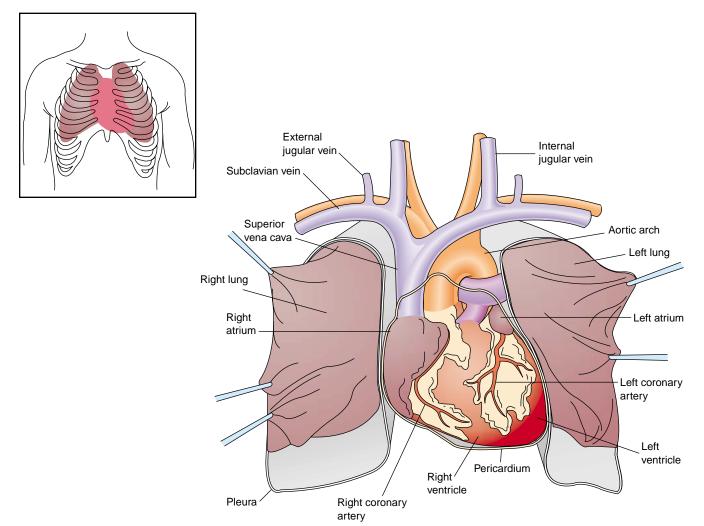

THE HEART

- The heart is a four-chambered pump consisting of two atria (the right atrium, which receives blood returning to the heart from the systemic circulation, and the left atrium, which receives oxygenated blood from the lungs) and two ventricles (a right ventricle, which pumps blood to the lungs, and a left ventricle, which pumps blood into the systemic circulation).
- Heart valves control the direction of blood flow from the atria to the ventricles (the atrioventricular valves), from the right side of the heart to the lungs (pulmonic valve), and from the left side of the heart to the systemic circulation (aortic valve).
- The cardiac cycle is divided into two major periods: systole, when the ventricles are contracting, and diastole, when the ventricles are relaxed and filling.
- The work and efficiency of the heart is determined by the volume of blood it pumps out (preload), the pressure that it must generate to pump the blood out of the heart (afterload), and the rate at which it performs these functions (heart rate).

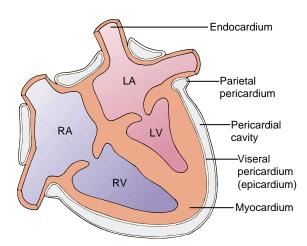

layer; and the smooth endocardium, which lines the chambers of the heart. A fibrous skeleton supports the valvular structures of the heart. The interatrial and interventricular septa divide the heart into a right and a left pump, each composed of two muscular chambers: a thin-walled atrium, which serves as a reservoir for blood coming into the heart, and a thick-walled ventricle, which pumps blood out of the heart. The increased thickness of the left ventricular wall results from the additional work this ventricle is required to perform.

Pericardium

The pericardium forms a fibrous covering around the heart, holding it in a fixed position in the thorax and providing physical protection and a barrier to infection. The pericardium consists of a tough outer fibrous layer and a thin inner serous layer. The outer fibrous layer is attached to the great vessels that enter and leave the heart, the sternum, and the diaphragm. The fibrous pericardium is highly resistant to distention; it prevents acute dilatation of the heart chambers and exerts a restraining effect on the left ventricle. The inner serous layer consists of a visceral layer and a parietal layer. The visceral layer, also known as the epicardium, covers the entire heart and great vessels and then folds over to form the parietal layer that lines the fibrous pericardium (Fig. 14-8). Between the visceral and parietal layers is the pericardial cavity, a potential space that contains 30 to 50 mL of serous fluid. This fluid acts as a lubricant to minimize friction as the heart contracts and relaxes.

■ FIGURE 14-7 ■ Anterior view of the heart and great vessels and their relationship to lungs and skeletal structures of the chest cage (*upper left box*).

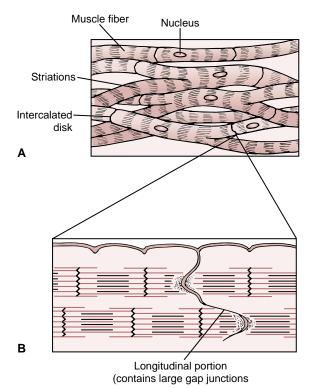

■ FIGURE 14-8 ■ Layers of the heart, showing the visceral pericardium, pericardial cavity, parietal pericardium, myocardium, and endocardium. RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle.

Myocardium

The myocardium, or muscular portion of the heart, forms the wall of the atria and ventricles. Cardiac muscle cells, like skeletal muscle, are striated and composed of *sarcomeres* that contain actin and myosin filaments (see Chapter 1). They are smaller and more compact than skeletal muscle cells and contain many large mitochondria, reflecting their continuous energy needs.

Cardiac muscle contracts much like skeletal muscle, except the contractions are involuntary and the duration of contraction is much longer. Unlike the orderly longitudinal arrangement of skeletal muscle fibers, cardiac muscle cells are arranged as an interconnecting latticework, with their fibers dividing, recombining, and then dividing again (Fig. 14-9). The fibers are separated from neighboring cardiac muscle cells by dense structures called *intercalated disks*. The intercalated disks, which are unique to cardiac muscle, contain gap junctions that serve as low-resistance pathways for passage of ions and electrical impulses from one cardiac cell to another (Fig. 14-9). Thus, the myocardium behaves as a single unit, or *syncytium*, rather than

■ FIGURE 14-9 ■ (A) Cardiac muscle fibers showing the branching structure. (B) Area indicated where cell junctions lie in the intercalated disks.

as a group of isolated units, as does skeletal muscle. When one myocardial cell becomes excited, the impulse travels rapidly so the heart can beat as a unit.

As in skeletal muscle, cardiac muscle contraction involves actin and myosin filaments, which interact and slide along one another during muscle contraction. However, compared with skeletal muscle cells, cardiac muscle cells have less well-defined sarcoplasmic reticulum for storing calcium, and the distance from the cell membrane to the myofibrils is shorter. Because less calcium can be stored in the muscle cells, cardiac muscle relies more heavily than skeletal muscle on an influx of extracellular calcium ions for contraction.

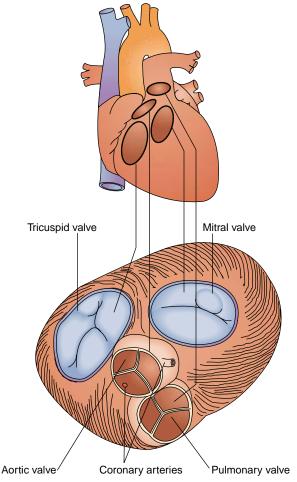

Endocardium

The endocardium is a thin, three-layered membrane that lines the heart and covers the valves. The innermost layer consists of smooth endothelial cells supported by a thin layer of connective tissue. The endothelial lining of the endocardium is continuous with the lining of the blood vessels that enter and leave the heart. The middle layer consists of dense connective tissue with elastic fibers. The outer layer, composed of irregularly arranged connective tissue cells, contains blood vessels and branches of the conduction system and is continuous with the myocardium.

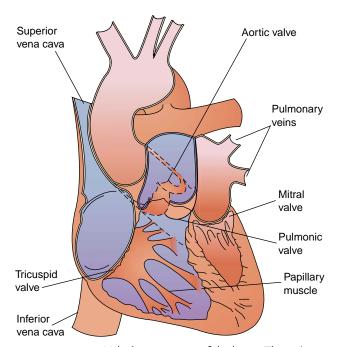

Heart Valves and Fibrous Skeleton

An important structural feature of the heart is its fibrous skeleton, which consists of four interconnecting valve rings and surrounding connective tissue. The fibrous skeleton separates the atria and ventricles and forms a rigid support for attachment of the valves and insertion of the cardiac muscle (Fig. 14-10). The tops of the valve rings are attached to the muscle tissue of the atria, pulmonary trunks, aorta, and valve rings. The bottoms are attached to the ventricular walls. For the heart to function effectively, blood flow must occur in a one-way direction, moving forward through the chambers of the right heart to the lungs and then through the chambers of the left heart to the systemic circulation. This unidirectional flow is provided by the heart's two atrioventricular (*i.e.*, tricuspid and mitral) valves and two semilunar (*i.e.*, pulmonic and aortic) valves (Fig. 14-11).

The atrioventricular (AV) valves control the flow of blood between the atria and the ventricles (Fig. 14-12). The thin edges of the AV valves form cusps, two on the left side of the heart (*i.e.*, *bicuspid* or *mitral valve*) and three on the right side (*i.e.*, *tricuspid valve*). The AV valves are supported by the papillary muscles, which project from the wall of the ventricles, and the chordae tendineae, which attach to the valve. Contraction of the papillary muscles at the onset of systole ensures closure by producing tension on the leaflets of the AV valves before the full force of ventricular contraction pushes against them. The chordae tendineae are cordlike structures that support the

■ FIGURE 14-11 ■ Valvular structures of the heart. The atrioventricular valves are in an open position, and the semilunar valves are closed. There are no valves to control the flow of blood at the inflow channels (*i.e.*, vena cava and pulmonary veins) to the heart.

AV valves and prevent them from everting into the atria during systole.

The *aortic* and *pulmonic* valves control the movement of blood out of the ventricles (Fig.14-12). Because of their half-moon shape, they often are referred to as the semilunar valves.

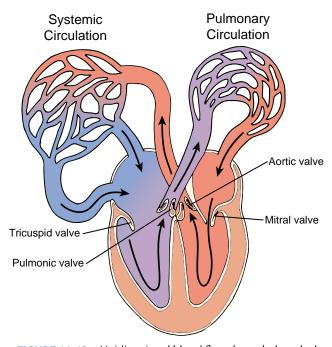

FIGURE 14-12 Unidirectional blood flow through the valvular structures of the heart.

The semilunar valves have three little teacup-shaped leaflets. These cuplike structures collect the *retrograde*, or backward, flow of blood that occurs toward the end of systole, enhancing closure. For the development of a perfect seal along the free edges of the semilunar valves, each valve cusp must have a triangular shape, which is facilitated by a nodular thickening at the apex of each leaflet (Fig. 14-13). The openings for the coronary arteries are located in the aorta just above the aortic valve.

There are no valves at the atrial sites (*i.e.*, venae cavae and pulmonary veins) where blood enters the heart. This means that excess blood is pushed back into the veins when the atria become distended. For example, the jugular veins typically become prominent in severe right-sided heart failure, whereas normally they are flat or collapsed. Likewise, the pulmonary venous system becomes congested when outflow from the left atrium is impeded.

Cardiac Conduction System

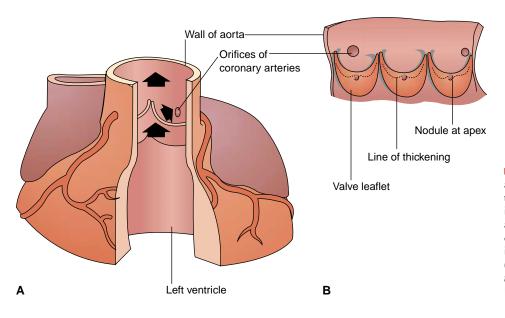

Heart muscle is unique among other muscles in that it is capable of generating and rapidly conducting its own action potentials (*i.e.*, electrical impulses). These action potentials result in excitation of muscle fibers throughout the myocardium. Impulse formation and conduction result in weak electrical currents that spread through the entire body. When electrodes are applied to various positions on the body and connected to an electrocardiograph machine, an electrocardiogram (ECG) can be recorded.

In certain areas of the heart, the myocardial cells have been modified to form the specialized cells of the conduction system (Fig. 14-14). Although most myocardial cells are capable of initiating and conducting impulses, it is this specialized conduction system that maintains the pumping efficiency of the heart. Specialized pacemaker cells generate impulses at a faster rate than do other types of heart tissue, and the conduction tissue transmits impulses at a faster rate than do other types of heart tissue. Because of these properties, the conduction system usually controls the rhythm of the heart.

The conduction system consists of the sinoatrial node (SA node), where the rhythmic impulse is generated; the internodal pathways, which conduct the impulse from the SA node to the atrioventricular (AV) node; the AV node, in which the impulse from the atria is delayed before passing to the ventricles; the AV bundle, which conducts the impulse from the atria to the ventricles; and the left and right bundles of the Purkinje system, which conduct the cardiac impulses to all parts of the ventricles.

The *sinoatrial (SA) node* has the fastest intrinsic rate of firing (60 to 100 beats per minute) and is normally the pacemaker of the heart. The heart essentially has two conduction systems: one that controls atrial activity and one that controls ventricular activity. The *AV node* connects the two conduction systems and provides one-way conduction between the atria and ventricles. Within the AV node, atrial fibers connect with very small junctional fibers of the node itself. The velocity of conduction through these fibers is very slow (approximately one half that of normal cardiac muscle), which greatly delays transmission of the impulse into the AV node. A further delay occurs as the impulse travels through the AV node into the transitional fibers and into the AV bundle, also called the *bundle of His.* This delay provides a mechanical advantage whereby the atria complete

their ejection of blood before ventricular contraction begins. Under normal circumstances, the AV node provides the only connection between the two conduction systems. The atria and ventricles would beat independently of each other if the transmission of impulses through the AV node were blocked.

The Purkinje fibers lead from the AV node through the AV bundle into the ventricles where they divide to form the *right and left bundle branches* that straddle the interventricular septum. The main trunk of the left bundle branch extends for approximately 1 to 2 cm before fanning out as it enters the septal

KEY CONCEPTS

CARDIAC CONDUCTION SYSTEM

- The cardiac conduction system consists of the SA node, which functions as the pacemaker of the heart; the AV node, which connects the atrial and ventricular conduction systems; and the AV bundle and large Purkinje fibers, which provide for rapid depolarization of the ventricles.
- Cardiac action potentials are controlled by three types of ion channels—the fast sodium channels, which are responsible for the spikelike onset of the action potential; the slower calcium-sodium channels, which are responsible for the plateau; and the potassium channels, which are responsible for the repolarization phase and return of the membrane to the resting potential.
- There are two types of cardiac action potentials: the fast response, which occurs in atrial and ventricular muscle cells and the Purkinje conduction system and uses the fast sodium channels; and the slow response of the SA and AV nodes, which uses the slow calcium channels.

area and divides further into two segments: the *left posterior* and *anterior fascicles*. The Purkinje system has very large fibers that allow for rapid conduction and almost simultaneous excitation of the entire right and left ventricles. This rapid rate of conduction is necessary for the swift and efficient ejection of blood from the heart.

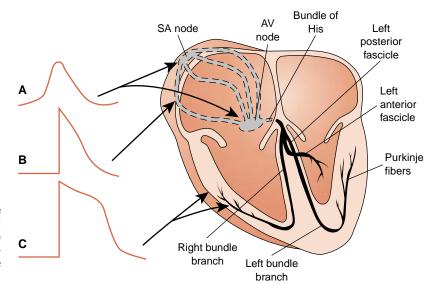

Action Potentials

A stimulus delivered to excitable tissues evokes an action potential that is characterized by a sudden change in voltage resulting from transient depolarization and subsequent repolarization. These action potentials are electrical currents involving the movement or flow of electrically charged ions at the level of the cell membrane (see Chapter 1).

The action potential of cardiac muscle is divided into five phases: phase 0—the upstroke or rapid depolarization; phase 1-early repolarization; phase 2-the plateau; phase 3rapid repolarization; and *phase* 4—the resting membrane potential (Fig. 14-15). Cardiac muscle has three types of membrane ion channels that contribute to the voltage changes that occur during these phases of the action potential. They are the (1) fast sodium channels, (2) slow calcium-sodium channels, and (3) potassium channels. During phase 0 in atrial and ventricular muscle and in the Purkinje system, opening of the fast sodium channels for a few ten-thousandths of a second is responsible for the spikelike onset of the action potential. The point at which the sodium gates open is called the depolarization threshold. When the cell has reached this threshold, a rapid influx of sodium ions to the interior of the membrane causes the membrane potential to shift from a resting membrane potential of approximately -90 mV to +20 mV.

Phase 1 occurs at the peak of the action potential and signifies inactivation of the fast sodium channels with an abrupt decrease in sodium permeability. *Phase 2* represents the plateau of the action potential. It is caused primarily by the slower opening of the calcium-sodium channels, which lasts for a few tenths of a second. Calcium ions entering the muscle during this phase of the action potential play a key role in the contractile process of the cardiac muscle fibers. These

241

■ FIGURE 14-14 ■ Conduction system of the heart and action potentials. (A) Action potential of sinoatrial (SA) and atrioventricular (AV) nodes; (B) atrial muscle action potential; (C) action potential of ventricular muscle and Purkinje fibers.

unique features of the phase 2 plateau cause the action potential of cardiac muscle to last 3 to 15 times longer than that of skeletal muscle and cause a corresponding increased period of contraction.

Phase 3 reflects final rapid repolarization and begins with the downslope of the action potential. During the phase 3 repolarization period, the slow channels close and the influx of calcium and sodium ceases. There is a sharp rise in potassium permeability, contributing to the rapid outward movement of potassium during this phase and facilitating the reestablishment of the resting membrane potential (–90 mV). At the conclusion of phase 3, distribution of sodium and potassium returns to the normal resting state. *Phase 4* is the resting membrane potential. During phase 4, the sodiumpotassium pump is activated, transporting sodium out of the cell and moving potassium back into the cell.

There are two main types of action potentials in the heart-the slow response and the fast response. The slow response, which is initiated by the slow calcium-sodium channels, is found in the SA node, which is the natural pacemaker of the heart, and the conduction fibers of the AV node (see Fig. 14-15). The fast response, which is characterized by opening of the fast sodium channels, occurs in the normal myocardial cells of the atria, the ventricles, and the Purkinje fibers. The fast-response cardiac cells do not normally initiate cardiac action potentials. Instead, these impulses originate in the specialized slow-response cells of the SA node and are conducted to the fast-response myocardial cells in the atria and ventricles, where they effect a change in membrane potential to the threshold level. On reaching threshold, the voltagedependent sodium channels open to initiate the rapid upstroke of the phase 1 action potential. The amplitude and the rate of rise of phase 1 are important to the conduction velocity of the fast response.

The hallmark of the pacemaker cells in the SA and AV nodes is a spontaneous phase 4 depolarization. The membrane permeability of these cells allows a slow inward leak of current to occur through the slow channels during phase 4. This leak continues until the threshold for firing is reached, at which point the cell spontaneously depolarizes. The rate of pacemaker cell discharge varies with the resting membrane potential and the slope of phase 4 depolarization (see Fig. 14-15). Catecholamines (*i.e.*, epinephrine and norepinephrine) increase the heart rate by increasing the slope or rate of phase 4 depolarization. Acetylcholine, which is released during vagal stimulation of the heart, slows the heart rate by decreasing the slope of phase 4.

Absolute and Relative Refractory Periods

The pumping action of the heart requires alternating contraction and relaxation. There is a period in the action potential curve during which no stimuli can generate another action potential (Fig. 14-16). This period, which is known as the absolute refractory period, includes phases 0, 1, 2, and part of phase 3. During this time, the cell cannot depolarize again under any circumstances. In skeletal muscle, the refractory period is very short compared with the duration of contraction, such that a second contraction can be initiated before the first is over, resulting in a summated tetanized contraction. In cardiac muscle, the absolute refractory period is almost as long as the contraction, and a second contraction cannot be stimulated until the first is over. The longer length of the absolute refractory period of cardiac muscle is important in maintaining the alternating contraction and relaxation that is essential to the pumping action of the heart and for the prevention of fatal dysrhythmias. When repolarization has returned the membrane potential to below the threshold potential, but not to the resting membrane potential, the cell is capable of responding to a greater-than-normal stimulus. This condition is referred to as the *relative refractory period*. After the relative refractory period there is a short period of time, called the supernormal excitatory period, during which a weak stimulus can evoke a response. It is during this period that many cardiac dysrhythmias develop.

Dysrhythmias and Conduction Disorders

Dysrhythmias represent disorders of cardiac rhythm. Cardiac dysrhythmias are commonly divided into two categories: supraventricular and ventricular dysrhythmias. The supraventricular dysrhythmias include those that are generated in the SA

242 Unit Four: Alterations in the Cardiovascular System

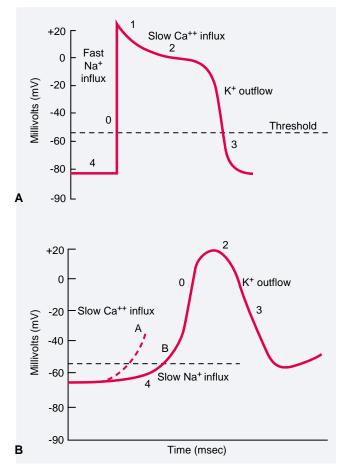

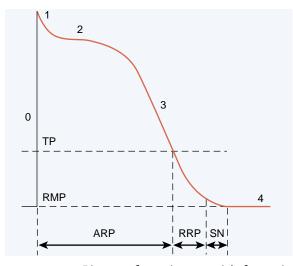

FIGURE 14-15 Changes in action potential recorded from a fast response in cardiac muscle cell (**A**) and from a slow response recorded in the sinoatrial and atrioventricular nodes (**B**). The phases of the action potential are identified by numbers: phase 4, resting membrane potential; phase 0, depolarization; phase 1, brief period of repolarization; phase 2, plateau; phase 3, repolarization. The slow response is characterized by a slow, spontaneous rise in the phase 4 membrane potential to threshold levels; it has a lesser amplitude and shorter duration than the fast response. Increased automaticity (*A*) occurs when the rate of phase 4 depolarization is increased.

node, atria, AV node, and junctional tissues. The ventricular dysrhythmias include those that are generated in the ventricular conduction system and the ventricular muscle. Because the ventricles are the pumping chambers of the heart, ventricular dysrhythmias (*e.g.*, ventricular tachycardia and fibrillation) are the most serious in terms of immediate life-threatening events.

Disorders of cardiac rhythm can range from excessively rapid heart rate (tachyarrhythmias) to an extremely slow heart rate (bradyarrhythmias). Conduction disorders disrupt the flow of impulses through the conduction system of the heart. *Heart block* occurs when the conduction of impulses is blocked, often in the AV node. Under normal conditions, the AV junction provides the only connection for transmission of impulses between the atrial and ventricular conduction systems; in complete heart block, the atria and ventricles beat independently of

■ FIGURE 14-16 ■ Diagram of an action potential of a ventricular muscle cell, showing the threshold potential (TP), resting membrane potential (RMP), absolute refractory period (ARP), relative refractory period (RRP), and supernormal (SN) period.

each other. The most serious effect of some forms of AV block is a slowing of heart rate to the extent that circulation to the brain is compromised. An *ectopic pacemaker* is an excitable focus outside the normally functioning SA node. A *premature ventricular contraction* (PVC) occurs when an ectopic pacemaker initiates a beat. The occurrence of frequent PVCs in the diseased heart predisposes one to the development of other, more serious dysrhythmias, including ventricular tachycardia and ventricular fibrillation.

Fibrillation is the result of disorganized current flow within the atria (atrial fibrillation) or ventricle (ventricular fibrillation). Fibrillation interrupts the normal contraction of the atria or ventricles. In ventricular fibrillation, the ventricle quivers but does not contract. When the ventricle does not contract, there is no cardiac output, and there are no palpable or audible pulses. Ventricular fibrillation is a fatal event unless treated with immediate defibrillation.

Electrocardiography

The ECG is a recording of the electrical activity of the heart. The electrical currents generated by the heart spread through the body to the skin, where they can be sensed by appropriately placed electrodes, amplified, and viewed on an oscilloscope or chart recorder. The deflection points of an ECG are designated by the letters P, Q, R, S, and T. Figure 14-17 depicts the electrical activity of the conduction system on an ECG tracing. The P wave represents the SA node and atrial depolarization; the QRS complex (*i.e.*, beginning of the Q wave to the end of the S wave) depicts ventricular depolarization; and the T wave portrays ventricular repolarization. The isoelectric line between the P wave and the Q wave represents depolarization of the AV node, bundle branches, and Purkinje system (Fig. 14-17). Atrial repolarization occurs during ventricular depolarization and is hidden in the QRS complex.

The horizontal axis of the ECG measures time in seconds, and the vertical axis measures the amplitude of the impulse in

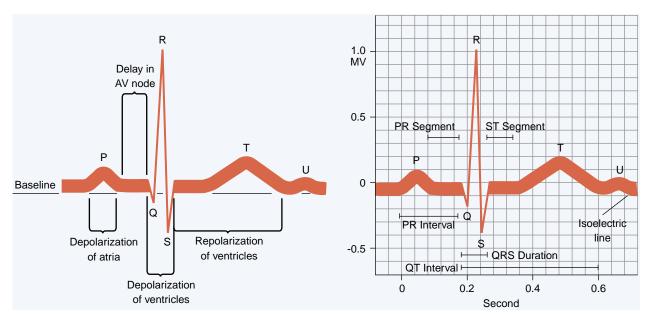

FIGURE 14-17 Diagram of the electrocardiogram (lead II) and representative depolarization and repolarization of the atria and ventricle. The P wave represents atrial depolarization, the QRS complex ventricular depolarization, and the T wave ventricular repolarization. Atrial repolarization occurs during ventricular depolarization and is hidden under the QRS complex.

millivolts (mV). Each heavy vertical line represents 0.2 second, and each thin line represents 0.04 second (see Fig. 14-17). The widths of ECG complexes are commonly referred to in terms of duration of time. On the vertical axis, each heavy horizontal line represents 0.5 mV. The connections of the ECG are arranged such that an upright deflection indicates a positive potential and a downward deflection indicates a negative potential.

The ECG records the potential difference in charge between two electrodes as the depolarization and repolarization waves move through the heart and are conducted to the skin surface. The shape of the recorder tracing is determined by the direction in which the impulse spreads through the heart muscle in relation to electrode placement. A depolarization wave that moves toward the recording electrode registers as a positive, or upward, deflection. Conversely, if the impulse moves away from the recording electrode, the deflection is downward, or negative. When there is no flow of charge between electrodes, the potential is zero, and a straight line is recorded at the baseline of the chart.

Conventionally, 12 leads are recorded for a diagnostic ECG, each providing a unique view of the electrical forces of the heart from a different position on the body's surface. Six limb leads view the electrical forces as they pass through the heart on the frontal or vertical plane. The electrodes for the limb leads are attached to the four extremities or representative areas on the body near the shoulders and lower chest or abdomen. Chest electrodes provide a view of the electrical forces as they pass through the heart on the horizontal plane. They are moved to different positions on the chest, including the right and left sternal borders and the left anterior surface. The right lower extremity lead is used as a ground electrode. When indicated, additional electrodes may be applied to other areas of the body, such as the back or right anterior chest.

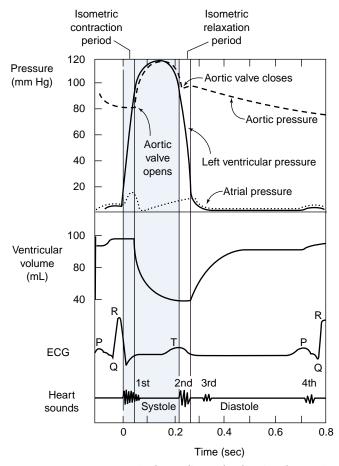

Cardiac Cycle

The term *cardiac cycle* is used to describe the rhythmic pumping action of the heart. The cardiac cycle is divided into two parts: *systole*, the period during which the ventricles are contracting, and *diastole*, the period during which the ventricles are relaxed and filling with blood. Simultaneous changes occur in atrial pressure, ventricular pressure, aortic or pulmonary artery pressure, ventricular volume, the electrocardiogram (ECG), and heart sounds during the cardiac cycle (Fig. 14-18).

Ventricular Systole and Diastole

Ventricular systole is divided into two periods: the isovolumetric contraction period and the ejection period. The isovolumetric contraction period, which begins with the closure of the AV valves and occurrence of the first heart sound, heralds the onset of systole. Immediately after closure of the AV valves, there is an additional 0.02 to 0.03 second during which the semilunar outlet (pulmonic and aortic) valves remain closed. During this period, the ventricular volume remains the same while the ventricles contract, producing an abrupt increase in pressure. The ventricles continue to contract until left ventricular pressure is slightly higher than aortic pressure, and right ventricular pressure is higher than pulmonary artery pressure. At this point, the semilunar valves open, signaling the onset of the ejection period. Approximately 60% of the stroke volume is ejected during the first quarter of systole, and the remaining 40% is ejected during the next two quarters of systole. Little blood is ejected from the heart during the last quarter of systole, although the ventricle remains contracted. At the end of systole, the ventricles relax, causing a precipitous fall in intraventricular pressures. As this occurs, blood from the large arteries flows back toward the ventricles, causing the aortic and

Unit Four: Alterations in the Cardiovascular System

■ FIGURE 14-18 ■ Events in the cardiac cycle, showing changes in aortic pressure, left ventricular pressure, atrial pressure, left ventricular volume, the electrocardiogram (ECG), and heart sounds.

pulmonic valves to snap shut—an event that is marked by the second heart sound.

The aortic pressure reflects changes in the ejection of blood from the left ventricle. There is a rise in pressure and stretching of the elastic fibers in the aorta as blood is ejected into the aorta at the onset of the ejection period. The aortic pressure continues to rise and then begins to fall during the last quarter of systole as blood flows out of the aorta into the peripheral vessels. The incisura, or notch, in the aortic pressure tracing represents closure of the aortic valve. The aorta is highly elastic and as such stretches during systole to accommodate the blood that is being ejected from the left heart during systole. During diastole, recoil of the elastic fibers in the aorta serves to maintain the arterial pressure.

Diastole is marked by ventricular relaxation and filling. After closure of the semilunar valves, the ventricles continue to relax for another 0.03 to 0.06 second. During this time, which is called the isovolumetric relaxation period, ventricular volume remains the same but ventricular pressure drops until it becomes less than atrial pressure. As this happens, the AV valves open, and the blood that has been accumulating in the atria during systole flows into the ventricles. Most of ventricular filling occurs during the first third of diastole, which is called the rapid filling period. During the middle third of diastole, inflow into the ventricles is almost at a standstill. The last third of diastole is marked by atrial contraction, which gives an additional thrust to ventricular filling. When audible, the third heart sound is heard during the rapid filling period of diastole as blood flows into a distended or noncompliant ventricle. A fourth heart sound, when present, occurs during the last third of diastole as the atria contract.

During diastole, the ventricles increase their volume to approximately 120 mL (i.e., the end-diastolic volume), and at the end of systole, approximately 50 mL of blood (i.e., the endsystolic volume) remains in the ventricles (Fig. 14-19). The difference between the end-diastolic and end-systolic volumes (approximately 70 mL) is called the stroke volume. The ejection fraction, which is the stroke volume divided by the enddiastolic volume, represents the fraction or percentage of the diastolic volume that is ejected from the heart during systole.

Atrial Filling and Contraction

Because there are no valves between the junctions of the central veins (i.e., venae cavae and pulmonary veins) and the atria, atrial filling occurs during both systole and diastole. During normal quiet breathing, right atrial pressure usually varies between -2 and +2 mm Hg. It is this low atrial pressure that maintains the movement of blood from the systemic veins into the right atrium and from the pulmonary veins into the left atrium.

Right atrial pressure is regulated by a balance between the ability of the right ventricle to move blood out of the right heart and the pressures that move blood from the venous circulation into the right atrium (venous return). When the heart pumps strongly, right atrial pressure is decreased and atrial filling is enhanced. Right atrial pressure is also affected by changes in intrathoracic pressure. It is decreased during inspiration when intrathoracic pressure becomes more negative, and it is increased during coughing or forced expiration when intrathoracic pressure becomes more positive. Venous return is a reflection of the amount of blood in the systemic circulation that is available for return to the right heart and the forces that move blood back to the right heart. Venous return is in-

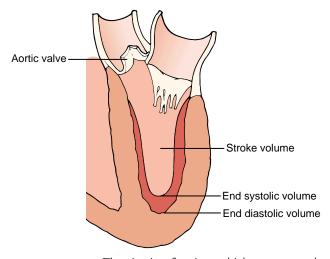

FIGURE 14-19 The ejection fraction, which represents the difference between left ventricular end-diastolic and end-systolic volumes.

creased when the blood volume is expanded or when right atrial pressure falls and is decreased in hypovolemic shock or when right atrial pressure rises.

Although the main function of the atria is to store blood as it enters the heart, these chambers also act as pumps that aid in ventricular filling. Atrial contraction occurs during the last third of diastole. Atrial contraction becomes more important during periods of increased activity when the diastolic filling time is decreased because of an increase in heart rate or when heart disease impairs ventricular filling. In these two situations, the cardiac output would fall drastically were it not for the action of the atria. It has been estimated that atrial contraction can contribute as much as 30% to cardiac reserve during periods of increased need, while having little or no effect on cardiac output during rest.

Regulation of Cardiac Performance

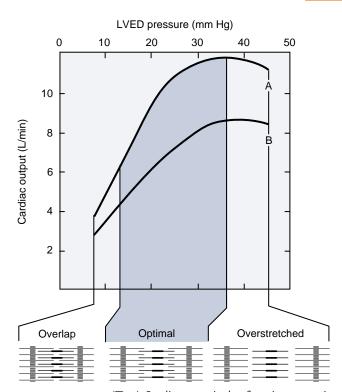

The efficiency and work of the heart as a pump often is measured in terms of *cardiac output* or the amount of blood the heart pumps each minute. The cardiac output (CO) is the product of the *stroke volume* (SV) and the *heart rate* (HR) and can be expressed by the equation: $CO = SV \times HR$. The cardiac output varies with body size and the metabolic needs of the tissues. It increases with physical activity and decreases during rest and sleep. The average cardiac output in normal adults ranges from 3.5 to 8.0 L/minute. In the highly trained athlete, this value can increase to levels as high as 32 L/minute during maximum exercise.

The *cardiac reserve* refers to the maximum percentage of increase in cardiac output that can be achieved above the normal resting level. The normal young adult has a cardiac reserve of approximately 300% to 400%. The heart's ability to increase its output according to body needs mainly depends on four factors: the *preload*, or ventricular filling; the *afterload*, or resistance to ejection of blood from the heart; *cardiac contractility*; and the *heart rate*. Cardiac performance is influenced by the work demands of the heart and the ability of the coronary circulation to meet its metabolic needs.

Preload

The preload represents the volume work of the heart. It is called the *preload* because it is the work imposed on the heart before the contraction begins. Preload represents the amount of blood that the heart must pump with each beat and is largely determined by the venous return to the heart and the accompanying stretch of the muscle fibers.

The increased force of contraction that accompanies an increase in ventricular end-diastolic volume is referred to as the *Frank-Starling mechanism* or Starling's law of the heart (Fig. 14-20). The anatomic arrangement of the actin and myosin filaments in the myocardial muscle fibers is such that the tension or force of contraction is greatest when the muscle fibers are stretched just before the heart begins to contract. The maximum force of contraction and cardiac output is achieved when venous return produces an increase in left ventricular end-diastolic filling (*i.e.*, preload) such that the muscle fibers are stretched about two and one-half times their normal resting length (Fig. 14-20, *curve B*). When the muscle fibers are stretched to this degree, there is optimal overlap of the actin and myosin filaments needed for maximal contraction.

■ FIGURE 14-20 ■ (Top) Starling ventricular function curve in normal heart. An increase in left ventricular end-diastolic (LVED) pressure produces an increase in cardiac output (*curve B*) by means of the Frank-Starling mechanism. The maximum force of contraction and increased stroke volume are achieved when diastolic filling causes the muscle fibers to be stretched about two and one half times their resting length. In *curve A*, an increase in cardiac contractility produces an increase in cardiac output without a change in LVED volume and pressure. (**Bottom**) Stretching of the actin and myosin filaments at the different LVED filling pressures.

The Frank-Starling mechanism allows the heart to adjust its pumping ability to accommodate various levels of venous return. Cardiac output is less when decreased filling causes excessive overlap of the actin and myosin filaments or when excessive filling causes the filaments to be pulled too far apart.

Afterload

The afterload is the pressure or tension work of the heart. It is the pressure that the heart must generate to move blood into the aorta. It is called the *afterload* because it is the work presented to the heart after the contraction has commenced. The systemic arterial blood pressure is the main source of afterload work on the left heart and the pulmonary arterial pressure is the main source of afterload work for the right heart. The afterload work of the left ventricle is also increased with narrowing (*i.e.*, stenosis) of the aortic valve. For example, in the late stages of aortic stenosis, the left ventricle may need to generate systolic pressures as great as 300 mm Hg to move blood through the diseased valve.

Cardiac Contractility

Cardiac contractility refers to the ability of the heart to change its force of contraction without changing its resting (*i.e.*, diastolic) length. The contractile state of the myocardial muscle is determined by biochemical and biophysical properties that govern the actin and myosin interactions in the myocardial cells. It is strongly influenced by the number of calcium ions that are available to participate in the contractile process.

An *inotropic* influence is one that modifies the contractile state of the myocardium independent of the Frank-Starling mechanism (see Fig. 14-20, *curve A*). For instance, sympathetic stimulation produces a positive inotropic effect by increasing the calcium that is available for interaction between the actin and myosin filaments. Hypoxia exerts a negative inotropic effect by interfering with the generation of adenosine triphosphate (ATP), which is needed for muscle contraction.

Heart Rate

The heart rate influences cardiac output and the work of the heart by determining the frequency with which the ventricle contracts and blood is ejected from the heart. Heart rate also determines the time spent in diastolic filling. While systole and the ejection period remain fairly constant across heart rates, the time spent in diastolic and filling of the ventricles becomes shorter as the heart rate increases. This leads to a decrease in stroke volume, and at high heart rates, may produce a decrease in cardiac output. One of the dangers of ventricular tachycardia is a reduction in cardiac output because the heart does not have time to fill adequately.

In summary, the heart is a four-chambered muscular pump that lies in the pericardial sac within the mediastinal space of the intrathoracic cavity. The wall of the heart is composed of an outer epicardium, which lines the pericardial cavity; a fibrous skeleton; the myocardium, or muscle layer; and the smooth endocardium, which lines the chambers of the heart. The four heart valves control the direction of blood flow.

The specialized cells of the heart's conduction system control the rhythmic contraction and relaxation of the heart. The SA node has the fastest inherent rate of impulse generation and acts as the pacemaker of the heart. Impulses from the SA node travel through the atria to the AV node and then to the AV bundle and the ventricular Purkinje system. The AV node provides the only connection between the atrial and ventricular conduction systems. The action potential of cardiac muscle is controlled by the (1) fast sodium channels, (2) slow calcium-sodium channels, and (3) potassium channels. Opening of the fast sodium channels is responsible for the rapid spikelike onset of the ventricular action potential; the slower opening calcium-sodium channels for the plateau of the action potential, and potassium channels for repolarization and return to the resting membrane potential. The absolute refractory period, which represents the time during which a normal cardiac impulse cannot re-excite an already excited area of cardiac muscle, is important in preventing disorders of cardiac rhythm that would disrupt the normal pumping ability of the heart. Disorders of the cardiac conduction system include dysrhythmias and conduction defects. Ventricular dysrhythmias are generally more serious than atrial dysrhythmias because they afford the potential for disrupting the pumping ability of the heart.

The cardiac cycle describes the pumping action of the heart. It is divided into two parts: systole, during which the ventricles contract and blood is ejected from the heart, and diastole, during which the ventricles are relaxed and blood is filling the heart. The stroke volume (approximately 70 mL) represents the difference between the end-diastolic volume (approximately 120 mL) and the end-systolic volume (approximately 50 mL). Atrial contraction occurs during the last third of diastole. Although the main function of the atria is to store blood as it enters the heart, atrial contraction acts to increase cardiac output during periods of increased activity when the filling time is reduced or in disease conditions in which ventricular filling is impaired.

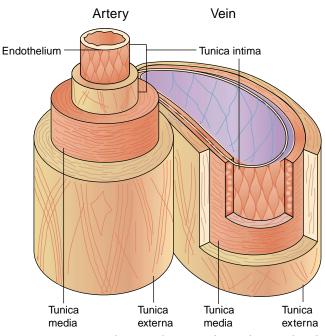

The heart's ability to increase its output according to body needs depends on the preload, or filling of the ventricles (*i.e.*, end-diastolic volume); the afterload, or resistance to ejection of blood from the heart; cardiac contractility, which is determined by the interaction of the actin and myosin filaments of cardiac muscle fibers; and the heart rate, which determines the frequency with which blood is ejected from the heart. The maximum force of cardiac contraction occurs when an increase in preload stretches muscle fibers of the heart to approximately two and one-half times their resting length (*i.e.*, Frank-Starling mechanism).

BLOOD VESSELS AND THE PERIPHERAL CIRCULATION

The vascular system functions in the delivery of oxygen and nutrients and removal of wastes from the tissues. It consists of arteries and arterioles, the capillaries, and the venules and veins. Blood vessels are dynamic structures that constrict and relax to adjust blood pressure and flow to meet the varying needs of the many different tissue types and organ systems. Structures such as the heart, brain, liver, and kidneys require a large and continuous flow to carry out their vital functions. In other tissues, such as the skin and skeletal muscle, the need for blood flow varies with the level of function. For example, there is a need for increased blood flow to the skin during fever and for increased skeletal muscle blood flow during exercise.

Blood Vessels

All blood vessels, except the capillaries, have walls composed of three layers, or coats, called *tunicae* (Fig. 14-21). The *tunica externa*, or *tunica adventitia*, is the outermost covering of the vessel. This layer is composed of fibrous and connective tissues that support the vessel. The *tunica media*, or middle layer, is largely a smooth muscle layer that constricts to regulate and control the diameter of the vessel. The *tunica intima*, or inner layer, has an elastic layer that joins the media and a thin layer of endothelial cells that lie adjacent to the blood. The endothelial layer provides a smooth and slippery inner surface for the vessel. This smooth inner lining, as long as it remains intact, prevents platelet adherence and blood clotting. The layers of the different types of blood vessels vary with vessel function.

■ FIGURE 14-21 ■ Medium-sized artery and vein, showing the relative thickness of the three layers.

The walls of the arterioles, which control blood pressure, have large amounts of smooth muscle. Veins are thin-walled, distensible, and collapsible vessels. Capillaries are single-cell– thick vessels designed for the exchange of gases, nutrients, and waste materials.

Vascular Smooth Muscle

Smooth muscle contracts slowly and generates high forces for long periods with low energy requirements; it uses only 1/10 to 1/300 the energy of skeletal muscle. These characteristics are important in structures, such as blood vessels, that must maintain their tone day in and day out.

Although vascular smooth muscle contains actin and myosin filaments, these contractile filaments are not arranged in striations as they are in skeletal and cardiac muscle. The smooth muscle fibers are instead linked together in a strong cablelike system that generates a circular pull as it contracts. In addition, smooth muscle has less well developed sarcoplasmic reticulum for storing intracellular calcium than do skeletal and cardiac muscle, and it has very few fast sodium channels. Instead, depolarization of smooth muscle relies largely on extracellular calcium, which enters through calcium channels in the muscle membrane. These channels respond to changes in membrane potential or receptor-activated responses to chemical mediators such as norepinephrine. Sympathetic nervous system control of vascular smooth muscle tone occurs by way of receptor-activated channels. In general, α -adrenergic receptors are excitatory and produce vasoconstriction, and β-adrenergic receptors are inhibitory and produce vasodilation. Calcium-channel blocking drugs cause vasodilation by blocking calcium entry through the calcium channels.

Arterial System

The arterial system consists of the large and medium-sized arteries and the arterioles. Arteries are thick-walled vessels with large amounts of elastic fibers. The elasticity of these vessels allows them to stretch during cardiac systole, when the heart contracts and blood is ejected into the circulation, and to recoil during diastole, when the heart relaxes. The arterioles, which are predominantly smooth muscle, serve as resistance vessels for the circulatory system. They act as control valves through which blood is released as it moves into the capillaries. Changes in the activity of sympathetic fibers that innervate these vessels cause them to constrict or to relax as needed to maintain blood pressure. The regulation of arterial blood pressure is discussed further in Chapter 16.

Aortic Pressure Pulse

The delivery of blood to the tissues of the body is dependent on pressure pulsations or waves of pressure that are generated by the intermittent ejection of blood from the left ventricle into the distensible aorta and large arteries of the arterial system. The aortic pressure pulse represents the energy that is transmitted from molecule to molecule along the length of the vessel (Fig. 14-22). In the aorta, this pressure pulse is transmitted at a velocity of 4 to 6 meters/second, which is approximately 20 times faster than the flow of blood. Therefore, the pressure pulse has no direct relation to blood flow and could occur if there was no flow at all. When taking a pulse, it is the pressure pulses that are felt, and it is the pressure pulses that produce the Korotkoff sounds heard during blood pressure measurement. The tip or maximum deflection of the pressure pulsation coincides with the systolic blood pressure, and the minimum point of deflection coincides with the diastolic pressure.

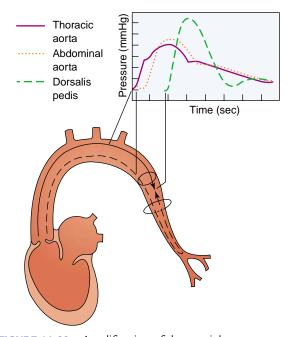

Both the pressure values and the conformation of the pressure wave changes as it moves though the peripheral arteries (Fig. 14-22). As the pressure wave moves out through the aorta into the arteries, it changes as it collides with reflected waves from the periphery. This is why the systolic pressure is higher in the medium-sized arteries than in the aorta even though the diastolic pressure is lower. After its initial amplification, the pressure pulse becomes smaller and smaller as it moves through the smaller arteries and arterioles, until it disappears almost entirely in the capillaries. This allows for continuous, rather than pulsatile, flow in the capillary beds.

Although the pressure pulses usually are not transmitted to the capillaries, there are situations in which this does occur. For example, injury to a finger or other area of the body often results in a throbbing sensation. In this case, extreme dilatation of the small vessels in the injured area produces a reduction in the dampening of the pressure pulse. Capillary pulsations also occur in conditions that cause exaggeration of aortic pressure pulses, such as aortic regurgitation (see Chapter 17).

Venous System

The veins and venules are thin-walled, distensible, and collapsible vessels. The venules collect blood from the capillaries, and the veins transport blood back to the heart. The veins are capable of enlarging and storing large quantities of blood, which can be made available to the circulation as needed. Even though the veins are thin walled, they are muscular. This allows

248 Unit Four: Alterations in the Cardiovascular System

■ FIGURE 14-22 ■ Amplification of the arterial pressure wave as it moves forward in the peripheral arteries. This amplification occurs as a forward-moving pressure wave merges with a backwardmoving reflected pressure wave. (Inset) The amplitude of the pressure pulse increases in the thoracic aorta, abdominal aorta, and dorsalis pedis.

them to contract or expand to accommodate varying amounts of blood. Veins are innervated by the sympathetic nervous system. When blood is lost from the circulation, the veins constrict as a means of maintaining intravascular volume.

The venous system is a low-pressure system, and when a person is in the upright position, blood flow in the venous system must oppose the effects of gravity. Valves in the veins of extremities prevent retrograde flow (Fig. 14-23), and with the

help of skeletal muscles that surround and intermittently compress the veins in a milking manner, blood is moved forward to the heart. Their pressure ranges from approximately 10 mm Hg at the end of the venules to approximately 0 mm Hg at the entrance of the vena cava into the heart. There are no valves in the abdominal or thoracic veins, and blood flow in these veins is heavily influenced by the pressure in the abdominal and thoracic cavities, respectively.

Lymphatic System

The lymphatic system, commonly called the *lymphatics*, serves almost all body tissues, except cartilage, bone, epithelial tissue, and tissues of the central nervous system. However, most of these tissues have prelymphatic channels that eventually flow into areas supplied by the lymphatics. Lymph is derived from interstitial fluids that flow through the lymph channels. It contains plasma proteins and other osmotically active particles that rely on the lymphatics for movement back into the circulatory system. The lymphatic system is also the main route for absorption of nutrients, particularly fats, from the gastrointestinal tract.

The lymphatic system is made up of vessels similar to those of the circulatory system. These vessels commonly travel along with an arteriole or venule or with its companion artery and vein. The terminal lymphatic vessels are made up of a single layer of connective tissue with an endothelial lining and resemble blood capillaries. The lymphatic vessels lack tight junctions and are loosely anchored to the surrounding tissues by fine filaments (Fig. 14-24). The loose junctions permit the entry of large particles, and the filaments hold the vessels open under conditions of edema, when the pressure of the surrounding tissues would otherwise cause them to collapse. The lymph capillaries drain into larger lymph vessels that ultimately empty into the right and left thoracic ducts (Fig. 14-25). The thoracic ducts empty into the circulation at the junctions of the subclavian and internal jugular veins.

Although the divisions are not as distinct as in the circulatory system, the larger lymph vessels show evidence of having intimal, medial, and adventitial layers similar to those of blood vessels. Contraction of the smooth muscle in the medial layer

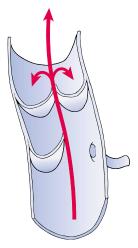

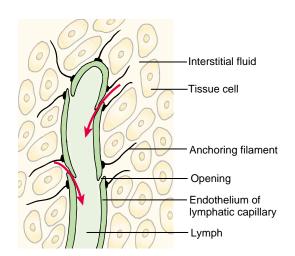

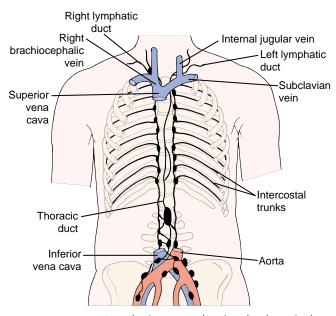

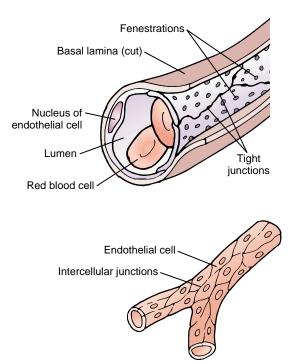

FIGURE 14-23 Portion of a femoral vein opened, to show the valves. The direction of flow is upward. Backward flow closes the valve.

■ FIGURE 14-24 ■ Details of a lymphatic capillary.

■ FIGURE 14-25 ■ Lymphatic system showing the thoracic duct and position of the left and right lymphatic ducts.

of the larger collecting lymph channels assists in propelling lymph fluid toward the thorax. External compression of the lymph channels by active and passive movements of body parts also aid in forward propulsion of lymph fluid. The rate of flow through the lymphatic system by way of all of the various lymph channels, approximately 120 mL per hour, is determined by the interstitial fluid pressure and the activity of lymph pumps.

The Microcirculation and Local Control of Blood Flow

The capillaries, venules, and arterioles of the circulatory system are collectively referred to as the *microcirculation*. It is here that exchange of gases, nutrients, and metabolites takes place between the tissues and the circulating blood. The lymphatic system represents an accessory system that removes excess fluid, proteins, and large particles from the interstitial spaces and returns them to the circulation. Because of their size, these particles cannot be reabsorbed into the capillaries.

Capillaries

Capillaries are microscopic, single-cell-thick vessels that connect the arterial and venous segments of the circulation. In each person, there are approximately 10 billion capillaries, with a total surface area of 500 to 700 m².

The capillary wall is composed of a single layer of endothelial cells surrounded by a basement membrane (Fig. 14-26). Intracellular junctions join the capillary endothelial cells; these are called the capillary pores. Lipid-soluble materials diffuse directly through the capillary cell membrane. Water and watersoluble materials leave and enter the capillary through the capillary pores. The size of the capillary pores varies with capillary function. In the brain, the endothelial cells are joined by tight junctions that form the blood-brain barrier. This prevents sub-

■ FIGURE 14-26 ■ Endothelial cells and intercellular junctions in a section of capillary.

stances that would alter neural excitability from leaving the capillary. In organs that process blood contents, such as the liver, capillaries have large pores so that substances can pass easily through the capillary wall. In the kidneys, the glomerular capillaries have small openings called *fenestrations* that pass directly through the middle of the endothelial cells. Fenestrated capillary walls are consistent with the filtration function of the glomerulus.

Blood enters the microcirculation through an arteriole, passes through the capillaries, and leaves by way of a small venule. The metarterioles serve as thoroughfare channels that link arterioles and capillaries (Fig. 14-27). Small cuffs of smooth muscle, the precapillary sphincters, are positioned at the arterial end of the capillary. The smooth muscle tone of the arterioles, venules, and precapillary sphincters serves to control blood flow through the capillary bed. Depending on venous pressure, blood flows through the capillary channels when the precapillary sphincters are open.

Blood flow through capillary channels, designed for exchange of nutrients and metabolites, is called nutrient flow. In some parts of the microcirculation, blood flow bypasses the capillary bed, moving through a connection called an arteriovenous shunt, which directly connects an arteriole and a venule. This type of blood flow is called non-nutrient flow because it does not allow for nutrient exchange. Non-nutrient channels are common in the skin and are important in terms of heat exchange and temperature regulation.

Autoregulation

Tissue blood flow is regulated on a minute-to-minute basis in relation to tissue needs and on a longer-term basis through the development of collateral circulation. Neural mechanisms

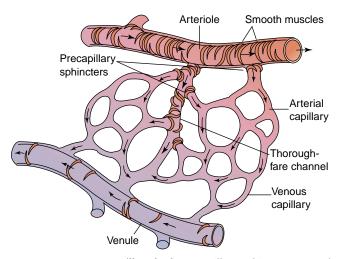

FIGURE 14-27 Capillary bed. Precapillary sphincters control the flow of blood through the capillary network. Thoroughfare channels (*i.e.*, arteriovenous shunts) allow blood to move directly from the arteriole into the venule without moving through nutrient channels of the capillary.

regulate the cardiac output and blood pressure needed to support these local mechanisms.

Local control of blood flow is governed largely by the nutritional needs of the tissue. For example, blood flow to organs such as the heart, brain, and kidneys remains relatively constant, although blood pressure may vary throughout a range of 60 to 180 mm Hg. The ability of the tissues to regulate their own blood flow throughout a wide range of pressures is called *autoregulation*. Autoregulation of blood flow is mediated by changes in blood vessel tone caused by changes in flow through the vessel or by local tissue factors, such as lack of oxygen or accumulation of tissue metabolites (*i.e.*, potassium, lactic acid, or adenosine, which is a breakdown product of ATP). Local control is particularly important in tissues such as skeletal muscle, which has blood flow requirements that vary according to the level of activity.

An increase in local blood flow is called *hyperemia*. The ability of tissues to increase blood flow in situations of increased activity, such as exercise, is called *functional hyperemia*. When the blood supply to an area has been occluded and then restored, local blood flow through the tissues increases within seconds to restore the metabolic equilibrium of the tissues. This increased flow is called *reactive hyperemia*. The transient redness seen on an arm after leaning on a hard surface is an example of reactive hyperemia. Local control mechanisms rely on a continuous flow from the main arteries; therefore, hyperemia cannot occur when the arteries that supply the capillary beds are narrowed. For example, if a major coronary artery becomes occluded, the opening of channels supplied by that vessel cannot restore blood flow.

Tissue Factors Contributing to Local Control of Blood Flow. Vasoactive substances, formed in tissues in response to a need for increased blood flow, also aid in the local control of blood flow. The most important of these are histamine, serotonin (*i.e.*, 5-hydroxytryptamine), the kinins, and the prostaglandins. *Histamine* increases blood flow. Most blood vessels contain histamine in mast cells and nonmast cell stores; when these tissues are injured, histamine is released. In certain tissues, such as skeletal muscle, the activity of the mast cells is mediated by the sympathetic nervous system; when sympathetic control is withdrawn, the mast cells release histamine. Vasodilation then results from increased histamine and the withdrawal of vasoconstrictor activity.

Serotonin is liberated from aggregating platelets during the clotting process; it causes vasoconstriction and plays a major role in the control of bleeding. Serotonin is found in brain and lung tissues, and there is some speculation that it may be involved in the vascular spasm associated with some allergic pulmonary reactions and migraine headaches.

The *kinins* (*i.e.*, kallidins and bradykinin) are liberated from the globulin kininogen, which is present in body fluids. The kinins cause relaxation of arteriolar smooth muscle, increase capillary permeability, and constrict the venules. In exocrine glands, the formation of kinins contributes to the vasodilation needed for glandular secretion.

Prostaglandins are synthesized from constituents of the cell membrane (*i.e.*, the long-chain fatty acid *arachidonic acid*). Tissue injury incites the release of arachidonic acid from the cell membrane, which initiates prostaglandin synthesis. There are several prostaglandins (*e.g.*, E_2 , F_2 , D_2), which are subgrouped according to their solubility; some produce vasoconstriction and some produce vasodilation. As a rule of thumb, those in the E group are vasodilators, and those in the F group are vasoconstrictors. The adrenal glucocorticoid hormones produce an anti-inflammatory response by blocking the release of arachidonic acid, preventing prostaglandin synthesis.

Endothelial Control of Vasodilation and Vasoconstriction. The *endothelium*, which lies between the blood and the vascular smooth muscle, serves as a physical barrier for vasoactive substances that circulate in the blood. Once thought to be nothing more than a single layer of cells that line blood vessels, it is now known that the endothelium plays an active role in controlling vascular function. In capillaries, which are composed of a single layer of endothelial cells, the endothelium is active in transporting cell nutrients and wastes. In addition to its function in capillary transport, the vascular endothelium removes vasoactive agents such as norepinephrine from the blood, and it produces enzymes that convert precursor molecules to active products (*e.g.*, angiotensin I to angiotensin II in lung vessels).

One of the important functions of the endothelial cells in the small arteries and arterioles is to synthesize and release factors that control vessel dilation. Of particular importance was the discovery, first reported in the early 1980s, that the intact endothelium was able to produce a factor that caused relaxation of vascular smooth muscle. This factor was originally named *endothelium-derived relaxing factor* and is now known to be *nitric oxide*. Many other cell types produce nitric oxide. In these tissues, nitric oxide has other functions, including modulation of nerve activity in the nervous system.

The normal endothelium maintains a continuous release of nitric oxide, which is formed from L-arginine through the action of an enzyme called *nitric oxide synthase* (Fig. 14-28). The production of nitric oxide can be stimulated by a variety of

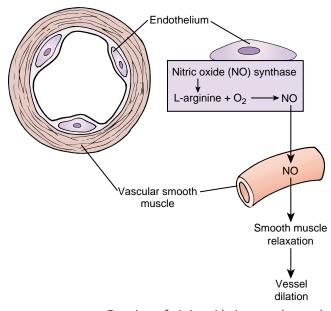

FIGURE 14-28 Function of nitric oxide in smooth muscle relaxation.

endothelial agonists, including acetylcholine, bradykinin, histamine, and thrombin. Shear stress on the endothelium, resulting from an increase in blood flow or blood pressure, also stimulates nitric oxide production and vessel relaxation. Nitric oxide also inhibits platelet aggregation and secretion of platelet contents, many of which cause vasoconstriction. The fact that nitric oxide is released into the vessel lumen (to inactivate platelets) and away from the lumen (to relax smooth muscle) suggests that it protects against both thrombosis and vasoconstriction. Nitroglycerin, which is used in treatment of angina, produces its effects by releasing nitric oxide in vascular smooth muscle of the target tissues.

The endothelium also produces a number of vasoconstrictor substances, including angiotensin II, vasoconstrictor prostaglandins, and a family of peptides called endothelins. There are at least three endothelins. Endothelin-1, made by human endothelial cells, is the most potent endogenous vasoconstrictor known. Receptors for endothelins also have been identified.

Collateral Circulation

Collateral circulation is a mechanism for the long-term regulation of local blood flow. In the heart and other vital structures, anastomotic channels exist between some of the smaller arteries. These channels permit perfusion of an area by more than one artery. When one artery becomes occluded, these anastomotic channels increase in size, allowing blood from a patent artery to perfuse the area supplied by the occluded vessel. For example, persons with extensive obstruction of a coronary blood vessel may rely on collateral circulation to meet the oxygen needs of the myocardial tissue normally supplied by that vessel. As with other long-term compensatory mechanisms, the recruitment of collateral circulation is most efficient when obstruction to flow is gradual, rather than sudden.

In summary, the walls of all blood vessels, except the capillaries, are composed of three layers: the tunica externa, tunica media, and tunica intima. The layers of the vessel vary with its function. Arteries are thick-walled vessels with large amounts of elastic fibers. The walls of the arterioles, which control blood pressure, have large amounts of smooth muscle. Veins are thin-walled, distensible, and collapsible vessels. Venous flow is designed to return blood to the heart. It is a low-pressure system and relies on venous valves and the action of muscle pumps to offset the effects of gravity. Capillaries are single-cell-thick vessels designed for the exchange of gases, nutrients, and waste materials.

The delivery of blood to the tissues of the body is dependent on pressure pulses that are generated by the intermittent ejection of blood from the left ventricle into the distensible aorta and large arteries of the arterial system. The combination of distensibility of the arteries and their resistance to flow reduces the pressure pulsations, therefore, blood flow is almost constant by the time blood reaches the capillaries. Two major factors affect the pressure pulsations: (1) the stroke volume output of the heart, and (2) and the compliance of the arterial system into which the blood is ejected. A large stroke volume and/or decrease in arterial compliance produce an increase in pulse pressure.

The mechanisms that control blood flow are designed to ensure adequate delivery of blood to the capillaries in the microcirculation, where the exchange of cellular nutrients and wastes occurs. Local control is governed largely by the needs of the tissues and is regulated by local tissue factors such as lack of oxygen and the accumulation of metabolites. Hyperemia is a local increase in blood flow that occurs after a temporary occlusion of blood flow. It is a compensatory mechanism that decreases the oxygen debt of the deprived tissues. Collateral circulation is a mechanism for long-term regulation of local blood flow that involves the development of collateral vessels.

NEURAL CONTROL OF CIRCULATORY FUNCTION

The neural control of the circulatory system occurs primarily through the sympathetic and parasympathetic divisions of the autonomic nervous system (ANS). The ANS contributes to the control of cardiovascular function through modulation of cardiac (*i.e.*, heart rate and cardiac contractility) and vascular (*i.e.*, peripheral vascular resistance) function.

The neural control centers for the integration and modulation of cardiac function and blood pressure are located bilaterally in the medulla oblongata. The medullary cardiovascular neurons are grouped into three distinct pools that lead to sympathetic innervation of the heart and blood vessels and parasympathetic innervation of the heart. The first two, which control sympathetic-mediated acceleration of heart rate and blood vessel tone, are called the vasomotor center. The third, which controls parasympathetic-mediated slowing of heart rate, is called the *cardioinhibitory center*. These brain stem centers receive information from many areas of the nervous system, including the hypothalamus. The arterial baroreceptors and chemoreceptors provide the medullary cardiovascular center with continuous information regarding changes in blood pressure (see Chapter 16).

Autonomic Regulation of Cardiac Function

The heart is innervated by the parasympathetic and sympathetic nervous systems. Parasympathetic innervation of the heart is achieved by means of the vagus nerve. The parasympathetic outflow to the heart originates from the vagal nucleus in the medulla. The axons of these neurons pass to the heart in the cardiac branches of the vagus nerve. The effect of vagal stimulation on heart function is largely limited to heart rate, with increased vagal activity producing a slowing of the pulse. Sympathetic outflow to the heart and blood vessels arises from neurons located in the reticular formation of the brain stem. The axons of these neurons exit the thoracic segments of the spinal cord to synapse with the postganglionic neurons that innervate the heart. Cardiac sympathetic fibers are widely distributed to the SA and AV nodes and the myocardium. Increased sympathetic activity produces an increase in the heart rate and the velocity and force of cardiac contraction.

Autonomic Regulation of Vascular Function

The sympathetic nervous system serves as the final common pathway for controlling the smooth muscle tone of the blood vessels. Most of the sympathetic preganglionic fibers that control vessel function originate in the vasomotor center of the brain stem, travel down the spinal cord, and exit in the thoracic and lumbar (T1-L2) segments. The sympathetic neurons that supply the blood vessels maintain them in a state of tonic activity, so that even under resting conditions, the blood vessels are partially constricted. Vessel constriction and relaxation are accomplished by altering this basal input. Increasing sympathetic activity causes constriction of some vessels, such as those of the skin, the gastrointestinal tract, and the kidneys. Blood vessels in skeletal muscle are supplied by both vasoconstrictor and vasodilator fibers. Activation of sympathetic vasodilator fibers causes vessel relaxation and provides the muscles with increased blood flow during exercise. Although the parasympathetic nervous system contributes to the regulation of heart function, it has little or no control over blood vessels.

Autonomic Neurotransmitters

The actions of the ANS are mediated by chemical neurotransmitters. *Acetylcholine* is the postganglionic neurotransmitter for parasympathetic neurons and *norepinephrine* is the main neurotransmitter for postganglionic sympathetic neurons. Sympathetic neurons also respond to epinephrine, which is released into the bloodstream by the adrenal medulla. The neurotransmitter *dopamine* can also act as a neurotransmitter for some sympathetic neurons. The synthesis, release, and inactivation of the autonomic neurotransmitters are discussed in Chapter 36. In summary, the neural control centers for the regulation of cardiac function and blood pressure are located in the reticular formation of the lower pons and medulla of the brain stem, where the integration and modulation of ANS responses occur. These brain stem centers receive information from many areas of the nervous system, including the hypothalamus. Both the parasympathetic and sympathetic nervous systems innervate the heart. The parasympathetic nervous system functions in regulating heart rate through the vagus nerve, with increased vagal activity producing a slowing of heart rate. The sympathetic nervous system has an excitatory influence on heart rate and contractility, and it serves as the final common pathway for controlling the smooth muscle tone of the blood vessels.

REVIEW QUESTIONS

Compare the functions and distribution of blood flow and blood pressure in the systemic and pulmonary circulations.

■ Use Laplace's law to explain the collapse of small blood vessels during shock caused by a loss of blood volume and to explain why atherosclerotic disease is usually a silent disorder until the disease has produced a 75% reduction in vessel radius.

Describe the cardiac conduction system and relate it to the mechanical functioning of the heart.

Characterize the four phases of a cardiac action potential and differentiate between the fast and slow responses.

Draw a figure of the cardiac cycle, incorporating volume, pressure, phonocardiographic, and electrocardiographic changes that occur during atrial and ventricular systole and diastole.

Explain the concepts of *preload* and *afterload* in terms of venous return to the heart, aortic valvular stenosis, and hypertension.

State the formula for calculating the cardiac output and explain the effects that venous return, cardiac contractility, and heart rate have on cardiac output.

Describe the cardiac reserve and relate it to the Frank-Starling mechanism.

Compare the structure and function of arteries, arterioles, veins, and capillaries.

Define autoregulation and characterize mechanisms responsible for short-term and long-term regulation of blood flow.

Describe the distribution of the sympathetic and parasympathetic nervous system in innervation of the circulatory system and their effects on heart rate and cardiac contractility.

B lood vessels function in the delivery of oxygen and nutrients to the tissues and in the removal of waste products from the tissues. Unlike disorders of the respiratory system or central circulation that cause hypoxia and impair oxygenation of tissues throughout the body, the effects of blood vessel disease usually are limited to local tissues supplied by a particular vessel or group of vessels.

Disturbances in blood flow can result from pathologic changes in the vessel wall (*i.e.*, atherosclerosis, vasculitides), acute vessel obstruction caused by thrombus or embolus, vasospasm (*i.e.*, Raynaud's phenomenon), abnormal vessel dilation (*i.e.*, arterial aneurysms or varicose veins), or compression of blood vessels by extravascular forces (*i.e.*, tumors, edema, or firm surfaces such as those associated with pressure ulcers).

DISORDERS OF THE ARTERIAL CIRCULATION

The arterial system distributes blood to all the tissues in the body. There are three types of arteries: large arteries, including the aorta and its distal branches; medium-size arteries, such as the coronary and renal arteries; and small arteries and arterioles that pass through the tissues. Each of these different types of arteries tends to be affected by different disease processes.

Pathology of the arterial system affects body function by impairing blood flow. The effect of impaired blood flow on the body depends on the structures involved and the extent of altered flow. The term *ischemia* (*i.e.*, holding back of blood) denotes a reduction in arterial flow to a level that is insufficient to meet the oxygen demands of the tissues. *Infarction* refers to an area of ischemic necrosis in an organ produced by occlusion of its blood supply. The discussion in this section focuses on hyperlipidemia, atherosclerosis, arterial aneurysms, vasculitides, and arterial disease of the extremities.

Hyperlipidemia

Hyperlipidemia with elevated cholesterol levels is a major cause of atherosclerosis with its attendant risk of heart attack and stroke. An estimated 41.3 million Americans have high

KEY CONCEPTS

DISORDERS OF THE ARTERIAL CIRCULATION

- The arterial system delivers oxygen and nutrients to the tissues. Disorders of the arterial circulation produce ischemia owing to narrowing of blood vessels, thrombus formation associated with platelet adhesion, and weakening of the vessel wall.
- Atherosclerosis is a progressive disease characterized by the formation of fibrofatty plaques in the intima of large and medium-sized arteries, producing a decrease in blood flow due to a narrowing of the vessel lumen.
- Aneurysms represent an abnormal localized dilatation of an artery due to a weakness in the vessel wall. As the aneurysm increases in size, the tension in the wall of the vessel increases, predisposing it to rupture.

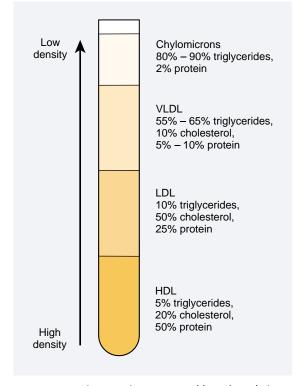

serum cholesterol levels that could contribute to a heart attack, stroke, or other cardiovascular event associated with atherosclerosis.¹

Lipoproteins

Because cholesterol and triglyceride are insoluble in plasma, they are encapsulated by special fat-carrying proteins called *lipoproteins* for transport in the blood. There are five types of lipoproteins, classified by their densities as measured by ultracentrifugation: chylomicrons, very–low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL) (see Fig. 15-1).

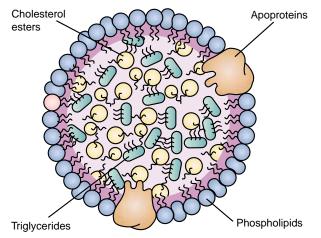

Each type of lipoprotein consists of a large molecular complex of lipids combined with proteins called *apoproteins*.^{2,3} The major lipid constituents are cholesterol esters, triglycerides, nonesterified cholesterol, and phospholipids. The insoluble cholesterol esters and triglycerides are located in the hydrophobic core of the lipoprotein macromolecule, surrounded by the soluble phospholipids, nonesterified cholesterol, and apoproteins (Fig. 15-2). Nonesterified cholesterol and phospholipids provide a negative charge that allows the lipoprotein to be soluble in plasma. The apoproteins control the interactions and ultimate metabolic fate of the lipoproteins. Some of the apoproteins activate the lipolytic enzymes that facilitate the removal of lipids from the lipoproteins; others serve as a reactive site that cellular receptors can recognize and use in the endocytosis and metabolism of the lipoproteins.

There are two sites of lipoprotein synthesis: the small intestine and the liver. The chylomicrons, which are the largest of the lipoprotein molecules, are synthesized in the wall of the small intestine. They are involved in the transport of dietary triglycerides and cholesterol that have been absorbed from the gastrointestinal tract. Chylomicrons transfer their triglycerides to the cells of adipose and skeletal muscle tissue. The remnant chylomicron particles, which contain cholesterol, are then taken up by the liver, and the cholesterol is used in the synthesis of VLDL or excreted in the bile.

■ FIGURE 15-1 ■ Lipoproteins are named based on their protein content, which is measured as density. Because fats are less dense than proteins, as the proportion of triglycerides decreases, the density increases.

The liver synthesizes and releases VLDL and HDL. The VLDLs contain large amounts of triglycerides and lesser amounts of cholesterol esters.⁴ They provide the primary pathway for transport of the triglycerides produced in the liver, as opposed to those obtained from the diet. Like chylomicrons, VLDLs carry their triglycerides to fat and muscle cells, where the triglycerides are removed. The resulting IDL fragments are reduced in triglyceride content and enriched in cholesterol. They

■ FIGURE 15-2 ■ General structure of a lipoprotein. The cholesterol esters and triglycerides are located in the hydrophobic core of the macromolecule, surrounded by phospholipids and apoproteins.

are taken to the liver and recycled to form VLDL, or converted to LDL in the vascular compartment. The pathways for triglyceride and cholesterol transport are shown in Figure 15-3.

LDL, sometimes called the bad cholesterol, is the main carrier of cholesterol. The IDLs are the main source of LDL. The LDL is removed from the circulation by either LDL receptors or by scavenger cells such as monocytes or macrophages. Approximately 70% of LDL is removed by way of the LDL receptordependent pathway.⁴ Although LDL receptors are widely distributed, approximately 75% are located on hepatocytes; thus the liver plays an extremely important role in LDL metabolism. Tissues with LDL receptors can control their cholesterol intake by adding or removing LDL receptors.

The scavenger cells, such as the monocytes and macrophages, have receptors that bind LDL that has been oxidized or chemically modified. The amount of LDL that is removed by the "scavenger pathway" is directly related to the plasma cholesterol level. When there is a decrease in LDL receptors or when LDL levels exceed receptor availability, the amount of LDL that is removed by scavenger cells is greatly increased. The uptake of LDL by macrophages in the arterial wall can result in the accumulation of insoluble cholesterol esters, the formation of foam cells, and the development of atherosclerosis.

HDL is synthesized in the liver and often is referred to as the good cholesterol. Epidemiological studies show an inverse relation between HDL levels and the development of atherosclerosis.⁵ It is thought that HDL, which is low in cholesterol and rich in surface phospholipids, facilitates the clearance of cholesterol from atheromatous plagues and transports it back to the liver, so that it can be excreted in the bile. HDL also is believed to inhibit the uptake of LDL into the arterial wall. It has been observed that regular exercise and moderate alcohol consumption increase HDL levels. Smoking and diabetes, which are in themselves risk factors for atherosclerosis, are associated with decreased levels of HDL.⁴

Hypercholesterolemia

The Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults has published a classification system for hyperlipidemia that list the laboratory values for optimal to very high levels of LDL cholesterol, desirable to high levels of total cholesterol, and low and high levels of HDL cholesterol (see Table 15-1).6 The NCEP recommends that all adults 20 years of age and older should have a fasting lipoprotein profile (total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides) measured once every 5 years.6 If testing is done in the nonfasting state, only the total cholesterol and HDL are considered useful. A follow-up lipoprotein profile should be done on persons with nonfasting total cholesterol levels ≥200 mg/dL or HDL levels <40 mg/dL. Lipoprotein measurements are particularly important in persons at high risk for the development of coronary heart disease (CHD).

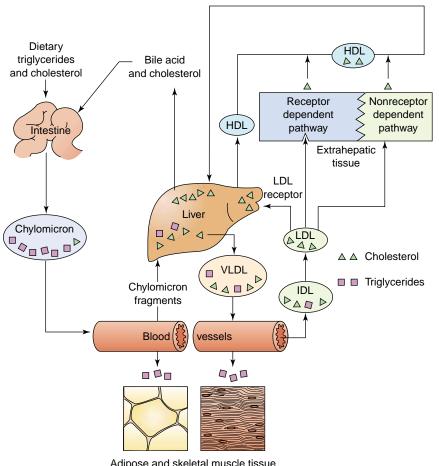

FIGURE 15-3 Schematic representation of the exogenous and endogenous pathways for triglyceride and cholesterol transport.

Adipose and skeletal muscle tissue

TABLE 15-1 NCEP A	dult Treatment
Panel III Classification of LDL, Total, and HDL Cholesterol	
Cholesterol Level (mg/dL)	Classification
LDL Cholesterol	
<100	Optimal
100–129	Near optimal/above optimal
130–159	Borderline high
160–189	High
≥190	Very high
Total Cholesterol	
<200	Desirable
200–239	Borderline high
≥240	High
HDL Cholesterol	
<40	Low
≥60	High

National Institutes of Health Expert Panel. (2001). Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). (NIH publication no. 01-3670). Bethesda, MD: National Institutes of Health.

Causes. Three factors-genetics, nutrition, and metabolic diseases-contribute to an increase in blood lipid levels. Many types of hyperlipidemia have a genetic basis. There may be a defective synthesis of the apoproteins, a lack of LDL receptors, defective LDL receptors, or defects in the intracellular handling of cholesterol.² The LDL receptor is deficient or defective in the genetic disorder known as familial hypercholesterolemia. This autosomal dominant type of hyperlipoproteinemia results from a mutation in the gene specifying the receptor for LDL. Because most of the circulating cholesterol is removed by receptordependent mechanisms, blood cholesterol levels are markedly elevated in persons with this disorder. The disorder is probably one of the most common of all mendelian disorders; the frequency of heterozygotes is 1 in 500 persons in the general population.² Although heterozygotes commonly have an elevated cholesterol level from birth, they do not experience symptoms until adult life, when xanthomas (i.e., cholesterol deposits) develop along the tendons and atherosclerosis occurs (Fig. 15-4). Myocardial infarction before the age of 40 years is common. Homozygotes are much more severely affected; they develop cutaneous xanthomas in childhood and may experience myocardial infarction by the age of 20 years.²

Secondary causes of hyperlipoproteinemia include diets high in saturated fats and cholesterol, obesity caused by highcalorie intake, and diabetes mellitus. Diets that are high in triglycerides and saturated fats increase cholesterol synthesis and suppress LDL receptor activity. Excess ingestion of cholesterol reduces the formation of LDL receptors and thereby decreases LDL removal. In diabetes mellitus, metabolic derangements cause an elevation of lipoproteins.7

The management of hyperlipidemia focuses on dietary and lifestyle modifications; when these are unsuccessful, pharmacologic treatment may be necessary. Lifestyle modification includes increased emphasis on physical activity, dietary measures to reduce LDL cholesterol levels, and weight reduction for people who are overweight. The aim of dietary therapy is to reduce total and LDL cholesterol levels and increase HDL levels. Three dietary elements affect serum cholesterol and its lipoprotein fractions: excess calorie intake, saturated fats, and cholesterol. High-calorie diets increase the production of VLDL, with triglyceride elevation and high conversion of VLDL to LDL. Saturated fats and cholesterol in the diet tend to increase LDL cholesterol levels.

The third report of the NCEP continues to identify reduction in LDL cholesterol as the primary target for cholesterol-lowering therapy, particularly in people at risk for CHD.⁶ Lipid-lowering drugs work mainly by decreasing cholesterol absorption from the intestine, decreasing cholesterol synthesis by the liver, or

FIGURE 15-4 Xanthomas in the skin and tendons (A, C, D). Arcus lipoides represents the deposition of lipids in the peripheral cornea (**B**). (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 506]. Philadelphia: Lippincott Williams & Wilkins)

inhibiting VLDL release. Drugs that act directly to decrease cholesterol levels also have the beneficial effect of further lowering cholesterol levels by stimulating the production of additional LDL receptors. Because many of these drugs have significant adverse effects, they usually are used only in persons with significant hyperlipidemia that cannot be controlled by other means, such as diet.

Atherosclerosis

Atherosclerosis is a type of arteriosclerosis or hardening of the arteries. The term *atherosclerosis*, which comes from the Greek words *atheros* (meaning "gruel" or "paste") and *sclerosis* (meaning "hardness"), denotes the formation of fibrofatty lesions in the intimal lining of the large and medium-size arteries such as the aorta and its branches, the coronary arteries, and the large vessels that supply the brain. Atherosclerosis contributes to more mortality and more serious morbidity than any other disorder in the western world.⁴ The major complications of atherosclerosis, including ischemic heart disease, stroke, and peripheral vascular disease, account for more than 40% of the deaths in the United States.⁸

Risk Factors

The cause or causes of atherosclerosis have not been determined with certainty. However, epidemiologic studies have identified predisposing risk factors, which are listed in Chart 15-1.^{2,4} Some risk factors can be affected by a change in health behavior and others cannot. Risk factors that cannot be changed in-

CHART 15-1 Risk Factors in Coronary Heart Disease Other Than Low-Density Lipoproteins

Positive Risk Factors

Age

Men: ≥45 years

Women: ≥55 years or premature menopause without estrogen replacement therapy

Family history of premature coronary heart disease (definite myocardial infarction or sudden death before 55 years of age in father or other male first-degree relative, or before 65 years of age in mother or other female first-degree relative)

Current cigarette smoking

Hypertension (≥140/90 mm Hg* or on antihypertensive medication)

Low HDL cholesterol (<40 mg/dL*) Diabetes mellitus

Negative Risk Factor

High HDL cholesterol (≥60 mg/dL)

HDL, high-density lipoprotein.

*Confirmed by measurements on several occasions.

(Modified from National Institute of Health Expert Panel [2001]. Third Report of the National Cholesterol Program [NCEP] Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults [Adult Treatment Panel III]. [NIH Publication No. 01-3670]. Bethesda, MD: National Institutes of Health.) clude age, male gender, and family history of premature coronary heart disease.

The tendency to develop atherosclerosis appears to run in families. Persons who come from families with a strong history of heart disease or stroke caused by atherosclerosis are at greater risk for developing atherosclerosis than are those with a negative family history. Several genetically determined alterations in lipoprotein and cholesterol metabolism have been identified, and it seems likely that others will be identified in the future. The incidence of atherosclerosis also increases with age. Other factors being equal, men are at greater risk for coronary heart disease than are premenopausal women, probably because of the protective effects of natural estrogens. After menopause, the incidence of atherosclerotic-related diseases in women increases, and by the 7th to 8th decade of life, the frequency of myocardial infarction in the two sexes tends to equalize.⁴

The major risk factors that can be affected by a change in health behaviors include hyperlipidemia, cigarette smoking, hypertension, and diabetes mellitus. These risk factors can often be modified or controlled by a change in diet, exercise, health care practices, or medications. The presence of hyperlipidemia is the strongest risk factor for atherosclerosis in persons younger than 45 years of age. Both primary and secondary hyperlipidemia increase the risk. Cigarette smoking is closely linked with coronary heart disease and sudden death. Cessation of smoking reduces the risk substantially. High blood pressure produces mechanical stress on the vessel endothelium. It is a major risk factor for atherosclerosis in all age groups and may be as important or more important than hypercholesterolemia after the age of 45 years. Both systolic and diastolic pressures are important in increasing risk. Diabetes mellitus (type 2) typically develops in middle-aged persons and those who are overweight. Diabetes elevates blood lipid levels and otherwise increases the risk of atherosclerosis (see Chapter 32). Controlling other risk factors, such as hypertension and hypercholesterolemia, is particularly important in persons with diabetes.

Other factors, known as "soft" risk factors, are not as convincing as the established risk factors. These include insufficient physical activity, a stressful lifestyle, and obesity. These "soft" risk factors commonly are linked with the established and other contributing risk factors. For example, obesity and physical inactivity often are observed in the same person. Both conditions are reported to bring about elevations in blood lipid levels. Likewise, major risk factors such as cigarette smoking are closely associated with stress and personality patterns.

There are a number of other less well-established risk factors for atherosclerosis, including high serum homocysteine levels, elevated serum C-reactive protein, and infectious agents.^{9,10} Homocysteine is derived from the metabolism of dietary methionine, an amino acid that is abundant in animal protein. Homocysteine inhibits elements of the anticoagulant cascade and is associated with endothelial damage, which is thought to be an important first step in the development of atherosclerosis.¹⁰ Factors tending to increase plasma levels of homocysteine include lower serum levels of folate and vitamins B₆ and B₁₂; genetic defects in homocysteine metabolism; renal impairment; malignancies, increasing age; male gender; and female menopause.¹¹ *C-reactive protein* (CRP) is a serum marker for systemic inflammation. Several prospective studies have indicated that elevated CRP levels are associated with vascular disbus formation.¹⁰ Recently, there has been increased interest in the possible connection between infectious agents (*Chlamydia pneumoniae*, *herpesvirus hominis, cytomegalovirus*) and the development of vascular disease. The presence of these organisms in atheromatous lesions has been demonstrated by immunocytochemistry, but no cause-and-effect relationship has been established. The organisms may play a role in atherosclerotic development by initiating and enhancing the inflammatory response.¹²

Pathology and Pathogenesis

The lesions associated with atherosclerosis are of three types: the fatty streak, the fibrous atheromatous plaque, and the complicated lesion. The latter two are responsible for the clinically significant manifestations of the disease.

Fatty streaks are thin, flat yellow intimal discolorations that progressively enlarge by becoming thicker and slightly elevated as they grow in length (Fig. 15-5). Histologically, they consist of macrophages and smooth muscle cells that have become distended with lipid to form foam cells. Fatty streaks are present in children, often in the first year of life.^{2,4} This occurs regardless of geographic setting, gender, or race. They increase in number until about age 20 years, and then they remain static or regress. There is controversy about whether fatty streaks, in and of themselves, are precursors of atherosclerotic lesions.

The *fibrous atheromatous plaque* is the basic lesion of clinical atherosclerosis. It is characterized by the accumulation of intracellular and extracellular lipids, proliferation of vascular smooth muscle cells, and formation of scar tissue. The lesions begin as a gray to pearly white elevated thickening of the vessel intima with a core of extracellular lipid (mainly cholesterol, which usually is complexed to proteins) covered by a fibrous cap of connective tissue and smooth muscle (Fig. 15-6). As the lesions increase in size, they encroach on the lumen of the artery and eventually may occlude the vessel or predispose to throm-

■ FIGURE 15-6 ■ Fatty plaque of atherosclerosis. The aorta shows discrete, raised, tan plaques. Focal ulcerations are also present. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 497]. Philadel-phia: Lippincott Williams & Wilkins)

bus formation, causing a reduction of blood flow. Because blood flow is related to the fourth power of the radius, reduction in blood flow becomes more severe as the disease progresses.

The more advanced *complicated lesions* are characterized by hemorrhage, ulceration, and scar tissue deposits. Thrombosis is the most important complication of atherosclerosis. It is

■ FIGURE 15-5 ■ Fatty streaks of atherosclerosis. The aorta of a young man shows numerous fatty streaks on the luminal surface when stained with Sudan red, shown on the left. The unstained specimen is shown on the right. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 496]. Philadelphia: Lippincott Williams & Wilkins)

caused by slowing and turbulence of blood flow in the region of the plaque and ulceration of the plaque. The thrombus may cause occlusion of small vessels in the heart and brain. Aneurysms may develop in arteries weakened by extensive plaque formation.

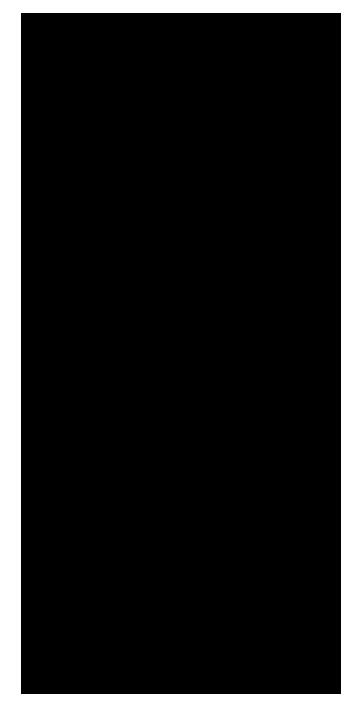

Although the risk factors associated with atherosclerosis have been identified through epidemiologic studies, many unanswered questions remain regarding the mechanisms by which these risk factors contribute to the development of atherosclerosis. There is increasing evidence that atherosclerosis is at least partially the result of (1) endothelial injury with leukocyte (lymphocyte and monocyte) adhesion and platelet adherence, (2) smooth muscle cell emigration and proliferation, (3) lipid engulfment of activated macrophages, and (4) subsequent development of an atherosclerotic plaque with lipid core (Fig. 15-7).

The vascular endothelial layer, which consists of a single layer of cells with cell-to-cell attachments, normally serves as a selective barrier that protects the subendothelial layers by interacting with blood cells and other blood components. One hypothesis of plaque formation suggests that injury to the endothelial vessel layer is the initiating factor in the development of atherosclerosis.^{2,4} A number of factors are regarded as possible injurious agents, including products associated with smoking, immune mechanisms, and mechanical stress, such as that associated with hypertension. The fact that atherosclerotic lesions tend to form where vessels branch or where there is turbulent flow suggests that hemodynamic factors also play a role.

Hyperlipidemia, particularly LDL with its high cholesterol content, is also believed to play an active role in the pathogenesis of the atherosclerotic lesion. Interactions between the endothelial layer of the vessel wall and white blood cells, particularly the macrophages (blood monocytes), normally occur throughout life; these interactions increase when blood cholesterol levels are elevated. One of the earliest responses to elevated cholesterol levels is the attachment of monocytes to the endothelium.¹⁰ The monocytes have been observed to emigrate through the cell-to-cell attachments of the endothelial layer into the subendothelial spaces, where they are transformed into macrophages. Activated macrophages release free radicals that oxidize LDL. Oxidized LDL is toxic to the endothelium, causing endothelial loss and exposure of the subendothelial tissue to blood components. This leads to platelet adhesion and aggregation and fibrin deposition. Platelets and activated macrophages release various factors that are thought to promote growth factors that modulate the proliferation of smooth muscle cells and deposition of extracellular matrix in the lesions.^{2,4} Activated macrophages also ingest oxidized LDL to become foam cells, which are present in all stages of atherosclerotic plaque formation. Lipids released from necrotic foam cells accumulate to form the lipid core of unstable plaques.

Clinical Manifestations

The clinical manifestations of atherosclerosis depend on the vessels involved and the extent of vessel obstruction. Atherosclerotic lesions produce their effects through narrowing of the vessel and production of ischemia; sudden vessel obstruction caused by plaque hemorrhage or rupture; thrombosis and formation of emboli resulting from damage to the vessel endothelium; and aneurysm formation caused by weakening of the vessel wall.⁴ In larger vessels such as the aorta, the important complications are those of thrombus formation and weakening of the vessel

wall. In medium-size arteries such as the coronary and cerebral arteries, ischemia and infarction caused by vessel occlusion are more common. Although atherosclerosis can affect any organ or tissue, the arteries supplying the heart, brain, kidneys, lower extremities, and small intestine are most frequently involved.

Aneurysms

An *aneurysm* is an abnormal localized dilatation of a blood vessel. Aneurysms can occur in different types of arterial vessels, but they are most common in the aorta. Aneurysms can assume

several forms and may be classified according to their cause, location, and anatomic features (Fig. 15-8). A *berry aneurysm* consists of a small spherical dilatation of the vessel at a bifurcation.² This type of aneurysm usually is found in the circle of Willis in the cerebral circulation. A *fusiform aneurysm* involves the entire circumference of the vessel and is characterized by a gradual and progressive dilatation of the vessel. These aneurysms, which vary in diameter (as large as 20 cm) and length, may involve the entire ascending and transverse portions of the thoracic aorta or may extend over large segments of the abdominal aorta.² A *saccular aneurysm* extends over part of the circumference of the vessel and appears saclike. An *aortic dissection* is a false aneurysm resulting from a tear in the intimal layer of the vessel that allows blood to enter the vessel wall, dissecting its layers to create a blood-filled cavity.

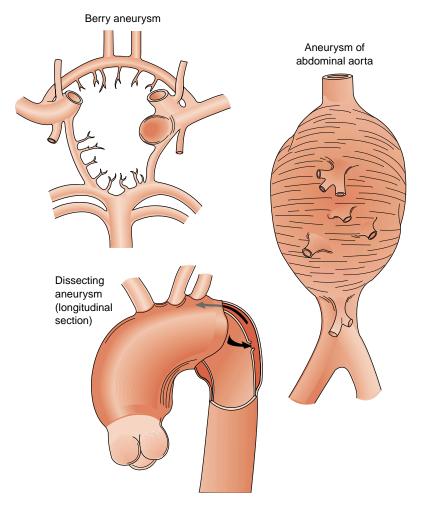

The weakness that leads to aneurysm formation may be caused by several factors, including congenital defects, trauma, infections, and atherosclerosis. Once initiated, the aneurysm grows larger as the tension in the vessel wall increases. As an aneurysm increases in diameter, the tension in the wall of the vessel increases in direct proportion to its increased size. If untreated, the aneurysm may rupture because of the increased tension. Even an unruptured aneurysm can cause damage by exerting pressure on adjacent structures and interrupting blood flow.

Aortic Aneurysms

Aortic aneurysms may involve any part of the thoracic or abdominal aorta. Aortic aneurysms occur more often in men than women. The two most common causes of aortic aneurysms are atherosclerosis and degeneration of the vessel media. Half of the people with aortic aneurysms have hypertension.² Populationbased studies suggest that as many as 9% of persons older than 65 years have unsuspected and asymptomatic abdominal aortic aneurysms and that ruptured abdominal aortic aneurysms cause at least 15,000 deaths each year in the United States.¹³

Most abdominal aortic aneurysms are located below the level of the renal artery and involve the bifurcation of the aorta and proximal end of the common iliac arteries.^{2,4} They can involve any part of the vessel circumference (saccular) or extend to involve the entire circumference (fusiform). The greatest threat associated with abdominal aortic aneurysms is that of rupture. The risk of rupture rises from less than 2% for small abdominal aneurysms (those less than 4 cm in diameter) to 5% to 10% per year for aneurysms larger than 5 cm in diameter.⁴

The clinical manifestations of abdominal aortic aneurysms depend on its size and location. Most abdominal aneurysms are asymptomatic and are often discovered during a routine physical examination. Sometimes, the first evidence of an abdominal aneurysm is associated with vessel rupture. Because an aneurysm is of arterial origin, a pulsating mass may provide the

■ FIGURE 15-8 ■ Three forms of aneurysms—berry aneurysm in the circle of Willis, fusiform-type aneurysm of the abdominal aorta, and aortic dissection.

262 Unit Four: Alterations in the Cardiovascular System

first evidence of the disorder. As the aneurysm expands, it may compress the lumbar nerve roots, causing lower back pain that radiates to the posterior aspects of the legs. The aneurysm may extend to and produce obstruction of the renal, iliac, mesenteric arteries, or vertebral arteries that supply the spinal cord. Stasis of blood favors thrombus formation along the wall of the vessel (Fig. 15-9), and peripheral emboli may develop, causing symptomatic arterial insufficiency.

Aneurysms of the thoracic aorta are less common than abdominal aneurysms. They account for less than 10% of aortic aneurysms and may present with substernal, back, or neck pain. There also may be dyspnea, stridor, or a brassy cough caused by pressure on the trachea. Hoarseness may result from pressure on the recurrent laryngeal nerve, and there may be difficulty swallowing because of pressure on the esophagus.¹⁴

Diagnostic methods include use of ultrasound imaging, computed tomographic (CT) scans, and magnetic resonance imaging (MRI). Surgical repair, in which the involved section of the aorta is replaced with a synthetic graft of woven Dacron, frequently is the treatment of choice.¹⁵

Aortic dissection

Aortic dissection is an acute, life-threatening condition. It involves hemorrhage into the vessel wall with longitudinal tearing or separation (*i.e.*, dissection) of the vessel wall to form

■ FIGURE 15-9 ■ Atherosclerotic aneurysm of the abdominal aorta. The aneurysm has been opened longitudinally to reveal a large thrombus in the lumen. The aorta and common iliac arteries display complicated lesions of atherosclerosis. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 521]. Philadelphia: Lippincott Williams & Wilkins)

a blood-filled channel. Unlike atherosclerotic aneurysms, aortic dissection often occurs without evidence of previous vessel dilatation. They can originate anywhere along the length of the aorta. Two thirds of dissections involve the ascending aorta.^{14,15} The second most common site is the thoracic aorta just distal to the origin of the subclavian artery.

Aortic dissections are caused by conditions that weaken or cause degenerative changes in the elastic and smooth muscle of the layers of the aorta. They are most common in the 40- to 60-year-old age group and more prevalent in men than in women.⁴ There are two risk factors that predispose to a dissection: hypertension and degeneration of the medial layer of the vessel wall. Aortic dissections also are associated with connective tissue diseases, such as Marfan's syndrome. Other factors that predispose to aortic dissection are congenital defects of the aortic valve (*i.e.*, bicuspid or unicuspid valve structures) and aortic coarctation.

Aortic dissections can originate at different sites in the aorta. When the ascending aorta is involved, expansion of the wall of the aorta may impair closure of the aortic valve. There also is risk of aortic rupture, with blood moving into the pericardium and compressing the heart. Although the length of dissection varies, it is possible for the abdominal aorta to be involved with progression into the renal, iliac, or femoral arteries. Partial or complete occlusion of the arteries that arise from the aortic arch or the intercostal or lumbar arteries may lead to stroke, ischemic peripheral neuropathy, or impaired blood flow to the spinal cord.

A major symptom of an aortic dissection is the abrupt presence of excruciating pain, described as tearing or ripping. The location of the pain may point to the site of dissection.⁴ Pain associated with dissection of the ascending aorta frequently is located in the anterior chest, and pain associated with dissection of the descending aorta often is located in the back. In the early stages, blood pressure typically is moderately or markedly elevated. Later, the blood pressure and the pulse rate become unobtainable in one or both arms as the dissection disrupts arterial flow to the arms. Syncope, hemiplegia, or paralysis of the lower extremities may occur because of occlusion of blood vessels that supply the brain or spinal cord. Heart failure may develop when the aortic valve is involved.

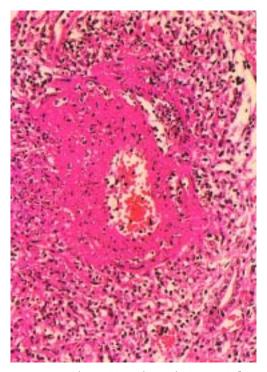

Diagnosis of aortic dissection is based on history and physical examination. Aortic angiography, transesophageal echocardiography, CT scans, and MRI studies aid in the diagnosis. The treatment may be medical or surgical. Aortic dissection is a life-threatening emergency situation; persons with a probable diagnosis are stabilized medically even before the diagnosis is confirmed. Two important factors that participate in propagating the dissection are high blood pressure and the steepness of the pulse wave. Without intervention, these forces continue to cause extension of the dissection. Thus, medical treatment focuses on control of hypertension and the use of drugs that lessen the force of systolic blood ejection from the heart. Surgical intervention may be indicated when there is threat of rupture or compromise of major aortic branches.

The Vasculitides

The vasculitides, which are a group of vascular disorders that cause inflammatory injury of blood vessels (vasculitis), are a common pathway for tissue and organ involvement in many different disease conditions.^{16,17} Vessels of any type (arteries, veins, and capillaries) in virtually any organ can be affected. Clinical manifestations often include fever, myalgia, arthralgia, and malaise. Vasculitis may result from direct injury to the vessel, infectious agents, or immune processes, or may be secondary to other disease states such as systemic lupus erythematosus. Physical agents such as cold (*i.e.*, frostbite), irradiation (*i.e.*, sunburn), mechanical injury, and toxins may secondarily cause vessel damage, often leading to necrosis of the vessels.

The vasculitides are commonly classified based on etiology, pathologic findings, and prognosis. One classification system divides the conditions into three groups: (1) small vessel, (2) medium-size vessel, and (3) large vessel vasculitides.^{2,4} The small vessel vasculitides are involved in a number of different diseases, most of which are mediated by type III immune complex hypersensitivity reaction (see Chapter 10). They commonly involve the skin and are often a complication of an underlying disease (*i.e.*, vasculitis associated with neoplasms or connective tissue disease) and exposure to environmental agents (*i.e.*, serum sickness and urticarial vasculitis).

Medium-size vessel vasculitides produce necrotizing damage to medium-size muscular arteries of major organ systems. This group includes polyarteritis nodosa, Kawasaki's disease (discussed in Chapter 17), and thromboangiitis obliterans (discussed in the section on arterial diseases of the extremities). Polyarteritis nodosa is an uncommon acute multisystem inflammatory disease of small and medium-size blood vessels of the kidney, liver, intestine, peripheral nerves, skin, and muscles (Fig. 15-10). The usual course of the disease is progressive with various signs and symptoms according to the pattern of organ

■ FIGURE 15-10 ■ Polyarteritis nodosa. The intense inflammatory cell infiltration in the arterial wall and surrounding connective tissue is mediated by fibrinoid necrosis and disruption of the vessel wall. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 515]. Philadelphia: Lippincott Williams & Wilkins)

involvement. Most cases were fatal before corticosteroid and immunosuppressant agents became available for use in treatment of the disorder.⁴

Large vessel vasculitides involve large elastic arteries; they are called *giant cell arterides* because they involve infiltration of the vessel wall with giant cells and mononuclear cells. Giant cell (temporal) arteritis, the most common of the large vessel vasculitides, is an acute and chronic inflammation of large to small size arteries. It mainly affects arteries of the head especially the temporal arteries—but may include the vertebral and ophthalmic arteries. About half of persons with the disease have an accompanying pain and stiffness of the shoulder and hip (polymyalgia rheumatica, see Chapter 43). The most common clinical presentation is with headache and tenderness over the superficial temporal artery. Diagnosis is by biopsy of the artery. Diagnosis followed by treatment with corticosteroid drugs is important because involvement of the ophthalmic artery can cause blindness.⁴

Arterial Disease of the Extremities

Disorders of the circulation in the extremities often are referred to as *peripheral vascular disorders*. In many respects, the disorders that affect arteries in the extremities are the same as those affecting the coronary and cerebral arteries in that they produce ischemia, pain, impaired function, and in some cases infarction and tissue necrosis. Not only are the effects similar, but the pathologic conditions that impair circulation in the extremities are identical. This section focuses on acute arterial occlusion of the extremities, atherosclerotic occlusive disease, thromboangiitis obliterans, and Raynaud's disease and phenomenon.

Acute Arterial Occlusion

Acute arterial occlusion is a sudden event that interrupts arterial flow to the affected tissues or organ. Most acute arterial occlusions are the result of an embolus or a thrombus. Although much less common than emboli and thrombi, trauma or arterial spasm caused by arterial cannulation can be another cause of acute arterial occlusion.

An embolus is a freely moving particle such as a blood clot that breaks loose and travels in the larger vessels of the circulation until lodging in a smaller vessel and occluding blood flow. Most arterial emboli arise in the heart and are caused by conditions that cause blood clots to develop on the wall of a heart chamber or valve surface. Arterial emboli usually are a complication of heart disease: ischemic heart disease with or without infarction, atrial fibrillation, or rheumatic heart disease. Prosthetic heart valves can be another source of emboli. Other types of emboli are fat emboli that originate from bone marrow of fractured bones or amniotic fluid emboli that develop during childbirth.

A thrombus is a blood clot that forms on the wall of a vessel and continues to grow until reaching a size that obstructs blood flow. These thrombi often arise as the result of rupture of the fibrous cap of an atherosclerotic plaque.

The signs and symptoms of acute arterial occlusion depend on the artery involved and the adequacy of the collateral circulation. Emboli tend to lodge in bifurcations of the major arteries, including the aorta and iliac, femoral, and popliteal arteries. Occlusion in an extremity causes sudden onset of acute pain with numbness, tingling, weakness, pallor, and coldness. There often is a sharp line of demarcation between the oxygenated tissue above the line of obstruction and that below the line of obstruction. Pulses are absent below the level of the occlusion. These changes are followed rapidly by cyanosis, mottling, and loss of sensory, reflex, and motor function. Tissue death occurs unless blood flow is restored.

Diagnosis of acute arterial occlusion is based on signs of impaired blood flow. It uses visual assessment, palpation of pulses, and methods to assess blood flow. Treatment of acute arterial occlusion is aimed at restoring blood flow. Thrombolytic therapy (*i.e.*, streptokinase or tissue plasminogen activator) may be used in an attempt to dissolve the clot. Anticoagulant therapy (*i.e.*, heparin) usually is given to prevent extension of the embolus. Application of heat and cold should be avoided, and the extremity should be protected from injury resulting from hard surfaces and overlying bedclothes. An embolectomy—surgical removal of the embolus—may be indicated.

Atherosclerotic Occlusive Disease

Atherosclerosis is an important cause of peripheral vascular disease and is seen most commonly in the vessels of the lower extremities. The condition is sometimes referred to as *arteriosclerosis obliterans*. The superficial femoral and popliteal arteries are the most commonly affected vessels. When lesions develop in the lower leg and foot, the tibial, common peroneal, or pedal vessels are the arteries most commonly affected. The disease is seen most commonly in men in their 60s and 70s.^{18,19} The risk factors for this disorder are similar to those for atherosclerosis. Cigarette smoking contributes to the progress of the atherosclerosis of the lower extremities and to the development of symptoms of ischemia. Persons with diabetes mellitus experience more extensive and rapidly progressive vascular disease than do individuals without diabetes.

As with atherosclerosis in other locations, the signs and symptoms of vessel occlusion are gradual. Usually, there is at least a 50% narrowing of the vessel before symptoms of ischemia arise. The primary symptom of chronic obstructive arterial disease is intermittent claudication or pain with walking.¹⁸ Typically, persons with the disorder report calf pain caused by ischemia of the gastrocnemius muscle, which has the highest oxygen consumption of any muscle group in the leg during walking. Some persons may report a vague aching feeling or numbness, rather than pain. Other signs of ischemia include atrophic changes and thinning of the skin and subcutaneous tissues of the lower leg and diminution in the size of the leg muscles. The foot often is cool, and the popliteal and pedal pulses are weak or absent. Limb color blanches with elevation of the leg because of the effects of gravity on perfusion pressure and becomes deep red when the leg is in the dependent position because of an autoregulatory increase in blood flow and a gravitational increase in perfusion pressure.

When blood flow is reduced to the extent that it no longer meets the minimal needs of resting muscle and nerves, ischemic pain at rest, ulceration, and gangrene develop. As tissue necrosis develops, there typically is severe pain in the region of skin breakdown, which is worse at night with limb elevation and is improved with standing.¹⁸

Diagnostic methods include inspection of the limbs for signs of chronic low-grade ischemia, such as subcutaneous atrophy, brittle toenails, hair loss, pallor, coolness, or dependent rubor. Palpation of the femoral, popliteal, posterior tibial, and dorsalis pedis pulses allows for an estimation of the level and degree of obstruction. Blood pressures may be taken at various levels on the leg to determine the level of obstruction. A Doppler ultrasound stethoscope may be used for detecting pulses and measuring blood pressure. Ultrasound imaging, radionuclide imaging, and contrast angiography also may be used as diagnostic methods.¹⁸

The tissues of extremities affected by atherosclerosis are easily injured and slow to heal. Treatment includes measures directed at protection of the affected tissues and preservation of functional capacity. Walking (slowly) to the point of claudication usually is encouraged because it increases collateral circulation.

Surgery (*i.e.*, femoropopliteal bypass grafting using a section of saphenous vein) may be indicated in severe cases. In persons with diabetes, the peroneal arteries between the knees and ankles commonly are involved, making revascularization difficult. Thromboendarterectomy with removal of the occluding core of atherosclerotic tissue may be done if the section of diseased vessel is short. Percutaneous transluminal angioplasty, in which a balloon catheter is inserted into the area of stenosis and the balloon inflated to increase vessel diameter, is another form of treatment.^{18,19}

Thromboangiitis Obliterans

Thromboangiitis obliterans (*e.g.*, Buerger's disease) is a vasculitis affecting the medium-size arteries, usually the plantar and digital vessels in the foot and lower leg. Arteries in the arm and hand also may be affected. Although primarily an arterial disorder, the inflammatory process often extends to involve adjacent veins and nerves. It usually is a disease of men between the ages of 25 and 40 years who are heavy cigarette smokers, but it can occur in women. The pathogenesis of the disorder remains speculative, although cigarette smoking and in some instances tobacco chewing seem to be involved. It has been suggested that the tobacco may trigger an immune response in susceptible persons or it may unmask a clotting defect, either of which could incite an inflammatory reaction of the vessel wall.²⁰

Pain is the predominant symptom of the disorder. It usually is related to distal arterial ischemia. During the early stages of the disease, there is intermittent claudication in the arch of the foot and the digits. In severe cases, pain is present even when the person is at rest. The impaired circulation increases sensitivity to cold. The peripheral pulses are diminished or absent, and there are changes in the color of the extremity. In moderately advanced cases, the extremity becomes cyanotic when the person assumes a dependent position, and the digits may turn reddish blue even when in a nondependent position. With lack of blood flow, the skin assumes a thin, shiny look, and hair growth and skin nutrition suffer. Chronic ischemia causes thick, malformed nails. If the disease continues to progress, tissues eventually ulcerate and gangrenous changes arise that may necessitate amputation.

Diagnostic methods are similar to those for atherosclerotic disease of the lower extremities. It is essential that the person stop smoking cigarettes or using tobacco. Other treatment measures are of secondary importance and focus on methods for producing vasodilation and preventing tissue injury. Sympathectomy may be done to alleviate the vasospastic manifestations of the disease.

Raynaud's Disease and Phenomenon

Raynaud's disease or phenomenon is a functional disorder caused by intense vasospasm of the arteries and arterioles in the fingers and, less often, the toes. The disorder is divided into two types: the primary type, called *Raynaud's disease*, occurs without demonstrable cause, and the secondary type, called *Raynaud's phenomenon*, is associated with other disease states or known causes of vasospasm.^{21,22}

Vasospasm implies an excessive vasoconstrictor response to stimuli that normally produce only moderate vasoconstriction. In contrast to other regional circulations that are supplied by vasodilator and vasoconstrictor fibers, the cutaneous vessels of the fingers and toes are innervated only by sympathetic vasoconstrictor fibers. In these vessels, vasodilation depends on withdrawal of sympathetic stimulation. Cooling of specific body parts such as the head, neck, and trunk produces a sympathetic-mediated reduction in digital blood flow, as does emotional stress.

Raynaud's disease is usually seen in otherwise healthy young women. It often is precipitated by exposure to cold or by strong emotions and usually is limited to the fingers. It also follows a more benign course than Raynaud's phenomenon, seldom causing tissue necrosis. The cause of vasospasm in primary Raynaud's disease is unknown. Hyperreactivity of the sympathetic nervous system has been suggested as a contributing cause.²¹ Raynaud's phenomenon is associated with previous vessel injury, such as frostbite, occupational trauma associated with the use of heavy vibrating tools, collagen diseases, neurologic disorders, and chronic arterial occlusive disorders. Another occupation-related cause is the exposure to alternating hot and cold temperatures such as that experienced by butchers and food preparers.²¹ Raynaud's phenomenon often is the first symptom of collagen diseases. It occurs in persons with scleroderma and those with systemic lupus erythematosus.

In Raynaud's disease and Raynaud's phenomenon, ischemia caused by vasospasm causes changes in skin color that progress from pallor to cyanosis, a sensation of cold, and changes in sensory perception, such as numbness and tingling. The color changes usually are first noticed in the tips of the fingers, later moving into one or more of the distal phalanges (Fig.15-11). After the ischemic episode, there is a period of

FIGURE 15-11 Raynaud's phenomenon. The tips of the fingers show marked pallor. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 514]. Philadelphia: Lippincott Williams & Wilkins)

hyperemia with intense redness, throbbing, and paresthesia. The period of hyperemia is followed by a return to normal color. Although all of the fingers usually are affected symmetrically, the involvement may affect only one or two digits. In some cases, only a portion of the digit is affected.

In severe, progressive cases usually associated with Raynaud's phenomenon, trophic changes may develop. The nails may become brittle, and the skin over the tips of the affected fingers may thicken. Nutritional impairment of these structures may give rise to arthritis. Ulceration and superficial gangrene of the fingers, although infrequent, may occur.

The initial diagnosis is based on history of vasospastic attacks supported by other evidence of the disorder. Immersion of the hand in cold water may be used to initiate an attack as an aid to diagnosis. Laser-Doppler velocimetry may be used to quantify digital blood flow during changes in temperature. Serial computed thermography (finger skin temperature) also may be a useful tool in diagnosing the extent of disease. Raynaud's disease is differentiated from Raynaud's phenomenon by excluding secondary disorders known to cause vasospasm.²²

Treatment measures are directed toward eliminating factors that cause vasospasm and protecting the digits from trauma during an ischemic episode. Abstinence from smoking and protection from cold are priorities. Avoidance of emotional stress is another important factor in controlling the disorder because anxiety and stress may precipitate a vascular spasm in predisposed persons. Vasoconstrictor medications, such as the decongestants contained in allergy and cold preparations, should be avoided. Drugs with a vasodilating action (*e.g.*, calcium channel blockers and α -adrenergic receptor blocking agents) may be indicated, particularly if episodes are frequent. Surgical interruption of sympathetic nerve pathways (sympathectomy) may be used for persons with severe symptoms.²²

In summary, the arterial system distributes blood to all the tissues of the body, and lesions of the arterial system exert their effects through ischemia or impaired blood flow. Hyperlipidemia with elevated cholesterol levels play a major role in the development of atherosclerotic disorders of the arterial system. Because cholesterol and triglycerides are insoluble in plasma, they transported as lipoproteins. Elevated levels of LDLs, which carry large amounts of cholesterol, are a major risk factor for atherosclerosis. The HDLs, which are protective, remove cholesterol from the tissues and carry it back to the liver for disposal. LDL receptors play a major role in removing cholesterol from the blood; persons with reduced numbers of LDL receptors are at particularly high risk for the development of atherosclerosis.

Atherosclerosis affects large and medium-size arteries, such as the coronary and cerebral arteries. It has an insidious onset, and its lesions usually are far advanced before symptoms appear. Risk factors associated with its development include factors such as heredity, sex, and age, which cannot be controlled; factors such as smoking, high blood pressure, high serum cholesterol levels, and diabetes, which can be modified; and other contributing factors such as obesity, lack of exercise, and stress.

Aneurysms are localized areas of vessel dilation caused by weakness of the arterial wall. Abdominal aortic aneurysms are the most common type of aneurysm. They are characterized by gradual and progressive enlargement of the abdominal aorta. The most serious consequence of abdominal aneurysms is rupture. Aortic dissection is an acute, life-threatening condition. It involves hemorrhage into the vessel wall with longitudinal tearing (dissection) of the vessel wall to form a blood-filled channel.

The vasculitides are a group of vascular disorders characterized by inflammation and necrosis of blood vessels in various tissues and organs. They can be caused by injury, infectious agents, or immune processes, or can occur secondary to other disease conditions, such as systemic lupus erythematosus. Occlusive disorders interrupt arterial flow of blood and interfere with the delivery of oxygen and nutrients to the tissues. Occlusion of flow can result from a thrombus, embolus, vessel compression, vasospasm, or structural changes in the vessel. Peripheral arterial diseases affect blood vessels outside the heart and thorax. They include atherosclerotic occlusive disease, thromboangiitis obliterans, and Raynaud's disease or phenomenon, caused by vessel spasm.

DISORDERS OF THE VENOUS CIRCULATION

Veins are low-pressure, thin-walled vessels that rely on the ancillary action of skeletal muscle pumps and changes in abdominal and intrathoracic pressure to return blood to the heart. Unlike the arterial system, the venous system is equipped with valves that prevent retrograde flow of blood. Although its structure enables the venous system to serve as a storage area for blood, it also renders the system susceptible to problems related to stasis and venous insufficiency. This section focuses on three common problems of the venous system: varicose veins, venous insufficiency, and venous thrombosis.

Venous Circulation of the Lower Extremities

The venous system in the legs consists of two components: the superficial veins (*i.e.*, saphenous vein and its tributaries) and the deep venous channels (Fig. 15-12). Perforating or commu-

KEY CONCEPTS

DISORDERS OF THE VENOUS CIRCULATION

- The venous system is a low-pressure system that relies on the pumping action of the skeletal muscles to move blood forward and the presence of venous valves to prevent retrograde flow.
- Varicose veins are dilated and tortuous veins that result from a sustained increase in pressure that causes the venous valves to become incompetent, allowing for reflux of blood and vein engorgement.
- Thrombophlebitis refers to thrombus formation and the accompanying inflammatory response that occurs in veins. Deep vein thrombosis may be a precursor to pulmonary embolism.

nicating veins connect these two systems. Blood from the skin and subcutaneous tissues in the leg collects in the superficial veins and is then transported across the communicating veins into the deeper venous channels for return to the heart. Venous valves prevent the retrograde flow of blood and play an important role in the function of the venous system. Although these valves are irregularly located along the length of the veins, they almost always are found at junctions where the communicating veins merge with the larger deep veins and where two veins meet. The number of venous valves differs somewhat from one person to another, as does the structural competence, factors that may help to explain the familial predisposition to development of varicose veins.

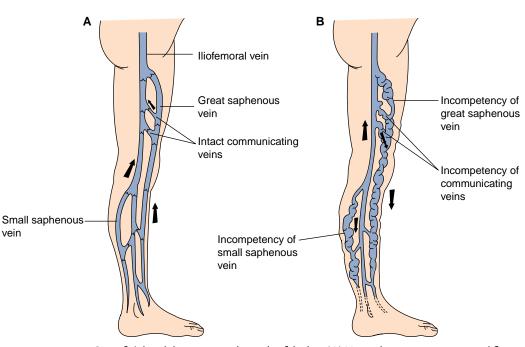

The action of the leg muscles assists in moving venous blood from the lower extremities back to the heart. When a person walks, the action of the leg muscles serves to increase flow in the deep venous channels and return venous blood to the heart (Fig. 15-13). The function of the so-called muscle pump, located in the gastrocnemius and soleus muscles of the lower extremities, can be compared with the pumping action of the heart.²³ During muscle contraction, which is similar to systole, valves in the communicating channels close to prevent backward flow of blood into the superficial system, as blood in the deep veins is moved forward by the action of the contracting muscles. During relaxation, which is similar to diastole, the communicating valves open, allowing blood from the superficial veins to move into the deep veins.

Varicose Veins

Varicose, or dilated, tortuous veins of the lower extremities are common and often lead to secondary problems of venous insufficiency (Fig. 15-12). Varicose veins are described as being primary or secondary. Primary varicose veins originate in the superficial saphenous veins, and secondary varicose veins result from impaired flow in the deep venous channels. Approximately 80% to 90% of venous blood from the lower extremities is transported through the deep channels. The development of secondary varicose veins becomes inevitable when flow in these deep channels is impaired or blocked. The most common cause of secondary varicose veins is deep vein thrombosis (DVT). Other causes include congenital or acquired arteriovenous fistulas, congenital venous malformations, and pressure on the abdominal veins caused by pregnancy or a tumor.

Primary varicose veins is more common after 50 years of age and in obese persons, and it occurs more often in women than men, probably because of venous stasis caused by pregnancy.² More than 50% of persons with primary varicose veins have a family history of the disorder, suggesting that heredity may play a role. Prolonged standing and increased intra-abdominal pressure are important contributing factors in the development of primary varicose veins. One of the most important factors in the elevation of venous pressure is the hydrostatic effect associated with the standing position. When a person is in the erect position, the full weight of the venous columns of blood is transmitted to the leg veins. The effects of gravity are compounded in persons who stand for long periods without using their leg muscles to assist in pumping blood back to the heart.

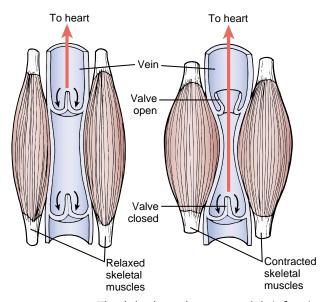

Because there are no valves in the inferior vena cava or common iliac veins, blood in the abdominal veins must be supported by the valves located in the external iliac or femoral

■ FIGURE 15-12 ■ Superficial and deep venous channels of the leg. (A) Normal venous structures and flow patterns. (B) Varicosities in the superficial venous system are the result of incompetent valves in the communicating veins. The arrows in both views indicate the direction of blood flow. (Modified from Abramson D.I. [1974]. *Vascular disorders of the extremities* [2nd ed.]. Philadelphia: Lippincott Williams & Wilkins)

veins. When intra-abdominal pressure increases, as it does during pregnancy, or when the valves in these two veins are absent or defective, the stress on the saphenofemoral junction is increased. Lifting also increases intra-abdominal pressure and decreases flow of blood through the abdominal veins. Occupations that require repeated heavy lifting predispose to development of varicose veins.

Prolonged exposure to increased pressure causes the venous valves to become incompetent so they no longer close properly. When this happens, the reflux of blood causes fur-

■ FIGURE 15-13 ■ The skeletal muscle pumps and their function in promoting blood flow in the deep and superficial calfvessels of the leg.

ther venous enlargement, pulling the valve leaflet apart and causing valvular incompetence in sections of adjacent distal veins. Another consideration in the development of varicose veins is the fact that the superficial veins have only subcutaneous fat and superficial fascia for support, but the deep venous channels are supported by muscle, bone, and connective tissue. Obesity reduces the support provided by the superficial fascia and tissues, increasing the risk for development of varicose veins.

The signs and symptoms associated with primary varicose veins vary. Most women with superficial varicose veins complain of their unsightly appearance. In many cases, aching in the lower extremities and edema, especially after long periods of standing, may occur. The edema usually subsides at night when the legs are elevated. When the communicating veins are incompetent, symptoms are more common.

The diagnosis of varicose veins often can be made after physical inspection. The Doppler ultrasonic flow probe also may be used to assess the flow in the large vessels. Angiographic studies using a radiopaque contrast medium also are used to assess venous function.

After the venous channels have been repeatedly stretched and the valves rendered incompetent, little can be done to restore normal venous tone and function. Ideally, measures should be taken to prevent the development and progression of varicose veins. These measures center on avoiding activities such as continued standing that produce prolonged elevation of venous pressure. Treatment measures for varicose veins focus on improving venous flow and preventing tissue injury. When correctly fitted, elastic support stockings or leggings compress the superficial veins and prevent distention. The most precise control is afforded by prescription stockings, measured to fit properly. These stockings should be applied before the standing position is assumed, when the leg veins are empty.

268 Unit Four: Alterations in the Cardiovascular System

Sclerotherapy, which often is used in the treatment of small residual varicosities, involves the injection of a sclerosing agent into the collapsed superficial veins to produce fibrosis of the vessel lumen. Surgical treatment consists of removing the varicosities and the incompetent perforating veins, but it is limited to persons with patent deep venous channels.

Chronic Venous Insufficiency

The term *venous insufficiency* refers to the physiologic consequences of DVT, valvular incompetence, or a combination of both conditions. The most common cause is DVT, which causes deformity of the valve leaflets, rendering them incapable of closure. In the presence of valvular incompetence, effective unidirectional flow of blood and emptying of the deep veins cannot occur. The muscle pumps also are ineffective, often driving blood in retrograde directions. Secondary failure of the communicating and superficial veins subjects the subcutaneous tissues to high pressures.

With venous insufficiency, there are signs and symptoms associated with impaired blood flow. In contrast to the ischemia caused by arterial insufficiency, venous insufficiency leads to tissue congestion, edema, and eventual impairment of tissue nutrition.^{23,24} The edema is exacerbated by long periods of standing. Necrosis of subcutaneous fat deposits occurs, followed by skin atrophy. Brown pigmentation of the skin caused by hemosiderin deposits resulting from the breakdown of red blood cells is common. Secondary lymphatic insufficiency occurs, with progressive sclerosis of the lymph channels in the face of increased demand for clearance of interstitial fluid.

In advanced venous insufficiency, impaired tissue nutrition causes stasis dermatitis and the development of stasis or venous ulcers (Fig. 15-14).² Stasis dermatitis is characterized by the presence of thin, shiny, bluish brown, irregularly pigmented desquamative skin that lacks the support of the underlying subcutaneous tissues. Minor injury leads to relatively painless ulcerations that are difficult to heal. The lower part of the leg is particularly prone to development of stasis dermatitis and venous ulcers. Most lesions are located medially over the ankle and lower leg, with the highest frequency just above the medial malleolus. Persons with long-standing venous insufficiency may experience stiffening of the ankle joint and loss of muscle mass and strength.

Venous Thrombosis

The term *venous thrombosis*, or *thrombophlebitis*, describes the presence of thrombus in a vein and the accompanying inflammatory response in the vessel wall. Thrombi can develop in the superficial or the deep veins. DVT most commonly occurs in the lower extremities. DVT of the lower extremity is a serious disorder, complicated by pulmonary embolism (see Chapter 21), recurrent episodes of DVT, and development of chronic venous insufficiency.²⁵

In 1846, Virchow described the triad that has come to be associated with venous thrombosis: stasis of blood, increased blood coagulability, and vessel wall injury.²⁶ Risk factors for DVT are summarized in Chart 15-2. *Stasis of blood* occurs with immobility of an extremity or the entire body. Bed rest and immobilization are associated with decreased blood flow, venous pooling in the lower extremities, and increased risk of DVT.

■ FIGURE 15-14 ■ Varicose veins of the legs. Severe varicosities of the superficial leg veins have led to stasis dermatitis and secondary ulcerations. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 525]. Philadelphia: Lippincott Williams & Wilkins)

CHART 15-2 Risk Factors Associated With Venous Thrombosis*

Venous Stasis

Bed rest Immobility Spinal cord injury Acute myocardial infarction Congestive heart failure Shock Venous obstruction

Hyperreactivity of Blood Coagulation

Stress and trauma Pregnancy Childbirth Oral contraceptive use Dehydration Cancer

Vascular Trauma

Indwelling venous catheters Surgery Massive trauma or infection Fractured hip Orthopedic surgery

*Many of these disorders involve more than one mechanism.

Persons who are immobilized by a hip fracture, joint replacement, or spinal cord injury are particularly vulnerable to DVT. The risk of DVT is increased in situations of impaired cardiac function. This may account for the relatively high incidence in persons with acute myocardial infarction and congestive heart failure. Elderly persons are more susceptible than younger persons, probably because disorders that produce venous stasis occur more frequently in older persons. Long airplane travel poses a particular threat in persons predisposed to DVT because of prolonged sitting and increased blood viscosity caused by dehydration.

Hypercoagulability and conditions that increase the concentration or activation of clotting factors predispose to DVT. The postpartum state is associated with increased levels of fibrinogen, prothrombin, and other coagulation factors. The use of oral contraceptives appears to increase coagulability and predispose to venous thrombosis, especially in women older than 30 years and in those who smoke. Certain cancers are associated with increased clotting tendencies, and although the reason for this is largely unknown, substances that promote blood coagulation may be released from the tissues because of the cancerous growth.

Vessel injury can result from a trauma situation or from surgical intervention. It also may occur secondary to infection or inflammation of the vessel wall. Persons undergoing hip surgerv and total hip replacement are at particular risk because of trauma to the femoral and iliac veins, and in the case of hip replacement, thermal damage from heat generated by the polymerization of the acrylic cement that is used in the procedure.²⁵ Venous catheters are another source of vascular injury.

Many persons with DVT are asymptomatic. The person may have experienced a pulmonary emboli with no previous signs or symptoms. When present, the most common signs and symptoms of DVT are those related to the inflammatory process: pain, swelling, and deep muscle tenderness. Fever, general malaise, and an elevated white blood cell count and sedimentation rate are accompanying indications of inflammation. There may be tenderness and pain along the vein. Swelling may vary from minimal to maximal. The site of thrombus formation determines the location of the physical findings. The most common site is in the venous sinuses in the soleus muscle and posterior tibial and peroneal veins. Swelling in these cases involves the foot and ankle, although it may be slight or absent. Calf pain and tenderness are common. Femoral vein thrombosis with calf thrombosis produces pain and tenderness in the distal thigh and popliteal area. Thrombi in ileofemoral veins produce the most profound manifestations, with swelling, pain, and tenderness of the entire extremity. With DVT in the calf veins, active dorsiflexion of the foot produces calf pain (Homans' sign).

The risk of pulmonary embolism emphasizes the need for early detection and treatment of DVT. Several tests are useful for this purpose: ascending venography, impedance plethysmography, and ultrasonography. The goals of treatment for DVT are to prevent formation of additional thrombi, prevent extension and embolization of existing thrombi, and to minimize venous valve damage. Anticoagulation therapy is used to treat and prevent venous thrombosis. A 15- to 20-degree elevation of the legs prevents stasis. Surgical removal of the thrombus may be undertaken in selected cases. Surgical interruption of the vena cava may be done in persons at high risk for experiencing pulmonary emboli. This procedure involves ligating the vena cava with a suture or clamp or in creating a filter-like insertion to prevent large clots from moving through the vessel.

When possible, venous thrombosis should be prevented in preference to being treated. Early ambulation after childbirth and surgery is one measure that decreases the risk of thrombus formation. Exercising the legs and wearing support stockings improve venous flow. A further precautionary measure is to avoid assuming body positions that favor venous pooling. Antiembolism stockings of the proper fit and length should be used routinely in persons at risk for DVT. Another strategy used for immobile persons at risk for experiencing DVT is a sequential pneumatic compression device. This consists of a plastic sleeve that encircles the legs and provides alternating periods of compression on the lower extremity. When properly used, these devices enhance venous emptying to augment flow and reduce stasis.

In summary, the storage function of the venous system renders it susceptible to venous insufficiency, stasis, and thrombus formation. Varicose veins occur with prolonged distention and stretching of the superficial veins owing to venous insufficiency. Varicosities can arise because of defects in the superficial veins (*i.e.*, primary varicose veins) or because of impaired blood flow in the deep venous channels (i.e., secondary varicose veins). Venous insufficiency reflects chronic venous stasis resulting from valvular incompetence. It is associated with stasis dermatitis and stasis or venous ulcers. Venous thrombosis describes the presence of thrombus in a vein and the accompanying inflammatory response in the vessel wall. It is associated with vessel injury, stasis of venous flow, and hypercoagulability states. Thrombi can develop in the superficial or the deep veins (*i.e.*, DVT). Thrombus formation in deep veins is a precursor to venous insufficiency and embolus formation.

DISORDERS OF BLOOD FLOW CAUSED BY EXTRAVASCULAR FORCES

Blood flow occurs along a pressure gradient, moving from the arterial to the venous side of the circulation. For blood to move through the vessels of the systemic circulation, arterial pressure must be greater than venous pressure, and the arterial and venous pressures must be greater than the external pressure of the surrounding tissues. Injury or infections that cause tissue swelling can compromise blood flow, particularly in parts of the body where the skin or other supporting tissues cannot expand to accommodate the increased volume. In other situations, external pressure may compress the tissues and the blood vessels. Two conditions resulting from compromised blood flow caused by extravascular forces are compartment syndrome and pressure ulcers.

Compartment Syndrome

The muscles and nerves of an extremity are enclosed in a tough, inelastic fascial envelope called a muscle compartment (Fig. 15-15). Compartment syndrome describes a condition of in-

KEY CONCEPTS

DISORDERS OF BLOOD FLOW DUE TO EXTRAVASCULAR FORCES

- Blood flow requires that arterial pressure is greater than venous pressure and that arterial, venous, and capillary pressures are greater than the pressure surrounding the vessels.
- Compartment syndrome describes a condition of compromised blood flow resulting from pressure in an anatomic space that cannot expand. Causes include decreases in compartment size (*i.e.*, cast) or increases in compartment volume (*i.e.*, internal bleeding or edema).
- Pressure ulcers are ischemic lesions of the skin and underlying tissues caused by compression of blood vessels due to external pressure, such as that exerted by the weight of the body on the bed or chair surface. Prevention of pressure ulcers is preferable to treatment. Frequent position changes and meticulous skin care are essential components of prevention.

creased pressure in a limited anatomic space, usually a muscle compartment, that impairs circulation and produces ischemic tissue injury.²⁷ If the pressure in the compartment is sufficiently high, tissue circulation is compromised, causing death of nerve and muscle cells. Permanent loss of function may occur.

The amount of pressure required to produce a compartment syndrome depends on many factors, including the duration of the pressure elevation, the metabolic rate of the tissues, vascular tone, and local blood pressure. Less tissue pressure is required to stop circulation when hypotension or vasoconstriction is present. Intracompartmental pressures of 30 to 40 mm Hg (normal is approximately 6 mm Hg) are considered sufficient to impair capillary blood flow.²⁸

Compartment syndrome can result from: (1) a decrease in compartment size or (2) an increase in the volume of its contents (Chart 15-3). Among the causes of decreased compartment size are constrictive dressings and casts, closure of fascial defects, and thermal injuries or frostbite. In persons with circumferential third-degree burns, the inelastic and constricting eschar decreases the size of the underlying compartments. Burns also are associated with the formation of massive edema and an increase in compartment volume. The combination of the two problems may lead to necrosis of the underlying neuromuscular tissues. Frostbite produces neuromuscular injury for similar reasons.

An increase in compartment volume can be caused by trauma, vascular injury and bleeding, infiltration of intravenous infusions, postischemic swelling, and venous obstruction. One of the most important causes of compartment syndrome is bleeding and edema caused by fractures and osteotomies (see Chapter 42). Contusions and soft tissue injury also are common causes of compartment syndrome. Bleeding can occur as a complication of arterial punctures, particularly in persons with bleeding disorders or those who are receiving anticoagulant drugs. Infiltration of intravenous fluids also can restrict compartment size and cause compartment ischemia and postischemic swelling. Increased compartment volume may follow ischemic events, such as arterial occlusion, that are of sufficient duration to produce capillary damage, causing increased capillary permeability and edema. During unattended coma caused by drug overdose or carbon monoxide poisoning, high compartment pressures are produced when an extremity is compressed by the weight of the overlying head or torso. Exercise may produce acute or chronic elevations in compartment pressure.

The most important symptom of compartment syndrome is unrelenting pain, usually described as a deep, throbbing sensation, that is greater than that expected for the primary problem, such as fracture or contusion. Pain with passive stretch

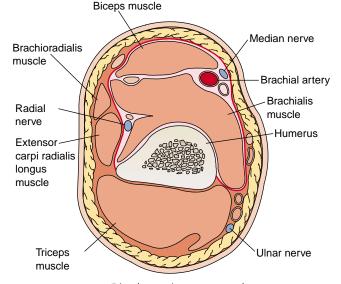

FIGURE 15-15 Distal anterior arm muscle compartments, showing the location of fascia, muscles, nerves, and blood vessels.

is a common finding. Tenseness and tenderness of the involved compartment are specific symptoms of compartment syndrome. The skin over the compartment may become taut, shiny, warm, and red. Paresthesias progressing to anesthesia occur secondary to nerve involvement. Muscle weakness results from muscle ischemia.

It is important that persons at risk for compartment syndrome be identified and that proper assessment methods be instituted. Assessment should include pain assessment, examination of sensory (*i.e.*, light touch and two-point discrimination) and motor function (*i.e.*, movement and muscle strength), test of passive stretch, and palpation of the muscle compartments. Peripheral pulses frequently are normal in the presence of compartment syndrome because the major arteries are located outside the muscle compartments. Although edema may make it difficult to palpate the pulse, the increased compartment pressure seldom is sufficient to occlude flow in a major artery. Doppler methods usually confirm the existence of a pulse. Direct measurements of tissue pressure can be obtained using a needle or wick catheter inserted into the muscle compartment. This method is particularly useful in persons who are unresponsive and in those with nerve deficits. Compartment decompression is recommended when pressures rise to 30 mm Hg.

Treatment consists of reducing compartmental pressures. This entails cast splitting or removal of restrictive dressings. These procedures often are sufficient to relieve most of the underlying pressure and symptoms. When an extremity is elevated, its arterial pressure falls because of the effects of gravity. Therefore, limb elevation is not recommended when compartment syndrome is suspected. When compartment syndrome cannot be relieved by conservative measures, a fasciotomy may become necessary. During this procedure, the fascia is incised longitudinally and separated so that the compartment volume can expand and blood flow can be re-established. Because of potential problems with wound infection and closure, this procedure is performed as a last resort.

Pressure Ulcers

Pressure ulcers are ischemic lesions of the skin and underlying structures caused by external pressure that impairs the flow of blood and lymph. Pressure ulcers often are referred to as decubitus ulcers or bedsores. The word decubitus comes from the Latin term meaning "lying down." However, a pressure ulcer may result from pressure exerted in the seated or the lying position. Pressure ulcers are most likely to develop over a bony prominence, but they may occur on any part of the body that is subjected to external pressure, friction, or shearing forces.

Several subpopulations are at particular risk, including persons with quadriplegia, elderly persons with restricted activity and hip fractures, and persons in the critical care setting. The prevention and treatment of pressure ulcers is a public health issue and is addressed in *Healthy People 2010*, a national public health policy statement, which has set a target of a 50% decrease in prevalence of pressure ulcers in nursing home residents.29

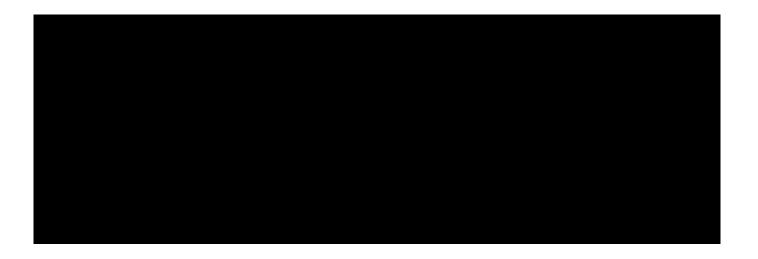

Mechanisms of Development

Two factors contribute to the development of pressure ulcers: (1) external pressure that compresses blood vessels and (2) friction and shearing forces that tear and injure blood vessels.

External pressure that exceeds capillary pressure interrupts blood flow in the capillary beds. When the pressure between a bony prominence and a support surface exceeds the normal capillary filling pressure of approximately 32 mm Hg, capillary flow essentially is obstructed.³⁰ If this pressure is applied constantly for 2 hours, oxygen deprivation coupled with an accumulation of metabolic end products leads to irreversible tissue damage. The same amount of pressure causes more damage when it is distributed over a small area than when it is distributed over a larger area. Approximately 7 lb of pressure per square inch of tissue surface is sufficient to obstruct blood flow.³¹

Whether a person is sitting or lying down, the weight of the body is borne by tissues covering the bony prominences. More than 90% of pressure ulcers are located on the lower part of the body, most often over the sacrum, the coccygeal areas, the ischial tuberosities, and the greater trochanter. Pressure over a bony area is transmitted from the surface to the underlying dense bone, compressing all of the intervening tissue. As a result, the greatest pressure occurs at the surface of the bone and dissipates outward in a conelike manner toward the surface of the skin (Fig. 15-16). Thus, extensive underlying tissue damage can be present when a small superficial skin lesion is first noticed.

Altering the distribution of pressure from one skin area to another prevents tissue injury. Pressure ulcers most commonly

occur in persons with conditions such as spinal cord injury in which normal sensation and movement to effect redistribution of body weight are impaired. Normally, persons unconsciously shift their weight to redistribute pressure on the skin and underlying tissues. For example, during the night, people turn in their sleep, preventing ischemic injury of tissues that overlie the bony prominences that support the weight of the body; the same is true for sitting for any length of time. The movements needed to shift the body weight are made unconsciously, and only when movement is restricted do people become aware of discomfort.

Shearing forces are caused by the sliding of one tissue layer over another with stretching and angulation of blood vessels, causing injury and thrombosis. For persons who are bedridden, injury commonly occurs when the head of the bed is elevated, causing the torso to slide down toward the foot of the bed. When this happens, friction and perspiration cause the skin and superficial fascia to remain fixed against the bed linens while the deep fascia and skeleton slide downward. The same thing can happen when a person sitting up in a chair slides downward. Another source of shearing forces is pulling, rather than lifting, the bedridden person up in bed. In this case, the skin remains fixed to the sheet while the fascia and muscles are pulled upward.

Prevention

The prevention of pressure ulcers is preferable to treatment. In 1992, a special panel of the Agency for Health Care Policy and Research (AHCPR; now the Agency for Healthcare Research and Quality), the Panel for the Prediction and Prevention of Pressure Ulcers in Adults, released the Clinical Practice Guidelines for Pressure Ulcers in Adults.³² The panel recommended four overall goals: (1) identifying at-risk persons who need preventative measures and the specific factors placing them at risk; (2) maintaining and improving tissue tolerance to prevent injury; (3) protecting against the adverse effects of external mechanical forces (*i.e.*, pressure, friction, and shear); and (4) reducing the incidence of pressure ulcers through educational programs.³² A 1994 publication of the AHCPR made specific recommendations for assessment of the person with pressure ulcers, management of tissue load, ulcer care, managing bacterial colonization and infection, operative repair, and education and quality control.³³

Risk factors identified as contributing to the development of pressure ulcers were those related to sensory perception (*i.e.*, ability to respond meaningfully to pressure-related discomfort), level of skin moisture, urine and fecal continence, nutrition and hydration status, mobility, circulatory status, and presence of shear and friction forces.

Methods for preventing pressure ulcers include frequent position change, meticulous skin care, and frequent and careful observation to detect early signs of skin breakdown. Adequate hydration of the stratum corneum appears to protect the skin against mechanical insult.³² The prevention of dehydration improves the circulation. It also decreases the concentration of urine, thereby minimizing skin irritation in persons who are incontinent, and it reduces urinary problems that contribute to incontinence. Maintenance of adequate nutrition is important. Anemia and malnutrition contribute to tissue breakdown and delay healing after tissue injury has occurred.

Staging and Treatment

Pressure ulcers can be staged using four categories.^{32,33} Stage I ulcers are characterized by a defined area of persistent redness in lightly pigmented skin or an area of persistent redness with blue or purple hues in darker pigmented skin. Stage II ulcers represent a partial-thickness loss of skin involving epidermis or dermis, or both. The ulcer is superficial and presents clinically as an abrasion, a blister, or a shallow crater. Stage III ulcers represent a full-thickness skin loss involving damage and necrosis of subcutaneous tissue that may extend down to but not through underlying fascia. The ulcer manifests as a deep crater with or without undermining of adjacent tissue. Stage IV ulcers involve full-thickness skin loss and necrosis with extensive destruction or damage to the underlying subcutaneous tissues that may extend to involve muscle, bone, and supporting structures (e.g., tendon or joint capsule).

After skin breakdown has occurred, special treatment measures are needed to prevent further ischemic damage, reduce bacterial contamination and infection, and promote healing. Treatment methods are selected based on the stage of the ulcer.^{30,33} Stage I ulcers usually are treated with frequent turning and measures to remove pressure. Stage II or III ulcers with little exudate are treated with petroleum gauze, or semipermeable or occlusive dressings to maintain a moist healing environment. Stage III ulcers usually require debridement (*i.e.*, removal of necrotic tissue and eschar). This can be done surgically, with wet-to-dry dressings, or through the use of proteolytic enzymes.³⁰ Stage IV wounds often require packing to obliterate dead space and are covered with nonadherent dressings. Stage IV ulcers may require surgical interventions, such as skin grafts or myocutaneous flaps.

In summary, blood flow to the tissues is dependent upon a pressure gradient between the arterial and venous side of the circulation and a transmural pressure (*i.e.*, internal minus external) that holds the vessel open. Under certain conditions, such as compartment syndrome and pressure ulcers, increases in external pressures can exceed intravascular pressure and interrupt blood flow.

Compartment syndrome is a condition of increased pressure in a muscle compartment that compromises blood flow and potentially leads to death of nerve and muscle tissue. It can result from a decrease in compartment size (*e.g.*, constrictive dressings, closure of fascial defects, thermal injury, frostbite) or an increase in compartment volume (*e.g.*, postischemic swelling, fractures, contusion and soft tissue trauma, bleeding caused by vascular injury, venous congestion).

Pressure ulcers are caused by ischemia of the skin and underlying tissues. They result from external pressure, which disrupts blood flow, or shearing forces, which cause stretching and injury to blood vessels. Pressure ulcers are divided into four stages, according to the depth of tissue involvement. The prevention of pressure ulcers is preferable to treatment. The goals of prevention should include identifying at-risk persons who need prevention along with the specific factors placing them at risk; maintaining and improving tissue tolerance to pressure to prevent injury; and protecting against the adverse effects of external mechanical forces (*i.e.*, pressure, friction, and shear).

REVIEW QUESTIONS

Characterize the role of LDL, HDL, and LDL receptors in the pathogenesis of atherosclerosis.

List risk factors in atherosclerosis and relate them to the possible mechanisms associated with the development of atherosclerosis.

Compare the mechanisms and manifestations of ischemia associated with atherosclerotic peripheral vascular disease and Raynaud's phenomenon.

Compare the pathology and manifestations of thoracic or abdominal and aortic dissection.

Describe the pathology of venous insufficiency and relate it to the development of stasis dermatitis and venous ulcers.

Cite risk factors associated with venous thrombosis and describe the manifestation of the disorder and its treatment.

Characterize the impairment of blood flow caused by external compression of blood vessels in compartment syndrome and relate it to five possible causes of compartment syndrome.

Explain how pressure and shearing forces contribute to the development of pressure ulcers.

Aging Bed Rest Disorders of Autonomic Nervous System Function Diagnosis and Treatment

Blood pressure is probably one of the most variable but best regulated functions of the body. The purpose of the control of blood pressure is to keep blood flow constant to vital organs such as the heart, brain, and kidneys. Without constant flow to these organs, death ensues within seconds, minutes, or days. Although a decrease in flow produces an immediate threat to life, the continuous elevation of blood pressure that occurs with hypertension is a contributor to premature death and disability due to its effect on the heart, blood vessels, and kidneys.

CONTROL OF BLOOD PRESSURE

The arterial blood pressure reflects the rhythmic ejection of blood from the left ventricle into the aorta. It rises as the left ventricle contracts and falls as it relaxes. The contour of the arterial pressure tracing shown in Figure 16-1 is typical of the pressure changes that occur in the large arteries of the systemic circulation. There is a rapid rise in the pulse contour during left ventricular contraction, followed by a slower rise to peak pressure. Approximately 70% of the blood that leaves the left ventricle is ejected during the first one third of systole; this accounts for the rapid rise in the pressure contour. The end of systole is marked by a brief downward deflection and formation of the dicrotic notch, which occurs when ventricular pressure falls below that in the aorta. The sudden closure of the aortic valve is associated with a small rise in pressure due to continued contraction of the aorta and other large vessels against the closed valve. As the ventricles relax and blood flows into the peripheral vessels during diastole, the arterial pressure falls rapidly at first and then declines slowly as the driving force decreases.

In healthy adults, the highest pressure, called the *systolic pressure*, ideally is less than 120 mm Hg, and the lowest pressure, called the *diastolic pressure*, is less than 80 mm Hg. The

■ FIGURE 16-1 ■ Intra-arterial pressure tracing made from the brachial artery. Pulse pressure is the difference between systolic and diastolic pressures. The darker area represents the mean arterial pressure, which can be calculated by using the formula of mean arterial pressure = diastolic pressure + pulse pressure/3.

difference between the systolic and diastolic pressure (approximately 40 mm Hg) is the *pulse pressure*. The *mean arterial pressure* (approximately 90 to 100 mm Hg), depicted by the darker area under the pressure tracing in Figure 16-1, represents the average pressure in the arterial system during ventricular contraction and relaxation.

Determinants of Blood Pressure

The systolic and diastolic components of blood pressure are determined by the cardiac output and the peripheral vascular resistance and can be expressed as a product of the two (blood pressure = cardiac output × peripheral vascular resistance). The cardiac output is the product of the stroke volume (amount of blood ejected from the heart with each beat) and the heart rate. The peripheral vascular resistance reflects changes in the radius of the arterioles as well as the viscosity or thickness of the blood. The arterioles often are referred to as the *resistance vessels* because they can selectively constrict or relax to control the resistance to outflow of blood into the capillaries. The body maintains its blood pressure by adjusting the cardiac output to compensate for changes in peripheral vascular resistance, and it changes the peripheral vascular resistance to compensate for changes in cardiac output.

In hypertension and disease conditions that affect blood pressure, changes in blood pressure are influenced by the stroke volume, the rapidity with which blood is ejected from the heart, the elastic properties of the aorta and large arteries and their ability to accept various amounts of blood as it is ejected from the heart, and the properties of the resistance blood vessels that control the runoff of blood into the smaller vessels and capillaries that connect the arterial and venous circulations.

KEY CONCEPTS

DETERMINANTS OF BLOOD PRESSURE

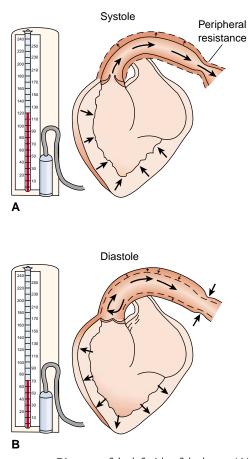

- The arterial blood pressure represents the pressure of the blood as it moves through the arterial system. It reaches its peak (systolic pressure) as blood is ejected from the heart during systole and its lowest level (diastolic pressure) as the heart relaxes during diastole.
- Blood pressure is determined by the cardiac output (stroke volume × heart rate) and the resistance that the blood encounters as it moves through the peripheral vessels (peripheral vascular resistance).
- The systolic blood pressure is largely determined by the characteristics of the stroke volume being ejected from the heart and the ability of the aorta to stretch and accommodate the stroke volume.
- The diastolic pressure is largely determined by the energy that is stored in the aorta as its elastic fibers are stretched during systole and by the resistance to the runoff of blood from the peripheral blood vessels.

Systolic Blood Pressure

The systolic blood pressure reflects the rhythmic ejection of blood into the aorta (Fig. 16-2). As blood is ejected into the aorta, it stretches the vessel wall and produces a rise in aortic pressure. The extent to which the systolic pressure rises or falls with each cardiac cycle is determined by the amount of blood ejected into the aorta with each heart beat (*i.e.*, stroke volume), the velocity of ejection, and the elastic properties of the aorta. Systolic pressure increases when there is a rapid ejection of a large stroke volume or when the stroke volume is ejected into a rigid aorta. The elastic walls of the aorta normally stretch to accommodate the varying amounts of blood that are ejected into the aorta; this prevents the pressure from rising excessively during systole and maintains the pressure during diastole. In some elderly persons, the elastic fibers of the aorta lose some of their elasticity, and the aorta becomes more rigid. When this occurs, the aorta is less able to stretch and buffer the pressure that is generated as blood is ejected into the aorta, resulting in an elevated systolic pressure.

Diastolic Blood Pressure

The diastolic blood pressure is maintained by the energy that has been stored in the elastic walls of the aorta during systole (see Fig. 16-2). The level at which the diastolic pressure is maintained depends on the elastic properties of the aorta and large arteries and their ability to stretch and store energy, the resistance of the arterioles that control the outflow of blood into the microcirculation, and the competency of the aortic valve. The small diameter of the arterioles contributes to their effectiveness as resistance vessels because it takes more force to push blood through a smaller vessel than a larger vessel. When

■ FIGURE 16-2 ■ Diagram of the left side of the heart. (A) Systolic blood pressure represents the ejection of blood into the aorta during ventricular systole; it reflects the stroke volume, the distensibility of the aorta, and the velocity with which blood is ejected from the heart. (B) Diastolic blood pressure represents the pressure in the arterial system during diastole; it is largely determined by the peripheral vascular resistance.

there is an increase in peripheral vascular resistance, as with sympathetic stimulation, diastolic blood pressure rises. Closure of the aortic valve at the onset of diastole is essential to the maintenance of the diastolic pressure. When there is incomplete closure of the aortic valve, as in aortic regurgitation (see Chapter 17), the diastolic pressure drops as blood flows backward into the left ventricle, rather than moving forward into the arterial system.

Pulse Pressure

The pulse pressure is the difference between the systolic and diastolic pressures. It reflects the pulsatile nature of arterial blood flow and is an important component of blood pressure. During the rapid ejection period of ventricular systole, the volume of blood that is ejected into the aorta exceeds the amount that exits the arterial system. The pulse pressure reflects this difference. The pulse pressure rises when additional amounts of blood are ejected into the arterial circulation, and it falls when the resistance to outflow is decreased. In hypovolemic shock, the pulse pressure declines because of a decrease in stroke volume and systolic pressure. This occurs despite an increase in peripheral vascular resistance, which maintains the diastolic pressure.

Mean Arterial Pressure

The mean arterial blood pressure represents the average blood pressure in the systemic circulation. The mean arterial pressure can be estimated by adding one third of the pulse pressure to the diastolic pressure (*i.e.*, diastolic blood pressure + pulse pressure/3). Hemodynamic monitoring equipment in intensive and coronary care units measures or computes mean arterial pressure automatically. Because it is a good indicator of tissue perfusion, the mean arterial pressure often is monitored, along with systolic and diastolic blood pressures, in critically ill patients.

Mechanisms of Blood Pressure Regulation

Although different tissues in the body are able to regulate their own blood flow, it is necessary for the arterial pressure to remain relatively constant as blood shifts from one area of the body to another. The method by which the arterial pressure is regulated depends on whether short-term or long-term adaptation is needed. The mechanisms of blood pressure regulation are illustrated in Figure 16-3.

Short-Term Regulation

The mechanisms for short-term regulation of blood pressure, those occurring over minutes or hours, are intended to correct temporary imbalances in blood pressure, such as occur during physical exercise and changes in body position. These mechanisms also are responsible for maintenance of blood pressure at survival levels during life-threatening situations. The short-term regulation of blood pressure relies mainly on neural and hormonal mechanisms, the most rapid of which are the neural mechanisms.

Neural Mechanisms. The neural control center for the regulation of blood pressure is located in the reticular formation of the lower pons and medulla of the brain where integration and modulation of autonomic nervous system (ANS) responses occur.1 This area of the brain contains the vasomotor and cardiac control centers and is often collectively referred to as the cardiovascular center. The cardiovascular center transmits parasympathetic impulses to the heart through the vagus nerve and transmits sympathetic impulses to the heart and blood vessels through the spinal cord and peripheral sympathetic nerves. Vagal stimulation of the heart produces a slowing of heart rate, whereas sympathetic stimulation produces an increase in heart rate and cardiac contractility. Blood vessels are selectively innervated by the sympathetic nervous system. Increased sympathetic activity produces constriction of the small arteries and arterioles with a resultant increase in peripheral vascular resistance.

The ANS control of blood pressure is mediated through intrinsic circulatory reflexes, extrinsic reflexes, and higher neural control centers. The *intrinsic reflexes*, including the *baroreflex* and *chemoreceptor-mediated reflex*, are located in the circulatory system and are essential for rapid and short-term regulation of blood pressure. The sensors for extrinsic reflexes are found outside the circulation. They include blood pressure responses associated with factors such as pain and cold. The neural path-

FIGURE 16-3 Mechanisms of blood pressure regulation. The *solid lines* represent the mechanisms for renal and baroreceptor control of blood pressure through changes in cardiac output and peripheral vascular resistance. The *dashed lines* represent the stimulus for regulation of blood pressure by the baroreceptors and the kidneys.

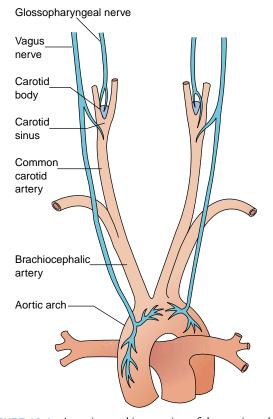

ways for these reactions are more diffuse, and their responses are less consistent than those of the intrinsic reflexes. Many of these responses are channeled through the hypothalamus, which plays an essential role in the control of sympathetic nervous system responses. Among higher-center responses are those due to changes in mood and emotion.

The *baroreceptors* are pressure-sensitive receptors located in the walls of blood vessels and the heart. The carotid and aortic baroreceptors are located in strategic positions between the heart and the brain (Fig. 16-4). They respond to changes in the stretch of the vessel wall by sending impulses to cardiovascular centers in the brain stem to effect appropriate changes in heart rate and vascular smooth muscle tone. For example, the fall in blood pressure that occurs on moving from the lying to the standing position produces a decrease in the stretch of the baroreceptors with a resultant increase in heart rate and sympathetically induced vasoconstriction that causes an increase in peripheral vascular resistance.

The *arterial chemoreceptors* are sensitive to changes in the oxygen, carbon dioxide, and hydrogen ion content of the blood. They are located in the carotid bodies, which lie in the bifurcation of the two common carotids, and in the aortic bodies of the aorta (see Fig.16-4). Because of their location, these chemoreceptors are always in close contact with the arterial blood. Although the main function of the chemoreceptors is to regulate ventilation, they also communicate with the cardiovascular center and can induce widespread vasoconstriction. When the arterial pressure drops below a critical level, the chemoreceptors are stimulated because of diminished oxygen supply and a buildup of carbon dioxide and hydrogen ions. In persons with chronic lung disease, systemic and pulmonary hypertension may develop because of hypoxemia (see Chapter 21).

Humoral Mechanisms. A number of hormones and humoral mechanisms contribute to blood pressure regulation, including the renin-angiotensin-aldosterone mechanism and vasopressin. Other humoral substances such as epinephrine, a sympathetic neurotransmitter released from the adrenal gland, has the effect of directly stimulating an increase in heart rate, cardiac contractility, and vascular tone.

The *renin-angiotensin-aldosterone* system plays a central role in blood pressure regulation. Renin is an enzyme that is synthesized, stored, and released by the kidneys in response to an increase in sympathetic nervous system activity or a decrease

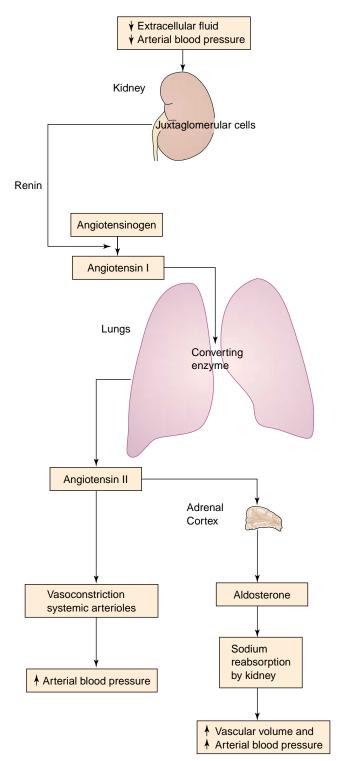

■ FIGURE 16-4 ■ Location and innervation of the aortic arch and carotid sinus baroreceptors and the carotid body chemoreceptors.

in blood pressure, extracellular fluid volume, or extracellular sodium concentration. Most of the renin that is released leaves the kidney and enters the bloodstream, where it acts enzymatically to convert an inactive circulating plasma protein called *angiotensinogen* to angiotensin I (Fig. 16-5). Angiotensin I travels to the small blood vessels of the lung, where it is converted to angiotensin II by the angiotensin-converting enzyme that is present in the endothelium of the lung vessels. Although angiotensin II has a half-life of several minutes, renin persists in the circulation for 30 minutes to 1 hour and continues to cause production of angiotensin II during this time.

Angiotensin II functions in both the short-term and longterm regulation of blood pressure. It is a strong vasoconstrictor, particularly of arterioles and to a lesser extent of veins. The vasoconstrictor response produces an increase in peripheral vascular resistance (and blood pressure) and functions in the shortterm regulation of blood pressure. A second major function of angiotensin II, stimulation of aldosterone secretion from the adrenal gland, contributes to the long-term regulation of blood pressure by increasing salt and water retention by the kidney. It also acts directly on the kidney to decrease the elimination of salt and water.

Vasopressin, also known as antidiuretic hormone (ADH), is released from the posterior pituitary gland in response to decreases in blood volume and blood pressure, an increase in the osmolality of body fluids, and other stimuli. The antidiuretic actions of vasopressin are discussed in Chapter 6. Vasopressin has a direct vasoconstrictor effect on blood vessels, particularly those of the splanchnic circulation that supplies the abdomi-

■ FIGURE 16-5 ■ Control of blood pressure by the reninangiotensin-aldosterone system. Renin enzymatically converts the plasma protein angiotensinogen to angiotensin I; angiotensinconverting enzyme in the lung converts angiotensin I to angiotensin II; and angiotensin II produces vasoconstriction and increases salt and water retention through direct action on the kidney and through increased aldosterone secretion by the adrenal cortex.

nal viscera. However, long-term increases in vasopressin cannot maintain volume expansion or hypertension, and it does not enhance hypertension produced by sodium-retaining hormones or other vasoconstricting substances. It has been suggested that vasopressin plays a permissive role in hypertension through its fluid-retaining properties or as a neurotransmitter that serves to modify ANS function.

Long-Term Regulation

Long-term mechanisms control the daily, weekly, and monthly regulation of blood pressure. Although the neural and hormonal mechanisms involved in the short-term regulation of blood pressure act rapidly, they are unable to maintain their effectiveness over time. Instead, the long-term regulation of blood pressure is largely vested in the kidneys and regulation of extracellular fluid volume.1 Blood pressure is normally regulated around an equilibrium point, which represents the normal pressure for a given individual. Accordingly, when the body contains too much extracellular fluid, the arterial pressure rises and the rate at which water (*i.e.*, pressure diuresis) and salt (*i.e.*, pressure natruresis) are excreted by the kidney is increased.¹ When blood pressure returns to its equilibrium point, water and salt excretion return to normal. A fall in blood pressure due to a decrease in extracellular fluid volume has the opposite effect. In persons with hypertension, renal control mechanisms are often altered such that the equilibrium point for blood pressure regulation is maintained at a higher level of salt and water elimination.

There are several ways that extracellular fluid volume serves to regulate blood pressure. One is through a direct effect on cardiac output and another is indirect resulting from autoregulation of blood flow and its effect on peripheral vascular resistance. Autoregulatory mechanisms function in distributing blood flow to the various tissues of the body, according to their metabolic needs (see Chapter 14). When the blood flow to a specific tissue bed is excessive, local blood vessels constrict, and when the flow is deficient the local vessels dilate. In situations of increased blood volume and cardiac output, all of the tissues of the body are exposed to the same increase in flow. This results in a generalized constriction of arterioles and an increase in the peripheral vascular resistance.

The role that the kidneys play in blood pressure regulation is emphasized by the fact that many hypertension medications produce their blood pressure-lowering effects by increasing salt and water elimination.

In summary, the arterial blood pressure that moves blood through the circulatory system reflects the alternating contraction and relaxation of the left heart. The systolic pressure denotes the peak pressure that occurs during ventricular contraction, and the diastolic pressure denotes the lowest point that occurs during relaxation. The pulse pressure is the difference between these two pressures, and the mean arterial pressure reflects the average pressure throughout the cardiac cycle.

The level to which the arterial blood pressure rises during systole and falls during diastole is determined by the cardiac output (stroke volume × heart rate) and the peripheral vascular resistance. Systolic pressure is determined primarily by the characteristics of the stroke volume and elastic properties of the aorta and large arteries and their ability to stretch and

accommodate the varying amounts of blood that is ejected from the heart. Diastolic pressure is determined largely by the smaller arteries and their ability to maintain the peripheral vascular resistance and accept the runoff of blood from the larger arteries.

Normally, blood pressure is regulated at levels sufficient to ensure adequate tissue perfusion. Blood pressure regulation requires the use of short-term and long-term mechanisms. Short-term regulation, which occurs over minutes and hours, involves ANS responses associated with baroreceptor and chemoreceptor stimulation and hormonal mechanisms such as the renin-angiotensin-aldosterone system and vasopressin. Long-term mechanisms are involved in the daily, weekly, and monthly regulation of blood pressure. They are largely vested in the kidney and involve regulation of the extracellular fluid volume through the elimination of water (pressure diuresis) and salt (pressure natruresis).

HYPERTENSION

Hypertension, or high blood pressure, is probably the most common of all health problems in adults and is the leading risk factor for cardiovascular disorders. In the United States, approximately 25% of all adults older than 18 years of age have high blood pressure.² It has been estimated that as many as 60 million adults have cardiovascular disease. In 50 million of these people (83%), the cause of cardiovascular disease is high blood pressure. Hypertension is more common in younger men compared with younger women, in blacks compared with whites, in persons from lower socioeconomic groups, and in older persons. Men have higher blood pressures than do women up until the time of menopause, at which point women quickly lose their protection.²

Hypertension commonly is divided into the categories of primary and secondary hypertension. In primary, or *essential*, hypertension, which accounts for 90% to 95% of all hypertension, the chronic elevation in blood pressure occurs without evidence of other disease. In secondary hypertension, the elevation of blood pressure results from some other disorder, such as kidney disease. Malignant hypertension, as the name implies, is an accelerated form of hypertension.

Essential Hypertension

The sixth report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC-VI) of the National Institutes of Health was published in 1997.² The JNC-VI report classifies blood pressure as optimal, normal, high-normal, and hypertensive (Table 16-1). Hypertension is further divided into stages 1, 2, and 3 based on systolic and diastolic blood pressure measurements. For adults with diabetes mellitus, the blood pressure goal has been lowered to less than 130/80 mm Hg.³

Mechanisms of Blood Pressure Elevation

Several factors, including hemodynamic, neural, humoral, and renal mechanisms, are thought to interact in producing long-term elevations in blood pressure. As with other disease

KEY CONCEPTS

HYPERTENSION

- Essential hypertension is characterized by a chronic elevation in blood pressure that occurs without evidence of other disease and secondary hypertension by an elevation of blood pressure that results from some other disorder, such as kidney disease.
- The pathogenesis of essential hypertension is thought to reside with the kidney and its role regulating vascular volume through salt and water elimination; the renin-angiotensin-aldosterone system through its effects on blood vessel tone, regulation of renal blood flow, and salt metabolism; and the sympathetic nervous system, which regulates the tone of the resistance vessels.
- Uncontrolled hypertension increases the work demands on the heart, resulting in left ventricular hypertrophy and heart failure, and on the vessels of the arterial system, leading to atherosclerosis, kidney disease, and stroke.

conditions, it is probable that there is not a single cause of essential hypertension or that the condition is a single disease. Because arterial blood pressure is the product of cardiac output and peripheral vascular resistance, all forms of hypertension involve hemodynamic mechanisms—an increase in either cardiac output or peripheral vascular resistance, or a combination of the two. Other factors, such as sympathetic

for Adults 18 Years of Age and Older*

nervous system activity, kidney function in terms of salt and water retention, the electrolyte composition of the intracellular and extracellular fluids, and humoral influences such as the renin-angiotensin-aldosterone mechanism, play an active or permissive role in regulating the hemodynamic mechanisms that control blood pressure.

Contributing Factors

Risk Factors. Although the cause or causes of essential hypertension are largely unknown, several constitutional factors have been implicated as contributing to its development. These risk factors include family history of hypertension, race, diabetes mellitus, and age-related increases in blood pressure. The inclusion of heredity as a contributing factor in the development of hypertension is supported by the fact that hypertension is seen most frequently among persons with a family history of hypertension. The inherited predisposition does not seem to rely on other risk factors, but when they are present, the risk apparently is additive. Hypertension not only is more prevalent in African Americans than whites, it is more severe, tends to occur earlier, and often is not treated early enough or aggressively enough. Blacks also tend to develop greater cardiovascular and renal damage at any level of pressure.⁴ Diabetes mellitus and hypertension are closely interrelated disorders that share similar genetic and life-style factors. Also, persons with both hypertension and diabetes have a greater risk of target organ damage. Maturation and growth are known to cause predictable increases in blood pressure from infancy to adolescence. In adult life, the systolic pressure continues to slowly rise, and hypertension becomes more common with increasing age.

Lifestyle Factors. Lifestyle factors can contribute to the development of hypertension by interacting with the constitutional risk factors. These lifestyle factors include high sodium intake,

TABLE 16-1

Category*	Systolic Blood Pressure (mm Hg)		Diastolic Blood Pressure (mm Hg)	Follow-up Recommended		
Optimal [†]	<120	and	<80	Recheck in 2 years		
Normal	<130	and	<85	Recheck in 2 years		
High-Normal	130–139	or	85–89	Recheck in 1 year		
Hypertension [‡]						
Stage 1	140–159	or	90–99	Confirm within 2 months		
Stage 2	160–179	or	100–109	Evaluate or refer to source of care within 1 month		
Stage 3	≥180	or	≥110	Evaluate or refer to source of care immediately or withir 1 week, depending on clinical situation		

Classification and Follow-up of Blood Pressure Measurements

*Not taking antihypertensive drugs and not acutely ill. When systolic and diastolic pressures fall into different categories, the higher category should be selected to classify the individual's blood pressure status. For instance, 160/92 should be classified as stage 2 and 174/120 should be classified as stage 3. Isolated systolic hypertension (ISH) is defined as systolic blood pressure ≥140 mm Hg and diastolic blood pressure <90 mm Hg and staged appropriately (*e.g.*, 170/82 mm Hg is defined as stage 2 ISH). In addition to classifying stages of hypertension on the basis of average blood pressure levels, clinicians should specify presence or absence of target-organ disease and additional risk factors. This specificity is important for risk classification and treatment.

[†]Optimal blood pressure with respect to cardiovascular risk is below 120/80 mm Hg. However, unusually low readings should be evaluated for clinical significance.

[‡]Based on the average of two or more readings taken at each of two or more visits after an initial screening. (Adapted from the National Heart, Lung, and Blood Institute. [1997]. *The sixth report of the National Committee on Detection,*

Evaluation, and Treatment of High Blood Pressure [pp. 11, 13]. NIH publication no. 98-4080. Bethesda, MD: National

Institutes of Health. Available: http://www.nhlbi.nih.gov/guidelines/hypertension/jncintro.htm)

excessive calorie intake and obesity, physical inactivity, and excessive alcohol consumption. Oral contraceptive drugs also may increase blood pressure in predisposed women. Although stress can raise blood pressure acutely, there is less evidence linking it to chronic elevations in blood pressure. Dietary fats and cholesterol are independent risk factors for cardiovascular disease, but there is no evidence that they raise blood pressure. Smoking, although not identified as a primary risk factor in hypertension, is an independent risk factor in coronary heart disease and should be avoided.

Increased salt intake has long been implicated as an etiologic factor in the development of hypertension.^{2,5} Just how increased salt intake contributes to the development of hypertension is still unclear. It may be that salt causes an elevation in blood volume, increases the sensitivity of cardiovascular or renal mechanisms to sympathetic nervous system stimuli, or exerts its effects through some other mechanisms such as the renin-angiotensin-aldosterone system.

Excessive weight commonly is associated with hypertension. It has been suggested that fat distribution might be a more critical indicator of hypertension risk than actual overweight. The waist-to-hip ratio commonly is used to differentiate central or upper body obesity (*i.e.*, fat cell deposits in the abdomen) from peripheral or lower body obesity with fat cell deposits in the buttocks and legs (see Chapter 29).⁶

Regular alcohol consumption can play a role in the development of hypertension. The effect is seen with different types of alcoholic beverages, in men and women, and in a variety of ethnic groups.^{7,8} Systolic pressure is usually more markedly affected than diastolic pressure. Blood pressure may improve or return to normal when alcohol consumption is decreased or eliminated.

Oral contraceptives cause a mild increase in blood pressure in many women and overt hypertension in approximately 5%.⁹ Why this occurs is largely unknown, although it has been suggested that estrogen and progesterone are responsible for the effect. Various contraceptive drugs contain different amounts and combinations of estrogen and progestational agents, and these differences may contribute to the occurrence of hypertension in some women but not others. Fortunately, the hypertension associated with oral contraceptives usually disappears after use of the drug has been discontinued, although it may take as long as 6 months for this to happen. However, in some women the blood pressure may not return to normal; they may be at risk for hypertension. The risk of hypertension-associated cardiovascular complications is found primarily in women older than 35 years of age and in those who smoke.²

Manifestations

Essential hypertension is typically an asymptomatic disorder. When symptoms do occur they are usually related to the longterm effects of hypertension on other organ systems of the body including the kidneys, heart, eyes, and blood vessels.

The 1997 JNC-VI report uses the term *target organ disease* to describe the cardiac, cerebrovascular, peripheral arterial disease, kidney, and retinal complications associated with hypertension (Chart 16-1).² The excess morbidity and mortality related to hypertension is progressive over the whole range of systolic and diastolic pressures. Target organ damage varies markedly among persons with similar levels of hypertension.

Hypertension is a major risk factor for atherosclerosis; it predisposes to all major atherosclerotic cardiovascular disorders,

CHART 16-1 Components of Target Organ Damage/Cardiovascular Disease in Persons With Hypertension

Heart disease

including heart failure, stroke, coronary artery disease, and peripheral artery disease. The risk of coronary artery disease and stroke depends to a great extent on other risk factors, such as obesity, smoking, and elevated cholesterol levels. If all else is favorable, the risk of a coronary event in persons with mild hypertension is no greater than in the average population of the same age. However, if a cluster of risk factors exists, the risk is greatly increased. The same is true for stroke. The risk of stroke in persons with hypertension occurs over an eightfold range, depending on the number of associated risk factors.¹⁰ Cerebrovascular complications are more closely related to systolic than diastolic hypertension.

Hypertension increases the workload of the left ventricle by increasing the pressure against which the heart must pump as it ejects blood into the systemic circulation. As the workload of the heart increases, the left ventricular wall hypertrophies to compensate for the increased pressure work. Despite its compensatory function, left ventricular hypertrophy is a major risk factor for ischemic heart disease, cardiac dysrhythmias, sudden death, and congestive heart failure. The prevalence of left ventricular hypertrophy increases with age and is highest in persons with blood pressures greater than 160/95 mm Hg.¹¹ Hypertensive left ventricular hypertrophy usually regresses with therapy. Regression is most closely related to systolic pressure reduction and does not appear to reflect the particular type of medication used.

Hypertension also can lead to nephrosclerosis, a common cause of renal insufficiency (see Chapter 23). Hypertensive kidney disease is more common in blacks than whites. Hypertension also plays an important role in accelerating the course of other types of kidney disease, particularly diabetic nephropathy.³ Because of the risk of diabetic nephropathy, the American Diabetes Association recommends that persons with diabetes maintain their blood pressure at levels less than 130/80 mm Hg (see Chapter 32).

Diagnosis and Treatment

Unlike disorders of organ structure that are diagnosed by methods such as x-rays and tissue examination, hypertension and other blood pressure disorders are determined by repeated blood pressure measurement. The diagnosis of hypertension in a person who is not taking antihypertensive medications should be based on the average of at least two or more blood pressure readings taken at each of two or more visits after an initial screening visit.² Laboratory tests, x-ray films, and other diagnostic tests usually are done to exclude secondary hypertension and determine the presence or extent of target organ disease.

Clinically, blood pressure measurements are usually obtained by the auscultatory method, which uses a sphygmomanometer and a stethoscope. Accuracy of blood pressure measurement requires that persons taking the pressure are adequately trained in blood pressure measurement, that the equipment is properly maintained and calibrated, and the cuff bladder is appropriate for the arm size.¹² The width of the bladder should be at least 40% of arm circumference and the length at least 80% of arm circumference. Undercuffing (using a cuff with a bladder that is too small) can cause an overestimation of blood pressure.¹³ This is because a cuff that is too small results in an uneven distribution of pressure across the arm, such that a greater cuff pressure is needed to occlude blood flow. Likewise, overcuffing (using a cuff with a bladder that is too large) can cause an underestimation of blood pressure.

The main objective for treatment of essential hypertension is to achieve and maintain arterial blood pressure of less than 140/90 mm Hg, with the goal of preventing morbidity and mortality. For persons with secondary hypertension, efforts are made to correct or control the disease condition causing the hypertension. Antihypertensive medications and other measures supplement the treatment for the underlying disease. The JNC-VI report contains a treatment algorithm for hypertension that includes lifestyle modification and, when necessary, guidelines for the use of pharmacologic agents to achieve and maintain systolic pressure below 140 mm Hg and diastolic pressure below 90 mm Hg.²

Lifestyle Modification. Lifestyle modification includes reduction in sodium intake, maintenance of adequate potassium intake, weight reduction if overweight, regular aerobic physical activity, and modification of alcohol intake. A reduction in dietary saturated fats and cholesterol is recommended for overall cardiovascular health. Smoking cessation should be encouraged for people who smoke. For persons with stage 1 hypertension (see Table 16-1), an attempt to control blood pressure with weight loss and other lifestyle modifications should be tried for at least 3 to 6 months before initiating pharmacologic treatment.⁴

The American Heart Association recommends the daily salt intake for adults in the general population should not exceed 6 g/day.¹⁴ Because many prepared foods are high in sodium, it was recommended that persons consult package labels for the sodium content of canned foods, frozen foods, soft drinks, and other foods and beverages to reduce sodium intake adequately. High dietary potassium intake may protect against the development of hypertension or improve blood pressure control in people with hypertension. Therefore, an adequate intake of potassium (approximately 90 mmol per day), preferably from food sources such as fresh fruits and vegetables, is recommended.²

Weight reduction of as little as 4.5 kg (10 lb) can produce a decrease in blood pressure in a large proportion of overweight people with hypertension.² Because of alcohol's association

with high blood pressure, the JNC-VI report recommends restriction of alcohol consumption to no more than 1 oz (30 mL) ethanol per day (equal to 2 oz of 100-proof whiskey, 10 oz of wine, or 24 oz of beer) or 0.5 oz per day for women or lighter weight people.²

A regular program of aerobic physical exercise (*e.g.*, walking, biking, swimming) is protective, especially for those at increased risk for cardiovascular disease because of hypertension. Exercise may have additional indirect benefits, such as weight loss or motivation for changing other risk factors.

Pharmacologic Treatment. The decision to initiate pharmacologic treatment is based on the severity of the hypertension, the presence of target organ disease, and the existence of other conditions and risk factors. Drug selection is based on the stage of hypertension. Among the drugs used in the treatment of hypertension are diuretics, β -adrenergic–blocking drugs, angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers, the calcium channel-blocking drugs, central α_2 -adrenergic agonists, α_1 -adrenergic receptor blockers, and vasodilators.

The physiologic mechanisms whereby the different hypertension drugs produce a reduction in blood pressure differ among agents. Diuretics lower blood pressure initially by decreasing vascular volume (by suppressing renal reabsorption of sodium and increasing salt and water excretion) and cardiac output. With continued therapy, a reduction in peripheral resistance becomes a major mechanism of blood pressure reduction. β-Adrenergic–blocking drugs are effective in treating hypertension because they decrease heart rate, cardiac output, and renin release by the kidney. The ACE inhibitors act by inhibiting the conversion of angiotensin I to angiotensin II, thus decreasing angiotensin II levels and reducing its effect on vasoconstriction, aldosterone levels, intrarenal blood flow, and the glomerular filtration rate. The calcium channel blockers decrease peripheral vascular resistance by inhibiting the movement of calcium into arterial smooth muscle cells. The centrally acting α_2 -adrenergic agonists act in a negative-feedback manner to decrease sympathetic outflow from the central nervous system. The α_1 -adrenergic receptor antagonists block α_1 receptors on vascular smooth muscle causing vasodilation and a reduction in peripheral vascular resistance. The direct-acting smooth muscle vasodilators promote a decrease in peripheral vascular resistance by producing relaxation of vascular smooth muscle, particularly of the arterioles.

Pharmacologic treatment of hypertension usually follows a stepwise approach.² It is usually initiated with a low dose of a single drug. The dose is slowly increased at a schedule dependent on the person's age, needs, and desired response.² If the response to the initial drug is not adequate, one of three approaches can be used: the dose can be increased if the initial dose was below the maximum recommended; a drug with a different mode of action can be added; or the initial drug can be discontinued and another substituted. Combining drugs with different modes of action often allows smaller doses to be used to achieve blood pressure control, while minimizing the dose-dependent side effects from any one drug. In treating stage 3 or 4 hypertension, it often is necessary to add a second or third drug after a short interval if the treatment goal is not achieved.

Systolic Hypertension

Essential hypertension may be classified as systolic/diastolic hypertension in which both the systolic and diastolic pressures are elevated; as diastolic hypertension in which the diastolic pressure is selectively elevated; or as systolic hypertension in which the systolic pressure is selectively elevated. The JNC-VI report defined systolic hypertension as a systolic pressure of 140 mm Hg or greater and a diastolic pressure less than 90 mm Hg and indicated a need for increased recognition and control of isolated systolic hypertension.² Historically, diastolic hypertension was thought to confer a greater risk for cardiovascular events than systolic hypertension.² However, there is mounting evidence that elevated systolic blood pressure is at least as important, if not more so, than diastolic hypertension.^{15,16}

There are two aspects of systolic hypertension that confer increased risk of cardiovascular events: one is the actual elevation in systolic pressure, and the other is the disproportionate rise in pulse pressure. Elevated pressures during systole favor the development of left ventricular hypertrophy, increased myocardial oxygen demands, and eventual left heart failure. At the same time, the absolute or relative lowering of diastolic pressure is a limiting factor in coronary perfusion because coronary perfusion is greatest during diastole. Elevated levels of pulse pressure produce greater stretch of arteries, causing damage to the elastic elements of the vessel and thus predisposing to aneurysms and development of the endothelial cell damage that leads to atherosclerosis and thrombosis.

Secondary Hypertension

Only 5% to 10% of hypertensive cases are classified as secondary hypertension (*i.e.*, hypertension due to another disease condition). Unlike essential hypertension, many of the conditions causing secondary hypertension can be corrected or cured by surgery or specific medical treatment. Secondary hypertension tends to be seen more commonly in persons younger than 30 years and those older than 50 years of age.¹⁷ Among the most common causes of secondary hypertension are kidney disease (*i.e.*, renovascular hypertension), adrenal cortical disorders, pheochromocytoma, and coarctation of the aorta. Cocaine and cocaine-like substances also can cause significant hypertension.

Renal Hypertension

With the dominant role that the kidney assumes in blood pressure regulation, it is not surprising that the largest single cause of secondary hypertension is renal disease. Most acute kidney disorders result in decreased urine formation, retention of salt and water, and hypertension. This includes acute glomerulonephritis, acute renal failure, and acute urinary tract obstruction. Hypertension also is common among persons with chronic pyelonephritis, polycystic kidney disease, diabetic nephropathy, and end-stage renal disease, regardless of cause.

Renovascular hypertension refers to hypertension caused by reduced renal blood flow and activation of the reninangiotensin-aldosterone mechanism. It is the most common cause of secondary hypertension, accounting for 1% to 2% of all cases of hypertension. The reduced renal blood flow that occurs with renovascular disease causes the affected kidneys to release excessive amounts of renin, increasing circulating levels of angiotensin II. One or both of the kidneys may be affected. Manifestations of renovascular hypertension include hypokalemia (caused by increased aldosterone levels), the presence of an abdominal bruit, and a duration of hypertension of less than 1 year (to help to distinguish renovascular hypertension from essential hypertension). Because renal blood flow depends on the increased blood pressure generated by the reninangiotensin system, administration of ACE inhibitors can cause a rapid decline in renal function.

Disorders of Adrenocorticosteroid Hormones

Excess production of aldosterone caused by adrenocortical hyperplasia or adenoma (primary hyperaldosteronism) and excess levels of glucocorticoid (Cushing's disease or syndrome) tend to raise the blood pressure (see Chapter 31). These hormones produce hypertension through increased salt and water retention by the kidney. For persons with primary hyperaldosteronism, a salt-restricted diet often produces a reduction in blood pressure. Because aldosterone acts on the distal renal tubule to increase sodium absorption in exchange for potassium elimination in the urine, persons with hyperaldosteronism usually have decreased potassium levels. Potassium-sparing diuretics, such as spironolactone, which is an aldosterone antagonist, often are used in the medical care of persons with the disorder.

Pheochromocytoma

A pheochromocytoma is a tumor of chromaffin tissue, which contains sympathetic nerve cells. The tumor is most commonly located in the adrenal medulla but can arise in other sites, such as sympathetic ganglia, where there is chromaffin tissue.¹⁸ Although only 0.1% to 0.5% of persons with hypertension have an underlying pheochromocytoma, the disorder can cause serious hypertensive crises. Eight percent to 10% of the tumors are malignant.

Like adrenal medullary cells, the tumor cells of a pheochromocytoma produce and secrete the catecholamines epinephrine and norepinephrine. The hypertension that develops is the result of a massive release of these catecholamines. Their release may be paroxysmal, rather than continuous, causing periodic episodes of headache, excessive sweating, and palpitations. Headache is the most common symptom and can be quite severe. Nervousness, tremor, facial pallor, weakness, fatigue, and weight loss occur less frequently. Marked variability in blood pressure between episodes is typical. Some persons with pheochromocytoma have paroxysmal episodes of hypertension, sometimes to dangerously high levels; others may have sustained hypertension; and some may even be normotensive.

Coarctation of the Aorta

Coarctation of the aorta represents a narrowing of the aorta just distal to the origin of the subclavian arteries (see Chapter 17).¹⁹ The ejection of a large stroke volume into a narrowed aorta with limited ability to accept the runoff results in an increase in systolic blood pressure and blood flow to the upper part of the body. Blood pressure in the lower extremities may be normal, although it frequently is low. It has been suggested that the increase in cardiac output and maintenance of the pressure to the lower part of the body is achieved through the reninangiotensin-aldosterone mechanism in response to a decrease in renal blood flow. Pulse pressure in the legs almost always is narrowed, and the femoral pulses are weak. Because the aortic

capacity is diminished, there usually is a marked increase in pressure (measured in the arms) during exercise, when the stroke volume and heart rate are exaggerated. It is important that blood pressure be measured in both arms and one leg when coarctation of the aorta is suspected. A 20 mm Hg or higher pressure in the arms than in the legs suggests coarctation of the aorta.

Malignant Hypertension

A small number of persons with secondary hypertension develop an accelerated and potentially fatal form of the disease malignant hypertension. This usually is a disease of younger persons, particularly young African-American men, women with hypertension of pregnancy, and persons with renal and collagen diseases.

Malignant hypertension is characterized by sudden marked elevations in blood pressure, with diastolic values above 120 mm Hg, renal disorders, vascular changes, and retinopathy. There may be intense arterial spasm of the cerebral arteries with hypertensive encephalopathy. Cerebral vasoconstriction probably is an exaggerated homeostatic response designed to protect the brain from excesses of blood pressure and flow. The regulatory mechanisms often are insufficient to protect the capillaries, and cerebral edema frequently develops. As it advances, papilledema (*i.e.*, swelling of the optic nerve at its point of entrance into the eye) ensues, giving evidence of the effects of pressure on the optic nerve and retinal vessels. The patient may have headache, restlessness, confusion, stupor, motor and sensory deficits, and visual disturbances. In severe cases, convulsions and coma follow.

Prolonged and severe exposure to exaggerated levels of blood pressure in malignant hypertension injures the walls of the arterioles, and intravascular coagulation and fragmentation of red blood cells may occur. The renal blood vessels are particularly vulnerable to hypertensive damage. Renal damage caused by vascular changes probably is the most important prognostic determinant in malignant hypertension. Elevated levels of blood urea nitrogen and serum creatinine, metabolic acidosis, hypocalcemia, and proteinuria provide evidence of renal impairment. The complications associated with a hypertensive crisis demand immediate and rigorous medical treatment in an intensive care unit with continuous monitoring of arterial blood pressure. With proper therapy, the death rate from this cause can be markedly reduced, as can the potential for additional episodes. Because chronic hypertension is associated with autoregulatory changes in cerebral blood flow, care is taken to avoid excessively rapid decreases in blood pressure, which can lead to cerebral hypoperfusion and brain injury.

Hypertension During Pregnancy

Hypertensive disorders complicate 6% to 8% of pregnancies. They are the second leading cause, after embolism, of maternal mortality in the United States, accounting for almost 15% of such deaths. Hypertensive disorders also contribute to stillbirths and neonatal morbidity and mortality. The incidence of hypertensive disorders of pregnancy increases with maternal age and is more common in African-American women.²⁰

Classification

The National Institutes of Health Working Group Report on High Blood Pressure in Pregnancy published a revised classification system for high blood pressure in pregnancy that included preeclampsia-eclampsia, preeclampsia superimposed on chronic hypertension, chronic hypertension, and gestational hypertension²¹ (Table 16-2).

Preeclampsia-Eclampsia. Preeclampsia-eclampsia is a pregnancy-specific syndrome. It is defined as an elevation in blood pressure and proteinuria developing after the 20th week of gestation. It is defined as an elevation in blood pressure (systolic >140 or diastolic >90 mm Hg) and proteinuria (≥ 0.3 g/24 hours) developing after the 20th week of gestation. The presence of systolic pressure ≥ 160 mm Hg, diastolic pressure ≥ 110 mm Hg; proteinuria (≥ 0.0 g/24 h); increased serum creatinine (>1.2 mg); platelet counts <100,000 cells/mm³; elevated liver enzymes; persistent headache or cerebral or visual disturbances; and persistent epigastric pain serve to reinforce the diagnosis.²¹ Preeclampsia may occur in women who already are hypertensive, in which case the prognosis for the mother and fetus tends

TABLE 16-2	Classif	Classification of High Blood Pressure in Pregnancy					
Classification		Description					
Gestational hypertension		Blood pressure elevation, without proteinuria, that is detected for the first time during midpregnancy and returns to normal by 12 weeks postpartum.					
Chronic hypertens	sion	Blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic that is present and observable before the 20th week of pregnancy. Hypertension that is diagnosed for the first time during pregnancy and does not resolve after pregnancy also is classified as chronic hypertension.					
Preeclampsia-eclampsia		Pregnancy-specific syndrome of blood pressure elevation (blood pressure >140 mm Hg systolic or >90 Hg diastolic) that occurs after the first 20 weeks of pregnancy and is accompanied by proteinuria (urinary excretion of 0.3 g protein in a 24-hour specimen).					
Preeclampsia supe on chronic hype		Chronic hypertension (blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic prior to 20th week of pregnancy) with superimposed proteinuria and with or without signs of the preeclampsia syndrome					

(Developed using information from National Institutes of Health. [2000]. *Working group report on high blood pressure in pregnancy*. NIH publication no. 00-3029. Bethesda, MD: Author. Available: http://www.nhlbi.gov/health/prof/heart/ hbp/hbp_preg.htm)

to be worse than for either condition alone.²¹ Eclampsia is the occurence, in a woman with preeclampsia, of seizures that cannot be attributed to other causes.

Preeclampsia occurs primarily during first pregnancies and during subsequent pregnancies in women with multiple fetuses, diabetes mellitus, or coexisting renal disease. It is associated with a condition called a *hydatidiform mole* (*i.e.*, abnormal pregnancy caused by a pathologic ovum, resulting in a mass of cysts). Women with chronic hypertension who become pregnant have an increased risk of preeclampsia and adverse neonatal outcomes, particularly when associated with proteinuria early in pregnancy.²²

Pregnancy-induced hypertension is thought to involve a decrease in placental blood flow, leading to the release of toxic mediators that alter the function of endothelial cells in blood vessels throughout the body, including those of the kidney, brain, liver, and heart.²² The endothelial changes result in signs and symptoms of preeclampsia and, in more severe cases, of intravascular clotting and hypoperfusion of vital organs. There is risk for development of disseminated intravascular coagulation, cerebral hemorrhage, hepatic failure, and acute renal failure. Thrombocytopenia is the most common hematologic complication of preeclampsia. Platelet counts of less than below 100,000/mm³ signal serious disease. The cause of thrombocytopenia has been ascribed to platelet deposition at the site of endothelial injury. The renal changes that occur with preeclampsia include a decrease in glomerular filtration rate and renal blood flow. Sodium excretion may be impaired, although this is variable. Edema may or may not be present. Some of the most severe forms of preeclampsia occur in the absence of edema. Even when there is extensive edema, the plasma volume usually is lower than that seen in normal pregnancy. Liver damage, when it occurs, may range from mild hepatocellular necrosis with elevation of liver enzymes to the more ominous hemolysis, elevated liver function tests, and low platelet count (HELLP) syndrome that is associated with significant maternal mortality. Eclampsia, the convulsive stage of preeclampsia, is a significant cause of maternal mortality. The pathogenesis of eclampsia remains unclear and has been attributed to both increased coagulability and fibrin deposition in the cerebral vessels.

Chronic Hypertension. Chronic hypertension is considered in the same manner as hypertension that is unrelated to the pregnancy. It is defined as a history of high blood pressure before pregnancy, identification of hypertension before 20 weeks of pregnancy, and hypertension that persists after pregnancy. In women with chronic hypertension, blood pressure often decreases in early pregnancy and increases during the last trimester (3 months) of pregnancy, resembling preeclampsia. Women with chronic hypertension are at increased risk for the development of preeclampsia.

Gestational Hypertension. Gestational hypertension represents a blood pressure elevation without proteinuria that is detected for the first time after midpregnancy. It includes women with preeclampsia syndrome who have not yet manifested proteinuria, as well as women who do not have the syndrome. The final determination that a woman does not have the preeclampsia syndrome is made only postpartum. If preeclampsia has not developed and blood pressure has returned to normal by 12 weeks postpartum, the condition is considered to be gestational hypertension. If blood pressure elevation persists, a diagnosis of chronic hypertension is made.

Diagnosis and Treatment

Early prenatal care is important in the detection of high blood pressure during pregnancy. It is recommended that all pregnant women, including those with hypertension, refrain from alcohol and tobacco use. Salt restriction usually is not recommended during pregnancy because pregnant women with hypertension tend to have lower plasma volumes than do normotensive pregnant women and because the severity of hypertension may reflect the degree of volume contraction. The exception is women with preexisting hypertension who have been following a salt-restricted diet.

In women with preeclampsia, delivery of the fetus is curative. The timing of delivery becomes a difficult decision in preterm pregnancies because the welfare of both the mother and the infant must be taken into account. Bed rest is a traditional therapy. Antihypertensive medications, when required, must be carefully chosen because of their potential effects on uteroplacental blood flow and on the fetus. For example, the ACE inhibitors can cause injury and even death of the fetus when given during the second and third trimesters of pregnancy.

Hypertension in Children

Blood pressure is known to increase from infancy to late adolescence. The average systolic pressure at 1 day of age is approximately 70 mm Hg and increases to approximately 85 mm Hg at 1 month of age.^{23,24} Systolic blood pressure continues to increase with physical growth to about 120 mm Hg at the end of adolescence. During the preschool years, blood pressure begins to follow a pattern that tends to be maintained as the children grow older. This pattern continues into adolescence and adulthood, suggesting the roots of essential hypertension are established early in life. A familial influence on blood pressure often can be identified early in life. Children of parents with high blood pressure tend to have higher blood pressures than do children with normotensive parents.

Blood pressure norms for children are based on age, height, and gender-specific percentiles. The 1996 Task Force updated earlier recommendations by including height as a variable in determination of blood pressure (Table 16-3).²⁵ The Task Force recommended continued classification of blood pressure into three ranges: normal (*i.e.*, systolic and diastolic pressures below the 90th percentile for age, height, and gender); high normal (*i.e.*, systolic or diastolic blood pressures between the 90th and 95th percentile for age, height, and gender); and high blood pressures, or hypertension (*i.e.*, systolic and diastolic blood pressures, or normal the 95th percentile for age, height, and gender); and high blood pressures equal to or greater than the 95th percentile for age, height, and gender on at least three occasions).

Secondary hypertension is the most common form of high blood pressure in infants and children. In later childhood and adolescence, essential hypertension is more common. Approximately 75% to 80% of secondary hypertension in children is caused by kidney abnormalities.²⁵ Coarctation of the aorta is another cause of hypertension in children and adolescents. Endocrine causes of hypertension such as pheochromocytoma and adrenal cortical disorders are rare. Hypertension in infants is associated most commonly with high umbilical catheterization and renal artery obstruction caused by thrombosis.²⁶ Most

Children and Adolescents. A working group report from the National High Blood Pressure Education Program.

Pediatrics 98, 653-654. Available: http://www.nhibi.nih.gov/health/prof/heart/hbp/hbp_ped.htm)

cases of essential hypertension are associated with obesity or a family history of hypertension.

A number of drugs of abuse, therapeutic agents, and toxins also may increase blood pressure. Alcohol should be considered as a risk factor in adolescents. Oral contraceptives may be a cause of hypertension in adolescent females. The nephrotoxicity of the drug cyclosporine, an immunosuppressant used in transplant therapy, may cause hypertension in children after bone marrow, heart, kidney, or liver transplantation. The coadministration of corticosteroid drugs appears to increase the incidence of hypertension.

Diagnosis and Treatment

The Task Force recommended that children 3 years of age through adolescence should have their blood pressure taken once each year. Repeated measurements over time, rather than a single isolated determination, are required to establish consistent and significant observations. Children with high blood pressure should be referred for medical evaluation and treatment as indicated. Treatment includes nonpharmacologic methods and, if necessary, pharmacologic therapy. The Task Force suggested use of the stepped-care approach for drug treatment of children who require antihypertensive medications.²⁵

The prevalence of hypertension in the elderly population (65 to 74 years of age) of the United States ranges from 60% for whites to 71% for African Americans.²⁷ The most common type of hypertension in the elderly is isolated systolic hypertension, in which systolic pressure is elevated while diastolic pressure remains within normal range. A Clinical Advisory Statement intended to advance and clarify the JNC-VI guidelines on the importance of systolic pressure in older Americans, issued by the Coordinating Committee of the National High Blood Pressure Education Program in 2000, reaffirmed the importance of lifelong maintenance of a blood pressure of 140/90 mm Hg or less.28

Among the aging processes that contribute to an increase in blood pressure are a stiffening of the large arteries, particularly the aorta; decreased baroreceptor sensitivity; increased peripheral vascular resistance; and decreased renal blood flow. Systolic blood pressure rises almost linearly between 30 and 84 years of age, whereas diastolic pressure rises until 50 years of age and then levels off or decreases.²⁹ This rise in systolic pressure is thought to be related to increased stiffness of the large arteries.

With aging, the elastin fibers in the walls of the arteries are gradually replaced by collagen fibers that render the vessels stiffer and less compliant. Differences in the central and peripheral arteries relate to the larger vessels containing more elastin, whereas the peripheral resistance vessels have more smooth muscle and less elastin. Because of increased wall stiffness, the aorta and large arteries are less able to buffer the increase in systolic pressure that occurs as blood is ejected from the left heart, and they are less able to store the energy needed to maintain the diastolic pressure. As a result, the systolic pressure increases, the diastolic pressure remains unchanged or actually decreases, and the pulse pressure or difference between the systolic pressure and diastolic pressure widens.

Isolated systolic hypertension (systolic pressure \geq 140 mm Hg and diastolic < 90 mm Hg) is recognized as an important risk factor for cardiovascular morbidity and mortality in older persons.²⁹ Stroke is two to three times more common in elderly hypertensive people than in age-matched normotensive subjects. The treatment of hypertension in the elderly has beneficial effects in terms of reducing the incidence of cardiovascular events such as stroke. The Systolic Hypertension in the Elderly Program (SHEP) showed a reduction of 36% in stroke and a 27% reduction in myocardial infarction in persons who were treated for hypertension compared with those who were not.³⁰

Diagnosis and Treatment

The recommendations for measurement of blood pressure in the elderly are similar to those for the rest of the population. Blood pressure variability is particularly prevalent among older persons, so it is especially important to obtain multiple measurements on different occasions to establish a diagnosis of hypertension. The effects of food, position, and other environmental factors also are exaggerated in older persons. Although sitting has been the standard position for blood pressure measurement, it is recommended that blood pressure also be taken in the supine and standing positions in the elderly. In some elderly persons with hypertension, a silent interval, called the auscultatory gap, may occur between the end of the first and beginning of the third phases of the Korotkoff sounds, providing the potential for underestimating the systolic pressure, sometimes by as much as 50 mm Hg. Because the gap occurs only with auscultation, it is recommended that a preliminary determination of systolic blood pressure be made by palpation and the cuff be inflated 30 mm Hg above this value for auscultatory measurement of blood pressure. In some older persons, the indirect measurement using a blood pressure cuff and the Korotkoff sounds has been shown to give falsely elevated reading compared with the direct intra-arterial method. This is because excessive cuff pressure is needed to compress the rigid vessels of some older persons. Pseudohypertension should be suspected in older persons with hypertension in whom the radial or brachial artery remains palpable but pulseless at higher cuff pressures.

The treatment of hypertension in the elderly is similar to that for younger age groups. However, blood pressure should be reduced slowly and cautiously. When possible, appropriate lifestyle modification measures should be tried first. Antihypertensive medications should be prescribed carefully because the older person may have impaired baroreflex sensitivity and renal function. Usually, medications are initiated at smaller doses, and doses are increased more gradually. There is also the dangers of adverse drug interactions in older persons,

who may be taking multiple medications, including over-thecounter drugs.

In summary, hypertension (systolic pressure \geq 140 mm Hg and/or diastolic pressure >90 mm Hg) is one of the most common cardiovascular disorders. It may occur as a primary disorder (*i.e.*, essential hypertension) or as a symptom of some other disease (i.e., secondary hypertension). Essential hypertension may be classified as systolic/diastolic hypertension in which both the systolic and diastolic pressures are elevated; as diastolic hypertension in which the diastolic pressure is selectively elevated; or as systolic hypertension in which the systolic pressure is selectively elevated. The incidence of essential hypertension increases with age; the condition is seen more frequently among African Americans, and it is linked to a family history of high blood pressure, obesity, and increased salt intake.

Causes of secondary hypertension include renal disorders and adrenal cortical disorders, such as hyperaldosteronism and Cushing's disease, which increase salt and water retention; pheochromocytomas, which increase catecholamine levels; and coarctation of the aorta, which produces a decrease in leg blood pressures and compensatory increase in arm pressures.

Uncontrolled hypertension increases the risk of heart disease, renal complications, retinopathy, and stroke. Treatment of essential hypertension focuses on nonpharmacologic methods such as weight reduction, reduction of sodium intake, regular physical activity, modification of alcohol intake, and smoking cessation. Among the drugs used in the treatment of hypertension are diuretics, adrenergic inhibitors, vasodilators, ACE inhibitors, and calcium channel-blocking drugs.

Hypertension that occurs during pregnancy can be divided into four categories: chronic hypertension, preeclampsiaeclampsia, chronic hypertension with superimposed preeclampsia-eclampsia, and gestational hypertension. Preeclampsia-eclampsia, which is hypertension that develops after 20 weeks' gestation, is accompanied by proteinuria, and poses a particular threat to the mother and the fetus. Blood pressure norms for children are based on age, height, and gender-specific percentiles. Secondary hypertension is the most common form of high blood pressure in infants and children. In later childhood and adolescence, essential hypertension is more common. Isolated systolic hypertension is the most common type of hypertension in the elderly. It represents the effects of aging on the distensibility of the aorta and its ability to stretch and accommodate blood being ejected from the left heart during systole. Untreated systolic hypertension is recognized as an important risk factor for stroke and other cardiovascular morbidity and mortality in older persons.

ORTHOSTATIC HYPOTENSION

Orthostatic or postural hypotension is an abnormal drop in blood pressure on assumption of the standing position. In the absence of normal circulatory reflexes or blood volume, blood pools in the lower part of the body; when the standing position is assumed, cardiac output falls, and blood flow to the brain is inadequate. Dizziness, syncope (*i.e.*, fainting), or both may occur.

After the assumption of the upright posture from the supine position, approximately 500 to 700 mL of blood is momentarily shifted to the lower part of the body, with an accompanying decrease in central blood volume and arterial pressure.³¹ Normally, this decrease in blood pressure is transient, lasting through several cardiac cycles, because the baroreceptors located in the thorax and carotid sinus area sense the decreased pressure and initiate reflex constriction of the veins and arterioles and an increase in heart rate, which brings blood pressure back to normal. Within a few minutes of a change to the standing position, blood levels of antidiuretic hormone and sympathetic neuromediators increase as a secondary means of ensuring maintenance of normal blood pressure in the standing position. Muscle movement in the lower extremities also aids venous return to the heart by pumping blood out of the legs.

In persons with healthy blood vessels and normal autonomic nervous system function, cerebral blood flow usually is not reduced on assumption of the upright position unless arterial pressure falls below 70 mm Hg. The strategic location of the arterial baroreceptors between the heart and brain is designed to ensure that the arterial pressure is maintained within a range sufficient to prevent a reduction in cerebral blood flow.

Classification

Although there is no firm agreement on the definition of orthostatic hypotension, many authorities consider a drop in systolic pressure of 20 mm Hg or more or a drop in diastolic blood pressure of 10 mm Hg or more as diagnostic of the condition.³² Some authorities regard the presence of orthostatic symptoms (*e.g.*, dizziness, syncope) as being more relevant than the numeric decrease in blood pressure.³³

Causes

A wide variety of conditions, acute and chronic, are associated with orthostatic hypotension. These include reduced blood volume, drug-induced hypotension, altered vascular responses associated with aging, bed rest, and autonomic nervous system dysfunction.

Reduced Blood Volume

Orthostatic hypotension often is an early sign of reduced blood volume or fluid deficit. When blood volume is decreased, the vascular compartment is only partially filled; although cardiac output may be adequate when a person is in the recumbent position, it often decreases to the point of causing weakness and fainting when the person assumes the standing position. Common causes of orthostatic hypotension related to hypovolemia are excessive use of diuretics, excessive diaphoresis, loss of gastrointestinal fluids through vomiting and diarrhea, and loss of fluid volume associated with prolonged bed rest.

Drug-Induced Hypotension

Antihypertensive drugs and psychotropic drugs are the most common cause of chronic orthostatic hypotension. In most cases, the orthostatic hypotension is well tolerated. If postural hypotension is severe enough to cause light-headedness or dizziness, it is recommended that the dosage of the drug be reduced or a different drug be used.³³

Aging

Weakness and dizziness on standing are common complaints of elderly persons. Orthostatic hypotension is associated with systolic hypertension, major electrocardiographic abnormalities, and carotid artery stenosis. Because cerebral blood flow primarily depends on systolic pressure, patients with impaired cerebral circulation may experience symptoms of weakness, ataxia, dizziness, and syncope when their arterial pressure falls even slightly. This may happen in older persons who are immobilized for brief periods or whose blood volume is decreased owing to inadequate fluid intake or overzealous use of diuretics.

Postprandial blood pressure often decreases in elderly persons.³⁴ The greatest postprandial changes occur after a highcarbohydrate meal. Although the mechanism responsible for these changes is not fully understood, it is thought to result from glucose-mediated impairment of baroreflex sensitivity and increased splanchnic blood flow mediated by insulin and vasoactive gastrointestinal hormones.

Bed Rest

Prolonged bed rest promotes a reduction in plasma volume, a decrease in venous tone, failure of peripheral vasoconstriction, and weakness of the skeletal muscles that support the veins and assist in returning blood to the heart. Physical deconditioning follows even short periods of bed rest. After 3 to 4 days, the blood volume is decreased. Loss of vascular and skeletal muscle tone is less predictable but probably becomes maximal after approximately 2 weeks of bed rest. Orthostatic intolerance is a recognized problem of space flight, a potential risk after re-entry into the earth's gravitational field.

Disorders of Autonomic Nervous System Function

The sympathetic nervous system plays an essential role in adjustment to the upright position. Sympathetic stimulation increases heart rate and cardiac contractility and causes constriction of peripheral veins and arterioles. Orthostatic hypotension caused by altered autonomic function is common in peripheral neuropathies associated with diabetes mellitus, after injury or disease of the spinal cord, or as the result of a cerebral vascular accident in which sympathetic outflow from the brain stem is disrupted. The American Autonomic Society and the American Academy of Neurology have distinguished three forms of primary autonomic nervous system dysfunction: pure autonomic failure, defined as a sporadic, idiopathic cause of persistent orthostatic hypotension and other manifestations of autonomic failure such as urinary retention, impotence, or decreased sweating; Parkinson's disease with autonomic failure; and multiple-system atrophy (Shy-Drager syndrome).35 The Shy-Drager syndrome usually develops in middle to late life and manifests as orthostatic hypotension associated with uncoordinated movements, urinary incontinence, constipation, and other signs of neurologic deficits referable to the corticospinal, extrapyramidal, corticobulbar, and cerebellar systems.

Diagnosis and Treatment

Orthostatic hypotension can be assessed with the blood pressure cuff. A reading should be made when the patient is supine, immediately after assumption of the seated or upright position,

and after 2 to 3 minutes following assumption of the standing position. A tilt table also can be used for this purpose. With a tilt table, the recumbent patient can be moved to a head-up position without voluntary movement when the table is tilted. The tilt table also has the advantage of rapidly and safely returning persons with a profound postural drop in blood pressure to the horizontal position. Persons with a drop in blood pressure to orthostatic levels should be evaluated to determine the cause and seriousness of the condition. A history should be done to elicit information about symptoms, particularly dizziness and history of syncope and falls; medical conditions, particularly those such as diabetes mellitus that predispose to orthostatic hypotension; use of prescription and over-the-counter drugs; and symptoms of autonomic nervous system dysfunction, such as impotence or bladder dysfunction. A physical examination should document blood pressure in both arms and the heart rate while the patient is in the supine, sitting, and standing positions and should note the occurrence of symptoms. Noninvasive, 24-hour ambulatory blood pressure monitoring may be used to determine blood pressure responses to other stimuli of daily life, such as food ingestion and exertion.

Treatment of orthostatic hypotension usually is directed toward alleviating the cause or, if this is not possible, helping people learn ways to cope with the disorder and prevent falls and injuries. Medications that predispose to postural hypotension should be avoided. Other measures include preventing or correcting the fluid deficit and avoidance of situations that encourage excessive vasodilatation (*e.g.*, drinking alcohol, exercising vigorously in a warm environment). Measures designed to help persons prevent symptomatic orthostatic drops in blood pressure include gradual ambulation (*i.e.*, sitting on the edge of the bed for several minutes and moving the legs to initiate skeletal muscle pump function before standing). Elastic support hose or an abdominal support garment may help prevent pooling of blood in the lower extremities and abdomen.

Pharmacologic treatment may be used when nonpharmacologic methods are unsuccessful. A number of types of drugs can be used for this purpose.³² Mineralocorticoids can be used to reduce salt and water loss. Vasopressin-2 receptor agonists (desmopressin as a nasal spray) may be used to reduce nocturnal polyuria. Sympathomimetic drugs that act directly on the resistance vessels or on the capacitance vessels may be used. Many of these agents have undesirable side effects.

In summary, orthostatic hypotension refers to an abnormal decrease in systolic and diastolic blood pressures that occurs on assumption of the upright position. An important consideration in orthostatic hypotension is the occurrence of dizziness and syncope. Among the factors that contribute to its occurrence are decreased fluid volume, medications, aging, defective function of the autonomic nervous system, and the effects of immobility. Diagnosis of orthostatic hypotension includes blood pressure measurement in the supine and upright positions, a history of symptomatology, medication use, and disease conditions that contribute to a postural drop in blood pressure. Treatment includes correcting the reversible causes and assisting the person to compensate for the disorder to prevent falls and injuries.

REVIEW QUESTIONS

Explain how cardiac output and peripheral vascular resistance interact in determining systolic and diastolic blood pressure.

Explain the difference between the essential and secondary forms of hypertension.

Cite some of the major contributing factors in the development of hypertension.

Cite the risks of hypertension in terms of target organ damage.

Explain the changes in blood pressure that accompany normal pregnancy and describe the four types of hypertension that can occur during pregnancy.

Cite the criteria for the diagnosis of high blood pressure in children.

Define systolic hypertension, characterize the effect of increased systolic and pulse pressure on the production of target organ damage, and explain why systolic hypertension is more common in the elderly.

Define the term orthostatic hypotension.

Explain how fluid deficit, medications, aging, disorders of the autonomic nervous system, and bed rest contribute to the development of orthostatic hypotension

eart disease remains a leading cause of death and disability in the United States and throughout the world. Currently, it is the number one cause of death in the United States. It is also the leading cause of permanent disability in the U.S. labor force and accounts for 19% of Social Security disability payments.¹ By the year 2020, it is projected that cardiovascular disease will, for the first time in human history, be the most common cause of death worldwide.²

In an attempt to focus on common heart problems that affect persons in all age groups, this chapter is organized into five sections: disorders of the pericardium, coronary heart disease, myocardial and endocardial diseases, valvular heart disease, and heart disease in infants and children.

DISORDERS OF THE PERICARDIUM

The pericardium is a double-layered serous membrane that isolates the heart from other thoracic structures, maintains its position in the thorax, and prevents it from overfilling. The two layers of the pericardium are separated by a thin layer of serous fluid, which prevents frictional forces from developing as the inner visceral layer, or epicardium, comes in contact with the outer parietal layer of the fibrous pericardium.

The pericardium is subject to many of the same pathologic processes (*e.g.*, congenital disorders, infections, trauma, immune mechanisms, and neoplastic disease) that affect other structures of the body. Pericardial disorders frequently are

KEY CONCEPTS

DISORDERS OF THE PERICARDIUM

- The pericardium isolates the heart from other thoracic structures, maintains its position in the thorax, and prevents it from overfilling.
- The two layers of the pericardium are separated by a thin layer of serous fluid, which prevents frictional forces from developing between the visceral and parietal layers of the pericardium.
- Disorders that produce inflammation of the pericardium interfere with the friction-reducing properties of the pericardial fluid and produce pain.
- Disorders that increase the fluid volume of the pericardial sac interfere with cardiac filling and produce a subsequent reduction in cardiac output.

associated with or result from another disease within the heart or in the surrounding structures.

Pericardial Effusion

Pericardial effusion refers to the accumulation of fluid in the pericardial cavity. Normally, there is about 30 to 50 mL of thin, clear, straw-colored fluid in the pericardial sac. The amount of fluid, the rapidity with which it accumulates, and the elasticity of the pericardium determine the effect the effusion has on cardiac function. Small pericardial effusions may produce no symptoms or abnormal clinical findings. Even a large effusion that develops slowly may cause few or no symptoms, provided the pericardium is able to stretch and avoid compressing the heart. However, a sudden accumulation of even 200 mL may raise intracardiac pressure to levels that seriously limit the venous return to the heart. Symptoms of cardiac compression also may occur with relatively small accumulations of fluid when the pericardium has become thickened by scar tissue or neoplastic infiltrations.

Cardiac tamponade represents an increase in intrapericardial pressure caused by an accumulation of fluid or blood in the pericardial sac. It can occur as the result of conditions such as trauma, cardiac surgery, cancer, uremia, or cardiac rupture caused by myocardial infarction. The seriousness of cardiac tamponade results from impairment in diastolic filling and reduction in stroke volume and cardiac output. The severity of the condition depends on the amount of fluid that is present and the rate at which it accumulated. A rapid accumulation of fluid results in an elevation of central venous pressure, jugular venous distention, a decline in venous return to the heart, a decrease in cardiac output despite an increase in heart rate, a fall in systolic blood pressure, pulsus paradoxus, and signs of circulatory shock.

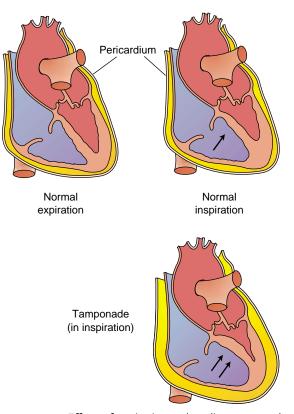

Pulsus paradoxus, which refers to an exaggeration (>10 mm Hg) of the normal (2 to 4 mm Hg) decrease in systolic blood pressure that occurs during inspiration, is a clinical indicator of cardiac tamponade. The decreased intrathoracic pressure that occurs during inspiration normally accelerates venous flow, increasing

right atrial and right ventricular filling. This causes the interventricular septum to bulge to the left, producing a decrease in left ventricular filling, stroke volume output, and systolic blood pressure. In cardiac tamponade, the left ventricle is compressed from within by movement of the interventricular septum and from without by fluid in the pericardium (Fig. 17-1). This produces a marked decrease in left ventricular filling and left ventricular stroke volume output, often within a beat of the beginning of inspiration.

The echocardiogram is a rapid, accurate, and widely used method for evaluating pericardial effusion. Aspiration and laboratory analysis of the pericardial fluid may be used to identify the causative agent. Cardiac catheterization may be used to determine the hemodynamic effects of pericardial effusion and cardiac tamponade. Pericardiocentesis, the removal of fluid from the pericardial sac, may be a lifesaving measure in severe cardiac tamponade.

Pericarditis

Pericarditis represents an inflammatory process of the pericardium.³ It can result from a number of diverse causes. Most forms of pericarditis occur secondary to other systemic or car-

■ FIGURE 17-1 ■ Effects of respiration and cardiac tamponade on ventricular filling and cardiac output. During inspiration venous flow into the right heart increases, causing the interventricular septum to bulge into the left ventricle. This produces a decrease in left ventricular volume, with a subsequent decrease in stroke volume output. In cardiac tamponade, the fluid in the pericardial sac produces further compression of the left ventricle, causing an exaggeration of the normal inspiratory decrease in stroke volume and systolic blood pressure.

diac disease. Primary pericarditis is unusual and most often of viral origin. Most causes of pericarditis evoke an acute pericarditis. Exceptions are tuberculosis and fungal infections, which often produce chronic reactions.⁴

Acute Pericarditis

Acute pericarditis can be classified according to cause (*e.g.*, infections, trauma, rheumatic fever) or the nature of the exudate (*e.g.*, serous, fibrinous, purulent, hemorrhagic). Like other inflammatory conditions, acute pericarditis often is associated with increased capillary permeability. The capillaries that supply the serous pericardium become permeable, allowing plasma proteins, including fibrinogen, to leave the capillaries and enter the pericardial space. This results in an exudate that varies in type and amount according to the causative agent. Acute pericarditis frequently is associated with a fibrinous (fibrin-containing) exudate, which heals by resolution or progresses to deposition of scar tissue and formation of adhesions between the layers of the serous pericardium (Fig. 17-2). Inflammation also may involve the superficial myocardium and the adjacent pleura.

Viral infection (especially infections with the coxsackieviruses and echoviruses, but also influenza, Epstein-Barr, varicella, hepatitis, mumps, and human immunodeficiency viruses) is one of the most common causes of acute pericarditis. Viral pericarditis is seen more frequently in men than in women. It is commonly preceded by a prodromal phase during which fever, malaise, and other flulike symptoms are present. Often it is preceded by an upper respiratory tract infection. Although the acute symptoms of viral pericarditis usually subside in several weeks, easy fatigability often continues for several months.

■ FIGURE 17-2 ■ Fibrinous pericarditis. The heart of a patient who died of uremia displays a shaggy, fibrinous exudate covering the visceral pericardium. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 585]. Philadelphia: Lippincott Williams & Wilkins)

In many cases, the condition is self-limited, resolving in 2 to 6 weeks. Rarely, it may persist and produce recurrent subacute or chronic disease.

Other causes of acute pericarditis are rheumatic fever, postpericardiotomy syndrome, post-traumatic pericarditis, metabolic disorders (*e.g.*, uremia, myxedema), and pericarditis associated with connective tissue diseases (*e.g.*, systemic lupus erythematosus, rheumatoid arthritis). With the increased use of open-heart surgery in the treatment of various heart disorders, postpericardiotomy syndrome has become a commonly recognized form of pericarditis. Pericarditis with effusion is a common complication in persons with renal failure, in those with untreated uremia, and in those being treated with hemodialysis. Irradiation may initiate a subacute pericarditis, with an onset usually within the first year of therapy. It is most commonly associated with high doses of radiation delivered to areas near the heart.

The manifestations of acute pericarditis include a triad of chest pain, pericardial friction rub, and serial electrocardiographic (ECG) changes. The clinical findings and other manifestations may vary according to the causative agent. Nearly all persons with acute pericarditis have chest pain. The pain usually is abrupt in onset, occurs in the precordial area, and is described as sharp. It may radiate to the neck, back, abdomen, or side. It typically is worse with deep breathing, coughing, swallowing, and positional changes because of changes in venous return and cardiac filling. A pericardial friction rub results from the rubbing and friction between the inflamed pericardial surfaces. Serial ECGs are useful in differentiating acute pericarditis from myocardial infarction. Treatment of acute pericarditis depends on the cause. When infection is present, antibiotics specific for the causative agent usually are prescribed. Anti-inflammatory drugs such as aspirin and nonsteroidal anti-inflammatory agents (NSAIDs) may be given to minimize the inflammatory response and the accompanying undesirable effects.

Chronic Pericarditis With Effusion

Chronic pericarditis with effusion is characterized by an increase in inflammatory exudate that continues beyond the acute period. In some cases, the exudate persists for several years. The process commonly is associated with other forms of heart disease, such as rheumatic fever, congenital heart lesions, or hypertensive heart disease. Systemic diseases, such as lupus erythematosus, rheumatoid arthritis, and scleroderma also are causes of chronic pericarditis, as are metabolic disturbances associated with acute and chronic renal failure. In most cases of chronic pericarditis, no specific pathogen or cause can be identified. Unlike with acute pericarditis, the signs and symptoms of chronic pericarditis often are minimal, with the condition being detected for the first time on a routine chest x-ray film. As the condition progresses, the fluid may accumulate and compress the adjacent cardiac structures and impair cardiac filling.

Constrictive Pericarditis

In constrictive pericarditis, fibrous scar tissue develops between the visceral and parietal layers of the serous pericardium. In time, the scar tissue contracts and interferes with diastolic filling of the heart, at which point cardiac output and cardiac reserve becomes fixed. Ascites is a prominent early finding and may be accompanied by pedal edema, dyspnea on exertion, and fatigue. The jugular veins also are distended. Surgical removal of the pericardium may be necessary in persons with severe compromise of cardiac function.

In summary, Disorders of the pericardium include pericardial effusion, acute and chronic pericarditis, and constrictive pericarditis. Pericardial effusion, which refers to the presence of an exudate in the pericardial cavity, can increase intracardiac pressure, compress the heart, and interfere with venous return to the heart. Cardiac tamponade is a life-threatening cardiac compression resulting from excess fluid in the pericardial sac. Acute pericarditis is characterized by chest pain, ECG changes, and a friction rub. Among its causes are infections, uremia, rheumatic fever, connective tissue diseases, and myocardial infarction. In constrictive pericarditis, scar tissue develops between the visceral and parietal layers of the serous pericardium. In time, the scar tissue contracts and interferes with cardiac filling.

CORONARY HEART DISEASE

The term *coronary heart disease* (CHD) describes heart disease caused by impaired coronary blood flow. In most cases, CHD is caused by atherosclerosis. Diseases of the coronary arteries can cause angina, myocardial infarction or heart attack, cardiac dysrhythmias, conduction defects, heart failure, and sudden death. Heart attack is the largest killer of American men and women, claiming more than 218,000 lives annually.¹ Each year, 1.5 million Americans have new or recurrent heart attacks, and one third of those die within the first hour, usually as the result of cardiac arrest resulting from ventricular fibrillation.

During the past 50 years, there have been phenomenal advances in understanding the pathogenesis of CHD and in the development of diagnostic techniques and treatment methods for disease. However, declines in morbidity and mortality have failed to keep pace with these scientific advances, probably because many of the outcomes are more dependent on lifestyle factors and age than on scientific advances.

Coronary Circulation

There are two main coronary arteries, the left and the right, which arise from the coronary sinus just above the aortic valve (Fig. 17-3). The left coronary artery extends for approximately 3.5 cm as the left main coronary artery and then divides into the anterior descending and circumflex branches. The left anterior descending artery passes down through the groove between the two ventricles, giving off diagonal branches, which supply the left ventricle, and perforating branches, which supply the anterior portion of the interventricular septum and the anterior papillary muscle of the left ventricle. The circumflex branch of the left coronary artery passes to the left and moves posteriorly in the groove that separates the left atrium and ventricle, giving off branches that supply the left lateral wall of the left ventricle. The *right coronary artery* lies in the right atrioventricular groove, and its branches supply the right ventricle. The sinoatrial node usually is supplied by the right coronary artery. The right coronary artery usually moves to the back of the heart, where it forms the *posterior descending artery*, which supplies the posterior portion of the heart (the interventricular septum, atrioventricular [AV] node, and posterior papillary muscle). In 10% to 20% of persons, the left circumflex, rather than the right coronary artery, moves posteriorly to form the posterior descending artery.

Although there are no connections between the large coronary arteries, there are anastomotic channels that join the small arteries (Fig. 17-4). With gradual occlusion of the larger vessels, the smaller collateral vessels increase in size and provide alternative channels for blood flow.⁵ One of the reasons CHD does

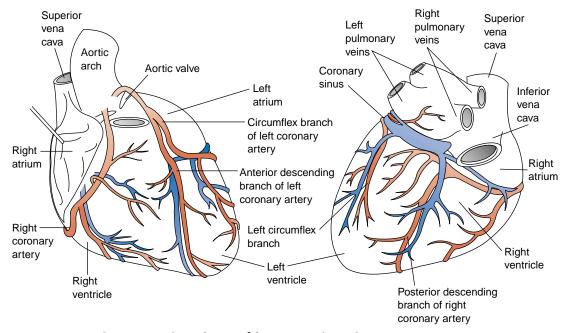

FIGURE 17-3 Coronary arteries and some of the coronary sinus veins.

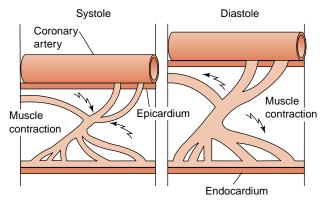

not produce symptoms until it is far advanced is that the collateral channels develop at the same time the atherosclerotic changes are occurring.

The openings for the coronary arteries originate in the root of the aorta just outside the aortic valve; thus, the primary factor responsible for perfusion of the coronary arteries is the aortic blood pressure. Changes in aortic pressure produce parallel changes in coronary blood flow.

In addition to generating the aortic pressure that moves blood through the coronary vessels, the contracting heart muscle influences its own blood supply by compressing the intramyocardial and subendocardial blood vessels.5 The large epicardial coronary arteries lie on the surface of the heart, with the smaller intramyocardial coronary arteries branching off and penetrating the myocardium before merging with a network or plexus of subendocardial vessels that supply the endocardium. During systole, contraction of the cardiac muscle compresses the intramyocardial vessels that feed the subendocardial plexus, and the increased pressure in the ventricle causes further compression of these vessels (Fig. 17-5). As a result, blood flow through the subendocardial vessels occurs mainly during diastole. Thus, there is increased risk of subendocardial ischemia and infarction when diastolic pressure is low, when a rapid heart rate decreases the time spent in diastole, and when an elevation in diastolic intraventricular pressure is sufficient to compress the vessels in the subendocardial plexus.5,6

Heart muscle relies primarily on fatty acids and aerobic metabolism to meet its energy needs. Although the heart can engage in anaerobic metabolism, this process relies on the continuous delivery of glucose and results in the formation of large amounts of lactic acid. Blood flow usually is regulated by the need of the cardiac muscle for oxygen. Even under normal rest-

■ FIGURE 17-5 ■ The compressing effect of the contracting myocardium on intramyocardial blood vessels and subendocardial blood flow during systole and diastole.

ing conditions, the heart extracts and uses 60% to 80% of oxygen in blood flowing through the coronary arteries, compared with the 25% to 30% extracted by skeletal muscle.5 Because there is little oxygen reserve in the blood, myocardial ischemia develops when the coronary arteries are unable to dilate and increase blood flow during periods of increased activity or stress.

Pathogenesis of Coronary Heart Disease

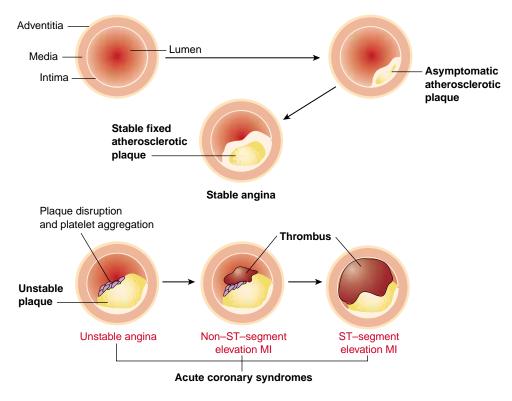

Atherosclerosis (discussed in Chapter 15) is by far the most common cause of CHD, and atherosclerotic plague disruption the most frequent cause of myocardial infarction and sudden death. More than 90% of persons with CHD have coronary atherosclerosis.4 Most, if not all, have one or more lesions causing at least 75% reduction in cross-sectional area, the point at which augmented blood flow provided by compensatory vasodilation no longer is able to keep pace with even moderate increases in metabolic demand.4

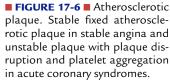

Atherosclerosis can affect one or all three of the major epicardial coronary arteries and their branches (i.e., one-, two-, or three-vessel disease). Clinically significant lesions may be located anywhere in these vessels but tend to predominate in the first several centimeters of the left anterior descending and left circumflex or the entire length of the right coronary artery.⁴ Sometimes the major secondary branches also are involved.

There are two types of atherosclerotic lesions: the *fixed* or stable plaque, which obstructs blood flow, and the unstable or vulnerable plaque, which can rupture and cause platelet adhesion and thrombus formation. The fixed or stable plaque is commonly implicated in chronic ischemic heart disease (stable angina, variant or vasospastic angina, and silent myocardial ischemia) and the unstable plaque in unstable angina and myocardial infarction (Fig. 17-6).

Atherosclerotic plaques are made up of a soft lipid-rich core with a fibrous cap. Plaques with a thin fibrous cap overlying a large lipid core are at greatest risk for rupture. Plaque disruption may occur with or without thrombosis. When the plaque injury is mild, intermittent thrombotic occlusions may occur and cause episodes of anginal pain at rest. More extensive thrombus formation can progress until the coronary artery becomes occluded, leading to myocardial infarction. Platelets play a major role in linking plaque disruption to acute CHD. As a part of the response to plaque disruption, platelets aggregate and release

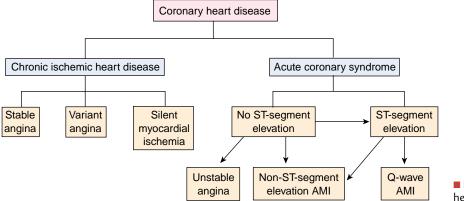

substances that further propagate platelet aggregation, vasoconstriction, and thrombus formation. Because of the role that platelets play in the pathogenesis of CHD, antiplatelet drugs (*e.g.*, low-dose aspirin) are frequently used for preventing heart attack.

There are two types of thrombi formed as a result of plaque disruption: white platelet-containing thrombi and red fibrincontaining thrombi. The thrombi in unstable angina have been characterized as grayish-white and presumably platelet rich.⁴ Red thrombi, which develop with vessel occlusion in myocardial infarction, are rich in fibrin and red blood cells superimposed on the platelet component and extended by the stasis of blood flow.

Coronary heart disease is commonly divided into two types of disorders: chronic ischemic heart disease and the acute coronary syndromes (Fig. 17-7). There are three types of chronic ischemic heart disease: chronic stable angina, variant or vasospastic angina, and silent myocardial ischemia. The acute coronary syndromes represent the spectrum of ischemic coronary disease ranging from unstable angina through myocardial infarction.

Chronic Ischemic Heart Disease

The term *ischemia* means "to suppress or withhold blood flow." Limitations in coronary blood flow most commonly are the result of atherosclerosis, with vasospasm and thrombosis as contributing factors. The metabolic demands of the heart are increased with everyday activities such as mental stress, exercise, and exposure to cold. In certain disease states such as thyrotoxicosis, the metabolic demands may be so excessive that the blood flow may be inadequate despite normal coronary arteries. In other situations, such as aortic stenosis, the coronary arteries may not be diseased, but the perfusion pressure may be insufficient to provide adequate blood flow.

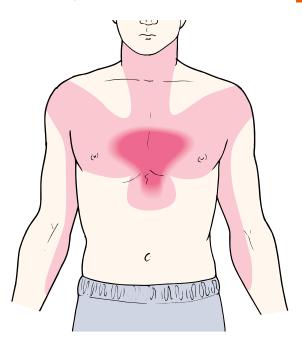

Chapter 17: Alterations in Cardiac Function 297

KEY CONCEPTS

ISCHEMIC HEART DISEASE

- The term ischemic heart disease refers to disorders in coronary blood flow due to stable or unstable atherosclerotic plaques.
- Stable atherosclerotic plaques produce fixed obstruction of coronary blood flow, with myocardial ischemia occurring during periods of increased metabolic need, such as in stable angina.
- Unstable atherosclerotic plaques tend to fissure or rupture, causing platelet aggregation and potential for thrombus formation with production of a spectrum of acute coronary syndromes of increasing severity, ranging from unstable angina, to non-ST-segment elevation myocardial infarction, to ST-segment elevation myocardial infarction.

■ FIGURE 17-8 ■ Areas of pain due to angina.

Stable Angina

The term *angina* is derived from a Latin word meaning "to choke." Angina pectoris is characterized by recurring episodes of chest pain or pressure sensation associated with transient myocardial ischemia. Stable angina is the initial manifestation of ischemic heart disease in approximately half of persons with CHD.⁷ Although most persons with stable angina have atherosclerotic heart disease; angina does not develop in a considerable number of persons with advanced coronary atherosclerosis. This probably is because of their sedentary lifestyle, the development of adequate collateral circulation, or the inability of these persons to perceive pain. In many instances, myocardial infarction occurs without a history of angina.

Stable angina is usually precipitated by situations that increase the work demands of the heart, such as physical exertion, exposure to cold, and emotional stress. The pain typically is described as a constricting, squeezing, or suffocating sensation. It usually is steady, increasing in intensity only at the onset and end of the attack. The pain of angina commonly is located in the precordial or substernal area of the chest; it is similar to myocardial infarction in that it may radiate to the left shoulder, jaw, arm, or other areas of the chest (Fig. 17-8). In some persons, the arm or shoulder pain may be confused with arthritis; in others, epigastric pain is confused with indigestion. Angina commonly is categorized according to whether it occurs with exercise or during rest, is of new onset, or is of increasing severity.

The diagnosis of stable angina is based on a detailed pain history and the presence of risk factors. Typically, chronic stable angina is provoked by exertion or emotional stress and relieved within minutes by rest or the use of nitroglycerin. A delay of more than 5 to 10 minutes before relief is obtained suggests that the symptoms are not caused by ischemia or that they are caused by severe ischemia.⁸ Angina that occurs at rest, is of new onset, or is increasing in intensity or duration denotes an increased risk for myocardial infarction and should be evaluated using the criteria for acute coronary syndromes. Noncoronary causes of chest pain, such as that caused by esophageal or musculoskeletal disorders, are excluded. ECG, echocardiography, exercise stress testing or pharmacologic imaging studies, and coronary angiography may be used to confirm the diagnosis and describe the type of angina (exercise vs. vasospastic).

The treatment goals for stable angina are directed toward prevention of myocardial infarction and symptom reduction.⁷ Both nonpharmacologic and pharmacologic treatment methods are used. Nonpharmacologic methods are aimed at symptom control and lifestyle modifications to lower risk factors for coronary disease. They include smoking cessation in persons who smoke, stress reduction, a regular exercise program, limiting dietary intake of cholesterol and saturated fats, weight reduction if obesity is present, and avoidance of cold or other stresses that produce vasoconstriction. Immediate cessation of activity often is sufficient to abort an anginal attack. Sitting down or standing quietly may be preferable to lying down because these positions decrease preload by producing pooling of blood in the lower extremities.

Pharmacologic methods include the use of antiplatelet drugs, β -adrenergic blocking drugs, calcium channel blockers, and/or long-acting nitrates. Sublingual nitroglycerin or nitroglycerin spray may be prescribed for immediate relief of anginal pain. Coronary artery bypass surgery or percutaneous transluminal coronary angioplasty may be indicated in persons with significant coronary artery occlusion (to be discussed).

Variant Angina

The syndrome of variant angina or *Prinzmetal's angina* was first described by the American cardiologist Myron Prinzmetal and associates in 1959.⁹ Subsequent evidence indicated variant angina is caused by spasms of the coronary arteries, so the condition is often referred to as *vasospastic angina*.¹⁰ In most instances, the spasms occur in the presence of coronary artery stenosis; however, variant angina has occurred in the absence of visible disease.

298 Unit Four: Alterations in the Cardiovascular System

Unlike stable angina that occurs with exertion or stress, variant angina usually occurs during rest or with minimal exercise and frequently occurs during sleep. It commonly follows a cyclic or regular pattern of occurrence (*e.g.*, it happens at the same time each day). Dysrhythmias often occur when the pain is severe, and most persons are aware of their presence during an attack. ECG changes are significant if recorded during an attack. Persons with variant angina who have serious dysrhythmias during spontaneous episodes of pain are at a higher risk of sudden death.

Persons with variant angina usually experience response to treatment with calcium antagonists. These agents, along with short- and long-term nitrates, are the mainstay of treatment of variant angina. Because the two drugs act through different mechanisms, their beneficial effects may be additive.

Silent Myocardial Ischemia

Silent myocardial ischemia occurs in the absence of anginal pain. The factors that cause silent myocardial ischemia appear to be the same as those responsible for angina: impaired blood flow from the effects of coronary atherosclerosis or vasospasm. Silent myocardial ischemia affects three populations: persons who are asymptomatic without other evidence of CHD, persons who have had a myocardial infarct and continue to have episodes of silent ischemia, and persons with angina who also have episodes of silent ischemia.11 The reason for the painless episodes of ischemia is unclear. The episodes may be shorter and involve less myocardial tissue than those producing pain. Another explanation is that persons with silent angina have defects in pain threshold or pain transmission, or autonomic neuropathy with sensory denervation. There is evidence of an increased incidence of silent myocardial ischemia in persons with diabetes mellitus, probably the result of autonomic neuropathy, which is a common complication of diabetes.12

Acute Coronary Syndromes

The term *acute coronary syndromes* (ACS) has recently been accepted to describe the spectrum of acute ischemic heart diseases that include (1) unstable angina, (2) non–ST-segment elevation (non–Q-wave) myocardial infarction, and (3) ST-segment elevation (Q-wave) myocardial infarction^{13,14} (Fig. 17-9).

Persons with an ACS are routinely classified as low risk or high risk based on presenting characteristics, ECG variables, serum cardiac markers, and the timing of presentation. Persons with ST-segment elevation on ECG are usually found to have complete coronary occlusion on angiography, and many ultimately have Q-wave myocardial infarction. Persons without ST-segment elevation are those in which coronary occlusion is subtotal or intermittent.

Unstable Angina/Non–ST-Segment Elevation Myocardial Infarction

Unstable angina is characterized by symptoms at rest (usually prolonged, *i.e.*, >20 minutes); new-onset (<2 months) exertional angina; or recent (<2 months) acceleration in angina severity.¹⁵ It is considered to be a clinical syndrome of myocardial ischemia ranging between stable angina and myocardial infarction. Unlike chronic stable angina, which is caused by a fixed obstruction, unstable angina most frequently results from atherosclerotic plaque disruption and repair. Unstable angina

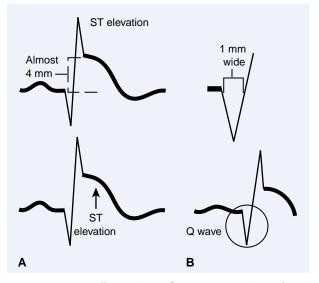

FIGURE 17-9 Illustration of an ECG tracing showing ST-segment elevation (\mathbf{A}) and Q wave in acute coronary syndromes (\mathbf{B}) .

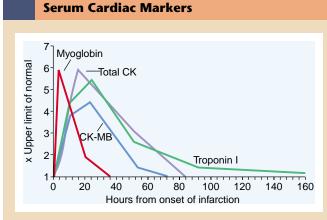

and non–ST-segment elevation myocardial infarction are similar conditions but have different severity.¹⁵ They differ primarily in whether the ischemia is severe enough to cause sufficient myocardial damage to release detectable quantities of serum cardiac markers.

The diagnosis of unstable angina/non–ST-segment elevation myocardial infarction is based on pain severity and presenting symptoms, hemodynamic stability, ECG findings, and serum cardiac markers (see Box 17-1). Persons who have no serum markers for myocardial damage are considered to have unstable angina, whereas those with serum markers are considered to have no–ST-segment elevation myocardial infarction. When chest pain has been unremitting for longer than 20 minutes, the possibility of ST-segment elevation myocardial infarction usually is considered.¹³

ST-Segment Elevation Myocardial Infarction

Acute myocardial infarction (AMI), also known as a heart attack, is characterized by the ischemic death of myocardial tissue associated with atherosclerotic disease of the coronary arteries. Elevation of the ST segment usually indicates acute myocardial injury. When the ST segment is elevated without associated Q waves, it is called a *non–Q-wave infarction*. A non–Q-wave infarction usually represents a small infarct that may evolve into a larger infarct. The area of infarction is determined by the coronary artery that is affected and by its distribution of blood flow. Approximately 30% to 40% of infarcts affect the right coronary artery, 40% to 50% affect the left anterior descending artery, and the remaining 15% to 20% affect the left circumflex artery.⁴

The onset of AMI usually is abrupt, with pain as the significant symptom. The pain typically is severe and crushing, often described as being constricting, suffocating, or like "someone sitting on my chest." It usually is substernal, radiating to the left arm, neck, or jaw, although it may be experienced in other areas of the chest. Unlike that of angina, the pain associated

The relative timing, rate of rise, peak values, and duration of cardiac marker elevation above the upper limit of normal for multiple serum markers following AMI. (Modified from Antman E.M. [1994]. General hospital management. In Julian D.G. & Braunwald E. [Eds.], *Management of acute myocardial infarction* [p. 63]. London: W.B. Saunders Ltd.).

Myoglobin is an oxygen-carrying protein, similar to hemoglobin, that is normally present in cardiac and skeletal muscle. It is a small molecule that is released quickly from infarcted myocardial tissue and becomes elevated within 1 hour after myocardial cell death, with peak levels reached within 4 to 8 hours. Because myoglobin is present in both cardiac and skeletal muscle, it is not cardiac specific.

- Creatine kinase (CK), formerly called creatinine phosphokinase, is an intracellular enzyme found in muscle cells. Muscles, including cardiac muscle, use adenosine triphosphate (ATP) as their energy source. Creatine, which serves as a storage form of energy in muscle, uses CK to convert ADP to ATP. CK exceeds normal range within 4 to 8 hours of myocardial injury and declines to normal within 2 to 3 days. There are three isoenzymes of CK, with the MB isoenzyme (CK-MB) being highly specific for injury to myocardial tissue.
- The troponin complex consists of three subunits (i.e., troponin C, troponin I, and troponin T) that regulate calcium-mediated contractile process in striated muscle. These subunits are released during myocardial infarction. Cardiac muscle forms of both troponin T and troponin I are used in diagnosis of myocardial infarction. Troponin I (and troponin T; not shown) rises more slowly than myoglobin and may be useful for diagnosis of infarction, even up to 3 to 4 days after the event. It is thought that cardiac troponin assays are more capable of detecting episodes of myocardial infarction in which cell damage is below that detected by CK-MB level.

with myocardial infarction is more prolonged and not relieved by rest or nitroglycerin, and narcotics frequently are required. Women often experience atypical ischemic-type chest discomfort, whereas the elderly may report shortness of breath more frequently than chest pain.¹⁶

Gastrointestinal complaints are common. There may be a sensation of epigastric distress; nausea and vomiting may occur. Reports of fatigue and weakness, especially of the arms and legs, are common. Pain and sympathetic stimulation combine to give rise to tachycardia, anxiety, restlessness, and feelings of impending doom. The skin often is pale, cool, and moist. The impaired myocardial function may lead to hypotension and shock.

Sudden death from AMI is death that occurs within 1 hour of symptom onset. It usually is attributed to fatal dysrhythmias, which may occur without evidence of infarction. Approximately 30% to 50% of persons with AMI die of ventricular fibrillation within the first few hours after symptoms begin.¹⁶ Early hospitalization after onset of symptoms greatly improves chances of averting sudden death because appropriate resuscitation facilities are immediately available when potentially fatal ventricular dysrhythmias occur.

Pathologic Changes. The extent of the infarct depends on the location and degree of occlusion, amount of heart tissue supplied by the vessel, duration of the occlusion, metabolic needs of the affected tissue, extent of collateral circulation, and other factors such as heart rate, blood pressure, and cardiac rhythm. A myocardial infarct may involve the endocardium, myocardium, epicardium, or a combination of these. *Transmural infarcts* involve the full thickness of the ventricular wall and most commonly occur when there is obstruction of a single artery.⁴ *Subendocardial infarcts* involve the inner one third to one half of the ventricular wall and occur more frequently in the presence of severely narrowed but still patent arteries. Most infarcts are transmural, involving the free wall of the left ventricle and often the interventricular septum (Fig. 17-10).

The principal biochemical consequence of AMI is the conversion from aerobic to anaerobic metabolism with inadequate production of energy to sustain normal myocardial function. Although gross tissue changes are not apparent for hours after onset of an AMI, the ischemic area ceases to function within a matter of minutes, and irreversible myocardial cell damage occurs after 20 to 40 minutes of severe ischemia.⁴

The term *reperfusion* refers to re-establishment of blood flow through use of thrombolytic therapy or revascularization procedures. Early reperfusion (within 15 to 20 minutes) after onset of ischemia can prevent necrosis. Reperfusion after a longer interval can salvage some of the myocardial cells that would have died because of longer periods of ischemia. Even though much of the viable myocardium existing at the time of reflow ultimately recovers, critical abnormalities in biochemical function may persist, causing impaired ventricular function. The recovering area of the heart is often referred to as a *stunned myocardium*. Because myocardial function is lost before cell death occurs, a stunned myocardium may not be capable of sustaining life, and persons with large areas of dysfunctional myocardium may require life support until the stunned regions regain their function.⁴

■ FIGURE 17-10 ■ Acute myocardial infarct. A cross-section of the ventricles of a man who died a few days after the onset of severe chest pain shows a transmural infarct in the posterior and septal regions of the left ventricle. The necrotic myocardium is soft, yellowish, and sharply demarcated. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 558]. Philadelphia: Lippincott Williams & Wilkins)

Myocardial cells that undergo necrosis are gradually replaced with scar tissue. An acute inflammatory response develops in the area of necrosis approximately 2 to 3 days after infarction. Thereafter, macrophages begin removing the necrotic tissue; the damaged area is gradually replaced with an ingrowth of highly vascularized granulation tissue, which gradually becomes less vascular and more fibrous.⁴ At approximately 3 to 7 days, the center of the infarcted area is soft and yellow; if rupture of the ventricle, interventricular septum, or valve structures occurs, it usually happens at this time. Replacement of the necrotic myocardial tissue usually is complete by the seventh week. Fibrous scar tissue lacks the contractile, elastic, and conductive properties of normal myocardial cells.

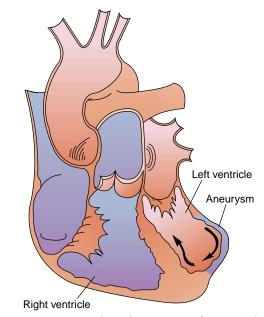

Complications. The size and location of the infarction determine the acute course, clinical complications, and long-term prognosis. Among the early complications of AMI are life-threatening dysrhythmias, sudden death, heart failure, and cardiogenic shock (see Chapter 18). Recurrent infarction may occur in the region of infarction (infarct extension). It may be associated with prolonged or intermittent episodes of chest pain.

Other complications of AMI include pericarditis, development of thromboemboli, rupture of the heart, and formation of ventricular aneurysms. Pericarditis may complicate the course of AMI. It usually appears on the second or third day after infarction. Dressler's syndrome describes the signs and symptoms associated with pericarditis, pleurisy, and pneumonitis: fever, chest pain, dyspnea, and abnormal laboratory test results (*i.e.*, elevated white blood cell count and sedimentation rate) and ECG findings. The symptoms may arise between 1 day and several weeks after infarction and are thought to represent a hypersensitivity response to tissue necrosis. Thromboemboli are a potential complication of AMI, arising as venous thrombi or occasionally as clots from the wall of the ventricle. Immobility and impaired cardiac function contribute to stasis of blood in the venous system. Infrequent, but dreaded, complications of AMI include rupture of the myocardium, the interventricular septum, or a papillary muscle. Complete rupture of the left ventricular wall, which usually occurs 3 to 7 days after AMI when the injured ventricular tissue is soft and weak, usually results in instant death.

An aneurysm is an outpouching of the ventricular wall that develops in 10% to 20% of persons surviving AMI, usually those with anterior Q-wave infarctions.¹⁶ Scar tissue does not have the characteristics of normal myocardial tissue; when a large section of ventricular muscle is replaced by scar tissue, an aneurysm may develop (Fig. 17-11). This section of the myocardium does not contract with the rest of the ventricle during systole. Instead, it diminishes the pumping efficiency of the heart and increases the work of the left ventricle, predisposing the patient to heart failure. Ischemia in the surrounding area predisposes the patient to development of dysrhythmias, and stasis of blood in the aneurysm can lead to thrombus formation. Surgical resection may be performed to improve ventricular function.

Diagnosis and Treatment. Diagnosis of AMI is based on presenting signs and symptoms, ECG charges, and serum cardiac markers. ECG changes may not be present immediately after the onset of symptoms, except as dysrhythmias. The occurrence of dysrhythmias and conduction defects depends on the areas of the heart and conduction pathways that are included in the infarct. Typical ECG changes include ST-segment elevation, prolongation of the Q wave, and inversion of the T wave.

The treatment of ACS depends on the extent of ischemia and/or infarction. Because the specific diagnosis of AMI is often difficult to make at the time of entry into the health care system, the immediate management of all ACS is generally

■ FIGURE 17-11 ■ Paradoxical movement of a ventricular aneurysm during systole.

the same. The American College of Cardiology/American Heart Association (ACC/AHA) Task Force guidelines for management of AMI recommend that the initial emergency department management of myocardial infarction include administration of oxygen by nasal prongs; sublingual nitroglycerin; adequate analgesia; and aspirin (160 to 325 mg).¹⁶ ECG monitoring should be instituted, and a 12-lead electrocardiogram should be performed. The severe pain of AMI gives rise to anxiety and recruitment of autonomic nervous system responses, both of which increase the work demands of the heart. Morphine is often given intravenously for pain relief because it has a rapid onset of action and the intravenous route does not elevate serum enzymes. Aspirin is given for its antiplatelet effects.

Immediate reperfusion therapy, using thrombolytic agents or revascularization procedures, is usually indicated for persons with ECG evidence of infarction. The best results occur if treatment is initiated within 60 to 90 minutes of symptom onset.¹⁷ The magnitude of benefit declines after this period, but it is possible that some benefit can be achieved for as long as 12 hours after the onset of pain.

Thrombolytic agents dissolve blood and platelet clots and are used to reduce mortality and limit infarct size. Revascularization interventions include percutaneous transluminal coronary angioplasty (PTCA), coronary stent implantation, and coronary artery bypass surgery. PTCA involves the recanalization of a stenotic vessel using balloon dilatation (Fig. 17-12). The procedure is done under local anesthesia in the cardiac catheterization laboratory and is similar to cardiac catheterization for coronary angiography. Implantation of coronary stents (fenestrated, stainless-steel tubes) reduces the occurrence of restenosis after PTCA. A new approach to the prevention of coronary restenosis after balloon angioplasty and stent placement is the use of localized intracoronary radiation. The procedure, also known as *brachytherapy*, is credited with inhibiting cell pro-

liferation, vascular lesion formation, and prevention of constrictive arterial remodeling. The radiation source can be impregnated into stents, or the radiation can be delivered by a radiation catheter containing a sealed source of radiation (radioactive seeds, wire, or ribbon) that is inserted into the treatment site and then removed.¹⁸

Coronary artery bypass surgery remains an option for patients who have significant CHD uncontrolled by angioplasty or pharmacologic therapy. In this surgical procedure, revascularization of the myocardium is effected by placing a saphenous vein graft between the aorta and the affected coronary artery distal to the site of occlusion or by using the internal mammary artery as a means of revascularizing the left anterior descending artery or its branches (Fig. 17-13).

Rehabilitation Programs. Rehabilitation programs for persons with ACS incorporate rest, exercise, and risk factor modification. An exercise program is an integral part of a cardiac rehabilitation program. It includes activities such as walking, swimming, and bicycling. These exercises involve changes in muscle length and rhythmic contractions of muscle groups. Most exercise programs are individually designed to meet each person's physical and psychological needs. The goal of the exercise program is to increase the maximal oxygen consumption by the muscle tissues, so that these persons are able to perform more work at a lower heart rate and blood pressure. In addition to

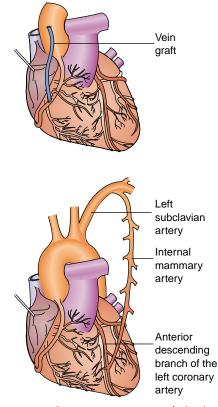

FIGURE 17-13 Coronary artery revascularization. (**Top**) Saphenous vein bypass graft. The vein segment is sutured to the ascending aorta and the right coronary artery at a point distal to the occluding lesion. (**Bottom**) Mammary artery bypass. The mammary artery is anastomosed to the anterior descending left coronary artery, bypassing the obstructing lesion.

exercise, cardiac risk factor modification incorporates strategies for smoking cessation, weight loss, stress reduction, and control of hypertension and diabetes.

In summary, CHD is a disorder of impaired coronary blood flow, usually caused by atherosclerosis. Myocardial ischemia occurs when there is a disparity between coronary blood flow and the metabolic needs of the heart. The *chronic ischemic heart diseases* include stable angina, variant angina, and silent myocardial ischemia. Stable angina is associated with a fixed atherosclerotic obstruction and pain that is precipitated by increased work demands on the heart and relieved by rest. Variant angina results from spasms of the coronary arteries. Silent myocardial ischemia occurs without symptoms. Treatment includes nonpharmacologic methods, such as pacing of activities and avoidance of activities that cause angina, and the use of pharmacologic agents, including aspirin, β -adrenergic blockers, calcium channel blockers, and nitrates.

The acute coronary syndromes result from unstable atherosclerotic plaques with plaque disruption, platelet aggregation, and thrombus formation. They include unstable angina, non–ST-segment elevation AMI, and ST-segment (Q wave) elevation AMI. Unstable angina is an accelerated form of angina in which the pain occurs more frequently, is more severe, and lasts longer than chronic stable angina. AMI refers to the ischemic death of myocardial tissue associated with obstructed blood flow in the coronary arteries. ST-segment elevation and Q wave AMI differ in terms of the extent of myocardial damage. The complications of AMI include potentially fatal dysrhythmias, heart failure and cardiogenic shock, pericarditis, thromboemboli, rupture of cardiac structures, and ventricular aneurysms. Treatment goals focus on the reestablishment of myocardial blood flow through rapid recanalization of the occluded coronary artery, prevention of clot extension through use of aspirin and other antiplatelet and antithrombotic agents, alleviation of pain, and measures such as the administration of oxygen to increase the oxygen saturation of hemoglobin. Thrombolytic agents, PTCA, and coronary artery bypass surgery are measures used to recanalize or bypass the occluded artery.

MYOCARDIAL AND ENDOCARDIAL DISEASE

Myocardial diseases, including myocarditis and the primary cardiomyopathies, are disorders originating in the myocardium, but not from cardiovascular disease. Both myocarditis and the primary cardiomyopathies are causes of sudden death and heart failure.

Myocarditis

The term *myocarditis* is used to describe an inflammation of the heart muscle and conduction system without evidence of myocardial infarction.^{19,20} Viruses are the most important cause of myocarditis in North America and Europe.²⁰ Coxsackieviruses

A and B and other enteroviruses probably account for most of the cases. Myocarditis is a frequent pathologic cardiac finding in persons with acquired immunodeficiency syndrome (AIDS), although it is unclear whether it is caused by the human immunodeficiency virus itself or by a secondary infection. Other causes of myocarditis are radiation therapy, hypersensitivity reactions, or exposure to chemical or physical agents that induce acute myocardial necrosis and secondary inflammatory changes. A drug that is increasingly associated with myocarditis is cocaine, probably because of its vasoconstrictor properties.²⁰

Myocardial injury attributable to infectious agents is thought to result from necrosis caused by direct invasion of the offending organism, toxic effects of exogenous toxins or endotoxins produced by a systemic pathogen, or destruction of cardiac tissue by immunologic mechanisms initiated by the infectious agent. The immunologic response may be directed at foreign antigens of the infectious agent that share molecular characteristics with those of the host cardiac myocardial cells (*i.e.*, molecular mimicry; see Chapter 10), providing a continuous stimulus for the immune response even after the infectious agent has been cleared from the body.

The manifestations of myocarditis vary from an absence of symptoms to profound heart failure or sudden death. When viral myocarditis occurs in children or young adults, it often is asymptomatic. Acute symptomatic myocarditis typically manifests as a flulike syndrome with malaise, low-grade fever, and tachycardia that is more pronounced than would be expected for the level of fever present. There commonly is a history of an upper respiratory tract or gastrointestinal tract infection, followed by a latent period of several days. Cardiac auscultation may reveal an S₃ ventricular gallop rhythm and a transient pericardial or pleurocardial rub. In approximately one half of the cases, myocarditis is transient, and symptoms subside within 1 to 2 months. In other cases, fulminant heart failure and life-threatening dysrhythmias develop, causing sudden death. Still others progress to subacute and chronic disease.

The diagnosis of myocarditis is based on clinical manifestations and ECG changes. Serum creatinine kinase often is elevated. Troponin T or troponin I, or both, may be elevated, providing evidence of myocardial cell damage.²⁰ Confirmation of active myocarditis requires endomyocardial biopsy.

Treatment measures focus on symptom management and prevention of myocardial damage. Bed rest is necessary, and activity restriction must be maintained until fever and cardiac symptoms subside to decrease the myocardial workload. Activity is gradually increased but kept at a sedentary level for 6 months to 1 year. The use of corticosteroids and immunosuppressant drugs remains a matter of controversy. Although treatment of myocarditis is successful in many persons, some experience congestive heart failure and can expect only a limited life span. For these persons, heart transplantation becomes an alternative.

Cardiomyopathies

The cardiomyopathies are a group of disorders that affect the heart muscle. They can develop as primary or secondary disorders. The primary cardiomyopathies, which are discussed in this chapter, are heart muscle diseases of unknown origin. Secondary cardiomyopathies are conditions in which the cardiac abnormality results from another cardiovascular disease, such as myocardial infarction. The onset of the primary cardiomyopathies often is silent, and symptoms do not occur until the disease is well advanced. The diagnosis is suspected when a young, previously healthy, normotensive person experiences cardiomegaly and heart failure.

In 1989, the International Society and Federation of Cardiology and the World Health Organization categorized the primary cardiomyopathies into three groups: dilated, hypertrophic, and restrictive²¹ (Fig. 17-14). This classification was enlarged in 1996 to include arrhythmogenic right ventricular cardiomyopathy.²² Peripartum cardiomyopathy is a disorder of pregnancy.

Dilated Cardiomyopathies

Dilated cardiomyopathies are characterized by progressive cardiac hypertrophy and dilation and impaired pumping ability of one or both ventricles. Although all four chambers of the heart are affected, the ventricles are more dilated than the atria. Because of the wall thinning that accompanies dilation, the thickness of the ventricular wall often is less than would be expected for the amount of hypertrophy present.²³ Mural thrombi are common and may be a source of thromboemboli. The cardiac valves are intrinsically normal. Microscopically, there is evidence of scarring and atrophy of myocardial cells.

Dilated cardiomyopathy may result from a number of different myocardial insults, including infectious myocarditis, alcohol and other toxic agents, metabolic influences, neuromuscular diseases, and immunologic disorders. Genetic influences have been documented in some cases. Often the cause is unknown; these cases are appropriately designated as *idiopathic dilated cardiomyopathy*.

The most common initial manifestations of dilated cardiomyopathy are those related to heart failure. There is a profound reduction in the left ventricular ejection fraction (*i.e.*, ratio of stroke volume to end-diastolic volume) to 40% or less, compared with a normal value of approximately 67%. After symptoms have developed, the course of the disorder is characterized by a worsening of heart failure, development of mural thrombi, and ventricular dysrhythmias. The most striking symptoms of dilated cardiomyopathy are dyspnea on exertion, paroxysmal nocturnal dyspnea, orthopnea, weakness, fatigue, ascites, and peripheral edema. The systolic blood pressure is normal or low, and the peripheral pulses often are of low amplitude. Pulsus alternans, in which the pulse regularly alternates between weaker and stronger volume, may be present. Tachycardia, atrial fibrillation, and complex ventricular dysrhythmias leading to sudden cardiac death are common.

The treatment of dilated cardiomyopathy is directed toward relieving the symptoms of heart failure and reducing the workload of the heart. Digoxin, diuretics, and afterload-reducing drugs are used to improve myocardial contractility and decrease left ventricular filling pressures. Avoiding myocardial depressants, including alcohol, and pacing rest with asymptomatic levels of exercise or activity is imperative. Insertion of an internal cardioverter-defibrillator may be indicated for controlling recurrent ventricular dysrhythmias. In persons with severe heart failure that is refractory to treatment, cardiac transplantation may be considered.

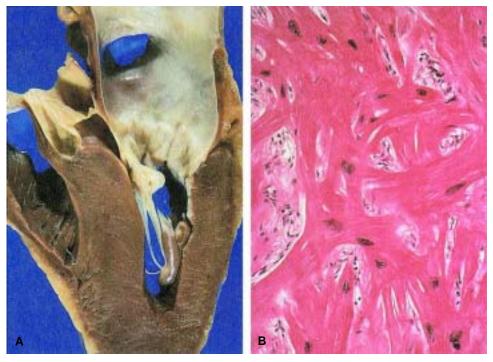

Hypertrophic Cardiomyopathies

Hypertrophic cardiomyopathy is characterized by left, right, or left and right ventricular hypertrophy and abnormal diastolic filling. Although the hypertrophy may be symmetric, the involvement of the ventricular septum often is disproportionate, producing intermittent left ventricular outflow obstruction.²⁴ Synonyms for this disorder include *idiopathic hypertrophic subaortic stenosis* and *asymmetric septal hypertrophy*.

Symptomatic hypertrophic cardiomyopathy commonly is a disease of young adulthood. The cause of the disorder is unknown, although it often is of familial origin, with the disorder being inherited as an autosomal dominant trait. Molecular studies of the genetic alterations responsible for hypertrophic cardiomyopathy suggest that the disease is caused by mutation in one of four genes encoding the proteins of the cardiac muscle fibers.²⁴ More than 50 mutations in these proteins have been identified. The prognosis of persons with different myosin mutations varies greatly; some mutations are relatively benign, whereas others are associated with premature death.

A distinctive microscopic finding in hypertrophic cardiomyopathy is myofibril disarray (Fig. 17-15). Instead of the normal parallel arrangement of myofibrils, the myofibrils branch off at random angles, sometimes at right angles to an adjacent fiber with which they connect. Small bundles of fibers may course haphazardly through normally arranged muscle fibers.^{4,25} These disordered fibers may produce abnormal movements of the ventricles, with uncoordinated contraction and impaired relaxation. Arrhythmias and premature sudden death are common with this disorder. Study results have shown that 36% of young athletes who die suddenly have probable or definite hypertrophic cardiomyopathy.¹

The manifestations of hypertrophic cardiomyopathy are variable; for reasons that are unclear, in some persons, the dis-

■ FIGURE 17-15 ■ Hypertrophic cardiomyopathy. (A) The heart has been opened to show striking asymmetric left ventricular hypertrophy. The interventricular septum is thicker than the free wall of the ventricle and impinges on the outflow tract. (B) A section of the myocardium shows myocardial fiber disarray characterized by oblique and often perpendicular orientation of adjacent hypertrophic myocytes. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 580]. Philadelphia: Lippincott Williams & Wilkins)

order remains stable for many years, with symptoms gradually increasing as the disease progresses, but others experience sudden cardiac death as first evidence of the disease.²⁴ Atrial fibrillation is a common precursor to sudden death in those who die of dysrhythmias. Dyspnea is the most common symptom associated with a gradual elevation in left ventricular diastolic pressure resulting from impaired ventricular filling and increased wall stiffness caused by ventricular hypertrophy. Because of the obstruction to outflow from the left ventricle, increasingly greater levels of ventricular pressure are needed to eject blood into the aorta, limiting cardiac output. Chest pain, fatigue, and syncope are common and worsen during exertion.

The treatment of hypertrophic cardiomyopathy includes medical and surgical management. The goal of medical management is to relieve the symptoms by lessening the pressure difference between the left ventricle and the aorta, thereby improving cardiac output. Drugs that block the β -adrenergic receptors may be used in persons with chest pain, dysrhythmias, or dyspnea.²⁴ These drugs reduce the heart rate and improve myocardial function by allowing more time for ventricular filling and reducing ventricular stiffness. The calcium channelblocking drug verapamil may be used as an alternative to the β -adrenergic blockers. Increased calcium uptake and increased intracellular calcium content are associated with an increased contractile state, a characteristic finding in patients with hypertrophic cardiomyopathy.

Surgical treatment may be used if severe symptoms persist despite medical treatment. It involves incision of the septum with or without the removal of part of the muscle tissue (*i.e.*, myectomy). It is accompanied by all the risks of open heart surgery. Implantable cardioverter-defibrillators may be used to abort lethal arrhythmias.²⁴

Restrictive Cardiomyopathies

Of the three categories of cardiomyopathies, the restrictive type is the least common in Western countries. With this form of cardiomyopathy, ventricular filling is restricted because of excessive rigidity of the ventricular walls, although the contractile properties of the heart remain relatively normal. The condition is endemic in parts of Africa, India, South and Central America, and Asia.²⁶ Outside the tropics, the most common causes of restrictive cardiomyopathy are endocardial infiltrations such as amyloidosis. Amyloid infiltrations of the heart are common in the elderly. The idiopathic form of the disorder may have a familial origin.

Symptoms of restrictive cardiomyopathy include dyspnea, paroxysmal nocturnal dyspnea, orthopnea, peripheral edema, ascites, fatigue, and weakness. The manifestations of restrictive cardiomyopathy resemble those of constrictive pericarditis. In the advanced form of the disease, all the signs of heart failure are present except cardiomegaly.

Arrhythmogenic Right Ventricular Cardiomyopathy

In arrhythmogenic right ventricular cardiomyopathy, the right ventricular myocardium is replaced with a fibrofatty deposit. This condition frequently has a familial predisposition, with an autosomal dominant inheritance pattern. Sudden death caused by arrhythmias is common, particularly in the young.²²

Peripartum Cardiomyopathy

Peripartum cardiomyopathy refers to left ventricular dysfunction developing during the last month before delivery to 5 months after delivery. The condition is relatively rare, with an estimated incidence of 1 per 3000 to 4000 live birth pregnancies.²⁷ Risk factors for peripartum cardiomyopathy include advanced maternal age, African-American race, multifetal pregnancies, preeclampsia, and gestational hypertension.²⁷ The reported mortality rate ranges from 18% to 56%. Survivors may not recover completely and may require heart transplantation.

The cause of peripartum cardiomyopathy is uncertain. A number of causes have been proposed, including myocarditis, an abnormal immune response to pregnancy, maladaptive response to the hemodynamic stresses of pregnancy, or prolonged inhibition of contractions in premature labor.

The signs and symptoms resemble those of dilated cardiomyopathy. Because many women experience dyspnea, fatigue, and pedal edema during the last month of normal pregnancy, the symptoms may be ignored and the diagnosis delayed. The diagnosis is based on echocardiography studies, ECG, and other tests of cardiac function. Treatment methods are similar to those used in dilated cardiomyopathy.

There are two possible outcomes of peripartum cardiomyopathy. In approximately one half of cases, the heart returns to normal within 6 months, and the chances for long-term survival are good. In these women, heart failure returns only during subsequent pregnancies. In the other one half of cases, cardiomegaly persists, the prognosis is poor, and death is probable if another pregnancy occurs. In women with cardiomyopathy associated with documented viral myocarditis, the likelihood of recurrence is low.

Disorders Affecting the Endocardium

Infective Endocarditis

Infective endocarditis is a relatively uncommon, life-threatening infection of the endocardial surface of the heart, including the heart valves. Because bacteria are the most common infecting organisms, the condition may be referred to as *bacterial endocarditis*. Despite important advances in antimicrobial therapy and improved ability to diagnose and treat complications, infective endocarditis continues to produce substantial morbidity and mortality.

Two factors contribute to the development of infective endocarditis: a damaged endocardial surface and a portal of entry by which the organism gains access to the circulatory system. The presence of valvular disease, prosthetic heart valves, or congenital heart defects provides an environment conducive to bacterial growth.^{4,28,29} In persons with pre-existing valvular or endocardial defects, simple gum massage or an innocuous oral lesion may afford the pathogenic bacteria access to the bloodstream. Transient bacteremia may emerge in the course of seemingly minor health problems, such as an upper respiratory tract infection, a skin lesion, or a dental procedure.

Although infective endocarditis usually occurs in persons with pre-existing heart lesions, it also can develop in normal hearts of intravenous drug abusers. The mode of infection is a contaminated drug solution or a needle contaminated with skin flora. Intravenous drug abuse is the most common source of right-sided (tricuspid) lesions. Although staphylococcal infections are common, intravenous drug users may be infected with unusual organisms, such as gram-negative bacilli, yeasts, and fungi.

In hospitalized patients, infective endocarditis may arise as a complication of infected intravascular or urinary tract catheters. Infective endocarditis also may complicate prosthetic heart valve replacement. It can develop as an early infection that follows surgery or as a later infection that results from the longterm presence of the prosthesis.

Depending on the duration of the disease, presenting manifestations, and complications, cases of infective endocarditis can be classified as acute, subacute, or chronic.³⁰ Acute infective endocarditis is thought primarily to affect persons with normal hearts and usually is caused by suppurative organisms such as Staphylococcus aureus and Streptococcus pyogenes. Subacute endocarditis is seen most frequently in patients with damaged hearts and usually is caused by less virulent organisms such as Streptococcus viridans and Staphylococcus epidermis. Certain lowvirulence organisms such as Legionella and Brucella may produce a chronic form of the disease.

Pathophysiology. The pathophysiology of infective endocarditis involves the formation of intracardiac vegetative lesions that have local and distant systemic effects. The vegetative lesion that is characteristic of infective endocarditis consists of a collection of infectious organisms and cellular debris enmeshed in the fibrin strands of clotted blood. The infectious loci continuously release bacteria into the bloodstream and are a source of persistent bacteremia. These lesions may be singular or multiple, may grow to be as large as several centimeters, and usually are found loosely attached to the free edges of the valve surface (Fig. 17-16). As the lesions grow, they cause valve destruction, leading to valvular regurgitation, ring abscesses with heart block, and valve perforation. The loose organization of these lesions permits the organisms and fragments of the lesions to form emboli and travel in the bloodstream. The fragments may lodge in small blood vessels, causing small hemorrhages, abscesses, and infarction of tissue. The bacteremia also can initiate immune responses thought to be responsible for the skin manifestations, arthritis, glomerulonephritis, and other immune disorders associated with the condition.

■ FIGURE 17-16 ■ Bacterial endocarditis. The mitral valve shows destructive vegetations, which have eroded through the free margin of the valve leaflet. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 572]. Philadelphia: Lippincott Williams & Wilkins)

306 Unit Four: Alterations in the Cardiovascular System

Clinical Course. The clinical course of infective endocarditis is determined by the extent of heart damage, the type of organism involved, site of infection (*i.e.*, right or left side of the heart), and whether embolization from the site of infection occurs. Destruction of infected heart valves is common with certain forms of organisms, such as *S. aureus*. Peripheral embolization can lead to metastatic infections and abscess formation; these are particularly serious when they affect organs such as the brain and kidneys. In right-sided endocarditis, which usually involves the tricuspid valve, septic emboli travel to the lung, causing infarction and lung abscesses.

The signs and symptoms of infective endocarditis include fever and signs of systemic infection, change in the character of an existing heart murmur, and evidence of embolic distribution of the vegetative lesions. In the acute form, the fever usually is spiking and accompanied by chills. In the subacute form, the fever usually is low grade, of gradual onset, and frequently accompanied by other systemic signs of inflammation, such as anorexia, malaise, and lethargy. Small petechial hemorrhages frequently result when emboli lodge in the small vessels of the skin, nail beds, and mucous membranes. Splinter hemorrhages (*i.e.*, dark red lines) under the nails of the fingers and toes are common. Cough, dyspnea, arthralgia or arthritis, diarrhea, and abdominal or flank pain may occur as the result of systemic emboli.

The blood culture is the most definitive diagnostic procedure and is essential in determining treatment. The optimal time to obtain cultures is during a chill, just before a temperature rise. Usually two separate positive cultures are required for diagnosis. The echocardiogram is useful in detecting underlying valvular disease. Transesophageal echocardiography is rapid and noninvasive, and has proved useful for detecting vegetations. Other signs, such as the presence of embolic disease or evidence of immunologic phenomena such as glomerulonephritis or rheumatoid factor, provide useful diagnostic information.

Treatment of infective endocarditis focuses on identifying and eliminating the causative microorganism, minimizing the residual cardiac effects, and treating the pathologic effects of the emboli. Antibiotic therapy is used to eradicate the pathogen. Surgery may be indicated for moderate to severe heart failure, progressive renal failure, significant emboli, dysrhythmias, or left-sided endocarditis. Infected prosthetic valves may need to be replaced.

Of great importance is the prevention of infective endocarditis in persons with prosthetic heart valves, previous bacterial endocarditis, certain congenital heart defects, and other known risk factors.³⁰ Prevention can be largely accomplished through prophylactic administration of an antibiotic before dental and other procedures that may cause bacteremia.³⁰

Rheumatic Heart Disease

Rheumatic fever is an acute, immune-mediated, multisystem inflammatory disease that follows a group A (β -hemolytic) streptococcal (GAS) throat infection. The most serious aspect of rheumatic fever is the development of chronic valvular disorders that produce permanent cardiac dysfunction and sometimes cause fatal heart failure years later. In the United States and other industrialized countries, the incidence of rheumatic fever and the prevalence of rheumatic heart disease has markedly declined during the past 40 to 50 years. This decline has been attributed to the introduction of antimicrobial agents for improved treatment of GAS pharyngitis, increased access to medical care, and improved economic standards, along with better and less crowded housing. Unfortunately, rheumatic fever and rheumatic heart disease continue to be major health problems in many underdeveloped countries, where inadequate health care, poor nutrition, and crowded living conditions still prevail.

Rheumatic fever is primarily a disease of school-aged children. The incidence of acute rheumatic fever peaks between 5 and 15 years of age.⁴ The disease usually follows an inciting GAS throat infection by 1 to 4 weeks. Rheumatic fever and its cardiac complications can be prevented by antibiotic treatment of the initial GAS throat infection. Evidence of a streptococcal infection is established through the use of throat cultures, antigen tests, and antibodies to products liberated by the streptococci. Throat cultures taken at the time of the acute infection usually are positive for GAS infection. It takes several days to obtain the results of a throat culture. The development of rapid tests for direct detection of GAS antigens has provided at least a partial solution for this problem. Penicillin (or another antibiotic in penicillin-sensitive patients) is the treatment of choice for GAS.

Pathogenesis. The pathogenesis of rheumatic fever is unclear, and why only a small percentage of persons with uncomplicated streptococcal infections contract rheumatic fever remains unknown. The time frame for development of symptoms in relation to the sore throat and the presence of antibodies to the GAS organism strongly suggest an immunologic origin. Like other immunologic phenomena, rheumatic fever requires an initial sensitizing exposure to the offending streptococcal agent, and the risk of recurrence is high after each subsequent exposure.

Rheumatic fever can manifest as an acute, recurrent, or chronic disorder. The acute stage of rheumatic fever includes a history of an initiating streptococcal infection and subsequent involvement of the connective tissue of the heart, blood vessels, joints, and subcutaneous tissues. Common to all is a lesion called the *Aschoff body*, which is a localized area of tissue necrosis surrounded by immune cells.⁴ The *recurrent phase* usually involves extension of the cardiac effects of the disease. The *chronic phase* of rheumatic fever is characterized by permanent deformity of the heart valves and is a common cause of mitral valve stenosis. Chronic rheumatic heart disease usually does not appear until at least 10 years after the initial attack, sometimes decades later.

Clinical Course. Most children with rheumatic fever have a history of sore throat, headache, fever, abdominal pain, nausea, vomiting, swollen glands (usually at the angle of the jaw), and other signs and symptoms of streptococcal infection. Other clinical features associated with an acute episode of rheumatic fever are related to the acute inflammatory process and the structures involved in the disease process. The course of rheumatic fever is characterized by a constellation of disorders that include carditis, migratory polyarthritis of the large joints, erythema marginatum, subcutaneous nodules, and Sydenham's chorea.

Acute rheumatic carditis, which complicates the acute phase of rheumatic fever, may progress to chronic valvular disorders. The carditis can affect the pericardium, myocardium, or endocardium, and all of these layers of the heart usually are involved. Both the pericarditis and myocarditis usually are selflimited manifestations of the acute stage of rheumatic fever.

Chapter 17: Alterations in Cardiac Function 307

The involvement of the endocardium and valvular structures produces the permanent and disabling effects of rheumatic fever. Although any of the four valves can be involved, the mitral and aortic valves are affected most often. During the acute inflammatory stage of the disease, the valvular structures become red and swollen; small vegetative lesions develop on the valve leaflets. The acute inflammatory changes gradually proceed to development of fibrous scar tissue, which tends to contract and cause deformity of the valve leaflets and shortening of the chordae tendineae. In some cases, the edges or commissures of the valve leaflets fuse together as healing occurs.

The manifestations of acute rheumatic carditis include a heart murmur in a child without a previous history of rheumatic fever, change in the character of a murmur in a person with a previous history of the disease, cardiomegaly or enlargement of the heart, friction rub or other signs of pericarditis, and congestive heart failure in a child without discernible cause.

Although not a cause of permanent disability, polyarthritis is the most common finding in rheumatic fever. The arthritis involves the larger joints, particularly the knees, ankles, elbows, and wrists, and almost always is migratory, affecting one joint and then moving to another. In untreated cases, the arthritis lasts approximately 4 weeks. A striking feature of rheumatic arthritis is the dramatic response (usually within 48 hours) to salicylates.

Erythema marginatum lesions are maplike, macular areas most commonly seen on the trunk or inner aspects of the upper arm and thigh. Skin lesions are present only in approximately 10% of patients who have rheumatic fever; they are transitory and disappear during the course of the disease. The subcutaneous nodules are 1 to 4 cm in diameter. They are hard, painless, and freely movable and usually overlie the extensor muscles of the wrist, elbow, ankle, and knee joints. Subcutaneous nodules are rare, but when present, they occur most often in persons with carditis.

Chorea (i.e., Sydenham's chorea), sometimes called St. Vitus' dance, is the major central nervous system manifestation. It is seen most frequently in girls and is the least common of the clinical manifestations. The choreic movements are spontaneous, rapid, purposeless, jerking movements that interfere with voluntary activities. Facial grimaces are common, and even speech may be affected. The chorea is self-limited, usually running its course within a matter of weeks or months.

Diagnosis and Treatment. The diagnosis of rheumatic fever is based on the Jones criteria, which were initially proposed in 1955 and revised in 1984 and 1992 by a committee of the AHA.^{31,32} The criteria group the signs and symptoms of rheumatic fever into major and minor categories. The presence of two major signs (i.e., carditis, polyarthritis, chorea, erythema marginatum, and subcutaneous nodules) or one major and two minor signs (*i.e.*, arthralgia, fever, and prolonged PR interval) accompanied by evidence of a preceding GAS infection indicates a high probability of rheumatic fever. The erythrocyte sedimentation rate, C-reactive protein, and white blood cell count commonly are used to confirm recent infection. Echocardiography/Doppler ultrasound (echo-Doppler) may be used to identify cardiac lesions in persons who do not have typical signs of cardiac involvement during an attack of rheumatic fever.32

Treatment of acute rheumatic fever is designed to control the acute inflammatory process and prevent cardiac complications and recurrence of the disease. During the acute phase, antibiotics, anti-inflammatory drugs, and selective restriction of physical activities are prescribed. Penicillin is usually the antibiotic of choice. Salicylates are used to reduce fever and relieve joint pain and swelling. A short course of corticosteroids may be used when the response to salicylates is ineffective. Because of the high risk for recurrence after subsequent GAS throat infections, treatment during the acute phase of the disease is usually followed by secondary prophylaxis using penicillin or an alternative antibiotic.³³ The duration of prophylaxis depends on whether residual valvular disease is present or absent. Usually, prophylaxis is also instituted during dental or other procedures that might provide the GAS with access to the bloodstream.

In summary, myocardial disorders represent a diverse group of disorders of myocardial muscle cells, not related to coronary artery disease. Myocarditis is an acute inflammation of cardiac muscle cells, most often of viral origin. Myocardial injury from myocarditis is thought to result from necrosis caused by direct invasion of the offending organism, toxic effects of exogenous toxins or endotoxins produced by a systemic pathogen, and destruction of cardiac tissue by immunologic mechanisms initiated by the infectious agent. Although the disease usually is benign and self-limited, it can result in sudden death or chronic heart failure, for which heart transplantation may be considered.

The cardiomyopathies represent disorders of the heart muscle. Cardiomyopathies may manifest as primary or secondary disorders such as myocardial infarction. There are four main types of primary cardiomyopathies: dilated cardiomyopathy, in which fibrosis and atrophy of myocardial cells produces progressive dilation and impaired pumping ability of the heart; hypertrophic cardiomyopathy, characterized by myocardial hypertrophy, abnormal diastolic filling, and in many cases intermittent left ventricular outflow obstruction; restrictive cardiomyopathy, in which there is excessive rigidity of the ventricular wall; and arrhythmogenic right ventricular cardiomyopathy. Peripartum cardiomyopathy occurs during pregnancy. The cause of many of the primary cardiomyopathies is unknown. The disease is suspected when cardiomegaly and heart failure develop in a young, previously healthy person.

Infective endocarditis involves the invasion of the endocardium by pathogens that produce vegetative lesions on the endocardial surface. The loose organization of these lesions permits the organisms and fragments of the lesions to be disseminated throughout the systemic circulation. Two predisposing factors contribute to the development of infective endocarditis: a damaged endocardium and a portal of entry through which the organisms gain access to the bloodstream.

Rheumatic fever, which is associated with an antecedent GAS throat infection, is an important cause of heart disease. Its most serious and disabling effects result from involvement of the heart valves. Because there is no single laboratory test, sign, or symptom that is pathognomonic of acute rheumatic fever, the Jones criteria are used to establish the diagnosis during the acute stage of the disease.

VALVULAR HEART DISEASE

The function of the heart valves is to promote directional flow of blood through the chambers of the heart. Dysfunction of the heart valves can result from a number of disorders, including congenital defects, trauma, ischemic damage, degenerative changes, and inflammation. Although any of the four heart valves can become diseased, the most commonly affected are the mitral and aortic valves. Disorders of the pulmonary and tricuspid valves are uncommon, probably because of the low pressure in the right side of the heart.

Hemodynamic Derangements

The heart valves consist of thin leaflets of tough, flexible, endothelium-covered fibrous tissue firmly attached at the base to the fibrous valve rings (see Chapter 14). Capillaries and smooth muscle are present at the base of the leaflet but do not extend up into the valve. The leaflets of the heart valves may be injured or become the site of an inflammatory process that can deform their line of closure. Healing of the valve leaflets often is associated with increased collagen content and scarring, causing the leaflets to shorten and become stiffer. The edges of the valve leaflets can heal together so that the valve does not open or close properly.

Two types of mechanical disruptions occur with valvular heart disease: narrowing of the valve opening so it does not open properly and distortion of the valve so it does not close properly (Fig. 17-17). *Stenosis* refers to a narrowing of the valve orifice and failure of the valve leaflets to open normally. Blood flow through a normal valve can increase by five to seven times the resting volume; consequently, valvular stenosis must be severe before it causes problems. Significant narrowing of the valve orifice increases the resistance to blood flow through the valve, converting the normally smooth laminar flow to a less efficient turbulent flow. This increases the volume and

KEY CONCEPTS

VALVULAR HEART DISEASE

- The heart valves determine the direction of blood flow through the heart chambers.
- Valvular heart defects exert their effects by obstructing flow of blood (stenotic valve disorder) or allowing backward flow of blood (regurgitant valve disorders).
- Stenotic valvular defects produce distention of the heart chamber that empties blood through the diseased valve and impaired filling of the chamber that receives blood that moves through the valve.
- Regurgitant valves allow blood to move back through the valve when it should be closed. This produces distention and places increased work demands on the chamber ejecting blood through the diseased valve.

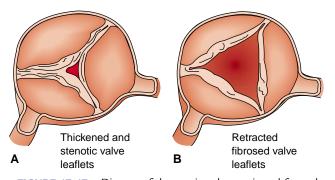

FIGURE 17-17 Disease of the aortic valve as viewed from the aorta. (A) Stenosis of the valve opening. (B) An incompetent or regurgitant valve that is unable to close completely.

work of the chamber emptying through the narrowed valve the left atrium in the case of mitral stenosis and the left ventricle in aortic stenosis. Symptoms usually are noticed first during situations of increased flow, such as exercise. An *incompetent* or *regurgitant valve* permits backward flow to occur when the valve should be closed, with blood flowing back into the left ventricle during diastole when the aortic valve is affected and back into the left atrium during systole when the mitral valve is diseased.

The effect that valvular heart disease has on cardiac function is related to alterations in blood flow across the valve and to the resultant increase in work demands on the heart that the disorder generates. Many valvular heart defects are characterized by heart murmurs resulting from turbulent blood flow through a diseased valve. Disorders in valve flow and heart chamber size for mitral and aortic valve disorders are illustrated in Figure 17-18.

Mitral Valve Disorders

The mitral valve controls the directional flow of blood between the left atrium and the left ventricle. The edges or cusps of the AV valves are thinner than those of the semilunar valves; they are anchored to the papillary muscles by the chordae tendineae. During much of systole, the mitral valve is subjected to the high pressure generated by the left ventricle as it pumps blood into the systemic circulation. During this period of increased pressure, the chordae tendineae prevent the eversion of the valve leaflets into the left atrium.

Mitral Valve Stenosis

Mitral valve stenosis represents the incomplete opening of the mitral valve during diastole with left atrial distention and impaired filling of the left ventricle. Mitral valve stenosis most commonly is the result of rheumatic fever. Less frequently, the defect is congenital and manifests during infancy or early childhood.³⁴ Mitral valve stenosis is a continuous, progressive, lifelong disorder, consisting of a slow, stable course in the early years and progressive acceleration in later years. The 10-year survival rate for persons with untreated mitral stenosis is 50% to 60%, depending on symptoms at the time of presentation.^{34,35}

Mitral valve stenosis is characterized by fibrous replacement of valvular tissue, along with stiffness and fusion of the valve apparatus (Fig. 17-19). Typically, the mitral cusps fuse at the edges, and involvement of the chordae tendineae causes short-

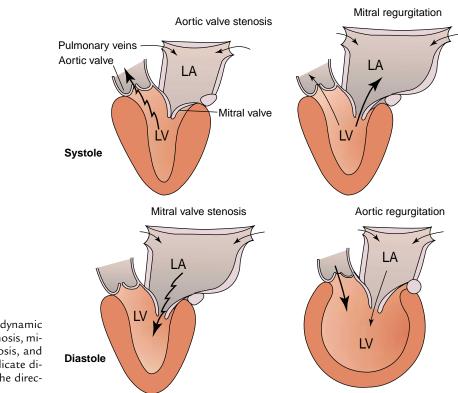

FIGURE 17-18 Alterations in hemodynamic function that accompany aortic valve stenosis, mitral valve regurgitation, mitral valve stenosis, and aortic valve regurgitation. *Thin arrows* indicate direction of normal flow, and *thick arrows* the direction of abnormal flow.

ening, which pulls the valvular structures more deeply into the ventricles. As the resistance to flow through the valve increases, the left atrium becomes dilated and left atrial pressure rises (see Fig. 17-18). The increased left atrial pressure eventually is transmitted to the pulmonary venous system, causing pulmonary congestion.

The rate of flow across the valve depends on the size of the valve orifice, the driving pressure (*i.e.*, atrial minus ventricular pressure), and the time available for flow during diastole. As the condition progresses, symptoms of decreased cardiac out-

■ FIGURE 17-19 ■ Chronic rheumatic valvulitis. A view of the mitral valve from the left atrium shows rigid, thickened, and fused leaflets with a narrow orifice, creating the characteristic "fish mouth" appearance of the rheumatic mitral stenosis. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 570]. Philadelphia: Lippincott Williams & Wilkins)

put occur during extreme exertion or other situations that cause tachycardia and thereby reduce diastolic filling time. In the late stages of the disease, an increase in pulmonary vascular resistance leads to the development of pulmonary hypertension; this increases the pressure against which the right heart must pump and eventually leads to right-sided heart failure.

The signs and symptoms of mitral valve stenosis depend on the severity of the obstruction and are related to the elevation in left atrial pressure and pulmonary congestion, decreased cardiac output caused by impaired left ventricular filling, and left atrial enlargement with development of atrial arrhythmias and mural thrombi. The murmur of mitral valve stenosis is heard during diastole when blood is flowing through the constricted valve orifice; it is characteristically a low-pitched, rumbling murmur, best heard at the apex of the heart.

The symptoms are those of pulmonary congestion, including recurrent nocturnal dyspnea and orthopnea. Palpitations, chest pain, weakness, and fatigue are common complaints. Premature atrial beats, paroxysmal atrial tachycardia, and atrial fibrillation may occur as a result of distention of the left atrium. Atrial fibrillation develops in 30% to 40% of persons with symptomatic mitral stenosis.³⁴ Together, the fibrillation and distention predispose to mural thrombus formation. The risk of arterial embolization, particularly stroke, is significantly increased in persons with atrial fibrillation. Anticoagulation therapy is often used to prevent systemic embolization in persons with atrial fibrillation.

Mitral Valve Regurgitation

Mitral valve regurgitation is characterized by incomplete closure of the mitral valve, with the left ventricular stroke volume being divided between the forward stroke volume that moves

310 Unit Four: Alterations in the Cardiovascular System

into the aorta and the regurgitant stroke volume that moves back into the left atrium during systole (see Fig. 17-18). Mitral valve regurgitation can result from many processes. Rheumatic heart disease is associated with a rigid and thickened valve that does not open or close completely. In addition to rheumatic disease, mitral regurgitation can occur as the result of papillary muscle dysfunction, stretching of the valve structures caused by dilatation of the left ventricle or valve orifice, or mitral valve prolapse. Acute mitral regurgitation can result from rupture of the chordae tendineae or papillary muscles, most commonly the result of myocardial infarction.

The hemodynamic changes that occur with mitral valve regurgitation occur more slowly, allowing for recruitment of compensatory mechanisms. An increase in left ventricular enddiastolic volume permits an increase in total stroke volume, with restoration of forward flow into the aorta. Augmented preload and reduced or normal afterload (provided by unloading the left ventricle into the left atrium) facilitates left ventricular ejection. At the same time, a gradual increase in left atrial size allows for accommodation of the regurgitant volume at a lower filling pressure.

The increased volume work associated with mitral regurgitation is relatively well tolerated, and many persons with the disorder remain asymptomatic for 10 to 20 years despite severe regurgitation.^{34,35} The degree of left ventricular enlargement reflects the severity of regurgitation. As the disorder progresses, left ventricular function becomes impaired, the forward (aortic) stroke volume decreases, and the left atrial pressure increases, with the subsequent development of pulmonary congestion. Mitral regurgitation, like mitral stenosis, predisposes to atrial fibrillation.

Mitral Valve Prolapse

Sometimes referred to as the *floppy mitral valve syndrome*, mitral valve prolapse occurs in 2% to 6% of the population.³⁶ The disorder is seen more frequently in women than in men and may have a familial basis. Although the cause of the disorder usually is unknown, it has been associated with Marfan's syndrome, osteogenesis imperfecta, and other connective tissue disorders and with cardiac, hematologic, neuroendocrine, metabolic, and psychological disorders.

Pathologic findings in persons with mitral valve prolapse include a myxedematous (mucinous) degeneration of mitral valve leaflets that causes them to become enlarged and floppy so that they prolapse or balloon back into the left atrium during systole (Fig. 17-20).²⁵ Secondary fibrotic changes reflect the stresses and injury that the ballooning movements impose on the valve. Certain forms of mitral valve prolapse may arise from disorders of the myocardium that result in abnormal movement of the ventricular wall or papillary muscle; this places undue stress on the mitral valve.

Most persons with mitral valve prolapse are asymptomatic, and the disorder is discovered during a routine physical examination. A minority of persons have chest pain mimicking angina, dyspnea, fatigue, anxiety, palpitations, and lightheadedness. Unlike angina, the chest pain often is prolonged, ill defined, and not associated with exercise or exertion. The pain has been attributed to ischemia resulting from traction of the prolapsing valve leaflets. The anxiety, palpitations, and dysrhythmias may result from abnormal autonomic nervous

■ FIGURE 17-20 ■ Mitral valve prolapse. A view of the mitral valve from the left atrium shows redundant and deformed leaflets that billow into the left atrial cavity. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 574]. Philadelphia: Lippincott Williams & Wilkins)

system function that commonly accompanies the disorder. Rare cases of sudden death have been reported for persons with mitral valve prolapse, mainly those with a family history of similar occurrences.

The treatment of mitral valve prolapse focuses on the relief of symptoms and the prevention of complications. Persons with palpitations and mild tachyarrhythmias or increased adrenergic symptoms and those with chest discomfort, anxiety, and fatigue often have response to therapy with the β adrenergic–blocking drugs. In many cases, the cessation of stimulants such as caffeine, alcohol, and cigarettes may be sufficient to control symptoms. Infective endocarditis is an uncommon complication in persons with a murmur; antibiotic prophylaxis usually is recommended before dental or surgical procedures associated with bacteremia. Persons with severe valve dysfunction may require valve surgery.

Aortic Valve Disorders

The aortic valve is located between the aorta and left ventricle. The aortic valve has three cusps and sometimes is referred to as the *aortic semilunar valve* because its leaflets are crescent or moon shaped (see Chapter 14, Fig. 14-10). The aortic valve has no chordae tendineae. Although their structures are similar, the cusps of the aortic valve are thicker than those of the mitral valve. The middle layer of the aortic valve is thickened near the middle, where the three leaflets meet, ensuring a tight seal. Between the thickened tissue and their free margins, the leaflets are more thin and flimsy.

An important aspect of the aortic valve is the location of the orifices for the two main coronary arteries, which are located behind the valve and at right angles to the direction of blood flow. It is the lateral pressure in the aorta that propels blood into the coronary arteries. During the ejection phase of the cardiac cycle, the lateral pressure is diminished by conversion of potential energy to kinetic energy as blood moves forward into the aorta. This process is grossly exaggerated in aortic stenosis because of the high flow velocities.

Aortic Valve Stenosis

Aortic stenosis is characterized by increased resistance to ejection of blood from the left ventricle into the aorta (see Fig. 17-18). Because of the increased resistance, the work demands on the left ventricle are increased, and the volume of blood ejected into the systemic circulation is decreased. The most common causes of aortic stenosis are rheumatic fever and congenital valve malformations. Congenital malformations may result in unicuspid, bicuspid, or misshaped valve leaflets. In elderly persons, stenosis may be related to degenerative atherosclerotic changes of the valve leaflets. Approximately 25% of persons older than 65 years and 35% of those older than 70 years of age have echocardiographic evidence of sclerosis, with 2% to 3% having evidence of aortic stenosis.³⁵

The progression of aortic stenosis varies widely among individuals. The progression may be more rapid in persons with degenerative calcific disease than in those with congenital or rheumatic disease.³⁵ The aortic valve must be reduced to approximately one fourth its normal size before critical changes in cardiac function occur.³⁴ Significant obstruction to aortic outflow causes a decrease in stroke volume, along with a reduction in systolic blood pressure and pulse pressure. Because of the narrowed valve opening, it takes longer for the heart to eject blood; the heart rate often is slow, and the pulse is of low amplitude. There is a soft, absent, or paradoxically split S₂ sound and a harsh systolic ejection murmur that is heard best along the left sternal border.

Persons with aortic stenosis tend to be asymptomatic for many years despite severe obstruction. Eventually, symptoms of angina, syncope, and heart failure develop. Angina occurs in approximately two thirds of persons with advanced aortic stenosis and is similar to that observed in CHD. Syncope (fainting) is most commonly caused by the reduced cerebral circulation that occurs during exertion when the arterial pressure declines consequent to vasodilation in the presence of a fixed cardiac output. Exertional hypotension may cause "graying out" spells or dizziness on exercise.³⁶ Dyspnea, marked fatigability, peripheral cyanosis, and other signs of low-output heart failure usually are not prominent until late in the course of the disease.

Aortic Valve Regurgitation

Aortic regurgitation is the result of an incompetent aortic valve that allows blood to flow back to the left ventricle during diastole (see Fig. 17-18). As a result, the left ventricle must increase its stroke volume to include blood entering from the lungs as well as that leaking back through the regurgitant valve. This defect may result from conditions that cause scarring of the valve leaflets or from enlargement of the valve orifice to the extent that the valve leaflets no longer meet. Rheumatic fever ranks first on the list of causes of aortic regurgitation; failure of a prosthetic valve is another cause.

Chronic aortic regurgitation, which usually has a gradual onset, represents a condition of combined left ventricular volume and pressure overload. As the valve deformity increases, regurgitant flow into the left ventricle increases, diastolic blood pressure falls, and the left ventricle progressively enlarges. Hemodynamically, the increase in left ventricular volume results in the ejection of a large stroke volume that usually is adequate to maintain the cardiac output until late in the course of the disease. Most persons remain asymptomatic during this compensated phase, which may last decades. The only sign for many years may be soft systolic aortic murmur.

As the disease progresses, signs and symptoms of left ventricular failure begin to appear. These include exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. In aortic regurgitation, failure of aortic valve closure during diastole causes an abnormal drop in diastolic pressure. Because coronary blood flow is greatest during diastole, the drop in diastolic pressure produces a decrease in coronary perfusion. Although angina is rare, it may occur when the heart rate and diastolic pressure fall to low levels. Persons with severe aortic regurgitation often report an uncomfortable awareness of heartbeat, particularly when lying down, and chest discomfort caused by pounding of the heart against the chest wall. Tachycardia, occurring with emotional stress or exertion, may produce palpitations, head pounding, and premature ventricular contractions.

The major physical findings relate to the widening of the arterial pulse pressure. The pulse has a rapid rise and fall, with an elevated systolic pressure and low diastolic pressure caused by the large stroke volume and rapid diastolic runoff of blood back into the left ventricle. Korotkoff sounds may persist to zero, even though intra-arterial pressure rarely falls below 30 mm Hg.³⁴ The large stroke volume and wide pulse pressure may result in prominent carotid pulsations in the neck, throbbing peripheral pulses, and a left ventricular impulse that causes the chest to move with each beat. The turbulence of flow across the aortic valve during diastole produces a high-pitched or blowing sound.

Diagnosis and Treatment

Valvular defects usually are detected through cardiac auscultation (*i.e.*, heart sounds). Diagnosis is aided by echocardiography and cardiac catheterization. Echocardiography uses ultrasound signals in the range of 2 to 5 million Hz to create an image of the internal structures of the heart because the chest wall, blood, and different heart structures all reflect ultrasound differently. The echocardiogram is useful for determining ventricular dimensions and valve movements, obtaining data on the movement of the left ventricular wall and septum, estimating diastolic and systolic volumes, and viewing the motion of individual segments of the left ventricular wall during systole and diastole. Transesophageal echocardiography is particularly useful in assessing valve function.

The treatment of valvular defects consists of medical management of heart failure and associated problems and surgical intervention to repair or replace the defective valve. Surgical valve repair or replacement depends on the valve that is involved and the extent of deformity. Valvular replacement with a prosthetic device usually is reserved for severe disease. Percutaneous balloon valvuloplasty involves the opening of a stenotic valve by guiding an inflated balloon through the valve orifice. The procedure is done in the cardiac catheterization laboratory and involves the insertion of a balloon catheter into the heart by way of a peripheral blood vessel. In summary, dysfunction of the heart valves can result from a number of disorders, including congenital defects, trauma, ischemic heart disease, degenerative changes, and inflammation. Rheumatic endocarditis is a common cause. Valvular heart disease produces its effects through disturbances of blood flow. A stenotic valvular defect is one that causes a decrease in blood flow through a valve, resulting in impaired emptying and increased work demands on the heart chamber that empties blood across the diseased valve. A regurgitant valvular defect permits the blood flow to continue when the valve is closed. Valvular heart disorders produce blood flow turbulence and often are detected through cardiac auscultation.

HEART DISEASE IN INFANTS AND CHILDREN

Heart disease in infants and children encompasses both congenital and acquired disorders. About 40,000 infants are born each year with a congenital heart defect, and 25% of these have defects that are severe enough to cause death within the first year if not corrected.¹ Premature infants have a higher incidence of congenital heart defects, most commonly patent ductus arteriosus and atrial septal defects. Advances in diagnostic methods and surgical treatment have greatly increased the long-term survival and outcomes for children born with congenital heart defects. This section of the chapter provides a discussion of the fetal and perinatal circulations; congenital heart disorders, and Kawasaki's disease, an acquired heart disorder of young children.

The major development of the fetal heart occurs between the fourth and seventh weeks of gestation, and during this time, most congenital heart defects arise. The development of the heart may be altered by environmental, genetic, and chromosomal influences. Most congenital heart defects are thought to be multifactorial in origin, resulting from an interaction between a genetic predisposition to develop a heart defect and environmental influences. Infants born to parents with congenital heart defects or with siblings who have congenital heart defects are at higher risk. A number of chromosomal abnormalities are associated with congenital heart disease, most prominently Down syndrome and Turner's syndrome (see Chapter 4). Other intrauterine factors such as maternal diabetes, congenital rubella, maternal alcohol ingestion, and treatment with anticonvulsant drugs are also associated with congenital heart disorders.37

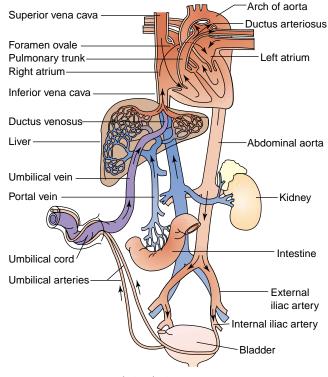

Fetal and Perinatal Circulation

The birth process produces dramatic changes in the circulation. It produces an increased risk of disorders such as patent ductus arteriosus in infants who are born prematurely, and it challenges the circulatory function in infants with congenital heart defects.

The fetal circulation is different anatomically and physiologically from the postnatal circulation. Before birth, oxygenation of blood occurs by way of the placenta, and after birth, it occurs by way of the lungs. The fetus is maintained in a lowoxygen state (PO₂ to 30 to 35 mm Hg and 60% to 70% hemoglobin saturation).³⁸ To compensate, fetal cardiac output is higher than at any other time (400 to 500 mL/kg/minute).

In the fetus, blood enters the circulation through the umbilical vein and returns to the placenta by way of the two umbilical arteries (Fig. 17-21). A vessel called the ductus venosum allows blood from the umbilical vein to bypass the hepatic circulation and pass directly into the inferior vena cava. From the inferior vena cava, blood flows into the right atrium and then is directed through the foramen ovale into the left atrium. Blood then passes into the left ventricle and is ejected into the ascending aorta to perfuse the head and upper extremities. In this way, the best-oxygenated blood from the placenta is used to perfuse the brain. At the same time, venous blood from the head and upper extremities returns to the right side of the heart by way of the superior vena cava, moves into the right ventricle, and is ejected into the pulmonary artery. The pulmonary vascular resistance is very high because the lungs are fluid filled, and the resultant alveolar hypoxia contributes to intense vasoconstriction. Because of the high pulmonary vascular resistance, the blood that is ejected into the pulmonary artery is diverted through the ductus arteriosus into the descending aorta. This blood perfuses the lower extremities and is returned to the placenta by way of the umbilical arteries.

At birth, the infant takes its first breath and switches from placental to pulmonary oxygenation of the blood. The most dramatic alterations in the circulation after birth are the elimination of the low-resistance placental vascular bed and the marked pulmonary vasodilation that is produced by initiation of ventilation. The pressure in the pulmonary circulation and the right side of the heart fall as fetal lung fluid is replaced by

■ FIGURE 17-21 ■ Fetal circulation.

air and as lung expansion decreases the pressure transmitted to the pulmonary blood vessels. With lung inflation, the alveolar oxygen tension increases, causing reversal of the hypoxemiainduced pulmonary vasoconstriction of the fetal circulation. Cord clamping and removal of the low-resistance placental circulation produce an increase in peripheral vascular resistance and a resultant increase in left ventricular pressure. The accompanying increase in left atrial pressure as compared to right atrial pressure promotes closure of the foramen ovale. Reversal of the fetal hypoxemic state also produces constriction of ductal smooth muscle, contributing to closure of the ductus arteriosus. Closure of the foramen ovale and the ductus arteriosus normally occur within the first day of life, effectively separating the pulmonary and systemic circulations.

The birth process also initiates a sequence of maturational changes in the pulmonary blood vessels and pulmonary vascular resistance. After the initial precipitous fall in pulmonary vascular resistance, a more gradual decrease in pulmonary vascular resistance is related to regression of the medial smooth muscle layer in the pulmonary arteries. During the first 2 to 9 weeks of life, gradual thinning of the medial smooth muscle layer of pulmonary arteries results in further decreases in pulmonary vascular resistance. By the time a healthy, term infant is several weeks old, the pulmonary vascular resistance has fallen to adult levels.

Several factors, including prematurity, alveolar hypoxia, lung disease, and congenital heart defects, may affect postnatal pulmonary vascular development.37 If an infant is born prematurely, the smooth muscle layers of the pulmonary vasculature may develop incompletely or regress in a shorter period. Much of the development of the smooth muscle layer in the pulmonary arterioles occurs during the latter part of gestation; as a result, infants who are born prematurely have less medial smooth muscle. These infants follow the same pattern of smooth muscle regression, but because less muscle exists, the muscle layer may regress in a shorter period. The pulmonary vascular smooth muscle in premature infants also may be less responsive to hypoxia. For these reasons, a premature infant may demonstrate a larger decrease in pulmonary vascular resistance and a resultant shunting of blood from the aorta through the ductus arteriosus to the pulmonary artery within hours of birth.

Hypoxia during the first days of life may delay or prevent the normal decrease in pulmonary vascular resistance. During this period, the pulmonary arteries remain reactive and can constrict in response to hypoxia, acidosis, hyperinflation of the alveoli, and hypothermia. Alveolar hypoxia is one of the most potent stimuli of pulmonary vasoconstriction and pulmonary hypertension in the neonate.

Congenital Heart Disorders

Congenital heart diseases are commonly classified according to their anatomic defects (atrial septal or ventricular septal defects), the hemodynamic alterations caused by the anatomic defects (left-to-right or right-to-left shunts), and their effect on tissue oxygenation (cyanotic or noncyanotic defects).^{39,40}

Shunting and Cyanotic Disorders

Shunting of blood refers to the diverting of blood flow from one system to the other—from the arterial to the venous system (*i.e.*, left-to-right shunt) or from the venous to the arterial system (*i.e.*, right-to-left shunt). The shunting of blood in congenital heart defects is determined by the presence of an abnormal opening between the right and left circulations and the degree of resistance to flow through the opening. The shunting of blood can affect both the oxygen content of the blood and the volume of blood being delivered to the vessels in the pulmonary circulation.

A *right-to-left* shunt results in unoxygenated blood moving from the right side of the heart into the left side of the heart and then being ejected into the systemic circulation. Cyanosis develops when sufficient unoxygenated blood mixes with oxygenated blood in the left side of the heart. Children with rightto-left shunts are considered to have a cyanotic heart defect, whether they have recognizable cyanosis or not. In a *left-toright* shunt, blood intended for ejection into the systemic circulation is recirculated through the right side of the heart and back through the lungs; this increased volume distends the right side of the heart and pulmonary circulation and increases the workload placed on the right ventricle. Children with leftto-right shunts are considered to have a noncyanotic heart defect, even though they are cyanotic for other reasons, such as low cardiac output.

Congenital heart defects manifest with numerous signs and symptoms. Some defects, such as patent ductus arteriosus and small ventricular septal defects, close spontaneously, and in other, less severe defects, there are no signs and symptoms. The disorder typically is discovered during a routine health examination. Pulmonary congestion, heart failure, and decreased peripheral perfusion are the chief concerns in children with more severe defects. Such defects often cause problems shortly after birth or early in infancy. The child may exhibit cyanosis, respiratory difficulty, and fatigability and is likely to have difficulty with feeding and failure to thrive. A generalized cyanosis that persists longer than 3 hours after birth suggests congenital heart disease.

One technique for evaluating the cyanosis consists of administering 100% oxygen for 10 minutes. If the infant "pinks up," the cyanosis probably was caused by a respiratory problem and not a heart deffect. Because infant cyanosis may appear as a duskiness, it is important to assess the color of the mucous membranes, fingernails, toenails, tongue, and lips.

The manifestations and treatment of heart failure in the infant and young child are similar to those in the adult, but the infant's small size and limited physical reserve makes the manifestations more serious and treatment more difficult (see Chapter 18). The treatment plan usually includes supportive therapy designed to help the infant compensate for the limitations in cardiac reserve and to prevent complications. Surgical intervention often is required for severe defects; it may be done in the early weeks of life or, conditions permitting, delayed until the child is older.

Most children with structural congenital heart disease and those who have had corrective surgery are at risk for the development of infectious endocarditis. These children should receive prophylactic antibiotic therapy during periods of increased risk of bacteremia.

Types of Defects

Congenital heart defects can affect almost any of the cardiac structures or central blood vessels. Defects include communication between heart chambers, interrupted development of the heart chambers or valve structures, malposition of heart chambers and great vessels, and altered closure of fetal communication channels. The particular defect reflects the embryo's stage of development at the time it occurred. Some congenital heart disorders, such as tetralogy of Fallot, involve several defects. At least 35 types of defects have been identified, the most common being patent ductus arteriosus (6% to 11%), atrial septal defects (8% to 13%), and ventricular septal defects (20% to 25%).¹

Patent Ductus Arteriosus. Patent ductus arteriosus results from persistence of the fetal ductus beyond the prenatal period. In fetal life, the ductus arteriosus is the vital link by which blood from the right side of the heart bypasses the lungs and enters the systemic circulation (Fig. 17-22G). After birth, this passage no longer is needed, and it usually closes during the first 24 to 72 hours. The physiologic stimulus and mechanisms associated with permanent closure of the ductus are not entirely known, but the fact that infant hypoxia predisposes to a delayed closure suggests that the increase in arterial oxygen levels that occurs immediately after birth plays a role. Additional factors that contribute to closure are a fall in endogenous levels of prostaglandins and adenosine and the release of

other vasoactive substances. After constriction, the lumen of the ductus becomes permanently sealed with fibrous tissue within 2 to 3 weeks. Ductal closure may be delayed or prevented in very premature infants, probably as a result of a combination of factors, including decreased medial muscle in the ductus wall, decreased constrictive response to oxygen, and increased circulating levels of vasodilating prostaglandins. Hemodynamically significant patent ductus arteriosus is observed in approximately one half of infants with birth weights of less than 1000 g.³⁸ Ductal closure also may be delayed in infants with congenital heart defects that produce a decrease in oxygen tension.

As is true of other heart and circulatory defects, patency of the ductus arteriosus may vary; the size of the opening may be small, medium, or large. After the infant's pulmonary vascular resistance falls, the patent ductus arteriosus provides for a continuous runoff of aortic blood into the pulmonary artery, causing a decrease in aortic diastolic and mean arterial pressure and a widening of the pulse pressure. With a large patent ductus, the runoff is continuous, resulting in increased pulmonary blood flow, pulmonary congestion, and increased resistance against which the right side of the heart must pump. Increased pul-

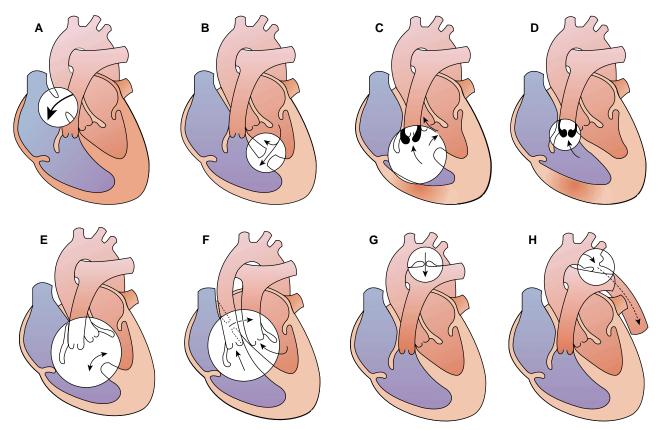

FIGURE 17-22 Congenital heart defects. (A) Atrial septal defect. Blood is shunted from left to right. (B) Ventricular septal defect. Blood is usually shunted from left to right. (C) Tetralogy of Fallot. This involves a ventricular septal defect, dextroposition of the aorta, right ventricular outflow obstruction, and right ventricular hypertrophy. Blood is shunted from right to left. (D) Pulmonary stenosis, with decreased pulmonary blood flow and right ventricular hypertrophy. (E) Endocardial cushion defects. Blood flows between the chambers of the heart. (F) Transposition of the great vessels. The pulmonary artery is attached to the left side of the heart and the aorta to the right side. (G) Patent ductus arteriosus. The high-pressure blood of the aorta is shunted back to the pulmonary artery. (H) Postductal coarctation of the aorta.

monary venous return and increased work demands may lead to left ventricular failure.

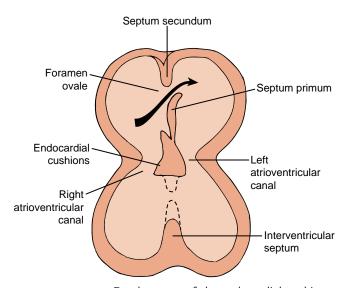

Patent ductus arteriosus can be treated either pharmacologically or surgically. Drugs that inhibit prostaglandin synthesis (*e.g.*, indomethacin), may be used to induce closure of a patent ductus arteriosus.

Atrial Septal Defects. An atrial septal defect is an abnormal opening in the atrial septum that allows communication between the left and right atrium (see Fig. 17-22A). It differs from a patent foramen ovale, which does not usually permit flow unless right atrial pressures are elevated.

Partitioning of the atria takes place during the 4th and 5th weeks of development and occurs in two stages, beginning with the formation of a thin, crescent-shaped membrane called the *septum primum* followed by the development of a second membrane called the *septum secundum*. As the septum secundum develops, it gradually overlaps an opening in the upper part of septum primum, forming an oval opening with a flap-type valve called the foramen ovale (see Fig. 17-23). The foramen ovale, which closes shortly after birth, allows blood from the umbilical vein to pass directly into the left heart, bypassing the lungs.

Atrial septal defects may be single or multiple and vary from a small, asymptomatic opening to a large, symptomatic opening. Most atrial septal defects are small and discovered inadvertently during a routine physical examination.⁴¹ In the case of an isolated septal defect that is large enough to allow shunting, the flow of blood usually is from the left to the right side of the heart because of the more compliant right ventricle and because the pulmonary vascular resistance is lower than the systemic vascular resistance. This produces right ventricular volume overload and increased pulmonary blood flow.

Young children with atrial septal defects are usually asymptomatic but experience symptoms later in life, usually during

■ FIGURE 17-23 ■ Development of the endocardial cushions, right and left atrioventricular canals, the interventricular septum, and septum primum and septum secundum of the foramen ovale. Note that blood from the right atrium flows through the foramen ovale to the left atrium. *Dotted line* indicates site for development of the membranous intraventricular septum.

adolescence when the changes in pulmonary vasculature may reverse the direction flow through the defect and create a rightto-left shunt with development of cyanosis. Adolescents and young adults may experience atrial fibrillation or atrial flutter and palpations because of atrial dilation. Symptomatic defects are usually treated surgically.

Ventricular Septal Defects. A ventricular septal defect is an opening in the ventricular septum that results from an imperfect separation of the ventricles during early fetal development (see Fig. 17-22B). Ventricular septal defects are the most common form of congenital heart defect, accounting for 20% to 25% of congenital heart disorders.³⁸ Ventricular septal defects may be the only cardiac defect, or they may be one of multiple cardiac anomalies.

The ventricular septum originates from two sources: the interventricular groove of the folded tubular heart that gives rise to the muscular part of the septum, and the endocardial cushions that extend to form the membranous portion of the septum (Fig. 17-23). The upper membranous portion of the septum is the last area to close, and it is here that most defects occur.

Depending on the size of the opening, the signs and symptoms of a ventricular septal defect may range from an asymptomatic murmur to congestive heart failure. If the defect is small, it allows a small shunt and small increases in pulmonary blood flow. These defects produce few symptoms, and approximately one third close spontaneously.³⁷ With mediumsize defects, a larger shunt occurs, producing a larger increase in pulmonary blood flow (*i.e.*, twice as much blood may pass through the pulmonary circulation as through the systemic circulation). The increased pulmonary flow most often occurs under relatively low pressure. Most of the children with such defects are asymptomatic and have a low risk for development of pulmonary vascular disease. Children with large defects often have a severe left-to-right shunt, often complicated by pulmonary hypertension and congestive heart failure.

Most infants with a ventricular septal defect are asymptomatic during early infancy because the higher pulmonary vascular resistance prevents shunting. The infant with a large, uncomplicated ventricular septal defect usually is asymptomatic until pulmonary vascular resistance begins to fall at approximately 4 to 25 weeks of age. After a large shunt develops, the infant breathes rapidly, feeds poorly, and is diaphoretic (*i.e.*, signs of congestive heart failure). Right-to-left shunting produces cyanosis.

The treatment of a ventricular septal defect depends on the size of the defect and accompanying hemodynamic derangements. Children with small or medium-size defects are followed up closely in the hope that the defect will close spontaneously. Prophylactic antibiotic therapy is given during periods of increased risk for bacteremia. Congestive heart failure is treated medically. Surgical intervention is required for infants who do not have a response to medical management.

Endocardial Cushion Defects. The endocardial cushions form the AV canals, the upper part of the ventricular septum, and the lower part of the atrial septum (Fig. 17-23). Endocardial cushion defects are responsible for approximately 5% of all congenital heart defects. As many as 50% of children with Down's syndrome have endocardial cushion defects.³⁷

316 Unit Four: Alterations in the Cardiovascular System

Because the endocardial cushions contribute to multiple aspects of heart development, several variations with this type of defect are possible. The terms most commonly used to categorize endocardial cushion defects are *partial* and *complete AV canal defects*.³⁷ In partial AV canal defects, the two AV valve rings are complete and separate. In complete canal defect, there is a common AV valve orifice along with defects in both the atrial and ventricular septal tissue. Many variations of these two forms of endocardial cushion defect are possible (see Fig. 17-22E).

The direction and magnitude of a shunt in a child with endocardial cushion defects are determined by the combination of defects and the child's pulmonary and systemic vascular resistance. With complete AV canal defects, congestive heart failure and intercurrent pulmonary infections appear early in infancy. There is left-to-right shunting and transatrial and transventricular mixing of blood. Pulmonary hypertension and increased pulmonary vascular resistance are common. Cyanosis develops with progressive shunting.

The treatment for endocardial cushion defects is determined by the severity of the defect. With an atrial septal defect, surgical repair usually is planned on an elective basis before the child enters school. Palliative or corrective surgery is required in infants with complete AV canal defects who have congestive heart failure and do not experience a response to medical treatment.

Pulmonary Valve Stenosis. Pulmonary valve stenosis may occur as an isolated valvular lesion or in conjunction with more complex defects, such as tetralogy of Fallot. In isolated valvular defects, the pulmonary cusps may be absent or malformed, or they may remain fused at their commissural edges; all three abnormalities often coexist.

Pulmonary valvular defects usually cause some impairment of pulmonary blood flow and increase the workload imposed on the right side of the heart (see Fig. 17-22D). Most children with pulmonic valve stenosis have mild to moderate stenosis that does not increase in severity. These children are largely asymptomatic. Severe defects are manifested by marked impairment of pulmonary blood flow that begins during infancy and is likely to become more severe as the child grows. Cyanosis develops in approximately one third of children younger than 2 years of age.³⁷ The ductus arteriosus may provide the vital accessory route for perfusing the lungs in infants with severe stenosis. When pulmonary stenosis is extreme, increased pressures in the right side of the heart may delay closure of the foramen ovale.

Treatment measures designed to maintain the patency of the ductus arteriosus may be used as a temporary measure to maintain or increase pulmonary blood flow in infants with severe pulmonary stenosis. Pulmonary valvotomy often is the treatment of choice. Transcatheter balloon valvuloplasty may be used in some infants with moderate degrees of obstruction.³⁸

Tetralogy of Fallot. As the name implies, tetralogy of Fallot consists of four associated congenital heart defects: (1) a ventricular septal defect involving the membranous septum and the anterior portion of the muscular septum; (2) dextroposition or shifting to the right of the aorta, so that it overrides the right ventricle and is in communication with the septal defect; (3) obstruction or narrowing of the pulmonary outflow channel, including pulmonic valve stenosis, a decrease in the size of the pulmonary trunk, or both; and (4) hypertrophy of the

right ventricle because of the increased work required to pump blood through the obstructed pulmonary channels³⁸ (see Fig. 17-22C).

Most children with tetralogy of Fallot display some degree of cyanosis, thus the term blue babies. The cyanosis develops as the result of decreased pulmonary blood flow and because the right-to-left shunt causes mixing of unoxygenated blood with the oxygenated blood, which is ejected into the peripheral circulation. Hypercyanotic attacks ("tet spells") may occur during the first months of life. These spells typically occur in the morning during crying, feeding, or defecating. These activities increase the infant's oxygen requirements. Crying and defecating may further increase pulmonary vascular resistance, thereby increasing right-to-left shunting and decreasing pulmonary blood flow. With the hypercyanotic spell, the infant becomes acutely cyanotic, hyperpneic, irritable, and diaphoretic. Later in the spell, the infant becomes limp and may lose consciousness. Placing the infant in the knee-chest position increases systemic vascular resistance, which increases pulmonary blood flow and decreases right-to-left shunting. During a hypercyanotic spell, toddlers and older children may spontaneously assume the squatting position, which functions like the knee-chest position to relieve the spell.37

Because of the hypoxemia that occurs in these children, palliative surgery designed to increase pulmonary blood flow often is needed during early infancy, with corrective surgery performed at a later age. Palliative surgery involves the creation of a surgical shunt to increase pulmonary blood flow. The most popular procedures use the subclavian artery or prosthetic material to create a shunt between the aorta and pulmonary artery.

Transposition of the Great Vessels. In complete transposition of the great vessels, the aorta originates in the right ventricle, and the pulmonary artery originates in the left ventricle (see Fig. 17-22F). The defect is more common in infants whose mothers have diabetes and in boys. In infants born with this defect, survival depends on communication between the right and left sides of the heart in the form of a patent ductus arteriosus or septal defect. Prostaglandin E1 may be administered in an effort to maintain the patency of the ductus arteriosus. Balloon atrial septostomy may be done to increase the blood flow between the two sides of the heart. In this procedure, a balloon-tipped catheter is inserted into the heart through the vena cava and then passed through the foramen ovale into the left atrium. The balloon is inflated and brought back through the foramen ovale, enlarging the opening as it goes. Corrective surgery is essential for long-term survival.38

Coarctation of the Aorta. Coarctation of the aorta is a localized narrowing of the aorta, proximal (preductal or coarctation of infancy) or distal (postductal) to the ductus. Approximately 98% of coarctations are postductal (see Fig. 17-22H). The anomaly occurs twice as often in males as in females. Coarctation of the aorta may be a feature of Turner's syndrome (see Chapter 4).

The classic sign of coarctation of the aorta is a disparity in pulsations and blood pressures in the arms and legs. The femoral, popliteal, and dorsalis pedis pulsations are weak or delayed compared with the bounding pulses of the arms and carotid vessels. The systolic blood pressure in the legs obtained by the cuff method normally is 10 to 20 mm Hg higher than in the arms.³⁸ In coarctation, the pressure is lower and may be difficult to obtain. The differential in blood pressure is common in children older than 1 year of age, approximately 90% of whom have hypertension in the upper extremities greater than the 95th percentile for age (see Chapter 16).

Children with significant coarctation should be treated surgically; the optimal age for surgery is 2 to 4 years. If untreated, most persons with coarctation of the aorta die between 20 and 40 years of age. The common serious complications are related to the hypertensive state. In some centers, balloon valvoplasty has been used for treatment of unoperated coarctation. This method is still being developed, and ongoing clinical trials are needed to determine its long-term effectiveness and possible complications.³⁸

Kawasaki's Disease

Kawasaki's disease is an acute febrile disease of young children. First described in Japan in 1967 by Dr. Tomisaku Kawasaki, the disease affects the skin, brain, eyes, joints, liver, lymph nodes, and heart. The disease can produce aneurysmal disease of the coronary arteries and is the most common cause of acquired heart disease in young children. Although first reported in Japanese children, the disease affects children of many races, occurs worldwide, and is increasing in frequency.

Kawasaki's disease is characterized by a vasculitis (*i.e.*, inflammation of the blood vessels) that begins in the small vessels (*i.e.*, arterioles, venules, and capillaries) and progresses to involve some of the larger arteries, such as the coronaries.⁴² The cause of Kawasaki's disease is unknown, but it is thought to be of immunologic origin. It has been hypothesized that some unknown antigen, possibly a common infectious agent, triggers the immune response in a genetically predisposed child.

Clinical Course

The course of the disease is triphasic and includes an acute febrile phase that lasts approximately 7 to 14 days; a subacute phase that follows the acute phase and lasts from days 10 through 24; and a convalescent phase that follows the subacute stage and continues until the signs of the acute-phase inflammatory response have subsided and the signs of the illness have disappeared.⁴²

The *acute phase* begins with an abrupt onset of fever, followed by bilateral conjunctivitis, usually without exudates; erythema of the oral and pharyngeal mucosa with "strawberry tongue" and dry fissured lips; redness and swelling of the hands and feet; rash of various forms; and enlarged cervical lymph nodes. The fever typically is high, reaching 40 °C (104 °F) or more, has an erratic spiking pattern, is unresponsive to antibiotics, and persists for 5 or more days.⁴² The conjunctivitis begins shortly after the onset of fever, persists throughout the febrile course of the disease, and may last as long as 3 to 5 weeks.

The *subacute phase* begins when fever and other acute signs have subsided and lasts until all signs of the disease have disappeared. The subacute phase is associated with peeling of the skin of the fingertips and ends of the toes, thrombocytosis, the development of coronary aneurysms, and the greatest risk of sudden death. The *convalescent stage* persists from the complete resolution of symptoms until all signs of inflammation have disappeared. This usually takes approximately 8 weeks. In addition to the major manifestations that occur during the acute stage of the illness, there are several associated, less specific characteristics of the disease, including arthritis, urethritis and pyuria, gastrointestinal manifestations (*e.g.*, diarrhea, abdominal pain), hepatitis, and hydrops of the gallbladder.⁴² Arthritis or arthralgia occurs in approximately 30% of children with the disease, characterized by symmetric joint swelling that involves large and small joints. Central nervous system involvement occurs in almost all children and is characterized by pronounced irritability and lability of mood.

Cardiac involvement is the most important manifestation of Kawasaki's disease. Coronary vasculitis develops in between 10% and 40% of children within the first 2 weeks of the illness, manifested by dilatation and aneurysm formation in the coronary arteries, as seen on two-dimensional echocardiography. The manifestations of coronary artery involvement include signs and symptoms of myocardial ischemia or, rarely, overt myocardial infarction or rupture of the aneurysm. Pericarditis, myocarditis, endocarditis, heart failure, and dysrhythmias also may develop.

Diagnosis and Treatment

As with rheumatic fever, the diagnosis of Kawasaki's disease is based on clinical findings because no specific laboratory test for the disease exists. Clinical criteria developed by the Japan Kawasaki Disease Research Committee and subsequently by the AHA are used in establishing a diagnosis of Kawasaki's disease.⁴³ Chest radiographs, ECG tests, and two-dimensional echocardiography are used to detect coronary artery involvement and follow its progress. Coronary angiography may be used to determine the extent of coronary artery involvement.

Intravenous gamma globulin and aspirin are considered the best therapy for prevention of coronary artery abnormalities in children with Kawasaki's disease.⁴² During the acute phase of the illness, aspirin usually is given in larger doses and for its anti-inflammatory and antipyretic effects.⁴² After the fever is controlled, the aspirin dose is lowered, and the drug is given for its anti-platelet-aggregating effects.

In summary, congenital heart defects arise during fetal heart development and reflect the stage of development at the time the causative event occurred. Several factors contribute to the development of congenital heart defects, including genetic and chromosomal influences, viruses, and environmental agents such as drugs and radiation. The cause of the defect often is unknown. The defect may produce no effects, or it may markedly affect cardiac function. Congenital heart defects commonly produce shunting of blood from the right to the left side of the heart or from the left to the right side of the heart. Left-to-right shunts typically increase the volume of the right side of the heart and pulmonary circulation, and right-to-left shunts transfer unoxygenated blood from the right side of the heart to the left side, diluting the oxygen content of blood that is being ejected into the systemic circulation and causing cyanosis. The direction and degree of shunt depend on the size of the defect that connects the two sides of the heart and the difference in resistance between the two sides of the circulation. Congenital heart defects often are classified as defects that produce cyanosis and those that produce little or no cyanosis. Depending on the

severity of the defect, congenital heart defects may be treated medically or surgically. Medical and surgical treatment often is indicated in children with severe defects.

Kawasaki's disease is an acute febrile disease of young children that affects the skin, brain, eyes, joints, liver, lymph nodes, and heart. The disease can produce aneurysmal disease of the coronary arteries and is the most common cause of acquired heart disease in young children.

REVIEW QUESTIONS

Explain the decrease in cardiac output and pulsus paradoxus that occur with cardiac tamponade.

Describe blood flow in the coronary circulation and relate it to anginal pain that occurs during increased activity and tachycardia.

Characterize the pathogenesis of atherosclerosis in terms of fixed atherosclerotic lesions, unstable plaque, and thrombosis with obstruction. Explain the role of low-dose aspirin in prevention of CHD.

Define the term acute coronary syndromes and distinguish among chronic stable angina, unstable angina, non–ST-segment elevation myocardial infarction, and ST-segment elevation myocardial infarction in terms of pathology, symptomatology, ECG changes, and serum cardiac markers.

Compare the heart changes that occur with dilated, hypertrophic, constrictive cardiomyopathies, and arrhythmogenic right ventricular cardiomyopathy.

Describe the relation between the infective vegetations associated with infective endocarditis and explain their relationship to the extracardiac manifestations of the disease.

State the function of the heart valves and relate to alterations in hemodynamic changes (obstruction or regurgitation of blood flow), changes in stroke volume output, and nature of the heart murmur in terms of its occurrence during systole or diastole.

Describe the anatomic defects and altered patterns of blood flow in children with atrial septal defects, ventricular septal defects, endocardial cushion defects, pulmonary stenosis, tetralogy of Fallot, patent ductus arteriosus, transposition of the great vessels, and coarctation of the aorta.

dequate perfusion of body tissues depends on the pumping ability of the heart, a vascular system that transports blood to the cells and back to the heart, sufficient blood to fill the circulatory system, and tissues that are able to extract and use the oxygen and nutrients from the blood. Heart failure and circulatory shock are separate conditions that reflect failure of the circulatory system. Both conditions exhibit common compensatory mechanisms even though they differ in terms of pathogenesis and causes.

HEART FAILURE

Heart failure affects an estimated 4.8 million Americans.¹ Although morbidity and mortality rates from other cardiovascular diseases have decreased during the past several decades, the incidence of heart failure is increasing at an alarming rate. This change undoubtedly reflects treatment improvements and survival from other forms of heart disease. Despite advances in treatment, the 5-year survival rate for heart failure is only about 50%.

Physiology of Heart Failure

The term *heart failure* denotes the failure of the heart as a pump. The heart has the amazing capacity to adjust its pumping ability to meet the varying needs of the body. During sleep, its output declines, and during exercise, it increases markedly. The ability to increase cardiac output during increased activity is called the *cardiac reserve*. For example, competitive swimmers and long-distance runners have large cardiac reserves. During exercise, the cardiac output of these athletes rapidly increases to as much as five to six times their resting level. In sharp contrast with healthy athletes, persons with heart failure often use their cardiac reserve at rest. For them, just climbing a flight of stairs may cause shortness of breath because they have exceeded their cardiac reserve.

The pathophysiology of heart failure involves an interaction between two factors: (1) a decrease in cardiac output with a consequent decrease in blood flow to the kidneys and other body organs and tissues; (2) the recruitment of compensatory mechanisms designed to maintain tissue perfusion.

KEY CONCEPTS

HEART FAILURE

- The function of the heart is to move deoxygenated blood from the venous system through the right heart into the pulmonary circulation and to move the oxygenated blood from the pulmonary circulation through the left heart into the arterial system.
- To function effectively, the right and left hearts must maintain an equal output.
- Right heart failure represents failure of the right heart to pump blood forward into the pulmonary circulation; blood backs up in the systemic circulation, causing peripheral edema and congestion of the abdominal organs.
- Left heart failure represents failure of the left heart to move blood from the pulmonary circulation into the systemic circulation; blood backs up in the pulmonary circulation.

Cardiac Output

The cardiac output is the amount of blood that the heart pumps each minute. It reflects how often the heart beats each minute (heart rate) and how much blood the heart pumps with each beat (stroke volume) and can be expressed as the product of the heart rate and stroke volume (cardiac output = heart rate × stroke volume). Heart rate is a function of sympathetic nervous system reflexes, which accelerate heart rate and parasympathetic nervous system reflexes, which slows it down. Stroke volume is a function of preload, afterload, and cardiac contractility.

Preload and Afterload. The work that the heart performs consists mainly of ejecting blood into the pulmonary or systemic circulations. It is determined largely by the loading conditions or what is called the preload and afterload.

Preload reflects the loading condition of the heart at the end of diastole just before the onset of systole. It is the volume of blood stretching the resting heart muscle and is determined mainly by the venous return to the heart. Afterload represents the force that the contracting heart must generate to eject blood from the filled heart. The main components of afterload are ventricular wall tension and the peripheral vascular resistance. The greater the peripheral vascular resistance, the greater the ventricular wall tension and intraventricular pressure required to open the aortic valve and pump blood into the peripheral circulation.

Cardiac Contractility. Cardiac contractility refers to the mechanical performance of the heart: the ability of the contractile elements (actin and myosin filaments) of the heart muscle to interact and shorten against a load. Contractility increases cardiac output independent of preload filling and muscle stretch.

An inotropic influence is one that increases cardiac contractility. Sympathetic stimulation increases the strength of cardiac contraction (*i.e.*, positive inotropic action), and hypoxia and ischemia decrease contractility (*i.e.*, negative inotropic effect). The inotropic drug digitalis, which is used in the treatment of heart failure, increases cardiac contractility such that the heart is able to eject more blood at any level of preload filling.

Compensatory Mechanisms

Heart failure is characterized by a decrease in cardiac output with a consequent decline in blood flow to the kidneys as well as other body organs and tissues. With a decrease in cardiac performance, tissue and organ perfusion is largely maintained through compensatory mechanisms such as the Frank-Starling mechanism, activation of the sympathetic nervous system and the renin-angiotensin-aldosterone mechanism, and myocardial hypertrophy (Fig. 18-1). In the failing heart, early decreases in cardiac function often go unnoticed because these compensatory mechanisms are used to maintain the cardiac output. This state is called compensated heart failure. Unfortunately, these mechanisms were not intended for long-term use. In severe and prolonged heart failure, the compensatory mechanisms are no longer effective and may themselves worsen the failure, causing what is termed *decompensated failure*.

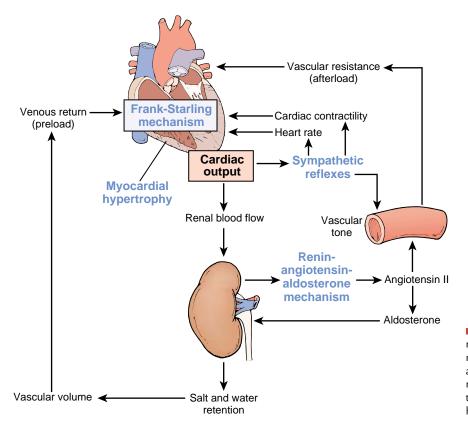

Frank-Starling Mechanism. The Frank-Starling mechanism relies on an increase in venous return and a resultant increase in diastolic filling of the ventricles. Known as the *end-diastolic vol*ume, this volume causes the tension in the wall of the ventricles and the pressure in the ventricles to rise. With increased ventricular end-diastolic volume, there is increased stretching of the myocardial fibers, more optimal approximation of the actin and myosin filaments, and a resultant increase in the stroke volume in accord with the Frank-Starling mechanism (see Chapter 14, Fig. 14-20).

In heart failure a decrease in cardiac output and renal blood flow leads to increased salt and water retention, a resultant increase in vascular volume and venous return to the heart, and an increase in ventricular end-diastolic volume. Within limits, as preload and ventricular end-diastolic volume increase, there is a resultant increase in cardiac output. Thus, cardiac output may be normal at rest in persons with heart failure. However, as myocardial function deteriorates, the heart becomes overfilled, the muscle fibers become overstretched, and the ventricular function curve flattens (Fig. 18-2). The maximal increase in cardiac output that can be achieved may severely limit activity, while producing an elevation in left ventricular and pulmonary capillary pressure and development of dyspnea and pulmonary congestion.

An important determinant of myocardial energy consumption is ventricular wall tension. Overfilling of the ventricle produces a decrease in wall thickness and an increase in wall tension. Because increased wall tension increases myocardial oxygen requirements, it can produce ischemia and further impairment of cardiac function. The use of diuretics in the treatment of heart failure helps to reduce vascular volume and ventricular filling, thereby unloading the heart and reducing ventricular wall tension.

Increased Sympathetic Nervous System Activity. Stimulation of the sympathetic nervous system plays an important role in the compensatory response to decreased cardiac output and the pathogenesis of heart failure.^{2,3} Both cardiac sympathetic tone

322 Unit Four: Alterations in the Cardiovascular System

■ FIGURE 18-1 ■ Compensatory mechanisms in heart failure. The Frank-Starling mechanism, sympathetic reflexes, reninangiotensin-aldosterone mechanism, and myocardial hypertrophy function in maintaining the cardiac output for the failing heart.

and circulating catecholamine (epinephrine and norepinephrine) levels are elevated during the late stages of most forms of heart failure. By direct stimulation of heart rate and cardiac contractility and by regulation of vascular tone, the sympathetic nervous system helps to maintain perfusion of the various organs, particularly the heart and brain.

The negative aspects of increased sympathetic activity include an increase in peripheral vascular resistance and the after-

load against which the heart must pump. Excessive sympathetic stimulation also may result in decreased blood flow to skin, muscle, kidney, and abdominal organs. The catecholamines also may contribute to the high rate of sudden death by promoting dysrhythmias.⁴

Renin-Angiotensin Mechanism. One of the most important effects of a lowered cardiac output in heart failure is a reduction in renal blood flow and glomerular filtration rate, which leads to salt and water retention. Normally, the kidneys receive approximately 25% of the cardiac output, but this may be decreased to as low as 8% to 10% in persons with heart failure. With decreased renal blood flow, there is a progressive increase in renin secretion by the kidneys along with parallel increases in circulating levels of angiotensin II. The increased concentration of angiotensin II contributes to a generalized vasoconstriction and serves as a stimulus for aldosterone production by the adrenal cortex (see Chapter 16). Aldosterone, in turn, increases tubular reabsorption of sodium, with an accompanying increase in water retention. Because aldosterone is metabolized in the liver, its levels are further increased when heart failure causes liver congestion.

Recent evidence suggests that angiotensin is also a growth factor for cardiac muscle cells and fibroblasts and, as such, may play a central role in modifying the structure and function of the myocardium in persons with heart failure.² Angiotensin-converting enzyme (ACE) inhibitor drugs, which block the conversion of angiotensin I to angiotensin II, are often used in the treatment of heart failure.^{2–4}

Myocardial Hypertrophy. Myocardial hypertrophy is a longterm compensatory mechanism. Cardiac muscle, like skeletal muscle, responds to an increase in work demands by undergoing hypertrophy. Hypertrophy increases the number of contractile elements in myocardial cells as a means of increasing their contractile performance.

Myocardial hypertrophy occurs early in the course of heart failure and is an important risk factor for subsequent morbidity and mortality. Although hypertrophy increases the systolic function of the heart, it also eventually can lead to diastolic dysfunction and myocardial ischemia. Some forms of hypertrophy may lead to abnormal remodeling of the ventricular wall with a reduction in chamber size, reduced diastolic filling, and increased ventricular wall tension. For example, untreated hypertension causes hypertrophy that may preserve systolic function for a time, but eventually the work performed by the ventricle exceeds the augmented muscle mass and the heart dilates.² The increased muscle mass of the hypertrophied heart increases the need for oxygen delivery. When the oxygen requirements of the increased muscle mass exceed the ability of the coronary vessels to bring blood to the area, myocardial hypertrophy is no longer beneficial and may result in ischemia with decreased contractility. In addition, hypertrophy of cardiac muscle cells may be accompanied by the growth of nonmyocardial tissue (e.g., fibrous tissue) that produces stiffness of the ventricle and further impairment of ventricular function.

Congestive Heart Failure

Heart failure occurs when the pumping ability of the heart becomes impaired. The term congestive heart failure (CHF) refers to heart failure that is accompanied by congestion of body tissues.

Heart failure may be caused by a variety of conditions, including acute myocardial infarction, hypertension, valvular heart disease, or degenerative conditions of the heart muscle known collectively as cardiomyopathies (see Chapter 17). Heart failure also may occur because of excessive work demands, such as occurs with hypermetabolic states, or with volume overload, such as occurs with renal failure. Either of these states may exceed the work capacity of even a healthy heart. In persons with asymptomatic heart disease, heart failure may be precipitated by an unrelated illness or stress. Table 18-1 lists major causes of heart failure.

Types of Heart Failure

Heart failure may be described as high-output or low-output failure, systolic or diastolic failure, and right-sided or left-sided failure.

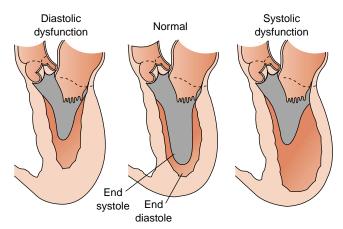

High- and Low-Output Failure. High- and low-output failure are described in terms of cardiac output. High-output failure is an uncommon type of heart failure that is caused by an excessive need for cardiac output. With high-output failure, the function of the heart may be supernormal but inadequate because of excessive metabolic needs. Causes of high-output failure include severe anemia, thyrotoxicosis, and conditions that cause arteriovenous shunting. High-output failure tends to be specifically treatable. Low-output failure is caused by disorders that im-

TABLE 18-1 Causes	of Heart Failure

Myocardial Disease Cardiomyopathies Myocarditis Coronary insufficiency Myocardial infarction	Increased Pressure Work Systemic hypertension Pulmonary hypertension Coarctation of the aorta
Valvular Heart Disease Stenotic valvular disease Regurgitant valvular disease	Increased Volume Work Arteriovenous shunt Excessive administration of intravenous fluids
Congenital Heart Defects	Increased Perfusion Work Thyrotoxicosis Anemia
Constrictive Pericarditis	

pair the pumping ability of the heart, such as ischemic heart disease and cardiomyopathy.

Systolic Versus Diastolic Failure. A recent classification separates the pathophysiology of CHF into two categories—systolic dysfunction and diastolic dysfunction. Systolic dysfunction is characterized by impaired ejection of blood from the heart during systole and diastolic dysfunction by impaired filling of the ventricles during diastole (Fig. 18-3). Many persons with heart failure fall into an intermediate category, with combined elements of both systolic and diastolic failure.

Systolic dysfunction involves a decrease in cardiac contractility and ejection fraction. It commonly results from conditions that impair the contractile performance of the heart (e.g., ischemic heart disease and cardiomyopathy), produce a volume

■ FIGURE 18-3 ■ Congestive heart failure due to systolic and diastolic dysfunction. The ejection fraction represents the difference between the end-diastolic and end-systolic volumes. Normal systolic and diastolic function with normal ejection fraction (middle); diastolic dysfunction with decreased ejection fraction due to decreased diastolic filling (left); systolic dysfunction with decreased ejection fraction due to impaired systolic function (right).

overload (*e.g.*, valvular insufficiency and anemia), or generate a pressure overload (*e.g.*, hypertension and valvular stenosis) on the heart.

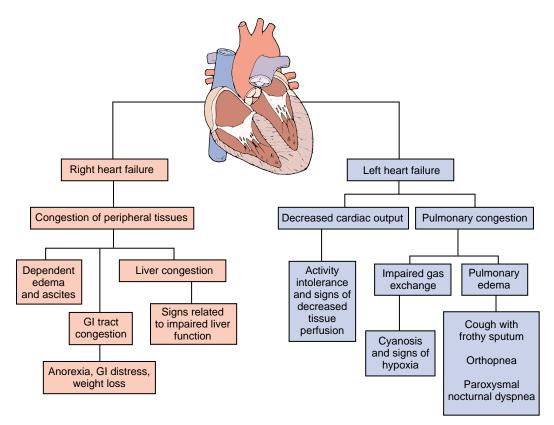

A normal heart ejects approximately 65% of the blood that is present in the ventricle at the end of diastole when it contracts. This is called the *ejection fraction*. In systolic heart failure, the ejection fraction declines progressively with increasing degrees of myocardial dysfunction. In very severe forms of heart failure, the ejection fraction may drop to a single-digit percentage. With a decrease in ejection fraction, there is a resultant increase in diastolic volume, ventricular dilation, ventricular wall tension, and ventricular end-diastolic pressure. The symptoms of persons with systolic dysfunction result mainly from reductions in ejection fraction and cardiac output.

Diastolic dysfunction, which reportedly accounts for approximately 40% of all cases of CHF, is characterized by a smaller ventricular chamber size, ventricular hypertrophy, and poor ventricular compliance (*i.e.*, ability to stretch during filling).⁵ Because of impaired filling, congestive symptoms tend to predominate in diastolic dysfunction. Among the conditions that cause diastolic dysfunction are those that restrict diastolic filling (*e.g.*, mitral stenosis), those that increase ventricular wall thickness and reduce chamber size (*e.g.*, myocardial hypertrophy caused by lung disease and hypertrophic cardiomyopathy), and those that delay diastolic relaxation (*e.g.*, aging, ischemic heart disease). Aging often is accompanied by a delay in relaxation of the heart during diastole; diastolic filling begins while the ventricle is still stiff and resistant to stretching to accept an increase in volume.⁶ A similar delay occurs with myocardial ischemia, resulting from a lack of energy to break the rigor bonds that form between the actin and myosin filaments of the contracting cardiac muscle.⁷ Because tachycardia produces a decrease in diastolic filling time, persons with diastolic dysfunction often become symptomatic during activities and situations that increase heart rate.

Right-Sided Versus Left-Sided Heart Failure. Heart failure also can be classified according to the side of the heart (right or left) that is affected. An important feature of the circulatory system is that the right and left ventricles act as two pumps that are connected in series. To function effectively, the right and left ventricles must maintain an equal output. Although the initial event that leads to heart failure may be primarily right sided or left sided in origin, long-term heart failure usually involves both sides.

Right-Sided Heart Failure. Right-sided heart failure impairs the ability to move deoxygenated blood from the systemic venous circulation into the pulmonary circulation. Consequently, when the right heart fails, there is an accumulation of blood in the systemic venous system (Fig. 18-4). This causes an increase in the right atrial, right ventricular end-diastolic, and systemic venous pressures.

A major effect of right-sided heart failure is the development of peripheral edema. Because of the effects of gravity, the edema is most pronounced in the dependent parts of the body—in the lower extremities when the person is in the upright position and in the area over the sacrum when the person is supine. The

■ FIGURE 18-4 ■ Manifestations of left- and right-sided heart failure.

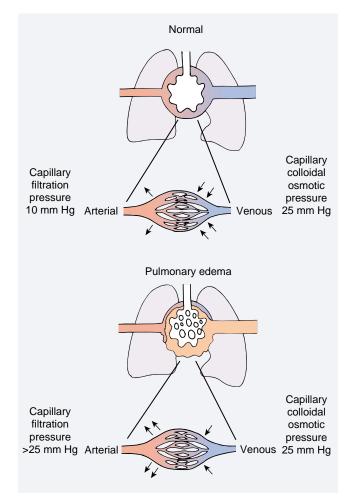

accumulation of edema fluid is evidenced by a gain in weight (*i.e.*, 1 pint of accumulated fluid results in a 1-lb weight gain). Daily measurement of weight can be used as a means of assessing fluid accumulation in a patient with chronic CHF. As a rule, a weight gain of more than 2 lb in 24 hours or 5 lb in 1 week is considered a sign of worsening failure.

Right-sided heart failure also produces congestion of the viscera. As venous distention progresses, blood backs up in the hepatic veins that drain into the inferior vena cava, and the liver becomes engorged. This may cause hepatomegaly and right upper quadrant pain. In severe and prolonged right-sided failure, liver function is impaired and hepatic cells may die. Congestion of the portal circulation also may lead to engorgement of the spleen and the development of ascites. Congestion of the gastrointestinal tract may interfere with digestion and absorption of nutrients, causing anorexia and abdominal discomfort. The jugular veins, which are above the level of the heart, are normally collapsed in the standing position or when sitting with the head at higher than a 30-degree angle. In severe rightsided failure, the external jugular veins become distended and can be visualized when the person is sitting up or standing.

The causes of right-sided heart failure include conditions that restrict blood flow into or through the lungs. Stenosis or regurgitation of the tricuspid or pulmonic valves, right ventricular infarction, cardiomyopathy, and persistent left-sided failure are common causes. *Cor pulmonale* refers to right heart failure resulting from pulmonary disease. *Acute cor pulmonale* results from right heart strain or overload secondary to acute pulmonary hypertension, often caused by massive pulmonary embolism. *Chronic cor pulmonale* occurs secondary to diseases that affect pulmonary tissues (chronic obstructive lung disease) or pulmonary vasculature (primary pulmonary hypertension).

Left-Sided Heart Failure. Left-sided heart failure impairs the pumping of blood from the low-pressure pulmonary circulation into the high-pressure arterial side of the systemic circulation (Fig. 18-4). With impairment of left heart function, there is a decrease in cardiac output, an increase in left atrial and left ventricular end-diastolic pressures, and congestion in the pulmonary circulation. When the pulmonary capillary filtration pressure (normally approximately 10 mm Hg) exceeds the capillary osmotic pressure (normally approximately 25 mm Hg), there is a shift of intravascular fluid into the interstitium of the lung and development of pulmonary edema (Fig 18-5). An episode of pulmonary edema often occurs at night, after a person has been reclining for some time and gravitational forces have been removed from the circulatory system. It is then that edema fluid that has been sequestered in the lower extremities during the day is returned to the vascular compartment and redistributed to the pulmonary circulation.

The most common causes of left-sided heart failure are acute myocardial infarction and cardiomyopathy. Left-sided heart failure and pulmonary congestion can develop very rapidly in persons with acute myocardial infarction. Even when the infarcted area is small, there may be a surrounding area of ischemic tissue. This may result in a large area of nonpumping ventricle and rapid onset of pulmonary edema. Aortic and aortic valve disorders can also cause left-sided heart failure. Pulmonary edema also may develop during rapid infusion of intravenous fluids or blood transfusions in an elderly person or in a person with limited cardiac reserve.

■ FIGURE 18-5 ■ Mechanism of respiratory symptoms in leftsided heart failure. Normal exchange of fluid in the pulmonary capillaries (top). The capillary filtration pressure that moves fluid out of the capillary into the lung is less than the capillary colloidal osmotic pressure that pulls fluid back into the capillary. Development of pulmonary edema (bottom) occurs when the capillary filtration pressure exceeds the capillary colloidal osmotic pressure that pulls fluid back into the capillary.

Manifestations of Heart Failure

The manifestations of heart failure depend on the extent and type of cardiac dysfunction (e.g., systolic versus diastolic) that is present and the rapidity with which it develops. Many persons with heart failure have concomitant cardiovascular and noncardiovascular disorders that may exacerbate the condition.7 The concomitant conditions include cardiovascular disorders such as hypertension, coronary artery disease, diabetes, and cardiac dysrhythmias. Associated noncardiovascular diseases include renal insufficiency, thyroid disease, and pulmonary disease. A person with previously stable compensated heart failure may experience signs of heart failure for the first time when the condition has advanced to a critical point, such as with a progressive increase in pulmonary hypertension in a person with mitral valve regurgitation. Overt heart failure also may be precipitated by conditions such as infection, emotional stress, uncontrolled hypertension, administration of fluid overload, or inappropriate reduction in therapy. Many persons with serious underlying heart disease, regardless of whether they have previously experienced heart failure, may be relatively asymptomatic as long they carefully adhere to their treatment regimen. A dietary excess of sodium is a frequent cause of sudden cardiac decompensation.

The manifestations of heart failure reflect the physiologic effects of the impaired pumping ability of the heart, decreased renal blood flow, and activation of the sympathetic compensatory mechanisms. The signs and symptoms include fluid retention and edema, shortness of breath and other respiratory manifestations, fatigue and limited exercise tolerance, cyanosis, cachexia and malnutrition, and cyanosis. Distention of the jugular veins may be present in right-sided failure. Excessive sympathetic stimulation may produce diaphoresis and tachycardia in persons with severe heart failure.

Fluid Retention and Edema. Many of the manifestations of CHF result from the increased capillary pressures that develop in the peripheral circulation in right-sided heart failure and in the pulmonary circulation in left-sided heart failure. The increased capillary pressure reflects an overfilling of the vascular system because of increased salt and water retention and venous congestion resulting from the impaired pumping ability of the heart.

Nocturia is a nightly increase in urine output that occurs relatively early in the course of CHF. It results from the return to the circulation of edema fluids from the dependent parts of the body when the person assumes the supine position for the night. As a result, the cardiac output, renal blood flow, glomerular filtration, and urine output increase. Oliguria is a late sign related to a severely reduced cardiac output and resultant renal failure.

Respiratory Manifestations. Shortness of breath caused by congestion of the pulmonary circulation is one of the major manifestations of left-sided heart failure. Perceived shortness of breath (i.e., breathlessness) is called dyspnea. Dyspnea related to an increase in activity is called exertional dyspnea. Orthopnea is shortness of breath that occurs when a person is supine. The gravitational forces that cause fluid to become sequestered in the lower legs and feet when the person is standing or sitting are removed when a person with CHF assumes the supine position; fluid from the legs and dependent parts of the body is mobilized and redistributed to an already distended pulmonary circulation. Paroxysmal nocturnal dyspnea is a sudden attack of dyspnea that occurs during sleep. It disrupts sleep, and the person awakens with a feeling of extreme suffocation that resolves when he or she sits up. Initially, the experience may be interpreted as awakening from a bad dream.

A subtle and often overlooked symptom of heart failure is a chronic dry, nonproductive cough, which becomes worse when the person is lying down. Bronchospasm caused by congestion of the bronchial mucosa may cause wheezing and difficulty in breathing. This condition is sometimes referred to as *cardiac asthma*.

Cheyne-Stokes respiration, also known as periodic breathing, is characterized by a slow waxing and waning of respiration. The person breathes deeply for a period when the arterial carbon dioxide pressure (PCO_2) is high and then slightly or not at all when the PCO_2 falls. In persons with left-sided heart failure, the condition is thought to be caused by a prolongation of the

heart-to-brain circulation, particularly in persons with hypertension and associated cerebral vascular disease. Cheyne-Stokes breathing may contribute to daytime sleepiness, and occasionally the person awakens at night with dyspnea precipitated by Cheyne-Stokes breathing.

Fatigue and Limited Exercise Tolerance. Fatigue and limb weakness often accompany diminished output from the left ventricle. Cardiac fatigue is different from general fatigue in that it usually is not present in the morning but appears and progresses as activity increases during the day. In acute or severe left-sided failure, cardiac output may fall to levels that are insufficient for providing the brain with adequate oxygen, and there are indications of mental confusion and disturbed behavior. Confusion, impairment of memory, anxiety, restlessness, and insomnia are common in elderly persons with advanced heart failure, particularly in those with cerebral atherosclerosis. These very symptoms may confuse the diagnosis of heart failure in the elderly because of the myriad other causes associated with aging.

Cachexia and Malnutrition. Cardiac cachexia is a condition of malnutrition and tissue wasting that occurs in persons with end-stage heart failure. A number of factors probably contribute to its development, including the fatigue and depression that interfere with food intake, congestion of the liver and gastrointestinal structures that impairs digestion and absorption and produces feelings of fullness, and the circulating toxins and mediators released from poorly perfused tissues that impair appetite and contribute to tissue wasting.

Cyanosis. Cyanosis is the bluish discoloration of the skin and mucous membranes caused by excess desaturated hemoglobin in the blood; it often is a late sign of heart failure. Cyanosis may be central or peripheral. Central cyanosis is caused by conditions that impair oxygenation of the arterial blood, such as pulmonary edema, left heart failure, or right-to-left shunting. Central cyanosis is best monitored in the lips and mucous membranes because these areas are not subject to conditions such as cold that cause peripheral cyanosis. Peripheral cyanosis is caused by conditions such as low-output failure that cause delivery of poorly oxygenated blood to the peripheral tissues, or by conditions such as peripheral vasoconstriction that cause excessive removal of oxygen from the blood.

Diagnosis and Treatment

Diagnostic methods in heart failure are directed toward establishing the cause of the disorder and determining the extent of the dysfunction. Because heart failure represents the failure of the heart as a pump and can occur in the course of a number of heart diseases or other systemic disorders, the diagnosis of heart failure often is based on signs and symptoms related to the failing heart itself, such as shortness of breath and fatigue. The functional classification of the New York Heart Association is one guide to classifying the extent of dysfunction (Table 18-2).

The diagnostic methods used for determining the presence of heart failure, its cause, and extent of dysfunction include history and physical examination, laboratory studies, chest radiography, electrocardiography (ECG), and echocardiography.⁸ The history should include information related to dyspnea, cough, nocturia, generalized fatigue, and other signs and symptoms of heart failure. A complete physical examination in-

TABLE 18-2	New Yorl	k Heart
Association		Classification
of Patients V	With Heart	Disease

Classification	Characteristics
Class I	Patients with cardiac disease but without the resulting limitations in physical activity. Ordinary activity does not cause undue fatigue, palpitation, dyspnea, or anginal
	pain.
Class II	Patients with heart disease resulting in slight limitations of physical activity. They are
	comfortable at rest. Ordinary physical
	activity results in fatigue, palpitation,
a	dyspnea, or anginal pain.
Class III	Patients with cardiac disease resulting in
	marked limitation of physical activity. They
	are comfortable at rest. Less than ordinary
	physical activity causes fatigue, palpitation,
	dyspnea, or anginal pain.
Class IV	Patients with cardiac disease resulting in
	inability to carry on any physical activity
	without discomfort. The symptoms of
	cardiac insufficiency or of the anginal syn-
	drome may be present even at rest. If any
	physical activity is undertaken, discomfort
	increases.

cludes assessment of heart rate, heart sounds, blood pressure, jugular veins for venous congestion, lungs for signs of pulmonary congestion, and lower extremities for edema. Laboratory tests are used in the diagnosis of anemia and electrolyte imbalances, and to detect signs of chronic liver congestion.

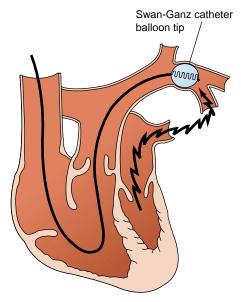

Chest radiographs provide information about the size and shape of the heart and pulmonary vasculature. The cardiac silhouette can be used to detect cardiac hypertrophy and dilatation. X-ray films can indicate the relative severity of the failure by revealing if pulmonary edema is predominantly vascular, interstitial, or advanced to the alveolar and bronchial stages. ECG findings may indicate atrial or ventricular hypertrophy, underlying disorders of cardiac rhythm, or conduction abnormalities such as right or left bundle branch block. Echocardiography plays a key role in assessing the anatomic and functional abnormalities in CHF, which include the size and function of cardiac valves, the motion of both ventricles, and the ventricular ejection fraction.9 Radionuclide angiography and cardiac catheterization are other diagnostic tests used to detect the underlying causes of heart failure, such as heart defects and cardiomyopathy.

Invasive hemodynamic monitoring often is used in the management of acute, life-threatening episodes of heart failure. These monitoring methods include measurement of central venous pressure (CVP), pulmonary capillary wedge pressure (PCWP), thermodilution cardiac output, and intra-arterial blood pressure. Measurements of CVP are obtained from a catheter inserted into the right atrium; they provide information about the pumping ability of the right heart and its ability to move blood into the pulmonary circulation. PCWP is obtained from a balloon-tipped catheter that is advanced into a small pulmonary vessel (Fig. 18-6). When the balloon on pulmonary catheter is inflated, the catheter monitors pulmonary capillary pressures that are in direct communication with those of the left heart. Thus, PCWP provide information about the pumping ability of the left heart.

The goals of treatment for chronic heart failure are directed toward relieving the symptoms and improving the quality of life, with a long-term goal of slowing, halting, or reversing the cardiac dysfunction.^{10,11} Treatment measures include correction of reversible causes such as anemia or thyrotoxicosis, surgical repair of a ventricular defect or an improperly functioning valve, pharmacologic and nonpharmacologic control of afterload stresses such as hypertension, modification of activities and lifestyle to a level consistent with the functional limitations of a reduced cardiac reserve, and the use of medications to improve cardiac function and limit excessive compensatory mechanisms. Restriction of salt intake and diuretic therapy facilitate the excretion of edema fluid.

In severe heart failure, restriction of activity, including bed rest if necessary, often facilitates temporary recompensation of cardiac function. However, there is no convincing evidence that continued bed rest is of benefit. Carefully designed and managed exercise programs for patients with CHF are well tolerated and beneficial to patients with stable New York Heart Association (NYHA) class I to III heart failure.¹²

Pharmacologic Treatment. Once heart failure is moderate to severe, polypharmacy becomes a management standard and often includes diuretics, digoxin, ACE inhibitors, and β -adrenergic–blocking agents.^{13,14} The choice of pharmacologic agents is determined by problems caused by the disorder (*i.e.*, systolic or diastolic dysfunction) and those brought about by activation of compensatory mechanisms (*e.g.*, excess fluid retention, inappropriate activation of sympathetic mechanisms).

■ FIGURE 18-6 ■ Swan-Ganz balloon-tipped catheter positioned in a pulmonary capillary. The pulmonary capillary wedge pressure, which reflects the left ventricular diastolic pressure, is measured with the balloon inflated.

328 Unit Four: Alterations in the Cardiovascular System

Diuretics are among the most frequently prescribed medications for heart failure. They promote the excretion of edema fluid and help to sustain cardiac output and tissue perfusion by reducing preload and allowing the heart to operate at a more optimal part of the Frank-Starling curve. Digitalis drugs are inotropic agents that improve cardiac function by increasing the force and strength of ventricular contraction. They also produce a decrease in sinoatrial node activity and conduction through the atrioventricular node, thus slowing the heart rate and increasing diastolic filling time. Although not a diuretic, digitalis promotes urine output by improving cardiac output and renal blood flow. The ACE inhibitors, which prevent the conversion of angiotensin I to angiotensin II, have been effectively used in the treatment of heart failure. In heart failure, renin activity frequently is elevated because of decreased renal blood flow. The net result is an increase in angiotensin II, which causes vasoconstriction and increased aldosterone production with a subsequent increase in salt and water retention by the kidney. The ACE inhibitors reduce both mechanisms to decrease the workload of the heart.

 β -adrenergic–blocking agents are used to decrease left ventricular dysfunction associated with activation of the sympathetic nervous system.^{13,15} Chronic elevation of norepinephrine levels has been shown to cause cardiac muscle cell death and progressive left ventricular dysfunction, and is associated with poor prognosis in heart failure. The β -adrenergic–blocking agents also decrease the risk of serious cardiac dysrhythmias in the person with heart failure.

Acute Pulmonary Edema

Acute pulmonary edema is the most dramatic symptom of left heart failure. It is a life-threatening condition in which capillary fluid moves into the alveoli. The accumulated fluid in the alveoli and respiratory airways causes lung stiffness, makes lung expansion more difficult, and impairs the gas exchange function of the lung. With the decreased ability of the lungs to oxygenate the blood, the hemoglobin leaves the pulmonary circulation without being fully oxygenated.

Manifestations

Acute pulmonary edema usually is a terrifying experience. The person usually is seen sitting and gasping for air, in obvious apprehension. The pulse is rapid, the skin is moist and cool, and the lips and nail beds are cyanotic. As the lung edema worsens and oxygen supply to the brain drops, confusion and stupor appear. Dyspnea and air hunger are accompanied by a cough productive of frothy and often blood-tinged sputum—the effect of air mixing with serum albumin and red blood cells that have moved into the alveoli. The movement of air through the alveolar fluid produces fine crepitant sounds called *crackles*, which can be heard through a stethoscope placed on the chest. As fluid moves into the larger airways, the breathing becomes louder. The crackles heard earlier become louder and coarser. In the terminal stage the breathing pattern is called the *death rattle*. Persons with severe pulmonary edema literally drown in their own secretions.

Treatment

Treatment of acute pulmonary edema is directed toward reducing the fluid volume in the pulmonary circulation. This can be accomplished by reducing the amount of blood that the right heart delivers to the lungs or by improving the work performance of the left heart. Several measures can decrease the blood volume in the pulmonary circulation; the seriousness of the pulmonary edema determines which are used. One of the simplest measures to relieve orthopnea is assumption of the seated position, in which gravity causes blood to be redistributed to the lower extremities. For many persons, sitting up or standing is almost instinctive and may be sufficient to relieve the symptoms associated with mild accumulation of fluid.

Measures to improve left heart performance focus on decreasing the preload by reducing the filling pressure of the left ventricle and on reducing the afterload against which the left heart must pump. This can be accomplished through the use of diuretics, vasodilator drugs, treatment of arrhythmias that impair cardiac function, and improvement of the contractile properties of the left ventricle with digitalis. Rapid digitalization can be accomplished with intravenous administration of the drug.

Oxygen therapy increases the oxygen content of the blood and helps relieve anxiety. Positive-pressure breathing, which is administered through a specially designed mask, increases the intra-alveolar pressure, opposes the capillary filtration pressure in the pulmonary capillaries, and sometimes is used as a temporary measure to decrease the amount of fluid moving into the alveoli. However, in the most severe cases, endotracheal intubation and mechanical ventilation may be necessary. Although its mechanisms of action are unclear, morphine sulfate usually is the drug of choice in acute pulmonary edema. Morphine relieves anxiety and depresses the pulmonary reflexes that cause spasm of the pulmonary vessels. It also increases venous pooling by vasodilatation.

Cardiogenic Shock

Cardiogenic shock refers to the pronounced failure of the heart as a pump. Cardiogenic shock can occur relatively quickly because of the damage to the heart that occurs during myocardial infarction; ineffective pumping caused by cardiac dysrhythmias; mechanical defects that may occur as a complication of myocardial infarction, such as ventricular septal defect; ventricular aneurysm; acute disruption of valvular function; or problems associated with open heart surgery. Cardiogenic shock also may ensue as an end-stage condition of coronary artery disease or cardiomyopathy.

The most common cause of cardiogenic shock is myocardial infarction. Most patients who die of cardiogenic shock have lost at least 40% of the contracting muscle of the left ventricle because of a recent infarct or a combination of recent and old infarcts.¹⁶ Cardiogenic shock can follow other types of shock associated with inadequate coronary blood flow.

In all cases of cardiogenic shock, there is failure to eject blood from the heart, hypotension, and inadequate cardiac output. Increased systemic vascular resistance often contributes to the deterioration of cardiac function by increasing afterload or the resistance to ventricular systole. The filling pressure, or preload of the heart, also is increased as blood returning to the heart is added to blood that previously was returned but not pumped forward, resulting in an increase in end-systolic ventricular volume. Increased resistance to ventricular systole (*i.e.*, afterload) combined with the decreased myocardial contractility causes the increased end-systolic ventricular volume and increased preload, which further complicate cardiac status.

Manifestations

The signs and symptoms of cardiogenic shock are consistent with those of extreme heart failure. The lips, nail beds, and skin are cyanotic because of stagnation of blood flow and increased extraction of oxygen from the hemoglobin as it passes through the capillary bed. The CVP and PCWP rise as a result of volume overload caused by the pumping failure of the heart.

Treatment

Treatment of cardiogenic shock requires a precarious balance between improving cardiac output, reducing the workload and oxygen needs of the myocardium, and preserving coronary perfusion. Fluid volume must be regulated within a level that maintains the filling pressure (*i.e.*, venous return) of the heart and maximum use of the Frank-Starling mechanism without causing pulmonary congestion.

Pharmacologic treatment includes the use of vasodilator drugs such as nitroprusside and nitroglycerin that cause arterial and venous dilatation. These drugs produce venous and arterial dilation, thus decreasing the venous return to the heart and the arterial resistance against which the left heart must pump. Catecholamines increase cardiac contractility but must be used with caution because they also produce vasoconstriction and increase cardiac workload by increasing the afterload.

The *intra-aortic balloon pump* may be used for persons who do not experience response to medical treatment. It provides a means of increasing aortic diastolic pressure and enhancing coronary and peripheral blood flow without increasing systolic pressure and the afterload, against which the left ventricle must pump.¹⁶ The device, which pumps in synchrony with the heart, consists of a balloon that is inserted through a catheter into the descending aorta (Fig. 18-7). The balloon is filled with helium

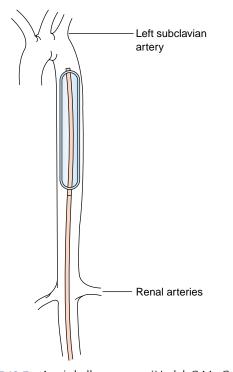

FIGURE 18-7 Aortic balloon pump. (Hudak C.M., Gallo B.M. [1994]. *Critical care nursing* [6th ed.]. Philadelphia: J.B. Lippincott)

and is timed to inflate during ventricular diastole and deflate just before ventricular systole. Diastolic inflation creates a pressure wave in the ascending aorta that increases coronary artery flow and a less intense wave in the lower aorta that enhances organ perfusion. The sudden balloon deflation at the onset of systole lowers the resistance to ejection of blood from the left ventricle, thereby increasing the heart's pumping efficiency and decreasing myocardial oxygen consumption.

Mechanical Support of the Failing Heart and Heart Transplantation

Refractory heart failure reflects deterioration in cardiac function that is unresponsive to medical or surgical interventions. With improved methods of treatment, more people are reaching a point where a cure is unachievable and death is imminent without mechanical support or heart transplantation.

Since the early 1960s, significant progress has been made in improving the efficacy of *ventricular assist devices* (VADs), which are mechanical pumps used to support ventricular function. VADs are used to decrease the workload of the myocardium while maintaining cardiac output and systemic arterial pressure.¹⁷ This decreases the workload on the ventricle and allows it to rest and recover.

Heart transplantation remains the treatment of choice for many persons with end-stage cardiac failure. The number of successful heart transplantations has been steadily climbing, with more than 2800 procedures performed per year. Patients with heart transplants who are treated with triple-immunosuppressant therapy have a 5-year survival rate of 70% to 80%.¹⁸ Despite the overall success of heart transplantation, donor availability and complications associated with infection, rejection, and immunosuppression drug therapy remain problems.

In summary, heart failure occurs when the heart fails to pump sufficient blood to meet the metabolic needs of body tissues. The physiology of heart failure reflects an interplay between a decrease in cardiac output that accompanies impaired function of the failing heart and the compensatory mechanisms designed to preserve the cardiac reserve. Compensatory mechanisms that contribute to maintenance of the cardiac reserve include the Frank-Starling mechanism, sympathetic nervous system responses, the renin-angiotensinaldosterone mechanism, and myocardial hypertrophy. In the failing heart, early decreases in cardiac function may go unnoticed because these compensatory mechanisms maintain the cardiac output. This is called compensated heart failure. Unfortunately, the mechanisms were not intended for longterm use, and in severe and prolonged heart failure, the compensatory mechanisms no longer are effective and further impair cardiac function.

Heart failure may be described as high-output or lowoutput failure, systolic or diastolic failure, and right-sided or left-sided failure. With high-output failure, the function of the heart may be supernormal but inadequate because of excessive metabolic needs, and low-output failure is caused by disorders that impair the pumping ability of the heart. With systolic dysfunction, there is impaired ejection of blood from the heart during systole; with diastolic dysfunction, there is impaired filling of the heart during diastole. Right-sided failure is characterized by congestion in the peripheral circulation, and left-sided failure by congestion in the pulmonary circulation.

The manifestations of heart failure include edema, nocturia, fatigue and impaired exercise tolerance, cyanosis, signs of increased sympathetic nervous system activity, and impaired gastrointestinal function and malnutrition. In rightsided failure, there is dependent edema of the lower parts of the body, engorgement of the liver, and ascites. In left-sided failure, shortness of breath and chronic, nonproductive cough are common.

Acute pulmonary edema is a life-threatening condition in which the accumulation of fluid in the interstitium of the lung and alveoli interferes with lung expansion and gas exchange. It is characterized by extreme breathlessness, crackles, frothy sputum, cyanosis, and signs of hypoxemia. In cardiogenic shock, there is failure to eject blood from the heart, hypotension, inadequate cardiac output, and impaired perfusion of peripheral tissues. Mechanical support devices, including the intra-aortic balloon pump (for acute failure) and the VAD, sustain life in persons with severe heart failure. Heart transplantation remains the treatment of choice for many persons with end-stage heart failure.

CIRCULATORY FAILURE (SHOCK)

The functions of the circulatory system are to perfuse body tissues and supply them with oxygen. Whereas heart failure results from impaired ability of the heart as a pump, circulatory shock results from a failure of the circulatory system to supply the peripheral tissues and organs of the body with an adequate blood supply. As with heart failure, circulatory shock is not a specific disease but can occur in the course of many life-threatening traumatic or disease states. In situations of severe cardiovascular compromise, signs of heart failure and vascular compromise may coexist. Although circulatory shock produces hypotension, it should not be equated with a drop in blood pressure. Hypotension often is a late sign and indicates a failure of compensatory mechanisms.

Adequate perfusion of body tissues depends on the pumping ability of the heart, a vascular system that transports blood to the cells and back to the heart, sufficient blood to fill the vascular system, and tissues that are able to use and extract oxygen and nutrients from the blood. As with heart failure, circulatory shock produces compensatory physiologic responses that eventually decompensate into various shock states if the condition is not properly treated in a timely manner.

Types of Shock

Circulatory shock is used to describe a critical decrease in tissue perfusion caused by a loss or redistribution of intravascular fluid. It can be classified as hypovolemic, obstructive, or distributive. These three main types of shock are summarized in Chart 18-1 and depicted in Figure 18-8. Cardiogenic shock, which results from failure of the heart as a pump, was discussed earlier in the chapter.

KEY CONCEPTS

CIRCULATORY SHOCK

- Circulatory shock represents the inability of the circulation to adequately perfuse the tissues of the body.
- It can result from a loss of fluid from the vascular compartment, an increase in the size of the vascular compartment that interferes with the distribution of blood, or obstruction of flow through the vascular compartment.
- The manifestations of shock reflect both the impaired perfusion of body tissues and the body's attempt to maintain tissue perfusion through conservation of water by the kidney, translocation of fluid from the extracellular to the intravascular compartment, and activation of sympathetic nervous system mechanisms that increase heart rate and divert blood from less to more essential body tissues.

Hypovolemic Shock

Hypovolemic shock is characterized by diminished blood volume such that there is inadequate filling of the vascular compartment (see Fig. 18-9). It occurs when there is an acute loss of 15% to 20% of the circulating blood volume. The decrease may be caused by an external loss of whole blood (*e.g.*, hemorrhage), plasma (*e.g.*, severe burns), or extracellular fluid (*e.g.*, gastrointestinal fluids lost in vomiting or diarrhea). Hypovolemic shock also can result from an internal hemorrhage or from third-space losses, when extracellular fluid is shifted from the vascular compartment to the interstitial space or compartment.

Hypovolemic shock has been the most widely studied type of shock and usually serves as a prototype in discussions of the manifestations of shock. Approximately 10% of the total

Distributive

Loss of sympathetic vasomotor tone Presence of vasodilating substances in the blood (anaphylactic shock) Presence of inflammatory mediators (septic shock)

■ **FIGURE 18-8** ■ Types of shock.

blood volume can be removed without changing the cardiac output or arterial pressure.¹⁹ The average blood donor loses a pint of blood without experiencing adverse effects. As increasing amounts of blood (10% to 25%) are removed, the cardiac output falls, but the arterial pressure is maintained because of sympathetic-mediated increases in heart rate and vasoconstriction. Blood pressure is the product of cardiac output and peripheral vascular resistance (BP = CO × PVR); an increase in peripheral vascular resistance maintains blood pressure in the presence of decreased cardiac output for a short period. Cardiac output and tissue perfusion decrease before signs of hypotension occur. The arterial pressure falls to zero when approximately 35% to 45% of the total blood volume has been removed.¹⁹

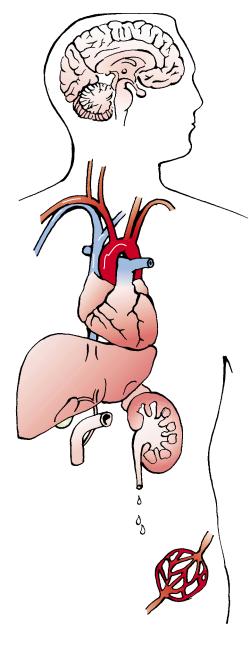

Manifestations. The signs and symptoms of hypovolemic shock depend on shock stage and are closely related to low peripheral blood flow and excessive sympathetic stimulation. They include thirst, an increase in heart rate, cool and clammy skin, a decrease in arterial blood pressure, a decrease in urine output, and changes in mentation (Fig. 18-9). Laboratory tests of hemoglobin and hematocrit provide information regarding

the severity of blood loss or hemoconcentration caused by dehydration. Serum lactate and arterial pH provide information about the severity of acidosis.

An increase in heart rate is often an early sign of shock. As shock progresses, the pulse becomes weak and thready, indicating vasoconstriction and a reduction in filling of the vascular compartment, and the respirations become rapid and deep. Arterial blood pressure is decreased in moderate to severe shock. However, controversy exists regarding the value of blood pressure measurements in the early diagnosis and management of shock. This is because compensatory mechanisms tend to preserve blood pressure until shock is relatively far advanced. Furthermore, an adequate arterial pressure does not ensure adequate perfusion and oxygenation of vital organs at the cellular level. This does not imply that blood pressure should not be closely monitored in patients at risk for development of shock, but it does indicate the need for other assessment measures by which shock may be detected at an earlier stage.

Decreased intravascular volume results in decreased venous return to the heart and a decrease in CVP. When shock becomes severe, the peripheral veins collapse, making it difficult to insert peripheral venous lines. Sympathetic stimulation also leads

■ **FIGURE 18-9** ■ Compensatory mechanisms in hypovolemic shock.

to intense vasoconstriction of the skin vessels and activation of the sweat glands. As a result, the skin is cool and moist. When shock is caused by hemorrhage, the loss of red blood cells leaves the skin and mucous membranes looking pale.

Urine output decreases very quickly in hypovolemic and other forms of shock. Compensatory mechanisms decrease renal blood flow as a means of diverting blood flow to the heart and brain. Oliguria of 20 mL/hour or less indicates severe shock and inadequate renal perfusion. Continuous measurement of urine output is essential for assessing the circulatory status of the person in shock.

Restlessness and apprehension are common behaviors in early shock. As the shock progresses and blood flow to the brain decreases, restlessness is replaced by apathy and stupor. If shock is unchecked, the apathy progresses to coma. Coma caused by blood loss alone and not related to head injury or other factors is an unfavorable sign. *Treatment.* The treatment of hypovolemic shock is directed toward correcting or controlling the underlying cause and improving tissue perfusion. Persons who have sustained blood loss are commonly placed in supine position with the legs elevated to maximize cerebral blood flow. Oxygen is administered to persons with signs of hypoxemia. Because subcutaneous administration is unpredictable, pain medications usually are administered intravenously. Frequent measurements of heart rate and cardiac rhythm, blood pressure, and urine flow are used to assess the severity of circulatory compromise and to monitor treatment.

In hypovolemic shock, the goal of treatment is to restore vascular volume. This can be accomplished through intravenous administration of fluids and blood. The crystalloids (*e.g.*, isotonic saline and glucose solutions) are readily available for emergencies and mass casualties. They often are effective, at least temporarily, when given in adequate doses. Blood or

blood products (packed or frozen red cells) are administered based on hematocrit and hemodynamic findings. Fluids and blood are best administered based on volume indicators such as CVP and PCWP.

Vasoactive drugs (*e.g.*, adrenergic agents) are agents capable of constricting or dilating blood vessels. As a general rule, the adrenergic drugs are not used as a primary form of therapy in hypovolemic shock. Simple blood pressure elevation produced by vasopressor drugs has little effect on the underlying cause of shock and in many cases may be detrimental. These agents are given only when hypotension persists after volume deficits have been corrected.

Dopamine, which induces more favorable actions than many of the other adrenergic drugs, may be used in the treatment of severe and prolonged shock. Dopamine, when given in low doses, is thought to increase blood flow to the kidneys, liver, and other abdominal organs while maintaining vasoconstriction in less vital structures, such as the skin and skeletal muscles. In severe shock, higher doses may be needed to maintain blood pressure. After dopamine administration exceeds this low-dose range, it has vasoconstrictive effects on blood flow to the kidneys and abdominal organs that are similar to those of epinephrine.

Obstructive Shock

The term *obstructive shock* is used to describe circulatory shock that results from mechanical obstruction of the flow of blood through the central circulation (great veins, heart, or lungs; see Fig. 18-8). Obstructive shock may be caused by a number of conditions, including dissecting aortic aneurysm, cardiac tamponade, pneumothorax, atrial myxoma, or evisceration of abdominal contents into the thoracic cavity because of a ruptured hemidiaphragm. The most common cause of obstructive shock is pulmonary embolism.

The primary physiologic results of obstructive shock are elevated right heart pressure and impaired venous return to the heart. The signs of right heart failure are seen, including elevation of central venous pressure and jugular vein distention. Treatment modalities focus on correcting the cause of the disorder, frequently with surgical interventions such as pulmonary embolectomy, pericardiocentesis (*i.e.*, removal of fluid from the pericardial sac) for cardiac tamponade, or the insertion of a chest tube for correction of a tension pneumothorax or hemothorax. In select cases of pulmonary embolus, thrombolytic drugs may be used to dissolve the clots causing the obstruction.

Distributive Shock

Distributive shock is characterized by loss of blood vessel tone, enlargement of the vascular compartment, and displacement of the vascular volume away from the heart and central circulation. With distributive shock, the capacity of the vascular compartment expands to the extent that a normal volume of blood does not fill the circulatory system (see Fig. 18-8). Loss of vessel tone has two main causes: a decrease in the sympathetic control of vasomotor tone and the presence of vasodilator substances in the blood. Venous return is decreased in distributive shock, which leads to a diminished cardiac output but not a decrease in total blood volume; this type of shock is also referred to as *normovolemic shock*. There are two shock states that share the basic circulatory pattern of distributive shock: neurogenic shock and anaphylactic shock. Septic shock shares many of the features of distributive shock.

Neurogenic Shock. Neurogenic shock describes shock caused by decreased sympathetic control of blood vessel tone caused by a defect in the vasomotor center in the brain stem or the sympathetic outflow to the blood vessels. Output from the vasomotor center can be interrupted by brain injury, the depressant action of drugs, general anesthesia, hypoxia, or lack of glucose (e.g., insulin reaction). Fainting attributable to emotional causes is a transient form of neurogenic shock. Spinal anesthesia or spinal cord injury above the midthoracic region can interrupt the transmission of outflow from the vasomotor center. The term spinal shock is used to describe the neurogenic shock that occurs in persons with spinal cord injury. Many general anesthetic agents can cause a neurogenic shock-like reaction, especially during induction, because of interference with sympathetic nervous system function. In contrast to hypovolemic shock, the heart rate in neurogenic shock often is slower than normal, and the skin is dry and warm. This type of distributive shock is rare and usually transitory.

Anaphylactic Shock. Anaphylactic shock is characterized by massive vasodilatation, pooling of blood in the peripheral blood vessels, and increased capillary permeability.²⁰ This type of shock, which is a manifestation of systemic anaphylaxis, is caused by an immune-mediated reaction in which vasodilator substances such as histamine are released into the blood (see Chapter 10). These substances cause dilatation of arterioles and venules along with a marked increase in capillary permeability. The vascular response in anaphylactic shock is often accompanied by bronchospasm, contraction of gastrointestinal and uterine smooth muscle, and urticaria or angioedema (swelling of the face and throat).

Among the most common causes of anaphylactic shock are reactions to drugs, such as penicillin; foods, such as nuts and shellfish; and insect venoms. The most common cause is stings from insects of the order Hymenoptera (*i.e.*, bees, wasps, and fire ants). Latex allergy has caused life-threatening anaphylaxis in a growing segment of the population (see Chapter 10).²¹ Health care workers and others who are exposed to latex are developing latex sensitivities that range from mild urticaria, contact dermatitis, and mild respiratory distress to anaphylactic shock.²⁰ Children with spina bifida also are at extreme risk for this increasingly serious allergy.

The onset of anaphylaxis depends on the sensitivity of the person and the rate and quantity of antigen exposure. Anaphylactic shock often develops suddenly; death can occur within a matter of minutes unless appropriate medical intervention is promptly instituted. Signs and symptoms of impending anaphylactic shock include abdominal cramps; apprehension; burning and warm sensation of the skin, itching, urticaria (*i.e.*, hives); coughing, choking, wheezing, chest tightness, and difficulty in breathing. After blood begins to pool peripherally, there is a precipitous drop in blood pressure, and the pulse becomes so weak that it is difficult to detect. Life-threatening airway obstruction may ensue as a result of laryngeal edema or bronchial spasm.

Treatment includes immediate discontinuance of the inciting agent or institution of measures to decrease its absorption (*e.g.*, application of ice); close monitoring of cardiovascular and respiratory function; and maintenance of adequate respiratory gas exchange, cardiac output, and tissue perfusion. Epinephrine constricts the blood vessels and relaxes the smooth muscle in the bronchioles; it usually is the first drug to be given to a patient believed to be experiencing an anaphylactic reaction. Other treatment measures include the administration of oxygen, antihistaminic drugs, and corticosteroids. Resuscitation measures may be required.

The prevention of anaphylactic shock is preferable to treatment. Once a person has been sensitized to an antigen, the risk of repeated anaphylactic reactions with subsequent exposure is high. Persons with known hypersensitivities should carry some form of medical identification to alert medical personnel if they become unconscious or unable to relate this information. Persons who are risk for anaphylaxis should be provided with emergency medications (*e.g.*, epinephrine autoinjector) and instructed in procedures to follow in case they are inadvertently exposed to the offending antigen.

Sepsis and Septic Shock

Septic shock is associated with severe infection and the systemic response to infection. It is associated most frequently with gram-negative bacteremia, although it can be caused by gram-positive bacilli and other microorganisms such as fungi, which carry an even greater risk of mortality.²² Unlike other types of shock, septic shock commonly is associated with pathologic complications, such as acute respiratory distress syndrome, disseminated intravascular coagulation, and multiple organ dysfunction syndrome.

Septic shock has become the most common type of distributive shock. There are approximately 400,000 to 500,000 septic episodes each year in the United States. The growing incidence has been attributed to an increased awareness of the diagnosis, increased numbers of immunocompromised patients, increased use of invasive procedures, increased number of resistant organisms, and an increased number of elderly patients with critical illnesses.²³ Despite advances in treatment methods, the mortality rate is approximately 40%.²⁴

Septic shock has been described in the context of the *systemic inflammatory response*.²⁵ Although usually associated with infection, the systemic inflammatory response syndrome can be initiated by noninfectious disorders such as acute trauma and pancreatitis.

Mechanisms. The mechanisms of septic shock are thought to be related to mediators of the inflammatory response.^{26,27} Although the immune system and the inflammatory response are designed to overcome infection, the dysregulated release of inflammatory mediators such as tumor necrosis factor (TNF) and the interleukins (see Chapter 10) may initiate the potentially fatal sepsis syndrome. These inflammatory mediators, which are released in the presence of bacterial toxins, promote endothelial cell–leukocyte adhesion, release of cell-damaging proteases and prostaglandins, and activation of the blood coagulation cascade. The prostaglandins participate in the generation of fever, tachycardia, ventilation-perfusion abnormalities, and lactic acidosis that occur with septic shock.²⁸

In addition to inducing the release of inflammatory mediators, endotoxins may themselves induce tissue damage by directly activating pathways such as the coagulation cascade, the complement cascade, vessel injury, or release of vasodilating prostaglandins.²⁷ Thus, the sepsis syndrome represents the complex consequences of microbial products that produce profound dysregulation of the inflammatory response.

Manifestations. Septic shock typically manifests with fever, vasodilatation, and a warm, flushed skin. Mild hyperventilation, respiratory alkalosis, and abrupt changes in personality and behavior caused by reduction in cerebral blood flow may be the earliest signs and symptoms of septic shock. These manifestations, which are thought to be a primary response to the bacteremia, commonly precede the usual signs and symptoms of sepsis by several hours or days.

Unlike other forms of shock (*i.e.*, cardiogenic, hypovolemic, and obstructive) that are characterized by a compensatory increase in systemic vascular resistance, septic shock often presents with hypovolemia because of arterial and venous dilatation and leakage of plasma into the interstitial spaces. Aggressive treatment of the hypovolemia in septic shock leads to a decrease in systemic vascular resistance and increased cardiac output and tachycardia. With the development of refined resuscitation methods and better hemodynamic monitoring systems, approximately 90% of patients in septic shock convert to this hyperdynamic response with high cardiac output and low systemic vascular resistance.²⁷ However, as the condition progresses, cardiac function is depressed; the heart becomes dilated, and the ejection fraction decreases.

Treatment. The treatment of septic shock focuses on the causative agent and support of the circulation. The administration of antibiotics specific to the infectious agent is essential. The cardiovascular status of the patient must be supported to maintain oxygen delivery to the cells. Swift and aggressive fluid administration is needed to compensate for third spacing, and equally aggressive use of vasopressor agents is needed to counteract the vasodilation caused by endotoxins.

Complications of Shock

Wiggers, a noted circulatory physiologist, stated, "Shock not only stops the machine, but it wrecks the machinery."²⁹ Many body systems are wrecked by severe shock. Some of the major complications of severe shock are acute respiratory distress syndrome, acute renal failure, gastrointestinal ulceration, disseminated intravascular coagulation, and multiple organ dysfunction syndrome.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is a potentially lethal form of respiratory failure that can follow severe shock (see Chapter 21). The symptoms of ARDS usually do not develop until 24 to 48 hours after the initial trauma; in some instances, they occur much later. The respiratory rate and effort of breathing increase, and arterial blood gas analysis demonstrates the presence of profound hypoxemia with hypercapnia.

The exact cause of ARDS is unknown. Neutrophils are thought to play a key role in the pathogenesis of ARDS. A cytokine-mediated activation and accumulation of neutrophils in the pulmonary vasculature and subsequent endothelial injury is thought to cause leaking of fluid and plasma proteins into the interstitium and alveolar spaces.^{30,31} The fluid leakage impairs gas exchange and makes the lung stiffer and more difficult to inflate. Abnormalities in the production, composition, and function of surfactant may contribute to alveolar collapse and gas exchange abnormalities.³¹

Interventions for ARDS focus on increasing the oxygen concentration in the inspired air and supporting ventilation mechanically to optimize gas exchange while avoiding oxygen toxicity and preventing further lung injury.^{30,31} Despite the delivery of high levels of oxygen using high-pressure mechanical ventilatory support and positive end-expiratory pressure, many persons with ARDS remain hypoxic, often with a fatal outcome.

Acute Renal Failure

The renal tubules are particularly vulnerable to ischemia, and acute renal failure is one important late cause of death in severe shock. Sepsis and trauma account for most cases of acute renal failure (see Chapter 24). The endotoxins implicated in septic shock are powerful vasoconstrictors that are capable of activating the sympathetic nervous system and causing intravascular clotting. They have been shown to trigger all the separate physiologic mechanisms that contribute to the onset of acute renal failure. The degree of renal damage is related to the severity and duration of shock. The normal kidney is able to tolerate severe ischemia for 15 to 20 minutes. The renal lesion most frequently seen after severe shock is acute tubular necrosis. Acute tubular necrosis usually is reversible, although return to normal renal function may require weeks or months. Continuous monitoring of urine output during shock provides a means of assessing renal blood flow. Frequent monitoring of serum creatinine and blood urea nitrogen levels also provides valuable information regarding renal status.

Gastrointestinal Complications

The gastrointestinal tract is particularly vulnerable to ischemia because of the changes in distribution of blood flow to its mucosal surface. In shock, there is widespread constriction of blood vessels that supply the gastrointestinal tract, causing a redistribution of blood flow that severely diminishes mucosal perfusion. Superficial mucosal lesions of the stomach and duodenum can develop within hours of severe trauma, sepsis, or burn.

Bleeding is a common symptom of gastrointestinal ulceration caused by shock. Hemorrhage has its onset usually within 2 to 10 days after the original insult and often begins without warning. Poor perfusion in the gastrointestinal tract has been credited with allowing intestinal bacteria to enter the bloodstream, thereby contributing to the development of sepsis and shock.

Histamine type 2 receptor antagonists, proton pump inhibitors, or mucosal protective agents may be given prophylactically to prevent gastrointestinal ulcerations caused by shock. Nasogastric tubes, when attached to intermittent suction, also help to diminish the accumulation of hydrogen ions in the stomach.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is characterized by widespread activation of the coagulation system with resultant formation of fibrin clots and thrombotic occlusion of small and midsize vessels (see Chapter 12). The systemic formation of fibrin results from increased generation of thrombin, the simultaneous suppression of physiologic anticoagulation mechanisms, and the delayed removal of fibrin as a consequence of impaired fibrinolysis. Clinically overt DIC is reported to occur in as many as 30% to 50% of persons with sepsis and septic shock.³² As with other systemic inflammatory responses, the derangement of coagulation and fibrinolysis is thought to be mediated by inflammatory mediators.

The contribution of DIC to morbidity and mortality in sepsis depends on the underlying clinical condition and the intensity of the coagulation disorder. Depletion of the platelets and coagulation factors increases the risk of bleeding. Deposition of fibrin in the vasculature of organs contributes to ischemic damage and organ failure.

The management of sepsis-induced DIC focuses on treatment of the underlying disorder and measures to interrupt the coagulation process. Anticoagulation therapy and administration of platelets and plasma may be used.

Multiple Organ Dysfunction Syndrome

Multiple organ dysfunction syndrome (MODS) represents the presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention. As the name implies, MODS commonly affects multiple organ systems, including the kidneys, lungs, liver, brain, and heart. MODS is a particularly life-threatening complication of shock, especially septic shock. It has been reported as the most frequent cause of death in the noncoronary intensive care unit. Mortality rates vary from 30% to 100%, depending on the number of organs involved.33 Mortality rates increase with an increased number of organs failing. A high mortality rate is associated with failure of the brain, liver, kidney, and lung. The pathogenesis of MODS is not clearly understood, so current management is primarily supportive. Major risk factors for the development of MODS are sepsis, shock, prolonged periods of hypotension, hepatic dysfunction, trauma, infarcted bowel, advanced age, and alcohol abuse.³³ Interventions for multiple organ failure are focused on support of the affected organs.

In summary, circulatory shock is an acute emergency in which body tissues are deprived of oxygen and cellular nutrients or are unable to use these materials in their metabolic processes. Circulatory shock may develop because there is not enough blood in the circulatory system (i.e., hypovolemic shock), blood flow or venous return is obstructed (i.e., obstructive shock), or there is excessive vasodilation and pooling of blood (i.e., distributive shock). Two types of shock share the circulatory features of distributive shock: neurogenic shock and anaphylactic shock. Septic shock, which shares many of the features of distribution shock, is associated with a severe, overwhelming infection and has a mortality rate of approximately 40%.

The manifestations of circulatory shock are related to low peripheral blood flow and excessive sympathetic stimulation. The low peripheral blood flow produces thirst, changes in skin temperature, a decrease in blood pressure, an increase in heart rate, decreased venous pressure, decreased urine output, and changes in the sensorium. Signs and symptoms, such as changes in skin temperature (i.e., increased in septic shock and decreased in hypovolemic and other forms of shock), may differ with the type of shock. The intense vasoconstriction that serves to maintain blood flow to the heart and brain causes a decrease in tissue perfusion, impaired cellular metabolism, liberation of lactic acid, and, eventually, cell death. Whether the shock will be irreversible or the patient will survive is determined largely by changes that occur at the cellular level.

The complications of shock result from the deprivation of blood flow to vital organs or systems, such as the lungs, kidneys, gastrointestinal tract, and blood coagulation system. ARDS is characterized by changes in the permeability of the alveolar-capillary membrane with the development of interstitial edema and severe hypoxia that does not respond to oxygen therapy. The renal tubules are particularly vulnerable to ischemia, and acute renal failure is an important complication of shock. Gastrointestinal ischemia may lead to gastrointestinal bleeding and increased permeability to the intestinal bacteria, which cause further sepsis and shock. DIC is characterized by formation of small clots in the circulation. MODS, perhaps the most ominous complication of shock, rapidly depletes the body's ability to compensate and recover from a shock state.

HEART FAILURE IN CHILDREN AND THE ELDERLY

Heart Failure in Infants and Children

As in adults, heart failure in infants and children results from the inability of the heart to maintain the cardiac output required to sustain metabolic demands.^{34,35} Congenital heart defects are the most common cause of CHF during childhood. Surgical correction of congenital heart defects may cause heart failure as a result of intraoperative manipulation of the heart and resection of heart tissue, with subsequent alterations in pressure, flow, and resistance relations. Usually, the heart failure that results is acute and resolves after the effects of the surgical procedure have subsided. Chronic congestive failure occasionally is observed in children with severe chronic anemia, inflammatory heart disease, end-stage congenital heart disease, or cardiomyopathy. Inflammatory heart disorders (e.g., myocarditis, rheumatic fever, bacterial endocarditis, Kawasaki's disease), cardiomyopathy, and congenital heart disorders are discussed in Chapter 17.

Manifestations

Many of the signs and symptoms of heart failure in infants and children are similar to those in adults. They include fatigue, effort intolerance, cough, anorexia, and abdominal pain. A subtle sign of cardiorespiratory distress in infants and children is a change in disposition or responsiveness, including irritability or lethargy. Sympathetic stimulation produces peripheral vasoconstriction and diaphoresis. Decreased renal blood flow often results in a urine output of less than 0.5 to 1.0 mL/kg/hour, despite adequate fluid intake. When right ventricular function is impaired, systemic venous congestion develops. Hepatomegaly caused by liver congestion often is one of the first signs of systemic venous congestion in infants and children. However, dependent edema or ascites rarely is seen unless the CVP is extremely high. Because of their short, fat necks, jugular venous distention is difficult to detect in infants; it is not a reliable sign until the child is of school age or older.

Most commonly, children experience interstitial edema, rather than alveolar pulmonary edema. This reduces lung compliance and increases the work of breathing, causing tachypnea and increased respiratory effort. Older children display use of accessory muscles (*i.e.*, scapular and sternocleidomastoid). Head bobbing and nasal flaring may be observed in infants. Signs of respiratory distress often are the first and most noticeable indication of heart failure in infants and young children. Pulmonary congestion may be mistaken for bronchiolitis or lower respiratory tract infection. The infant or young child with respiratory distress often grunts with expiration. This grunting effort (essentially, exhaling against a closed glottis) is an instinctive effort to increase end-expiratory pressures and prevent collapse of small airways and the development of atelectasis. Respiratory crackles are uncommon in infants and usually suggest development of a respiratory tract infection. Wheezes may be heard, particularly if there is a large left-to-right shunt.

Infants with heart failure often have increased respiratory problems during feeding.³⁴ The history is one of prolonged feeding with excessive respiratory effort and fatigue. Weight gain is slow because of high energy requirements and low calorie intake. Other frequently occurring manifestations of heart failure in infants are excessive sweating (caused by increased sympathetic tone), particularly over the head and neck, and repeated lower respiratory tract infections. Peripheral perfusion usually is poor, with cool extremities; tachycardia is common (resting heart rate >150 beats per minute); and respiratory rate is increased (resting rate >50 breaths per minute).

Diagnosis and Treatment

Diagnosis of congestive failure in infants and children is based on symptomatology, chest radiographic films, ECG findings, echocardiographic techniques to assess cardiac structures and ventricular function (*i.e.*, end-systolic and end-diastolic diameters), arterial blood gases to determine intracardiac shunting and ventilation-perfusion inequalities, and other laboratory studies to determine anemia and electrolyte imbalances.

Treatment of congestive failure in infants and children includes measures aimed at improving cardiac function and eliminating excess intravascular fluid. Oxygen delivery must be supported and oxygen demands controlled or minimized. When possible, the cause of the disorder is corrected (*e.g.*, medical treatment of sepsis and anemia, surgical correction of congenital heart defects). With congenital anomalies that are amenable to surgery, medical treatment often is needed for a time before surgery and usually is continued during the immediate postoperative period. For many children, only medical management can be provided.

Medical management of heart failure in infants and children is similar to that in the adult, although it is tailored to the special developmental needs of the child. Inotropic agents such as digitalis often are used to increase cardiac contractility. Diuretics may be given to reduce preload and vasodilating drugs used to manipulate the afterload. Drug doses must be carefully tailored to control for the child's weight and conditions such as reduced renal function. Daily weighing and accurate measurement of intake and output are imperative during acute episodes of failure.

Most children feel better in the semiupright position. An infant seat is useful for infants with chronic CHF. Activity restrictions usually are designed to allow children to be as active as possible within the limitations of their heart disease. Infants with congestive failure often have problems feeding. Small, frequent feedings usually are more successful than larger, less frequent feedings. Severely ill infants may lack sufficient strength to suck and may need to be tube fed.

Heart Failure in the Elderly

Heart failure is one of the most common causes of disability in the elderly and is the most common hospital discharge diagnosis for the elderly. More than 75% of patients with heart failure are older than 65 years.³⁶ Among the factors that have contributed to the increased numbers of older people with heart failure are the improved therapies for ischemic and hypertensive heart disease. Thus, persons who would have died of acute myocardial disease 20 years ago are now surviving, but with residual left ventricular dysfunction. Similarly, improved blood pressure control has led to a 60% decline in stroke mortality rates, yet these same people remain at risk for CHF as a complication of hypertension. In addition, advances in treatment of other diseases have contributed indirectly to the rising prevalence of heart failure in the older population.

Coronary heart disease, hypertension, and valvular heart disease (particularly aortic stenosis and mitral regurgitation) are common causes of heart failure in older adults.^{36,37} Although the pathophysiology of heart failure is similar in younger and older persons, elderly persons tend to experience cardiac failure when confronted with stresses that would not produce failure in younger persons. There are four principal changes associated with cardiovascular aging that impair the ability to respond to stress.³⁶ First, reduced responsiveness to β-adrenergic stimulation limits the heart's capacity maximally to increase heart rate and contractility. A second major effect of aging is increased vascular stiffness, which results in an increased resistance to left ventricular ejection (afterload) and contributes to the development of systolic hypertension in the elderly. Third, in addition to increased vascular stiffness, the heart itself becomes stiffer and less compliant with age. The changes in diastolic stiffness result in important alterations in diastolic filling and atrial function. A reduction in ventricular filling not only affects cardiac output, but also produces an elevation in diastolic pressure that is transmitted back to the left atrium, where it stretches the muscle wall and predisposes to atrial ectopic beats and atrial fibrillation. The fourth major effect of cardiovascular aging is altered myocardial metabolism at the level of the mitochondria. Although older mitochondria may be able to generate sufficient adenosine triphosphate to meet the normal energy needs of the heart, they may not be able to respond under stress.

Manifestations

The manifestations of heart failure in the elderly often are masked by other disease conditions. Nocturia is an early symptom but may be caused by other conditions such as prostatic hypertrophy. Dyspnea on exertion may result from lung disease, lack of exercise, and deconditioning. Lower extremity edema commonly is caused by venous insufficiency.

Among the acute manifestations of heart failure in the elderly are increasing lethargy and confusion, probably the result of impaired cerebral perfusion. Activity intolerance is common. Instead of dyspnea, the prominent sign may be restlessness. Impaired perfusion of the gastrointestinal tract is a common cause of anorexia and profound loss of lean body mass. Loss of lean body mass may be masked by edema. The elderly also maintain a precarious balance between the managed symptom state and acute symptom exacerbation. During the managed symptom state, they are relatively symptom free while adhering to their treatment regimen. Acute symptom exacerbation, often requiring emergency medical treatment, can be precipitated by seemingly minor conditions such as poor compliance with sodium restriction, infection, or stress. Failure promptly to seek medical care is a common cause of progressive acceleration of symptoms.

Diagnosis and Treatment

The diagnosis of heart failure in the elderly is based on the history, physical examination, chest radiograph, and ECG findings. However, the presenting symptoms of heart failure often are difficult to evaluate.

Treatment of heart failure in the elderly involves many of the same methods as in younger persons. Activities are restricted to a level that is commensurate with the cardiac reserve. Seldom is bed rest recommended or advised. Bed rest causes rapid deconditioning of skeletal muscles and increases the risk of complications, such as orthostatic hypotension and thromboemboli. Instead, carefully prescribed exercise programs can help to maintain activity tolerance. Even walking around a room usually is preferable to continuous bed rest. Sodium restriction usually is indicated.

Age- and disease-related changes increase the likelihood of adverse drug reactions and drug interactions. Drug dosages and the number of drugs that are prescribed should be kept to a minimum. Compliance with drug regimens often is difficult; the simpler the regimen, the more likely it is that the older person will comply. In general, the treatment plan for elderly persons with heart failure must be put in the context of the person's overall needs. An improvement in the quality of life may take precedence over increasing the length of survival.

In summary, the mechanisms of heart failure in children and the elderly are similar to those in adults. However, the causes and manifestations may differ because of age. In children, CHF is seen most commonly during infancy and immediately after heart surgery. It can be caused by congenital and acquired heart defects and is characterized by fatigue, effort intolerance, cough, anorexia, abdominal pain, and impaired growth. Treatment of CHF in children includes correction of the underlying cause when possible. For congenital anomalies that are amenable to surgery, medical treatment often is needed for a time before surgery and usually is continued in the immediate postoperative period. For many children, only medical management can be provided.

In the elderly, age-related changes in cardiovascular functioning contribute to CHF but are not in themselves sufficient to cause heart failure. The manifestations of congestive failure often are different and superimposed on other disease conditions; therefore, CHF often is more difficult to diagnose in the elderly than in younger persons. Because the elderly are more susceptible to adverse drug reactions and have more problems with compliance, the number of drugs that are prescribed is kept to a minimum, and the drug regimen is kept as simple as possible.

REVIEW QUESTIONS

Explain the effect of decreased cardiac reserve on symptom development in heart failure.

Explain how increased sympathetic activity, fluid retention, the Frank-Starling mechanism, and myocardial hypertrophy function as compensatory mechanisms in heart failure.

Differentiate high-output versus low-output heart failure, systolic versus diastolic heart failure, and right-sided versus left-sided heart failure.

Relate the effect of left ventricular failure to the development of and manifestations of pulmonary edema.

Describe the pathophysiology of cardiogenic shock.

Describe the compensatory mechanisms that are activated in circulatory shock.

List the chief characteristics of hypovolemic shock, cardiogenic shock, obstructive shock, and distributive shock.

Characterize changes in thirst, skin blood flow, pulse rate, urine output, and sensorium that are indicative of shock.

Describe the complications of shock as they relate to the lung, kidney, gastrointestinal tract, and blood clotting.

Define multiple organ dysfunction syndrome and cite its significance in shock.

Describe the manifestations of heart failure in infants and children.

Explain how the aging process affects heart failure in the elderly.

Respiration provides the body with a means of gas exchange. It is the process whereby oxygen from the air is transferred to the blood and carbon dioxide is eliminated from the body. The nervous system controls the movement of the respiratory muscles and adjusts the rate of breathing so that it matches the needs of the body during various levels of activity. The content in this chapter focuses on the structure and function of the respiratory system as it relates to these aspects of respiration. The function of the red blood cell in the transport of oxygen is discussed in Chapter 13.

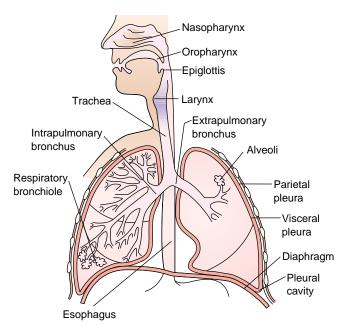

STRUCTURAL ORGANIZATION OF THE RESPIRATORY SYSTEM

The respiratory system consists of the air passages and the lungs. Functionally, the respiratory system can be divided into two parts: the *conducting airways*, through which air moves as it passes between the atmosphere and the lungs, and the *respiratory tissues* of the lungs, where gas exchange takes place.

The Conducting Airways

The conducting airways consist of the nasal passages, mouth and pharynx, larynx, trachea, bronchi, and bronchioles (Fig. 19-1). The air we breathe is warmed, filtered, and moistened as it moves through these structures. Heat is transferred to the air from the blood flowing through the walls of the respiratory passages; the mucociliary blanket removes foreign materials; and water from the mucous membranes is used to moisten the air.

The conducting airways are lined with a pseudostratified columnar epithelium that contains a mosaic of mucus-secreting goblet cells and cells that contain hairlike projections called cilia (Fig. 19-2). The larger bronchi contain additional mucussecreting glands that connect to the epithelium through long epithelial ducts. The epithelial layer gradually becomes thinner as it moves from the pseudostratified epithelium of the bronchi to cuboidal epithelium of the bronchioles and then to squamous epithelium of the alveoli. The mucus produced by the goblet cells in the conducting airways forms a layer, called the *mucocil*iary blanket, that protects the respiratory system by entrapping dust and other foreign particles that enter the airways. The cilia, which constantly are in motion, move the mucociliary blanket with its entrapped particles in an escalator-like fashion toward the oropharynx, from which it is expectorated or swallowed. The function of the mucociliary blanket in clearing the lower airways and alveoli is optimal at normal oxygen levels and is impaired

■ FIGURE 19-1 ■ Structures of the respiratory system.

in situations of low and high oxygen levels. It is impaired by drying, such as breathing heated but unhumidified indoor air during winter. Cigarette smoking slows down or paralyzes the motility of the cilia. This slowing allows the residue from tobacco smoke, dust, and other particles to accumulate in the lungs, decreasing the efficiency of this pulmonary defense system.

The airways are kept moist by water contained in the mucous layer. Moisture is added to the air as it moves through the conducting airways. The capacity of the air to contain moisture or water vapor without condensation increases as the temperature rises. Thus, the air in the alveoli, which is maintained at body temperature, usually contains considerably more water vapor than the atmospheric-temperature air that we breathe. The difference between the water vapor contained in the air we breathe and that found in the alveoli is drawn from the moist surface of the mucous membranes that line the conducting airways and is a source of insensible water loss (see Chapter 6). Under normal conditions, approximately 1 pint of water per day is lost in humidifying the air breathed. During fever, the water vapor in the lungs increases, causing more water to be lost from the respiratory mucosa. In addition, fever usually is accompanied by an increase in respiratory rate so that more air passes through the airways, withdrawing moisture from its mucosal surface. As a result, respiratory secretions thicken, preventing free movement of the cilia and impairing the protective function of the mucociliary defense system. This is particularly true in persons whose water intake is inadequate.

Nasopharyngeal Airways

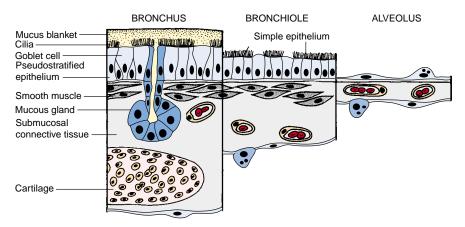

The nose is the preferred route for the entrance of air into the respiratory tract during normal breathing. As air passes through the nasal passages, it is filtered, warmed, and humidified. The outer nasal passages are lined with coarse hairs, which filter and trap dust and other large particles from the air. The upper portion of the nasal cavity is lined with mucous membrane that contains a rich network of small blood vessels; this portion of the nasal cavity supplies warmth and moisture to the air we breathe.

The mouth serves as an alternative airway when the nasal passages are plugged or when there is a need for the exchange of large amounts of air, as occurs during exercise. The oropharvnx extends posteriorly from the soft palate to the epiglottis. The oropharynx is the only opening between the nose and mouth and the lungs. Both swallowed food on its way to the esophagus and air on its way to the larynx pass through it. Obstruction of the oropharynx leads to immediate cessation of ventilation. Neural control of the tongue and pharyngeal muscles may be impaired in coma and certain types of neurologic disease. In these conditions, the tongue falls back into the pharynx and obstructs the airway, particularly if the person is lying on his or her back. Swelling of the pharyngeal structures caused by injury, infection, or severe allergic reaction also predisposes a person to airway obstruction, as does the presence of a foreign body.

Laryngotracheal Airways

The larynx connects the oropharynx with the trachea. The walls of the larynx are supported by firm cartilaginous structures that prevent collapse during inspiration. The functions of the larynx can be divided into two categories: those associated with speech and those associated with protecting the lungs from substances other than air. The larynx is located in a strate-

■ FIGURE 19-2 ■ Airway wall structure: bronchus, bronchiole, and alveolus. The bronchial wall contains pseudostratified epithelium, smooth muscle cells, mucous glands, connective tissue, and cartilage. In smaller bronchioles, a simple epithelium is found, cartilage is absent, and the wall is thinner. The alveolar wall is designed for gas exchange, rather than structural support. (From Weibel E.R., Taylor R.C. [1988]. Design and structure of the human lung. In Fishman A.P. [ed.]. *Pulmonary diseases and disorders*. Vol. 1. [p. 14]. New York: McGraw-Hill. Reproduced with permission of the McGraw-Hill Companies)

gic position between the upper airways and the lungs and sometimes is referred to as the "watchdog of the lungs."

The cavity of the larynx is divided into two pairs of two-bytwo folds of mucous membrane stretching from front to back with an opening in the midline (Fig. 19-3). The upper pair of folds, called the *vestibular folds*, has a protective function. The lower pair of folds has cordlike margins; they are termed the *vocal folds* because their vibrations are required for making vocal sounds. The true vocal folds and the elongated opening between them are called the *glottis*. A complex set of muscles controls the opening and closing of the glottis. Speech involves the intermittent release of expired air and opening and closing of the glottis. The epiglottis, which is located above the vocal folds, is a large, leaf-shaped piece of cartilage that is covered with epithelium. During swallowing, the free edges of the epiglottis move downward to cover the larynx, thus routing liquids and foods into the esophagus.

In addition to opening and closing the glottis for speech, the vocal folds of the larynx can perform a sphincter function in

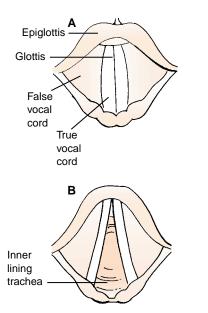

FIGURE 19-3 Epiglottis and vocal cords viewed above with (A) glottis closed and (B) glottis open.

closing off the airways. When confronted with substances other than air, the laryngeal muscles contract and close off the airway. At the same time, the cough reflex is initiated as a means of removing a foreign substance from the airway. If the swallowing mechanism is partially or totally paralyzed, food and fluids can enter the airways instead of the esophagus when a person attempts to swallow. These substances are not easily removed; and when they are pulled into the lungs, they can cause a serious inflammatory condition called *aspiration pneumonia*.

Tracheobronchial Tree

The tracheobronchial tree, which consists of the trachea, bronchi, and bronchioles, can be viewed as a system of branching tubes (Fig. 19-5). It is similar to a tree whose branches become smaller and more numerous as they divide. There are approximately 23 levels of branching, beginning with the conducting airways and ending with the respiratory airways, where gas exchange takes place (Fig. 19-5).

The trachea, or windpipe, is a continuous tube that connects the larynx and the major bronchi of the lungs (see Fig. 19-4). The walls of the trachea are supported by horseshoe-shaped cartilages, which prevent it from collapsing when the pressure in the thorax becomes negative.

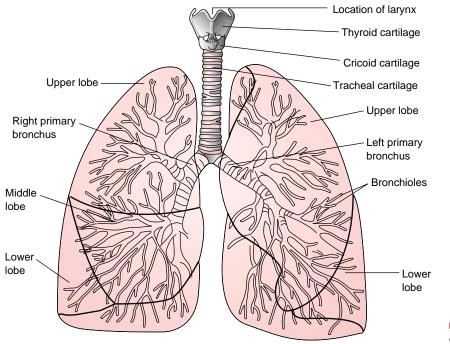

The trachea divides to form the right and the left primary bronchi. Each bronchus enters the lung through a slit called the hilus. The structure of the primary bronchi is similar to that of the trachea in that these airways are supported by cartilaginous rings.

Each primary bronchus divides into *secondary*, or *lobular*, *bronchi*, which supply each of the lobes of the lungs—three in the right lung and two in the left. The right middle lobe bronchus is of relatively small diameter and length and sometimes bends sharply near its bifurcation. It is surrounded by a collar of lymph nodes that drain the middle and the lower lobe and is particularly subject to obstruction. The secondary bronchi divide to form the segmental bronchi, which supply the bronchopulmonary segments of the lung. These segments are identified according to their location in the lung (*e.g.*, the apical segment of the right upper lobe) and are the smallest named units in the lung. Lung lesions such as atelectasis and pneumonia often are localized to a particular bronchopulmonary segment.

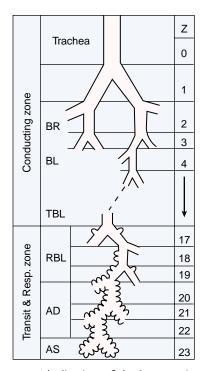

The bronchi continue to branch, forming smaller bronchi, until they become the terminal bronchioles, the smallest of

■ FIGURE 19-5 ■ Idealization of the human airways. The first 16 generations of branching (Z) make up the conducting airways, and the last seven constitute the respiratory zone (or transitional and respiratory zone). BR, bronchus; BL, bronchiole; TBL, terminal bronchiole; RBL, respiratory bronchiole; AD, alveolar ducts; AS, alveolar sacs. (Weibel E.R. [1962]. *Morphometry of the human lung* [p. 111]. Berlin: Springer-Verlag)

the conducting airways. As these bronchi branch and become smaller, this cartilaginous support becomes thinner and then disappears at the level of the respiratory bronchioles. Between the cartilaginous support and the mucosal surface are two crisscrossing layers of smooth muscle that wind in opposite directions (Fig. 19-6). Bronchospasm, or contraction of these muscles, causes narrowing of the bronchioles and impairs air flow. The epithelial lining of conducting airways gradually becomes reduced from pseudostratified epithelium in the bronchi to a thin layer of tightly joined epithelial cells in the alveoli.

The Lungs and Respiratory Airways

The lungs are soft, spongy, cone-shaped organs located side by side in the chest cavity (see Fig. 19-1). They are separated from each other by the *mediastinum* (*i.e.*, the space between the lungs) and its contents—the heart, blood vessels, lymph nodes, nerve fibers, thymus gland, and esophagus. The upper part of the lung, which lies against the top of the thoracic cavity, is called the *apex*, and the lower part, which lies against the diaphragm, is called the *base*. The lungs are divided into lobes: three in the right lung and two in the left (see Fig. 19-4).

The lungs are the functional structures of the respiratory system. In addition to their gas exchange function, they inactivate vasoactive substances such as bradykinin; they convert angiotensin I to angiotensin II; and they serve as a reservoir for blood storage. Heparin-producing cells are particularly abundant in the capillaries of the lung, where small clots may be trapped.

Respiratory Lobules

The gas exchange function of the lung takes place in the lobules of the lungs. Each lobule, which is the smallest functional unit of the lung, is supplied by a branch of a terminal bron-

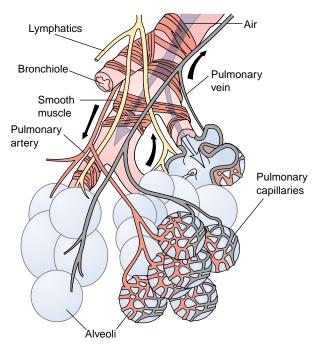

FIGURE 19-6 Lobule of the lung, showing the bronchial smooth muscle fibers, pulmonary blood vessels, and lymphatics.

chiole, an arteriole, the pulmonary capillaries, and a venule (see Fig. 19-6). Gas exchange takes place in the terminal respiratory bronchioles and the alveolar ducts and sacs. Blood enters the lobules through a pulmonary artery and exits through a pulmonary vein. Lymphatic structures surround the lobule and aid in the removal of plasma proteins and other particles from the interstitial spaces.

Unlike larger bronchi, the respiratory bronchioles are lined with simple epithelium, rather than ciliated pseudostratified epithelium. The respiratory bronchioles also lack the cartilaginous support of the larger airways. Instead, they are attached to the elastic spongework of tissue that contains the alveolar air spaces. When the air spaces become stretched during inspiration, the bronchioles are pulled open by expansion of the surrounding tissue.

The alveolar sacs are cup-shaped, thin-walled structures that are separated from each other by thin alveolar septa. Most of the septa are occupied by a single network of capillaries so that blood is exposed to air on both sides. There are approximately 300 million alveoli in the adult lung, with a total surface area of approximately 50 to 100 m². Unlike the bronchioles, which are tubes with their own separate walls, the alveoli are interconnecting spaces that have no separate walls (Fig. 19-7). As a result of this arrangement, there is a continual mixing of air in the alveolar structures.

The alveolar structures are composed of two types of cells: type I alveolar cells and type II alveolar cells (Fig. 19-8). The type I alveolar cells are flat squamous epithelial cells across which gas exchange takes place. The type II alveolar cells produce surfactant, a lipoprotein substance that decreases the surface tension in the alveoli. The alveoli also contain alveolar macrophages, which are responsible for the removal of offending substances from the alveolar epithelium.

Lung Circulation

The lungs are provided with a dual blood supply: the pulmonary and bronchial circulations. The pulmonary circulation arises from the pulmonary artery and provides for the gas exchange function of the lungs. Deoxygenated blood leaves the right heart through the pulmonary artery, which divides into a left pulmonary artery that enters the left lung and a right pulmonary artery that enters the right lung. Return of oxygenated blood to the heart occurs by way of the pulmonary veins, which empty into the left atrium.

The bronchial circulation distributes blood to the conducting airways and supporting structures of the lung. The bronchial circulation has a secondary function of warming and humidifying incoming air as it moves through the conducting airways. The bronchial arteries arise from the thoracic aorta and enter the lungs with the major bronchi, dividing and subdividing along with the bronchi as they move out into the lung, supplying them and other lung structures with oxygen. The capillaries of the bronchial circulation drain into the bronchial veins, the larger of which empties into the vena cava. The smaller of the bronchial veins empties into the pulmonary veins. This blood is unoxygenated because the bronchial circulation does

■ FIGURE 19-8 Schematic drawing of the two types of alveolar cells and their relation to alveoli and capillaries. Alveolar type I cells comprise most of the alveolar surface. Alveolar type II cells are located in the corner between two adjacent alveoli. Also shown are endothelial cells that line the pulmonary capillaries. (Rhoades R.A., Tanner G.A. [1996]. *Medical physiology* [p. 362]. Boston: Little, Brown).

not participate in gas exchange. As a result, this blood dilutes the oxygenated blood returning to the left side of the heart.

Pleura

A thin, transparent, double-layered serous membrane, called the *pleura*, lines the thoracic cavity and encases the lungs. The outer parietal layer lies adjacent to the chest wall, and the inner visceral layer adheres to the outer surface of the lung (see Fig. 19-1). The parietal pleura forms part of the mediastinum and lines the inner wall of the thoracic or chest cavity. A thin film of serous fluid separates the two pleural layers, and this allows the two layers to glide over each other and yet hold together, so there is no separation between the lungs and the chest wall. The pleural cavity is a potential space in which serous fluid or inflammatory exudate can accumulate. The term *pleural effusion* is used to describe an abnormal collection of fluid or exudate in the pleural cavity.

In summary, the respiratory system consists of the air passages and the lungs, where gas exchange takes place. Functionally, the air passages of the respiratory system can be structurally divided into two parts: the conducting airways, through which air moves as it passes into and out of the lungs, and the respiratory tissues, where gas exchange actually takes place. The conducting airways include the nasal passages, mouth and nasopharynx, larynx, and tracheobronchial tree. Air is warmed, filtered, and humidified as it passes through these structures. The lungs are the functional structures of the respiratory system. In addition to their gas exchange function, they inactivate vasoactive substances such as bradykinin; they convert angiotensin I to angiotensin II; and they serve as a reservoir for blood. The lobules, which are the functional units of the lung, consist of the respiratory bronchioles, alveoli, and pulmonary capillaries. It is here that gas exchange takes place. Oxygen from the alveoli diffuses across the alveolar capillary membrane into the blood, and carbon dioxide from the blood diffuses into the alveoli.

The lungs are provided with a dual blood supply: the pulmonary circulation provides for the gas exchange function of the lungs, and the bronchial circulation distributes blood to the conducting airways and supporting structures of the lung. The lungs are encased in a thin, transparent, doublelayered serous membrane called the *pleura*. The pressure in the pleural space, which is negative in relation to alveolar pressure, prevents the lungs from collapsing.

EXCHANGE OF GASES BETWEEN THE ATMOSPHERE AND THE LUNGS

Basic Properties of Gases

The air we breathe is made up of a mixture of gases, mainly nitrogen and oxygen. These gases exert a combined pressure called the *atmospheric pressure*. The pressure at sea level is defined as 1 atmosphere, which is equal to 760 millimeters of mercury (mm Hg) or 14.7 pounds per square inch (PSI). When measuring respiratory pressures, atmospheric pressure is assigned a value of 0. A respiratory pressure of +15 mm Hg means that the pressure is 15 mm Hg above atmospheric pressure, and a respiratory pressure of -15 mm Hg is 15 mm Hg less than atmospheric pressure. Respiratory pressures often are expressed in centimeters of water (cm H₂O) because of the small pressures involved (1 mm Hg = 1.35 cm H₂O pressure).

The pressure exerted by a single gas in a mixture is called the *partial pressure*. The capital letter "P" followed by the chemical symbol of the gas (PO₂) is used to denote its partial pressure. The law of partial pressures states that the total pressure of a mixture of gases, as in the atmosphere, is equal to the sum of the partial pressures of the different gases in the mixture. If the concentration of oxygen at 760 mm Hg (1 atmosphere) is 20%, its partial pressure is 152 mm Hg (760 × 0.20).

Water vapor is different from other types of gases; its partial pressure is affected by temperature but not atmospheric pressure. The relative humidity refers to the percentage of moisture in the air compared with the amount that the air can hold without causing condensation (100% saturation). Warm air holds more moisture than cold air. This is the reason that precipitation in the form of rain or snow commonly occurs when the relative humidity is high and there is a sudden drop in atmospheric temperature. The air in the alveoli, which is 100% saturated at normal body temperature, has a water vapor pressure of 47 mm Hg. The water vapor pressure must be included in the sum of the total pressure of the gases in the alveoli (*i.e.*, the total pressure of the other gases in the alveoli is 760 – 47 = 713 mm Hg). Air moves between the atmosphere and the lungs because of a pressure difference. According to the laws of physics, the pressure of a gas varies inversely with the volume of its container, provided the temperature remains constant. If equal amounts of a gas are placed in two different-size containers, the pressure of the gas in the smaller container is greater than the pressure in the larger container. The movement of gases is always from the container with the greater pressure to the one with the lesser pressure. The chest cavity can be viewed as a volume container. During inspiration, the size of the chest cavity increases and air moves into the lungs; during expiration, air moves out as the size of the chest cavity decreases.

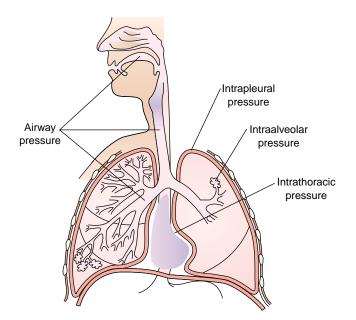

Ventilation and the Mechanics of Breathing

Ventilation is concerned with the movement of gases into and out of the lungs. It relies on a system of open airways and the respiratory pressures created as the movements of the respiratory muscles change the size of the chest cage. The degree to which the lungs inflate and deflate depends on the respiratory pressures inflating the lung, compliance of the lungs, and airway resistance.

Respiratory Pressures

The pressure inside the airways and alveoli of the lungs is called the *intrapulmonary pressure* or *alveolar pressure*. The gases in this area of the lungs are in communication with atmospheric pressure (Fig. 19-9). When the glottis is open and air is not moving into or out of the lungs, as occurs just before inspiration or expiration, the intrapulmonary pressure is zero or equal to atmospheric pressure.

The pressure in the pleural cavity is called the *intrapleural pressure*. The intrapleural pressure is always negative in relation to alveolar pressure, approximately –4 mm Hg between breaths when the glottis is open and the alveolar spaces are open to the atmosphere. The lungs and the chest wall have elastic proper-

■ FIGURE 19-9 ■ Partitioning of respiratory pressures.

ties, each pulling in the opposite direction. If removed from the chest, the lungs would contract to a smaller size, and the chest wall, if freed from the lungs, would expand. The opposing forces of the chest wall and lungs create a pull against the visceral and parietal layers of the pleura, causing the pressure in the pleural cavity to become negative. During inspiration, the elastic recoil of the lungs increases, causing intrapleural pressure to become more negative than during expiration. Without the negative intrapleural pressure holding the lungs against the chest wall, their elastic recoil properties would cause them to collapse. Although the intrapleural pressure of the inflated lung is always negative in relation to alveolar pressure, it may become positive in relation to atmospheric pressure (*e.g.*, during forced expiration and coughing).

The *intrathoracic pressure* is the pressure in the thoracic cavity. It is essentially equal to intrapleural pressure and is the pressure to which the lungs, heart, and great vessels are exposed. Forced expiration against a closed glottis (Valsalva maneuver) compresses the air in the thoracic cavity and produces marked increases in intrathoracic and intrapleural pressures.

The Chest Cage and Respiratory Muscles

The lungs and major airways share the chest cavity with the heart, great vessels, and esophagus. The chest cavity is a closed compartment bounded on the top by the neck muscles and at the bottom by the diaphragm. The outer walls of the chest cavity are formed by 12 pairs of ribs, the sternum, the thoracic vertebrae, and the intercostal muscles that lie between the ribs. Mechanically, the act of breathing depends on the fact that the chest cavity is a closed compartment whose only opening to the exterior is the trachea.

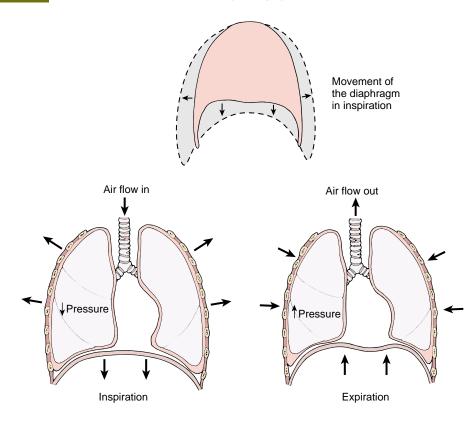

Ventilation consists of inspiration and expiration. During *inspiration*, the size of the chest cavity increases, the intrathoracic pressure becomes more negative, and air is drawn into the lungs. *Expiration* occurs as the elastic components of the chest wall and lung structures that were stretched during inspiration recoil, causing the size of the chest cavity to decrease and the pressure in the chest cavity to increase (Fig. 19-10).

Inspiration. The diaphragm is the principal muscle of inspiration. When the diaphragm contracts, the abdominal contents are forced downward and the chest expands from top to bottom (Fig. 19-10). The diaphragm is innervated by the phrenic nerve roots, which arise from the cervical level of the spinal cord, mainly from C4 but also from C3 and C5.

The external intercostal muscles, which also aid in inspiration, connect to the adjacent ribs and slope downward and forward (Fig. 19-11). When they contract, they raise the ribs and rotate them slightly so that the sternum is pushed forward; this enlarges the chest from side to side and from front to back. The intercostal muscles receive their innervation from nerves that exit the central nervous system at the thoracic level of the spinal cord. Paralysis of these muscles usually does not have a serious effect on respiration because of the effectiveness of the diaphragm.

The accessory muscles of inspiration include the scalene muscles and the sternocleidomastoid muscles. The scalene muscles elevate the first two ribs, and the sternocleidomastoid muscles raise the sternum to increase the size of the chest cavity. These muscles contribute little to quiet breathing but

346 Unit Five: Alterations in the Respiratory System

■ FIGURE 19-10 ■ Movement of the diaphragm and changes in chest volume and pressure during inspiration and expiration. (A) Movement of diaphragm and expansion of the chest cavity during inspiration. (B) During inspiration, contraction of the diaphragm and expansion of the chest cavity produce a decrease in intrathoracic pressure, causing air to move into the lungs. (C) During expiration, relaxation of the diaphragm and chest cavity produce an increase in intrathoracic pressure, causing air to move out of the lungs.

contract vigorously during exercise. For the accessory muscles to assist in ventilation, they must be stabilized in some way. For example, persons with bronchial asthma often brace their arms against a firm object during an attack as a means of stabilizing their shoulders so that the attached accessory muscles can exert their full effect on ventilation. The head commonly is bent backward so that the scalene and sternocleidomastoid muscles

can elevate the ribs more effectively. Other muscles that play a minor role in inspiration are the alae nasi, which produce flaring of the nostrils during obstructed breathing.

Expiration. Expiration is largely passive. It occurs as the elastic components of the chest wall and lung structures that were stretched during inspiration recoil, causing air to leave the lungs as the intrathoracic pressure increases. When needed, the abdominal and the internal intercostal muscles can be used to increase expiratory effort (see Fig. 19-11). The increase in intraabdominal pressure that accompanies the forceful contraction of the abdominal muscles pushes the diaphragm upward and results in an increase in intrathoracic pressure. The internal intercostal muscles move inward, which pulls the chest downward, increasing expiratory effort.

Lung Compliance

Lung compliance refers to the ease with which the lungs can be inflated. It is determined by the elastin and collagen fibers of the lung, its water content, and surface tension. Compliance can be appreciated by comparing the ease of blowing up a new balloon that is stiff and noncompliant with one that has been previously blown up and stretched.

Specifically, lung compliance describes the change in lung volume that can be accomplished with a given change in respiratory pressure. The normal compliance of both lungs in the average adult is approximately 200 mL/cm H₂O. This means that every time the transpulmonary pressure increases by 1 cm/H₂O, the lung volume expands by 200 mL. It would take more pressure to move the same amount of air into a non-compliant lung.

Changes in Elastin/Collagen Composition of Lung Tissue. Lung tissue is made up of elastin and collagen fibers. The elastin fibers are easily stretched and increase the ease of lung inflation, whereas the collagen fibers resist stretching and make lung inflation more difficult. In lung diseases such as interstitial lung disease and pulmonary fibrosis, the lungs become stiff and noncompliant as the elastin fibers are replaced with scar tissue. Pulmonary congestion and edema produce a reversible decrease in pulmonary compliance.

Elastic recoil describes the ability of the elastic components of the lung to recoil to their original position after having been stretched. Overstretching the airways, as occurs with emphysema, causes the elastic components of the lung to lose their recoil, making the lung easier to inflate but more difficult to deflate because of its inability to recoil.

Surface Tension. An important factor in lung compliance is the *surface tension* in the alveoli. The alveoli are lined with a thin film of liquid, and it is at the interface between this liquid film and the alveolar air that surface tension develops. This is because the forces that hold the liquid film molecules together are stronger than those that hold the air molecules together. In the alveoli, excess surface tension causes the liquid film to contract, making lung inflation more difficult.

The pressure in the alveoli (which are modeled as spheres with open airways projecting from them) can be predicted using Laplace's law (pressure = $2 \times \text{surface tension/radius}$). If the surface tension were equal throughout the lungs, the alveoli with the smallest radii would have the greatest pressure, and this would cause them to empty into the larger alveoli (Fig. 19-12). The reason this does not occur is because of special surface tension-lowering molecules, called *surfactant*, that line the inner surface of the alveoli.

Surfactant is a complex mixture of lipoproteins (largely phospholipids) and small amounts of carbohydrates that is synthesized in the type II alveolar cells. The surfactant molecule has two ends: a hydrophobic (water-insoluble) tail and a hydrophilic (water-soluble) head (Fig. 19-13). The hydrophilic head of the surfactant molecule attaches to the liquid mole-

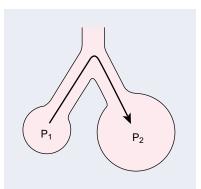

FIGURE 19-12 Law of Laplace (P = 2 T/r, P = pressure, T = tension, r = radius). The effect of the radius on the pressure and movement of gases in the alveolar structures is depicted. Air moves from P₁ with a small radius and higher pressure to P₂ with its larger radius and lower pressure.

cules and the hydrophobic tail to the gas molecules, interrupting the intermolecular forces that are responsible for creating the surface tension.

Surfactant exerts four important effects on lung inflation: (1) it lowers the surface tension; (2) it increases lung compliance and ease of inflation; (3) it provides for stability and more even inflation of the alveoli; and (4) it assists in preventing pulmonary edema by keeping the alveoli dry. Without surfactant, lung inflation would be extremely difficult, requiring an intrapleural pressure of -20 to -30 mm Hg, compared with the -3 to -5 mm Hg pressure that normally is needed. The surfactant molecules are more densely packed in the small alveoli

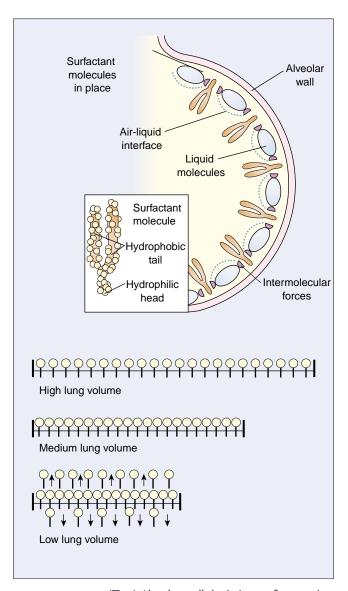

FIGURE 19-13 (**Top**) Alveolar wall depicting surface tension resulting from the intramolecular forces in the air-liquid film interface; the surfactant molecule with its hydrophobic tail and hydrophilic head; and its function in reducing surface tension by disrupting the intermolecular forces. (**Bottom**) The surface concentration of surfactant molecules at high, medium, and low lung volumes.

348 Unit Five: Alterations in the Respiratory System

than in larger alveoli, where the density of the molecules is less. Therefore, surfactant reduces the surface tension more effectively in the small alveoli, which have the greatest tendency to collapse, providing for stability and more even distribution of ventilation. Surfactant also helps to keep the alveoli dry and prevent pulmonary edema. This is because water is pulled out of the pulmonary capillaries into the alveoli when increased surface tension causes the alveoli to contract.

The type II alveolar cells that produce surfactant do not begin to mature until the 26th to 28th week of gestation; consequently, many premature infants have difficulty producing sufficient amounts of surfactant. This can lead to alveolar collapse and severe respiratory distress. This condition, called *infant respiratory distress syndrome*, is the single most common cause of respiratory disease in premature infants. Surfactant dysfunction also is possible in the adult. This usually occurs as the result of severe injury or infection and can contribute to the development of a condition called *acute respiratory distress syndrome* (see Chapter 21).

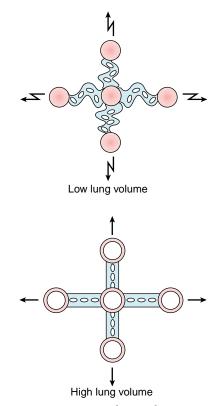

Airway Resistance

The volume of air that moves into and out of the air exchange portion of the lungs is directly related to the pressure difference between the lungs and the atmosphere and inversely related to the resistance that the air encounters as it moves through the airways. The effects of airway resistance on airflow can be illustrated using *Poiseuille's law*. According to Poiseuille's law, the resistance to flow is inversely related to the fourth power of the radius ($R = 1/r^4$). If the radius is reduced by one half, the resistance increases 16-fold ($2 \times 2 \times 2 \times 2 = 16$). Because the resistance of the airways is inversely proportional to the fourth power of the radius, small changes in airway caliber, such as those caused by pulmonary secretions or bronchospasm, can produce a marked increase in airway resistance.

Airway resistance is also affected by lung volumes, being less during inspiration than during expiration. This is because elastic-type fibers connect the outside of the airways to the surrounding lung tissues. As a result, these airways are pulled open as the lungs expand during inspiration, and they become narrower as the lungs deflate during expiration (Fig. 19-14). This is one of the reasons that persons with conditions that increase airway resistance, such as bronchial asthma, usually have less difficulty during inspiration than during expiration.

Airway Compression. Airflow through the collapsible airways in the lungs depends on the distending airway (intrapulmonary) pressures that hold the airways open and the external (intrapleural or intrathoracic) pressures that surround and compress the airways. The difference between these two pressures (airway pressure minus intrathoracic pressure) is called the *transpulmonary pressure*. For airflow to occur, the distending pressure inside the airways must be greater than the compressing pressure outside the airways (Fig. 19-15).

During forced expiration, the transpulmonary pressure is decreased because of a disproportionate increase in the intrathoracic pressure compared with airway pressure. The resistance that air encounters as it moves out of the lungs causes a further drop in airway pressure. If this drop in airway pressure is sufficiently great, the surrounding intrathoracic pressure will compress the collapsible airways (*i.e.*, those that lack cartilaginous support), causing airflow to be interrupted and air to be

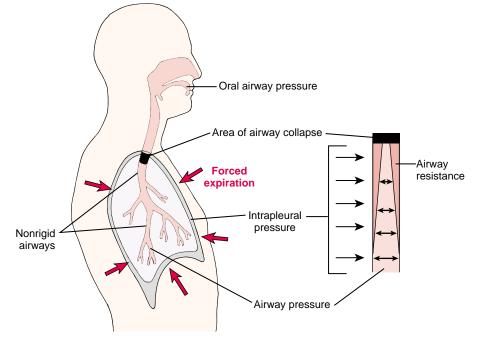

■ FIGURE 19-14 ■ Interaction of tissue forces on airways during low and high lung volumes. At low lung volumes, the tissue forces tend to fold and place less tension on the airways and they become smaller; during high lung volumes, the tissue forces are stretched and pull the airways open.

trapped in the alveoli (Fig. 19-15). Although this type of airway compression usually is seen only during forced expiration in persons with normal respiratory function, it may occur during normal breathing in persons with lung disease. For example, in conditions that increase airway resistance, such as chronic obstructive airway disease (COPD), the pressure drop along the smaller airways is magnified, and an increase in intra-airway pressure is needed to maintain airway patency (see Chapter 20). Measures such as pursed-lip breathing increase airway pressure and improve expiratory flow rates in persons with COPD.

Lung Volumes

Lung volumes, or the amount of air exchanged during ventilation, can be subdivided into three components: (1) the tidal volume (TV), (2) the inspiratory reserve volume (IRV), and (3) the expiratory reserve volume (ERV). The TV, usually about 500 mL, is the amount of air that moves into and out of the lungs during a normal breath (Fig. 19-6). The IRV is the maximum amount of air that can be inspired in excess of the normal TV, and the ERV is the maximum amount that can be exhaled in excess of the normal TV. Approximately 1200 mL of air always remains in the lungs after forced expiration; this air is the *residual volume* (RV). The RV increases with age because there is more trapping of air in the lungs at the end of expiration. These volumes can be measured using an instrument called a *spirometer*. ■ FIGURE 19-15 ■ Mechanism that limits maximal expiratory flow rate. (A) Airway patency and airflow in the nonrigid airways of the lungs rely on a transpulmonary pressure gradient in which airway pressure is greater than intrapleural pressure. (B) Airway resistance normally produces a drop in airway pressure as air moves out of the lungs. The increased intrapleural pressure that occurs with forced expiration produces airway collapse in the nonrigid airways at the point where intrapleural pressure exceeds airway pressure.

Lung capacities include two or more lung volumes. The *vital capacity* (VC) equals the IRV plus the TV plus the ERV and is the amount of air that can be exhaled from the point of maximal inspiration. The *inspiratory capacity* (IC) equals the TV plus the IRV. It is the amount of air a person can breathe in beginning at the normal expiratory level and distending the lungs to the maximal amount. The *functional residual capacity* (FRC) is the sum of the RV and ERV; it is the volume of air that remains in the lungs at the end of normal expiration. The *total lung capacity* (TLC) is the sum of all the volumes in the lungs. The RV cannot be measured with the spirometer because this air cannot be expressed from the lungs. It is measured by indirect methods, such as the helium dilution methods, the nitrogen washout methods, or body plethysmography. Lung volumes and capacities are summarized in Table 19-1.

Pulmonary Function Studies

The previously described lung volumes and capacities are anatomic or static measures, determined by lung volumes and measured without relation to time. The spirometer also is used to measure dynamic lung function (*i.e.*, ventilation with respect to time); these tests often are used in assessing pulmonary function (Table 19-2). The *maximum voluntary ventilation* measures the volume of air that a person can move into and out of the lungs during maximum effort lasting for a specific period of time. This measurement usually is converted to liters per minute. Two other useful tests are the forced vital capacity (FVC) and the *forced expiratory volume* (FEV). The FVC involves full inspiration to total lung capacity followed by forceful maximal expiration. Obstruction of airways produces a FVC that is lower than that observed with more slowly performed vital

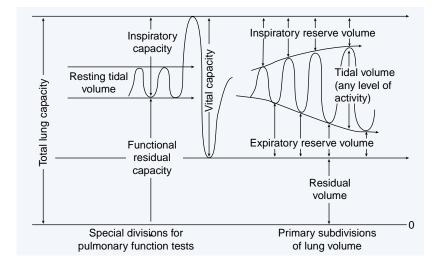

FIGURE 19-16 A tracing of respiratory volumes and capacities made with the use of a spirometer.

TABLE 19-1	LE 19-1 Lung Volumes and Capacities				
Volume		Symbol	Measurement		
Tidal volume (about 500 mL at rest) Inspiratory reserve volume (about 3000 mL)		TV IRV	Amount of air that moves into and out of the lungs with each breath Maximum amount of air that can be inhaled from the point of maximal expiration		
Expiratory reserve volume (about 1100 mL)		ERV	Maximum volume of air that can be exhaled from the resting end- expiratory level		
Residual volume (about 1200 mL)		RV	Volume of air remaining in the lungs after maximal expiration. This volur cannot be measured with the spirometer; it is measured indirectly using methods such as the helium dilution method, the nitrogen washout technique, or body plethysmography.		
Functional residual capacity (about 2300 mL)		FRC	Volume of air remaining in the lungs at end-expiration (sum of RV and ERV)		
Inspiratory capacit	y (about 3500 mL)	IC	Sum of IRV and TV		
Vital capacity (abo	ut 4600 mL)	VC	Maximal amount of air that can be exhaled from the point of maximal inspiration		
Total lung capacity	y (about 5800 mL)	TLC	Total amount of air that the lungs can hold; it is the sum of all the volume components after maximal inspiration. This value is about 20% to 25% less in females than in males.		

capacity measurements. The forced expiratory volume (FEV) is the expiratory volume achieved in a given time period. The $FEV_{1.0}$ is the forced expiratory volume that can be exhaled in 1 second. The $FEV_{1.0}$ frequently is expressed as a percentage of the FVC. The $FEV_{1.0}$ and FVC are used in the diagnosis of obstructive lung disorders. contrast, persons with obstructive airway disease usually find it less difficult to inflate their lungs but expend more energy in moving air through the airways. As a result, these persons take deeper breaths and breathe at a slower rate (*e.g.*, $600 \times 10 = 6000$ mL) to achieve their oxygen needs.

Efficiency and the Work of Breathing

The *minute volume*, or total ventilation, is the amount of air that is exchanged in 1 minute. It is determined by the metabolic needs of the body. The minute volume is equal to the TV multiplied by the respiratory rate. During normal activity it is about 6000 mL (500 mL TV \times respiratory rate of 12 breaths per minute). The efficiency of breathing is determined by matching the TV and respiratory rate in a manner that provides an optimal minute volume while minimizing the work of breathing.

The work of breathing is determined by the amount of effort required to move air through the conducting airways and by the ease of lung expansion or compliance. Expansion of the lungs is difficult for persons with stiff and noncompliant lungs; they usually find it easier to breathe if they keep their TV low and breathe at a more rapid rate (*e.g.*, $300 \times 20 = 6000$ mL) to achieve their minute volume and meet their oxygen needs. In

In summary, the movement of air between the atmosphere and the lungs follows the laws of physics as they relate to gases. The air in the alveoli contains a mixture of gases, including nitrogen, oxygen, carbon dioxide, and water vapor. With the exception of water vapor, each gas exerts a pressure that is determined by the atmospheric pressure and the concentration of the gas in the mixture. Water vapor pressure is affected by temperature but not atmospheric pressure. Air moves into the lungs along a pressure gradient. The pressure inside the airways and alveoli of the lungs is called *intrapulmonary* (or *alveolar*) *pressure*; the pressure in the pleural cavity is called *pleural pressure*; and the pressure in the thoracic cavity is called *intrathoracic pressure*.

Breathing is the movement of gases between the atmosphere and the lungs. It requires a system of open airways and pressure changes resulting from the action of the respiratory

*By convention, all the lung volumes and rates of flow are expressed in terms of body temperature and pressure and saturated with water vapor (BTPS), which allows for a comparison of the pulmonary function data from laboratories with different ambient temperatures and altitudes. muscles in changing the volume of the chest cage. The diaphragm is the principal muscle of inspiration, assisted by the external intercostal muscles. The scalene and sternocleidomastoid muscles elevate the ribs and act as accessory muscles for inspiration. Expiration is largely passive, aided by the elastic recoil of the respiratory muscles that were stretched during inspiration. When needed, the abdominal and internal intercostal muscles can be used to increase expiratory effort.

Lung compliance describes the ease with which the lungs can be inflated. It reflects the elasticity of the lung tissue and the surface tension in the alveoli. Surfactant molecules, produced by type II alveolar cells, reduce the surface tension in the lungs, thereby increasing lung compliance. Airway resistance refers to the impediment to flow that the air encounters as it moves through the airways. The minute volume, which is determined by the metabolic needs of the body, is the amount of air that is exchanged in 1 minute (*i.e.*, respiratory rate and TV). The efficiency and work of breathing are determined by factors such as impaired lung compliance and airway diseases that increase the work involved in maintaining the minute volume. Lung volumes and lung capacities can be measured using a spirometer. Pulmonary function studies are used to assess ventilation with respect to time.

EXCHANGE AND TRANSPORT OF GASES

The primary functions of the lungs are oxygenation of the blood and removal of carbon dioxide. Pulmonary gas exchange is conventionally divided into three processes: (1) ventilation or the flow of gases into and out of the alveoli of the lungs, (2) perfusion or flow of blood in the adjacent pulmonary capillaries, and (3) diffusion or transfer of gases between the alveoli and the pulmonary capillaries. The efficiency of gas exchange requires that alveolar ventilation occur adjacent to perfused pulmonary capillaries.

Ventilation

Ventilation refers to the exchange of gases in the respiratory system. There are two types of ventilation: pulmonary and alveolar. *Pulmonary ventilation* refers to the total exchange of gases between the atmosphere and the lungs. *Alveolar ventilation* is the exchange of gases within the gas exchange portion of the lungs. Ventilation requires a system of open airways and a pressure difference that moves air into and out of the lungs. It is affected by body position and lung volume as well as by disease conditions that affect the heart and respiratory system.

Distribution of Ventilation

The distribution of ventilation between the base (bottom) and apex (top) of the lung varies with body position and the effects of gravity on intrapleural pressure. Compliance reflects the change in volume that occurs with a change in intrapleural pressure. It is less in fully expanded alveoli, which have difficulty accommodating more air, and greater in alveoli that are less inflated. In the seated or standing position, gravity exerts a downward pull on the lung, causing intrapleural pressure at the apex of the lung to become more negative. As a result, the alveoli at the apex of the lung are more fully expanded and less compliant than those at the base of the lung. The same holds true for lung expansion in the dependent portions of the lung in the supine or lateral position. In the supine position, ventilation in the lowermost (posterior) parts of the lung exceeds that in the uppermost (anterior) parts. In the lateral position (*i.e.*, lying on the side), the dependent lung is better ventilated.

The distribution of ventilation also is affected by lung volumes. During full inspiration (high lung volumes) in the seated or standing position, the airways are pulled open and air moves into the more compliant portions of the lower lung. At low lung volumes, the opposite occurs. At functional residual capacity (see Fig. 19-16), the pleural pressure at the base of the lung exceeds airway pressure, compressing the airways so that ventilation is greatly reduced. In contrast, the airways in the apex of the lung remain open, and this area of the lung is well ventilated.

Perfusion

The term *perfusion* is used to describe the flow of blood through the pulmonary capillary bed. The primary functions of the pulmonary circulation are to perfuse or provide blood flow to the gas exchange portion of the lung and to facilitate gas exchange. The pulmonary circulation serves several important functions in addition to gas exchange. It filters all the blood that moves from the right to the left side of the circulation; it removes most of the thromboemboli that might form; and it serves as a reservoir of blood for the left side of the heart.

The gas exchange function of the lungs requires a continuous flow of blood through the respiratory portion of the lungs. Deoxygenated blood enters the lung through the pulmonary artery, which has its origin in the right side of the heart and enters the lung at the hilus, along with the primary bronchus. The pulmonary arteries branch in a manner similar to that of the airways. The small pulmonary arteries accompany the bronchi as they move down the lobules and branch to supply the capillary network that surrounds the alveoli (see Fig. 19-6). The oxygenated capillary blood is collected in the small pulmonary veins of the lobules, and then it moves to the larger veins to be collected in the four large pulmonary veins that empty into the left atrium.

Distribution of Blood Flow

As with ventilation, the distribution of pulmonary blood flow is affected by body position and gravity. In the upright position, the distance of the upper apices of the lung above the level of the heart may exceed the perfusion capabilities of the mean pulmonary arterial pressure (approximately 12 mm Hg); therefore, blood flow in the upper part of the lungs is less than that in the base or bottom part of the lungs. In the supine position, the lungs and the heart are at the same level, and blood flow to the apices and base of the lungs becomes more uniform. In this position, blood flow to the posterior or dependent portions (*e.g.*, bottom of the lung when lying on the side) exceeds flow in the anterior or nondependent portions of the lungs. In persons with left-sided heart failure, congestion develops in the dependent portions of the lungs exposed to increased blood flow.

Effects of Hypoxia

The blood vessels in the pulmonary circulation undergo marked vasoconstriction when they are exposed to hypoxia. The precise mechanism for this response is unclear. When alveolar oxygen levels drop below 60 mm Hg, marked vasoconstriction may occur, and at very low oxygen levels, the local flow may be almost abolished. In regional hypoxia, as occurs with a localized airway obstruction (*e.g.*, atelectasis), vasoconstriction is localized to a specific region of the lung. Vasoconstriction has the effect of directing blood flow away from the hypoxic regions of the lungs. When alveolar hypoxia no longer exists, blood flow is restored.

Generalized hypoxia causes vasoconstriction throughout the lung. Generalized vasoconstriction occurs when the partial pressure of oxygen is decreased at high altitudes, or it can occur in persons with chronic hypoxia caused by lung disease. Prolonged hypoxia can lead to pulmonary hypertension and increased workload on the right heart. A low blood pH also produces vasoconstriction, especially when alveolar hypoxia is present (*e.g.*, during circulatory shock).

Diffusion

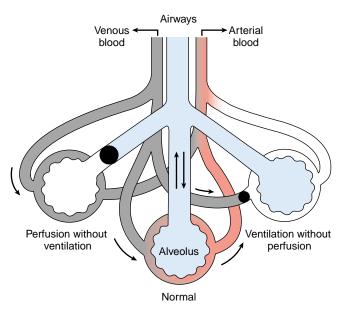

Diffusion refers to the movement of gases in the alveoli and across the alveolar capillary membrane. Diffusion of gases in the lung is affected by the difference in the pressure of gas across the membrane, the surface area that is available for diffusion, and the thickness of the alveolar capillary membrane through which the gas must pass. Administration of high concentrations of oxygen increases the pressure difference between the two sides of the membrane and increases the diffusion of the gas. Diseases that destroy lung tissue and the surface area for diffusion and those that increase the thickness of the alveolar-capillary membrane adversely influence the diffusing capacity of the lungs. For example, the removal of one lung reduces the diffusing capacity by one half. The thickness of the alveolar-capillary membrane and the distance for diffusion are increased in persons with pulmonary edema or pneumonia. The characteristics of the gas and its molecular weight and solubility constitute the diffusion coefficient and determine how rapidly the gas diffuses through the respiratory membranes. For example, carbon dioxide diffuses 20 times more rapidly than oxygen because of its greater solubility in the respiratory membranes.

Matching of Ventilation and Perfusion

The gas exchange properties of the lung depend on matching ventilation and perfusion, ensuring that equal amounts of air and blood are entering the respiratory portion of the lungs (Fig. 19-17). There are two factors that may interfere with the matching of ventilation and perfusion: (1) dead air space and (2) shunt.

Dead Air Space

Dead space refers to the air that must be moved with each breath but does not participate in gas exchange. The movement of air through dead space contributes to the work of breathing but not to gas exchange. There are two types of dead space: that contained in the conducting airways, called the *anatomic dead space*, and that contained in the respiratory portion of the lung,

■ **FIGURE 19-17** ■ Matching of ventilation and perfusion. (**Center**) Normal matching of ventilation and perfusion; (**left**) perfusion without ventilation (*i.e.*, shunt); (**right**) ventilation without perfusion (*i.e.*, dead air space).

called the *alveolar dead space*. The volume of anatomic airway dead space is fixed at approximately 150 to 200 mL, depending on body size. It constitutes air contained in the nose, pharynx, trachea, and bronchi. The creation of an opening in the trachea to facilitate ventilation (tracheostomy) decreases anatomic dead space ventilation because air does not have to move through the nasal and oral airways. Alveolar dead space, normally about 5 to 10 mL, constitutes alveolar air that does not participate in gas exchange. When alveoli are ventilated but deprived of blood

KEY CONCEPTS

MATCHING OF VENTILATION AND PERFUSION

- Exchange of gases between the air in the alveoli and the blood in pulmonary capillaries requires a matching of ventilation and perfusion.
- Dead air space refers to air that is moved with each breath but is not ventilated. Anatomic dead space is that contained in the conducting airways that normally do not participate in gas exchange. Alveolar dead space results from alveoli that are ventilated but not perfused.
- Shunt refers to blood that moves from the right to the left side of the circulation without being oxygenated. With an anatomic shunt, blood moves from the venous to the arterial side of the circulation without going through the lungs. Physiologic shunting results from blood moving through unventilated parts of the lung.

flow, they do not contribute to gas exchange and thereby constitute alveolar dead space.

The *physiologic dead space* includes the anatomic dead space plus alveolar dead space. In persons with normal respiratory function, physiologic dead space is about the same as anatomic dead space. Only in lung disease does physiologic dead space increase.

Shunt

Shunt refers to blood that moves from the right to the left side of the circulation without being oxygenated. There are two types of shunts: physiologic and anatomic. In a physiologic shunt, there is mismatching of ventilation and perfusion, resulting in insufficient ventilation to provide the oxygen needed to oxygenate the blood flowing through the alveolar capillaries. Physiologic shunting of blood usually results from destructive lung disease that impairs ventilation or from heart failure that interferes with movement of blood through sections of the lungs. In an anatomic shunt, blood moves from the venous to the arterial side of the circulation without moving through the lungs. Anatomic intracardiac shunting of blood caused by congenital heart defects is discussed in Chapter 17.

Mismatching of Ventilation and Perfusion

Mismatching of ventilation and perfusion occurs when there is perfusion without ventilation or ventilation without perfusion (see Figure 19-17). Perfusion without ventilation (shunt) results in a low ventilation-perfusion ratio. This is the type of situation that occurs when there is incomplete expansion of the lung, such as in atelectasis (Chap-ter 21). Ventilation without perfusion (dead air space) results in a high ventilation-perfusion ratio. An example of this type of situation is pulmonary embolism, when a blood clot obstructs flow (Chapter 21). The PO₂ in the arterial blood leaving the pulmonary circulation reflects mixing of blood from areas of shunt and dead air space.

Gas Transport

The lungs enable inhaled air to come in contact with blood flowing through the pulmonary capillaries so that exchange of gases between the external environment and the internal environment of the body can occur. The lungs restore the oxygen content of the arterial blood and remove carbon dioxide from the venous blood.

The blood carries oxygen and carbon dioxide in the dissolved state and in combination with hemoglobin. Carbon dioxide also is converted to bicarbonate and transported in that form. The amount of a gas that can dissolve in plasma is determined by two factors: the solubility of the gas in the plasma and the partial pressure of the gas in the alveoli. Oxygen and carbon dioxide dissolve in plasma. The gases that are dissolved in plasma are similar to the carbon dioxide that is dissolved in a capped bottle of a carbonated drink. In the case of the carbonated drink, increased pressure is used to increase the dissolved carbon dioxide to the drink. When the bottle cap is removed and the pressure reduced, tiny bubbles can be seen as the gas moves from the dissolved to the gaseous state.

In the clinical setting, blood gas measurements are used to determine the level of the partial pressure of oxygen (PO_2) and carbon dioxide (PCO₂) in the blood. Arterial blood commonly is used for measuring blood gases. Venous blood is not used because venous levels of oxygen and carbon dioxide reflect the metabolic demands of the tissues, rather than the gas exchange function of the lungs. The PO₂ of arterial blood normally is greater than 80 mm Hg, and the PCO_2 is in the range of 35 to 45 mm Hg. Normally, the arterial blood gases are the same or nearly the same as the partial pressure of the gases in the alveoli. The arterial PO_2 often is written PaO_{2} , and the alveolar PO_2 as PAO_{2} , with the same types of designations being used for PCO_2 . This text uses PO_2 and PCO_2 to designate both arterial and alveolar levels of the gases.

Oxygen Transport

Oxygen is transported in two forms: (1) in chemical combination with hemoglobin and (2) in the dissolved state. The hemoglobin in red blood cells serves as a transport vehicle for oxygen. It binds oxygen in the pulmonary capillaries and releases it in the tissue capillaries. As oxygen moves into or out of the red blood cells, it dissolves in the plasma. It is the dissolved form of oxygen that leaves the capillary, crosses cell membranes, and participates in cell metabolism. Only approximately 1% of the oxygen in the blood is carried in the dissolved state; the remainder is carried in combination with hemoglobin. The oxygen content of the blood (measured in milliliters per 100 milliliters of blood) includes the oxygen carried by hemoglobin and dissolved oxygen.

Hemoglobin Transport. Hemoglobin is a highly efficient carrier of oxygen, and approximately 98% to 99% of the oxygen used by body tissues is carried in this manner. Hemoglobin with bound oxygen is called *oxyhemoglobin*, and when oxygen is removed, it is called deoxygenated or reduced hemoglobin. Each gram of hemoglobin carries approximately 1.34 mL of oxygen when it is fully saturated. This means that a person with a hemoglobin of 14 g/100 mL carries 18.8 mL of oxygen per 100 mL of blood. In the lungs, oxygen moves across the alveolar-capillary membrane, through the plasma, and into

KEY CONCEPTS

OXYGEN TRANSPORT

- Oxygen is transported in chemical combination with hemoglobin and as a gas dissolved in the plasma.
- Hemoglobin, which is the main transporter for oxygen, binds oxygen as it passes through the lungs and releases it as it moves through the tissues.
- The amount of oxygen that is carried as a dissolved gas is determined by the partial pressure of the gas in the lungs.
- The oxygen content of the blood, or the amount of oxygen that is available to the tissues, represents the total amount of oxygen carried by the hemoglobin plus the amount of oxygen that is carried in the dissolved state.

the red blood cell, where it forms a loose and reversible bond with the hemoglobin molecule. In normal lungs, this process is rapid, so that even with a fast heart rate, the hemoglobin is almost completely saturated with oxygen during the short time it spends in the pulmonary capillaries.

The oxygenated hemoglobin is transported in the arterial blood to the peripheral capillaries, where the oxygen is released and made available to the tissues for use in cell metabolism. As the oxygen moves out of the capillaries in response to the needs of the tissues, the hemoglobin saturation, which usually is approximately 95% to 97% as the blood leaves the left side of the heart, drops to approximately 75% as the mixed venous blood returns to the right side of the heart.

Dissolved Oxygen. The partial pressure of oxygen (PO₂) represents the level of dissolved oxygen in plasma. The amount of gas that can be dissolved in a liquid depends on the solubility of the gas and its pressure. The solubility of oxygen in plasma is fixed and very small. For every 1 mm Hg of PO₂ present in the alveoli, 0.003 mL of oxygen becomes dissolved in 100 mL of plasma. This means that at a normal alveolar PO₂ of 100 mm Hg, the blood carries only 0.3 mL of dissolved oxygen in each 100 mL of plasma. This amount is very small compared with the amount that can be carried in an equal amount of blood when oxygen is attached to hemoglobin.

Although the amount of oxygen carried in plasma under normal conditions is small, it can become a life-saving mode of transport in carbon monoxide poisoning, when most of the hemoglobin sites are occupied by carbon monoxide and are unavailable for transport of oxygen. The use of a hyperbaric chamber, in which 100% oxygen can be administered at high atmospheric pressures, increases the amount of oxygen that can be carried in the dissolved state.

Oxygen-Hemoglobin Dissociation. Oxygen that remains bound to hemoglobin cannot participate in tissue metabolism. The efficiency of the oxygen dissociation transport system depends on the ability of the hemoglobin molecule to bind oxygen in the lungs and release it, as it is needed in the tissues. The affinity of hemoglobin refers to its capacity to bind oxygen. Hemoglobin binds oxygen more readily when its affinity is increased and releases it more readily when its affinity is decreased. As described in Chapter 13, the hemoglobin molecule is composed of four polypeptide chains bound to an iron-containing heme group. Because oxygen binds to the iron atom, each hemoglobin molecule can bind four molecules of oxygen. When oxygen is bound to all four of the heme groups, the hemoglobin molecule is said to be fully saturated. Hemoglobin is partially saturated when it contains only one, two, or three molecules of oxygen.

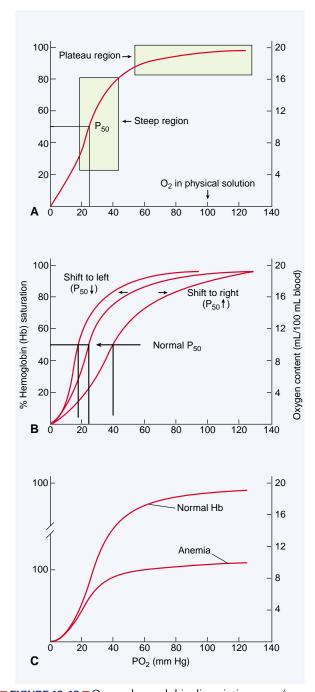

Hemoglobin's affinity for oxygen is influenced by pH, carbon dioxide concentration, and temperature. Hemoglobin binds oxygen more strongly under conditions of increased pH (alkalosis), decreased carbon dioxide concentration, and decreased body temperature, and releases it more readily under conditions of decreased pH (acidosis), increased carbon dioxide concentration, and fever. Conditions that decrease affinity and favor unloading of oxygen reflect the level of tissue metabolism and need for oxygen. For example, increased tissue metabolism generates carbon dioxide and metabolic acids, thereby decreasing the affinity of hemoglobin for oxygen. Heat also is a byproduct of tissue metabolism, explaining the effect of fever on oxygen binding. Red blood cells contain a metabolic intermediate called 2,3-diphosphoglycerate (2,3-DPG) that also affects the affinity of hemoglobin for oxygen. An increase in 2,3-DPG enhances unloading of oxygen from hemoglobin at the tissue level. An increase in 2,3-DPG occurs with exercise and the hypoxia that occurs with high altitude and chronic lung disease.

The relation between the oxygen carried in combination with hemoglobin and the PO₂ of the blood is described by the oxygen-hemoglobin dissociation curve, which is shown in Figure 19-18A. The x axis depicts the PO_2 ; the left y axis, hemoglobin saturation, and the right y axis, the oxygen content or total amount of oxygen in the blood, including the dissolved oxygen and that carried by the hemoglobin. There are three important things to observe about the relationships among PO_{2} , hemoglobin saturation, and oxygen content. First, PO_{2} is the dissolved oxygen. It reflects the partial pressure of the gas in the lung (*i.e.*, the PO_2 is approximately 100 mm Hg when room air is being breathed but can rise to 200 mm Hg or higher when oxygen-enriched air is breathed). Second, hemoglobin saturation reflects the amount of oxygen that is carried by the hemoglobin. Third, it is the oxygen content of the blood, rather than the PO₂, or even hemoglobin saturation, that determines the amount of oxygen that is delivered to the tissues. An anemic person may have a normal PO₂ and hemoglobin saturation level but decreased oxygen content because of the lower amount of hemoglobin for binding oxygen (Fig. 19-18C).

The oxygen-hemoglobin dissociation curve has a flat top portion representing binding of oxygen by the hemoglobin in the lungs and a steep portion representing its release into the tissue capillaries. The S shape of the curve reflects the effect that oxygen saturation has on the affinity of hemoglobin for oxygen. At approximately 100 mm Hg PO₂, a plateau occurs, at which point the hemoglobin is approximately 98% saturated. Increasing the alveolar PO₂ above this level does not increase the hemoglobin saturation. Even at high altitudes, when the partial pressure of oxygen is considerably decreased, the hemoglobin remains relatively well saturated. For example, at 60 mm Hg PO₂, the hemoglobin is still approximately 89% saturated.

The steep portion of the dissociation curve—between 60 and 40 mm Hg—represents the removal of oxygen from the hemoglobin as it moves through the tissue capillaries. This portion of the curve shows that there is considerable transfer of oxygen from hemoglobin to the tissues with only a small drop in PO_2 , thereby ensuring a gradient for oxygen to move into body cells. The tissues normally remove approximately 5 mL of oxygen per 100 mL of blood, and the hemoglobin of mixed venous blood is approximately 75% saturated as it returns to the right side of the heart.

Hemoglobin can be regarded as an oxygen buffer system that regulates oxygen pressure in the tissues. Hemoglobin affinity for oxygen must change with the metabolic needs of the tissues. This change is represented by a shift to the right or left in the dissociation curve, as shown in Figure 19-18B. The P_{50} represents the PO₂ at a hemoglobin of 50%. It can be used

■ FIGURE 19-18 ■ Oxygen-hemoglobin dissociation curve (oxygen content at hemoglobin of 14 gm/dL). (A) Left boxed area represents the steep portion of the curve where oxygen is released from hemoglobin (Hb) to the tissues, and the top boxed area the plateau of the curve where oxygen is loaded onto hemoglobin in the lung. P₅₀ partial pressure of oxygen required to saturate 50% of hemoglobin with oxygen. (B) The effect of body temperature, arterial PCO₂, and pH on hemoglobin affinity for oxygen as indicated by a shift in the curve and position of the P₅₀. A shift of the curve to the right due to an increase in temperature, PCO₂, or decreased pH favors release of oxygen to the tissues. A decrease in temperature, PCO₂, or increase in pH shifts the curve to the left. (C) Effect of anemia on the oxygen-carrying capacity of blood. The hemoglobin can be completely saturated, but the oxygen content of the blood is reduced. (Adapted from Rhoades R.A., Tanner G.A. [1996]. Medical physiology. Boston: Little, Brown)

to determine whether the dissociation curve has shifted to the right or to the left. A *shift to the right* indicates that the tissue PO_2 is greater for any given level of hemoglobin saturation and represents reduced affinity of the hemoglobin for oxygen at any given PO_2 . It usually is caused by conditions such as fever or acidosis or by an increase in PCO_2 , which reflects increased tissue metabolism. High altitude and conditions such as pulmonary insufficiency, heart failure, and severe anemia also cause the oxygen dissociation curve to shift to the right.

A *shift to the left* in the oxygen dissociation curve represents enhanced affinity of hemoglobin for oxygen and occurs in situations associated with a decrease in tissue metabolism, such as alkalosis, decreased body temperature, and decreased carbon dioxide levels.

Carbon Dioxide Transport

Carbon dioxide is transported in the blood in three forms: as dissolved carbon dioxide (10%), attached to hemoglobin (30%), and as bicarbonate (60%). Acid-base balance is influenced by the amount of dissolved carbon dioxide and the bicarbonate level in the blood (see Chapter 6).

As carbon dioxide is formed during the metabolic process, it diffuses out of cells into the tissue spaces and then into the capillaries. The amount of dissolved carbon dioxide that can be carried in plasma is determined by the partial pressure of the gas and its solubility coefficient (0.03 mL/100 mL/1 mm Hg PCO₂). Carbon dioxide is 20 times more soluble in plasma than oxygen. Thus, the dissolved state plays a greater role in transport of carbon dioxide compared with oxygen.

Most of the carbon dioxide diffuses into the red blood cells, where it forms carbonic acid or combines with hemoglobin. Carbonic acid (H_2CO_3) is formed when carbon dioxide combines with water ($CO_2 + H_2O = H^+ + HCO_3^-$). The process is catalyzed by an enzyme called *carbonic anhydrase*, which greatly increases the rate of the reaction. Carbonic acid readily ionizes to form a bicarbonate (HCO_3^-) and a hydrogen (H^+) ion. The hydrogen ion that is generated combines with the hemoglobin, which is a powerful acid-base buffer, and the bicarbonate ion diffuses into plasma in exchange for a chloride ion.

In addition to the carbonic anhydrase-mediated reaction with water, carbon dioxide reacts directly with hemoglobin to form carbaminohemoglobin. The combination of carbon dioxide with hemoglobin is a reversible reaction that involves a loose bond, which allows transport of carbon dioxide from tissues to the lungs, where it is released into the alveoli for exchange with the external environment. The release of oxygen from hemoglobin in the tissues enhances the binding of carbon dioxide to hemoglobin; in the lungs, the combining of oxygen with hemoglobin displaces carbon dioxide. The binding of carbon dioxide to hemoglobin is determined by the acidic nature of hemoglobin. Binding with carbon dioxide causes the hemoglobin to become a stronger acid. In the lungs, the highly acidic hemoglobin has a lesser tendency to form carbaminohemoglobin, and carbon dioxide is released from hemoglobin into the alveoli. In the tissues, the release of oxygen from hemoglobin causes hemoglobin to become less acid, thereby increasing its ability to combine with carbon dioxide and form carbaminohemoglobin.

356 Unit Five: Alterations in the Respiratory System

In summary, the primary functions of the lungs are oxygenation of the blood and removal of carbon dioxide. Pulmonary gas exchange is conventionally divided into three processes: ventilation, or the flow of gases into the alveoli of the lungs; perfusion, or movement of blood through the adjacent pulmonary capillaries; and diffusion, or transfer of gases between the alveoli and the pulmonary capillaries.

Ventilation is the movement of air between the atmosphere and the lungs. Pulmonary ventilation refers to the total exchange of gases between the atmosphere and the lungs, and alveolar ventilation refers to ventilation in the gas exchange portion of the lungs. The distribution of alveolar ventilation and pulmonary capillary blood flow varies with lung volume and body position. In the upright position and at high lung volumes, ventilation is greatest in the lower parts of the lungs. The upright position also produces a decrease in blood flow to the upper parts of the lung, resulting from the distance above the level of the heart and the low mean arterial pressure in the pulmonary circulation.

The diffusion of gases in the lungs is influenced by four factors: the surface area available for diffusion; the thickness of the alveolar-capillary membrane, through which the gases diffuse; the differences in the partial pressure of the gas on either side of the membrane; and the characteristics of the gas. The efficiency of gas exchange requires matching of ventilation and perfusion so that equal amounts of air and blood enter the respiratory portion of the lungs. Two factors—dead air space and shunt—interfere with matching of ventilation and perfusion and do not contribute to gas exchange. Dead air space occurs when areas of the lungs are ventilated but not perfused. Shunt is the condition under which areas of the lungs are perfused but not ventilated.

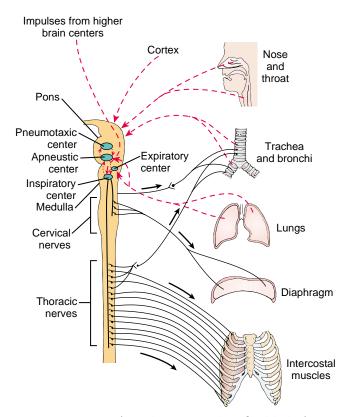

The blood transports oxygen to the cells and returns carbon dioxide to the lungs. Oxygen is transported in two forms: in chemical combination with hemoglobin and physically dissolved in plasma (PO_2). Hemoglobin is an efficient carrier of oxygen, and approximately 98% to 99% of oxygen is transported in this manner. Carbon dioxide is carried in three forms: carbaminohemoglobin (30%), dissolved carbon dioxide (10%), and bicarbonate (60%).

CONTROL OF BREATHING

Unlike the heart, which has inherent rhythmic properties and can beat independently of the nervous system, the muscles that control respiration require continuous input from the nervous system. Movement of the diaphragm, intercostal muscles, sternocleidomastoid, and other accessory muscles that control ventilation is integrated by neurons located in the pons and medulla. These neurons are collectively referred to as the *respiratory center* (Fig. 19-19).

Respiratory Center

The medullary respiratory center consists of two groups of neurons involved in initiating inspiration and expiration and incorporating afferent impulses into the motor responses of the respiratory muscles. The first, or inspiratory area, which is

■ FIGURE 19-19 ■ Schematic representation of activity in the respiratory center. Impulses traveling over afferent neurons (*red dashed lines*) communicate with central neurons, which activate efferent neurons that supply the muscles of respiration. Respiratory movements can be altered by a variety of stimuli.

located in the dorsal region of the medulla, controls the activity of the phrenic nerves that innervate the diaphragm and another group of neurons, which innervate the spinal motor neurons of the intercostals and abdominal muscles. The second group of neurons is concerned with the expiratory phase of respiration.

The pacemaker properties of the respiratory center result from the cycling of the two groups of respiratory neurons in the pons: the *pneumotaxic center* in the upper pons and the *apneustic center* in the lower pons. These two groups of neurons contribute to the function of the respiratory center in the medulla. The apneustic center has an excitatory effect on inspiration, tending to prolong inspiration. The pneumotaxic center switches inspiration off, assisting in the control of respiratory rate and inspiratory volume. Brain injury that damages the connection between the pneumotaxic and apneustic centers results in an irregular breathing pattern that consists of prolonged inspiratory gasps interrupted by expiratory efforts.

Axons from the neurons in the respiratory center cross in the midline and descend in the ventrolateral columns of the spinal cord. The tracts that control expiration and inspiration are spatially separated in the cord, as are the tracts that transmit specialized reflexes (*i.e.*, coughing and hiccupping) and voluntary control of ventilation. Only at the level of the spinal cord are the respiratory impulses integrated to produce a reflex response.

The control of breathing has automatic and voluntary components. The automatic regulation of ventilation is controlled by input from two types of sensors or receptors: chemoreceptors and lung receptors. Chemoreceptors monitor blood levels of oxygen, carbon dioxide, and pH and adjust ventilation to meet the changing metabolic needs of the body. Lung receptors monitor breathing patterns and lung function. Voluntary regulation of ventilation integrates breathing with voluntary acts, such as speaking, blowing, and singing. These voluntary acts, initiated by the motor and premotor cortex, cause temporary suspension of automatic breathing. The automatic and voluntary components of respiration are regulated by afferent impulses that come to the respiratory center from a number of sources. Afferent input from higher brain centers is evidenced by the fact that a person can consciously alter the depth and rate of respiration. Fever, pain, and emotion exert their influence through lower brain centers. Vagal afferents from sensory receptors in the lungs and airways are integrated in the dorsal area of the respiratory center.

Chemoreceptors

Tissue needs for oxygen and the removal of carbon dioxide are regulated by chemoreceptors that monitor blood levels of these gases. Input from these sensors is transmitted to the respiratory center, and ventilation is adjusted to maintain the arterial blood gases within a normal range.

There are two types of chemoreceptors: central and peripheral. The most important chemoreceptors for sensing changes in blood carbon dioxide content are the *central chemoreceptors*. These receptors are located in chemosensitive regions near the respiratory center in the medulla and are bathed in cerebrospinal fluid. Although the central chemoreceptors monitor carbon dioxide levels, the actual stimulus for these receptors is provided by hydrogen ions in the cerebrospinal fluid (CSF). The CSF is separated from the blood by the blood-brain barrier, which permits free diffusion of carbon dioxide but not bicarbonate or hydrogen ions. The carbon dioxide combines rapidly with water to form carbonic acid, which dissociates into hydrogen and bicarbonate ions. The carbon dioxide content in the blood regulates ventilation through its effect on the pH of the extracellular fluid of the brain. The central chemoreceptors are extremely sensitive to short-term changes in carbon dioxide. An increase in plasma carbon dioxide levels increases ventilation, reaching its peak within a minute or so and then declining if the carbon dioxide level remains elevated. Thus, persons with chronically elevated levels of carbon dioxide no longer have a response to this stimulus for increased ventilation but rely on the stimulus provided by a decrease in blood oxygen levels.

The *peripheral chemoreceptors* are located in the carotid and aortic bodies, which are found at the bifurcation of the common carotid arteries and in the arch of the aorta, respectively. These chemoreceptors monitor arterial blood oxygen levels. Although the peripheral chemoreceptors also monitor carbon dioxide, they play a much more important role in monitoring oxygen levels. These receptors exert little control over ventilation until the PO₂ has dropped below 60 mm Hg. Thus, hypoxia is the main stimulus for ventilation in persons with chronically elevated levels of carbon dioxide. If these patients are given oxygen therapy at a level sufficient to increase the PO₂

above that needed to stimulate the peripheral chemoreceptors, their ventilation may be seriously depressed.

Lung Receptors

Lung and chest wall receptors provide information on the status of breathing in terms of airway resistance and lung expansion. There are three types of lung receptors: stretch, irritant, and juxtacapillary receptors.

Stretch receptors are located in the smooth muscle layers of the conducting airways. They respond to changes in pressure in the walls of the airways. When the lungs are inflated, these receptors inhibit inspiration and promote expiration. They are important in establishing breathing patterns and minimizing the work of breathing by adjusting respiratory rate and TV to accommodate changes in lung compliance and airway resistance.

The *irritant receptors* are located between the airway epithelial cells. They are stimulated by noxious gases, cigarette smoke, inhaled dust, and cold air. Stimulation of the irritant receptors leads to airway constriction and a pattern of rapid, shallow breathing. This pattern of breathing probably protects respiratory tissues from the damaging effects of toxic inhalants. It also is thought that the mechanical stimulation of these receptors may ensure more uniform lung expansion by initiating periodic sighing and yawning. It is possible that these receptors are involved in the bronchoconstriction response that occurs in some persons with bronchial asthma.

The *juxtacapillary* or *J receptors* are located in the alveolar wall, close to the pulmonary capillaries. It is thought that these receptors sense lung congestion. These receptors may be responsible for the rapid, shallow breathing that occurs with pulmonary edema, pulmonary embolism, and pneumonia.

Cough Reflex

Coughing is a neurally mediated reflex that protects the lungs from the accumulation of secretions and from entry of irritating and destructive substances. It is one of the primary defense mechanisms of the respiratory tract. The cough reflex is initiated by receptors located in the tracheobronchial wall; these receptors are extremely sensitive to irritating substances and to the presence of excess secretions. Afferent impulses from these receptors are transmitted through the vagus to the medullary center, which integrates the cough response.

Coughing itself requires the rapid inspiration of a large volume of air (usually about 2.5 L), followed by rapid closure of the glottis and forceful contraction of the abdominal and expiratory muscles. As these muscles contract, intrathoracic pressures are elevated to levels of 100 mm Hg or more. The rapid opening of the glottis at this point leads to an explosive expulsion of air.

Many conditions can interfere with the cough reflex and its protective function. The reflex is impaired in persons whose abdominal or respiratory muscles are weak. This problem can be caused by disease conditions that lead to muscle weakness or paralysis, by prolonged inactivity, or as an outcome of surgery involving these muscles. Bed rest interferes with expansion of the chest and limits the amount of air that can be taken into the lungs in preparation for coughing, making the cough weak and ineffective. Disease conditions that prevent effective closure of

358 Unit Five: Alterations in the Respiratory System

the glottis and laryngeal muscles interfere with production of the marked increase in intrathoracic pressure that is needed for effective coughing. For example, the presence of a nasogastric tube may prevent closure of the upper airway structures and may fatigue the receptors for the cough reflex that are located in the area. The cough reflex also is impaired when there is depressed function of the medullary centers in the brain that integrate the cough reflex. Interruption of the central integration aspect of the cough reflex can arise as the result of disease of this part of the brain or the action of drugs that depress the cough center.

Although the cough reflex is a protective mechanism, frequent and prolonged coughing can be exhausting and painful and can exert undesirable effects on the cardiovascular and respiratory systems and on the elastic tissues of the lungs. This is particularly true in young children and elderly persons.

In summary, the respiratory system requires continuous input from the nervous system. Movement of the diaphragm, intercostal muscles, and other respiratory muscles is controlled by neurons of the respiratory center located in the pons and medulla. The control of breathing has automatic and voluntary components. Voluntary respiratory control is needed for integrating breathing and actions such as speaking, blowing, and singing. These acts, which are initiated by the motor and premotor cortex, cause temporary suspension of automatic breathing.

The automatic regulation of ventilation is controlled by two types of receptors: lung receptors, which protect respiratory structures, and chemoreceptors, which monitor the gas exchange function of the lungs by sensing changes in blood levels of carbon dioxide, oxygen, and pH. There are three types of lung receptors: stretch receptors, which monitor lung inflation; irritant receptors, which protect against the damaging effects of toxic inhalants; and J receptors, which are thought to sense lung congestion. There are two groups of chemoreceptors: central and peripheral. The central chemoreceptors are the most important in sensing changes in carbon dioxide levels, and the peripheral chemoreceptors function in sensing arterial blood oxygen levels.

The cough reflex protects the lungs from the accumulation of secretions and from the entry of irritating and destructive substances; it is one of the primary defense mechanisms of the respiratory tract.

REVIEW QUESTIONS

State the difference between the conducting and the respiratory airways.

Describe the function of the mucociliary blanket.

Define the term water vapor pressure and cite the source of water for humidification of air as it moves through the airways.

State the function of the two types of alveolar cells and use Laplace's law to explain the need for surfactant in maintaining the inflation of small alveoli.

State the definition of intrathoracic, intrapleural, and intraalveolar pressures, and state how each of these pressures changes in relation to atmospheric pressure during inspiration and expiration.

Explain why ventilation and perfusion must be matched and describe their relation to dead air space and shunt.

Explain the difference between PO_2 and hemoglobin-bound oxygen and O_2 saturation and content and explain the effect of administering 40% oxygen on O_2 saturation and PO_2 .

Explain the significance of a shift to the right and a shift to the left in the oxygen-hemoglobin dissociation curve.

Describe the function of the chemoreceptors and lung receptors in the regulation of ventilation.

Trace the integration of the cough reflex from stimulus to explosive expulsion of air that constitutes the cough.

Respiratory illnesses represent one of the more common reasons for visits to the physician, admission to the hospital, and forced inactivity among all age groups. Pneumonia is the sixth leading cause of death in the United States, particularly among the elderly and those with compromised immune function. Tuberculosis remains one of the deadliest diseases in the world. It has been estimated that between 19% and 43% of the world population is infected with tuberculosis. Of all neoplasms, lung cancer remains the leading cause of death in the United States.

RESPIRATORY TRACT INFECTIONS

Respiratory tract infections can involve the upper respiratory tract (*i.e.*, nose, oropharynx, and larynx), the lower respiratory tract (*i.e.*, lower airways and lungs), or the upper and lower airways. The discussion in this section of the chapter focuses on influenza, pneumonia, tuberculosis, and fungal infections of the lung. Acute respiratory infections in children are discussed in the last section of the chapter.

Influenza

Influenza is a viral infection that can affect the upper and lower respiratory tracts. It usually occurs in epidemics or pandemics. Until the advent of acquired immunodeficiency syndrome (AIDS), it was the last uncontrolled pandemic killer of humans. More persons died in the 1918 and 1919 influenza pandemic than in World War I. In the United States, approximately 20,000 persons die each year of influenza-related illness during nonpandemic years.¹ Most deaths are caused by pneumonia or exacerbation of cardiopulmonary or other conditions; 80% to 90% of those who die are 65 years of age or older.

There are two types of influenza viruses that cause epidemics in humans: types A and B. Infection with type A is most common and causes the most severe disease. Influenza A is further divided into subtypes based on two surface antigens: hemagglutinin (H) and neuraminidase (N). Influenza B has not been categorized into subtypes. Host antibodies to the surface antigens, which provide entrance in host cells, prevent future infection with influenza virus. New variants result from frequent mutations or antigenic shifts in the surface antigens.¹ Influenza B undergoes less frequent shifts than influenza A. The incubation period for influenza is 1 to 4 days, with 2 days being the average. Persons become infectious starting 1 day before their symptoms begin and remain infectious through approximately 5 days after illness onset. Children can be infectious for a longer time.

The influenza viruses can cause three types of infections: an uncomplicated rhinotracheitis, a respiratory viral infection followed by a bacterial infection, and viral pneumonia. In the early stages, the symptoms of influenza often are indistinguishable from other viral infections. There is an abrupt onset of fever and chills, malaise, muscle aching, headache, profuse, watery nasal discharge, nonproductive cough, and sore throat. One distinguishing feature of an influenza viral infection is the rapid onset, sometimes in as little as 1 to 2 minutes, of profound malaise.² The infection causes necrosis and shedding of the serous and ciliated cells that line the respiratory tract, leaving gaping holes between the underlying basal cells and allowing extracellular fluid to escape. This is the reason for the "runny nose" that is characteristic of this phase of the infection. During recovery, the serous cells are replaced more rapidly than the ciliated cells. Mucus is produced, but the ciliated cells are unable to move it adequately; people recovering from influenza continue to blow their nose to clear the nasopharynx and cough to clear the trachea.

The symptoms of uncomplicated rhinotracheitis usually peak by days 3 to 5 and disappear by days 7 to 10. Persons who have secondary complications usually report that they were beginning to feel better when they experienced a return of symptoms. Complications typically include sinusitis, otitis media, bronchitis, and bacterial pneumonia. The clinical course of influenza pneumonia progresses rapidly. It can cause hypoxemia and death within a few days of onset. The rapid onset is thought to be related to the mode of spread and the absence of an initial rhinotracheitis. If the virus is spread by fingers or largedroplet spray, as from sneezing or coughing, only the upper respiratory tract is involved. Infection of the upper respiratory tract is thought to give the immune system enough time to build the defenses needed to protect against viral pneumonia. When the virus is contained in small droplets, it can bypass the upper respiratory tract and travel directly into the lungs to establish infection.2

The goals of treatment for influenza are designed to limit the infection to the upper respiratory tract. The symptomatic approach, which uses rest, keeping warm, and drinking large amounts of liquids, helps to accomplish this. Rest decreases the oxygen requirements of the body and reduces the respiratory rate and the chance of moving the virus from the upper to lower respiratory tract. Keeping warm helps maintain the respiratory epithelium at a core body temperature of 37°C (or higher if fever is present), thereby inhibiting viral replication, which is optimal at 35°C. Drinking large amounts of liquids ensures that the function of the epithelial lining of the respiratory tract is not further compromised by dehydration.

The appropriate pharmacologic treatment of people with influenza depends on accurate and timely diagnosis. Rapid antigen detection tests are available to confirm a diagnosis of influenza A or B infection. These tests allow health care providers to monitor influenza type and its prevalence in their community, to diagnose influenza more accurately, and to consider treatment options more carefully.³

Four antiviral drugs are available for the treatment of influenza.^{3,4} The first-generation antiviral drugs amantadine and rimantadine are similarly effective against influenza A but not influenza B. These agents inhibit the uncoating of viral RNA in the host cells and prevent its replication. Both drugs are effective in prevention of influenza A in high-risk groups and in the treatment of persons who acquire the disease. The secondgeneration antiviral drugs zanamivir and oseltamivir are inhibitors of neuraminidase, a viral glycoprotein that is necessary for viral replication and release. These drugs, which have been approved for treatment of acute uncomplicated influenza infection, are effective against both influenza A and B viruses. To be effective, the antiviral drugs should be initiated within 30 hours after onset of symptoms.

Vaccines are available to protect against influenza infections. The formulation of the vaccine must be changed yearly in response to changes in the influenza virus. Immunization is recommended for high-risk groups who, because of their age or underlying health problems, are unable to cope well with the infection and often require medical attention, including hospitalization. Immunization is also recommended for persons who can transmit the infection to high-risk groups (*e.g.*, health care worker and care givers).

Pneumonias

The term *pneumonia* describes inflammation of parenchymal structures of the lung, such as the alveoli and the bronchioles.⁵ Pneumonia is the sixth leading cause of death in the United States and the most common cause of death from infectious disease, particularly among the elderly and persons with debilitating diseases. Etiologic agents include infectious and non-infectious agents. Although much less common than infectious pneumonia, inhalation of irritating fumes or aspiration of gastric contents can result in severe pneumonia.

Pneumonias can be classified as typical (*i.e.*, bacterial) or atypical (*i.e.*, viral or mycoplasmal) pneumonias (Fig. 20-1). Typical pneumonia results from infection by bacteria that multiply extracellularly in the alveoli and cause inflammation and exudation of fluid into the air-filled spaces of the alveoli. Acute bacterial pneumonias are also classified according to two anatomic and radiologic patterns: *lobar pneumonia* (affecting part or all of a lung lobe) and *bronchopneumonia* (a patchy distribution involving more than one lobe). Atypical pneumonias produce patchy inflammatory changes that are confined to the alveolar septum and the interstitium of the lung. They usually produce less striking symptoms and physical findings than bacterial pneumonia; there is a lack of alveolar infiltration and purulent sputum, leukocytosis, and lobar consolidation on the radiograph.

Because of the overlap in symptomatology and changing spectrum of infectious organisms involved, pneumonias are increasingly being classified as community-acquired and hospitalacquired pneumonias. Persons with compromised immune function constitute a special concern in both categories.

Community-acquired pneumonia results from organisms found in the community, rather than in the hospital or nursing home.^{6,7} Common causes of community-acquired pneumonia include *Streptococcus pneumoniae* (single most common cause), *Haemophilus influenzae*, *Staphylococcus aureus*, *Klebsiella pneumo*-

Dr Murtadha Alshareifi e-Library

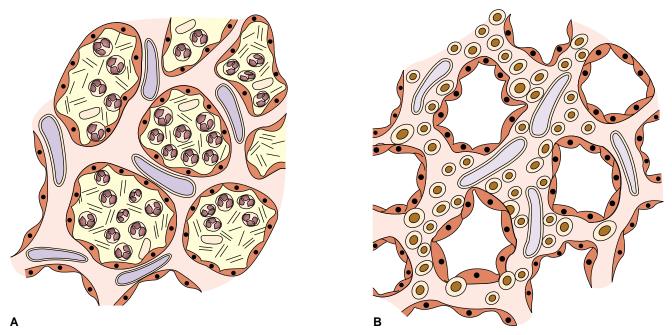

FIGURE 20-1 Location of inflammatory processes in (A) typical and (B) atypical forms of pneumonia.

niae and other gram-negative bacilli, *Legionella pneumophila*, and the influenza and respiratory syncytial viruses.

Hospital-acquired, or nosocomial, pneumonia is defined as a lower respiratory tract infection that was not present or incubating on admission to the hospital. Usually, infections occurring 48 hours or more after admission are considered hospital acquired.^{6,8} Most hospital-acquired pneumonias are bacterial. The organisms are those present in the hospital environment and include *Pseudomonas aeruginosa*, *S. aureus, Enterobacter* species, *Klebsiella* species, *Escherichia coli*, and *Serratia*. The organisms that are responsible for hospital-acquired pneumonias are different from those responsible for community-acquired pneumonia, and many of them have acquired antibiotic resistance and are more difficult to treat. Persons requiring mechanical ventilation are particularly at risk, as are those with compromised immune function, chronic lung disease, or airway instrumentation, such as endotracheal intubation or tracheotomy.

Although almost all types of microorganisms can cause pulmonary infection in immunocompromised persons, certain types of immunologic defects tend to favor certain types of infection. Defects in humoral immunity predispose to bacterial infections against which antibodies play an important role; defects in cellular immunity predispose to infections with viruses, fungi, mycobacteria, and protozoa. Neutropenia and impaired granulocyte function, as occurs in persons with leukemia, chemotherapy, and bone marrow metaplasia, predispose to infections caused by *S. aureus, Aspergillus,* gram-negative bacilli, and *Candida*. Pneumocystis pneumonia is an opportunistic, often fatal form of lung infection that occurs in persons with impaired cell-mediated immunity, particularly those with AIDS (see Chapter 10).

Acute Bacterial (Typical) Pneumonias

Most of the bacteria that cause pneumonia are normal inhabitants of the nasopharynx or oropharynx and are aspirated into the lung.^{5,9} Most persons unknowingly aspirate small amounts of organisms that have colonized their upper airways, particularly during sleep. Normally, these organisms do not cause infection because of the small numbers that are aspirated and because of the respiratory tract's defense mechanisms (Table 20-1). Loss of the cough reflex, damage to the ciliated endothelium that lines the respiratory tract, or impaired immune defenses predispose to colonization and infection of the lower respiratory system. Immune defenses include the bronchial-associated lymphoid tissue, phagocytic cells (*i.e.*, polymorphonuclear cells and macrophages), immunoglobulins (*i.e.*, IgA and IgG), and T-cell–mediated cellular immunity

KEY CONCEPTS

PNEUMONIAS

- Pneumonias are respiratory disorders involving inflammation of the lung structures, such as the alveoli and bronchioles.
- Pneumonia can be caused by infectious agents, such as bacteria and viruses, and noninfectious agents, such as gastric secretions that are aspirated into the lungs.
- The development of pneumonia is facilitated by an exceedingly virulent organism, large inoculum, and impaired host defenses.
- Pneumonias caused by infectious agents commonly are classified according to the source of infection (community- vs. hospital-acquired) and according to the immune status of the host (pneumonia in the immunocompromised person).

Their Effectiveness						
Defense Mechanism	Function	Factors That Impair Effectiveness				
Nasopharyngeal defenses	Remove particles from the air; contact with surface lysosomes and immunoglobulins (IgA) protects against infection	IgA deficiency state, hay fever, common cold, trauma to the nose, others				
Glottic and cough reflexes	Protect against aspiration into tracheo- bronchial tree	Loss of cough reflex due to stroke or neural lesion, neuromuscular disease, abdominal or chest sur- gery, depression of the cough reflex due to seda- tion or anesthesia, presence of a nasogastric tube (tends to cause adaptation of afferent receptors)				
Mucociliary blanket	Removes secretions, microorganisms, and particles from the respiratory tract	Smoking, viral diseases, chilling, inhalation of irritat- ing gases				
Pulmonary macrophages	Remove microorganisms and foreign parti- cles from the lung	Chilling, alcohol intoxication, smoking, anoxia				

TABLE 20-1

espiratory Defense Mechanisms and Conditions That Impair

(see Chapter 8). Bacterial adherence also plays a role in colonization of the lower airways. The epithelial cells of critically and chronically ill persons are more receptive to binding microorganisms that cause pneumonia. Other clinical risk factors favoring colonization of the tracheobronchial tree include antibiotic therapy that alters the normal bacterial flora, diabetes, smoking, chronic bronchitis, and viral infection.

Pneumococcal Pneumonia. Streptococcus pneumoniae (pneumococcus) remains the most common cause of bacterial pneumonia. *S. pneumoniae* colonizes the upper respiratory system and, in addition to pneumonia and lower respiratory tract infections, the organism is an important cause of upper respiratory infections, including sinusitis and otitis media, and of disseminated invasive infections such as bacteremia and meningitis.¹⁰ It is among the leading causes of illness and death of young children, persons with other health problems, and the elderly worldwide.

S. pneumoniae are gram-positive diplococci, possessing a capsule of polysaccharide. There are 90 serologically distinct types of *S. pneumoniae* based on the antigenic properties of their capsular polysaccharides. The virulence of *S. pneumoniae* is a function of its capsule, which prevents or delays digestion by phagocytes. The polysaccharide is an antigen that primarily elicits a B-cell response with antibody production. In the absence of antibody, clearance of the pneumococci from the body relies on the reticuloendothelial system, with the macrophages in the spleen playing a major role in elimination of the organism.¹¹ This, along with the spleen's role in antibody production, increases the risk of pneumococcal bacteremia in persons who are anatomically or functionally asplenic, such as children with sickle cell disease.

The initial step in the pathogenesis of pneumococcal infection is the attachment and colonization of the organism to the mucus and cells of nasopharynx. Colonization does not equate with signs of infection. Perfectly healthy people can be colonized and carry the organism without evidence of infection. The spread of particular strains of pneumococci, particularly antibiotic-resistant strains, is largely by healthy colonized individuals. The factors that permit the pneumococci to spread beyond the nasopharynx vary depending on the virulence of organism, impaired host defense mechanisms, and the existence of preceding viral infection.

The signs and symptoms of pneumococcal pneumonia vary widely, depending on the age and health status of the infected person. In previously healthy persons, the onset usually is sudden and is characterized by malaise; a severe, shaking chill; and fever. The temperature may go as high as 106°F. During the initial or congestive stage, the sputum is watery and breath sounds are limited, with fine crackles. As the disease progresses, the character of the sputum changes; it may be blood tinged or rust colored to purulent. Pleuritic pain, a sharp pain that is more severe with respiratory movements, is common. Elderly persons are less likely to experience marked elevations in temperature; in these persons, the only sign of pneumonia may be a loss of appetite and deterioration in mental status.

Treatment includes the use of antibiotics that are effective against *S. pneumoniae*. In the past, *S. pneumoniae* was uniformly susceptible to penicillin. However, penicillin-resistant and multidrug-resistant strains have been emerging in the United States and other countries.¹²

Pneumococcal pneumonia can be prevented through immunization. A 23-valent pneumococcal vaccine, composed of antigens from 23 types of *S. pneumoniae* capsular polysaccharides, is used. The vaccine is recommended for persons 65 years of age or older and persons aged 2 to 65 years with chronic illnesses, immunocompromised persons 2 years of age or older, and for residents in special environments or social settings in which the risk for invasive pneumococcal disease is increased, and for residents of nursing homes and long-term care facilities. Because their immune system is immature, the antibody response to most pneumococcal capsular polysaccharides usually is poor or inconsistent in children younger than 2 years.¹⁰ A 7-valent pneumococcal polysaccharide-protein conjugate vaccine (Prevnar) is now available for use among infants and children.¹³

Legionnaire's Disease. Legionnaire's disease is a bacterial pneumonia caused by a gram-negative rod, *Legionella pneumophila*. It ranks among the three or four most common causes of community-acquired pneumonia.⁶ Although more than 14 serotypes of *L. pneumophila* have been identified, serotype 1

accounts for more than 80% of reported cases of legionellosis.¹⁴ The organism frequently is found in water, particularly in warm, standing water. The disease was first recognized and received its name after an epidemic of severe and, for some, fatal pneumonia that developed among delegates to the 1976 American Legion convention held in a Philadelphia hotel. The spread of infection was traced to a water-cooled air-conditioning system. Although healthy persons can contract the infection, the risk is greatest among smokers, persons with chronic diseases, and those with impaired cell-mediated immunity.^{6,15}

Symptoms of the disease typically begin approximately 2 to 10 days after infection, with malaise, weakness, lethargy, fever, and dry cough. Other manifestations include disturbances of central nervous system function, gastrointestinal tract involvement, arthralgias, and elevation in body temperature, sometimes to more than 104°F. The presence of pneumonia along with diarrhea, hyponatremia, and confusion is characteristic of Legionella pneumonia. The disease causes consolidation of lung tissues and impairs gas exchange.

Diagnosis is based on clinical manifestations, radiologic studies, and specialized laboratory tests to detect the presence of the organism. Of these, the Legionella urinary antigen test is a relatively inexpensive, rapid test that detects antigens of *L. pneumophila* in the urine.^{14,15} The urine test usually is easier to obtain because people with legionellosis often have a non-productive cough and the results remain positive for weeks despite antibiotic therapy.

Treatment consists of administration of antibiotics that are known to be effective against *L. pneumophila*. Delay in instituting antibiotic therapy significantly increases mortality rates, so antibiotics known to be effective against *L. pneumophila* usually are included in the treatment regimen for severe community-acquired pneumonia.¹⁴

Primary Atypical Pneumonias

The primary atypical pneumonias are characterized by patchy involvement of the lung. They are usually preceded by pharyngitis and systemic flulike symptoms that evolve into laryngitis and finally tracheobronchitis and pneumonia. The most common pathogens are *Mycoplasma pneumoniae*, viruses, and *Chlamydia pneumoniae*.

Mycoplasma and Viral Pneumonias. The mycoplasmas are the smallest free-living agents of disease, having characteristics of viruses and bacteria. The influenza virus is the most common cause of viral pneumonia. Less common offenders are para-influenza and respiratory syncytial viruses. Other viruses sometimes are implicated, including the measles and chickenpox viruses.

The clinical course among persons with mycoplasmal and viral pneumonias varies widely from a mild infection (*e.g.*, influenza types A and B, adenovirus) that masquerades as a chest cold to a more serious and even fatal outcome (*e.g.*, chickenpox pneumonia). The symptoms may remain confined to fever, headache, and muscle aches and pains. Cough, when present, is characteristically dry, hacking, and nonproductive. Viruses impair the respiratory tract defenses and predispose to bronchopneumonia. Some viruses such as herpes simplex, varicella, and adenovirus may be associated with necrosis of the alveolar epithelium and acute inflammation.

Tuberculosis

Tuberculosis is the world's foremost cause of death from a single infectious agent, causing 25% of avoidable deaths in developing countries. With the introduction of antibiotics in the 1950s, the United States and other Western countries enjoyed a long decline in the number of infections until the mid-1980s. Since that time, the rate of infection has increased, particularly among people with the human immunodeficiency virus (HIV). In the United States, the biggest increase in new cases was from 1985 to 1993, after which the rate of cases reported yearly has again declined.¹⁶ Tuberculosis is more common among foreign-born persons from countries with a high incidence of tuberculosis and among residents of high-risk congregate settings, such as correctional facilities, drug treatment facilities, and homeless shelters. Outbreaks of a drug-resistant form of tuberculosis are being reported, complicating the selection of drugs and affecting the duration of treatment.

Tuberculosis is an infectious disease caused by the mycobacterium *M. tuberculosis*. The mycobacteria are slender, rodshaped, aerobic bacteria that do not form spores. They are similar to other bacterial organisms except for an outer waxy capsule that makes them more resistant to destruction; the organism can persist in old necrotic and calcified lesions and remain capable of reinitiating growth. The waxy coat also causes the organism to retain red dye when treated with acid in acidfast staining.¹⁷ Thus, the mycobacteria are often referred to as *acid-fast bacilli*. Although *M. tuberculosis* can infect practically any organ of the body, the lungs are most frequently involved. The tubercle bacilli are strict aerobes that thrive in an oxygenrich environment. This explains their tendency to cause disease in the upper lobe or upper parts of the lower lobe of the lung, where ventilation is greatest.

Tuberculosis is an airborne infection spread by minute, invisible particles, called *droplet nuclei*, that are harbored in the respiratory secretions of persons with active tuberculosis.^{17,18} Coughing, sneezing, and talking all create respiratory droplets; these droplets evaporate, leaving the organisms (droplet nuclei), which remain suspended in the air and are circulated by air currents. Living in crowded and confined conditions increases the risk for spread of the disease.

The tubercle bacillus incites a distinctive chronic inflammatory response referred to as *granulomatous inflammation*. The destructiveness of the disease results from the hypersensitivity response that the bacillus evokes, rather than its inherent destructive capabilities. Cell-mediated immunity and hypersensitivity reactions contribute to the evolution of the disease. Tuberculosis can manifest as a primary or reactivated infection.

Primary Tuberculosis

Primary tuberculosis occurs in a person lacking previous contact with the tubercle bacillus. It typically is initiated as a result of inhaling droplet nuclei that contain the tubercle bacillus (Fig. 20-2).¹⁸ Inhaled droplet nuclei pass down the bronchial tree without settling on the epithelium and implant in a respiratory bronchiole or alveolus beyond the mucociliary system. Soon after entering the lung, the bacilli are surrounded and engulfed by macrophages. *M. tuberculosis* has no known endotoxins or exotoxins; therefore, there is no early immunoglobulin response to infection.

KEY CONCEPTS

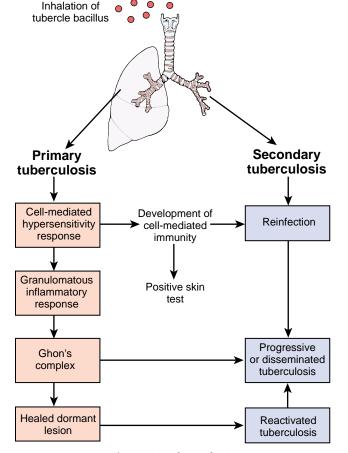

TUBERCULOSIS

- Tuberculosis is an infectious disease caused by Mycobacterium tuberculosis, a rod-shaped aerobic bacteria that is resistant to destruction and can persist in necrotic and calcified lesions for prolonged periods and remain capable of reinstating growth.
- The organism is spread by inhaling the mycobacterium-containing droplet nuclei that circulate in the air.
- The cell-mediated response plays a dominant role in walling off the tubercle bacilli and preventing the development of active tuberculosis. People with impaired cell-mediated immunity are more likely to experience active tuberculosis when infected.
- A positive tuberculin skin test results from a cellmediated immune response and implies that a person has been infected with *M. tuberculosis* and has mounted a cell-mediated immune response. It does not mean that the person has active tuberculosis.

The tubercle bacillus grows slowly, dividing every 25 to 32 hours in the macrophage.¹⁸ As the bacilli multiply, the macrophages degrade some mycobacteria and present antigen to the T lymphocytes for development of a cell-mediated immune response. The organisms grow for 2 to 12 weeks until they reach sufficient numbers to elicit a cellular immune response. In persons with intact cell-mediated immunity, this action is followed by the development of a single, gray-white, circumscribed granulomatous lesion, called a Ghon's focus, that contains the tubercle bacilli, modified macrophages, and other immune cells. Within 2 to 3 weeks, the central portion of the Ghon's focus undergoes soft, caseous (cheeselike) necrosis. This occurs at approximately the time that the tuberculin test result becomes positive, suggesting that the necrosis is caused by the cell-mediated hypersensitivity immune response (see Chapter 10). During this same period, tubercle bacilli, free or inside macrophages, drain along the lymph channels to the tracheobronchial lymph nodes of the affected lung and there evoke the formation of caseous granulomas. The combination of the primary lung lesion and lymph node granulomas is called Ghon's complex (Fig. 20-3).

The cell-mediated hypersensitivity response plays a dominant role in limiting further replication of the bacilli. The immune response also provides protection against additional tubercle bacilli that may be inhaled at a later time. People with HIV infection and others with disorders of cell-mediated immunity are more likely to acquire active tuberculosis if they become infected.

When the number of organisms inhaled is small and the body's resistance is adequate, scar tissue forms and encapsu-

■ FIGURE 20-3 ■ Primary tuberculosis. A healed Ghon's complex is represented by a subpleural nodule and involved hilar lymph nodes. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 606]. Philadelphia: Lippincott Williams & Wilkins)

lates the primary lesion. In time, most of these lesions become calcified and are visible on a chest radiograph.

Primary tuberculosis usually is asymptomatic, with the only evidence of the disease being a positive tuberculin skin test result and calcified lesions seen on the chest radiograph. Occasionally, primary tuberculosis may progress, causing more extensive destruction of lung tissue and spreading through the airways and lymphatics to multiple sites within the lung. As the disease spreads, the organism gains access to the sputum, allowing the person to infect others.

In rare instances, tuberculosis may erode into a blood vessel, giving rise to hematogenic dissemination. Miliary tuberculosis describes minute lesions, resembling millet seeds, which can involve almost any organ, resulting from this type of dissemination.

Secondary Tuberculosis

Secondary tuberculosis represents either reinfection from inhaled droplet nuclei or reactivation of a previously healed primary lesion (Fig. 20-2). It often occurs in situations of impaired body defense mechanisms. The partial immunity that follows primary tuberculosis affords protection against reinfection and to some extent aids in localizing the disease should reactivation occur. In secondary tuberculosis, the hypersensitivity reaction can be an aggravating factor, as evidenced by the frequency of cavitation and bronchial dissemination. The cavities may coalesce to a size as large as 10 to 15 cm in diameter (Fig. 20-4).6 Pleural effusion and tuberculous empyema are common as the disease progresses.

Persons with secondary tuberculosis commonly present with low-grade fevers, night sweats, easy fatigability, anorexia, and weight loss. A cough initially is dry but later becomes productive with purulent and sometimes blood-tinged sputum. Dyspnea and orthopnea develop as the disease advances.

Diagnosis and Treatment

The most frequently used screening methods for pulmonary tuberculosis are the tuberculin skin tests and chest radiographic studies. The tuberculin skin test measures delayed hypersensitivity (*i.e.*, cell-mediated, type IV) that follows exposure

FIGURE 20-4 Cavitary tuberculosis in the apex of the left upper lobe of the lung. (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 607]. Philadelphia: Lippincott Williams & Wilkins)

to the tubercle bacillus. Persons who become tuberculin positive usually remain so for the remainder of their lives. A positive reaction to the skin test does not mean that a person has active tuberculosis, only that there has been exposure to the bacillus and that cell-mediated immunity to the organism has developed. False-positive and false-negative skin test reactions can occur. False-positive reactions often result from crossreactions with nontuberculous mycobacteria, such as M. aviumintracellulare complex. Because the hypersensitivity response to the tuberculin test depends on cell-mediated immunity, a falsenegative test result can occur because of immunodeficiency states that result from HIV infection, immunosuppressive therapy, lymphoreticular malignancies, or aging. This is called anergy. In the immunocompromised person, a negative tuberculin test result can mean that the person has a true lack of exposure to tuberculosis or is unable to mount an immune response to the test. Because of the problem with anergy in persons with HIV infection and other immunocompromised states, the use of control tests is recommended. Three antigens that can be used for control testing are *Candida*, mumps virus, and tetanus toxoid. Most healthy persons in the population have been exposed to these antigens and will display a positive response to these control tests.

Diagnosis of active pulmonary tuberculosis requires identification of the organism in respiratory tract secretions. Bacteriologic studies (*i.e.*, acid-fast stain and cultures) of early-sputum specimens, gastric aspirations, or bronchial washings obtained during fiber-optic bronchoscopy may be used. Genotyping can be done to identify different strains of M. tuberculosis. It is useful in investigating outbreaks of tuberculosis, tracing the sources of infection, and determining whether new episodes of the disease are caused by reinfection or reactivation. In addition, genotyping is useful in determining sites and patterns of M. tuberculosis transmission in communities.

The primary drugs used in the treatment of tuberculosis are isoniazid (INH), rifampin, pyrazinamide, ethambutol, and streptomycin. Two groups meet the criteria established for the use of antimycobacterial therapy for tuberculosis: (1) persons with an active form of the disease and (2) those who have had contact with cases of active tuberculosis and who are at risk for development of active tuberculosis.

The tubercle bacillus is an aerobic organism that multiplies slowly and remains relatively dormant in oxygen-poor caseous material. It undergoes a high rate of mutation and tends to acquire resistance to any one drug. For this reason, multidrug regimens are used for treating persons with active tuberculosis. Tuberculosis is an unusual disease in that chemotherapy is required for a relatively long period of time. Short-course programs of therapy (usually for 6 to 12 months) have replaced the earlier 18- to 24-month multidrug regimens. Treatment may need to be prolonged in persons with HIV infection and in those with drug-resistant strains of M. tuberculosis. Drug susceptibility tests are used to guide treatment in drug-resistant forms of the disease.

Prophylactic treatment is used for persons who are infected with M. tuberculosis but do not have active disease (e.g., persons with a positive skin test or those who have had close contact with an active case of tuberculosis).¹⁹

Success of chemotherapy for prophylaxis and treatment of tuberculosis depends on strict adherence to a lengthy drug regimen. This often is a problem, particularly for asymptomatic

persons with tuberculosis infections and for poorly motivated groups, such as intravenous drug abusers. Directly observed therapy, which requires that a health care worker observe while the person takes the antituberculosis drug, is recommended for some persons and for certain types of treatment protocols.

Fungal Infections

Fungal infections are commonly classified as superificial, subcutaneous, deep-seated, and opportunistic pathogenic fungi. The superficial and subcutaneous fungi almost always limit their infections to the skin and subcutaneous tissues. Opportunistic fungi are organisms of low virulence that cause localized or systemic infections in people who are immunocompromised, such as those with AIDS (see Chapter 10). Examples of opportunistic fungi include molds (*e.g., Aspergillus* species) as well as yeast-like species (*e.g., Candida* species).

The deep-seated fungal infections are caused by highly virulent dimorphic fungi, with the ability to invade deeply into tissues and cause systemic disease. They include *Histoplasma capsulatum* (histoplasmosis), *Coccidioides immitis* (coccidioidomycosis), and *Blastomycoses capsulatum* (blastomycosis). Isolated, self-limited pulmonary involvement is commonly seen in people with normal immune function, whereas immunocompromised people often present with disseminated disease. In HIV-infected persons in endemic areas, coccidioidomycosis is now a common opportunistic infection.

Each of the dimorphic fungi has a typical geographic distribution. *H. capsulatum* is endemic along the major river valleys of the Midwest—the Ohio, the Mississippi, and the Missouri.²⁰ The organism grows in soil and other areas that have been enriched with bird excreta: old chicken houses, pigeon lofts, barns, and trees where birds roost. The infection is acquired by inhaling the fungal spores that are released when the dirt or dust from the infected areas is disturbed. C. immitis is most prevalent in the southwestern United States, principally in California, Arizona, and Texas.²¹ Because of its prevalence in the San Joaquin Valley, the disease is sometimes referred to as San Joaquin fever or valley fever. The C. immitis organism lives in soil and can establish new sites in the soil. Events such as dust storms and digging for construction have been associated with increased incidence of the disease. B. capsulatum is most commonly found in the southern and north central United States, especially in areas bordering the Mississippi and Ohio River basins and the Great Lakes.²²

The signs and symptoms of the fungal infections commonly resemble those of tuberculosis. Depending on the host's resistance and immunocompetence, the diseases usually take one of three forms: (1) an acute primary disease, (2) a chronic (cavitary) pulmonary disease, or (3) a disseminated infection. The primary pulmonary lesions consist of nodules containing aggregates of macrophages with engulfed microorganisms. Similar nodules develop in the regional lymph nodes. There is a striking similarity to the primary lesions of tuberculosis. The clinical manifestations consist of a mild, self-limited flulike syndrome.

In the vulnerable host, chronic cavitary lesions develop, with a predilection for the upper lobe, resembling the secondary form of tuberculosis. The most common manifestations are productive cough, fever, night sweats, and weight loss. Disseminated disease most often develops as an acute and fulminating infection in the very old or the very young or in persons with compromised immune function. Although the macrophages of the reticuloendothelial system can remove the fungi from the bloodstream, they are unable to destroy them. Characteristically, this form of the disease presents with a high fever, generalized lymph node enlargement, hepatosplenomegaly, muscle wasting, anemia, leukopenia, and thrombocytopenia. There may be hoarseness, ulcerations of the mouth and tongue, nausea, vomiting, diarrhea, and abdominal pain. Often, meningitis becomes a dominant feature of the disease. Persons with blastomycosis may experience cutaneous infections that induce pseudoepitheliomatous hyperplasia, which may be mistaken for squamous cell carcinoma.

Skin tests similar to the tuberculin test can be used to detect exposure to *Histoplasma* and *Coccidioides*. There is no reliable skin test for *Blastomyces*. The diagnosis of acute infection is usually made by direct visualization of the organism in tissue sections or sputum culture. Serologic tests, detecting antibodies against the specific fungi are available, but lack sensitivity and specificity.

Treatment depends on the severity of infection. Persons without associated risk factors such as HIV infection or without specific evidence of progressive disease usually can be treated without antifungal therapy. The oral or intravenous antifungal drugs are used in the treatment of persons with progressive disease.

In summary, respiratory infections are the most common cause of respiratory illness. The influenza virus causes three syndromes: an uncomplicated rhinotracheitis, a respiratory viral infection followed by a bacterial infection, and viral pneumonia.

Pneumonia describes an infection of the parenchymal tissues of the lung. Loss of the cough reflex, damage to the ciliated endothelium that lines the respiratory tract, or impaired immune defenses predispose to pneumonia. Pneumonia is being increasingly classified as community acquired or hospital acquired. Community-acquired pneumonia involves infections from organisms that are present more often in the community than in the hospital or nursing home. Hospital-acquired, or nosocomial, pneumonia is defined as a lower respiratory tract infection occurring 72 hours or more after hospital admission. Persons with compromised immune function constitute a special concern in both categories. Typical or bacterial pneumonias result from infection by bacteria such as Streptococcus pneumoniae that multiply extracellularly in the alveoli and cause inflammation and exudation of fluid into the air-filled spaces of the alveoli. Atypical pneumonias, such as those caused by Mycoplasma pneumoniae and respiratory viruses, involve the interstitium of the lung and often masquerade as chest colds.

Tuberculosis is a chronic respiratory infection caused by *M. tuberculosis*, which is spread by minute, invisible particles called *droplet nuclei*. Tuberculosis is a particular threat among persons with HIV infection, foreign-born persons from countries with a high incidence of tuberculosis, and residents of high-risk congregate settings, such as correctional facilities, drug treatment facilities, and homeless shelters. The tubercle bacillus incites a distinctive chronic inflammatory response re-

ferred to as *granulomatous inflammation*. The destructiveness of the disease results from the hypersensitivity response that the bacillus evokes, rather than its inherent destructive capabilities. Cell-mediated immunity and hypersensitivity reactions contribute to the evolution of the disease. The treatment of tuberculosis has been complicated by outbreaks of drugresistant forms of the disease.

Infections caused by the fungi *H. capsulatum* (histoplasmosis), *C. immitis* (coccidioidomycosis), and *B. dermatitidis* (blastomycosis) produce pulmonary manifestations that resemble tuberculosis. These infections are common but seldom serious unless they produce progressive destruction of lung tissue or the infection disseminates to organs and tissues outside the lungs.

CANCER OF THE LUNG

Lung cancer is the leading cause of cancer deaths among men and women in the United States, accounting for 25% of all cancer deaths. The increases in lung cancer incidence and deaths during the past 50 years have coincided closely with the increase in cigarette smoking during the same period. Industrial hazards also contribute to the incidence of lung cancer. A commonly recognized hazard is exposure to asbestos, with the mean risk of lung cancer being significantly greater in asbestos workers than in the general population. Tobacco smoke contributes heavily to the development of lung cancer in persons exposed to asbestos; the risk in this population group is estimated to be 50 to 90 times greater than that for nonsmokers.9 Because cancer of the lung usually is far advanced before it is discovered, the prognosis in general is poor. The overall 5-year survival rate is 13% to 15%, a dismal statistic that has not changed since the late 1960s.23

Bronchogenic Carcinoma

Bronchogenic carcinoma, which has its origin in the bronchial or bronchiolar epithelium, constitutes 90% to 95% of all lung cancers. Bronchogenic carcinomas are aggressive, locally invasive, and widely metastatic tumors that arise from the epithelial lining of the major bronchi. These tumors begin as small mucosal lesions that may follow one of several patterns of growth. They may form masses within the lumen of the bronchi that invade the mucosal layer and surrounding connective tissue layer, or they may form large, bulky masses that extend into the adjacent lung tissue. Some large tumors undergo central necrosis and acquire local areas of hemorrhage, and some invade the pleural cavity and chest wall and spread to adjacent intrathoracic structures.⁹

Bronchogenic carcinomas can be subdivided into four major categories: squamous cell lung carcinoma (25% to 40%), adenocarcinoma (20% to 40%), small cell carcinoma (20% to 25%), and large cell carcinoma (10% to 15%).⁹ *Squamous cell carcinoma* is found most commonly in men and is closely correlated with a smoking history. Squamous cell carcinoma tends to originate in the central bronchi as an intraluminal growth and thus is more amenable to early detection through cytologic examination of the sputum than other forms of lung cancer

■ FIGURE 20-5 ■ Squamous cell carcinoma of the lung. The tumor grows within the lumen of a bronchus and invades the adjacent intrapulmonary lymph node. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 656]. Philadelphia: Lippincott Williams & Wilkins)

(Fig. 20-5). It tends to spread centrally into major bronchi and hilar lymph nodes and disseminates outside the thorax later than other types of bronchogenic cancers.

Adenocarcinoma is the most common type of lung cancer in women and nonsmokers. Its association with cigarette smoking is weaker than for squamous cell carcinoma. Adenocarcinomas can have their origin in either the bronchiolar or alveolar tissues of the lung. These tumors tend to be located more peripherally than squamous cell sarcomas and sometimes are associated with areas of scarring (Fig. 20-6). The scars may be attributable to old infarcts, metallic foreign bodies, wounds, or

■ FIGURE 20-6 ■ Adenocarcinoma of the lung. A peripheral tumor in the upper right lobe of the lung. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 657]. Philadelphia: Lippincott Williams & Wilkins)

granulomatous infections such as tuberculosis. In general, these tumors grow more slowly than squamous cell carcinomas.

The *small cell carcinomas* are more common in men than women and are strongly associated with smoking. They are characterized by a distinctive cell type—small, dark, round-tooval shape, lymphocyte-like cells that have a scant cytoplasm and highly colored nuclei. Because of their cellular appearance, these cancers are sometimes referred to as "oat cell" tumors.⁹ The small cell carcinomas are highly malignant, tend to infiltrate widely, disseminate early in their course, and rarely are resectable. These tumors are sensitive to chemotherapy and irradiation, and newer protocols have improved the outlook somewhat.

Large cell carcinomas have large polygonal cells. They constitute a group of neoplasms that are highly anaplastic and difficult to categorize as squamous or adenocarcinoma. They are associated with a poor prognosis because of their tendency to spread to distant sites early in their course.

In general, adenocarcinoma and squamous cell carcinoma tend to remain localized longer and have a better prognosis than do other, less differentiated cancers, which usually are far advanced at the time of diagnosis. All varieties of bronchogenic carcinomas, especially small cell lung carcinoma, have the capacity to synthesize bioactive products and produce paraneoplastic syndromes, including adrenocorticotropic hormone (ACTH), antidiuretic hormone (ADH), parathyroid-like hormone, gonadotropins, and gastrin-releasing peptide.

Manifestations

Cancer of the lung develops insidiously, often giving little or no warning of its presence. Because its symptoms are similar to those associated with smoking and chronic bronchitis, they often are disregarded.

The manifestations of lung cancer can be divided into three categories: those caused by involvement of the lung and adjacent structures, the effects of local spread and metastasis, and the nonmetastatic paraneoplastic manifestations involving endocrine, neurologic, and connective tissue function. As with other cancers, lung cancer causes nonspecific symptoms such as anorexia and weight loss.

Many of the manifestations of lung cancers result from local irritation and obstruction of the airways and from invasion of the mediastinum and pleural space. The earliest symptoms usually are chronic cough, shortness of breath, and wheezing because of airway irritation and obstruction. Hemoptysis (*i.e.*, blood in the sputum) occurs when the lesion erodes blood vessels. Pain receptors in the chest are limited to the parietal pleura, mediastinum, larger blood vessels, and peribronchial afferent vagal fibers. Dull, intermittent, poorly localized retrosternal pain is common in tumors that involve the mediastinum. Pain becomes persistent, localized, and more severe when the disease invades the pleura.

Tumors that invade the mediastinum may cause hoarseness because of the involvement of the recurrent laryngeal nerve and cause difficulty in swallowing because of compression of the esophagus. An uncommon complication called the *superior vena cava syndrome* can occur in some persons with mediastinal involvement. Interruption of blood flow in this vessel usually results from compression by the tumor or involved lymph nodes. The disorder can interfere with venous drainage from the head, neck, and chest wall. The outcome is determined by the speed with which the disorder develops and the adequacy of the collateral circulation.

Tumors adjacent to the visceral pleura often insidiously produce pleural effusion. This effusion can compress the lung and cause atelectasis and dyspnea. It is less likely to cause fever, pleural friction rub, or pain than pleural effusion resulting from other causes.

Metastatic spread occurs by way of lymph channels and the vascular system. Metastases already exist in 50% of patients presenting with evidence of lung cancer and develop eventually in 90% of patients. The most common sites of these metastases are the brain, bone, and liver.

Paraneoplastic disorders are those that are unrelated to metastasis. These include hypercalcemia from secretion of parathyroid-like peptide, Cushing's syndrome from ACTH secretion, inappropriate secretion of ADH, neuromuscular syndromes (e.g., myasthenic syndromes, peripheral neuropathy, polymyositis), and hematologic disorders (e.g., migratory thrombophlebitis, nonbacterial endocarditis, disseminated intravascular coagulation). Neurologic or muscular symptoms can develop 6 months to 4 years before the lung tumor is detected. One of the more common of these problems is weakness and wasting of the proximal muscles of the pelvic and shoulder girdles, with decreased deep tendon reflexes but without sensory changes. Hypercalcemia is seen most often in persons with squamous cell carcinoma, hematologic syndromes in persons with adenocarcinomas, and the remaining syndromes in persons with small cell neoplasms.9 Manifestations of the paraneoplastic syndrome may precede the onset of other signs of lung cancer and may lead to discovery of an occult tumor.

Diagnosis and Treatment

The diagnosis of lung cancer is based on a careful history and physical examination and other tests such as chest radiography, bronchoscopy, cytologic studies (Papanicolaou's test) of the sputum or bronchial washings, percutaneous needle biopsy of lung tissue, and scalene lymph node biopsy. Computed tomography scans, magnetic resonance imaging studies, and ultrasonography are used to locate lesions and evaluate the extent of the disease. The carcinoembryonic antigen (CEA) is produced by undifferentiated lung tumor cells; high CEA titers usually correlate with extensive disease. This test often is used to follow the progress of the disease and its response to treatment.

Like other types of cancer, lung cancers are classified according to cell type (*i.e.*, squamous cell carcinoma, adenocarcinoma, and large cell carcinoma) and staged according to the TNM system. These classifications are used for treatment planning. Small cell carcinoma is not evaluated by the TNM system but staged as limited (confined to the one hemithorax and hilar, mediastinal, and supraclavicular nodes) and extensive (spread to more distant sites).^{6,9}

Treatment methods for lung cancer include surgery, radiation therapy, and chemotherapy.⁶ These treatments may be used singly or in combination. Surgery is used for the removal of small, localized tumors. It can involve a lobectomy, pneumonectomy, or segmental resection of the lung. Radiation therapy can be used as a definitive or main treatment modality, as part of a combined treatment plan, or for palliation of symptoms. Because of the frequency of metastases, chemotherapy often is used in treating lung cancer. Combination chemotherapy, which uses a regimen of several drugs, usually is used. Chemotherapy is the treatment of choice for small cell carcinoma. Advances in the use of combination chemotherapy have improved the outlook for persons with small cell carcinoma.

In summary, cancer of the lung is a leading cause of death among men and women between the ages of 50 and 75 years, and the death rate is increasing among women. In the United States, the increased death rate has coincided with an increase in cigarette smoking. Industrial hazards, such as exposure to asbestos, increase the risk for development of lung cancer. Of all forms of lung cancer, bronchogenic carcinoma is the most common, accounting for 90% to 95% of cases. Because lung cancer develops insidiously, it often is far advanced before it is diagnosed, a fact that is used to explain the poor 5-year survival rate.

The manifestations of lung cancer can be attributed to the involvement of the lung and adjacent structures, the effects of local spread and metastasis, and the nonmetastatic paraneoplastic manifestations involving endocrine, neurologic, and connective tissue function. As with other cancers, lung cancer causes nonspecific symptoms such as anorexia and weight loss. Treatment methods for lung cancer include surgery, irradiation, and chemotherapy.

RESPIRATORY DISORDERS IN INFANTS AND CHILDREN

Acute respiratory disease is the most common cause of illness in infancy and childhood, accounting for 50% of illness in children younger than 5 years.²⁴ This section focuses on respiratory disorders in the neonate and respiratory infections in children. Discussions of bronchial asthma in children and cystic fibrosis are included in Chapter 21.

Lung Development

Although other body systems are physiologically ready for extrauterine life as early as 25 weeks of gestation, the lungs require much longer. Immaturity of the respiratory system is a major cause of morbidity and mortality in infants born prematurely. Even at birth, the lungs are not fully mature, and additional growth and maturation continue well into childhood.

Lung development may be divided into five stages: the embryonic, glandular, canicular, saccular, and alveolar periods.²⁵ The first three phases are devoted to development of the conducting airways, and the last two phases are devoted to development of the gas exchange portion of the lung. By the 25th to 28th weeks of gestation, sufficient terminal air sacs are present to permit survival. It is also during this period that the type II alveolar cells, which produce surfactant, begin to function. Lung development is incomplete at birth; an infant is born with only one eighth to one sixth the adult number of alveoli. Alveoli continue to be formed during early childhood, reaching the adult number of 300 million alveoli by 5 to 6 years of age.25

Breathing in the Fetus and Neonate

Effective ventilation in infants, older children, and adults requires coordinated interaction between the muscles of the upper airways, including those of the pharynx and larynx, the diaphragm, and the intercostal muscles of the chest wall. In the infant, the diaphragm inserts more horizontally than in the adult. As a result, contraction of the diaphragm tends to draw the lower ribs inward, especially if the infant is placed in the horizontal position. The intercostal muscles, which normally lift the ribs during inspiration, are not fully developed in the infant. Instead, they function largely to stabilize the chest. Under circumstances such as crying, the intercostal muscles of the neonate function together with the diaphragm to splint the chest wall and prevent its collapse.

The chest wall of the neonate is highly compliant. A striking characteristic of neonatal breathing is the paradoxical inward movement of the upper chest during inspiration, especially during active sleep. Normally, the infant's lungs also are compliant, which is advantageous to the infant with its compliant chest cage because it takes only small changes in inspiratory pressure to inflate a compliant lung. However, with respiratory disorders that decrease lung compliance, the diaphragm must generate more negative pressure; as a result, the compliant chest wall structures are sucked inward. Retractions are abnormal inward movements of the chest wall during inspiration; they may occur intercostally (between the ribs), in the substernal or epigastric area, and in the supraclavicular spaces.

Airway Resistance. Normal lung inflation requires uninterrupted movement of air through the extrathoracic airways (i.e., nose, pharynx, larynx, and upper trachea) and intrathoracic airways (*i.e.*, bronchi and bronchioles). The neonate (0 to 4 weeks of age) breathes predominantly through the nose and does not adapt well to mouth breathing. Any obstruction of the nose or nasopharynx may increase upper airway resistance and increase the work of breathing.

The airways of the infant and small child are much smaller than those of the adult. Because the resistance to airflow is directly related to the fourth power of the radius, relatively small amounts of mucus secretion, edema, or airway constriction can produce marked changes in airway resistance and airflow. Nasal flaring is a method that infants use to take in more air. This method of breathing increases the size of the nares and decreases the resistance of the small airways.

The airways of infants and small children are also less rigid that those of older children and adults. Cartilaginous support of the extrathoracic (e.g., larynx, trachea) airways is poorly developed in infants and small children. These structures are soft and tend to collapse when the airway is obstructed and the child cries, causing the inspiratory pressures to become more negative.

Lung Volumes and Gas Exchange

In infants, the functional residual capacity (FRC), which is the air left in the lungs at the end of normal expiration, plays an important role in gas exchange (see Chapter 19). The FRC occurs at a higher lung volume in the infant than in the older child or adult.²⁶ This higher end-expiratory volume results from a more rapid respiratory rate, which leaves less time for expiration. The increased end-expiratory volume is important to the neonate because it holds the airways open throughout all phases of respiration to maintain a more uniform lung expansion and gas exchange. During sleep the tone of the upper airway muscles in the neonate is reduced, the intercostal activity that stabilizes the chest wall is less, and the time spent in expiration is increased. As a result, end-expiratory volume decreases and there is less optimal gas exchange during active sleep.²⁶

Control of Ventilation

Fetal blood oxygen (PO₂) levels normally range from 25 to 30 mm Hg, and carbon dioxide (PCO₂) levels range from 45 to 50 mm Hg, independent of any respiratory movements. Any decrease in oxygen levels induces quiet sleep in the fetus, with subsequent cessation of breathing movements, both of which lead to a decrease in oxygen consumption. Switching to oxygen derived from the aerated lung at birth causes an immediate increase in PO₂ to approximately 50 mm Hg; within a few hours, it increases to approximately 70 mm Hg.27 These levels, which greatly exceed fetal levels, cause the chemoreceptors (see Chapter 19) to become silent for several days. Although the infant's PO₂ may fluctuate during this critical time, the chemoreceptors do not respond appropriately. It is not until several days after birth that the chemoreceptors "reset" their PO₂ threshold; only then do they become the major controller of breathing. However, the response seems to be biphasic, with an initial hyperventilation followed by a decreased respiratory rate and even apnea. In neonates, particularly in preterm infants, breathing patterns and respiratory reflexes depend on the arousal state. Periodic breathing and apnea are characteristic of premature infants and reflect patterns of fetal breathing. The fact that they occur with sleep and disappear during wakefulness underscores the importance of arousal.

Alterations in Breathing Patterns. Most lung diseases in infants and small children produce a decrease in lung compliance with manifestations of restrictive lung disease or airway obstruction. Children with restrictive lung disease breathe at faster rates, and their respiratory excursions are shallow. Grunting is an audible noise that occurs as the child tries to raise the FRC and improve gas exchange by closing the glottis at the end of expiration. Airway obstruction produces turbulence. When it occurs in the extrathoracic airways (larynx and trachea) it produces an increase in inspiratory effort and a crowing sound called stridor. With intrathoracic (e.g., bronchi and bronchioles) obstruction, as in bronchiolitis and bronchial asthma, the intrapleural pressure becomes more positive during expiration because of air trapping; this causes collapse of intrathoracic airways. Expiration is prolonged, and the child uses the accessory muscles to aid in expiration. Often an audible wheezing or whistling sound is heard during expiration.

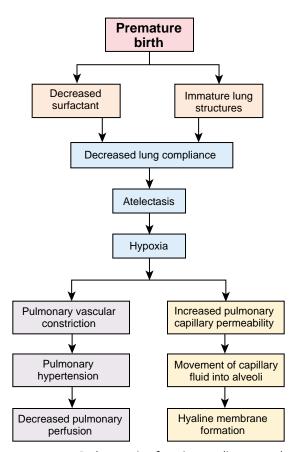

Respiratory Disorders in the Neonate

The neonatal period is one of transition from placental dependency to air breathing. This transition requires functioning of the surfactant system, conditioning of the respiratory muscles, and establishment of parallel pulmonary and systemic circulations. Respiratory disorders develop in infants who are born prematurely or who have other problems that impair this transition. Among the respiratory disorders of the neonate are the respiratory distress syndrome (RDS) and bronchopulmonary dysplasia (BPD).

Respiratory Distress Syndrome

Respiratory distress syndrome, also known as *hyaline membrane disease*, is one of the most common causes of respiratory disease in premature infants. In these infants, pulmonary immaturity, together with surfactant deficiency, leads to alveolar collapse (Fig. 20-7). The type II alveolar cells that produce surfactant do not begin to mature until approximately the 25th to 28th weeks of gestation, and consequently, many premature infants are born with poorly functioning type II alveolar cells and have difficulty producing sufficient amounts of surfactant.²⁵ The incidence of RDS is higher among preterm male infants, white infants, infants of mothers with diabetes, and those who experience asphyxia, cold stress, precipitous deliveries, and delivery by cesarean section (when performed before the 38th week of gestation).

Surfactant synthesis is influenced by several hormones, including insulin and cortisol. Insulin tends to inhibit surfactant production; this explains why infants of mothers with insulindependent diabetes are at increased risk for the development of RDS. Cortisol can accelerate maturation of type II cells and formation of surfactant. The reason premature infants born by cesarean section presumably are at greater risk for the development of RDS is because they are not subjected to the stress of vaginal delivery, which is thought to increase the infants'

■ **FIGURE 20-7** ■ Pathogenesis of respiratory distress syndrome (RSD) in the infant.

cortisol levels. These observations have led to administration of corticosteroid drugs before delivery to mothers with infants at high risk for the development of RDS.²⁷

Surfactant reduces the surface tension in the alveoli, thereby equalizing the retractive forces in the large and small alveoli and reducing the amount of pressure needed to inflate and hold the alveoli open (see Chapter 19). At birth, the first breath requires high inspiratory pressures to expand the lungs. With normal levels of surfactant, the lungs retain as much as 40% of the residual volume after the first breath, and subsequent breaths require far lower inspiratory pressures.9 With a surfactant deficiency, the lungs collapse between breaths, making the infant work as hard with each successive breath as with the first breath. The airless portions of the lungs become stiff and noncompliant. The pulmonary capillary membranes become more permeable, allowing fibrin-rich fluids to be pulled into the alveolar spaces and form a hyaline membrane. The hyaline membrane constitutes a barrier to gas exchange, leading to hypoxemia and carbon dioxide retention, a condition that further impairs surfactant production.

Infants who have RDS present with multiple signs of respiratory distress, usually within the first 24 hours of birth. Central cyanosis is a prominent sign. Breathing becomes more difficult, and retractions occur as the infant's soft chest wall is pulled in as the diaphragm descends. Grunting sounds occur during expiration. As the tidal volume drops because of airway obstruction and alveolar collapse, the respiration rate increases (usually to 60 to 120 breaths/minute) in an effort to maintain normal minute ventilation. Fatigue may develop rapidly because of the increased work of breathing. The stiff lung of infants with RDS also increases the resistance to blood flow in the pulmonary circulation, leading to the development of pulmonary hypertension and decreased pulmonary perfusion.

Infants with suspected RDS require continuous cardiorespiratory monitoring. Oxygen levels can be assessed through an arterial line (umbilical) or by a transcutaneous oxygen sensor. Treatment includes administration of supplemental oxygen, continuous positive airway pressure through nasal prongs, and often assisted mechanical ventilation. A neutral thermal environment and prevention of hypoglycemia are recommended.

Surfactant therapy is used to prevent and treat RDS. There are two types of surfactants available in the United States: surfactants prepared from animal sources and synthetic surfactants.²⁸ The surfactants are suspended in saline and administered into the airways, usually through an endotracheal tube. The treatment often is initiated soon after birth in infants who are at high risk for RDS.

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is a chronic lung disease that develops in premature infants who were treated with mechanical ventilation, mainly for RDS. The condition is considered to be present if the neonate is oxygen dependent at 36 weeks after gestation. The disorder is thought to be a response of the premature lung to early injury. High concentrations of inspired oxygen and injury from positive-pressure ventilation (*i.e.*, barotrauma) have been implicated. Newer therapies, such as administration of surfactants, high-frequency ventilation, and prenatal or postnatal administration of corticosteroids, may have altered the severity of BPD, but the condition remains a major health problem.^{29,30} BPD is characterized by chronic respiratory distress, persistent hypoxemia when breathing room air, reduced lung compliance, increased airway resistance, and severe expiratory flow limitation. There is a mismatching of ventilation and perfusion with development of hypoxemia and hypercapnia. An increase in pulmonary vascular resistance may lead to the development of pulmonary hypertension and cor pulmonale (*i.e.*, right heart failure associated with lung disease). The infant with BPD may have tachycardia, shallow breathing, chest retractions, cough, barrel chest, and poor weight gain. Clubbing of the fingers occurs in children with severe disease. In infants with right heart failure, tachycardia, tachypnea, hepatomegaly, and periorbital edema develop.

The treatment is mechanical ventilation and administration of adequate oxygenation. Weaning from ventilation is accomplished gradually, and some infants may require ventilation at home. Rapid lung growth occurs during the first year of life, and lung function usually improves. Adequate nutrition is essential for the recovery of infants with BPD.

Most adolescents and young adults who had severe BPD during infancy have some degree of pulmonary dysfunction, consisting of airway obstruction, airway hyperreactivity, or hyperinflation.

Respiratory Infections in Children

In children, respiratory tract infections are common, and although they are troublesome, they usually are not serious. Frequent infections occur because the immune system of infants and small children has not been exposed to many common pathogens; consequently, they tend to contract infections with each new exposure.

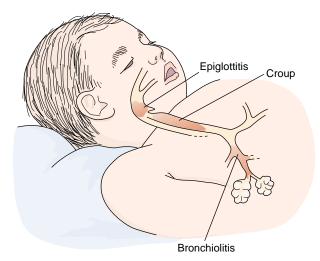

Upper Airway Infections

Acute inflammation of the upper airway is of particular importance in infants and small children because the airway is smaller, predisposing young children to a relatively greater narrowing than is produced by the same degree of inflammation in an older child. Two acute upper respiratory tract infections are relatively common during early childhood—croup and epiglottitis. Croup, the most common form of acute respiratory obstruction in children, is usually relatively benign and selflimited. Epiglottitis is a rapidly progressive and life-threatening condition. The site of involvement is illustrated in Figure 20-8.

Obstruction of the upper airways because of infection tends to exert its greatest effect during the inspiratory phase of respiration. Movement of air through an obstructed upper airway, particularly the vocal cords in the larynx, causes stridor.^{31,32} Impairment of the expiratory phase of respiration also can occur, causing wheezing. With mild to moderate obstruction, inspiratory stridor is more prominent than expiratory wheezing because the airways tend to dilate with expiration. When the swelling and obstruction become severe, the airways no longer can dilate during expiration, and both stridor and wheezing occur.

Viral Croup. Viral croup, more appropriately called *acute laryngotracheobronchitis*, is a viral infection that affects the larynx, trachea, and bronchi. It is characterized by a brassy or "croupy" cough, which may or may not be accompanied by inspiratory stridor, hoarseness, and signs of respiratory distress

372 Unit Five: Alterations in the Respiratory System

■ FIGURE 20-8 ■ Location of airway obstruction in epiglottitis, acute laryngotracheobronchitis (croup), and bronchiolitis. (Courtesy of Carole Russell Hilmer, C.M.I.)

caused by various degrees of laryngeal swelling. The parainfluenza viruses account for approximately 75% all cases; the remaining 25% are caused by adenoviruses, respiratory syncytial virus, influenza A and B viruses, and measles virus.³²

Viral croup usually is seen in children 3 months to 5 years of age. The condition may affect the entire laryngotracheal tree, but because the subglottic area is the narrowest part of the respiratory tree in this age group, the obstruction usually is greatest in this area. Although the respiratory manifestations of croup often appear suddenly, they usually are preceded by upper respiratory infections that cause rhinorrhea (*i.e.*, runny nose), coryza (*i.e.*, common cold), hoarseness, and a low-grade fever. In most children, the manifestation of croup advances only to stridor and slight dyspnea before they begin to recover.

Airway obstruction may progress in some children. As obstruction increases, the stridor becomes continuous and is associated with nasal flaring with substernal and intercostal retractions. Agitation and crying aggravate the signs and symptoms, and the child prefers to sit up or be held upright. In the cyanotic, pale, or obstructed child, any manipulation of the pharynx, including use of a tongue depressor, can cause cardiorespiratory arrest and should be done only in a medical setting that has the facilities for emergency airway management.

Viral croup does not respond to antibiotics. The child should be disturbed as little as possible and carefully monitored for signs of respiratory distress. The use of steam from a shower or bath in a closed bathroom often brings prompt and dramatic relief of symptoms. Exposure to cold air also seems to relieve airway spasm; often, the severe symptoms are relieved simply because the child is exposed to cold air on the way to the hospital emergency room. Other treatment methods may be required when a humidifier or cold mist is ineffective. Administration of a racemic mixture of epinephrine (L-epinephrine and D-epinephrine) by positive-pressure breathing through a face mask often results in transient relief of symptoms.³⁴ Inhaled or systemically administered (oral or intramuscular) corticosteroid therapy may also be used. Children with progressive stridor or signs of respiratory distress may require hospitalization. Establishment of an artificial airway may become necessary in severe airway obstruction.

Spasmodic Croup. Spasmodic croup manifests with symptoms similar to those of acute viral croup. Because the child is afebrile and lacks other manifestations of the viral prodrome, it is thought that it may have an allergic origin. Spasmodic croup characteristically occurs at night and tends to recur with respiratory tract infections. The episode usually lasts several hours and may recur several nights in a row.

Most children with spasmodic croup can be effectively treated at home. An environment of high humidification (*i.e.*, cold-water room humidifier or taking the child into a bathroom with a warm, running shower) lessens irritation and prevents drying of secretions.

Epiglottitis. Acute epiglottitis is a dramatic, potentially fatal condition most often caused by the *H. influenzae* type B bacterium. It is usually seen in children 2 to 7 years of age, with a peak incidence at approximately 3.5 years.³² Epiglottitis is seen less commonly since the widespread use of immunization against *H. influenzae* type B.

Epiglottitis is characterized by inflammatory edema of the supraglottic area, including the epiglottis and pharyngeal structures, that comes on suddenly, bringing danger of airway obstruction and asphyxia. Within a matter of hours, epiglottitis may progress to complete obstruction of the airway and death unless adequate treatment is instituted.

The child appears pale, toxic, and lethargic and assumes a distinctive position—sitting up with the mouth open and the chin thrust forward. The child has difficulty in swallowing, a muffled voice, drooling, fever, and extreme anxiety. Moderate to severe respiratory distress is evident. There is inspiratory and sometimes expiratory stridor, flaring of the nares, and inspiratory retractions of the suprasternal notch and supraclavicular and intercostal spaces. Usually, no other family members are ill with acute respiratory disease.

The child with epiglottitis requires immediate hospitalization. Establishment of an airway by endotracheal tube or tracheotomy usually is needed. If epiglottitis is suspected, the child should never be forced to lie down because this causes the epiglottis to fall backward and may lead to complete airway obstruction. Examination of the throat with a tongue blade or other instrument may cause cardiopulmonary arrest and should be done only by medical personnel experienced in intubation of small children. It also is unwise to attempt any procedure, such as drawing blood, which would heighten the child's anxiety, because this also could precipitate airway spasm and cause death. Recovery from epiglottitis usually is rapid and uneventful after an adequate airway has been established and appropriate antibiotic therapy has been initiated.

Lower Airway Infections

Lower airway infections produce air trapping with prolonged expiration. The child presents with increased expiratory effort, increased respiratory rate, and wheezing. If the infection is severe, there also are marked intercostal retractions and signs of impending respiratory failure.

Acute Bronchiolitis. Acute bronchiolitis is a viral infection of the lower airways, most commonly caused by the respiratory

syncytial virus (RSV).³³ Other viruses, such as parainfluenza 3 virus and some adenoviruses, as well as mycoplasma, also are causative. The infection produces inflammatory obstruction of the small airways and necrosis of the cells lining the lower airways. Because the resistance to airflow in a tube is related to the fourth power of the radius, even minor swelling of bronchioles in an infant can produce profound changes in airflow.

Acute bronchiolitis usually occurs during the first 2 years of life, with a peak incidence between 3 to 6 months of age. The source of infection usually is a family member with a minor respiratory illness. Older children and adults tolerate bronchiolar edema much better than do infants and do not manifest the clinical picture of bronchiolitis.

Most affected infants in whom bronchiolitis develops have a history of a mild upper respiratory tract infection. These symptoms usually last several days and may be accompanied by fever and diminished appetite. There is then a gradual development of respiratory distress, characterized by a wheezy cough, dyspnea, and irritability. The infant usually is able to take in sufficient air but has trouble exhaling it. Air becomes trapped in the lung distal to the site of obstruction and interferes with gas exchange. Hypoxemia and, in severe cases, hypercapnia may develop. Airway obstruction may produce air trapping and hyperinflation of the lungs or collapse of the alveoli.

Infants with acute bronchiolitis have a typical appearance, marked by breathlessness with rapid respirations, a distressing cough, and retractions of the lower ribs and sternum (see Table 20-2). Crying and feeding exaggerate these signs. Wheezing and rales may or may not be present, depending on the degree of airway obstruction. In infants with severe airway obstruction, wheezing decreases as the airflow diminishes.

Usually, the most critical phase of the disease is the first 48 to 72 hours. Cyanosis, pallor, listlessness, and sudden diminution or absence of breath sounds indicate impending respiratory failure. Hospitalization is often indicated during this period. Treatment is largely supportive and includes administration of humidified oxygen to relieve hypoxia. Elevation of the head facilitates respiratory movements and avoids airway compression. Handling is kept at a minimum to avoid tiring. Because the infection is viral, antibiotics are not effective and are given only for a secondary bacterial infection. Dehydration may occur as the result of increased insensible water losses because of the rapid respiratory rate and feeding difficulties, and measures to ensure adequate hydration are needed. Recovery usually begins after the first 48 to 72 hours and usually is rapid and complete.

There is a reported increase in hyperactive airways during later childhood in infants who have had bronchiolitis.³⁴ The reason this occurs is not understood, and further investigation is needed.

Signs of Impending Respiratory Failure

Respiratory problems of infants and small children often are of sudden origin, and recovery usually is rapid and complete. Infants and children are at risk for the development of airway obstruction and respiratory failure resulting from obstructive disorders or lung infection. The child with epiglottitis is at risk for respiratory failure resulting from impaired gas exchange. Children with impending respiratory failure caused by airway or lung disease have rapid breathing, exaggerated use of the accessory muscles, retractions (which are more pronounced in the child than in the adult because of more compliant chest), nasal flaring, and grunting during expiration.³⁵ The signs and symptoms of impending respiratory failure are listed in Chart 20-1.

In summary, acute respiratory disease is the most common cause of illness in infancy and childhood. Although other body systems are physiologically ready for extrauterine life as early as 25 weeks of gestation, the lungs take longer. Immaturity of the respiratory system is a major cause of morbidity and mortality in premature infants. RDS is one of the most common causes of respiratory disease in premature infants. In these infants, pulmonary immaturity, together with surfactant deficiency, leads to alveolar collapse. BPD is a chronic

TABLE 20-2 Characteristics of Epiglottitis, Croup, and Bronchiolitis in Small Children

Characteristics	Epiglottitis	Croup	Bronchiolitis			
Common causative agent	Haemophilus influenzae type B bacterium	Mainly parainfluenza virus	Respiratory syncytial virus			
Most commonly affected age group	2–7 years (peak 3–5 years)	3 months to 5 years	Less than 2 years (most severe in infants younger than 6 months)			
Onset and preceding history	Sudden onset	Usually follows symptoms of a cold	Preceded by stuffy nose and other signs			
Prominent features	Child appears very sick and toxic Sits with mouth open and chin thrust forward Low-pitched stridor, difficulty swallow- ing, fever, drooling, anxiety Danger of airway obstruction and asphyxia	Stridor and a wet, barking cough Usually occurs at night Relieved by exposure to cold or moist air	Breathlessness, rapid, shallow breathing, wheezing, cough, and retractions of lower ribs and sternum during inspiration			
Usual treatment	Hospitalization Intubation or tracheotomy Treatment with appropriate antibiotic	Mist tent or vaporizer Administration of oxygen	Supportive treatment, administra- tion of oxygen and hydration			

CHART 20-1 Signs of Respiratory Distress and Impending Respiratory Failure in the Infant and Small Child

Severe increase in respiratory effort, including severe retractions or grunting, decreased chest movement

Cyanosis that is not relieved by administration of oxygen (40%)

Heart rate of 150 per minute or greater and increasing Bradycardia

Very rapid breathing (rate 60 per minute in the newborn to 6 months or above 30 per minute in children 6 months to 2 years)

Very depressed breathing (rate 20 per minute or below)

Retractions of the supraclavicular area, sternum, epigastrium, and intercostal spaces

Extreme anxiety and agitation

Fatigue

Decreased level of consciousness

pulmonary disease that develops in premature infants who were treated with mechanical ventilation.

Because of the smallness of the airway of infants and children, respiratory tract infections in these groups often are more serious. Infections that may cause only a sore throat and hoarseness in the adult may produce serious obstruction in the child. Obstruction of the extrathoracic airways often produces turbulence of airflow and an audible inspiratory crowing sound called *stridor*, and obstruction of the intrathoracic airways produces an audible expiratory wheezing or whistling sound. Among the respiratory tract infections that produce airway obstruction in small children are croup, epiglottitis, and bronchiolitis. Epiglottitis is a life-threatening supraglottic infection that may cause airway obstruction and asphyxia. Bronchiolitis is a viral infection of the lower airways; infants and small children with bronchiolitis are at risk for respiratory failure resulting from impaired gas exchange.

Infants and children with impending respiratory failure caused by airway or lung disease have rapid and shallow breathing, exaggerated use of the accessory muscles, retractions (which are more pronounced in the child than in the adult because of more compliant chest), and grunting during expiration.

REVIEW QUESTIONS

Differentiate among community-acquired pneumonia, hospital-acquired pneumonia, and pneumonia in immunocompromised persons in terms of pathogens, manifestations, and prognosis.

Explain the rationale for using the 7-valent, rather than the 23-valent, pneumococcus vaccine for children younger than 2 years.

Explain the difference between primary tuberculosis and reactivated tuberculosis on the basis of their pathophysiology and symptoms. Describe the manifestations of lung cancer and list two symptoms of lung cancer that are related to the invasion of the mediastinum.

Define the term *paraneoplastic* and cite three paraneoplastic manifestations of lung cancer.

Characterize the 5-year survival rate for lung cancer.

Cite the function of surfactant in lung function in the neonate and relate it to the development of respiratory distress syndrome.

Cite the possible causes and manifestations of bronchopulmonary dysplasia.

Describe the physiologic basis for sternal and chest wall retractions and grunting, stridor, and wheezing as signs of respiratory distress in infants and small children.

Compare croup, epiglottitis, and bronchiolitis in terms of incidence by age, site of infection, and signs and symptoms.

List the signs of impending respiratory failure in small children.

he major function of the lungs is to oxygenate and remove carbon dioxide from the blood as a means of supporting the metabolic functions of body cells. The gas exchange function of the lungs depends on a system of open airways, expansion of the lungs, an adequate area for gas diffusion, and blood flow that carries the gases to the rest of the body. This chapter focuses on diseases that disrupt ventilation and gas exchange and on respiratory failure and hyperventilation.

DISORDERS OF LUNG INFLATION

Air entering through the airways inflates the lung, and the negative pressure in the pleural cavity keeps the lung from collapsing. Disorders of lung inflation are caused by conditions that produce lung compression or lung collapse. There can be compression of the lung by an accumulation of fluid in the intrapleural space, complete collapse of an entire lung as in pneumothorax, or collapse of a segment of the lung as in atelectasis.

Disorders of the Pleura

The pleura is a thin, double-layered membrane that encases the lungs. The two layers of the pleurae are separated by a thin layer of serous fluid (Fig. 21-1). The right and left pleural cavities are separated by the mediastinum, which contains the heart and other thoracic structures. Both the chest wall and the lungs have elastic properties. The pressure in the pleural cavity, which is negative in relation to atmospheric pressure, holds the lungs

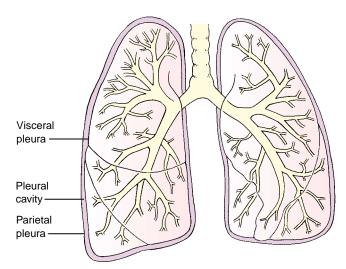

FIGURE 21-1 The parietal and visceral pleura and site of fluid accumulation in pleural effusions.

against the chest wall and keeps them from collapsing (see Chapter 19). Disorders of the pleura include pleural pain, pleural effusion, and pneumothorax.

Pleuritis and Pleural Pain

Pain is a common symptom of pleuritis, or inflammation of the pleura. Pleuritis is common in infectious processes such as viral respiratory infections or pneumonia that extend to involve the pleura. Most commonly the pain is abrupt in onset, such that the person experiencing it can cite almost to the minute when the pain started. It usually is unilateral and tends to be localized to the lower and lateral part of the chest. When the central part of the diaphragm is irritated, the pain may be referred to the shoulder. The pain is usually made worse by chest movements, such as deep breathing and coughing, that exaggerate pressure changes in the pleural cavity and increase movement of the inflamed or injured pleural surfaces. Because deep breathing is painful, tidal volumes usually are kept small, and breathing becomes more rapid. Reflex splinting of the chest muscles may occur, causing a lesser respiratory excursion on the affected side.

It is important to differentiate pleural pain from pain produced by other conditions, such as musculoskeletal strain of chest muscles, bronchial irritation, and myocardial disease. Musculoskeletal pain may occur as the result of frequent, forceful coughing. This type of pain usually is bilateral and located in the inferior portions of the rib cage, where the abdominal muscles insert into the anterior rib cage. It is made worse by movements associated with contraction of the abdominal muscles. The pain associated with irritation of the bronchi usually is substernal and dull, rather than sharp, in character. It is made worse with coughing but is not affected by deep breathing. Myocardial pain, which is discussed in Chapter 17, usually is located in the substernal area and is not affected by respiratory movements.

Pleural Effusion

Pleural effusion refers to an abnormal collection of fluid in the pleural cavity (see Fig. 21-1). The fluid may be a transudate, exudate, purulent drainage (empyema), chyle, or blood. Normally, only a thin layer (<10 to 20 mL) of serous fluid separates the visceral and parietal layers of the pleural cavity. Like fluid developing in other transcellular spaces in the body, pleural effusion occurs when the rate of fluid formation exceeds the rate of its removal (see Chapter 6). Five mechanisms have been linked to the abnormal collection of fluid in the pleural cavity: (1) increased capillary pressure, as in congestive heart failure; (2) increased capillary permeability, which occurs with inflammatory conditions; (3) decreased colloidal osmotic pressure, such as the hypoalbuminemia occurring with liver disease and nephrosis; (4) increased negative intrapleural pressure, which develops with atelectasis; and (5) impaired lymphatic drainage of the pleural space, which results from obstructive processes such as mediastinal carcinoma.

The accumulation of a serous transudate (clear fluid) in the pleural cavity often is referred to as *hydrothorax*. The condition may be unilateral or bilateral. The most common cause of hydrothorax is congestive heart failure.¹ Other causes are renal failure, nephrosis, liver failure, and malignancy. An *exudate* is a pleural fluid that has a specific gravity greater than 1.020 and, often, inflammatory cells. Conditions that produce exudative pleural effusions are infections, pulmonary infarction, malignancies, rheumatoid arthritis, and lupus erythematosus.

Empyema refers to pus in the pleural cavity. It is caused by direct infection of the pleural space from an adjacent bacterial pneumonia, rupture of a lung abscess into the pleural space, invasion from a subdiaphragmatic infection, or infection associated with trauma.

Chylothorax is the effusion of lymph in the thoracic cavity.² Chyle, a milky fluid containing chylomicrons, is found in the lymph fluid originating in the gastrointestinal tract. The thoracic duct transports chyle to the central circulation. Chylothorax also results from trauma, inflammation, or malignant infiltration obstructing chyle transport from the thoracic duct into the central circulation. It also can occur as a complication of intrathoracic surgical procedures and use of the great veins for total parenteral nutrition and hemodynamic monitoring.

Hemothorax is the presence of blood in the pleural cavity. Bleeding may arise from chest injury, a complication of chest surgery, malignancies, or rupture of a great vessel such as an aortic aneurysm. It is usually diagnosed by the presence of blood in the pleural fluid. Hemorrhagic pleural fluid is a mixture of blood and pleural fluid. Hemothorax usually requires drainage, and if the bleeding continues, surgery to control the bleeding may be required.

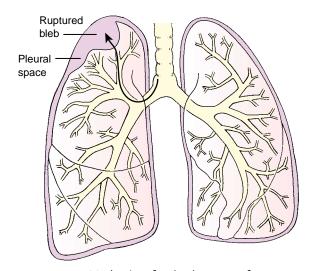

The manifestations of pleural effusion vary with the cause. Hemothorax may be accompanied by signs of blood loss and empyema by fever and other signs of inflammation. Fluid in the pleural cavity acts as a space-occupying mass; it causes a decrease in lung expansion on the affected side that is proportional to the amount of fluid that is present. The effusion may cause a shift in the mediastinal structures toward the opposite side of the chest with a decrease in lung volume on that side as well as the side with the pneumothorax. Characteristic signs of pleural effusion are dullness or flatness to percussion and diminished breath sounds. Dyspnea, the most common symptom, occurs when fluid compresses the lung, resulting in decreased ventilation. Pleuritic pain usually occurs only when inflammation is present, although constant discomfort may be felt with large effusions. Mild hypoxemia may occur and usually is corrected with supplemental oxygen.

Diagnosis of pleural effusion is based on chest radiographs, chest ultrasound, and computed tomography (CT). Thoracentesis is the aspiration of fluid from the pleural space. It can be used to obtain a sample of pleural fluid for diagnosis, or it can be used for therapeutic purposes. The treatment of pleural effusion is directed at the cause of the disorder. With large effusions, thoracentesis may be used to remove fluid from the intrapleural space and allow for re-expansion of the lung. A palliative method used for treatment of pleural effusions caused by a malignancy is the injection of a sclerosing agent into the pleural cavity. This method of treatment causes obliteration of the pleural space and prevents the reaccumulation of fluid. Open surgical drainage may be necessary in cases of continued effusion.

Pneumothorax

Normally, the pleural cavity is free of air and contains only a thin layer of fluid. When air enters the pleural cavity, it is called *pneumothorax*. Pneumothorax causes partial or complete collapse of the affected lung. Pneumothorax can occur without an obvious cause or injury (*i.e.*, spontaneous pneumothorax) or as a result of direct injury to the chest or major airways (*i.e.*, traumatic pneumothorax). Tension pneumothorax describes a life-threatening condition of excessive pressure in the pleural cavity.

Spontaneous Pneumothorax. Spontaneous pneumothorax occurs when an air-filled bleb, or blister, on the lung surface ruptures. Rupture of these blebs allows atmospheric air from the airways to enter the pleural cavity (Fig. 21-2). Because alveolar pressure normally is greater than pleural pressure, air flows from the alveoli into the pleural space, causing the involved portion of the lung to collapse as a result of its own recoil. Air continues to flow into the pleural space until a pressure gradient no longer exists or until the decline in lung size causes the leak to seal. Spontaneous pneumothoraces.³ Primary sponta-

■ FIGURE 21-2 ■ Mechanism for development of spontaneous pneumothorax.

neous pneumothorax occurs in otherwise healthy persons. Secondary spontaneous pneumothorax occurs in persons with underlying lung disease.

In primary spontaneous pneumothorax, the air-filled bleb that ruptures is usually on the top of the lung. The condition is seen most often in tall boys and young men between 10 and 30 years of age.³ It has been suggested that the difference in pleural pressure from the top to the bottom of the lung is greater in tall persons and that this difference in pressure may contribute to the development of blebs. Another factor that has been associated with primary spontaneous pneumothorax is smoking. Disease of the small airways related to smoking probably contributes to the condition.

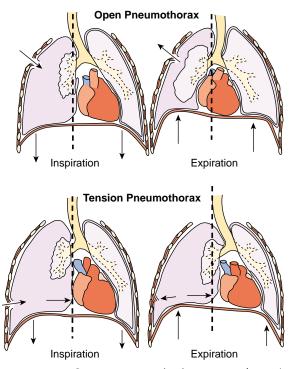

Secondary spontaneous pneumothoraces usually are more serious because they occur in persons with lung disease. They are associated with many different types of lung conditions that cause trapping of gases and destruction of lung tissue, including asthma, tuberculosis, cystic fibrosis, sarcoidosis, bronchogenic carcinoma, and metastatic pleural diseases. The most common cause of secondary spontaneous pneumothorax is emphysema.

Traumatic Pneumothorax. Traumatic pneumothorax may be caused by penetrating or nonpenetrating chest injuries. Fractured or dislocated ribs that penetrate the pleura are the most common cause of pneumothorax from nonpenetrating chest injuries. Hemothorax often accompanies these injuries. Pneumothorax also may accompany fracture of the trachea or major bronchus or rupture of the esophagus. Persons with pneumothorax caused by chest trauma frequently have other complications and may require chest surgery. Medical procedures such as transthoracic needle aspirations, intubation, and positive-pressure ventilation occasionally may cause pneumothorax. Traumatic pneumothorax also can occur as a complication of cardiopulmonary resuscitation.

Tension Pneumothorax. Tension pneumothorax occurs when the intrapleural pressure exceeds atmospheric pressure. It is a life-threatening condition and occurs when injury to the chest or respiratory structures permits air to enter but not leave the pleural space (Fig. 21-3). This results in a rapid increase in pressure in the chest with a compression atelectasis of the unaffected lung, a shift in the mediastinum to the opposite side of the chest, and compression of the vena cava with impairment of venous return to the heart.⁴ Although tension pneumothorax can develop in persons with spontaneous pneumothoraces, it is seen most often in persons with traumatic pneumothoraces.

With tension pneumothorax, the structures in the mediastinal space shift toward the opposite side of the chest (see Fig. 21-3). When this occurs, the position of the trachea, normally located in the midline of the neck, deviates with the mediastinum. There may be distention of the neck veins and subcutaneous emphysema (*i.e.*, air bubbles in the subcutaneous tissues of the chest and neck) and clinical signs of shock.

Clinical Features. The manifestations of pneumothorax depend on its size and the integrity of the underlying lung. In spontaneous pneumothorax, manifestations of the disorder include development of ipsilateral (same side) chest pain in an otherwise healthy person. There is an almost immediate in-

■ FIGURE 21-3 ■ Open or communicating pneumothorax (top) and tension pneumothorax (bottom). In an open pneumothorax, air enters the chest during inspiration and exits during expiration. There may be slight inflation of the affected lung due to a decrease in pressure as air moves out of the chest. In tension pneumothorax, air can enter but not leave the chest. As the pressure in the chest increases, the heart and great vessels are compressed and the mediastinal structures are shifted toward the opposite side of the chest. The trachea is pushed from its normal midline position toward the opposite side of the chest, and the unaffected lung is compressed.

crease in respiratory rate, often accompanied by dyspnea that occurs as a result of the activation of receptors that monitor lung volume. Heart rate is increased. Asymmetry of chest movement may occur because of the air trapped in the pleural cavity on the affected side. Percussion of the chest produces a more hyperresonant sound, and breath sounds are decreased or absent over the area of the pneumothorax.

Hypoxemia usually develops immediately after a large pneumothorax, followed by vasoconstriction of the blood vessels in the affected lung, causing the blood flow to shift to the unaffected lung. In persons with primary spontaneous pneumothorax, this mechanism usually returns oxygen saturation to normal within 24 hours. Hypoxemia usually is more serious in persons with underlying lung disease in whom secondary spontaneous pneumothorax develops. In these persons, the hypoxemia caused by the partial or total loss of lung function can be life threatening.

Diagnosis of pneumothorax can be confirmed by chest radiograph or CT scan. Blood gas analysis may be done to determine the effect of the condition on blood oxygen levels. Treatment varies with the cause and extent of the disorder. Even without treatment, air in the pleural space usually reabsorbs after the pleural leak seals. In small spontaneous pneumothoraces, the air usually reabsorbs, and observation and follow-up chest radiographs are all that is required. Supplemental oxygen may be used to increase the rate at which the air is reabsorbed. In larger pneumothoraces, the air is removed by needle aspiration or a closed drainage system used with or without an aspiration pump. This type of drainage system uses a one-way valve or a tube submerged in water to allow air to exit the pleural space and prevent it from re-entering the chest. In secondary pneumothorax, surgical closure of the chest wall defect, ruptured airway, or perforated esophagus may be required.

Emergency treatment of tension pneumothorax involves the prompt insertion of a large-bore needle or chest tube into the affected side of the chest along with one-way valve drainage or continuous chest suction to aid in lung expansion. Sucking chest wounds, which allow air to pass in and out of the chest cavity, should be treated by promptly covering the area with an airtight covering. Chest tubes are inserted as soon as possible.

Atelectasis

Atelectasis refers to the incomplete expansion of a lung or portion of a lung. It can be caused by airway obstruction, lung compression such as occurs in pneumothorax or pleural effusion, or the increased recoil of the lung caused by inadequate pulmonary surfactant (see Chapter 19).

Atelectasis is caused most commonly by airway obstruction (Fig. 21-4). Obstruction can be caused by a mucus plug in the airway or by external compression by fluid, tumor mass, exudate, or other matter in the area surrounding the airway. A small segment of lung or an entire lung lobe may be involved in obstructive atelectasis. Complete obstruction of an airway is followed by the absorption of air from the dependent alveoli and collapse of that portion of the lung. The danger of obstructive atelectasis increases after surgery. Anesthesia, pain, administration of narcotics, and immobility tend to promote retention of viscid bronchial secretions and thus airway obstruction.

Another cause of atelectasis is compression of lung tissue. It occurs when the pleural cavity is partially or completely filled with fluid, exudate, blood, a tumor mass, or air. It is observed most commonly in persons with pleural effusion from

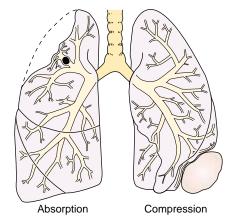

FIGURE 21-4 Atelectasis caused by airway obstruction and absorption of air from the involved lung area on the *left* and by compression of lung tissue on the right.

congestive heart failure or cancer. In compression atelectasis, the mediastinum shifts away from the affected lung.

The clinical manifestations of atelectasis include tachypnea, tachycardia, dyspnea, cyanosis, signs of hypoxemia, diminished chest expansion, absence of breath sounds, and intercostal retractions. Fever and other signs of infection may develop. Both chest expansion and breath sounds are decreased on the affected side. There may be intercostal retraction (pulling in of the intercostal spaces) over the involved area during inspiration. If the collapsed area is large, the mediastinum and trachea shift to the affected side. Signs of respiratory distress are proportional to the extent of lung collapse.

The diagnosis of atelectasis is based on signs and symptoms. Chest radiographs are used to confirm the diagnosis. CT scans may be used to show the exact location of the obstruction. Treatment depends on the cause and extent of lung involvement. It is directed at reducing the airway obstruction or lung compression and at reinflating the collapsed area of the lung. Ambulation and body positions that favor increased lung expansion are used when appropriate. Administration of oxygen may be needed to treat the hypoxemia. Bronchoscopy may be used as a diagnostic and treatment method.

In summary, lung inflation depends on a negative intrapleural pressure and unobstructed intrapulmonary airways. Disorders of the pleura include pleuritis and pain, pleural effusion, and pneumothorax. Pain is commonly associated with conditions that produce inflammation of the pleura. Characteristically, it is unilateral, abrupt in onset, and exaggerated by respiratory movements. Pleural effusion refers to the abnormal accumulation of fluid in the pleural cavity. The fluid may be a transudate (i.e., hydrothorax), exudate (*i.e.*, empyema), blood (*i.e.*, hemothorax), or chyle (i.e., chylothorax). Pneumothorax refers to an accumulation of air in the pleural cavity with the partial or complete collapse of the lung. It can result from rupture of an air-filled bleb on the lung surface or from penetrating or nonpenetrating injuries. A tension pneumothorax is a life-threatening event in which air progressively accumulates in the thorax, collapsing the lung on the injured side and progressively shifting the mediastinum to the opposite side of the thorax, producing severe cardiorespiratory impairment.

Atelectasis refers to an incomplete expansion of the lung. In adults, atelectasis usually results from airway obstruction caused by mucus plug or because of external compression by fluid, tumor mass, exudate, or other matter in the area surrounding the airway.

OBSTRUCTIVE AIRWAY DISORDERS

Obstructive airway diseases are caused by disorders that limit expiratory airflow. Bronchial asthma represents a reversible form of airway disease caused by narrowing of airways due to bronchospasm, inflammation, and increased airway secretions. Chronic obstructive airway disease can be caused by a variety of airway diseases, including chronic bronchitis, emphysema, bronchiectasis, and cystic fibrosis.

Physiology of Airway Disease

Air moves through the upper airways (*i.e.*, trachea and major bronchi) into the lower or pulmonary airways (*i.e.*, bronchi and alveoli), which are located in the lung. In the pulmonary airways, the cartilaginous layer that provides support for the trachea and major bronchi gradually disappears and is replaced with crisscrossing strips of smooth muscle (see Chapter 19). The contraction and relaxation of the smooth muscle layer, which is innervated by the autonomic nervous system (ANS), controls the diameter of the airways and consequent resistance to airflow. Parasympathetic stimulation, through the vagus nerve and cholinergic receptors, produces bronchoconstriction, and sympathetic stimulation, through β_2 -adrenergic receptors, increases bronchodilation. Normally, a slight vagal-mediated bronchoconstrictor tone predominates. When there is need for increased airflow, as during exercise, the vagal-mediated bronchoconstrictor tone is inhibited, and the bronchodilator effects of the sympathetic nervous system are increased.

Bronchial smooth muscle also responds to inflammatory mediators, such as histamine, that act directly on smooth muscle cells to produce bronchoconstriction. During an antigenantibody response, inflammatory mediators are released by a special type of cell, called the *mast cell*, which is present in the airways. The binding of immunoglobulin E (IgE) antibodies to receptors on mast cells prepares them for an allergic response when antigen appears (see Chapter 10).

Bronchial Asthma

Bronchial asthma is a chronic inflammatory airway disease. According to 1998 data, an estimated 26 million Americans have received diagnoses of asthma, and 10.6 million have had

KEY CONCEPTS

- Airway disorders involve the movement of gases into and out of the lung. They involve bronchial smooth muscle tone, mucosal injury, and obstruction due to secretions.
- The tone of the bronchial smooth muscles surrounding the airways determines airway radius, and the presence or absence of airway secretions influences airway patency.
- Bronchial smooth muscle is innervated by the autonomic nervous system—the parasympathetic nervous system, via the vagus nerve, produces bronchoconstriction and the sympathetic nervous system produces bronchodilation.
- Inflammatory mediators that are released in response to environmental irritants, immune responses, and infectious agents increase airway responsiveness by producing bronchospasm, increasing mucus secretion, and producing injury to the mucosal lining of the airways.

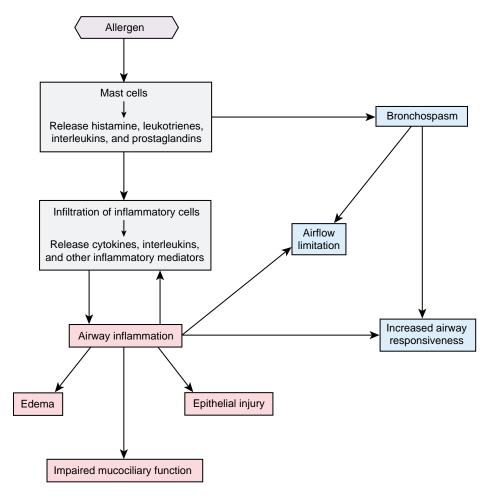

an asthma episode during the past 12 months.⁵ Of the 26 million Americans with diagnoses of asthma, 8.6 million are younger than 18 years. In the general population, asthma prevalence rates increased 102% between 1980 and 1994.⁵ There also has been a reported increase in incidence and mortality associated with asthma during the past several decades.

The National Heart, Lung, and Blood Institute's Second Expert Panel on the Management of Asthma defined bronchial asthma as "a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role, in particular, mast cells, eosinophils, T lymphocytes, and epithelial cells."⁶ This inflammatory process produces recurrent episodes of airway obstruction, characterized by wheezing, breathlessness, chest tightness, and a cough that often is worse at night and in the early morning. These episodes, which usually are reversible either spontaneously or with treatment, also cause an associated increase in bronchial responsiveness to a variety of stimuli.⁶

Pathogenesis

In susceptible persons, an asthma attack can be triggered by a variety of stimuli that do not normally cause symptoms. Based on their mechanism of response, these triggers can be divided into two categories—bronchospastic or inflammatory. Bronchospastic triggers depend on the existing level of airway responsiveness. They do not normally increase airway responsiveness but produce symptoms in persons who already are predisposed to bronchospasm. Bronchospastic triggers include cold air, exercise, emotional upset, and exposure to bronchial irritants such as cigarette smoke. Inflammatory triggers exert their effects through the inflammatory response. They cause inflammation and prime the sensitive airways so they are hyperresponsive to nonallergic stimuli. The mechanisms whereby these two types of triggers produce an asthmatic attack can be further described as the early or acute response versus the late phase response.⁷ The acute or early response results in immediate bronchoconstriction on exposure to an inhaled antigen or irritant (Fig. 21-5). The symptoms of the acute response, which usually develop within 10 to 20 minutes, are caused by the release of chemical mediators from IgE-sensitized mast cells. In the case of airborne antigens, the reaction occurs when antigen binds to sensitized mast cells on the mucosal surface of the airways. Mediator release results in the infiltration of inflammatory cells and opening of the mucosal intercellular junctions and enhancement of antigen movement to the more prevalent submucosal mast cells (Fig. 21-5). In addition, there is bronchoconstriction caused by direct stimulation of parasympathetic receptors, mucosal edema caused by increased vascular permeability, and increased mucus secretions.

The *late phase response* develops 4 to 8 hours after exposure to an asthmatic trigger.^{7,8} The late phase response involves inflammation and increased airway responsiveness that prolong

the asthma attack and set into motion a vicious cycle of exacerbations. Typically, the response reaches a maximum within a few hours and may last for days or even weeks. An initial trigger in the late phase response causes the release of inflammatory mediators from mast cells, macrophages, and epithelial cells. These substances induce the migration and activation of other inflammatory cells (*e.g.*, basophils, eosinophils, neutrophils), which then produce epithelial injury and edema, changes in mucociliary function and reduced clearance of respiratory tract secretions, and increased airway responsiveness (see Fig. 21-6). Responsiveness to cholinergic mediators often is heightened, suggesting changes in parasympathetic control of airway function. Chronic inflammation can lead to airway remodeling, with more permanent changes in airway resistance.⁶

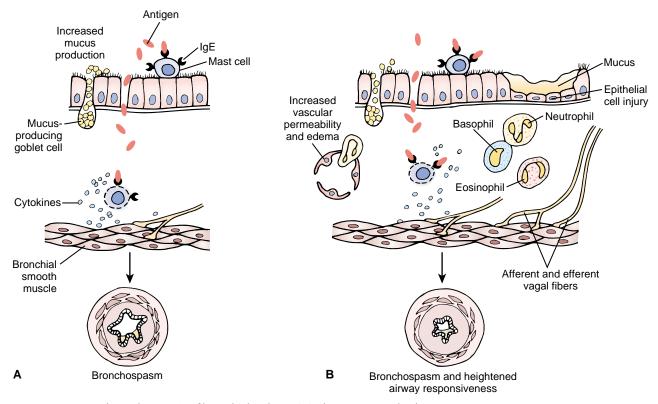

Causes. A number of factors can contribute to an asthmatic attack, including allergens, respiratory tract infections, hyperventilation, cold air, exercise, drugs and chemicals, hormonal changes and emotional upsets, airborne pollutants, and gastroesophageal reflux.

Inhalation of allergens is a common cause of asthma. Usually, this type of asthma has its onset in childhood or adolescence and is seen in persons with a family history of atopic allergy (see Chapter 10). Persons with allergic asthma often have other allergic disorders, such as hay fever, hives, and eczema. Attacks are related to exposure to specific allergens. Among airborne allergens implicated in perennial (year-around) asthma are house dust mite allergens, cockroach allergens, animal danders, and the fungus *Alternaria*.

Respiratory tract infections, especially those caused by viruses, may produce their effects by causing epithelial damage and stimulating the production of IgE antibodies directed toward the viral antigens. In addition to precipitating an asthmatic attack, viral respiratory infections increase airway responsiveness to other asthma triggers that may persist for weeks beyond the original infection.

Exercise-induced asthma occurs in 40% to 90% of persons with bronchial asthma.⁹ The cause of exercise-induced asthma is unclear. It has been suggested that during exercise, bronchospasm may be caused by the loss of heat and water from the tracheobronchial tree because of the need for conditioning (*i.e.*, warming and humidification) of large volumes of air. The response is commonly exaggerated when the person exercises in a cold environment.

Inhaled irritants, such as tobacco smoke and strong odors, are thought to induce bronchospasm by way of irritant receptors and a vagal reflex. Exposure to parental smoking has been reported to increase asthma severity in children.¹⁰ High doses of irritant gases such as sulfur dioxide, nitrogen dioxide, and ozone may induce inflammatory exacerbations of airway responsive-

■ FIGURE 21-6 ■ The pathogenesis of bronchial asthma. (A) The acute or early phase response. On exposure to an antigen, the immediate reaction is triggered by an IgE-mediated release of chemical mediators from sensitized mast cells. The release of chemical mediators results in increased mucus secretion, opening of mucosal intercellular junctions with increased antigen exposure of submucosal mast cells, and bronchoconstriction. Inhaled antigen produces release of chemical mediators from sensitized mast cells. (B) The late phase response involves release of inflammatory mediators from mast cells, macrophages, basophils, neutrophils, and eosinophils; epithelial cell injury and edema, decreased mucociliary function, and accumulation of mucus; and increased airway responsiveness.

ness (*e.g.*, smog-related asthma). Occupational asthma is stimulated by fumes and gases (*e.g.*, epoxy resins, plastics, toluene), organic and chemical dusts (*i.e.*, wood, cotton, platinum), and other chemicals (*e.g.*, formaldehyde) in the workplace.¹¹

There is a small group of persons with asthma in whom aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with asthmatic attacks, the presence of nasal polyps, and recurrent episodes of rhinitis.¹² An addition to the list of chemicals that can provoke an asthmatic attack are the sulfites used in food processing and as a preservative added to beer, wine, and fresh vegetables.

Both emotional factors and changes in hormone levels are thought to contribute to an increase in asthma symptoms. Emotional factors produce bronchospasm by way of vagal pathways. They can act as a bronchospastic trigger, or they can increase airway responsiveness to other triggers through noninflammatory mechanisms. The role of sex hormones in asthma is unclear, although there is much circumstantial evidence to suggest they may be important. As many as 40% of women with asthma report a premenstrual increase in asthma symptoms.¹³ Female sex hormones have a regulatory role on β_2 -adrenergic function, and it has been suggested that abnormal regulation may be a possible mechanism for premenstrual asthma.¹³

Symptoms of gastroesophageal reflux are common in both adults and children with asthma, suggesting that reflux of gastric secretions may act as a bronchospastic trigger. Reflux during sleep can contribute to nocturnal asthma.⁶

Clinical Features

Persons with asthma exhibit a wide range of signs and symptoms, from episodic wheezing and feelings of chest tightness to an acute, immobilizing attack. The attacks differ from person to person, and between attacks, many persons are symptom free. Attacks may occur spontaneously or in response to various triggers, respiratory infections, emotional stress, or weather changes. Asthma is often worse at night. Nocturnal asthma attacks usually occur at approximately 4 AM because of the occurrence of the late response to allergens inhaled during the evening and because of circadian variations in bronchial reactivity.¹⁴

During an asthmatic attack, the airways narrow because of bronchospasm, edema of the bronchial mucosa, and mucus plugging. Expiration becomes prolonged because of progressive airway obstruction. The amount of air that can be forcibly expired in 1 second (forced expiratory volume $[FEV_{1,0}]$) and the peak expiratory flow rate (PEF), measured in liters per second, are decreased (see Chapter 19). A fall in the PEF to levels below 50% of the predicted value during an acute asthmatic attack indicates a severe exacerbation and the need for emergency room treatment.6 With a prolonged attack, air becomes trapped behind the occluded and narrowed airways, causing hyperinflation of the lungs and an increase in the residual volume (RV). As a result, more energy is needed to overcome the tension already present in the lungs, and the accessory muscles (i.e., sternocleidomastoid muscles) are used to maintain ventilation and gas exchange. This causes dyspnea and fatigue. Because air is trapped in the alveoli and inspiration is occurring at higher residual lung volumes, the cough becomes less effective. As the condition progresses, the effectiveness of alveolar ventilation declines, and mismatching of ventilation and perfusion occurs, causing hypoxemia and hypercapnia. Pulmonary vascular resistance may increase as a result of the hypoxemia and hyperinflation, leading to a rise in pulmonary artery pressure and increased work demands on the right heart.

The physical signs of bronchial asthma vary with the severity of the attack. A mild attack may produce a feeling of chest tightness, a slight increase in respiratory rate with prolonged expiration, and mild wheezing. A cough may accompany the wheezing. More severe attacks are associated with use of the accessory muscles, distant breath sounds caused by air trapping, and loud wheezing. As the condition progresses, fatigue develops, the skin becomes moist, and anxiety and apprehension are obvious. Dyspnea may be severe, and often the person is able to speak only one or two words before taking a breath. At the point at which airflow is markedly decreased, breath sounds become inaudible with diminished wheezing, and the cough becomes ineffective despite being repetitive and hacking. This point often marks the onset of respiratory failure.

With increased air trapping, a greater negative intrapleural pressure is needed to inflate the lungs. This increased negative pressure, which is transmitted to the heart and blood vessels, causes the systolic blood pressure to fall during inspiration, a condition called *pulsus paradoxus*. It can be detected by using a blood pressure cuff and a mercury manometer (see Chapter 17).

Diagnosis and Management. The diagnosis of asthma is based on a careful history and physical examination, laboratory findings, and pulmonary function studies. Spirometry provides a means for measuring the PEF, FEV_{1.0}, forced vital capacity (FVC), and other indices of lung function (see Chapter 19). The level of airway responsiveness can be measured by inhalation challenge tests using methacholine (a cholinergic agonist), histamine, or exposure to a nonpharmacologic agent such as cold air. The Expert Panel of the National Education and Prevention Program of the National Heart, Lung, and Blood Institute has developed an asthma severity classification system intended for use in directing asthma treatment and identifying persons at high risk for the development of life-threatening asthma attacks⁶ (Table 21-1).

Small, inexpensive, portable meters that measure PEF are available. Although not intended for use in diagnosis of asthma, they can be used in clinics and physicians' offices and in the home to provide frequent measures of flow rates. Day-night (circadian) variations in asthma symptoms and PEF variability can be used to indicate the severity of bronchial hyperreactivity. A *person's best performance* (personal best) is established from readings taken throughout several weeks and is used as a reference to indicate changes in respiratory function.⁶

The treatment of bronchial asthma focuses on control of factors contributing to asthma severity and pharmacologic treatment.⁶ Measures to control factors contributing to asthma severity are aimed at prevention of exposure to irritants and factors that increase asthma symptoms and precipitate asthma exacerbations.

Pharmacologic treatment is used to prevent or treat reversible airway obstruction and airway hyperreactivity caused by the inflammatory process. The medications used in the treatment of asthma include those with bronchodilator and anti-inflammatory actions. The bronchodilators include the β_2 -adrenergic agonists and ipratroprium. The β_2 -adrenergic agonists, which are usually administered by inhalation methods,

TABLE 21-1	Classification of Asthma Severity		
	Symptoms	Nighttime Symptoms	Lung Function
Mild intermittent	Symptoms ≤2 times a week Asymptomatic and normal PEF between exacerbations Exacerbations brief (from a few hours to a few days); intensity may vary	≤2 times a month	FEV _{1.0} or PEF ≥80% predicted PEF variability <20%
Mild persistent	Symptoms >2 times a week but <1 time a day Exacerbations may affect activity	>2 times a month	FEV _{1.0} or PEF ≥80% predicted PEF variability 20%–30%
Moderate persister	It Daily symptoms Daily use of inhaled short-acting β_2 -agonist Exacerbations affect activity Exacerbations ≥ 2 times a week; may last days	>1 time a week	FEV _{1.0} or PEF >60%—<80% predicted PEF variability >30%
Severe persistent	Continual symptoms Limited physical activity Frequent exacerbations	Frequent	FEV _{1.0} or PEF ≤60% predicted PEF variability >30%

FEV_{1.0}, forced expiratory volume in 1 second; PEF, peak expiratory flow rate. (Adapted from National Education and Prevention Program. [1997]. Expert Panel report 2: Guidelines for the diagnosis and management of asthma. National Institutes of Health publication no. 97-4051. Bethesda, MD: National Institutes of Health.)

relax bronchial smooth muscle. Ipratropium is an inhaled anticholinergic drug that blocks the postganglionic efferent vagal pathways that cause bronchoconstriction. The antiinflammatory drugs include the corticosteroids, mast cell stabilizers, and leukotriene modifiers. The corticosteroids, which are often administered by inhalation methods, are considered the most effective anti-inflammatory agents for use in the long-term treatment of asthma. The anti-inflammatory agents sodium cromolyn and nedocromil are used to prevent an asthmatic attack. These agents, which are used prophylactically, act by stabilizing mast cells, thereby preventing release of the inflammatory mediators that cause an asthmatic attack. A newer group of drugs called the leukotriene modifiers are available for use in the treatment of asthma. The leukotrienes are potent biochemical mediators released from mast cells that cause bronchoconstriction, increased mucus secretion, and attraction and activation of inflammatory cells in the airways of people with asthma.

Status Asthmaticus and Fatal Asthma

Status asthmaticus is severe, prolonged asthma that is refractory to conventional methods of therapy. Most asthma deaths have occurred outside the hospital. Persons at highest risk are those with previous exacerbations resulting in respiratory failure, respiratory acidosis, and the need for intubation. Risk factors for fatal asthma are described in Chart 21-1.6 Although the cause of death during an acute asthmatic attack is largely unknown, both cardiac dysrhythmias and asphyxia caused by severe airway obstruction have been implicated. It has been suggested that an underestimation of the severity of the attack may be a contributing factor. Deterioration often occurs rapidly during an acute attack, and underestimation of its severity may lead to a life-threatening delay in seeking medical attention. Frequent and repetitive use of β_2 -agonist inhalers (more than twice in a month) far in excess of the recommended doses may temporarily blunt symptoms and mask the severity of the condition. Lack of access to medical care is another risk factor associated with asthma-related death. Distance, as in rural areas, or lack of financial resources, as in the uninsured or underinsured, may limit access to emergency care.

Bronchial Asthma in Children

Asthma is a leading cause of chronic illness in children and is responsible for a significant number of lost school days. It is the most frequently occurring admitting diagnosis in children's hospitals. As many as 10% to 15% of boys and 7% to 10% of girls have asthma at some time during childhood.¹⁵ Asthma

Risk Factors for Death CHART 21-1 From Asthma

- Past history of sudden severe exacerbations
- Prior intubation for asthma
- Two or more hospitalizations for asthma in the past year
- Three or more emergency care visits for asthma in the past year
- Hospitalization or an emergency care visit for asthma within the past month
- Use of more than two canisters per month of inhaled short-acting β₂-agonist
- Current use of systemic corticosteroids or recent withdrawal from systemic corticosteroids
- Difficulty perceiving airflow obstruction or its severity
- Comorbidity, as from cardiovascular diseases or chronic obstructive pulmonary disease
- Serious psychiatric disease or psychosocial problems
- Low socioeconomic status and urban residence
- Illicit drug use
- Sensitivity to Alternaria

(From National Education and Prevention Program. [1997]. Expert Panel report 2: Guidelines for the diagnosis and management of asthma. National Institutes of Health publication no. 97-4051. Bethesda, MD: National Institutes of Health.)

may have its onset at any age; 30% of children are symptomatic by 1 year of age, and 80% to 90% are symptomatic by 4 to 5 years of age.¹⁵

As with adults, asthma in children commonly is associated with an IgE-related reaction. It has been suggested that IgE directed against respiratory viruses in particular may be important in the pathogenesis of the wheezing illnesses in infants (*i.e.*, bronchiolitis), which often precede the onset of asthma. The respiratory syncytial virus and parainfluenza viruses are the most commonly involved.¹⁵ Other contributing factors include exposure to environmental allergens such as pet danders, dust mite antigens, and cockroach allergens. Exposure to environmental tobacco smoke also may contribute to asthma in children. Of particular concern is the effect of in utero exposure to maternal smoking on lung function in infants and children.¹⁶

The signs and symptoms of asthma in infants and small children vary with the stage and severity of an attack. Because airway patency decreases at night, many children have acute signs of asthma at this time. Often, previously well infants and children experience what may seem to be a cold with rhinorrhea, rapidly followed by irritability, a tight and nonproductive cough, wheezing, tachypnea, dyspnea with prolonged expiration, and use of accessory muscles of respiration. Cyanosis, hyperinflation of the chest, and tachycardia indicate increasing severity of the attack. Wheezing may be absent in children with extreme respiratory distress. The symptoms may progress rapidly and require a trip to the emergency room or hospitalization.

The Expert Panel of the National Heart, Lung, and Blood Institute's National Asthma Education Program has developed guidelines for the management of asthma in infants and children younger than 5 years and for adults and children older than 5 years.⁶ The Panel recommends that adolescents (and younger children when appropriate) be directly involved in developing their asthma management plans. Active participation in physical activities, exercise, and sports should be encouraged. A written asthma management plan should be prepared for the student's school, including plans to ensure reliable, prompt access to medications.⁶

Chronic Obstructive Pulmonary Disease

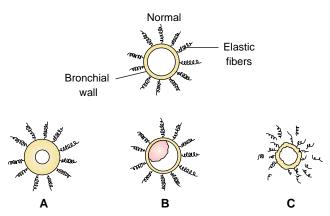

Chronic obstructive pulmonary disease (COPD) denotes a group of respiratory disorders characterized by chronic and recurrent obstruction of airflow in the pulmonary airways. Airflow obstruction usually is progressive, may be accompanied by airway hyperreactivity, and may be partially reversible.¹⁷ The most common cause of COPD is smoking.^{17,18} Thus, the disease is largely preventable. Unfortunately, clinical findings are almost always absent during the early stages of COPD, and by the time symptoms appear, the disease usually is far advanced. For smokers with early signs of airway disease, there is hope that early recognition, combined with appropriate treatment and smoking cessation, may prevent or delay the usually relentless progression of the disease.

The term *chronic obstructive pulmonary disease* encompasses two types of obstructive airway disease: *emphysema*, with enlargement of air spaces and destruction of lung tissue, and *chronic obstructive bronchitis*, with obstruction of small airways. The mechanisms involved in the pathogenesis of COPD usually are multiple and include inflammation and fibrosis of the bronchial wall, hypertrophy of the submucosal glands and hypersecretion of mucus, and loss of elastic lung fibers and alveolar tissue (Fig. 21-7).¹⁸ Inflammation and fibrosis of the bronchial wall, along with excess mucus secretion, obstruct airflow and cause mismatching of ventilation and perfusion. Destruction of alveolar tissue decreases the surface area for gas exchange, and the loss of elastic fibers leads to airway collapse. Normally, recoil of the elastic fibers that were stretched during inspiration provides the force needed to move air out of the lung during expiration. Because the elastic fibers are attached to the airways, they also provide radial traction to hold the airways open during expiration. In persons with COPD, the loss of elastic fibers impairs the expiratory flow rate, increases air trapping, and predisposes to airway collapse.

Emphysema

Emphysema is characterized by a loss of lung elasticity and abnormal enlargement of the air spaces distal to the terminal bronchioles, with destruction of the alveolar walls and capillary beds. Enlargement of the air spaces leads to hyperinflation of the lungs and produces an increase in total lung capacity (TLC). Two of the recognized causes of emphysema are smoking, which incites lung injury, and an inherited deficiency of α_1 -antitrypsin, an antiprotease enzyme that protects the lung from injury. Genetic factors, other than an inherited α_1 -antitrypsin deficiency, also may play a role in smokers who experience COPD at an early age.¹⁹

Emphysema is thought to result from the breakdown of elastin and other alveolar wall components by enzymes, called *proteases*, that digest proteins. These proteases, particularly elastase, which is an enzyme that digests elastin, are released from polymorphonuclear leukocytes (*i.e.*, neutrophils), alveolar macrophages, and other inflammatory cells.¹⁸ Normally, the lung is protected by antiprotease enzymes, including α_1 -antitrypsin. Cigarette smoke and other irritants stimulate the movement of inflammatory cells into the lungs, resulting in increased release of elastase and other proteases. In smokers in whom COPD develops, antiprotease production and release may be inadequate to neutralize the excess protease production

■ FIGURE 21-7 ■ Mechanisms of airflow obstruction in chronic obstructive lung disease. (**Top**) The normal bronchial airway with elastic fibers that provide traction and hold the airway open. (**Bottom**) Obstruction of the airway caused by (**A**) hypertrophy of the bronchial wall, (**B**) inflammation and hypersecretion of mucus, and (**C**) loss of elastic fibers that hold the airway open.

such that the process of elastic tissue destruction goes unchecked (Fig. 21-8).

A hereditary deficiency in α_1 -antitrypsin accounts for approximately 1% of all cases of COPD and is more common in young persons with emphysema.¹⁸ An α_1 -antitrypsin deficiency is inherited as an autosomal recessive disorder. Homozygotes who carry two defective genes have only about 15% to 20% of the normal plasma concentration of α_1 -antitrypsin. It is most common in persons of Scandinavian descent and is rare in Jews, blacks, and the Japanese.²⁰ Smoking and repeated respiratory tract infections, which also decrease α_1 -antitrypsin levels, contribute to the risk of emphysema in persons with an α_1 -antitrypsin deficiency. Laboratory methods are available for measuring α_1 -antitrypsin levels. Human α_1 -antitrypsin is available for replacement therapy in persons with a hereditary deficiency of the enzyme.

There are two commonly recognized types of emphysema: centriacinar and panacinar (Fig. 21-9). The centriacinar type affects the bronchioles in the central part of the respiratory lobule, with initial preservation of the alveolar ducts and sacs²⁰ (Fig. 21-10). It is the most common type of emphysema and is seen predominantly in male smokers. The panacinar type produces initial involvement of the peripheral alveoli and later extends to involve the more central bronchioles. This type of emphysema is more common in persons with α_1 -antitrypsin deficiency. It also is found in smokers in association with centrilobular emphysema. In such cases, panacinar changes are seen in the lower parts of the lung and the centriacinar changes in the upper parts of the lung.

Chronic Bronchitis

In chronic bronchitis, airway obstruction is caused by inflammation of the major and small airways. There is edema and hyperplasia of submucosal glands and excess mucus excretion

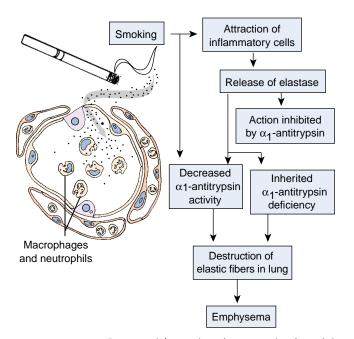

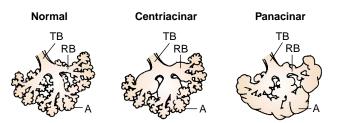

FIGURE 21-8 Protease (elastase)-antiprotease (antitrypsin) mechanisms of emphysema. The effects of smoking and an inherited α_1 -antitrypsin deficiency on the destruction of elastic fibers in the lung and development of emphysema.

■ FIGURE 21-9 ■ Centriacinar and panacinar emphysema. In centriacinar emphysema, the destruction is confined to the terminal (TB) and respiratory bronchioles (RB). In panacinar emphysema, the peripheral alveoli (A) are also involved. (West J.B. [1997]. *Pulmonary pathophysiology* [5th ed., p. 53]. Philadelphia: Lippincott-Raven)

into the bronchial tree. A history of a chronic productive cough of more than 3 months' duration for more than 2 consecutive years is necessary for the diagnosis of chronic bronchitis.^{17,18} Typically, the cough has been present for many years, with a gradual increase in acute exacerbations that produce frankly purulent sputum. Chronic bronchitis without airflow obstruction often is referred to as *simple bronchitis*, and chronic bronchitis with airflow obstruction as *chronic obstructive bronchitis*. The outlook for persons with simple bronchitis is good, compared with the premature morbidity and mortality associated with chronic obstructive bronchitis.

Chronic bronchitis is seen most commonly in middleaged men and is associated with chronic irritation from smok-

■ FIGURE 21-10 ■ Centrilobular emphysema. A whole mount of the left lung of a smoker with mild emphysema shows enlarged air spaces scattered throughout both lobes, which represent destruction of terminal bronchioles in the central part of the pulmonary lobule. These abnormal spaces are surrounded by intact pulmonary parenchyma. (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 628]. Philadelphia: Lippincott Williams & Wilkins)

ing and recurrent infections. In the United States, smoking is the most important cause of chronic bronchitis. Viral and bacterial infections are common in persons with chronic bronchitis and are thought to be a result, rather than a cause, of the problem.

Clinical Features

The mnemonics "pink puffer" and "blue bloater" have been used to differentiate the clinical manifestations of emphysema and chronic obstructive bronchitis. The important features of these two forms of COPD are described in Table 21-2. In practice, differentiation between the two types is not as vivid as presented here. This is because persons with COPD often have some degree of both emphysema and chronic bronchitis.

A major difference between the pink puffers and the blue bloaters is the respiratory responsiveness to the hypoxic stimuli. With pulmonary emphysema, there is a proportionate loss of ventilation and perfusion area in the lung. These persons are pink puffers, or fighters, who are able to overventilate and thus maintain relatively normal blood gas levels until late in the disease. Chronic obstructive bronchitis is characterized by excessive bronchial secretions and airway obstruction that causes mismatching of ventilation and perfusion. Thus, persons with chronic bronchitis are unable to compensate by increasing their ventilation; instead, hypoxemia and cyanosis develop. These are the blue bloaters, or nonfighters.

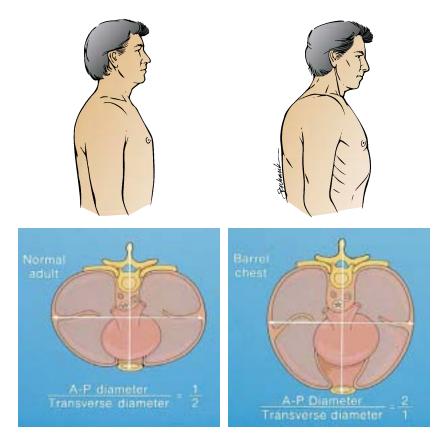

Persons with emphysema have marked dyspnea and struggle to maintain normal blood gas levels with increased breathing effort, including prominent use of the accessory muscles. The seated position, which stabilizes chest structures and allows for maximum chest expansion and use of accessory muscles, is preferred. With loss of lung elasticity and hyperinflation of the lungs, the airways often collapse during expiration because pressure in surrounding lung tissues exceeds airway pressure. Air becomes trapped in lungs, producing an increase in the anteroposterior dimensions of the chest, the so-called *barrel chest* that is typical of persons with emphysema (Fig. 21-11). Expiration often is accomplished through pursed lips. Pursedlip breathing, which increases the resistance to the outflow of air, helps to prevent airway collapse by increasing airway pressure. The work of breathing is greatly increased in persons with emphysema, and eating often is difficult. As a result, there often is considerable weight loss.

Chronic obstructive bronchitis is characterized by shortness of breath with a progressive decrease in exercise tolerance. As the disease progresses, breathing becomes increasingly more labored, even at rest. The expiratory phase of respiration is prolonged, and expiratory wheezes and crackles can be heard on auscultation. In contrast to persons with emphysema, those with chronic obstructive bronchitis are unable to maintain normal blood gases by increasing their breathing effort. Hypoxemia, hypercapnia, and cyanosis develop, reflecting an imbalance between ventilation and perfusion. Hypoxemia, in which arterial PO₂ levels fall below 55 mm Hg, causes reflex vasoconstriction of the pulmonary vessels and further impairment of gas exchange in the lung. Hypoxemia also stimulates red blood cell production, causing polycythemia. As a result, persons with chronic obstructive bronchitis develop pulmonary hypertension and, eventually, right-sided heart failure with peripheral edema (*i.e.*, cor pulmonale).

Chronic Obstructive Lung Disease				
Characteristic	Type A Pulmonary Emphysema ("Pink Puffers")	Type B Chronic Bronchitis ("Blue Bloaters")		
Smoking history	Usual	Usual		
Age of onset	40 to 50 years of age	30 to 40 years of age; disability in middle age		
Clinical features				
Barrel chest (hyperinflation of	Often dramatic	May be present		
the lungs)				
Weight loss	May be severe in advanced disease	Infrequent		
Shortness of breath	May be absent early in disease	Predominant early symptom, insidious in onset, exertional		
Decreased breath sounds	Characteristic	Variable		
Wheezing	Usually absent	Variable		
Rhonchi	Usually absent or minimal	Often prominent		
Sputum	May be absent or may develop late in the course	Frequent early manifestation, frequent infec- tions, abundant purulent sputum		
Cyanosis	Often absent, even late in the disease when there is low PO_2	Often dramatic		
Blood gases	Relatively normal until late in the disease process	Hypercapnia may be present Hypoxemia may be present		
Cor pulmonale	Only in advanced cases	Frequent Peripheral edema		
Polycythemia	Only in advanced cases	Frequent		
Prognosis	Slowly debilitating disease	Numerous life-threatening episodes due to acute exacerbations		

TABLE 21-2 Characteristics of Chronic Bronchitis and Emphysematous Types of Chronic Obstructive Lung Disease

388 Unit Five: Alterations in the Respiratory System

■ FIGURE 21-11 ■ Characteristics of normal chest wall and chest wall in emphysema. The normal chest wall and its cross section are illustrated on the left (A). The barrel-shaped chest of emphysema and its cross section are illustrated on the right (B). (Smeltzer S.C., Bare B.G. [2000]. *Medical-surgical nursing*. [9th ed., p. 454]. Philadelphia: Lippincott Williams & Wilkins)

Persons with combined forms of COPD (*i.e.*, some degree of both emphysema and chronic bronchitis) characteristically seek medical attention in the fifth or sixth decade of life, complaining of cough, sputum production, and shortness of breath. The symptoms typically have existed to some extent for 10 years or longer. The productive cough usually occurs in the morning. Dyspnea becomes more severe as the disease progresses. Frequent exacerbations of infection and respiratory insufficiency are common, causing absence from work and eventual disability.

The late stages of COPD are characterized by pulmonary hypertension, cor pulmonale, recurrent respiratory infections, and chronic respiratory failure. Death usually occurs during an exacerbation of illness associated with infection and respiratory failure.

Diagnosis and Treatment. The diagnosis of COPD is based on a careful history and physical examination, pulmonary function studies, chest radiographs, and laboratory tests. Airway obstruction prolongs the expiratory phase of respiration and affords the potential for impaired gas exchange because of the mismatching of ventilation and perfusion. The FVC is the amount of air that can be forcibly exhaled after maximal inspiration (see Chapter 19, Fig. 19-16). In an adult with normal respiratory function, this should be achieved in 4 to 6 seconds. In patients with COPD, the time required for FVC is increased, the FEV_{1.0} is decreased, and the ratio of FEV_{1.0} to FVC is decreased. In severe disease, the FVC is markedly reduced. Lung volume measurements reveal a marked increase in residual volume (RV), an increase in TLC, and elevation of the RV to TLC ratio. These and other measurements of expiratory flow are determined by spirometry and are used in the diagnosis of COPD.

The treatment of COPD depends on the stage of the disease and often requires an interdisciplinary approach. Smoking cessation is the only measure that slows the progression of the disease.²⁰ Persons in more advanced stages of the disease often require measures to maintain and improve physical and psychosocial functioning, pharmacologic interventions, and oxygen therapy. Respiratory tract infections can prove life threatening to persons with severe COPD. A person with COPD should avoid exposure to others with known respiratory tract infections. Immunization for influenza and pneumococcal infections decreases the likelihood of their occurrence.

Pharmacologic treatment includes the use of bronchodilators, including β_2 -adrenergic agonist drugs; the anticholinergic drug, ipratropium; and theophylline preparations. A long-term pulmonary rehabilitation program can significantly reduce episodes of hospitalization and add measurably to a person's ability to manage and cope with his or her impairment in a positive way.

Oxygen therapy is prescribed for selected persons with significant hypoxemia (arterial $PO_2 < 55 \text{ mm Hg}$). The use of continuous low-flow oxygen decreases dyspnea, helps to prevent pulmonary hypertension, and improves neuropsychological function and activity tolerance. Portable oxygen administration units, which allow mobility and the performance of activities of daily living, usually are used. The overall goal of oxygen therapy is to maintain the hemoglobin oxygen saturation at 89% to 90%, representing an arterial PO_2 of approximately 60 mm Hg (see Chapter 19, Fig. 19-18). Because the ventilatory drive associated with hypoxic stimulation of the peripheral chemoreceptors does not occur until the arterial PO₂ has been reduced to about 60 mm Hg or less, the oxygen flow rate usually is titrated to provide an arterial PO₂ of 55 to 65 mm Hg. Increasing the arterial PO₂ above that level tends to depress ventilation, leading to hypoventilation and carbon dioxide retention.

Bronchiectasis

Bronchiectasis is a chronic obstructive lung disease characterized by an abnormal dilatation of the large bronchi associated with infection and destruction of the bronchial walls (Fig. 21-12). To be diagnosed as bronchiectasis, the dilatation must be permanent, as compared with the reversible bronchial dilatation that sometimes accompanies viral and bronchial pneumonias

The pathogenesis of bronchiectasis can be either obstructive or nonobstructive.²⁰ Obstructive bronchiectasis is confined to a segment of the lung distal to a mechanical obstruction. It is caused by conditions such as tumors, foreign bodies, and mucus plugs in asthma. Nonobstructive bronchiectasis can be either localized or generalized. The use of immunizations and antibiotics has largely eliminated localized bronchiectasis

FIGURE 21-12 Bronchiectasis. The resected upper lobe shows widely dilated bronchi, with thickening of the bronchial walls and collapse and fibrosis of the pulmonary parenchyma. (Rubin E., Farber J.L. [1999]. Pathology [3rd ed., p. 601]. Philadelphia: Lippincott Williams & Wilkins)

caused by childhood bronchopulmonary infections such as measles, pertussis, and other bacterial infections.²¹

Generalized bronchiectasis is attributable largely to inherited impairments of host mechanisms or acquired disorders that permit introduction of infectious organisms into the airways. They include inherited conditions such as cystic fibrosis, in which airway obstruction is caused by impairment of normal mucociliary function; congenital and acquired immunodeficiency states, which predispose to respiratory tract infections; lung infection (e.g., tuberculosis, fungal infections, lung abscess); and exposure to toxic gases that cause airway obstruction.

Generalized bronchiectasis usually is bilateral and most commonly affects the lower lobes. Localized bronchiectasis can affect any area of the lung, the area being determined by the site of obstruction or infection. As the disease progresses, airway obstruction leads to smooth muscle relaxation with dilatation and eventual destruction of the bronchial walls. Infection produces inflammation, impairs mucociliary function, and causes weakening and further dilatation of the walls of the bronchioles. Pooling of secretions produces a vicious cycle of chronic inflammation and development of new infections.

Bronchiectasis is associated with an assortment of abnormalities that profoundly affect respiratory function, including atelectasis, obstruction of the smaller airways, and diffuse bronchitis. Affected persons have fever, recurrent bronchopulmonary infection, coughing, production of copious amounts of foul-smelling, purulent sputum, and hemoptysis. Weight loss and anemia are common. The physiologic abnormalities that occur in bronchiectasis are similar to those seen in chronic bronchitis and emphysema. As in the latter two conditions, chronic bronchial obstruction leads to marked dyspnea and cyanosis. Clubbing of the fingers is common in moderate to advanced bronchiectasis and is not seen in other types of obstructive lung diseases.21

Diagnosis is based on history and imaging studies. The condition often is evident on chest radiographs. High-resolution CT scanning of the chest allows for definitive diagnosis. Treatment consists of early recognition and treatment of infection along with regular postural drainage and chest physical therapy. Persons with this disorder benefit from many of the rehabilitation and treatment measures used for chronic bronchitis and emphysema. Localized bronchiectasis may be treated surgically.

Cystic Fibrosis

Cystic fibrosis is an autosomal recessive disorder involving fluid secretion in the exocrine glands and epithelial lining of the respiratory, gastrointestinal, and reproductive tracts. Most of the clinical manifestations of the disease are related to abnormal secretions that result in obstruction of organ passages such as the respiratory airways and pancreatic ducts. It is the most common fatal hereditary disorder of whites in the United States and is the most common cause of chronic lung disease in children.22

The cystic fibrosis gene, present on the long arm of chromosome 7, encodes the production of a single protein, the cystic fibrosis transmembrane conductance regulator (CFTR),

390 Unit Five: Alterations in the Respiratory System

which functions in chloride transport across cell membranes.^{23,24} Because of defective chloride transport, there is a threefold increase in sodium reabsorption. Water moves out of the extracellular fluid with the sodium, causing exocrine (*e.g.*, mucus) secretions to become exceedingly viscid. The cystic fibrosis gene is rare in African blacks and Asians. Homozygotes (*i.e.*, persons with two defective genes) have all or substantially all of the clinical symptoms of the disease, compared with heterozygotes, who are carriers of the disease but have no recognizable symptoms.

Clinically, cystic fibrosis is manifested by (1) chronic respiratory disease, (2) pancreatic exocrine deficiency, and (3) elevation of sodium chloride in the sweat. Nasal polyps, sinus infections, pancreatitis, and cholelithiasis also are common. Excessive loss of sodium in the sweat predisposes young children to salt depletion episodes. Most males with cystic fibrosis have congenital bilateral absence of the vas deferens with azoospermia.²³

Respiratory manifestations are caused by an accumulation of viscid mucus in the bronchi, impaired mucociliary clearance, and lung infections. Chronic bronchiolitis and bronchitis are the initial lung manifestations, but after months and years, structural changes in the bronchial wall lead to bronchiectasis. Widespread bronchiectasis is common by 10 years of age; large bronchiectatic cysts and abscesses develop in later stages of the disease. Infection and ensuing inflammation are causes of lung destruction in cystic fibrosis. *Staphylococcus aureus* and *Pseudomonas* infections are common. With advanced disease, 80% of persons harbor the *Pseudomonas* organism. New findings suggest that absence of CFTR predisposes to *Pseudomonas* infections, and once established, *Pseudomonas* is not easily cleared from the lungs, producing a cycle of chronic inflammation, tissue damage, and obstruction.

Pancreatic function is abnormal in approximately 80% to 90% of affected persons.²⁴ Steatorrhea, diarrhea, and abdominal pain and discomfort are common. In the newborn, meconium ileus may cause intestinal obstruction. The degree of pancreatic involvement is highly variable. In some children, the defect is relatively mild, and in others the involvement is severe and impairs intestinal absorption.

Early diagnosis and treatment are important in delaying the onset and severity of chronic illness. Diagnosis is based on the presence of respiratory and gastrointestinal manifestations typical of cystic fibrosis, a history of cystic fibrosis in a sibling, or a positive newborn screening test. Newborn screening consists of a test for determination of immunoreactive trypsinogen. Newborns with cystic fibrosis have elevated blood levels of immunoreactive trypsinogen, presumably because of secretory obstruction in the pancreas. Confirmatory tests include the sweat test to detect increased electrolytes in the sweat and genetic tests to detect the presence of the mutant CFTR genes.

The treatment of cystic fibrosis usually consists of replacement of pancreatic enzymes, physical measures to improve the clearance of tracheobronchial secretions (*i.e.*, postural drainage and chest percussion), bronchodilator therapy, and prompt treatment of respiratory tract infections. Lung transplantation is being used as a treatment for persons with end-stage lung disease.

Progress of the disease is variable. Improved medical management has led to longer survival—approximately half of children live beyond 20 years, and approximately one third of the nearly 30,000 persons with cystic fibrosis are adults.

In summary, obstructive ventilatory disorders are characterized by airway obstruction and limitation in expiratory airflow. Bronchial asthma is a chronic inflammatory disorder of the airways, characterized by airway hypersensitivity and episodic attacks of airway narrowing. An asthmatic attack can be triggered by a variety of stimuli. Based on their mechanism of response, these triggers can be divided into two types: bronchospastic and inflammatory. Bronchospastic triggers depend on the level of airway responsiveness. There are two types of responses in persons with asthma: the acute or early response and the late phase response. The acute response results in immediate bronchoconstriction on exposure to an inhaled antigen and usually subsides within 90 minutes. The late phase response usually develops 3 to 5 hours after exposure to an asthmatic trigger; it involves inflammation and increased airway responsiveness that prolong the attack and cause a vicious cycle of exacerbations.

COPD describes a group of conditions characterized by obstruction to airflow in the lungs. Among the conditions associated with COPD are emphysema, chronic bronchitis, and bronchiectasis. Emphysema is characterized by a loss of lung elasticity; abnormal, permanent enlargement of the air spaces distal to the terminal bronchioles; and hyperinflation of the lungs. Chronic bronchitis is caused by inflammation of major and small airways and is characterized by edema and hyperplasia of submucosal glands and excess mucus secretion into the bronchial tree. A history of a chronic productive cough that has persisted for at least 3 months and for at least 2 consecutive years in the absence of other disease is necessary for the diagnosis of chronic bronchitis. Emphysema and chronic bronchitis are manifested by the eventual mismatching of ventilation and perfusion. As the condition advances, signs of respiratory distress and impaired gas exchange become evident, with development of hypercapnia and hypoxemia. Bronchiectasis is a form of COPD that is characterized by an abnormal dilatation of the large bronchi associated with infection and destruction of the bronchial walls.

Cystic fibrosis is an autosomal recessive genetic disorder manifested by chronic lung disease, pancreatic exocrine deficiency, and elevation of sodium chloride in the sweat. Respiratory manifestations are caused by an accumulation of viscid mucus in the bronchi, impaired mucociliary clearance, lung infections, bronchiectasis, and dilatation. Mucus plugs can result in the total obstruction of an airway, causing atelectasis.

INTERSTITIAL LUNG DISEASES

The diffuse interstitial lung diseases are a diverse group of lung disorders that produce similar inflammatory and fibrotic changes in the interstitium or interalveolar septa of the lung. The disorders may be acute or insidious in onset; they may be rapidly progressive, slowly progressive, or static in their course. They include hypersensitivity pneumonitis (see Chapter 10), lung diseases caused by exposure to toxic drugs (*e.g.*, amio-

darone) and radiation, and occupational lung diseases including the pneumoconioses that are caused by the inhalation of inorganic dusts such as silica, coal dust, and asbestos. Some of the most common interstitial lung diseases are caused by exposure to the inhaled dust and particles. In many cases, no specific cause can be found.^{25,26} Examples of interstitial lung diseases and their causes are listed in Chart 21-2.

Current theory suggests that most interstitial lung diseases, regardless of the causes, have a common pathogenesis. It is thought that these disorders are initiated by some type of injury to the alveolar epithelium, followed by an inflammatory process that involves the alveoli and interstitium of the lung. An accumulation of inflammatory and immune cells causes continued damage of lung tissue and the replacement of normal, functioning lung tissue with fibrous scar tissue.

Because the interstitial lung diseases result in a stiff and noncompliant lung, they are commonly classified as fibrotic or restrictive lung disorders. In contrast to obstructive lung diseases, the lungs are stiff and difficult to expand, despite normal functioning airways. Persons with interstitial lung diseases experience dyspnea, tachypnea, and eventual cyanosis, without evidence of wheezing or signs of airway obstruction. Usually there is an insidious onset of breathlessness that initially occurs during exercise and may progress to the point that the person is totally incapacitated. A nonproductive cough may develop, particularly with continued exposure to the in-

KEY CONCEPTS

INTERSTITIAL OR RESTRICTIVE LUNG DISEASES

- Interstitial lung diseases result from inflammatory conditions that affect the interalveolar structures of the lung and produce lung fibrosis and a stiff lung.
- A stiff and noncompliant lung is difficult to inflate, increasing the work of breathing and causing decreased exercise tolerance due to hypoxemia.
- Because of the increased effort needed for lung expansion, persons with interstitial lung disease tend to take small but more frequent breaths.

haled irritant. Typically, a person with a restrictive lung disease breathes with a pattern of rapid, shallow respirations. This tachypneic pattern of breathing, in which the respiratory rate is increased and the tidal volume is decreased, reduces the work of breathing because it takes less work to move air through the airways at an increased rate than it does to stretch a stiff lung to accommodate a larger tidal volume.

Although resting arterial blood gases usually are normal early in the course of the disease, arterial PO₂ levels may fall during exercise, and in cases of advanced disease, hypoxemia often is present, even at rest. In the late stages of the disease, hypercapnia and respiratory acidosis develop. Clubbing of the fingers and toes may develop because of chronic hypoxemia.

The diagnosis of interstitial lung disease requires a careful personal and family history, with particular emphasis on exposure to environmental, occupational, and other injurious agents. Chest radiographs may be used as an initial diagnostic method, and serial chest films often are used to follow the progress of the disease. A biopsy specimen for histologic study and culture may be obtained by surgical incision or bronchoscopy using a fiberoptic bronchoscope. Gallium lung scans often are used to detect and quantify the chronic alveolitis that occurs in interstitial lung disease. Gallium does not localize in normal lung tissue, but uptake of the radionuclide is increased in interstitial lung disease and other diffuse lung diseases.

The treatment goals for persons with interstitial lung disease focus on identifying and removing the injurious agent, suppressing the inflammatory response, preventing progression of the disease, and providing supportive therapy for persons with advanced disease. In general, the treatment measures vary with the type of lung disease. Corticosteroid drugs frequently are used to suppress the inflammatory response. Many of the supportive treatment measures used in the late stages of the disease, such as oxygen therapy and measures to prevent infection, are similar to those discussed for persons with COPD.

In summary, the interstitial lung diseases are characterized by fibrosis and decreased compliance of the lung. They include the occupational lung diseases, lung diseases caused by toxic drugs and radiation, and lung diseases of unknown origin, such as sarcoidosis. These disorders are thought to result from an inflammatory process that begins in the alveoli and extends to involve the interstitial tissues of the lung. Unlike COPD, which affects the airways, interstitial lung diseases affect the supporting collagen and elastic tissues that lie between the airways and blood vessels. These lung diseases decrease lung volumes, reduce the diffusing capacity of the lung, and cause various degrees of hypoxia. Because lung compliance is reduced, persons with this form of lung disease have a rapid, shallow breathing pattern.

PULMONARY VASCULAR DISORDERS

As blood moves through the lung, blood oxygen levels are raised, and carbon dioxide is removed. These processes depend on the matching of ventilation (*i.e.*, gas exchange) and perfusion (*i.e.*, blood flow). This section discusses three major disorders of the pulmonary circulation: pulmonary embolism, pulmonary hypertension, and acute respiratory distress syndrome. Pulmonary edema, another major problem of the pulmonary circulation, is discussed in Chapter 18.

Pulmonary Embolism

Pulmonary embolism develops when a blood-borne substance lodges in a branch of the pulmonary artery and obstructs the flow. The embolism may consist of a thrombus (Fig. 21-13), air that has accidentally been injected during intravenous infusion, fat that has been mobilized from the bone marrow after a fracture or from a traumatized fat depot (see Chapter 42), or

■ FIGURE 21-13 ■ Pulmonary embolism. The main pulmonary artery and its bifurcation have opened to reveal a large saddle embolus. (Rubin E., Farber J.L. [1999]. *Pathology* [3rd ed., p. 289]. Philadelphia: Lippincott Williams & Wilkins)

amniotic fluid that has entered the maternal circulation after rupture of the membranes at the time of delivery.

Almost all pulmonary emboli arise from deep vein thrombosis (DVT) in the lower extremities (see Chapter 15). The presence of thrombosis in the deep veins of the legs or pelvis often is unsuspected until embolism occurs. The effects of emboli on the pulmonary circulation are related to mechanical obstruction of the pulmonary circulation and neurohumoral reflexes causing vasoconstriction. Obstruction of pulmonary blood flow causes reflex bronchoconstriction in the affected area of the lung, wasted ventilation and impaired gas exchange, and loss of alveolar surfactant. Pulmonary hypertension and right heart failure may develop when there is massive vasoconstriction because of a large embolus. Although small areas of infarction may occur, frank pulmonary infarction is uncommon.

Persons at risk for DVT also are at risk for thromboemboli. Among the physiologic factors that contribute to venous thrombosis are venous stasis, venous endothelial injury, and hypercoagulability states. Venous stasis and venous endothelial injury can result from prolonged bed rest, trauma, surgery, childbirth, fractures of the hip and femur, myocardial infarction and congestive heart failure, and spinal cord injury. Persons undergoing orthopedic surgery and gynecologic cancer surgery are at particular risk, as are bedridden patients in an intensive care unit. Cancer cells can produce thrombin and synthesize procoagulation factors, increasing the risk of thromboembolism. Use of oral contraceptive, pregnancy, and hormone replacement therapy are thought to increase the resistance to endogenous anticoagulants. The risk of pulmonary embolism among users of oral contraceptives is approximately three times the risk of nonusers.²⁷ Women who smoke are at particular risk.

The manifestations of pulmonary embolism depend on the size and location of the obstruction. Chest pain, dyspnea, and increased respiratory rate are the most frequent signs and symptoms of pulmonary embolism. Pulmonary infarction often causes pleuritic pain that changes with respiration; it is more severe on inspiration and less severe on expiration. Moderate hypoxemia without carbon dioxide retention occurs as a result of impaired gas exchange. Small emboli that become lodged in the peripheral branches of the pulmonary artery may exert little effect and go unrecognized. However, repeated small emboli often result in a gradual the size of the pulmonary capillary bed, resulting in pulmonary hypertension. Moderate-size emboli often present with breathlessness accompanied by pleuritic pain, apprehension, slight fever, rapid and shallow breathing, and cough productive of blood-streaked sputum. Persons with massive emboli usually present with sudden collapse, crushing substernal chest pain, shock, and sometimes loss of consciousness. The pulse is rapid and weak, the blood pressure is low, the neck veins are distended, and the skin is cyanotic and diaphoretic. Massive pulmonary emboli often are fatal.

The diagnosis of pulmonary embolism is based on clinical signs and symptoms, blood gas determinations, venous thrombosis studies, lung scans, CT scans, and in selected cases, pulmonary angiography. Laboratory studies and radiologic films are useful in ruling out other conditions that might give rise to similar symptoms. The electrocardiogram (ECG) may be used to detect signs of right heart strain resulting in an increase in pulmonary vascular resistance. Because almost all

pulmonary emboli originate from DVT, venous studies such as lower limb compression ultrasonography, impedance plethysmography, and contrast venography often are used as initial diagnostic procedures.

The treatment goals for pulmonary emboli focus on the prevention DVT and the development of thromboemboli, protecting the lungs from exposure to thromboemboli when they occur, and in the case of large and life-threatening pulmonary emboli, sustaining life and restoring pulmonary blood flow. Thrombolytic therapy may be indicated in persons with multiple or large emboli. Restoration of blood flow in persons with life-threatening pulmonary emboli can often be accomplished through the surgical removal of the embolus or emboli.

Prevention focuses on identification of persons at risk, avoidance of venous stasis and hypercoagulability states, and early detection of venous thrombosis. For persons at risk, graded compression elastic stockings and intermittent pneumatic compression (IPC) boots can be used to prevent venous stasis. Pharmacologic prophylaxis involves the use of anticoagulant drugs.

Pulmonary Hypertension

The term *pulmonary hypertension* describes the elevation of pressure in the pulmonary arterial system. The pulmonary circulation is a low-pressure system designed to accommodate varying amounts of blood delivered from the right heart and to facilitate gas exchange. The normal mean pulmonary artery pressure is approximately 15 mm Hg (e.g., 28 systolic/8 diastolic). The main pulmonary artery and major branches are relatively thin-walled, compliant vessels. The distal pulmonary arterioles also are thin walled and have the capacity to dilate, collapse, or constrict, depending on the presence of vasoactive substances released from the endothelial cells of the vessel, neurohumoral influences, flow velocity, oxygen tension, and alveolar ventilation.

Pulmonary hypertension can be caused by an elevation in left atrial pressure, increased pulmonary blood flow, or increased pulmonary vascular resistance. Because of the increased pressure in the pulmonary circulation, pulmonary hypertension increases the workload of the right heart. Although pulmonary hypertension can develop as a primary disorder, most cases develop secondary to some other condition.

Secondary Pulmonary Hypertension

Secondary pulmonary hypertension refers to an increase in pulmonary pressures associated with other disease conditions, usually cardiac or pulmonary. Secondary causes, or mechanisms, of pulmonary hypertension can be divided into four major categories: (1) elevation of pulmonary venous pressure, (2) increased pulmonary blood flow, (3) pulmonary vascular obstruction, and (4) hypoxemia.²⁸ Often more than one factor, such as COPD, heart failure, and sleep apnea, contributes to the elevation in pulmonary pressures.

Elevation of pulmonary venous pressure is common in conditions such as mitral valve stenosis and left ventricular heart failure, in which an elevated left atrial pressure is transmitted to the pulmonary circulation. Continued increases in left atrial pressure can lead to medial hypertrophy and intimal thickening of the small pulmonary arteries, causing sustained hypertension.

Increased pulmonary blood flow results from increased flow through left-to-right shunts in congenital heart diseases such as atrial or ventricular septal defects and patent ductus arteriosus. If the high-flow state is allowed to continue, morphologic changes occur in the pulmonary vessels, leading to sustained pulmonary hypertension. The pulmonary vascular changes that occur with congenital heart disorders are discussed in Chapter 17.

Obstruction of pulmonary blood vessels is most commonly the result of pulmonary emboli. Once initiated, the pulmonary hypertension that develops is self-perpetuating because of hypertrophy and proliferation of vascular smooth muscle.

Hypoxemia is another common cause of pulmonary hypertension. Unlike the vessels in the systemic circulation, most of which dilate in response to hypoxemia and hypercapnia, the pulmonary vessels constrict. The stimulus for constriction is thought to originate in the air spaces near the smaller branches of the pulmonary arteries. In situations in which certain regions of the lung are hypoventilated, the response is adaptive in that it diverts blood flow away from the poorly ventilated areas to more adequately ventilated portions of the lung. However, this effect becomes less beneficial as more and more areas of the lung become poorly ventilated. Pulmonary hypertension is a common problem in persons with advanced COPD. It also may develop at high altitudes in persons with normal lungs. Persons who experience marked hypoxemia during sleep (*i.e.*, those with sleep apnea) may also experience marked elevations in pulmonary arterial pressure.

The signs and symptoms of secondary pulmonary hypertension reflect not only the underlying cause, but the effect that the elevated pressures have on right heart function and oxygen transport. Dyspnea and fatigue are common. Peripheral edema, ascites, and signs of right heart failure (cor pulmonale, to be discussed) develop as the condition progresses.

Diagnosis is based on radiographic findings, echocardiography, and Doppler ultrasonography. Precise measurement of pulmonary pressures can be obtained only through right heart cardiac catheterization. Treatment measures are directed toward the underlying disorder. Vasodilator therapy may be indicated for some persons.

Primary Pulmonary Hypertension

Primary pulmonary hypertension is a relatively rare and rapidly progressive form of pulmonary hypertension that leads to right ventricular failure and death within a few years. Estimates of incidence range from 1 to 2 cases per million people in the general population.²⁹ The disease can occur at any age, and familial occurrences have been reported. Persons with the disorder usually have a steadily progressive downhill course, with death occurring in 3 to 4 years. Overall, the 5-year survival rate of untreated primary pulmonary hypertension is approximately 20%.30

Primary pulmonary hypertension is thought to be associated with a number of factors, including an autosomal dominant genetic predisposition along with an exogenous trigger.³⁰ Triggers include low oxygen levels that occur at high altitudes, exposure to certain drugs, human immunodeficiency virus infection, and autoimmune disorders.

The disorder is characterized by endothelial damage, coagulation abnormalities, and marked intimal fibrosis leading to obliteration or obstruction of the pulmonary arteries and arterioles. Most of the manifestations of the disorder are attributable to increased work demands on the right heart and a decrease in cardiac output. Symptoms are the same as those for secondary hypertension. The most obvious are dyspnea and fatigue that is out of proportion to other signs of a person's well being.

The diagnosis of primary pulmonary hypertension is based on an absence of disorders that cause secondary hypertension and mean pulmonary artery pressures greater than 25 mm Hg at rest or 30 mm Hg with exercise.

Treatment consists of measures to improve right heart function to reduce fatigue and peripheral edema. Supplemental oxygen may be used to increase exercise tolerance. The most widely used drugs for long-term therapy are the calcium channel blockers. Anticoagulant (warfarin) therapy may be used to decrease the risk of thrombosis caused by sluggish pulmonary blood flow. Epoprostenol, a short-acting (half-life, 3 to 5 minutes) analog of the naturally occurring vasodilator prostacyclin (prostaglandin I₂), is increasingly used in the long-term care of persons with the disorder. Because of its short half-life, the drug must be administered by continuous infusion, usually through an indwelling venous catheter with an automatic ambulatory pump. Lung transplantation may be an alternative for persons who do not experience response to other forms of treatment.

Cor Pulmonale

The term cor pulmonale refers to right heart failure resulting from primary lung disease and longstanding primary or secondary pulmonary hypertension. It involves hypertrophy and the eventual failure of the right ventricle. The manifestations of cor pulmonale include the signs and symptoms of the primary lung disease and the signs of right-sided heart failure (see Chapter 18). Signs of right-sided heart failure include venous congestion, peripheral edema, shortness of breath and a productive cough, which becomes worse during periods of worsening failure. Plethora (i.e., redness) and cyanosis and warm, moist skin may result from the compensatory polycythemia and desaturation of arterial blood that accompany chronic lung disease. Drowsiness and altered consciousness may occur as the result of carbon dioxide retention. Management of cor pulmonale focuses on the treatment of the lung disease and the heart failure. Low-flow oxygen therapy may be used to reduce the pulmonary hypertension and polycythemia associated with severe hypoxemia caused by chronic lung disease.

Acute Respiratory Distress Syndrome
