The abnormal PR interval Xenobiotics that decrease interatrial or AV nodal conduction cause marked lengthening of the PR segment until such conduction completely ceases. At this point, the P wave no longer relates to the QRS complex; this is AV dissociation, or complete heart block. Some xenobiotics suppress AV nodal conduction by blocking calcium channels in nodal cells, as does magnesium, β-adrenergic receptor antagonists, or cholinergics through enhanced vagal tone. Although the therapeutic concentrations of digoxin, as well as early cardioactive steroid poisoning, cause PR prolongation through vagotonic effects, direct electrophysiologic effects account for the bradycardia of poisoning ("Bradydysrhythmias," Chap. 64, and Antidotes in Depth A20: Digoxin-Specific Antibody Fragments [DSFab]).

■ THE QRS COMPLEX

The QRS complex is the second and typically largest deflection on the ECG. The normal QRS duration in adults varies between 60 and 120 msec. The normal QRS complex axis in the frontal plane lies between −30° and 90°, although most individuals will have axes between 30° and 75°. This axis will vary with the weight and age of the patient. Alterations in myocardial function may also alter the electrical axis of the heart.

Electrophysiology The QRS complex reflects the electrical forces generated by ventricular depolarization mediated primarily by Na$^+$ influx into the myocardial cells. Although under normal conditions both ventricles depolarize nearly simultaneously, the greater mass of the left ventricle causes it to contribute the majority of the electrical forces. The QRS complex is primarily positive in leads I and aV$_L$ on the surface ECG recording because under normal conditions the depolarization vector is directed at 60° and is thus moving towards these leads.

The simultaneous and rapid depolarization of the ventricles results in a very short period of electrical activity recorded on the electrocardiogram. Of course, mechanical systole lasts well past the end of the QRS complex and is maintained by continued depolarization during the plateau phase of the action potential. The return and maintenance of the baseline, or isoelectric potential, is simply a result that the entire heart is depolarized and there is no significant flow of current during this period.

The axis of the terminal 40 msec (0.04 seconds) of the QRS complex represents the late stages of ventricular depolarization and generally follows the direction of the overall axis. This axis is determined by examining the last box (0.04 seconds or 40 msec) of the QRS complex.

The abnormal QRS complex In the presence of a bundle-branch block, the two ventricles depolarize sequentially rather than concurrently. Although, conceptually, conduction through either the left or right bundle may be affected (Fig. 22–8) many xenobiotics preferentially affect the right bundle. The specific reasons for this effect are unclear, but it may be related to differing refractory periods of the tissues. This effect typically results in the left ventricle depolarizing slightly more rapidly than the right. The consequence on the ECG is both a widening of the QRS complex and the appearance of the right ventricular electrical forces that were previously obscured by those of the left ventricle. These changes are typically the result of the effects of a xenobiotic that blocks fast sodium channels. Implicated xenobiotics include cyclic antidepressants,[9,11] quinidine and other type IA and IC antidysrhythmics[17] phenothiazines, amantadine,[51] diphenhydramine,[52] carbamazepine,[27] and cocaine.[2] In the setting of cyclic antidepressant poisoning, an increased QRS duration has both prognostic and therapeutic value (Chap. 73).[6,11,23] In one prospective analysis of ECGs, the maximal limb lead QRS duration was prognostic of seizures (0% if < 100 msec; 30% if greater) and ventricular dysrhythmias (0% if < 160 msec; 50% if greater).[11]

The terminal 40-msec axis of the QRS complex also contains information regarding the likelihood, but not the extent, of poisoning by sodium channel blockers. In a patient poisoned by a sodium channel blocker, the terminal portion of the QRS has a rightward deviation greater than 120°. The common abnormalities include, an R wave (positive deflection) in lead aV$_R$ and an S wave (negative deflection) in leads I and aV$_L$.[10,30] The combination of a rightward axis shift in the terminal 40 msec of the QRS complex (Fig. 22–9) with a prolonged QT and a sinus tachycardia is highly specific and sensitive for cyclic antidepressant poisoning.[41] Another study suggests that although ECG changes, like a prolonged QRS duration, are better at predicting severe outcomes than the cyclic antidepressant (CA) concentration, neither is very accurate.[6] One retrospective study suggests that an absolute height of the terminal portion of aV$_R$ that is greater than 3 mm, predicted seizures or dysrhythmias in CA-poisoned patients.[29] In infants younger than 6 months, however, a rightward deviation of the terminal 40-msec QRS axis is physiologic and not predictive of tricyclic antidepressant toxicity.[9]

An apparent increase in QRS complex duration and morphology, which is an elevation or distortion of the J point called a J wave or an Osborn wave (Fig. 15–3) is a common finding in patients with hypothermia.[43,57] Hypermagnesemia is also associated with a widening the QRS complex duration and a slight narrowing of the QRS complex may occur with hypomagnesemia. Significant elevation in the serum concentration K$^+$ may also cause widening and distortion of the QRS complex.

from the baseline and the length of this segment are important, the ST segment duration is usually measured by its effects on the QT duration (see "The QT Interval").

The abnormal ST segment   Displacement of the ST segment from its baseline typically characterizes myocardial ischemia or infarction (Fig. 22–10). The subsequent appearance of a Q wave is diagnostic of myocardial infarction. The ECG patterns of these entities reflect the different underlying electrophysiologic states of the heart. Ischemic regions are highly unstable and produce currents of injury because of

■ THE ST SEGMENT

The ST segment is defined as the distance between the end of the QRS complex and the beginning of the T wave.

Electrophysiology   The ST segment reflects the period of time between depolarization and the start of repolarization, or the plateau phase of the action potential. During this period, no major currents flow within the myocardium, which explains why under normal circumstances the ST segment is isoelectric. Although both the degree of displacement

FIGURE 22–10. Leads V$_4$–V$_6$ suggestive of a lateral STEMI are shown from the ECG of a 27-year-old man with substernal chest pain after using crack cocaine.

inadequate repolarization, which is related to lack of energy substrate to power the Na⁺-K⁺ ATPase. Myocardial infarction represents the loss of electrical activity from the necrotic, inactive ventricular tissue, allowing the contralateral ventricular forces to be predominant on the ECG. Patients who are poisoned by xenobiotics that cause vasoconstriction, such as cocaine (Chap. 76), other α-adrenergic agonists, or the ergot alkaloids, are particularly prone to develop focal myocardial ischemia and infarction. The specific ECG manifestations help to identify the region of injury and may, to some extent, be correlated with an arterial flow pattern: inferior (leads II, III, aV$_F$; right coronary artery); anterior (leads I, aV$_L$; left anterior descending artery); or lateral (leads aV$_L$, V$_{5-6}$; circumflex branch). However, any poisoning that results in profound hypotension or hypoxia may also result in ECG changes of ischemia and injury. In this patient, the injury may be more global, involving more than one arterial distribution. Diffuse myocardial damage may not be identifiable on the ECG because of global, symmetric electrical abnormalities. In this patient, the diagnosis is established by other noninvasive testing, such as by echocardiogram or by finding elevated concentrations of serum markers for myocardial injury such as troponin.

Many young, healthy patients have ST segment abnormalities that mimic those of myocardial infarction. The most common normal variant is termed "early repolarization" or "J-point elevation," and is identified as diffusely elevated, upwardly concave ST segments, located in the precordial leads and typically with corresponding T waves of large amplitude (Fig. 22–11).[12] The J point is located at the beginning of the ST segment just after the QRS complex. Because this ECG variant is common in patients with cocaine-associated chest pain (Chap. 76),[22] its recognition is critical to instituting appropriate therapy.

The Brugada electrocardiographic pattern (Fig. 22–12) is characterized by terminal positivity of the QRS complex and ST-segment elevation in the right precordial leads. The Brugada pattern is found in some patients with mutations of the gene that codes for the α subunit of the sodium channel. These patients are at risk for sudden death, but a similar ECG pattern often occurs in patients who are poisoned by sodium channel blocking xenobiotics, including CAs, cocaine, class IA (procainamide), and class IC (flecainide, encainide) antidysrhythmic.[31] In CA-poisoned patients this pattern is associated with an increased risk of hypotension, but not sudden death or dysrhythmias.[8] This pattern is also associated with lithium toxicity.
FIGURE 22–12. The Brugada pattern is characterized by terminal positivity of the QRS complex and ST-segment elevation in the right precordial leads and is a similar ECG pattern to that noted in patients poisoned by sodium channel blocking agents such as cyclic antidepressants.[4] (Image contributed by Vikhyat Bebarta, MD.)

Sagging ST segments, inverted T waves, and normal or shortened QT intervals are characteristic effects of cardioactive steroids, such as digoxin. These repolarization abnormalities are sometimes identified by their similar appearance to "Salvador Dali's mustache" (Fig. 22–13). As a group, these findings, along with PR prolongation, are commonly described as the "digitalis effect." They are found in patients with therapeutic drug concentrations and in patients with cardioactive steroid poisoning. As the serum concentration or, more precisely, the tissue concentration increases, clinical and electrocardiographic manifestations of toxicity will appear, which include profound bradycardia or ventricular dysrhythmias.

Changes in the ST segment duration are frequently caused by abnormalities in the serum Ca²⁺ concentration. Hypercalcemia causes shortening of the ST segment through enhanced calcium influx during
FIGURE 22–13. Two-day-old boy erroneously given 50 mcg/kg of digoxin, presented with heart rate 60 bpm, given digibind. (**A**) ECG from hospital day #2, after digoxin-specific Fab, and shows "digitalis effect" of the ST segment in leads V1–V3 (*free* digoxin concentration 4 ng/mL). FIGURE 22–15. Electrocardiographic manifestations associated with changes in serum potassium concentration.

the plateau phase of the cardiac cycle speeding the onset of repolarization. For practical purposes this effect is more commonly identified by reduction of the QT duration (Fig. 22–14). In patients with hypercalcemia, the morphology and duration of the QRS complex and T and P waves remain unchanged. Xenobiotic-induced hypercalcemia may result from exposure to antacids (milk alkali syndrome), diuretics (eg, hydrochlorothiazide), cholecalciferol (vitamin D), vitamin A, and other retinoids. Hypocalcemia causes prolongation of the ST segment and QT interval (see Fig. 22–14).

■ THE T WAVE

The T wave is the third deflection that occurs on the ECG.

Electrophysiology The T wave represents ventricular repolarization, during which time current is again flowing, although at a cellular level in the opposite direction from that during depolarization. Cardiac repolarization on the larger level generally follows the same pattern as depolarization and thus the deflection is usually in the same direction as the QRS complex. During repolarization, the intracellular potential of the cardiac myocyte becomes more negative as a result of a net loss of positive charge because of the increasing outward flow of potassium ions. As repolarization progresses, the voltage-dependent ion channels "reset" themselves as the intracellular potential falls past their set points. Thus, the initial part of the T wave represents the absolute refractory period of the heart, because at this time there are an insufficient number of reset voltage-dependent calcium channels to allow an impulse to cause a contraction. The latter part of the T wave represents the relative refractory period of the heart, during which time a sufficient number of these calcium channels are available to open with an aberrant depolarization and initiate a contraction.

The abnormal T wave Isolated peaked T waves are usually evidence of early hyperkalemia.[36] Hyperkalemia initially causes tall, tented T waves with normal QRS and QT interval, and a normal P wave (Fig. 22–15).
As the serum potassium concentration rises to 6.5–8 mEq/L, the P wave diminishes in amplitude and the PR and QRS intervals prolong. Progressive widening of the QRS complex causes it to merge with the ST segment and T wave, forming a "sine wave." ECG manifestations of hyperkalemia may occur following chronic exposure to numerous xenobiotics, including potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, (Chap. 16), or potassium supplements. Either fluoride, arsine or cardioactive steroid poisoning produces acute hyperkalemia, but the latter rarely produces hyperkalemic ECG changes. Peaked T waves also occur following myocardial ischemia and may also be confused with early repolarization effects ("The ST Segment"). Consequently, the ability to properly identify electrolyte abnormalities by electrocardiography is often limited.

Hypokalemia typically reduces the amplitude of the T wave and, ultimately, causes the appearance of prominent U waves (see Fig. 22–15). Its effects on the ECG are manifestations of altered myocardial repolarization. Lithium similarly affects myocardial ion fluxes and causes reversible changes on the ECG that may mimic mild hypokalemia, although documentation of low cellular potassium concentrations is lacking. Patients chronically poisoned with lithium have more T-wave abnormalities (typically flattening) than do those who are poisoned acutely, but these abnormalities are rarely of clinical significance.[55]

■ THE QT INTERVAL

The QT is measured from the beginning of the QRS complex to the end of the T wave. The QT interval normally varies because of biologic diurnal effects and autonomic tone; technical issues with the environment or with processing and acquiring the ECG; and intra- and inter-observer variability.[3,37,38] The bipolar limb lead with the largest T wave should therefore be used for this measurement.

The QT interval is normally prolonged at slower heart rates and shortens as the heart rate increases. This is especially important since many of the xenobiotics that affect the QT interval also affect the heart rate. As the normal QT varies also with the heart rate, numerous formulas and tables are available to obtain the corrected QT, known as the QTc.[21] Using the QTc allows the determination of the appropriateness of the QT independent of the heart rate.

With a rate of 50–90 beats/min, the commonly used Bazett formula (QTc (msec) = QT (msec)/$\sqrt{\text{RR interval (sec)}}$ is adequate for determining a rate corrected QT interval (QTc). The RR interval is calculated as 60/heart rate per minute. In this heart rate range, 99% of men have a QTc < 450 msec and 99% of women have a QTc < 460 msec.[39] A QTc interval > 500 msec weakly correlates with an increased risk of developing ventricular dysrhythmias. However, at higher heart rates, a normal patient will have an inaccurately calculated "prolonged" QTc interval using the Bazett formula. Studies suggest that medications such as bupropion prolong the QT interval when the "increase" in the QTc may be only a result of the increased heart rate.[24] A variety of formulas and corrections are proposed to attempt to identify normal QT intervals on ECGs at higher heart rates,[5,15,32] including the Friderician formula (QTc = QT/$^3\sqrt{\text{RR interval (sec)}}$) and the Framingham linear regression analysis (QTLC = QT + 0.154 (1-RR)).[50] Which correction formula is optimal remains unknown, and the FDA requests that sponsors use multiple calculations when performing a "thorough QT study" for any drug with prodysrhythmic potential.[19]

With slow heart rates, a prominent U wave can obscure the terminal portion of the T wave and with fast heart rates the subsequent P wave can obscure the terminal portion of the T wave. In these patients the QTc should be estimated by following the downslope of the T wave. The QTc is often measured to approximate repolarization, although this is not fully appropriate because alterations in depolarization, such as excess Na⁺ entry, may affect it.

QT interval measurements from the computerized ECG algorithms are less accurate than careful manual determinations of the interval.[25] In August 2000, a panel of experts convened to address these issues and suggested that the QT interval should be measured manually in one of the limb leads that best shows the end T wave; the QT interval should be measured and averaged over 3 to 5 beats; and large U waves should be included in the QT interval measurement if they merge into the T wave and obscure the end of the T wave.[4] However, a subsequent study of 334 healthcare practitioners found that only 60% of the physicians were able to correctly measure a sample QT interval on the survey, although nearly all indicated correctly the measurement should be from the beginning of the QRS to the end of the T wave.[28]

Electrophysiology The QT represents the entire duration of ventricular systole and thus is made up of several electrophysiologic periods. Prolongation of the QT interval generally corresponds to an increase in the duration of phase 2 or phase 3 of the action potential. Although as noted above depolarization abnormalities can affect the QT, these are uncommon, and the plateau phase and repolarization are primarily reflected by the QT. Variations in the speed of the paper,[18] T-wave morphology, irregular baseline, and the presence of U waves may make this determination difficult.[4]

The abnormal QT interval A prolonged QT reflects an increase in the time period that the heart is "vulnerable" to the initiation of ventricular

---

dysrhythmias (Table 22–1, Fig. 22–16). This occurs because although some myocardial fibers are refractory during this time period, others are not (ie, relative refractory period). Early afterdepolarizations (EADs) may occur in patients with lengthened repolarization time (Table 22–2). An EAD occurs when a myocardial cell spontaneously depolarizes before its repolarization is complete (Fig. 22–17). If this depolarization is of sufficient magnitude, it may capture and initiate a premature ventricular contraction, which itself may initiate ventricular tachycardia, ventricular fibrillation, or torsades de pointes. There are two types of EADs based on whether they occur during phase 2 (type 1) or phase 3 (type 2) of the cardiac action potential. The ionic basis of EADs is unclear, but may be via the L-type calcium channel; EADs are suppressed by magnesium.[7]

Xenobiotics that cause sodium channel blockade (Chap. 63) prolong the QT duration by slowing cellular depolarization during phase 0. Thus, the QT duration increases because of a prolongation of the QRS complex duration, and the ST segment duration remains near normal. Xenobiotics that cause potassium channel blockade similarly prolong the QT, but through prolongation of the plateau and repolarization phases. This specifically prolongs the ST segment duration. Although at a cellular level these xenobiotics are antidysrhythmic, the multicellular effects may be prodysrhythmic. The highly selective serotonin reuptake inhibitor citalopram, causes QT prolongation due

to the sodium and calcium channel blocking effects of its metabolite didemethyl-citalopram. In a recent large retrospective cohort study, users of both typical antipsychotics (thioridazine and haloperidol) and atypical antipsychotics (clozapine, quetiapine, olanzapine, risperidone) had a risk of sudden cardiac death that was twice that of non users of

antipsychotics. Xenobiotic induced QT prolongation and the subsequent risk of dysrhythmias is the postulated etiology.[46] Hypocalcemia may produce a prolonged QT interval, and is caused by a number of xenobiotics, including fluoride, calcitonin, ethylene glycol, phosphates, and mithramycin (Table 16-9). Hypokalemia alone does not usually prolong the QT. Arsenic poisoning may cause prolongation of the QT and result in torsades de pointes. The mechanism is unknown, although either a direct dysrhythmogenic effect or an autoimmune myocarditis are postulated.

QT dispersion The QT interval may vary in duration from lead to lead, reflecting a dispersion or variability in regional myocardial repolarization. The normal QT interval dispersion is around 30 to 70 msec. The conduction characteristics vary regionally throughout the heart. For example, the subendocardial cells have a longer action potential duration than do epicardial cells; this is called dispersion of repolarization and is normal. This is important to allow the heart to contract and relax in an appropriate manner even though the impulse takes time to travel through the full thickness of the myocardial wall, from endocardium to epicardium. The subpopulations of the various ion channels (primarily potassium channels in the setting of repolarization) differ in character and density and account for this variation.[40] Ischemia and drugs preferentially affect certain layers of the myocardium and alter, generally increase, the regional heterogeneity of repolarization. This is reflected on the ECG as an increase in QT dispersion. This prolonged vulnerable phase is associated with occurrences of ventricular dysrhythmias. A measured QT dispersion greater than 80 msec after myocardial infarction was associated with VT with a sensitivity of 73% and a specificity of 86%.[44] This heterogeneity is also correlated with both the efficacy and prodysrhythmic potential of therapy.[53] Overall however, assessment of QT dispersion (from a standard 12-lead ECG) has not gained popularity as a useful clinical tool in part due to technologic limitations.

FIGURE 22–17. Afterdepolarization. (**A**) The normal action potential. (**B**) Prolonged duration action potential. (**C**) Prolonged duration action potential with an early afterdepolarization (EAD) (↓) occurring during the downslope of phase 3 of the action potential. (**D**) Early afterdepolarization that reaches the depolarization threshold and initiates another depolarization, or a triggered beat. (**E**) Delayed afterdepolarization (↓) which occurs after repolarization is complete.

■ THE U WAVE

The U wave is a small deflection that occurs after the T wave and usually with a similar orientation. Distinguishing a U wave from a notched T wave is difficult. The apices of a notched T wave are usually < 150 msec apart, and the peaks of a TU complex are > 150 msec apart.

Electrophysiology U waves occur when there is fluctuation in the membrane potential following myocardial repolarization. Prominent U waves are generally representative of an underlying electrophysiologic abnormality, although they may be physiologic. Physiologic U waves may be caused by repolarization of the Purkinje fibers, or they may correspond to late repolarization of myocardial cells in the mid-myocardium, and are implicated in the initiation of cardiac dysrhythmias.[4]

FIGURE 22–18. Mechanism of reentry dysrhythmias. An impulse traveling down a conduction pathway reaches a branch point with one branch refractory (*C*). The impulse is conducted down branch *A* and spreads through the myocardium eventually to reach *B*, the distal end of the originally refractory branch. However, branch *C* is no longer refractory, and the impulse is conducted retrograde up through branch *C*, again to be conducted down branch *A*. The myocardium is depolarized during each loop around the circuit as the impulse spreads from the distal end of branch *A* to the rest of the heart.

The abnormal U wave Abnormal U waves are typically caused by spontaneous afterdepolarization of membrane potential that occurs in situations where repolarization is prolonged (see Fig. 22–17). EAD occurs in situations where the prolonged repolarization period allows calcium channels (which are both time and voltage dependent) to close and spontaneously reopen because they may close at a membrane potential that is above their threshold potential for opening. In this situation, the opening of the calcium channels produces a slight membrane depolarization that is identified as a U wave. Delayed afterdepolarization (DAD) occurs when the myocyte is overloaded with Ca^{2+}, as in the setting of cardioactive steroid toxicity. The excess intracellular Ca^{2+} can trigger the ryanodine receptors on the myocyte sarcoplasmic reticulum to release Ca^{2+}, causing slight depolarization that is recognized as a U wave. If the U waves are of sufficient magnitude to reach threshold, the cell may depolarize and initiate a premature ventricular contraction. Transient U-wave inversion can also be caused by myocardial ischemia or systemic hypertension.

The abnormal QU interval The QU interval is the distance between the end of the Q wave and the end of the U wave. Differentiation between the QU and the QT intervals is difficult if the T and U waves are superimposed. When hypomagnesemia coexists with hypokalemia, as is usually the case, QU prolongation and torsades de pointes may occur.[56]

CARDIAC DYSRHYTHMIAS AND CONDUCTION ABNORMALITIES

Xenobiotics may produce adverse effects on the electrical activity of the heart, often by acting directly on the myocardial cells. Because metabolic abnormalities (especially acidemia, hypotension, hypoxia, and electrolyte abnormalities) can further exacerbate the toxicity, or can actually be the sole cause of the cardiovascular abnormalities, correction of metabolic abnormalities must be a high priority in the treatment of patients with cardiovascular manifestations of poisoning. The terminal phase of any serious poisoning may include nonspecific hemodynamic abnormalities and cardiac dysrhythmias. However, many xenobiotics directly or primarily affect cardiac rhythm or conduction, often through effects on the cardiac ion channels.

The distinction between xenobiotics that cause a rapid rate and those that cause a slow rate on the ECG is somewhat artificial, because many can do both. For example, patients poisoned by CAs almost always develop sinus tachycardia, but most die with a wide complex bradycardia. In either case, abnormalities in the pattern or rate on the ECG can provide the clinician with immediate information about a patient's cardiovascular status. ECG disturbances in many poisoned patients may be categorized in more than one manner (abnormal pattern, fast rate, slow rate). In any case, when electrocardiographic abnormalities are detected, appropriate interpretation, evaluation, and therapy must be rapidly performed.

Xenobiotics that directly cause dysrhythmias or cardiac conduction abnormalities usually affect the myocardial cell membrane. Other xenobiotics that modify ion channels may alter the transmembrane potentials within myocytes and may result in the spontaneous generation of an abnormal rhythm.

■ MECHANISMS OF DYSRHYTHMIA INITIATION AND PROPAGATION

Dysrhythmias can be related to one or more of 3 mechanisms: abnormal spontaneous depolarization (enhanced automaticity), afterdepolarization (triggered automaticity), and reentry.[40] In normal myocardium, spontaneous, phase 4 depolarization occurs most rapidly in the sinus node, the normal pacemaker for the heart. Speeding or slowing the rate of phase 4 depolarization of the pacemaker cell results in sinus tachycardia or sinus bradycardia, respectively. However, xenobiotics can also speed the depolarization of other myocardial cells that have pacemaker potential allowing them to overtake the sinus node as the primary pacemaker. This mechanism, called increased automaticity, accounts for many of the dysrhythmias that occur with cardioactive steroid and β-adrenergic agonist poisoning.

Dysrhythmias can also result from spontaneous oscillations in the membrane potential, called afterdepolarizations, mentioned above, that occur during phase 3 or 4 of the action potential. If the oscillations are of sufficient magnitude to reach the threshold potential, the fast sodium channels open and an action potential occurs. These spontaneous oscillating depolarizations are mediated by depolarizing inward Ca^{2+} currents, primarily through the L-type calcium channels. EADs occur during the plateau phase (phase 2) or during the downslope (phase 3) of the action potential. Oscillations in the membrane potential that occur after repolarization is complete, during phase 4, are called DADs. EADs most commonly occur in situations in which the action potential is prolonged, typically as a consequence of the blockade of I_{Kr} (such as by antidysrhythmic agents). EADs account for the "trigger beats" that initiate episodes of VT, commonly torsades de pointes (TdP), as discussed below. DADs occur primarily under conditions of increased intracellular Ca^{2+}, and account for many of the dysrhythmias that are associated with cardioactive steroid toxicity.[40] The increased Ca^{2+} may also come from extensive sympathetic stimulation.

Most afterdepolarizations do not propagate rapidly throughout the myocardium and do not generate ectopic beats. However, because the normal dispersion of repolarization is increased by certain xenobiotics, ectopic beats (eg, an atrial premature contraction or ventricular premature contraction) may propagate abnormally within the myocardium. Ectopy is the ECG manifestation of myocardial depolarization initiated from a site other than the sinus node. Ectopy may be lifesaving under circumstances in which the atrial rhythm cannot be conducted to the ventricles (ie,"escape rhythm"), as during high-degree AV blockade induced by cardioactive steroids. (Chap. 64). Alternatively, ectopy may lead to dramatic alterations in the physiologic function of the heart or deteriorate into lethal ventricular dysrhythmias.
FIGURE 22–19. Digoxin-induced bidirectional ventricular tachycardia. The ECG demonstrates the alternating QRS axis characteristic of bidirectional ventricular tachycardia and is nearly pathognomonic for cardioactive steroid poisoning. The 89-year-old patient's serum digoxin concentration was 4.0 ng/mL. (Image contributed by Ruben Olmedo, MD, Mount Sinai School of Medicine.)

Occasionally, because of the altered regional repolarization, an impulse may reach a branch point with a partial block (ie, relatively refractory) to conduction in one of the branches (Fig. 22–18). The impulse is carried through only one of the branches and then spreads through the myocardial cells. After a short delay, the impulse reaches the distal end of the previously blocked pathway. By this time, the region is no longer refractory and conducts the impulse in a retrograde fashion. The impulse may continue in a continuous loop circuit, depolarizing the heart with each passage; this process is called reentry. Reentry mechanisms appear to be responsible for the majority of the malignant tachydysrhythmias attributable to poisoning.

■ TACHYDYSRHYTHMIAS

Both supraventricular and ventricular tachydysrhythmias can occur in poisoned patients (Table 22–3). Sinus tachycardia is the most common rhythm disturbance that occurs in poisoned patients. Parasympatholytic xenobiotics, such as atropine, raise the heart rate to its innate rate by eliminating the inhibitory tonic vagal influence. However, more rapid rates require direct myocardial stimulatory effects, generally mediated by β-adrenergic agonism. For example, catecholamine excess, as occurs in patients with cocaine use, psychomotor agitation, or fever, may cause sinus tachycardia with rates faster than 150 beats/min. Ventricular dysrhythmias frequently accompany hypotension, hypoxia, acidemia, electrolyte abnormalities, and other metabolic derangements that may be present in poisoned patients or may be a direct effect of the xenobiotic.

The intrinsic pacemaker cells of the heart undergo spontaneous depolarization and reach threshold at a predictable rate. Under normal circumstances the sinus node is the most rapidly firing pacemaker cell of the heart; and as a result it controls the heart rate. Spontaneous depolarization occurs via ion entry through potassium, sodium, and calcium channels via phase 4 of the action potential. Other potential pacemakers exist in the heart, but their rate of spontaneous depolarization is considerably slower than that of the sinus node. Thus, they are reset during depolarization of the myocardium and they never spontaneously reach threshold. Xenobiotics, such as sympathomimetics, which speed the rate of rise of phase 4, or diastolic depolarization, speed the rate of firing of the pacemaker cells. As long as the sinus node is preferentially affected, it maintains the pacemaker activity of the

heart. If the firing rate of another intrinsic pacemaker exceeds that of the sinus node, ectopic rhythms may develop. This effect may be either pathologic or lifesaving, depending on the clinical circumstances.

Certain xenobiotics are highly associated with ventricular tachydysrhythmias following poisoning. Those that increase the adrenergic tone on the heart, either directly, or indirectly, may cause ventricular dysrhythmias. Whether a result of excessive circulating catecholamines observed with cocaine and sympathomimetics, myocardial sensitization secondary to halogenated hydrocarbons or thyroid hormone, or increased second messenger activity secondary to theophylline, the extreme inotropic and chronotropic effects cause dysrhythmias. Altered repolarization, increased intracellular Ca^{2+} concentrations, or myocardial ischemia can cause the dysrhythmia. Additionally, xenobiotics that produce focal myocardial ischemia, such as cocaine, ephedrine, or ergots can lead to malignant ventricular dysrhythmias. Finally, an uncommon cause of xenobiotic-induced ventricular dysrhythmias is persistent activation of sodium channels, such as following aconitine poisoning. Although not all wide QRS complex tachydysrhythmias are ventricular in origin, making this assumption is generally considered to be prudent. For example, in a patient known to be poisoned with cyclic antidepressants, cocaine, or similar agents ("The QRS Complex"),
FIGURE 22–20. Torsades de pointes in a patient who ingested an unknown amount of thioridazine.

the differentiation of aberrantly conducted sinus tachycardia (common) from ventricular tachycardia (rare) is important, but difficult. Although guidelines for determining the origin of a wide complex tachydysrhythmia exist,[13] they are imperfect, difficult to apply, and unstudied in poisoned patients.

TABLE 22–4. Xenobiotics That Cause Conduction Abnormalities and/or Heart Block

α_1-Adrenergic agonists
α_2-Adrenergic agonists
β-Adrenergic antagonists
Amantadine
Anesthetics (local)
Antidepressants
Antidysrhythmics (class I and III)
Antihistamines
Antimicrobials
    Chloroquine and quinine
    Macrolides
    Quinolones
Antipsychotics
    Atypical antipsychotics (quetiapine, olanzapine, risperidone)
    Droperidol
    Haloperidol
    Phenothiazines
Calcium channel blockers
Carbamazepine
Cardioactive steroids
Cholinergics
Cocaine
Cyclic antidepressants
Cyclobenzaprine
Electrolytes
    Potassium
    Magnesium
Metal salts
    Arsenic
Methadone
Pentamidine
Propoxyphene

Bidirectional ventricular tachycardia is associated with severe cardioactive steroid toxicity and results from alterations of intraventricular conduction, junctional tachycardia with aberrant intraventricular conduction, or, on rare occasions, alternating ventricular pacemakers (see Figure 22–19). Aconitine, usually obtained from traditional Chinese or other alternative therapies that contain plants of the Aconitum spp (such as *Aconitum napellus* (monkshood)), may cause bidirectional ventricular tachycardia (Chaps. 43 and 118).

■ TACHYDYSRHYTHMIA ASSOCIATED WITH A PROLONGED QT INTERVAL: TORSADES DE POINTES

Xenobiotics that alter myocardial repolarization and prolong the QT interval predispose to the development of afterdepolarization-induced contractions during the relative refractory period (R on T phenomena), which may initiate ventricular tachycardia. If torsades de pointes (TdP) is noted this is undoubtedly the mechanism, and the QT interval should be carefully assessed and appropriate treatment initiated (Fig. 22–20).

Ventricular tachycardia, including TdP, is usually a reentrant-type rhythm. The presence of a prolonged QT interval on the ECG may indicate the possible existence of conditions within the myocardium that favor occurrence of reentry dysrhythmias, as discussed above. The long action potential duration resulting from prolongation in the duration of phase 2 or phase 3 increases the occurrence of EADs. These, in combination with an increased dispersion of repolarization, increase the risk for reentrant dysrhythmias, particularly TdP.

Many xenobiotics may also interact with cardiac membrane ion channels and increase the risk of TdP. Most of these xenobiotics interact with the HERG-encoded subunit of the potassium channel to reduce the current through the I_{Kr} channel and prolong the action potential duration. The HERG subunit of the channel is particularly susceptible to xenobiotic interactions because of the larger inner cavity with aromatic binding domains.[48,47,54] Acquired QT interval prolongation and TdP from xenobiotics occur most often with class Ia and Ic antidysrhythmics, the cyclic antidepressants, and the antipsychotics. Although the class Ic antidysrhythmics (such as encainide and flecainide) cause greater QT prolongation, the class Ia agents (such as quinidine and procainamide) are responsible for more reported cases. This is probably a result of the relatively infrequent use of the class Ic antidysrhythmics, due paradoxically, to concerns about the higher risk of prodysrhythmic effects. Class Ib agents, such as lidocaine, have no significant effect on potassium channels and the QT interval, and do not cause TdP. Acquired QT interval prolongation and TdP also commonly result from metabolic and electrolyte abnormalities, particularly hypocalcemia, hypomagnesemia, and hypokalemia (Chapters 16 and 63).

■ BRADYDYSRHYTHMIAS

Bradycardia, heart block, and asystole are the terminal events following fatal ingestions of many xenobiotics, but some xenobiotics tend to

cause sinus bradycardia (see Table 23–2) and conduction abnormalities (see Table 23–3) early in the course of toxicity. Sinus bradycardia with an otherwise normal electrocardiogram is characteristic of xenobiotics that reduce central nervous system outflow (Chap. 23). Xenobiotics that cause CNS sedation, such as the sedative-hypnotics, most opioids, and α_2-adrenergic receptor agonist ("centrally acting") antihypertensive drugs, will usually decrease sympathetic outflow to the heart and produce a heart rate in the range of 40–60 beats/min. Differentiating among these xenobiotics is not possible based on ECG criteria alone. Xenobiotics that directly affect ion flux across myocardial cell membranes cause abnormalities in AV nodal conduction. Calcium channel blockers, β-adrenergic receptor antagonists, and cardioactive steroids (Chaps. 60, 61, and 64) are the leading causes of sinus bradycardia and conduction disturbances. Indirect metabolic effects may also be contributory; such as severe hyperkalemia (which may accompany any acidosis) that results in a wide complex, sinusoidal bradycardic rhythm.

Xenobiotics that have direct depressant effects on the cardiac pacemaker are most likely to produce bradycardia. The ECG manifestations of calcium channel blocker and β-adrenergic antagonist overdoses are difficult to distinguish. In general, both drug classes cause decreased dromotropy (conduction), although the specific pharmacologic actions of the drugs differ even within the class. For example, most members of the dihydropyridine subclass of calcium channel blockers do not have any antidromotropic effect, whereas verapamil and diltiazem routinely produce PR prolongation. Similarly, while most β-adrenergic antagonists produce sinus bradycardia and first-degree heart block, certain members of this group, such as propranolol, may prolong the QRS complex through their sodium channel blocking abilities (Chap. 61). Others, such as sotalol, which have properties of the class III antidysrhythmics, block myocardial potassium channels and prolong the QT interval duration. The bradycardia produced by cardioactive steroids is typically accompanied by electrocardiographic signs of "digitalis effect," including PR prolongation and ST segment depression (Chap. 64).

TABLE 22–5. Classes of Antidysrhythmics

Class	Pharmacologic Blockade			Prolongation of ECG Intervals			
	Sodium Channels	Potassium Channels	Calcium Channels	PR	QRS	QT	Examples
Sodium channel blockers							
IA	++/+++	++	0	±	↑	↑	Disopyramide Procainamide Quinidine
IB	+/++	±	0	±	±	±	Lidocaine Phenytoin Mexiletine Tocainide
IC	+++	++/+++	0	↑	↑	↑↑	Encainide Flecainide Propafenone Moricizine
β-Adrenergic antagonists							
II	0	0	+(indirect)	↑	±	±	Propranolol Atenolol Esmolol Metoprolol Timolol
Potassium channel blockers							
III	+	++	0	↑	±	↑	Amiodarone Bretylium Sotalol Ibutilide[a]
Calcium channel blockers							
IV	0	0	+++	↑	±	±	Verapamil Diltiazem

+ = Mild blockade; + + = moderate blockade; + + + = marked blockade; ↑ = increases; ± = no significant effect

[a] Ibutilide activates a slow inward sodium channel rather than blocking outward potassium currents, but is classified as class III because of its increased action potential duration and atrial and ventricular refractoriness, which are typical of class III Antidysrhythmics. ∗ = Vaughan-Williams classification.

CONDUCTION ABNORMALITIES AND ATRIOVENTRICULAR NODAL BLOCK

The cardiac toxicity of some xenobiotics results from their effects on the propagation of the electrical impulse through the conduction system of the heart. The ECG abnormalities produced may be a result of effects on the AV node, producing first-, second-, or third-degree (complete) heart block, or on the His-Purkinje system, producing intraventricular conduction delays such as bundle-branch blocks. The effects of xenobiotics on myocardial conduction are often mediated through interactions with the sodium or potassium membrane channels. For example, xenobiotics that affect the fast inward I_{Na} currents (such as the type I antidysrhythmics and cyclic antidepressants) prolong the action potential duration, slow ventricular myocyte depolarization, and slow intraventricular conduction. This produces widening of the QRS complex and prolongation of the QT interval on the ECG. Table 22–4 lists some of the xenobiotics that cause conduction abnormalities. Many of the antidysrhythmics derive their clinical benefit from their ability to alter sodium and potassium channel function and slow conduction through the myocardium. Xenobiotics that depress phase 0 (the inward I_{Na} currents) produce slowing of conduction and widening of the QRS complex. Xenobiotics that prolong depolarization and repolarization (phase 2 or phase 3 of the action potential) produce prolongation of the QT interval on the ECG. The classes of the antidysrhythmics, their effects on the ion channels and on the action potential, and the resulting ECG abnormalities, are shown in Table 22–5 and discussed in detail in Chap. 63.

THE PEDIATRIC ELECTROCARDIOGRAM

■ THE NORMAL PEDIATRIC ECG

The normal pediatric ECG differs in many ways from the normal adult ECG. The resting heart rate of infants and children is substantially faster than that of adults and, in general, conduction is faster. In a term infant, the right ventricle is substantially larger than the left, and the ECG demonstrates prominent R waves in the right precordium and deep S waves in the left lateral precordium.[42] This may be misinterpreted as cyclic antidepressant toxicity.[9] An adult ratio of left to right ventricular size is usually reached by the age of 6 months. In infants, Q waves commonly exist in the inferior and lateral precordial leads, but are abnormal in leads I and aV_L. The T waves are the most notable difference between pediatric and adult ECGs. The T waves in the right precordial leads in children are deeply inverted until 7 years and sometimes older, in which case it is called a persistent juvenile T-wave pattern.

■ THE ABNORMAL PEDIATRIC ECG

Although congenital heart disease is the most common cause of ECG abnormalities in children, electrolyte disorders and xenobiotics may also cause changes in electrophysiology that are reflected on the ECG. Abnormalities that are useful markers on the adult ECG may not always be as useful in children. For example, in older children, a retrospective chart review of 37 children diagnosed with tricyclic antidepressant overdose and 35 controls (all younger than 11 years) found interpatient variability, unrelated to age, so great that a rightward deviation of the terminal 40-msec QRS axis could not distinguish between poisoned and healthy children.[9]

SUMMARY

The ECG is one of the few widely available diagnostic procedures that reveals immediate, useful clinical information. This has far-reaching implications in toxicology, where other diagnostic test results often return too late to effectively impact the care of an acutely poisoned patient.

CHAPTER 23
HEMODYNAMIC PRINCIPLES

Robert A. Hessler

Adequate tissue perfusion depends on maintenance of volume status, vascular resistance, cardiac contractility, and cardiac rhythm. The components of the hemodynamic system are vulnerable to the effects of xenobiotics. Cardiovascular toxicity may therefore be manifested by the development of hemodynamic instability, heart failure, cardiac conduction abnormalities, or dysrhythmias. The presence of a specific pattern of cardiovascular anomalies (toxicologic syndrome or "toxidrome") may suggest a particular class or type of xenobiotic. Conduction and rhythm disturbances are discussed in detail in Chapter 22.

An alteration in hemodynamic functioning may be a result of indirect metabolic effects. Poisoning with a xenobiotic may lead to hemodynamic changes secondary to the development of acid base disturbances, hypoxia, or electrolyte abnormalities. In these patients, supportive care with ventilation, oxygenation, and fluid and electrolyte repletion will usually improve the cardiovascular status

PHYSIOLOGY OF THE HEMODYNAMIC SYSTEM

Maintaining cardiac contractility, heart rate and rhythm, and vascular resistance requires complex modulation of the cardiac and vascular systems. Xenobiotics can cause hemodynamic abnormalities as a result of direct effects on the myocardial cells, on the cardiac conduction system, or on the arteriolar smooth muscle cells. These effects are frequently mediated by interactions with cellular ion channels or cell membrane neurohormonal receptors. Ion channels are discussed in detail in Chapter 22.

■ THE AUTONOMIC NERVOUS SYSTEM AND HEMODYNAMICS

In addition to the voltage dependent ion channels, the cell membrane contains channels that open in response to receptor binding of neurotransmitters or neurohormones.[42,43,44] The hemodynamic effects of many xenobiotics are mediated by interactions with membrane receptors and by changes in the autonomic nervous system. The autonomic nervous system is functionally divided into the sympathetic (ie, adrenergic) and parasympathetic (ie, cholinergic) systems. The two systems, which share certain common features, function semi-independently of each other. Through complex feedback, the two systems provide the balance needed for existence under changing external conditions.

The sympathetic nervous system is primarily responsible for the maintenance of arteriolar tone and cardiac function. Although the ganglionic neurotransmitter of the sympathetic nervous system is acetylcholine, norepinephrine is its primary postganglionic neurotransmitter. On release into the synapse, norepinephrine binds to the postsynaptic adrenergic receptors to elicit an effect by the postsynaptic cell.

ADRENERGIC RECEPTORS

■ CELLULAR PHYSIOLOGY OF ADRENERGIC RECEPTORS

The effects of adrenergic xenobiotics on the cell are primarily mediated through a secondary messenger system of cyclic adenosine monophosphate (cAMP). The intracellular cAMP concentration is regulated by the membrane interaction of three components: the adrenergic receptor, a "G-protein" complex, and adenyl cyclase, the enzyme that synthesizes cAMP in the cell.[7,19,59,60] These receptors are described in detail in Chap. 13.

The G protein serves as a "signal transducer" between the receptor molecule in the cell membrane and the effector enzyme, adenyl cyclase, in the cytosol. The G proteins consist of 3 subunits: α, β, and γ.[11,37,38] The α subunit of the G protein complex binds to the adrenergic receptor in the cell membrane and to the adenyl cyclase enzyme. The G protein complex exists in several isomeric forms, depending on their interactions with the adenyl cyclase enzyme. G_s proteins contain α_s subunits that stimulate adenyl cyclase when "activated" by adrenergic receptor interaction. β_1- and β_2-adrenergic receptors interact primarily with β_s subunits in stimulatory G_s protein complexes. The α_i subunits of G_i proteins inhibit the activity of adenyl cyclase. β_2-adrenergic receptors and α_2-adrenergic receptors interact with inhibitory G_i proteins. A third form, G_q, interacts with the α_1-adrenergic receptors, but does not interact directly with adenyl cyclase. Instead, the G_q interacts with phospholipase C to mediate the cell response to α_1-adrenergic stimulation.

In the absence of a catecholamine at the receptor site, the receptor protein is bound to the β and $\beta\gamma$ dimers of the G protein, and guanosine diphosphate (GDP) is bound to the α subunit. Catecholamine binding to the receptor causes a conformational change in the α subunit; GDP dissociates and guanosine triphosphate (GTP) binds to the α subunit. The α subunit (with GTP bound) then dissociates from the receptor and from the $\beta\gamma$ dimer. This "activated" α subunit can now interact with adenyl cyclase or other effector enzymes. Interaction of the α_s subunit with adenyl cyclase increases the activity of the enzyme resulting in a rapid increase in the intracellular cAMP (Fig. 23–1).[7,11,32,37,50]

cAMP acts as a secondary messenger in the cell. cAMP interacts with protein kinase A (PKA) and other cAMP-dependent protein kinases to increase their protein phosphorylating activity.[31] In the absence of cAMP, PKA is a tetramer of two regulatory and two catalytic subunits. cAMP binds to the regulatory subunits to release the active enzymatic units from the tetramer (see Fig. 23–1). The activated protein kinases then transfer phosphate groups from ATP to serine (as well as to threonine and tyrosine amino acid groups) on enzymes that are involved in intracellular regulation and activities. Phosphorylation may increase or decrease the activity of specific enzymes, and specific protein kinases are highly selective in the proteins that they phosphorylate.[56,57]

PKA phosphorylates a variety of cellular proteins involved in Ca^{2+} regulation, including the voltage-sensitive calcium channel, phospholamban, and troponin.[23,24,55] Phosphorylation of the L-type calcium channel increases the entry of calcium ions during membrane depolarization.[41] Phosphorylation of phospholamban decreases its activity to inhibit the calcium ATPase pump on the SR. This decreased inhibition of the calcium ATPase pump increases the efficiency of Ca^{2+} storage in the SR, which enhances both cellular contractility as the Ca^{2+} is released into the cell cytosol and the relaxation of muscle fibers as the Ca^{2+} is pumped back into the SR.[41]

Intracellular calcium, calcium channels, and myocyte contractility The contraction and relaxation cycle of the myocyte is controlled by the
FIGURE 23–1. Binding of the β-adrenergic agonist to the β receptor of a myocardial cell causes the Gs protein to activate adenyl cyclase (AC) to produce cyclic adenosine monophosphate (cAMP). The cAMP interacts with and activates protein kinase A (PKA). Subsequent phosphorylation by PKA changes the activity of multiple other various cellular proteins including phospholambam, calcium channels, and troponin, all of which increase the activity of the myocardial cell. (see text). Ca_v-L = L type voltage dependent calcium channel; SR = sarcoplasmic reticulum; RyR = ryanodyne receptor.

flux of Ca^{2+} into and out of the SR into the cytoplasm.[12,30,47] Only a small proportion of the Ca^{2+} involved in myofibril contraction actually enters the cell through the exterior cell membrane during the action potential and membrane depolarization. Invaginations of the myocyte membrane known as T-tubules place L-type calcium channels in close approximation to calcium release channels (ryanodine receptors [RyR]) on the sarcoplasmic reticulum (SR). The local increase in Ca^{2+} concentration that follows the opening of a single L-type calcium channel triggers the opening of the associated RyR channels resulting in a large release of Ca^{2+} from the SR.[9] Myocytes contain tens of thousands of *couplons*, clusters of L-type calcium channels and RyR channels. The Ca^{2+} released from one couplon is not sufficient to trigger firing of neighboring couplons. Myocyte contraction requires synchronized release of Ca^{2+} from numerous couplons throughout the myocyte. This process depends on membrane depolarization to synchronize opening of L-type channels and subsequent Ca^{2+} release.[13,41] This phenomenon of calcium-induced calcium release results in a rapid increase in the intracellular Ca^{2+} concentration, and initiates a rapid myosin and actin interaction.[12]

At the conclusion of cellular contraction, an SR-associated Ca^{2+} ATPase adenosine triphosphatase pump returns the cytosolic Ca^{2+} into the SR. This SR associated Ca^{2+} ATPase pump is regulated by phospholamban, a cellular protein. Phosphorylation of phospholamban decreases its affinity for binding to the Ca^{2+} pump; dissociation of the phosphorylated phospholamban increases the activity of the Ca^{2+} ATPase pump. β-Adrenergic stimulation leads to phosphorylation of phospholamban, dissociation of the phosphorylated phospholamban from the pump, and increase in the total SR Ca^{2+} stores.[16,17] The increased activity of the SR associated Ca^{2+} pump enhances the contractility and increases the rate of relaxation of the myocytes.

Cellular contraction occurs when myosin filaments interact with the actin-tropomyosin helix. A complex of troponin T, troponin I, and troponin C binds to the actin helix near the myosin binding site and act as regulators of the interaction. Troponin T binds the regulatory complex to the actin helix, troponin I prevents myosin from accessing its binding site on the actin helix, and troponin C acts as a Ca^{2+} trigger to initiate contraction. When the intracellular Ca^{2+} concentration increases, 4 molecules of Ca^{2+} bind to troponin C and a conformational shift occurs in the troponin complex. Troponin I shifts and the myosin-binding site is exposed; myosin binds to the exposed site and myofibril contraction occurs (Figure 23–2).[26,27,48,49]

Calcium transport through the cellular membrane ion channels is critical for normal cardiac muscle function and contractility and for maintenance of vascular smooth muscle tone. The physiologic response to calcium channel blockers and to xenobiotics that interact with the α- or β-adrenergic receptors is mediated through changes in the intracellular Ca^{2+}. Calcium channel blockers in current clinical use primarily block the L-type calcium channel, although their specificity differs for the calcium channels on the vascular smooth muscle cells versus myocardial cells. This results in variable effects of different calcium channel blockers on the vascular tone and peripheral vascular resistance, and on the contractility and electrical activity of the myocardial cells. Certain calcium channel blockers block neuronal calcium channels, such as the P/Q type, and are used to treat neurologic disorders such as migraine headache.

Patients poisoned by calcium channel blockers have less Ca^{2+} entry into the cell during cardiac membrane depolarization. Administration of exogenous Ca^{2+} increases the concentration gradient across the cell membrane, enhances flow through available Ca^{2+} channels and restores the triggered response of the RyR-2 channels to release Ca^{2+} from the sarcoplasmic reticulum (see Antidotes in Depth A30: Calcium). Because β-adrenergic antagonists have negative effects on Ca^{2+} handling by the SR, similar effects occur in the myocyte affected by these xenobiotics.

In the vascular smooth muscle, the cytosolic Ca^{2+} concentration maintains basal tone and any decrease of Ca^{2+} influx results in relaxation and arterial vasodilation.[39] The rapid influx of calcium binds
FIGURE 23–2. Troponin regulation of actin and myosin interaction. On the left, Troponin I (TnI) blocks the binding site for myosin on the tropomyosin-actin helix. On the right, calcium binding to troponin C (TnC) causes a conformational shift in the troponin molecules, and myosin is able to bind to the actin helix and initiate myofibril contraction. TnT is Troponin T.

calmodulin, and the resulting complex stimulates myosin light-chain kinase activity.[35] The myosin light-chain kinase phosphorylates, and thus activates, myosin, which subsequently binds actin, causing a contraction to occur (Fig. 60–1).[4,27]

■ PHYSIOLOGIC EFFECTS OF ADRENERGIC RECEPTORS

The existence of two types of adrenergic receptors, α and β, was first proposed in 1948 to explain both the excitatory and the inhibitory effects of catecholamines on different smooth muscle tissue.[1] The α receptor was subsequently further subdivided into α_1 and α_2 when norepinephrine and other α-adrenergic agonists were found to inhibit the release of additional norepinephrine from neurons into the synapse. The α_1-adrenergic receptors are located on postsynaptic cells outside the central nervous system, primarily on blood vessels, and mediate arteriole constriction. The "autoregulatory" α_2 receptors are primarily located on the presynaptic neuronal membrane and, when stimulated, decrease release of additional norepinephrine into the synapse. Some α_2-adrenergic receptors are also found on the postsynaptic membrane. Activation of these postsynaptic α_2-receptors in the cardiovascular control centers in the medulla and elsewhere in the central nervous system decreases sympathetic outflow from the brain. Therefore, α_2-adrenergic agonists generally cause decreased peripheral vascular resistance, decreased heart rate, and decreased blood pressure. The α_1 and α_2 adrenergic receptors also interact with circulating catecholamines and other sympathomimetics. The effects of sympathomimetics vary in the different organ systems due to differences in the adrenergic receptors and in the cellular responses to the receptor interactions.

The β-adrenergic receptors have been subclassified into 3 subtypes: β_1, β_2, and β_3 (Table 23–1). The most prevalent β-adrenergic subtype

TABLE 23–1. Types and Function of the Beta-Adrenergic Receptor

Type	Location	Function
β_1	Heart	Increase rate
		Increase inotropy
		Increase SA and AV node conduction
	Kidney	Increase renin
	Eye	Increase aqueous humor
	Adipose tissue	increase lipolysis
β_2	Heart	Increase rate (?)
		Increase inotropy
	Liver	Increase glycogenolysis
		Increase gluconeogenesis
	Skeletal muscle	Increase glycogenolysis
	Smooth muscle (bronchi, arterioles, GI tract, uterus)	Relaxation
β_3	Adipose tissue	Increase lipolysis
		Increase thermogenesis
	Heart	Decrease inotropy (?)

in the heart is β_1 (80%), although β_2 (20%) and β_3 (few) receptors are also present.[6,14,18,43] Stimulation of the β_1-adrenergic receptors increases heart rate, contractility, conduction velocity, and automaticity. The β_2-adrenergic receptors are primarily responsible for relaxation of smooth muscle with resulting bronchodilation and arteriolar dilation. The β_3 receptors are located primarily on adipocytes where they play a role in lipolysis and thermogenesis.[8]

The β_1, β_2, and α_2 adrenergic receptors all interact with G_s proteins and stimulate the adenyl cyclase enzyme. Differences in the resultant clinical effects are primarily related to the location and number of the different receptors in different tissues and to differences in the specificity of the protein kinases activated by cAMP. Stimulation of the β_1 receptor results in increased heart rate and increased contractility. However, β_2 stimulation causes relaxation, as opposed to contraction, of smooth muscle. Because both β-adrenergic receptor subtypes interact with stimulatory G_s proteins, their clinical effects would appear to be paradoxical. However, there are two primary reasons for the different effect. First, PKA is not a single enzyme, but a group of related isoenzymes variably expressed in different tissues.[5,25,40] The actions and the substrates of the varied protein kinase isoenzymes may differ between β_1- and β_2-responsive tissues. Second, whereas β_1 stimulation results in cAMP-mediated effects throughout the cytoplasm, β_2 stimulation is compartmentalized within the cell. The effect of β_2 stimulation of G_s type receptors is localized phosphorylation of the L-type calcium channels, increasing their activity.[10,28,64,65] β_2 receptors are also coupled to G_i-type receptors that inhibit adenyl cyclase and prevent the diffuse cytoplasmic increases in cAMP.[52,53,64] Additionally, β_2-receptor stimulation does not result in phosphorylation of phospholamban[29] or troponins.[10]

The α_2-adrenergic receptor interacts with a G_i protein that has an inhibitory interaction with adenyl cyclase. Binding of α_2 adrenergics to the receptor results in inhibition (not stimulation) of adenyl cyclase and to a decrease in the intracellular cAMP.

The α_1-adrenergic receptors also are associated with G proteins. However, rather than being associated with G_s proteins and adenyl cyclase, the α_1-adrenergic receptors are associated with G_q proteins that are linked to phospholipase C.[58] Binding to the receptor activates the hydrolysis of phosphatidyl inositol 4,5-bisphosphate (PIP_2) to 1,2-diacylglycerol (DAG) and inositol triphosphate (IP_3).[22] The IP_3, acting as an intracellular messenger, binds to receptors on the SR and initiates the release of calcium ion.[3] DAG activates protein kinase C, which phosphorylates slow calcium channels and other intracellular proteins, and increases the influx of calcium ion into the cell (Figure 23–3).[45,51,67]

Many xenobiotics interact with G-protein membrane receptors and alter the intracellular cAMP or Ca^{2+} concentration. β-Adrenergic antagonist overdose results in decreased stimulation of adenyl cyclase by G_s proteins, decreased production of cAMP, decreased activation of the cAMP-dependent kinases, and decreased Ca^{2+} release (Chap. 61). Similarly, by different mechanisms, calcium channel blocker overdose results in decreased cytoplasmic calcium concentration (Chap. 60).

Glucagon receptors, which are similar to the β-adrenergic receptors, are coupled to G_s proteins and stimulate adenyl cyclase activity.[2,20,29,62,66] The ability of glucagon to increase cAMP is further enhanced by its inhibitory activity on phosphodiesterase (preventing cAMP breakdown).[15,36] Phosphodiesterase inhibitors, such as amrinone, milrinone, and enoximone, exert at least some of their inotropic activity by preventing the degradation of cAMP and enhancing calcium cycling.[33,61,63] In a canine model of propranolol poisoning, amrinone significantly increased inotropy, stroke volume, and cardiac output.[33]

FIGURE 23–3. Binding of the α-adrenergic agonist to the α-1 adrenergic receptor causes the G protein to activate phospholipase C (PLC). PLC catalyzes the hydrolysis of 4,5-bisphosphate (PIP) to produce 1,2-diacylglycerol (DAG) and inositol triphosphate (IP_3). IP_3 interacts with the ryanodyne receptor (RyR) on the sarcoplasmic reticulum to enhance release of calcium from this cellular store. The calcium and DAG activate protein kinase C, which phosphorylates and changes the activity of various cellular proteins including phospholambam (see text) Ca_v-L = L type voltage dependent calcium channel.

TABLE 23–2. Xenobiotics that Cause Bradycardia

α_1-Adrenergic agonists (reflex bradycardia)
  Phenylephrine
  Phenylpropanolamine
α_2-Adrenergic agonists (centrally acting)
  Clonidine

  Physostigmine
Opioids
Sedative hypnotics
Sodium channel openers
  Aconitine
  Andromedotoxin
  Ciguatoxin
  Veratridine

CARDIOVASCULAR EFFECTS OF XENOBIOTICS

Xenobiotics may produce adverse effects on the cardiovascular system by acting on the myocardial cells or the autonomic nervous system to affect the heart rate, blood pressure or cardiac contractility, directly. Because metabolic abnormalities (especially acidemia, hypotension, hypoxia, and electrolyte abnormalities) can further exacerbate the toxicity, or can be the sole cause of the cardiovascular abnormalities, correction of metabolic abnormalities must be a high priority in the treatment of patients with cardiovascular manifestations of poisoning. The terminal phase of any serious poisoning may include nonspecific hemodynamic abnormalities and cardiac dysrhythmias.

■ HEART RATE ABNORMALITIES

Xenobiotics that directly cause dysrhythmias or cardiac conduction abnormalities usually affect the myocardial cell membrane. These abnormal rhythms, cardiac conduction abnormalities, and heart blocks are discussed in Chapter 22.

Bradycardia Sinus bradycardia is probably the most common xenobiotic-induced bradycardia. Xenobiotics (Table 23–2) produce bradycardia through different mechanisms. The xenobiotic may affect the central or peripheral nervous system, or may affect rhythm generation or conduction in the heart. Most xenobiotics that cause CNS sedation, such as the sedative-hypnotics, opioids, and α_2 adrenergic receptor agonist ("centrally acting") antihypertensives, will usually decrease sympathetic outflow to the heart and produce sinus bradycardia in the range

of 40–60 beats/min. Digoxin, certain cholinergics, and α_1 agonists may produce bradycardia and heart block through the enhancement of vagal tone. Sodium channel activators, such as aconitine, cause bradycardia due to intracellular Na^+ overload with a resultant alteration in calcium Ca^{2+} handling. The most profound bradycardia results from overdoses of xenobiotics that have direct depressant effects on the cardiac pacemakers.[54] The ultimate manifestation of pacemaker failure is asystole. Similarly, the inability to propagate an impulse within the cardiac conducting system may produce bradycardia. Examples of xenobiotics that can produce pacemaker or conduction effects include calcium channel blockers and β-adrenergic antagonists.

Bradycardia, heart block, and asystole are frequently the terminal events in patients with massive overdose of many noncardiotoxic xenobiotics. These dysrhythmias may occur as a result of direct effects on the myocardial system or of indirect metabolic effects. For instance, severe hyperkalemia or metabolic acidosis results in a wide complex, sinusoidal bradycardic rhythm.

Tachycardia Sinus tachycardia is the most common rhythm disturbance that occurs in poisoned patients. Parasympatholytic drugs, such as atropine, raise the heart rate by elimination of the inhibitory tonic vagal influence. However, more rapid rates require direct myocardial stimulatory effects, generally mediated by β-adrenergic agonism. For example, catecholamine excess (eg, cocaine, psychomotor agitation, methylxanthines, sedative-hypnotic withdrawal) may cause sinus tachycardia with rates faster than 150 beats/min. Tachycardia may also

be an indirect effect as occurs in response to hypotension, hypoxia, acidemia, fever electrolyte abnormalities, and other metabolic derangements that may be present in poisoned patients (Table 23–3).

■ DECREASED CARDIAC CONTRACTILITY AND CONGESTIVE HEART FAILURE

Xenobiotics can reduce cardiac contractility with a resulting decrease in cardiac ejection fraction and cardiac output, a decrease in blood pressure, and development of congestive heart failure (CHF). Cardiogenic pulmonary edema generally occurs as a result of the direct effects of the xenobiotic on the contractility, or inotropy, of the heart, or through increases in the preload or afterload. Acute cardiogenic pulmonary edema, resulting from impaired left heart filling (which may be due to decreased cardiac output), occurs in patients poisoned by a non-dihydropyridine calcium

channel blocker or β-adrenergic receptor antagonist. Other xenobiotics that can exert direct depressant effects on cardiac contractility include antihistamines, phenothiazines, antidysrhythmics, and local anesthetics. Many of these xenobiotics reduce contractility through sodium channel blockade, which, by slowing intraventricular conduction, reduces the ability of the heart to contract efficiently. Pulmonary edema may also result from the fluid overload accompanying ingestion of large quantities of sodium-containing xenobiotics (eg, sodium penicillin), the renal effects of medications such as NSAIDs, or as a late consequence of xenobiotics that cause renal failure (Chap. 27).

Xenobiotic can cause cardiomyopathy through chronic toxic effects directly on the myocardium or indirectly through effects on blood pressure or cardiac vasculature (Table 23–4). In most cases, the exact mechanism of the toxicity is not known. However, free radical generation, nitric oxide formation, acetaldehyde, myocardial ischemia, mechanical overload, nutritional deficiency, and persistent tachycardia are each implicated in the cellular toxicity of the various xenobiotics and development of cardiomyopathy.

■ BLOOD PRESSURE ABNORMALITIES

Blood pressure is dependent upon cardiac and vascular function. The blood pressure (BP) is directly related to the heart rate (HR), the stroke volume (SV), and the systemic vascular resistance (SVR): $BP = HR \times SV \times SVR$. The systolic component of the blood pressure measurement is a reflection of the inotropic state of the myocardium, whereas the diastolic component reflects the vascular tone. It is important to consider both components of the blood pressure. Blood pressure may be expressed also the mean arterial pressure (MAP) during a single cardiac cycle. Since at normal heart rates the duration of diastole is approximately twice that of systole, the MAP is calculated as $[(2 \times diastolic) + systolic]/3$. Xenobiotics may affect either component and compensatory mechanisms within the cardiovascular system may produce recognizable patterns of blood pressure alterations.

Many xenobiotics affect blood pressure by modulation of normal neurotransmission at the postganglionic sympathetic neurons. Through these effects they may cause, for example, vasoconstriction (α agonism) or inotropy (β₁ agonism). Because of the functional similarity of most sympathomimetics, physical examination alone seldom identifies the specific causative xenobiotic in any patient. However, often a clinical constellation of signs and symptoms can be identified that is associated with this general class. For example, patients who ingest sympathomimetic amines such as cocaine or amphetamines typically have central nervous system stimulation, hypertension, and tachycardia (Chap. 3).

Hypertension caused by xenobiotics Hypertension may be the result of an increase in either inotropy or vascular resistance or both. For example, stimulation of the α_1-adrenergic receptor causes hypertension

TABLE 23–4. Xenobiotics Commonly Associated with Cardiomyopathy

through vasoconstriction, and stimulation of the β_1-receptor causes hypertension through enhanced myocardial contractility (Table 23–5).

The hemodynamic results of a xenobiotic overdose depend on the specific xenobiotic ingested and the relative action on the various types of receptors (see Table 23–1). This suggests that, among β-adrenergic agonists, only those with a predominant β_1 adrenergic effect cause hypertension. Nonselective β-adrenergic agonists (those that agonize at both β_1 and β_2) produce β_1-mediated systolic hypertension (through inotropic effects) with β_2-mediated vascular vasodilation and diastolic hypotension. This may result in a widened pulse pressure, which is the numerical difference between the systolic and diastolic pressures. Thus after exposure to selective β agonist (eg, albuterol), tachycardia and enhanced inotropy may occur, resulting in a widened pulse pressure in a manner analagous to a nonselective beta agonist. The resulting blood pressure depends on the relative physiologic balance between inotropy and vasodilation.

Xenobiotics that interact only with the α_1-adrenergic receptor (such as phenylephrine) cause vasoconstriction and hypertension. Barorecptors detect the increased blood pressure and signal the parasympathetic nervous system neurons of the vagus nerve to fire and slow the heart rate. In the absence of β-adrenergic stimulation, a "reflex" bradycardia results. Norepinephrine is an α_1- adrenergic agonist with additional β-adrenergic activity. Profound hypertension is the primary hemodynamic toxic effect due to the activity of norepinephrine as both a positive inotrope

---

TABLE 23–5. Xenobiotics that Commonly Cause Hypertension

Hypertensive effects mediated by α-adrenergic receptor interaction	Hypertensive effects not mediated by α-adrenergic receptor interaction

[a] These may cause transient hypertension followed by hypotension.

[b] These can also cause hypotension.

(β_1) and a vasoconstrictor (α_1). Reflex bradycardia does not occur as a result of stimulation of the cardiac β-adrenergic receptors.

Hypotension caused by xenobiotics Typically, hypotension in adults is arbitrarily defined as a systolic blood pressure of less than 90 mm Hg or a MAP of less than 70 mm Hg. However, this is not an adequate clinical parameter. Young children and adults with a small body habitus may have a normal systolic pressure less than 90 mm Hg (Chap. 3). Patients with hypothermia have decreased metabolic demands, and a lower blood pressure may be considered "normal" for these patients. Most importantly, patients with long-standing hypertension may have inadequate tissue perfusion even with a MAP of more than 70 mm Hg. The cerebral arterioles normally constrict or dilate to maintain a relatively constant cerebrovascular blood flow despite changes in the peripheral blood pressure. Chronically hypertensive patients lose this autoregulatory response as a consequence of atherosclerotic disease, arteriolar hypertrophy, or arteriolar smooth muscle constriction. These narrowed arterioles may require a higher peripheral blood pressure to properly perfuse the brain.

Hypotension is clinically defined as a blood pressure that is inadequate to perfuse tissues. The clinical assessment of tissue perfusion is based on the vital signs, skin color, capillary refill, mental status, urine output and concentration, and acid—base balance (eg, serum lactate concentration). However, if a xenobiotic directly affects one or more of these clinical parameters, the clinical assessment of volume and hemodynamic status may be difficult. Measurement of central venous pressure is beneficial in the early treatment of the sepsis syndrome, and most likely would be beneficial in the treatment of other causes of hypotension, including those occurring in poisoned patients. Invasive measurement of cardiac filling pressure, cardiac output, systemic vascular resistance, and arterial pressures may be necessary in critically ill patients with severe poisoning.[46]

Poor tissue perfusion may result from hypovolemia, decreased peripheral vascular resistance, myocardial depression, or a dysrhythmia that reduces the cardiac output. A single xenobiotic may exert several effects on the hemodynamic system, such as diltiazem, a calcium channel blocker that causes negative inotropy and vasodilation. Appropriate treatment of the hypotension requires an understanding of the pathophysiologic consequences of the xenobiotic and the resultant hemodynamic derangement (Table 23–6).

A common etiology of hypotension in a poisoned patient is intravascular volume depletion. Intravascular volume may decrease due to gastrointestinal, urinary, or insensible losses; or fluid may redistribute from the intravascular space into the intracellular, interstitial, pleural, or peritoneal spaces. Xenobiotics can cause significant intravascular volume depletion through all of these mechanisms.

Hypotension may also be caused by xenobiotics that affect the venous tone. These xenobiotics increase venous capacitance, decrease the central venous pressure, and result in a relative hypovolemia. The effects may be mediated via central effects on the sympathetic nervous system or direct effects on the peripheral vasculature. Sedative hypnotics and central α_2-adrenergic agonists (eg, clonidine) decrease the central sympathetic outflow and may result in hypotension. Other xenobiotics directly block peripheral α_1-adrenergic receptors or stimulate β_2-adrenergic receptors on the blood vessels to produce vascular smooth muscle relaxation, venodilation, and hypotension. A large number of xenobiotics are reported to cause hypotension. However, the hypotension often is not a direct action of the xenobiotic. Rather, the cause of hypotension is coexisting hypoxia, acidosis, anaphylaxis, volume depletion, or dysrhythmias.

Identification of the specific xenobiotic causing hypotension requires the integration of a detailed history, complete physical examination, and laboratory studies. Often the identification of the specific xenobiotic responsible for hypotension is based on other physical findings associated with the xenobiotic or recognition of a specific toxic syndrome.

ASSESSMENT OF VOLUME STATUS IN THE POISONED PATIENT

Assessment of volume status may be particularly difficult in the poisoned patient because of functional alterations in the patient's autonomic nervous system and the pharmacologic effects of the xenobiotic. For example, the usual signs of salt and water depletion, such as dry mucous membranes, dry skin, low blood pressure, tachycardia, narrowed pulse pressure, clouded sensorium, and decreased urine output, can be mimicked by a number of xenobiotics, including tricyclic antidepressants. Additionally, hypovolemic patients may present with diaphoresis, flushed skin, hypertension, bradycardia, or increased urine output after the exposure to a cholinergic xenobiotic such as an organic phosphorus compound. In most cases, clinical assessment of central venous pressures and neck vein distension or the hemodynamic response to a fluid bolus can assist in the determination of the patient's volume status. A central venous or pulmonary artery pressure catheter may be required in some critically ill patients.

Additional information about the adequacy of the patient's volume status may be obtained by orthostatic vital sign testing (Table 23–7).[21] Normally, the cardiovascular system responds to sitting or standing with vasoconstriction and a slight increase in heart rate. Even with a 30% or greater volume loss, the supine blood pressure may remain normal in young, previously healthy patients. However, patients with hypovolemia are unable to maintain adequate intravascular pressure when upright and have either an exaggerated reflex increase in heart rate or a drop in blood pressure (ie, orthostasis).

A variety of xenobiotics can produce orthostatic blood pressure changes (Table 23–8).[21,34] Volume depletion is the most common cause of xenobiotic-induced orthostatic vital sign changes. However, xenobiotics may produce orthostatic vital sign changes even with a normal volume status. For instance, α_1-adrenergic antagonists or direct acting vasodilators may prevent an adequate vasoconstrictor response or β adrenergic antagonists may block the normal slight heart rate increase, and result in positive orthostatic vital sign testing. In these cases, cardiac output and blood pressure decrease when the patient is upright.

TABLE 23–7. Orthostatic Vital Signs ("Tilt" Testing)

1. After the patient is supine for 2 minutes, determine the blood pressure and pulse rate.

2. Stand the patient for at least 1 minute and determine the blood pressure and pulse rate again, and observe for any orthostatic symptoms such as dizziness or light-headedness. If it is impossible for the patient to stand, have the patient sit up with feet dangling for at least 2 minutes before determining vital signs.

The test is positive if *any one* of the following is true:

  Systolic blood pressure decreases > 20 mm Hg

  Diastolic blood pressure decreases > 10 mm Hg

  Pulse increases > 10 beats/min

  Development of clinical symptoms of hypovolemia (dizziness, syncope, light-headedness)

Significance of a positive test: 10-15 mL|Kg volume loss.

TABLE 23–9. Clues that an Unanticipated Xenobiotic Might be the Cause of Hemodynamic Compromise or Dysrhythmia

History
New-onset, concomitant seizure
Gastrointestinal disturbances (colicky pain, nausea, vomiting, diarrhea)
Prior ingestion of medications (consider possibility that the container is mislabeled or misidentified)
Depression (even if patient denies ingestion)
Suspected myocardial ischemia in patient younger than 35 years old
Past medical history
Treatment with *any* cardiac medications (especially antidysrhythmics or digoxin)
History of psychiatric illness, asthma, or hypertension
History of drug use or abuse
Physical examination and vital signs
Heart rate
  Sinus tachycardia with rate >130 beat/min
  Sinus tachycardia without apparent identified cause
  Sinus bradycardia
Respiratory rate
  Any unexplained depression or elevation in rate
Temperature
  Elevation especially if > 106°F (> 41.1°C)
  Hypothermia
Dissociation between typically paired changes, for example:
  Hypotension and bradycardia (tachycardia expected)
  Fever and dry skin (diaphoresis expected)
  Hypertension and tachycardia (reflex bradycardia anticipated)
  Depressed mental status and tachypnea (decreased respirations common)
Relatively rapid changes in vital signs
Initial hypertension becomes hypotension
Increasing sinus tachycardia or hypertension
General
Alteration in consciousness, such as depressed mental status, confusion, or agitation
Findings usually not associated with cardiovascular diseases
Ataxia, bullae, dry mucous membranes, lacrimation, miosis or mydriasis, nystagmus, unusual odor, flushed skin, salivation, tinnitus, tremor, visual disturbances
Findings consistent with a toxic syndrome
  Especially findings consistent with anticholinergics, sympathomimetics, or sedative hypnotics
Laboratory tests
Any unexpected or unexplained laboratory result, especially:
  Metabolic acidosis
  Respiratory alkalosis
  Hypokalemia or hyperkalemia

SUMMARY

Xenobiotics can interact with the heart or blood vessels to produce hypotension or hypertension, congestive heart failure, dysrhythmias (including bradycardias and tachycardias), or cardiac conduction delays. These toxic effects often occur through interactions with specific receptors or with the ion channels in the cell membrane. Disruption of the normal cellular regulation of metabolic processes or of the cellular ionic status leads to the cardiovascular and hemodynamic compromise.

The occurrence of these abnormalities, individually or in combination, might suggest a particular xenobiotic or class of xenobiotics as the etiologic (toxic syndrome) and might dictate initial treatment. Often, however, significant abnormalities in vital signs must be corrected before the xenobiotic is identified. By understanding both the pharmacology of the xenobiotic and the physiology of the heart and vasculature, appropriately tailored treatment can be delivered.

Definitive care of the poisoned patient with hemodynamic compromise or a dysrhythmia begins with recognition that a xenobiotic may be present. Infectious, cardiovascular disease, and other metabolic disorders must always be considered; however, the toxic effects of xenobiotics must be included in the differential diagnosis. A variety of clinical clues, when present, should heighten the clinician's suspicion that a xenobiotic effect may be responsible for the hemodynamic or dysrhythmic problem (Table 23–9).

CHAPTER 24
HEMATOLOGIC PRINCIPLES

Marco L.A. Sivilotti

Blood is rightfully considered the vital fluid, as every organ system depends on the normal function of blood. Blood delivers oxygen and other essential substances throughout the body, removes waste products of metabolism, transports hormones from their origin to site of action, signals and defends against threatened infection, promotes healing via the inflammatory response and maintains the vascular integrity of the circulatory system. It also contains the central compartment of classical pharmacokinetics, and thereby comes into direct contact with virtually every systemic toxin that acts on the organism.[162] The ease and frequency with which blood is assayed, its central role in functions vital to the organism, and the ability to analyze its characteristics, at first by light microscopy and more recently with molecular techniques, have enabled a detailed understanding of blood that has advanced the frontier of molecular medicine.

In addition to transporting xenobiotics throughout the body, blood and the blood-forming organs can at times be directly affected by these same xenobiotics. For example, decreased blood cell production, increased blood cell destruction, alteration of hemoglobin, and impairment of coagulation can all result from exposure to many xenobiotics. The response in many cases depends on the nature and quantity of the xenobiotic, and the capacity of the system to respond to the insult. In other cases, no clear and predictable dose–response relationship can be determined, especially when the interaction involves the immune system. These latter reactions are often termed idiosyncratic, reflecting an incomplete understanding of their causative mechanism. In general, such reactions can often be reclassified when advancing knowledge identifies the characteristics which render the individual vulnerable.

HEMATOPOIESIS

Hematopoiesis is the development of the cellular elements of blood. The majority of the cells of the blood system may be classified as either lymphoid (B, T, and natural-killer lymphocytes) or myeloid (erythrocytes, megakaryocytes, granulocytes, and macrophages). All of these cells are descended from a small common pool of totipotent cells called hematopoietic stem cells.[182] Indeed, the study of this process and its regulation has provided fundamental insight into embryogenesis, stem cell pluripotency, and complex cell-to-cell signaling and interaction.

■ BONE MARROW

Marrow spaces within bone begin to form in humans at about the 5th fetal month and become the sole site of granulocyte and megakaryocyte proliferation. Erythropoiesis moves from the liver to the marrow by the end of the last trimester. At birth, all marrow contributes to blood cell formation and is red, containing very few fat cells. By adulthood, the same volume of hematopoietic marrow is normally restricted to the sternum, ribs, pelvis, upper sacrum, proximal femora and humeri, skull, vertebrae, clavicles and scapulae. So-called extramedullary hematopoiesis in the liver and spleen may reemerge as a compensatory mechanism under severe stimulation.

Progenitor cells must interact with a supportive microenvironment to sustain hematopoiesis. The hematopoietic stroma consists of macrophages, fibroblasts, adipocytes, and endothelial cells. The extracellular matrix is produced by the stromal cells and is composed of various fibrous proteins, glycoproteins, and proteoglycans, such as collagen, fibronectin, laminin, hemonectin, and thrombospondin. Hematopoietic progenitor cells have receptors to particular matrix molecules. The extracellular matrix provides a structural network to which the progenitors are anchored. As the cells approach maturity, they lose their surface receptors, allowing them to leave the hematopoietic space and enter the venous sinuses. Blood cell release depends upon the development of a pressure gradient that drives mature cells through channels in endothelial cell cytoplasm.[191] Pressure within the marrow is increased by erythropoietin and by granulocyte colony-stimulating factor (G-CSF). [83,84]

■ STEM CELLS

A stem cell is capable of self-renewal, as well as differentiating into a specific cell type. The pluripotent hematopoietic stem cells can therefore continuously replicate while awaiting the appropriate signal to differentiate into either a myeloid stem cell (for myelo-, erythro-, mono-, or megakaryopoiesis) or a lymphoid stem cell (for lymphopoiesis of T, B, null, and natural-killer cells) (Fig. 24–1). The stem cell pool represents approximately 1 in 100,000 of the nucleated cells of the bone marrow, and the majority of these stem cells are usually quiescent. Nevertheless, these relatively few cells are directly responsible for the estimated 3 billion red cells, 2.5 billion platelets, and 1.5 billion granulocytes per kilogram of body weight produced each day. In response to hemolysis or infection, substantially larger numbers of blood cells can be produced.[130]

Hematopoietic stem cells are found in umbilical cord blood, bone marrow, and peripheral blood.[108] With subsequent division and maturation, these cells progressively display the antigenic, biochemical, and morphologic features characteristic of mature cells of the appropriate lineages, and lose their capacity for self-renewal. Multiple steps are involved in the commitment of less-differentiated cells to more mature cell lines. The final steps in the maturation of erythrocytes alone, for example, involve extensive remodeling, the restructuring of cellular membranes, the accumulation of hemoglobin, and the loss of nuclei and organelles. In the case of granulocytes, granules containing proteolytic enzymes are formed in cell cytoplasm, and the nucleus condenses to form the multilobulated nucleus of the mature cell. Megakaryocyte cytoplasm demarcates into units that are split off eventually as platelets.

Multipotent mesenchymal stem cells capable of differentiating into other tissue lines including hepatic, renal, muscle and perhaps nerves are also found in the bone marrow.[64] Furthermore, tissue-specific stem cells capable of self-renewal are believed to reside in numerous other organs and to play a fundamental role in repair and regeneration.[35] A variety of strategies have likely evolved to protect the stem cell from injury due to xenobiotics and radiation, and a better understanding of these effects promises to improve our understanding of toxicity and treatment. The hematopoietic stem cell has provided fundamental insights into regenerative biology, and remains a focus of intense research given the profound implications for organ homeostasis, tissue repair and gene therapy.[99,105]

■ CYTOKINES

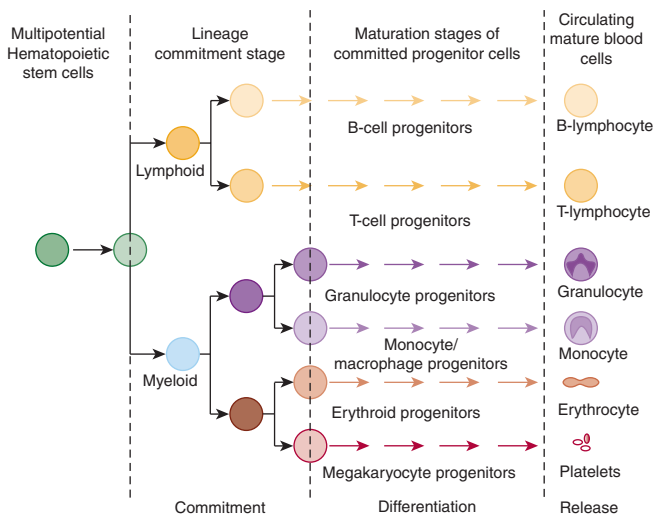
Cytokines are soluble mediators secreted by cells for cell-to-cell communication. Initially termed growth factors, it is now recognized that not all cytokines are growth factors. Cytokines promote or inhibit the differentiation, proliferation, and trafficking of blood cells and their precursors. Importantly, they can also inhibit apoptosis, and their


FIGURE 24–1. Principles of hematopoiesis. Commitment refers to the apparent inability of progenitor cells to generate hematopoietic stem cells. Following differentiation, the various mature blood cells are released into the circulation.

absence therefore results in the self-destruction of unwanted cells. They include growth factors or colony-stimulating factors (CSFs), interleukins, monokines, interferons, and chemokines. At baseline, these act in concert to maintain normal blood counts. In response to antigens or other stimuli, cytokines are released to combat perceived infection. Recombinant cytokines are being developed for therapeutic use in immunocompromised patients, transplant recipients, sepsis, and cancer. They have also been used in clinical toxicology for the treatment of colchicine and podophyllum toxicity.[45,69]

The growth factors are glycoproteins necessary for the differentiation and maturation of individual or multiple cell lines.[83,93,94,123] They fall into two families based on their target receptors. The ligands of the cytokine receptor family include growth hormone, interleukin-2 (IL-2), macrophage colony-stimulating factor-1 (CSF-1), granulocyte-macrophage colony-stimulating factor (GM-CSF), γ-interferon, and granulocyte colony-stimulating factor (G-CSF), to name a few. The second group, the tyrosine kinase family, includes Kit ligand and insulinlike growth factor-I receptor (IGF-1R), a member of the insulin family. The complete development of all of the mature blood cells from stem cells or multilineage progenitors requires the action of growth factors, either alone or in combination, for successful differentiation and final maturation.

■ CELL SURFACE ANTIGENS

Using monoclonal antibody technology, cell surface antigens are used to characterize cell types. The cluster designation (CD) nomenclature was introduced by immunologists to ensure a common language when confronted with multiple antibodies to the same leukocyte cell-surface molecule, and hundreds of such unique molecules have been classified.[198] For example, the CD34 antigen is a 115-kilodalton (kDa) highly glycosylated transmembrane protein that is selectively expressed by primitive multipotent hematopoietic stem cells shortly after activation, but is absent from mature T and B lymphocytes.[108] Advances in genomics and proteomics now complement the immunologic designation, but the ability to subtype blood cells phenotypically has transformed the approach to the leukemias, autoimmune disease, transplantation medicine and thromboembolic disease.

■ APLASTIC ANEMIA

Aplastic anemia is characterized by pancytopenia on peripheral smear, a hypocellular marrow, and delayed plasma iron clearance. Severe aplastic anemia denotes a granulocyte count of less than 500 cells/mm^3, a platelet count of less than 20,000/mm^3, and a reticulocyte count of less than 1% after correction for anemia. Following acute insult and depletion of extracirculatory reserves, cell line counts fall at a rate inversely proportional to their life span: granulocytes (half-life 6–12 hours in the circulation) disappear within days, platelets (life span of 7–10 days) decline by half in about one week, while erythrocytes (normal life span 120 days) decline over weeks in the absence of bleeding or hemolysis. Approximately 1000 new cases of aplastic anemia are diagnosed yearly in the United States. The incidence is two to three times higher in Asia, perhaps due to a combination of genetic, environmental and infectious factors.[195] Aplastic anemia may be inborn (as in Fanconi anemia) or acquired. A variety of xenobiotics have been associated with acquired aplastic anemia, such as benzene, environmental pesticides and chloramphenicol (Table 24–1).[32,196] However, much of this older literature is suspect given uncertain case ascertainment and other biases. More recent epidemiologic studies have shown that specific causes are identified in relatively few cases.[82]

Generally speaking, the majority of cases of so-called idiosyncratic aplastic anemia are caused by autoimmune attack on CD34+

TABLE 24–1. Xenobiotics Associated with Aplastic Anemia

Analgesics	Antirheumatics
Acetaminophen	Gold salts
Acetylsalicylic acid	Methotrexate
Diclofenac	D-Penicillamine
Dipyrone	Antithyroids
Indomethacin	Propylthiouracil
Phenylbutazone	Antineoplastics[a]
Antibiotics	Adriamycin[a]
Azidothymidine	Antimetabolites
Chloramphenicol	Colchicine
Mefloquine	Daunorubicin[a]
Penicillin	Mustards
Anticonvulsants	Vinblastine
Carbamazepine	Vincristine
Felbamate	Diuretics
Antidysrhythmics	Acetazolamide
Tocainide	Metolazone
Antihistamines	Occupational
Cimetidine	Arsenic[a]
Antiplatelets	Benzene[a]
Ticlopidine	Cadmium
Antipsychotics	Copper
Chlorpromazine	Pesticides
Clozapine	Pesticides
	Radiation[a]

[a]Denotes agents that predictably result in bone marrow aplasia following a sufficiently large exposure.

hematopoietic stem cells. Following an exposure to an inciting antigen, cytotoxic T cells secrete interferon-γ and tumor necrosis factor α which destroy progenitor cells, causing loss of circulating mature leukocytes, erythrocytes and platelets.[196] As with other autoimmune diseases, certain histocompatibility antigen patterns are associated with the condition, namely the human leukocyte antigen (HLA) DR2, indicating a genetic predisposition. Clozapine-induced agranulocytosis is associated with the HLA B38, DR4, and DQ3 haplotypes.[132] Immunosuppressive therapy or allogenic stem cell transplantation allow recovery of hematopoiesis, and survival is now expected.[195]

It is important to distinguish immunologic xenobiotic-induced aplastic anemia from the direct myelotoxic effects of radiation and chemotherapy. Following exposure to ionizing radiation, a pancytopenia ensues due to injury to both stem and progenitor cells. Nevertheless, atom bomb survivors rarely develop aplastic anemia.[79] Vacuolated pronormoblasts can be found in the bone marrow when aplasia is due to a myelotoxic drug, and treatment consists of stopping the offending agent. Other nonimmunologic mechanisms of aplasia have also been identified in specific cases. For example, the severe pancytopenia seen following 5-fluorouracil therapy is caused by a deficiency of dihydropyrimidine dehydrogenase present in 3% to 5% of whites.[187]

THE ERYTHRON

The erythron can be considered to be a single yet dispersed tissue, defined as the entire mass of erythroid cells from the first committed progenitor cell to the mature circulating erythrocyte. This functional definition emphasizes the integrated regulation of the erythron, both in health and disease. Homeostasis of the erythron is primarily maintained by the equilibrium between stimulation via the hormone erythropoietin, and apoptosis controlled by two receptors, Fas and FasL, expressed on the membranes of erythroid precursors. At the other extreme, erythrocytes are culled from the circulation at the end of their life span, primarily by the action of the spleen. Senescent erythrocytes less able to negotiate the narrow red pulp passages are phagocytosed by macrophages, thereby minimizing both entrapment in the microvasculature of other organs, and spillage of intracellular contents into the intravascular circulation.

The primary function of the erythron is to transport molecular oxygen throughout the organism. To accomplish this, adequate number of circulating erythrocytes must be maintained. These erythrocytes must be able to preserve their structure and flexibility to circuit repeatedly through the microcirculation and to resist oxidant stress accumulated during their life span.[150] The erythrocyte also plays a key role in modulating vascular tone. Interactions between oxyhemoglobin and nitric oxide help match vasomotor tone to local tissue oxygen demands.[46,62,68,119,160]

■ ERYTHROPOIETIN

Erythropoietin (EPO) is a glycoprotein hormone of molecular weight 34,000 Da that is produced in the epithelial cells lining the peritubular capillaries in the normal kidney. Anemia and hypoxemia stimulate its synthesis.[2,3] EPO receptors are found in human erythroid cells, megakaryocytes, and fetal liver. EPO promotes erythroid differentiation, the mobilization of marrow progenitor cells, and the premature release of marrow reticulocytes.[2] The cell most sensitive to EPO is a cell between the erythroid colony-forming unit (CFU-E) and the proerythroblast.[3] The absence of EPO results in DNA cleavage and erythroid cell death.

■ THE MATURE ERYTHROCYTE

The mature erythrocyte (red blood cell) is a highly specialized cell, designed primarily for oxygen transport. Accordingly, it is densely packed with hemoglobin, which constitutes approximately 90% of the dry weight of the erythrocyte. During maturation, the erythrocyte loses its nucleus, mitochondria and other organelles, rendering it incapable of synthesizing new protein, replicating, or using the oxygen being transported for oxidative phosphorylation. Its metabolic repertoire is also severely limited, and largely restricted to a few pathways described below under Metabolism. In general, the enzymatic pathways are those required for optimizing oxygen and carbon dioxide exchange, transiting the microcirculation while maintaining cellular integrity and flexibility, and resisting oxidant stress on the iron and protein of the cell. The characteristic biconcave discocyte shape is dynamically maintained, increasing membrane surface to cell volume.[117] This shape both decreases intracellular diffusion distances to the extracellular membrane[104] and allows plastic deformation when squeezing through the microcirculation.[36,161] The shape is the net sum of elastic and electrostatic forces within the membrane, surface tension, and osmotic and hydrostatic pressures. The cell membrane contains globular proteins floating within the phospholipid bilayer. The major blood group antigens are carried on membrane ceramide glycolipids and proteins, particularly glycophorin A and the Rh proteins.[40] Membrane proteins generally serve to maintain the structure of the cell, to transport ions and other substances across the membrane, or to catalyze a limited number of specific chemical reactions for the cell.

Structural proteins The cell membrane is coupled to, and interacts dynamically with the cytoskeleton, allowing changes in cell shape such as tank treading or rotation of the membrane relative to the cytoplasm. This cytoskeleton consists of a hexagonal lattice of proteins, especially spectrin, actin, and protein 4.1, which interact with ankyrin and band 3 in the membrane to provide a strong but flexible structure to the membrane.[21,101,159] Other essential structural proteins include tropomyosin, tropomodulin, and adducin. Absence or abnormalities of these proteins can result in abnormal erythrocyte shapes such as spherocytes and elliptocytes.

Transport proteins Many specialized transport proteins are embedded in the erythrocyte membrane. These include anion and cation transporters, glucose and urea transporters, and water channels.[177] The erythrocyte membrane is relatively impermeable to ion flux. Band 3 anion-exchange protein plays an important role in the chloride-bicarbonate exchanges that occur as the erythrocyte moves between the lung and tissues. Glucose, the sole source of energy of the erythrocyte, crosses the membrane by facilitated diffusion mediated by a transmembrane glucose transporter. Sodium-potassium adenosine triphosphatase (Na⁺,K⁺-ATPase) maintains the primary cation gradient by pumping sodium out of the erythrocyte in exchange for potassium.

Membrane-associated enzymes At least 50 membrane-bound or membrane-associated enzymes are known to exist in the human erythrocyte. Acetylcholinesterase is an externally oriented enzyme whose role in the function of the erythrocyte remains obscure.[178] Its function is inhibited by certain xenobiotics, most notably the organic phosphorus insecticides, and it can be conveniently assayed as a marker for such exposures (Chap. 113).

Metabolism Lacking mitochondria and the ability to generate adenosine triphosphate (ATP) using molecular oxygen, the mature erythrocyte has a severely limited repertoire of intermediary metabolism compared to most mammalian cells. Its metabolic capacity is also limited once its nucleus, ribosomes, and translational apparatus are lost. Unable to synthesize new enzymes, the capacity declines over the lifetime of the cell because of declining enzyme function with time. Fortunately, the metabolic demands of the erythrocyte are usually modest, but under conditions of stress the capacity can be overwhelmed, especially among senescent cells. The greatest expenditure of energy under physiologic

conditions is for the maintenance of transmembrane gradients and for the contraction of cytoskeletal elements. However, oxidant stress can put severe strain on the metabolic reserves of the erythrocyte, and lead ultimately to the premature destruction of the cell, a process termed hemolysis.

Figure 24–2 illustrates the main metabolic pathways and their purpose. The Embden-Meyerhof glycolysis is the only source of ATP for the erythrocyte, and consumes approximately 90% of the glucose imported by the cell. The reduced nicotinamide adenine dinucleotide (NADH) generated during glycolysis, which would ordinarily be used for oxidative phosphorylation in cells containing mitochondria, is directed toward the reduction of either methemoglobin to hemoglobin by cytochrome b5 reductase, or pyruvate to lactate. Both pyruvate and lactate are exported from the cell. During glycolysis, metabolism can be diverted into the Rapoport-Luebering shunt, generating 2,3-bisphosphoglycerate (2,3-BPG, formerly known as 2,3-diphosphoglycerate

or 2,3-DPG) in lieu of ATP. 2,3-BPG binds to deoxyhemoglobin to modulate oxygen affinity and allow unloading of oxygen at the capillaries. In response to anemia, altitude, or changes in cellular pH, the activity of the shunt increases, thereby favoring synthesis of 2,3-BPG and increasing oxygen delivery considerably.[42,113] Reduced levels of 2,3-BPG in stored blood are believed to result in impaired oxygen delivery for approximately 12 hours following massive transfusion.[183]

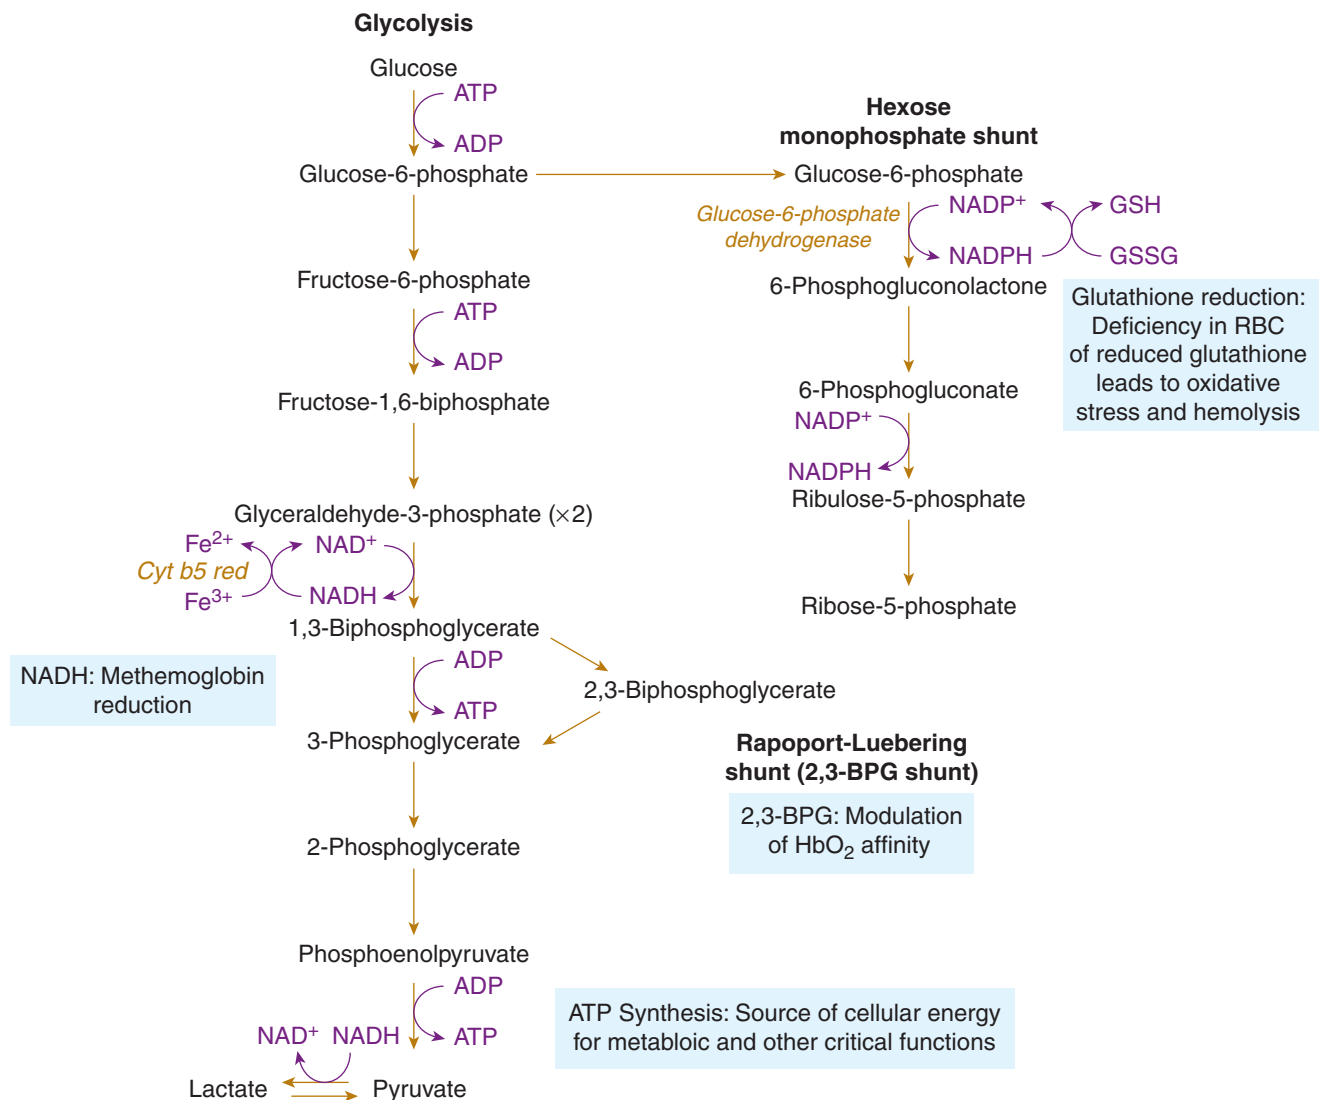
As an alternative to glycolysis, glucose can be directed toward the hexose monophosphate shunt during times of oxidant stress. This pathway results in the generation of reduced nicotinamide adenine dinucleotide phosphate (NADPH), which the erythrocyte uses to maintain reduced glutathione which, in turn, inactivates oxidants and protects the sulfhydryl groups of hemoglobin and other proteins. The initial, rate-limiting step of this pathway is controlled by glucose-6-phosphate dehydrogenase (G6PD). Accordingly, cells deficient in this enzyme are less able to maintain glutathione in a reduced state, and


FIGURE 24–2. Metabolic pathways of the erythrocyte. The main metabolic pathways available to the mature erythrocyte are shown (rectangles). Glucose is imported into the cell, while pyruvate, lactate, and oxidized glutathione (GSSG) are exported. 2,3-BPG = 2,3-Biphosphoglycerate; ADP = adenosine diphosphate; ATP = adenosine triphosphate; cyt b5 red = cytochrome b5 reductase; G6PD = glucose-6-phosphate dehydrogenase; GSH = reduced glutathione; Hb = hemoglobin; NADH reduced form of nicotinamide adenine dinucleotide (NAD+); NADPH = reduced form of nicotinamide adenine dinucleotide phosphate (NADP+); RBC = red blood cell (erythrocyte).

are vulnerable to irreversible damage under oxidant stress. The consequences of this deficiency are discussed in greater detail below under Glucose-6-Phosphate Dehydrogenase Deficiencies.

The erythrocyte also contains enzymes to synthesize glutathione (γ-glutamyl-cysteine synthetase and glutathione synthetase), to convert CO_2 to bicarbonate ion (carbonic anhydrase I), to remove pyrimidines resulting from the degradation of RNA (pyrimidine 5′-nucleotidase), to protect against free radicals (catalase, superoxide dismutase, glutathione peroxidase), and to conjugate glutathione to electrophiles (ρ glutathione-S-transferase).

■ HEMOGLOBIN

Hemoglobin, the major constituent of the cytoplasm of the erythrocyte, is a conjugated protein with a molecular weight of 64,500 Da. One molecule is composed of 4 protein or globin chains, each attached to a prosthetic group called heme. Heme contains an iron molecule complexed at the center of a porphyrin ring. The globin chains are held together by noncovalent electrostatic attraction into a tetrahedral array. Hemoglobin is so efficient at binding and carrying oxygen that it enables blood to transport 100 times as much oxygen as could be carried by plasma alone (Chap. 21). In addition, the capacity of hemoglobin to modulate oxygen binding under different conditions allows adaptation to a wide variety of environments and demands. Three complex and integrated pathways are required for the formation of hemoglobin: globin synthesis, protoporphyrin synthesis, and iron metabolism.

Globin synthesis The protein chains of hemoglobin are produced with information from two different genetic loci. The α-globin gene cluster spans 30 kb on the short arm of chromosome 16, and codes for 2 identical adult α-chain genes, as well as the ζ -chain, an embryonic globulin. The β cluster is 50 kb on chromosome 11, and codes for the 2 adult globins β and δ, as well as 2 nearly identical γ chains expressed in the fetus and an embryonic globulin ε. The expression of genes in each family changes during embryonic, fetal, neonatal, and adult development. Until 8 weeks of intrauterine life, ε, ζ, γ, and α chains are produced and assembled in various combinations in yolk sac-derived erythrocytes. With the shift in erythropoiesis from yolk sac to fetal liver and spleen, embryonic hemoglobin is no longer detectable, and the α and γ globin chains are paired into fetal hemoglobin (HbF = $α_2γ_2$). Erythrocytes containing HbF have a higher O_2 affinity than those containing adult hemoglobin, which is important for oxygen transfer across the placenta into the relatively hypoxic uterine environment. Beginning shortly before birth, expression shifts to the α and β globins, which constitute the predominant adult hemoglobin termed hemoglobin A ($α_2β_2$). Approximately 2.5% of normal adult hemoglobin is in the form of hemoglobin A_2 ($α_2 δ_2$).

The rate of globin synthesis is increased in the presence of heme, and inhibited in its absence.[116] As the globin chains are released from the ribosomes, they spontaneously assemble into αβ dimers, and then into $α_2β_2$ tetramers. The thalassemias, a group of inherited disorders, result from defective synthesis of one or more of the globin chains. Clinically this results in a hypochromic, microcytic anemia.[65,116]

Heme synthesis Heme is the iron complex of protoporphyrin IX. Protoporphyrin IX is a tetramer composed of four porphyrin rings joined in a closed, flat-ring structure. The IX designation refers to the order in which it was first synthesized in Hans Fischer's laboratory. Of the 15 possible isomers, only protoporphyrin IX occurs in living organisms. Technically, only iron complexes with the iron in the Fe^{2+} state can be called heme, but the term is commonly used to refer to the prosthetic group of metalloproteins such as peroxidase (ferric) and cytochrome c (both ferric and ferrous), whether the iron is in the

Fe^{2+} or Fe^{3+} state. The terms "hemiglobin" and "ferrihemoglobin" are synonymous with methemoglobin but rarely used. All animal cells can synthesize heme, with the notable exception of mature erythrocytes.[143] Hemoproteins are involved in a multitude of biologic functions, including oxygen binding (hemoglobin, myoglobin), oxygen metabolism (oxidases, peroxidases, catalases, and hydroxylases), and electron transport (cytochromes), as well as metabolism of xenobiotics (cytochrome P450 family).[144] Erythroid cells synthesize 85% of total body heme, with the liver synthesizing most of the balance. Hemoglobin is the most abundant hemoprotein, containing 70% of total body iron.[143]

The first step in the synthesis of heme takes place in the mitochondrion and is the condensation of glycine- and succinylcoenzyme A (CoA) to form 5-aminolevulinic acid (ALA) (Fig. 24–3).[116] The formation of 5-ALA is catalyzed by aminolevulinic acid synthase (ALAS), the rate-limiting step of the pathway. The rate of heme synthesis is closely controlled, given that free intracellular heme is toxic and that this first step is essentially irreversible.

Of the two isoforms of ALAS known to exist in mammals, erythroid cells express the ALAS 2 isoform which resides on the X chromosome. Comparatively more is known about ALAS 1 (chromosome 3), a housekeeping gene with a short half-life expressed ubiquitously allowing the synthesis of cellular and mitochondrial hemoproteins. ALAS 1 activity is induced by many factors, which can increase its expression by two orders of magnitude. Moreover, it is strongly inhibited by heme in a classical negative feedback fashion.[143] ALAS 2 is constitutively expressed at very high levels in erythroid precursors, allowing sustained synthesis of heme during erythropoiesis. Pyridoxal phosphate (active vitamin B_6) serves as a cofactor to both isoforms of ALAS. The clinical consequences of pyridoxine deficiency may include a hypochromic, microcytic anemia, iron overload, and neurologic impairment.

The next step in the synthesis of hemoglobin is the formation of the monopyrrole porphobilinogen via the condensation of two molecules of ALA. The subsequent steps in heme synthesis involve the condensation of four molecules of porphobilinogen into a flat ring, which is transported back into the mitochondrion by an unknown mechanism. The final step is the insertion of iron into protoporphyrin IX, a reaction that is catalyzed by ferrochelatase (also known as heme synthase) to form heme.

Understanding this carefully regulated synthetic pathway is relevant to understanding the laboratory evidence of lead exposure, and predicting the response of porphyric patients to a range of xenobiotics. Most steps in the heme biosynthetic pathway are inhibited by lead (see Fig. 24–3; Chap. 94). ALA dehydratase is the most sensitive, followed by ferrochelatase, coproporphyrinogen oxidase, and porphobilinogen (PBG) deaminase. As a consequence, ALA is increased in plasma and
FIGURE 24–3. The heme synthesis pathway. The enzymatic steps inhibited by lead are marked with an asterisk (∗) RBCs red blood cells; 5-ALA = 5-aminolevulinic acid.

especially urine. With increasing exposure, ferrochelatase inhibition coupled with iron deficiency causes zinc protoporphyrin to accumulate in erythrocytes, which can easily be detected by fluorescence. Coproporphyrinogen III also appears in the urine. These effects have served as the basis for a number of tests of lead exposure.

The porphyrias are a group of disorders resulting from an inherited deficiency of any given enzyme which follows ALAS on the heme biosynthetic pathway. As such, when ALAS activity outpaces the activity of this enzyme, the rate-limiting step shifts downstream, and intermediate metabolites accumulate. These metabolites can cause characteristic neuropsychiatric symptoms and palsies (due to 5-ALA and porphobilinogen), and cutaneous reactions including photosensitivity (caused by the fluorescence of the porphyrins). For example, porphobilinogen is excreted in large quantities by patients with acute intermittent porphyria (porphobilinogen deaminase deficiency), and the urine darkens with exposure to air and light due to oxidation to porphobilin and to non-enzymatic assembly into porphyrin rings. A variety of xenobiotics can precipitate a crisis in susceptible individuals, by inducing ALAS 1 and overloading the deficient enzyme.[181] The molecular mechanisms which allow xenobiotics to induce the ALAS 1 gene closely resemble those accounting for induction of the cytochrome P450 (CYP) genes, not surprisingly since both components are required to form the hemoprotein. The xenobiotic typically interacts with either the constitutive androstane receptor (CAR) or the pregnane X receptor (PXR), the two main so-called orphan nuclear receptors.[194] These transcriptional factors are DNA-binding proteins which induce the expression of a range of drug metabolizing and transporting genes in response to the presence of a xenobiotic, and have been termed "xenosensors." When activated, they associate with the 9-*cis* retinoic acid xenobiotic receptor (RXR), and then attach to enhancer sequences near the apoCYP or ALAS1 genes to enhance transcription.[142] The multifunctional inducers capable of activating a wide range of hepatic enzymes are therefore extremely porphyrogenic, and include phenobarbital, phenytoin, carbamazepine, and primidone. Furthermore, because CYP 3A4 and 2C9 represent nearly half of the hepatic CYP pool, inducers of these isoforms can also stimulate heme synthesis and induce a porphyric crisis. Examples of these agents included the anticonvulsants, nifedipine, sulfamethoxazole, rifampicin, ketoconazole, and the reproductive steroids progesterone, medroxyprogesterone and testosterone. Glucocorticoids, on the other hand, despite binding to PXR, suppress ALAS1 induction and translation, and are not porphyrogenic.[181]

Iron metabolism Unless appropriately chelated, free iron not bound by transport or storage proteins can generate harmful oxygen free radicals that damage cellular structures and metabolism (Chaps. 11 and 40).[145] For this reason, serum iron circulates bound to a transfer protein, transferrin, and is stored in the tissues using ferritin. Although each molecule of transferrin can bind two iron atoms, ferritin has a large internal cavity, approximately 80 Å in diameter, that can hold up to 4500 iron atoms per molecule. The amount of iron transported through plasma depends on total-body iron stores and the rate of erythropoiesis. Only about one-third of the iron-binding sites of circulating transferrin are normally saturated, as demonstrated by the usual serum iron content of 60–170 μg/dL (10–30 μmol/L) as compared to the total iron-binding capacity of 280–390 μg/dL (50–70 μmol/L).

Only transferrin can directly supply iron for hemoglobin synthesis.[143] The iron–transferrin complex binds to transferrin receptors on the surface of developing erythroid cells in bone marrow. Iron in the erythroid cell is used for hemoglobin synthesis or is stored in the form of ferritin.

The absorption of non-heme, free ferrous iron from the diet occurs via the divalent metal transporter of the duodenal enterocyte, which then passes it into the circulation via ferroportin. Oxidized to the ferric form, iron then circulates bound to transferrin.[71] Dietary iron

complexed with heme can also be absorbed via the recently discovered heme carrier protein 1, which transports either iron or zinc protoporphyrin into the erythrocyte.[164] The iron may then be freed by microsomal heme oxygenase, and follow the transport of atomic iron, or perhaps heme itself can be transferred to the circulation via specific export proteins, and circulate bound to its carrier protein, hemopexin.[9]

The senescent erythrocyte is usually removed from the circulation by splenic macrophages. Heme is degraded by heme oxygenase to carbon monoxide and biliverdin, and the iron extracted.[145] Some iron may remain in macrophages in the form of ferritin or hemosiderin. Most is delivered again by ferroportin back to the plasma, and bound to transferrin.

Iron homeostasis is largely regulated at the level of absorption, with little physiologic control over its rate of loss. Excess absorption relative to body stores is the hallmark of hereditary hemochromatosis. The iron regulatory hormone hepcidin produced by the liver is now believed to play a central role in iron control, including the anemia of chronic disease caused by inflammatory signals.[71] Hepcidin is a 25-amino acid peptide that senses iron stores, and controls the ferroportin-mediated release of iron from enterocytes, macrophages and hepatocytes. The liver is an important reservoir of iron as it can store considerable amounts of iron taken from portal blood, and release it when needed.

■ OXYGEN-CARBON DIOXIDE EXCHANGE

The evolutionary transition of organisms from anaerobic to aerobic life allowed the liberation of 18 times more energy from glucose. Vertebrates have developed 2 important systems to overcome the relatively small quantities of oxygen dissolved in aqueous solutions under atmospheric conditions: the circulatory system and hemoglobin. The circulatory system allows delivery of oxygen and removal of carbon dioxide throughout the organism. Hemoglobin also plays an essential role in the transport and exchange of both gases.[74] Moreover, the interactions between these gases and hemoglobin are directly linked in a remarkable story of molecular evolution. Understanding this interplay has allowed fundamental insight into protein conformation and the importance of allosteric interactions between molecules.

The binding of oxygen to each of the 4 iron molecules in heme results in conformational changes that affect binding of oxygen at the remaining sites. This phenomenon is known as cooperativity, and is a fundamental property to allow both the transport of relatively large quantities of oxygen and the unloading of most of this oxygen at tissue sites. Cooperativity results from the intramolecular interactions of the tetrameric hemoglobin, and is expressed in the sigmoidal shape of the oxyhemoglobin dissociation curve (Chap. 21). Conversely, the monomeric myoglobin has a hyperbolic oxygen binding curve. The partial pressure of oxygen at which 50% of the oxygen bindings sites of hemoglobin are occupied is about 26 mm Hg, in contrast with about 1 mm Hg for myoglobin. Moreover, hemoglobin is nearly 100% saturated at partial oxygen pressures of about 100 mm Hg in the pulmonary capillaries, transporting 1.34 mL of oxygen per gram of hemoglobin A. About one-third of this oxygen can be unloaded under normal conditions at tissue capillaries with partial oxygen pressures around 35 mm Hg. The proportion rises during exercise and sepsis, and with poisons that uncouple oxidative phosphorylation. Elite athletes can extract up to 80% of the available oxygen under conditions of maximal aerobic effort.

The oxygen reserve, however, is only one of the reasons for the large quantity of hemoglobin in circulation. The ability of hemoglobin to buffer the acid equivalent of CO_2 in solution is equally vital to respiratory physiology, as it allows the removal of large quantities of CO_2 from metabolically active tissues with minimal changes in blood pH. To put things in perspective, the typical adult male has approximately 75 mL/kg

of blood containing 15 g/100 mL of hemoglobin, or nearly 1 kg of hemoglobin. His 0.3-kg heart must pump this entire mass of hemoglobin every minute at rest, a substantial work expenditure. This expenditure may be explained in part by the observation that hemoglobin is by far the largest buffer in circulation, accounting for nearly seven times the buffer capacity of the serum proteins combined (28 vs. 4 mEq H^+/L of whole blood). For every 1 mol of oxygen unloaded in the tissue, about 0.5 mol of H^+ is loaded onto hemoglobin.

The linked interaction between oxygen and carbon dioxide transport can be first considered from the perspective of oxygen binding to hemoglobin. The affinity of oxygen for hemoglobin is directly affected by pH, which is a function of the CO_2 content of the blood. The oxyhemoglobin dissociation curve shifts to the left in lungs, where the level of carbon dioxide, and thus carbonic acid, are kept relatively low as a result of ventilation, an effect that promotes oxygen binding. The curve shifts to the right in tissues where cellular respiration increases CO_2 concentrations. This phenomenon, known as the *Bohr effect*, promotes the uptake of oxygen in the lungs and the release of oxygen at tissue sites.

From the perspective of carbon dioxide transport, hemoglobin also plays an essential albeit indirect role. Carbon dioxide dissolves into serum, and is slowly hydrated to carbonic acid which dissociates to H+ and HCO_3^-(pK_a 6.35). The hydration reaction is accelerated from about 40 seconds to 10 msec by the abundant enzyme carbonic anhydrase located within the erythrocyte. Most carbon dioxide collected at the tissues diffuses into erythrocytes where it becomes H^+ and HCO_3^-. This HCO_3^- is then rapidly transported back to the serum in exchange for chloride ion via the band 3 anion exchange transporter located in the erythrocyte membrane, thereby shifting serum Cl^- into the erythrocyte (the *chloride shift*).[177] The hydrogen ion is accepted by hemoglobin, largely at the imidazole ring of histidine residues which have a pK_a of about 7.0. A small amount of CO_2 reacts directly with the amino terminal of the globin chains to form carbamino residues ($HbNHCOO^-$). Thus, most of the transported carbon dioxide is transformed by the erythrocyte into bicarbonate ion that is returned to the serum, and hydrogen ion that is buffered by hemoglobin. Each liter of venous blood typically carries 0.8 mEq dissolved CO_2 and 16 mEq HCO_3^- in the serum, and 0.4 mEq dissolved CO_2, 4.6 mEq HCO_3^-, and 1.2 mEq $HbNHCOO^-$ in the erythrocyte (a total of 23 mEq CO_2, equivalent to 510 mL CO_2/L blood). Although two-thirds of the total CO_2 content appears to be carried in the serum, all of the serum bicarbonate is originally generated within erythrocytes. In the capillaries of the lungs, the reverse reactions occur to eliminate CO_2. Because deoxyhemoglobin is better able to buffer hydrogen ions, the release of oxygen from hemoglobin at the tissues facilitates the uptake of carbon dioxide into venous blood. This effect is known as the *Haldane effect*. In fact, 1 L of venous blood at 70% oxygen saturation can transport an additional 20 mL of CO_2 compared to arterial blood. Both the Bohr and Haldane effects can have important consequences, either at the extremes of acid–base perturbations or because of interference with oxygen metabolism, as can occur in a number of poisonings.

Finally, in addition to inactivating nitric oxide, hemoglobin can also reversibly bind it as *S*-nitrosohemoglobin, thereby playing an important role in the regulation of microvascular circulation and oxygen delivery. The ability of hemoglobin to vasodilate the surrounding microvasculature in response to oxygen desaturation using nitric oxide provides new insight into oxygen delivery, and may be pivotal in such disorders as septic shock, pulmonary hypertension, and senescence of stored red blood cells.[167]

■ ABNORMAL HEMOGLOBINS

Several alterations of the hemoglobin molecule are encountered in clinical toxicology. A detailed understanding of their molecular basis, clinical manifestations, and effects on gas exchange are essential. Unfortunately, the nomenclature can be ambiguous and overlap with distinct clinical entities such as oxidant injury and hemolysis. Therefore, although a detailed discussion of these abnormal hemoglobins appears elsewhere (Chaps. 125 and 127), an overview of the subject is presented here. It is helpful to recall that the iron atom has six binding positions. Four of these positions are attached in a single plane to the protoporphyrin ring to form heme. The remaining 2 binding positions lie on opposite sides of this plane. Iron is ordinarily bonded on one side to the F8 proximal histidine residue of the globin chain. The remaining site is available for binding molecular oxygen, but can also bind carbon monoxide, nitric oxide, cyanide, hydroxide ion, or water. The E7 distal histidine residue facilitates the binding of oxygen, while stearically hindering carbon monoxide binding.

Methemoglobin Methemoglobin (ferrihemoglobin or hemiglobin) is the oxidized form of deoxyhemoglobin in which at least one heme iron is in the oxidized (Fe^{3+}) valence state. A number of valency hybrids can occur depending on the number of ferric versus ferrous heme units within the tetramer. Methemoglobin therefore represents oxidation (loss of electrons) of the hemoglobin molecule at the iron atom. It occurs spontaneously as a consequence of interactions between the iron and oxygen. Normally, in deoxygenated hemoglobin, the heme iron is in the ferrous (Fe^{2+}) valence state. In this state, there are 6 electrons in the outer shell, 4 of which are unpaired. When oxygen is bound, one of these electrons is partially transferred to it and the iron is reversibly oxidized. When O_2 is released, the electron is usually transferred back to heme iron, yielding the normal reduced state. Sometimes, the electron remains with the O_2 yielding a superoxide anion radical O_2^- rather than molecular oxygen. In this case, heme iron is left in the Fe^{3+}, or oxidized, state and is unable to release another electron to bind oxygen. This oxidation is primarily reversed via the action of cytochrome b5 reductase, also known as NADH methemoglobin reductase, which uses the electron carrier NADH generated by glycolysis ("Metabolism" and Chap. 12).[77,112] Minor pathways are also involved in methemoglobin reduction, including NADPH methemoglobin reductase, which normally reduces only approximately 5% of the methemoglobin, and vitamin C, a nonenzymatic reducing agent. The activity of NADPH methemoglobin reductase may be significantly accelerated by the presence of the electron donor methylene blue (Antidotes in Depth: Methylene Blue and Chap. 127) or riboflavin.[91] Equilibrium is maintained with methemoglobin concentrations of 1% of total hemoglobin. Many xenobiotics are capable of increasing the rate of methemoglobin formation as much as 1000-fold. Nitrites, nitrates, chlorates, and quinones are capable of directly oxidizing hemoglobin.[30] Certain individuals may be especially vulnerable because of deficient methemoglobin reduction.[44] The fetus and neonate are more susceptible to methemoglobinemia than the adult, as HbF is more susceptible to oxidation of the heme iron than adult hemoglobin. The newborn also has a limited capacity to reduce methemoglobin, because levels of cytochrome b5 reductase only reach adult levels around 6 months of age.

Carboxyhemoglobin Carbon monoxide (CO) can reversibly bind to heme iron in lieu of molecular oxygen. The affinity of CO for hemoglobin is 200–300 times that of oxygen, despite the stearic hindrance of the E7 distal histidine. The presence of CO thereby precludes the binding of oxygen. In addition, CO binding within any one heme subunit degrades the cooperative binding of oxygen at the remaining heme groups of the same hemoglobin molecule. The oxyhemoglobin dissociation curve is therefore shifted to the left, reflecting the fact that oxygen is more tightly bound by hemoglobin and less able to be unloaded to the tissues. In addition, CO binds to the heme group of myoglobin and the cytochromes, interfering with cellular respiration, exacerbating the clinical symptoms of hypoxia (Chap. 125).[66]

Sulfhemoglobin Sulfhemoglobin is a bright green molecule in which the hydrosulfide anion HS⁻ irreversibly binds to ferrous hemoglobin. The sulfur atom is probably attached to a β carbon in the porphyrin ring, and not at the normal oxygen-binding site.[125] It has a spectrophotometric absorption band at approximately 618 nm,[23] is ineffective in oxygen transport, and clinically resembles cyanosis. The oxygen affinity of sulfhemoglobin is approximately 100 times less than that of oxyhemoglobin, shifting the oxyhemoglobin dissociation curve to the right, in favor of O_2 unbinding. Thus, the symptoms of hypoxia are not as severe with sulfhemoglobinemia as with carboxy- or methemoglobinemia.[136]

Oxidation of the globin chain Oxidation can also occur at the amino acid side chains of the globin protein. In particular, sulfhydryl groups can oxidize to form disulfide links between cysteine residues, which leads to the unfolding of the protein chain, exposure of other side chains and further oxidation. When these disulfide links join adjacent hemoglobin molecules, they cause the precipitation of the concentrated hemoglobin molecules out of solution. Covalent links can also form between hemoglobin and other cytoskeletal and membrane proteins.[39] Eventually, aggregates of denatured and insoluble protein are visible on light microscopy as Heinz bodies. The distortion of the cellular architecture, and the loss of fluidity in particular, is a signal to reticuloendothelial macrophages to excise sections of erythrocyte membrane ("bite cells") or to remove the entire erythrocyte from the circulation ("Hemolysis"). To guard against these oxidation reactions, the erythrocyte maintains a pool of reduced glutathione via the actions of the NADPH generated in the hexose monophosphate shunt (assuming adequate G6PD activity to initiate this pathway). This glutathione transfers electrons to break open disulfide links and to preserve sulfhydryl groups in their reduced state.

◼ HEMOLYSIS

Hemolysis is merely the acceleration of the normal process by which senescent or compromised erythrocytes are removed from the circulation.[168] The normal life span of a circulating erythrocyte is approximately 120 days, and any reduction in this life span represents some degree of hemolysis. If sufficiently rapid, hemolysis can overwhelm the regenerative capacity of the erythron, resulting in anemia. Intravascular hemolysis occurs when the rate of hemolysis exceeds the capacity of the reticuloendothelial macrophages to remove damaged erythrocytes, and free hemoglobin and other intracellular contents of the erythrocyte appear in the circulation.

Reticulocytosis, polychromasia, unconjugated hyperbilirubinemia, increased serum lactate dehydrogenase, and decreased serum haptoglobin are characteristic of hemolysis. A normal or elevated RBC distribution width and thrombocytosis are usually present on the automated complete blood count. The presence of spherocytes on peripheral blood smear suggests an autoimmune or hereditary process, and can be pursued with a Coombs' test. Schistocytes suggest thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome, disseminated intravascular coagulation, or valvular hemolysis. TTP and hemolytic uremic syndrome are characterized by a microangiopathic anemia, thrombocytopenia and normal coagulation parameters (unlike disseminated intravascular coagulation). TTP is discussed under platelet disorders below. Hemoglobinemia, hemoglobinuria, and hemosiderinuria can occur with intravascular hemolysis. Specialized tests to measure hemolysis detect shortened erythrocyte survival, increased endogenous carbon monoxide generation from heme oxygenase, and increased fecal urobilinogen.[175]

Table 24–2 presents a brief classification of acquired causes of hemolysis relevant to toxicology. Oxidant injury following xenobiotic

---

TABLE 24–2. Xenobiotics Causing Acquired Hemolysis

Immune-mediated
    Type I: IgG against drug tightly bound to red cell
    Type II: Complement activated by antibodies against drug-membrane complex
    Type III: True autoimmune response to red cell membrane
Nonimmune-mediated
Oxidants
    Aniline[107]
    Benzocaine[52;103]
    Chlorates[47;85]
    Dapsone[88]
    Hydrogen peroxide
    Hydroxylamine[174]
    Methylene blue[166]
    Naphthalene[184]
    Nitrites[16;28;31;154]
    Nitrofurantoin
    Oxygen[102;121]
    Phenacetin[122]
    Phenazopyridine[53;131]
    Phenol
    Platin salts[109]
    Sulfonamides[190]
Nonoxidants
    Arsine (AsH_3)
    Copper
    Lead
    Pyrogallic acid
    Stibine (SbH_3)
Microangiopathic (eg, ticlopidine, clopidogrel, cyclosporine, tacrolimus)[17;19;49;73;165;186]
Venoms (snake, spider)[60;78;127;189]
Osmotic agents (eg, water)[76;98]
Hypophosphatemia[5;90;120]

exposure is one of the triggers of hemolysis, as it may cause irreversible changes in the erythrocyte. Xenobiotics can also interact with the immune system to cause hemolysis. Finally, erythrocytes deficient in G6PD by virtue of cell age or enzyme mutations are particularly vulnerable to hemolysis following oxidant stress due to limited capacity to generate NADPH and reduced glutathione.[168]

◼ NONIMMUNE-MEDIATED CAUSES OF XENOBIOTIC-INDUCED HEMOLYSIS

A number of xenobiotics or their reactive metabolites can cause hemolysis via oxidant injury; Table 24–2 provides a partial list. A Heinz-body hemolytic anemia can result, which typically resolves within a few weeks of drug discontinuation. Some xenobiotics cause hemolysis in the absence of overt oxidant injury (see Table 24–2). Copper sulfate

hemolysis is described in Chap. 93, and the delayed hemolysis following exposure to arsine or stibine is described below.

Arsine Arsine (AsH_3) is a colorless, odorless, nonirritating gas that is 2.5 times denser than air (Chap. 88). Clinical signs and symptoms appear after a latent period of up to 24 hours after exposure to concentrations above 30 ppm, and may include headache, malaise, dyspnea, abdominal pain with nausea and vomiting, hepatomegaly, hemolysis with hemoglobinuric renal failure, and death.[38,54,87,97,141] The mechanism of hemolysis is believed to involve the fixation of arsine by sulfhydryl groups of hemoglobin and other essential proteins.[63,192] Interestingly, hemolysis is prevented in vitro by conversion to carboxy- or methemoglobin.[70] Impairment of membrane proteins including Na^+-K^+-ATPase is another potential mechanism for arsine-induced hemolysis.[148] Chronic exposure to low levels of arsine can produce clinically significant disease.[38] Stibine (SbH_3) an antimony derivative likely causes hemolysis via similar mechanisms.

■ IMMUNE-MEDIATED HEMOLYTIC ANEMIA

The immune-mediated hemolytic anemias occur when ingested xenobiotics trigger an antigen antibody reaction (see Table 24–2).[138] In general, these molecules are too small to be sensitizing agents, but antigenicity can be acquired after binding to carrier proteins in blood. The particulars of the xenobiotic-carrier immune activation sequence form the basis for the classification of this group of hemolytic anemias.[13]

The first class of reaction (hapten model, or drug adsorption) occurs when the xenobiotic acts as a hapten and binds tightly to cell membrane glycoproteins on the surface of the erythrocyte. IgG antibodies develop against the bound drug, leading to removal of the erythrocyte by splenic macrophages. The prototype of this reaction is the hemolytic anemia observed following high dose penicillin therapy.[55] Historically, approximately 3% of patients treated with megadose penicillin over weeks for infectious endocarditis developed a positive direct Coombs test, demonstrating erythrocytes become coated with IgG or complement. The positive direct Coombs test is a necessary, but insufficient, condition for the hemolytic reaction. The hemolysis is usually subacute, and requires at least a week to develop, but can become life threatening if the cause is not recognized. Discontinuation of the xenobiotic results in cessation of hemolysis, because its presence is needed for antibody binding.

The second class of reaction (immune complex, or neoantigen) occurs with drugs that have low affinity for cellular membrane glycoproteins. Examples are quinine, quinidine, stibophen and newer-generation cephalosporins, such as cefotetan, cefotaxime, and ceftriaxone. Antibodies are formed against the joint drug-membrane complex (neoantigen), and erythrocyte injury is primarily mediated by complement. Unlike the hapten model, small doses of xenobiotics are sufficient to trigger sudden intravascular hemolysis and hemoglobinuria, leading to renal failure. The direct Coombs test is positive only for complement, but the presence of drug is again necessary.

The third class of reaction (true autoimmune) occurs when the xenobiotic alters the natural suppressor system, allowing the formation of antibody to cellular components. This is a true autoantibody reaction directed against erythrocyte surface antigen rather than the drug.[15] The classic example is α-methyldopa, but chlorpromazine, cladribine, cyclosporine, fludarabine, levodopa, and procainamide can also trigger autoimmune hemolysis.[15,128,153] An indirect Coombs test that is positive in the absence of drug demonstrates the presence of IgG autoantibodies in the patient's serum when incubated with normal erythrocytes. The severity of hemolysis is variable, and its onset insidious, but hemolysis can continue for weeks to months despite removal of the inciting agent.

Glucose-6-phosphate dehydrogenase deficiencies (G6PD) G6PD is the enzyme that catalyzes the first step of the hexose monophosphate shunt: the conversion of glucose-6-phosphate to phosphogluconolactone (see Fig. 12-5). In the process, $NADP^+$ is reduced to NADPH, which the erythrocyte uses to maintain a supply of reduced glutathione and to defend against oxidation. It follows that erythrocytes deficient in G6PD activity are less able to resist oxidant attack and, in particular, to maintain sulfhydryl groups of hemoglobin in their reduced state, resulting in hemolysis. It is important to recognize that the term G6PD deficiency encompasses a wide range of differences in enzyme activities among individuals. These differences may result from decreased enzyme synthesis, altered catalytic activity, or reduced stability of the enzyme. Approximately 7.5% of the world population is affected to some degree, with more than 400 variants having been identified. Most cases involve relatively mild deficiency and minimal morbidity.[25,37,114] Ethnic populations from tropical and subtropical countries (the so-called malaria belt) have a much higher prevalence of G6PD deficiency, possibly because that phenotype protects against malaria.[129]

The gene that encodes for G6PD resides near the end of the long arm of the X-chromosome. Most mutations consist of a single amino acid substitution, as complete absence of this enzyme is lethal. Although males hemizygous for a deficient gene are more severely affected, females randomly inactivate one X-chromosome during cellular differentiation according to the Lyon hypothesis. Thus, female carriers heterozygous for a deficient G6PD gene have a mosaic of erythrocytes, some proportion of which expresses the deficient gene during maturation. Accordingly, approximately 10% of carrier females may be nearly as severely affected as a male hemizygous for the same deficient gene. Because of the high gene frequency in certain ethnic groups, another approximately 10% of females may be homozygous for the deficient gene.

Normal G6PD has a half-life of about 60 days. Because the erythrocyte cannot synthesize new protein, the activity of G6PD normally declines by approximately 75% over its 120-day life span. Consequently, even in unaffected individuals, susceptibility to oxidant stress varies based on the age mix of circulating erythrocytes. In all cases, older erythrocytes are less likely to recover following exposure to an oxidant and will hemolyze first. Moreover, after an episode of hemolysis following acute exposure to an oxidant stress, the higher G6PD activity of surviving erythrocytes will confer some resistance against further hemolysis in most individuals with relatively mild deficiency, even if the offending xenobiotic is continued. Phenotypic testing for G6PD deficiency is best done 2 to 3 months after a hemolytic crisis, after the reticulocyte count has normalized.

The World Health Organization classification of G6PD is based on the degree of enzyme deficiency and severity of hemolysis.[27] Both class I and class II patients are severely deficient, with less than 10% of normal G6PD activity. Class I individuals are prone to chronic hemolytic anemia, whereas class II patients experience intermittent hemolytic crises. Class III patients have only moderate (10%–60%) enzyme deficiency, and experience self-limiting hemolysis in response to certain drugs and infections. Approximately 11% of African Americans have a class III deficiency, traditionally termed type A⁻, and experience a decline of no more than 30% of the red blood cell mass during any single hemolytic episode. Another 20% of African Americans have type A⁺ G6PD enzyme, which is functionally normal, and therefore of no consequence despite a 1-base substitution compared to wild-type B. The Mediterranean type found in Sardinia, Corsica, Greece, the Middle East, and India is a class II deficiency, and hemolysis can occur spontaneously or in response to ingestion of oxidants, such as the β-glycosides found in fava (*Vicia fava)* beans.

The most common clinical presentation of previously unrecognized G6PD deficiency is the acute hemolytic crisis. Typically, hemolysis begins 1 to 4 days following the exposure to an offending xenobiotic or infection (Table 24–3). Jaundice, pallor, and dark urine may occur

TABLE 24–3. Representative Xenobiotics That Can Cause Hemolysis in Patients with Class I, II, or III G6PD Deficiency

Doxorubicin	Phenylhydrazine
Furazolidone	Primaquine
Isobutyl nitrite	Sulfacetamide
Methylene blue	Sulfamethoxazole
Nalidixic acid	Sulfanilamide
Naphthalene	Sulfapyridine
Nitrofurantoin	Toluidine blue
Phenazopyridine	Trinitrotoluene

with abdominal and back pain. A decrease in the concentration of hemoglobin occurs. The peripheral smear demonstrates cell fragments and cells that have had Heinz bodies excised. Bone marrow stimulation results in a reticulocytosis by day 5 and an increased erythrocyte mass. In general, a normal bone marrow can compensate for ongoing hemolysis, and can return the hemoglobin concentration to normal. Most crises are self-limiting because of the higher G6PD activity of younger erythrocytes. Historically, the anemia observed when primaquine was administered to type A⁻ military recruits for malaria prophylaxis resolved within 3 to 6 weeks in most patients.[26] Some xenobiotics, including acetaminophen, vitamin C, and sulfisoxazole, are safe at therapeutic doses but can cause hemolysis in G6PD-deficient patients following overdose.[24,170,193]

Other presentations of more severe variants of G6PD include neonatal jaundice and kernicterus, chronic hemolysis with splenomegaly and black pigment gallstones, megaloblastic crisis caused by folate deficiency, and aplastic crisis after parvovirus B19 infection.

MEGALOBLASTIC ANEMIA

Vitamin B_{12} and folate are essential for one-carbon metabolism in mammals. One-carbon fragments are necessary for the biosynthesis of thymidine, purines, serotonin and methionine, as well as the methylation of DNA, histones and other proteins, and the complete catabolism of branched chain fatty acids and histidine. Unable to synthesize vitamin B_{12} or folate, mammals are dependent on dietary sources and microorganisms for these cofactors. The hematologic manifestation of vitamin B_{12} or folate deficiency is a characteristic panmyelosis termed megaloblastic anemia. The hallmark nuclear-cytoplasmic asynchrony is due to disrupted DNA synthesis, halted interphase and ineffective erythropoiesis.[146] The hyperplastic bone marrow contains precursor cells with abnormal nuclei filled with incompletely condensed chromatin. Among circulating blood cells, macrocytic anemia (macro-ovalocytes) without reticulocytosis is followed by the appearance of granulocytes with an abnormally large, distorted nucleus (hypersegmented neutrophils with six or more lobes). Lymphocytes and platelets may appear normal but are also functionally impaired.

In addition to dietary deficiencies which have become less common, macrocytic anemia with or without megaloblastosis in adults is usually caused by chronic ethanol abuse, chemotherapy or antiretroviral agents, especially when mean corpuscular volumes are only moderately elevated (100–120 fL).[158] The folate antagonists aminopterin, methotrexate, hydantoins, pyrimethamine, proguanil, sulfasalazine,

trimethoprim-sulfamethoxazole and valproate can interfere with DNA synthesis. Ethanol affects folate metabolism and transport. Vitamin B_{12} deficiency can be induced by chronic exposure to nitrous oxide, biguanides, colchicine, neomycin, and the proton pump inhibitors. Purine analogs (eg, azathioprine, 6-mercaptopurine, 6-thioguanine, acyclovir) and pyrimidine analogs (eg, 5-fluorouracil, floxuridine, 5-azacitidine, and zidovudine) also disrupt nucleic acid synthesis. Hydroxyurea and cytarabine, which inhibit ribonucleotide reductase, also delay nuclear maturation and function and frequently cause megaloblastosis.

PURE RED CELL APLASIA

Pure red cell aplasia is an uncommon condition in which erythrocyte precursors are absent from an otherwise normal bone marrow. It results in a normocytic anemia with inappropriately low reticulocyte count. The other blood cell lines are unaffected, unlike aplastic anemia. Drugs cause less than 5% of cases of this uncommon condition, having been implicated in fewer than 100 human reports.[180] Only phenytoin, azathioprine, and isoniazid meet criteria for definite causality; chlorpropamide and valproic acid can only be considered as possible causes.[180] Most other xenobiotics are cited only in single case reports, and drug rechallenge was not used, making the association uncertain.

In part because of its rarity, a cluster of 13 cases in France of pure red cell aplasia in hemodialysis patients receiving subcutaneous recombinant erythropoietin ultimately led to an international effort by researchers, regulatory authorities and industry to identify the etiology.[20,41] To reduce theoretical concerns regarding transmission of variant Creutzfeldt-Jakob disease, human serum albumin was replaced with polysorbate 80 as the stabilizer in a formulation used in Europe and Canada. It is suspected that this change allowed rubber to leach from the uncoated stopper of prefilled syringes, triggering an immune response against both recombinant and endogenous erythropoietin in some patients.[118] This episode not only serves as a recent example of successful pharmacovigilance for rare adverse drug effects, but has also influenced safety assessments for an emerging class of biological therapies which include simple peptides, monoclonal antibodies and recombinant DNA proteins.[18,118]

ERYTHROCYTOSIS

Erythrocytosis denotes an increase in the red cell mass, either in absolute terms or relative to a reduced plasma volume. An increasingly recognized cause of drug-induced absolute erythrocytosis is the abuse of recombinant human erythropoietin by athletes to enhance aerobic capacity.[34,57,61,173] Autologous blood transfusions (doping) are also used in this population, and both can cause dangerous increases in blood viscosity. Cobalt was once considered for the treatment of chronic anemia[50] because of its ability to cause a secondary erythrocytosis. The mechanism may involve impaired degradation of the transcription factor Hypoxia Inducible Factor 1α, thereby prolonging erythropeitin transcription. This effect is more pronounced in high altitude dwellers, in whom elevated serum erythropoietin concentrations despite hematocrits in excess of 75% and chronic mountain sickness have been associated with increased serum cobalt concentrations.[86]

THE LEUKON

The leukon represents all leukocytes (white blood cells), including precursor cells, cells in the circulation, and the large number of extravascular cells. It includes the granulocytes (neutrophils, eosinophils, and basophils), lymphocytes, and monocytes. Neutrophils (polymorphonuclear leukocytes) are highly specialized mediators of the inflammatory response, and are a primary focus of concern regarding hematologic

toxicity of xenobiotics. B and T lymphocytes are involved in antibody production and cell-mediated immunity. Monocytes migrate out of the vascular compartment to become tissue macrophages and to regulate immune system function.

Immunity is generally divided into the *innate* and the *adaptive* responses. Innate immunity is an immediate but less specific defenses that is highly conserved in evolutionary terms. It is centered on the neutrophil response, and involves monocytes and macrophages as well as complement, cytokines and acute phase proteins. The innate system responds primarily to extracellular pathogens, especially bacteria, by recognizing structures commonly found on pathogens, namely lipopolysaccharide (Gram negative cell walls), lipotechoic acid (Gram positive) and mannans (yeast). Adaptive immunity is demonstrated only in higher animals, and is an antigen-specific response via T- and B-lymphocytes after antigen presentation and recognition. While this reaction is more specific, it requires several days to develop, unless that antigen has previously triggered a response (so-called immune memory). This response can also at times be directed against self antigens, resulting in autoimmune disorders.

The recruitment and activation of neutrophils provide the primary defense against the invasion of bacterial and fungal pathogens. They emerge from the bone marrow with the biochemical and metabolic machinery needed for the efficient killing of microorganisms. Activated macrophages release granulocyte and granulocyte-macrophage colony stimulating factors, which stimulate myeloid differentiation and can be recognized on blood testing as the classic neutrophil leucocytosis. Neutrophils are activated when circulating cells detect chemokines released from sites of inflammation. On activation, they undergo conformational and biochemical changes that transform them into powerful host defenders.[115] These changes allow rolling along the endothelial lining of postcapillary venules, migration toward the site of inflammation, adherence to the endothelium, migration through the endothelium to tissue sites, ingestion, killing, and digestion of invading organisms.[115]

Neutrophils migrate to sites of infection along gradients of chemoattractant mediators. An acute inflammatory stimulus leads to the accumulation of neutrophils along the endothelium of postcapillary venules.[33] The major molecules involved in this process are adhesion molecules, chemoattractants, and chemokines. Loose adhesions between neutrophils and endothelium are made and broken, resulting in the slow movement of leukocytes along endothelium and a more intense exposure of neutrophils to activating factors. Chemotaxis requires responses involving actin polymerization–depolymerization adhesion events mediated by integrins and involving microfilament–membrane interactions.[29] All leukocytes including lymphocytes localize infection using these same mediators. Colchicine depolymerizes microfilaments, causing the dissolution of the fibrillar microtubules in granulocytes and other motile cells, impairing this response.

Opsonized particles, immune complexes, and chemotactic factors activate neutrophils in tissues by binding to cell surface receptors. The neutrophil makes tight contact with its target, and the plasma membrane surrounds the organism completely enclosing it. Two mechanisms are then responsible for the destruction of the organism: the oxygen-dependent respiratory burst and the oxygen-independent response involving cationic enzymes found in cytoplasmic granules. The respiratory burst is caused by an NADPH oxidase complex that assembles at the phagosomal membrane. Electrons are transferred from cytoplasmic NADPH to oxygen on the phagosomal side of the membrane, generating superoxide, hydrogen peroxide, hydroxyl radical, singlet oxygen, hypochlorous acid, chloramines, nitric oxide, and peroxynitrite.[67] Cytoplasmic granules within the neutrophil fuse with the phagosome and empty their contents into it. There are at least four different classes of granules.[67] The components of these granules include myeloperoxidase (MPO), elastase, lipases, metalloproteinases, and a

pool of CD11b/CD18 proteins required for adhesion and migration.[149] Finally, the phagocytized organism is digested and eliminated by the neutrophil. Overstimulation of this complex and highly regulated but somewhat non-specific system can at times become deleterious, as is postulated to occur with reperfusion injury or carbon monoxide poisoning, to cite two examples.[179,188] Vasculitis and the systemic inflammatory response syndrome are further examples of excessive activation of the innate response.

■ NEUTROPENIA AND AGRANULOCYTOSIS

Neutropenia is a reduction in circulating neutrophils at least two standard deviations below the norm, but the threshold of 1500/mm^3 (1.5×10^9/L) is often used instead.[75] Severe neutropenia is termed *agranulocytosis,* and is generally defined to be an absolute neutrophil count of less than 500/mm^3 (0.5×10^9/L). Neutropenia can result from decreased production, increased destruction or retention of neutrophils in the various storage pools. Their high rate of turnover renders neutrophils vulnerable to any xenobiotic that inhibits cellular reproduction. As such, the various antineoplastic xenobiotics including antimetabolites, alkylating agents and antimitotics will predictably cause neutropenia. This predictable, dose-dependent reaction represents an important dose-limiting adverse effect of therapy. On the other hand, a number of xenobiotics are implicated in idiosyncratic neutropenia.[7,8] The parent drug or a metabolite usually act as a hapten to trigger antineutrophil antibodies. Table 24–4 provides an abbreviated list.[139,176] A recent

systematic review of published case reports identified a small subset of xenobiotics (denoted by an asterisk in the table) which were implicated in at least 10 cases and which account for the majority of reports deemed definitely or probably drug-induced. [6]

EOSINOPHILIA

Eosinophils are primarily responsible for protecting against parasitic infection. Allergic reactions and malignancies such as lymphoma are also common causes of eosinophilia, especially where nematode infection is rare.[155] Eosinophils bind to antigen-specific IgE, and discharge their large granules which contain major basic protein, peroxidase, and eosinophil-derived neurotoxin onto the surface of the antibody-coated organism. Two unusual toxicologic outbreaks were characterized by eosinophilia, acute cough, fever, and pulmonary infiltrates, followed by severe myalgia, neuropathy, and eosinophilia. The first outbreak, called the toxic oil syndrome, took place in central Spain in 1981, when industrial-use rapeseed oil denatured with 2% aniline was fraudulently sold as olive oil by door-to-door salesmen.[58] The precise causative agent remains uncertain, but may include fatty acid esters of 3-(N-phenylamino)-1,2-propanediol.[58] The second outbreak, called the eosinophilia-myalgia syndrome, occurred during 1988 and 1989 in users of L-tryptophan supplements traced back to a single wholesaler in Japan.[10] The causative contaminant has not been identified, but is believed to have been present in only trace quantities in the L-tryptophan purified from microbial culture. Both syndromes appear to be mediated by immunologic mechanisms.

LEUKEMIA

The leukemias represent the malignant, unregulated proliferation of hematopoietic cells. Although monoclonal in origin, they affect all cell lines derived from the progenitor cell. Acute myeloid leukemia (AML) and the myelodysplastic syndromes are the most common leukemias associated with xenobiotics. The long-recognized association between AML and occupational benzene exposure, radiation, or treatment with alkylating antineoplastic agents has helped to advance understanding of the molecular mechanisms underlying leukemogenesis.[22] The necessary events are believed to involve several sequential genetic and epigenetic alterations, as evidenced by a distinct pattern of chromosomal deletions preceding the development of AML.[80,81] Other recognized xenobiotics that can cause leukemia include topoisomerase

II inhibitors, 1,3-butanediol, styrol, ethylene oxide, and vinyl chloride.[92] In many cases, the latency period between exposure and illness is prolonged. For example, leukemia linked to benzene is preceded by several months of anemia, neutropenia, and thrombocytopenia. Benzene or other petroleum products are not believed to cause multiple myeloma.[22]

HEMOSTASIS

In the absence of pathology, blood remains in a fluid form with cells in suspension. Injury triggers coagulation and thrombosis. The resulting clot formation, retraction, and dissolution involve an interaction between the vessel endothelium, soluble constituents of the coagulation system, and proteins located on and within platelets. Platelets respond to signals within their immediate environment and from injured components of the distant microcirculation. A dynamic balance must be maintained between coagulation and fibrinolysis to maintain the integrity of the circulatory system (Fig. 24–4).

COAGULATION

Two basic pathways termed *intrinsic* and *extrinsic* are involved in the initiation of coagulation. Activation of the intrinsic system occurs when blood is exposed to tissue factor in damaged blood vessels or on the surface of activated leukocytes. Tissue factor binds factor VIIa, forming the intrinsic tenase complex, which activates factors IX and X. Factor IXa binds to the surface of activated platelets together with VIIIa and calcium, forming the extrinsic tenase complex. Factor X, which is activated by extrinsic and intrinsic tenase, binds to factor Va on the surface of activated platelets, forming the prothrombinase complex. The prothrombinase complex activates prothrombin, which results in the generation of thrombin activity. Thrombin activates platelets, promotes its own generation by activation of factors V, VIII, and XI, and converts fibrinogen to fibrin (Chap. 59).[72]

XENOBIOTIC-INDUCED DEFECTS IN COAGULATION

Warfarin The recognition of a hemorrhagic disease in cattle in the 1920s and the isolation of the causative agent dicoumarol from spoiled sweet clover in the 1940s resulted in the development of the warfarin-type anticoagulants (Chap. 59). This group of anticoagulants indirectly
FIGURE 24–4. The general relationships between thrombosis, coagulation, and fibrinolysis. Although these pathways are shown independently, they are intricately linked as outlined in the text. Von Willebrand factor stabilizes factor VIII and platelets on the surface of exposed endothelium. The star indicates that plasminogen is activated by t-PA, which itself is inhibited by plasminogen activator inhibitor (PAI; not shown). Recombinant t-PA (rt-PA) is commercially available. (▭) indicate inhibition; ⊕ denotes activation of catalytic activity. For a more detailed version, see Figure 59–1. AT = antithrombin; t-PA = tissue plasminogen activator.

inhibits hepatic synthesis of coagulation factors II, VII, IX, X, and proteins C and S.[140] Hepatic γ-carboxylation of glutamic acid residues by vitamin K-dependent carboxylase results in the formation of the vitamin K-dependent clotting factors. Vitamin K must be available in its reduced form, vitamin K quinol, to effectively catalyze this reaction. The carboxylation reaction oxidizes vitamin K quinol to vitamin K[2,3] epoxide, which must be reduced to vitamin K by reductase enzymes. The warfarin anticoagulants inhibit the reductase that is responsible for the regeneration of vitamin K quinone from vitamin K epoxide, impairing the synthesis of the vitamin K-dependent proteins.[95,171]

Heparin Heparin is a highly sulfated glycosaminoglycan that is normally present in tissues. Commercial unfractionated heparin is either bovine or porcine in origin, and consists of a mixture of polysaccharides with molecular weights ranging from 4000–30,000 Da. It is used extensively for the prophylaxis and treatment of venous thrombosis and thromboembolism. It is ineffective orally. This same property makes it safe for use during pregnancy because heparin cannot cross the placenta.[157] The anticoagulant activity of heparin is through its catalytic activation of antithrombin III. Antithrombin III acts as a suicide inhibitor of the serine proteases thrombin and factors IXa, Xa, XIa and XIIa.[126]

The low-molecular-weight heparins (LMWHs) have a mean molecular weight of 4000–6000 Da.[72] The pharmacokinetics and bioavailability of the LMWHs are more predictable, eliminating the need for close monitoring. They exhibit lower protein binding and a longer half-life than unfractionated heparin, making them more convenient to use.[126]

Other anticoagulants Heparinoids are glycosaminoglycans not derived from heparin with anticoagulant effects. This class includes dermatan sulfate, which activates the thrombin inhibitor heparin cofactor II, and danaparoid sodium, which inhibits factor Xa. Fondaparinux is a synthetic pentasaccharide that also inhibits factor Xa, and therefore acts upstream of thrombin. Several direct thrombin inhibitors are also in clinical use, including lepirudin, argatroban, bivalirudin, and dabigatran. These agents prolong the activated partial thromboplastin time and whole-blood activated clotting time, but also affect the INR.

■ FIBRINOLYSIS

The coagulation system is opposed by three major inhibitory systems. Components of the fibrinolytic system circulate as zymogens, activators, inhibitors, and cofactors.[51] Plasminogen can be activated to plasmin by an intrinsic pathway involving factor XII, prekallikrein, and high-molecular-weight kininogen. This produces the degradation products and fibrin monomers that are found in disseminated intravascular coagulation. The extrinsic pathway involves the release of tissue plasminogen activator (t-PA) from tissues and urokinase plasminogen activator (u-PA) from secretions.[51] Once activated, plasmin can degrade fibrinogen, fibrin, and coagulation factors V and VIII. The degradation of cross-linked fibrin strands results in the formation of D-dimers.

Several inhibitors oppose the fibrinolytic system, including α_2-antiplasmin, α_2-macroglobulin, both of which oppose plasmin activity, and plasminogen activator inhibitor (PAI) types 1 and 2, which oppose t-PA. PAI-1 and PAI-2 are opposed by activated protein C and protein S. Activated protein C is activated by thrombin. Congenital deficiencies of proteins C and S may result in pathologic venous thrombosis. Decreased fibrinolytic activity may result from decreased synthesis, release of t-PA, or from an elevation of the PAI-1 level. Both conditions have been observed postoperatively, with the use of oral contraceptives, in the third trimester of pregnancy, and in obesity. The activity of α_2-antiplasmin and α_2-macroglobulin are increased in pulmonary fibrosis, malignancy, infection, and myocardial infarction, and in thromboembolic disease.[51]

Hormones, including conjugated estrogens

■ XENOBIOTIC-INDUCED DEFECTS IN FIBRINOLYSIS.

Table 24–5 lists xenobiotics associated with an acquired defect of fibrinolysis. The antitumor agents may result in a reduction in serine protease inhibitors such as antithrombin. L-Asparaginase is associated with a reduction in circulating t-PA levels. Methotrexate can damage vascular endothelium, which may trigger thrombosis (Chap. 53).[51] Hemostatic drugs used therapeutically include the synthetic lysine derivatives aminocaproic acid and tranexamic acid, which bind reversibly to plasminogen; the bovine protease inhibitor aprotinin, which inhibits kallikrein; the vasopressin analog desmopressin, which increases plasma concentrations of factor VIII and vWF; and conjugated estrogens, which normalize bleeding times in uremia.[111]

■ PLATELETS

In the resting state, platelets maintain a discoid shape. The platelet membrane is a typical trilaminal membrane with glycoproteins, glycolipids, and cholesterol embedded in a phospholipid bilayer. The plasma membrane is in direct continuity with a series of channels, the surface-connected canalicular system (SCCS), which is sometimes referred to as the open canalicular system. The SCCS provides a route of entry and exit for various molecules, a storage pool for platelet glycoproteins, and an internal reservoir of membrane that may be recruited to increase platelet surface area.[133] This facilitates platelet spreading and pseudopod formation during the process of cell adhesion.

The glycocalyx, or outer coat, is heavily invested with glycoproteins that serve as receptors for a wide variety of stimuli. The β_1-integrin family includes receptors that mediate interactions between cells and mediators in the extracellular matrix, including collagen, laminin, and fibronectin.[169] The β_2-integrin receptors are present in inflammatory cells and platelets and are important in immune activation. The β_3-integrin receptors (also known as cytoadhesins) include the glycoprotein (GP) IIb-IIIa fibrinogen receptor, as well as vitronectin.[72] Vitronectin has binding sites for other integrins, collagen, heparin, and components of complement. All of the integrins are active in the process of platelet adhesion to surfaces. Platelet aggregation is mediated by the GP IIb-IIIa receptors.[72]

The submembrane region contains actin filaments that stabilize the platelets' discoid shape and are involved in the formation and stabilization of pseudopods. They also generate the force needed for the movement of receptor-ligand complexes from the outer plasma membrane to the SCCS. These mobile receptors are important in the spreading of platelets on surfaces, and for binding fibrin strands and other platelets. Platelet cytoplasm contains three types of membrane bound secretory granules.[72] The α granules contain β-thromboglobulin, which mediates inflammation, binds and inactivates heparin, and blocks the endothelial release of prostacyclin. In addition, platelet factor-4, which inactivates heparin, and fibrinogen are contained within the α granules. Dense granules store adenine nucleotides, serotonin, and calcium, which are secreted during the release reaction. Platelet lysosomes contain hydrolytic enzymes. Stimulation by platelet agonists causes the granules to fuse with the channels of the SCCS, driving the contents out of the platelets and into the surrounding media.

Platelet adhesion In the vessel wall, collagen, von Willebrand factor (vWF), and fibronectin are the adhesive proteins that play the most prominent role in the adhesion of platelets to vascular subendothelium.[169] On the exposure of collagen (eg, following a laceration or the rupture of an atherosclerotic plaque), platelet adhesion is triggered. Under conditions of high shear (flowing blood), platelet adhesion is mediated by the binding of GP Ib-V-IX receptors on platelet membranes to vWF in the vascular subendothelium.[72,169] Following adherence of platelets to subendothelial vWF, a conformational change in GP IIb-IIIa on platelet membrane occurs, activating this receptor complex to ligate vWF and fibrinogen. The result is the amplification of platelet adhesion and aggregation. An important interaction occurs between thrombosis and inflammation. Platelet-activating factor is synthesized and coexpressed with P-selectin on the surface of the endothelium in response to mediators such as hista-mine or thrombin. Platelet-activating factor interacts with a receptor on the surface of neutrophils that activates the CD11/CD18 adhesion complex, and results in adhesion of neutrophils to endothelium and to platelets. This results in the synthesis of leukotrienes and other mediators of inflammation.

Platelet activation Thrombin, collagen, and epinephrine can activate platelets. In response to thrombin, granules fuse with each other and with elements of the SCCS to form secretory vesicles.[133] These vesicles are believed to fuse with the surface membrane, releasing their contents into the surrounding medium. The membranes of the secretory granules become incorporated into the platelet surface membrane.

Platelet aggregation Following activation, GP IIb-IIIa is expressed in active form on platelet surface, serving as the final common pathway for platelet aggregation regardless of inciting stimulus. This receptor binds exogenous calcium and fibrinogen. GP IIb-IIIa ligates fibrinogen along with fibronectin, vitronectin, and vWF, resulting in the binding of platelets to other platelets, and ultimately the formation of the platelet plug. Collagen-induced platelet aggregation is mediated by adenosine diphosphate (ADP) and thromboxane A_2. ADP binds to the metabotropic purine receptors P2Y1 and P2Y12, leading to transient and sustained aggregation, respectively.[56] Thromboxane A_2 is formed from arachidonic acid by the action of cyclooxygenase 1. It is a potent vasoconstrictor and inducer of platelet aggregation and release reactions.[72] Platelets participate in triggering the coagulation cascade by binding coagulation factors II, VII, IX, and X to membrane phospholipid, a calcium-dependent process.

◼ ANTIPLATELET AGENTS

Aspirin Aspirin inhibits prostaglandin H synthase (cyclooxygenase [COX]) by irreversibly acetylating a serine residue at the active site of the enzyme. Aspirin inhibition of the COX-1 isoform of this enzyme is 100–150 times more potent than its inhibition of the COX-2 isoform. The inhibition of COX-1 results in the irreversible inhibition of thromboxane A_2 formation. Because platelets can be activated by other mechanisms including thrombin, thrombosis can develop despite aspirin therapy (Chap. 35).[163]

Selective COX-2 inhibitors Platelets express primarily COX-1 and use it to produce mostly thromboxane A_2, which leads to platelet aggregation and vasoconstriction. Endothelial cells express COX-2 and use it to produce prostaglandin I_2, an inhibitor of platelet aggregation and a vasodilator. Whereas aspirin and traditional (nonselective) nonsteroidal antiinflammatory medications inhibit the production of thromboxane A_2 and prostaglandin I_2 at both sites, the selective COX-2 inhibitors do not affect platelet derived thromboxane A_2, perhaps accounting for the increase in cardiovascular events associated with long-term use of some of these xenobiotics.[43,89,100,110,172,185]

GP IIb-IIIa antagonists The GP IIb-IIIa antagonist abciximab is a chimeric human-murine monoclonal antibody that binds the GP IIb-IIIa receptor of platelets and megakaryocytes. Two synthetic ligand-mimetic antagonists have also been developed: eptifibatide and tirofiban. These parenteral agents are used primarily in patients undergoing percutaneous coronary interventions.[72] By blocking the fibrogen binding site of IIb-IIIa, platelet aggregation is blocked and even reversed regardless of the inciting activation. Reversible thrombocytopenia can occur within hours of initiation of these xenobiotics.[156]

Thienopyridines The prodrugs clopidogrel and ticlopidine antagonize ADP-mediated platelet aggregation by noncompetitive inhibition of ADP binding to the P2Y12 receptor.[137,147] Both prodrugs are associated with thrombotic thrombocytopenic purpura, as well as neutropenia and aplastic anemia.[17,19,134,135,147]

Dipyridamole The pyrimidopyrimidine derivative dipyridamole inhibits cyclic nucleotide phosphodiesterase in platelets, resulting in the accumulation of cyclic adenosine monophosphate and perhaps cyclic guanine monophosphate.

◼ XENOBIOTIC-INDUCED THROMBOCYTOPENIA

Multiple drugs are reported to cause thrombocytopenia, either via the formation of drug-dependent antiplatelet antibodies or as thrombotic thrombocytopenic purpura. Drug-induced platelet antibodies are estimated to occur in 1 in 100,000 drug exposures. Reversible drug binding to platelet epitopes such as GP Ib-V-IX, GP IIb-IIIa, and platelet–endothelial cell adhesion molecule-1, lead to a structural change that can form or expose a neoepitope target for antibody formation.[11,152] The presence of the drug is required for antibody binding and increased platelet destruction, but there is no covalent bond (as occurs in the hapten model of penicillin binding to the erythrocyte membrane).

Thrombocytopenia can also occur as a result of spurious clumping, pregnancy, hypersplenism with cirrhosis, idiopathic thrombocytopenic purpura, heparin-induced thrombocytopenia (Chap. 59), bone marrow toxicity, and thrombotic thrombocytopenic purpura. After excluding these conditions and nontherapeutic exposures, a systematic literature search updated annually lists more than 1000 cases reported in English involving more than 150 xenobiotics.[1] Table 24–6 lists the xenobiotics appearing in multiple cases satisfying criteria for probable to definite causality including drug rechallenge. Nevertheless, a common clinical problem is to distinguish drug-induced thrombocytopenia from idiopathic thrombocytopenic purpura in a patient on multiple medications who develops thrombocytopenia. In the absence of validated laboratory assays for drug-dependent platelet antibodies other than heparin, diagnosis still depends on the clinical course following drug discontinuation and perhaps rechallenge. Large databases provide

TABLE 24–6. Xenobiotics Reported to Cause Thrombocytopenia as a Result of Antiplatelet Antibodies[a]

Abciximab	Indinavir
Acetaminophen	Levamisole
Aminoglutethimide	Linezolid
Aminosalicylic acid	Meclofenamic acid
Amiodarone	Nalidixic acid
Amphotericin B	Orbofiban
Carbamazepine	Oxprenolol
Cimetidine	Phenytoin
Danazol	Piperacillin
Diclofenac	Procainamide
Digoxin	Quinidine
Dipyridamole	Quinine
Eptifibatide	Rifampin
Famotidine	Tirofiban
Furosemide	Trimethoprim-sulfamethoxazole
Gold salts	Valproate
Heparin	Vancomycin
Imipenem-cilastatin	

[a]Xenobiotics reported in at least 2 cases to have definitely caused immune thrombocytopenia, or in at least 5 cases to have probably caused immune thrombocytopenia following therapeutic use.

Data adapted from George JN, Raskob GE, Shah SR, et al: Drug-induced thrombocytopenia: A systematic review of published case reports. Ann Intern Med 1998;129:886–890; Li X, Swisher KK, Vesely SK, George JN: Drug-induced thrombocytopenia: an updated systematic review. Drug Safety 2007;30:185–186 and http://w3.ouhsc.edu/platelets. Accessed January 12, 2009.

some guidance regarding past reported experience.[1,59,106,151] Severe (< 20,000 platelets/mm³), or acute transient thrombocytopenia are more likely to be drug-induced.[14]

In patients administered the sensitizing agent de novo, 5 to 7 days are typically required for the development of the immune response. During rechallenge, thrombocytopenia can develop within 12 hours.[14] Interestingly, the unique ability of GP IIb/IIIa inhibitors such as abciximab to cause thrombocytopenia within hours of first use suggests the presence of preformed antibodies directed against platelet epitopes, perhaps accounting for ex vivo clumping of platelets observed in each of approximately 500 normal patients.[152] Clinically, fever, chills, pruritus, and lethargy may occur. The onset of life-threatening bleeding may be abrupt. Hemorrhagic vesicles may be seen in the oral mucosa. Laboratory investigations will demonstrate an absence of platelets on peripheral smear, prolongation of the bleeding time, deficient clot retraction, and an abnormal prothrombin consumption test. Bone marrow aspiration will demonstrate normal or increased numbers of megakaryocytes and immature forms. Treatment includes the transfusion of blood products, glucocorticoids, and the withdrawal of the offending agent.[14]

Thrombotic thrombocytopenic purpura Thrombotic thrombocytopenic purpura (TTP) is characterized by the triad of microangiopathic hemolytic anemia, severe thrombocytopenia, and fluctuating neuro-

logic abnormalities.[124] Fever and renal dysfunction are also common, although overt renal failure is rare. The hallmark is the presence of platelet aggregates throughout the microvasculature, without fibrin clot, unlike the fibrin-rich thrombi seen in disseminated intravascular coagulation or the hemolytic uremic syndrome. In the acquired form, drug-induced autoantibodies inactivate a circulating zinc metalloprotease ADAMTS13, thereby blocking its ability to depolymerize large multimers of vWF and leading to platelet clumping.[11,12,17,186] Plasma exchange with fresh frozen plasma replenishes ADAMTS13 and removes the inhibitory antibodies. Prior to understanding of the molecular mechanism, other causes of microvascular hemolysis with thrombocytopenia were often confused with TTP. These causes included hemolytic uremic syndrome due to shiga toxin, the HELLP syndrome of pregnancy, Rocky Mountain spotted fever, and paroxysmal nocturnal hemoglobinuria. Also included were cases secondary to xenobiotics such as cyclosporine, cocaine, gemcitabine, mitomycin C and cisplatin, in which ADAMTS13 antibodies are not present.[48,186]

Heparin-induced thrombocytopenia An immune response to heparin, manifested clinically by the development of thrombocytopenia and, at times, venous thrombosis, is now recognized to result from antibodies to a complex of heparin and platelet factor 4.[4] The diagnosis is confirmed by testing for these antibodies. The heparin–platelet factor 4 antibody complex can directly activate platelets, and is believed to be the mechanism for the paradoxical thrombosis associated with this condition, which can be limb- or life-threatening[96] (Chap. 59).

SUMMARY

The mechanisms of toxic injury to the blood are extremely varied, reflecting the complexity of this vital fluid. The response to injury may be idiosyncratic, as in many xenobiotic-related causes of agranulocytosis and aplastic anemia, or predictable, as in the case of significant exposures to ionizing radiation or to benzene. Injury may depend on the presence of certain host factors, such as G6PD deficiency. Xenobiotics may directly injure mature cells, or prohibit their development by injuring the stem cell pool. Toxicity may result from the amplification of a potentially therapeutic intervention, such as occurs with many chemotherapeutic agents and anticoagulants. A common theme in hematologic toxicity is the perturbation of homeostatic equilibria that exist between cell proliferation and apoptosis, between immune activation and suppression, or between thrombophilia and thrombolysis. An improved awareness of these complex pathways allows the toxicologist to better understand, diagnose, and treat toxic injury to the blood.

CHAPTER 25
GASTROINTESTINAL PRINCIPLES

Richard G. Church and Kavita M. Babu

Humans are constantly in contact with a variety of xenobiotics. The gastrointestinal (GI) tract forms an important initial functional barrier, in addition to its critical role in absorbing nutrients. An understanding of the structure, physiology, and enteric autonomic system is critical to toxicologic concepts of absorption, gastric motility and appreciating the unique vulnerabilities of the GI tract to xenobiotics. This chapter discusses the role of the GI tract and its relation to toxicology. Anatomic, pathologic, and microbiologic principles are discussed, including the role of the GI tract in the metabolism of xenobiotics. Examples of GI pathologies and their clinical manifestations are discussed.

STRUCTURE AND INNERVATION OF THE GASTROINTESTINAL TRACT

The luminal gastrointestinal tract can be divided into five distinct structures: oral cavity and hypopharynx, esophagus, stomach, small intestine, and colon. These environments differ in luminal pH, specific epithelial cell receptors, and endogenous flora. The transitional areas between these distinct organs have specialized epithelia and muscular sphincters with specific functions and vulnerabilities. Knowledge of the anatomy of these transition zones is particularly important to the localization and management of foreign bodies. The functions of the pancreas and liver are closely integrated with those of the luminal organs, although they are not within the nutrient stream. The pancreas is discussed here; the liver and its metabolic functions are discussed in Chapters 12 and 26.

The visceral structures of the GI tract are composed of several layers, including the epithelium, lamina propria, submucosa, muscle layers and serosa (the last only in intraperitoneal organs). As the transition is made throughout the GI tract differences in luminal pH, epithelial cell receptors, muscularity and endogenous flora are encountered, affecting absorption and metabolism of individual xenobiotics.

The epithelium, the innermost layer of the GI tract, is the most specialized cell type in the intestine and is composed of epithelial, endocrine and receptor cells. Epithelial cells have polarity, with the basal surface facing the lamina propria and the apical surface facing the lumen. They are further specialized for specific functions of secretion or absorption. Additionally, the epithelial cell forms part of the mucosal immune defense, to detect the presence of microbial pathogens and down-regulate the immune system in the presence of nonpathogenic or probiotic microbes. The major barrier to penetration of xenobiotics and microbes is the GI epithelium, a single cell thick membrane.[13] The cell membrane is a lipid bilayer that contains proteins, which act as aqueous pores through which certain materials can pass, dependent on size or molecular structure, providing the basis for semi-permeability. The membrane is not continuous as it consists of individual epithelial cells; however, these cells are joined to each other by structures known as tight junctions, which are located on the lateral surfaces of the cells, near the apical membranes. The tight junctions have a gap of about 8 angstroms, which allows passage only of water, ions, and low-molecular weight substances.

The muscle layer found beneath the lamina propria is made up of the muscularis mucosa, the circular muscles and the longitudinal muscles. Contraction of the muscularis mucosa causes a change in the surface area of the gut lumen that alters secretion or absorption of nutrients. Depolarization of circular muscle leads to contraction of a ring of smooth muscle and a decrease in the diameter of that segment of the GI tract whereas depolarization of longitudinal muscle leads to contraction in the longitudinal direction and a decrease in the length of that segment. The function of the muscle layers is integrated with the enteric nervous system to provide for a coordinated movement of luminal contents through the GI tract so as to maximize absorption and minimize bacterial growth. This integration facilitates the flow of chyme (undigested food) via a coordinated sequence of muscular contractions and relaxations, leading to segmentation of luminal contents, peristaltic movements, and unidirectional flow through the intestine.

The GI tract is innervated by the autonomic nervous system via both extrinsic and intrinsic pathways. The extrinsic innervation permits communication between the brain, spinal cord, and chemoreceptors and mechanoreceptors located in the gut. Parasympathetic stimulation in the extrinsic pathway tends to be excitatory ("rest and digest"), and is carried via the vagus, splanchnic and pelvic nerves to the myenteric and submucosal plexuses. In contrast, increased sympathetic tone ("fight or flight") inhibits digestive and peristaltic activity via fibers that originate in the thoracolumbar cord and terminate in the myenteric and submucosal plexuses. The intrinsic innervation of the GI tract, or enteric nervous system, is responsible for the determination of parasympathetic and sympathetic tone to the GI tract. The intrinsic innervation provides local control of peristalsis and endocrine secretions, via the myenteric (Auerbach) and submucosal (Meissner) plexuses, respectively.

THE IMMUNE SYSTEM AND MICROBIOLOGY OF THE GI TRACT

An elaborate mucosal immune system has evolved to protect the GI tract from pathogens.[38] Mucosal immunity can be divided into an afferent limb, which recognizes a pathogen and induces the proliferation and differentiation of immunocompetent cells, and an efferent limb, which coordinates and affects the immune response. The afferent system includes the lymphoid follicles, and specialized M-cells found therein, that promote transit of antigens to antigen-presenting cells.[26] Once sensitized, immune cells undergo a complicated process of clonal expansion and differentiation, which occurs in mucosal and mesenteric lymphoid follicles, as well as in extraintestinal sites. Immunocompetent cells then return to the intestine and other mucous membranes, and are scattered diffusely within the epithelial and lamina propria compartments.

The normal endogenous flora in the GI tract includes more than 400 species of bacteria; the intestinal mucosa is normally colonized by nonpathogenic strains of *Esterichia coli, Proteus spp., Enterobacter spp., Serratia spp., and Klebsiella spp.* En masse, these bacteria are more metabolically active than the liver. The concentration of luminal bacteria varies by site, from lowest in the proximal small intestine to highest in the large intestine. Endogenous bacteria occupy unique niches related to host physiology, environmental pressures, and microbial interactions, which result in long-term stability.[17] The flora may be altered by various insults (particularly antibiotics), but usually returns to baseline once the insult is removed.

The endogenous flora has multiple metabolic functions. A primary function in the colon is the salvage of malabsorbed carbohydrates by fermentation and production of short-chain fatty acids, which is a preferred substrate for colonic epithelial cells. Hydrolysis of urea occurs following its passive diffusion into the intestinal lumen, producing NH_3

and a carbon skeleton. Elevated concentrations of nitrogenous compounds, including ammonia, may result from increased dietary load, or from gastrointestinal hemorrhage, or by decreased clearance, as occurs in patients with end-stage liver disease and hepatic encephalopathy.

Bacterial metabolism can significantly affect the disposition of enteral compounds. For example, the bacterial metabolism of digoxin contributes to its steady state concentrations, and antibiotic treatment may reduce or eradicate the intestinal flora, predisposing to digoxin toxicity.[7] Bacterial contribution to vitamin K metabolism is also demonstrated, necessitating dose adjustments of warfarin during and after antibiotic therapy. The metabolic activity of intraluminal bacteria has been exploited in treatment strategies. For example, sulfasalazine, used in the treatment of ulcerative colitis is created through the linkage of 5-aminosalicylic acid to sulfapyridine. The azo bonds of the nonabsorbable sulfasalazine are broken by bacterial azoreductases, permitting the absorption of active metabolites in the colon at the site of inflammation.[30]

The normal flora of the gut consists of probiotics—live, nonpathogenic bacteria and fungi that can also be used as prophylactic or therapeutic agents. These bacteria compete for and displace pathogenic bacteria, directly modulate intestinal immune function and exert a trophic effect on the gastrointestinal tract. They are used to decrease traveler's diarrhea, suppress antibiotic-induced diarrhea, and reduce inflammation in ileal pouches after colectomy in patients with ulcerative colitis.[10,15]

REGULATORY SUBSTANCES OF THE GASTROINTESTINAL TRACT

There are three groups of regulatory materials that act on target cells within the GI tract. These gastrointestinal hormones are released from endocrine cells in the GI mucosa into the portal circulation, enter the systemic circulation with resultant physiologic actions on target cells. Gastrin, cholecystokinin (CCK), secretin, and gastric inhibitory peptide (GIP) are considered the primary GI hormones. Somatostatin and histamine make up the paracrines, hormones that are released from endocrine cells and diffuse over short distances to act on target cells located in the GI tract. Vasoactive intestinal peptide (VIP), GRP (bombesin) and enkephalins compose the last group known as neurocrines, substances that are synthesized in neurons of the GI tract, move by axonal transport down the axon, and are then released by action potentials in the nerves. Effects on these regulatory substances are in summarized Table 25–1.[8]

ANATOMIC AND PHYSIOLOGIC PRINCIPLES

■ OROPHARYNX AND HYPOPHARYNX

The main functions of the mouth and oropharynx are chewing, lubrication of food with saliva, and swallowing. Saliva initiates digestion of

---

TABLE 25–1. Regulatory Substances of the GI Tract[8]

Substance	Site of Secretion/Release	Stimulus for Secretion/Release	Actions
Gastrin	G cells of gastric antrum	Small peptides and amino acids Stomach distention Vagal stimulation (via GRP) Inhibited by H+ in stomach (negative feedback)	↑ gastric H+ secretion, ↑ growth of gastric mucosa
Cholecystokinin	I cells of duodenum and jejunum	Small peptides and amino acids Fatty acids and monoglycerides	↑ contraction of gallbladder and relaxation of sphincter of Oddi ↑ pancreatic enzyme and HCO_3^- secretion ↑ growth of exocrine pancreas/gallbladder ↓ gastric emptying (allow more time for digestion and absorption)
Secretin	S cells of duodenum	H+ in duodenal lumen Fatty acids in duodenal lumen	Coordinated to reduce small intestinal H+ ↑ pancreatic HCO_3^- secretion ↑ biliary HCO_3^- secretion ↓ gastric H+ secretion ↑ growth of exocrine pancreas
Gastric Inhibitory Peptide	Duodenum and jejunum	Fatty acids, amino acids, oral glucose	↓ H+ secretion by gastric parietal cells ↑ insulin release
Somatostatin	Throughout GI tract	H+ in GI tract lumen Inhibited by vagal stimulation	↓ release of all GI hormones ↓ gastric H+ secretion
Histamine	Mast cells of gastric mucosa	Vagal stimulation gastrin	↑ gastric H+ secretion
Vasoactive Intestinal Peptide	GI tract mucosa and smooth muscle neurons	H+ in duodenal lumen	Smooth muscle relaxation ↑ pancreatic HCO_3^- secretion ↓ gastric H+ secretion
Bombesin	Vagus nerves that innervate G cells	Vagal stimulation	↑ gastrin release from G cells
Enkephalins (met-enkephalin, leu-enkephalin)	GI tract mucosa and smooth muscle neurons		↑ contraction of GI smooth muscle ↓ intestinal secretion of fluid and electrolytes

starch by α-amylase (ptyalin), triglyceride digestion by lingual lipase, lubrication of ingested food by mucus, and protection of the mouth and esophagus by dilution and buffering of ingested foods.

Saliva production is unique in that it is increased by both parasympathetic and sympathetic activity. Parasympathetic stimulation, via cranial nerves VII and IX acts on muscarinic cholinergic receptors on acinar and ductal cells, increases saliva production by causing vasodilation and increasing transport processes in the acinar and ductal cells. Parasympathetic pathways are stimulated by food in the mouth, smells, conditioned reflexes, and nausea, and are inhibited by sleep, dehydration, and fear. Sympathetic stimulation, originating from preganglionic nerves in the thoracic segments T1-3, requires receipt of norepinephrine by β-adrenergic receptors on acinar and ductal cells, leading to increases in the production of saliva, but at a rate less than that of parasympathetic stimulation.[8] Dysfunction of saliva production can lead to dry mouth, or xerostomia.

■ ESOPHAGUS

The normal esophagus is a distensible muscular tube that extends from the epiglottis to the gastroesophageal junction. The lumen of the esophagus narrows at several points along its course, first at the cricopharyngeus muscle, then midway down alongside the aortic arch and then distally where it crosses the diaphragm. The upper esophageal sphincter (UES) and lower esophageal sphincter (LES) are physiologic high-pressure regions that remain closed except during swallowing, and have no anatomic features to distinguish them from the intervening esophageal musculature.

The wall of the esophagus reflects the general structural organization of the GI tract noted previously, consisting of mucosa, submucosa, muscularis propria, and adventitia. The mucosal layer has three components. The nonkeratinizing stratified squamous epithelial layer faces the lumen, provides protection for underlying tissue, and houses several specialized cell types such as melanocytes, endocrine cells, dendritic cells, and lymphocytes. The lamina propria is the nonepithelialized portion of the mucosa, and the muscularis mucosa, a layer of longitudinally oriented smooth-muscle bundles is the third component.

The submucosa consists of loose connective tissue, and submucosal glands secrete a mucin-containing fluid via squamous epithelium-lined ducts which facilitates lubrication of the esophageal lumen. The muscularis propria consists of an inner circular and outer longitudinal coat of smooth muscle; this layer also contains striated muscle fibers in the proximal esophagus that is responsible for voluntary swallowing.

The esophagus has no serosal lining. Only small segments of the intraabdominal esophagus are covered by adventitia, a sheath-like structure that also surrounds the adjacent great vessels, tracheobronchial tree, and other structures of the mediastinum.

The esophagus provides a conduit for food and fluids from the pharynx to the stomach, and the sphincters generally prevent reflux of gastric contents into the esophagus. Normal transit of food involves coordinated motor activity including a wave of peristaltic contraction, relaxation of the LES (facilitated by nitric oxide and VIP), and subsequent closure of the LES (facilitated by several hormones and neurotransmitters such as gastrin, acetylcholine, serotonin, and motilin). Because of the rapid transit time of swallowed substances through this portion of the GI tract, digestion does not take place and passive diffusion of substances from the food into the bloodstream is prevented.[8,24]

■ STOMACH

The stomach is a saccular organ covered entirely by peritoneum that has a capacity greater than 3 liters. The stomach is divided into five anatomic regions: the cardia, fundus, corpus or body, antrum, and pyloric sphincter. The gastric wall consists of mucosa, submucosa, muscularis propria, and serosa. The interior surface of the stomach is marked by coarse rugae, or longitudinal folds. The mucosa is made up of a superficial epithelial cell compartment and a deep glandular compartment. The glandular compartment consists of gastric glands, which vary between regions of the stomach. The mucus glands of the cardia, fundus and body secrete mucus and pepsinogen. Oxyntic, or acid-forming glands, found in the fundus and body contain parietal, chief, and endocrine cells. The parietal cells contain vesicles that house hydrochloric acid-secreting proton pumps and also secrete intrinsic factor, a substance necessary for the ileal absorption of vitamin B$_{12}$. Chief cells secrete the proteolytic proenzyme pepsinogen which is cleaved to its active form, pepsin, upon exposure to the low luminal gastric pH of 3 to 4. Pepsin is subsequently inactivated in the duodenum when the pH increases to 6.0. The endocrine, or enterochromaffin-like (ECL), cells found in the mucosa of the body of the stomach produce histamine, which increases acid production and decreases gastric pH by stimulating H$_2$ receptors on the parietal cells. Somatostatin and endothelin, both modulators of acid production, are also produced in ECL cells (Fig. 50–3).

Hydrochloric acid is secreted when cephalic, gastric and intestinal signals converge on the gastric parietal cells to activate proton pumps and release hydrochloric acid in an ATP-dependent process. During the cephalic phase, or the preparatory phase of the brain for eating and digestion, acetylcholine is released from vagal afferents in response to sight, smell, taste, and chewing. Acetylcholine stimulates the parietal cells via muscarinic receptors, resulting in an increase in cytosolic calcium and activation of the proton pump. G cells, located in the antrum of the stomach, produce and release gastrin in response to luminal amino acids and peptides. Gastrin activates receptors within parietal cells, leading to a similar increase in cytosolic calcium. Additionally, gastrin and vagal afferents induce the release of histamine from ECL cells, which stimulates parietal cell H$_2$ receptors. Lastly, the intestinal phase is initiated when food containing digested protein enters the proximal small intestine and involves gastrin as well as a number of other polypeptides in the secretion of hydrochloric acid from the stomach.[24] See Fig 25–1.

The gastric mucosa is protected from the acidic secretions of the stomach by several mechanisms, including a thin layer of surface mucus, and channels that allow acid- and pepsin- containing fluids to exit glands without contact with the surface epithelium. Additionally, the surface epithelium secretes bicarbonate, creating a more neutral pH at the cell surface. Prostaglandins produced in the mucosal cells stimulate production of bicarbonate and mucus, and inhibit parietal cell production of acid; prostaglandin inhibition plays an important role in the pathogenesis of peptic ulcer disease.[24]

In the stomach, ingested products are ground to particle sizes of less than 0.2 mm, which are then further processed and digested in preparation for absorption of nutrients in the small intestine.[25] Many xenobiotics are weak acids that are no longer ionized in the acidic environment of the stomach, facilitating absorption through the lipid bilayer at the level of the stomach. Other factors that affect xenobiotic absorption include particle size, transit time, and type of drug delivery system. Different types of drug formulations, such as time-release, enteric coating, slowly dissolving matrices, dissolution control via osmotic pumps, ion exchange resins, and pH-sensitive mechanisms can affect bioavailability, as well as the site of maximal release within the GI tract.

Following processing, the stomach delivers the products to the small intestine.

The time required for gastric emptying is determined by the complex interplay of GI innervation, muscle action, underlying illness, and xenobiotic exposure. Digestion and absorption are time-dependent
FIGURE 25–1. Effects of various xenobiotics on the gastrointestinal tract. ECL cell, enterochromaffin-like cell; CCK-B, cholecystokinin receptor B; H, histamine; H$_2$, histamine-2 (H$_2$) receptor; M$_1$, M$_3$; muscarinic receptors; ST2, somatostatin-2 receptor.

processes and optimal absorption requires adjustment of the luminal environment through secretion of ions and water, to accommodate meals that vary considerably in nutrient composition and density. Osmoreceptors and chemoreceptors in the GI tract fine-tune the digestive and absorptive processes by regulating transit and secretion, using a variety of neurocrine, paracrine and endocrine mechanisms. Interference with this integrated response may lead to stasis and bacterial overgrowth, or rapid transit with decreased absorption and development of diarrhea. A large number of mediators affect motility, including common neurotransmitters, such as acetylcholine and nor-epinephrine, hormones, cytokines, inflammatory compounds, and others. In general, parasympathetic impulses promote motility, whereas sympathetic stimulation inhibits motility. Other transmitters, such as serotonin, promote transit, whereas dopamine and enkephalins can slow motility.

■ SMALL AND LARGE INTESTINES

In the average adult, the small intestine is approximately 6 meters in length, and begins retroperitoneally as the duodenum, becoming peritoneal at the jejunum and ileum. Small intestine transitions to large intestine at the ileocecal valve, and the large intestine typically measures 1.5 meters in an adult. The large intestine or colon is further divided into cecal, ascending, transverse, descending, and sigmoid segments. The sigmoid colon transitions to the rectum, and terminates at the anus. Anterograde and retrograde peristalsis occurs in the small intestine, whereas anterograde peristalsis predominates in the large

intestine. This movement allows for mixing of food, maximizes contact with the mucosa, and is mediated by both the extrinsic and intrinsic nervous systems. The remarkable absorptive capacity of the small intestine is created by innumerable villi of the intestinal wall, which are small epithelial-lined "fingers" that extend into the lumen. The epithelial border of the small intestine also contains mucin-secreting goblet cells, endocrine cells, and specialized absorptive cells; functionally, these cells create an ideal environment for maximal nutrient absorption. The mucosa of the large intestine is devoid of villi. The large intestine functions primarily to absorb electrolytes and water, secrete potassium, salvage any remaining nutrients, and to store and release waste.

Intestinal epithelial cells also have the ability to metabolize xenobiotics, a function typically attributed to the liver. Epithelial cells contain many of the same metabolic enzymes as the liver and are capable of performing multiple types of reactions including hydroxylation, sulfation, acetylation, and glucuronidation. These metabolic processes affect the amount of orally administered xenobiotic that enters the body and contributes to the first-pass effect, or presystemic disposition. Variations in intestinal metabolism also may influence the pharmacokinetics of a xenobiotic.

Regeneration of injured or senescent intestinal epithelial cells begins in the crypts, with differentiation occurring as these cells migrate towards to the intestinal lumen. This process occurs rapidly, with turnover of the small intestinal epithelium occurring every 4 to 6 days, and large intestinal epithelium every 3 to 8 days. This rapid regeneration leaves the intestinal epithelium vulnerable to processes that interfere

with cell replication. The sloughing of GI epithelium, typically manifested by hemorrhagic enteritis, is subsequently a valuable marker for xenobiotic insults that lead to mitotic arrest.

■ PANCREAS

The pancreas is a retroperitoneal organ that serves dual exocrine and endocrine functions. The exocrine portion of the gland produces digestive enzymes and occupies more than 80%–85% of the mass of the pancreas. The exocrine pancreas is comprised of acinar cells, specialized epithelial cells housing zymogen granules that release digestive enzymes and proenzymes on secretion. The digestive enzymes enter the duodenum, while columnar epithelial cells produce mucin and ductal cuboidal epithelial cells secrete a bicarbonate-rich fluid that neutralizes gastric acids. The pancreas secretes 2–2.5 liters per day of this mixed solution. Typically, the digestive enzymes are released as proenzymes, such as trypsinogen, chymotrypsinogen, and procarboxypeptidase, are activated upon contact with the higher pH of the duodenum; this process helps to prevent autodigestion of the pancreas itself. Enzymes on the brush border of the duodenum, including enteropeptidase, cleave proenzymes to their active forms. Only pancreatic amylase and lipase are secreted in their active forms.

Secretion of pancreatic enzymes is regulated by multiple factors, the most important of which are cholecystokinin and secretin, both produced in the duodenum. Cholecystokinin is released from the duodenum in response to fatty acids and the products of protein catabolism such as peptides and amino acids. Cholecystokinin stimulates acinar cells to release digestive enzymes and proenzymes. Secretin is released by the duodenum in the presence of lowered pH caused by gastric acids and luminal fatty acids. Secretin triggers ductal cells to secrete bicarbonate and water. Acetylcholine also plays a role in the regulation of pancreatic exocrine function, by stimulating digestive enzyme secretion from the acinus and potentiating the effects of secretin. Vagal reflexes increase acetylcholinergic tone in the setting of decreased pH, protein breakdown products, and fatty acids in the duodenal lumen.

The endocrine portion of the pancreas is comprised of approximately one million clusters of cells known as the islets of Langerhans which secrete insulin, glucagons, and somatostatin. Other products of the endocrine pancreas include serotonin and VIP. Injury to the endocrine pancreas can result in impaired glucose homeostasis.

XENOBIOTIC METABOLISM

Although the liver is usually identified as the site of xenobiotic metabolism, similar functions occur in the luminal GI tract. Biotransformation is a property both of luminal bacteria and enterocytes. Metabolism by the intestine affects the amount of orally administered xenobiotic that actually enters the body and therefore contributes to the first-pass effect, or presystemic disposition.

One of the most well-described families of export proteins, P-glycoprotein (PGP), is found in the mucosa of the small and large intestines, hepatocytes, the adrenal cortex, renal tubules, and the capillary cells lining the blood-brain barrier.[43] The PGPs are susceptible to induction and inhibition in a manner similar to hepatic cytochrome oxidase enzymes. Many of the substrates of CYP3A have inhibitory effects on PGPs. Inhibitors of PGPs may raise serum concentrations of the parent drug or metabolite, although inducers of PGPs may prevent therapeutic drug concentrations from ever reaching the target cell. The PGP system is important in drug interactions and drug resistance (Chap. 8).

Tetracycline	Yellow to brown-grey

■ PATHOLOGIC CONDITIONS OF THE GI TRACT

Oral Pathology Discoloration of the teeth has been reported with a number of medications, most notably tetracyclines. Medications known to cause dental pigmentation are listed in Table 25–2. Gingival hyperplasia in an uncommon, but reported adverse effect of the chronic use of several xenobiotics, including multiple anticonvulsants. Gingival hyperplasia describes overgrowth of the gums around the teeth which can result in loosening of teeth and severe periodontal disease. Some medications implicated in causing gingival hyperplasia include calcium channel blockers, cyclosporine, lithium, phenobarbital, phenytoin, topiramate, and valproic acid.[1] Xerostomia, or pathologic dryness of the mouth, is an uncomfortable adverse effect of many xenobiotics that can lead to increased dental decay. Xenobiotics that can cause xerostomia is extensive, and the most commonly implicated classes of xenobiotics causing xerostomia are listed in Table 25–3. Chronic methamphetamine use has been linked to characteristic oral pathology known as "meth mouth." This condition is characterized by extensive and severe tooth decay, and has been linked to poor hygiene, bruxism, and xerostomia associated with methamphetamine use.[9]

Esophagitis and Dysphagia Xenobiotic-induced esophageal injury includes esophagitis, ulceration, perforation, and stricture. The most common presenting complaint is a foreign body sensation in the throat.[5,18] Xenobiotics commonly implicated in the causation of esophagitis or esophageal ulcerations are listed in Table 25–4. Patient features that predict likelihood of esophageal pathology include preexisting esophageal motility disorderts. Conditions like Parkinsonism, cerebrovascular accidents, scleroderma, and myasthenia gravis can contribute to dysphagia. Xenobiotics with a gelatin matrix, rapid dissolvability, and large size predispose to esophageal injury. Although most symptoms resolve with withdrawal of the offending xenobiotics, patients with persistent or severe odynophagia should be evaluated with endoscopy to identify pathology and prevent perforation caused by retained pills.[11]

Webs, strictures, and esophageal malignancy Caustic injury is one of the most common causes of esophageal strictures. Some authors have also postulated the role of pill esophagitis in the evolution of esophageal strictures.[4] Caustic injury is also implicated in the causation of esophageal malignancy. As great as 4% of patients with esophageal cancer report a history of caustic injury and patients with a prior history of caustic ingestion may have more than a 1000-fold higher risk of developing an esophageal malignancy than the general population.[19,20] Other xenobiotics known to cause esophageal strictures include aluminum phosphide and ionizing radiation.[37]

Gastritis/Peptic Ulcer Disease Gastritis, or inflammation of the gastric mucosa, and peptic ulcer disease (PUD) are commonly related to xenobiotic exposure (Table 25–5). Symptoms of gastritis and PUD include epigastric pain, nausea and vomiting, but may include hematemesis and melena.[29] The primary distinction between gastritis and peptic ulcer disease is appearance at endoscopy where gastritis is characterized by diffuse inflammation of the gastric mucosa, whereas an ulcer is a discrete lesion of the mucosa. Nonsteroidal antiinflammatory drugs (NSAIDs) remain an important part of the pathogenesis of gastric and PUD by decreasing prostaglandin secretion and subsequently affecting the integrity of the gastric mucosal barrier to acid. Cyclooxygenase-2 (COX-2) selective inhibitors promised to decrease the incidence of gastric pathology caused by chronic NSAID use; however, the available COX-2 inhibitors now carry a black box warning in the United States that desribe an increased risk of significant adverse cardiovascular events.[14]

Chronic treatment of peptic ulcer disease with antacids, H_2 blockers, or proton pump inhibitors can lead to hypochlorhydria or achlorhydria, the reduction or absence of gastric acid, respectively. These conditions increase risk of bacterial overgrowth, atrophic gastritis, hip fracture (possibly caused by impaired calcium absorption), *Salmonella* and *Vibrio cholerae* infection, and gastric carcinoma.[32,42]

Enteritis The symptoms of GI distress are nonspecifically associated with xenobiotic exposure, as well as a myriad of infectious etiologies. However, certain xenobiotics that increase gastric emptying and peristalsis can result in significant diarrhea. Opioid withdrawal and serotonin syndrome are important toxidromes that may feature diarrhea as a prominent symtom. Additionally, the rapid turnover of the GI mucosa makes it uniquely susceptible to xenobiotics that cause cell death and mitotic arrest. Hemorrhagic enteritis, manifested by hematochezia, can be a characteristic finding of certain xenobiotic exposures (Table 25–6).

Pancreatitis Pancreatitis is an acute inflammatory process that results in autolysis of the pancreas from digestive enzymes.[41] Cases range from mild to severe, with mortality of 5%.[16] The most common causes of pancreatitis are alcohol abuse and gallbladder disease; however, xenobiotic-induced pancreatitis accounts for 0.1%–2% of cases of acute pancreatitis.[2] Populations at higher risk of drug-induced pancreatitis include children, women, the elderly, and patients with HIV and inflammatory bowel disease.[2] In acute pancreatitis, the most common diagnostic criterion is elevation of serum pancreatic enzymes, amylase or lipase, to more than three times the upper limit of the reference range. The diagnosis of xenobiotic-induced pancreatitis can be impossible to confirm, as no diagnostic test or pattern of injury distinguishes xenobiotic-induced pancreatitis from other etiologies. However, the symptoms and laboratory abnormalities associated with xenobiotic-induced pancreatitis tend to resolve shortly after withdrawal of the offending xenobiotic; again, this can be challenging to differentiate from the natural course of mild to moderate disease. It is unclear whether rechallenge with a culprit xenobiotic will cause pancreatitis again; however, any xenobiotic suspected of causing pancreatitis should be withheld unless the benefits outweigh this risk. The management of xenobiotic-induced pancreatitis does not differ from other causes, and hinges on aggressive volume resuscitation, bowel rest, and careful monitoring. Patients at the extremes of age, manifesting end organ dysfunction, acute lung injury, or signs of shock are at greatest risk of death.

There are numerous xenobiotics associated with pancreatitis, and the strength of that association has been described as definite, likely, or possible; representative xenobiotics are listed in Table 25–7. The pathogenic mechanism varies with the specific xenobiotic. The nucleoside reverse transcriptase inhibitor, didanosine, and exposure to dioxin,

Pesticides: Organic Phosphorous compounds

Sitagliptin

Venoms: *Buthus quiquestriatus, Tityus discrepan*s

may promote pancreatitis as a result of mitochondrial injury.[27,33,34] Cholinergic xenobiotics, like parathion and certain scorpion venoms, may result in pancreatitis caused by overstimulation.[21,31] Vasospasm and ischemia are also purported as a mechanism, as in cases of pancreatitis secondary to ergot alkaloids.[12]

The endocrine pancreas is also susceptible to injury from pancreatitis or toxic insult. Typically, dysfunction of the endocrine pancreas results from injury to pancreatic beta cells and impaired glucose homeostasis, similar to diabetes. There are rare xenobiotics that can cause damage to alpha cells in animal models; however, they do not consistently cause hypoglycemia (Table 25–8).

FOREIGN BODIES

The esophagus is the most common site of symptomatic foreign bodies. They tend to be found in the cervical esophagus, at the level of the aortic notch, just above the gastroesophageal junction, or just proximal to an esophageal narrowing.[6] The likelihood that a foreign object will lodge in the esophagus is related to its size and shape. The major complications of foreign bodies in the esophagus include pain, bleeding, obstruction or perforation, which may lead to subsequent mediastinitis or fistula. The general rule is that conservative means can be employed for up to 12 hours after ingestion of the esophageal foreign body. If serial radiographs demonstrate no movement after 12 hours, endoscopic retrieval or surgery should be considered, as the risk of perforation increases after that time; some authors will extend this observation period to 24 hours.[3,35] Ingestion of button batteries proves an important exception to this rule. Esophageal button batteries can cause significant mucosal injury in four hours, with perforation in as little as 6 hours.[22] Proposed mechanisms for the rapid development of esophageal injury include alkaline burn, local current and pressure necrosis.[23,36] As a result, all suspected esophageal button batteries should undergo immediate endoscopic removal, and success rates with this modality have been reported as excellent.[23]

Foreign bodies are also commonly found in the stomach. Many small foreign bodies will pass through the stomach and the remainder of the GI tract without difficulty. Objects greater than 5 cm in length or 2 cm in diameter may be unable to traverse the duodenum, and may require endoscopic or surgical removal. Foreign bodies beyond the duodenum may not require any intervention except observation; however, some objects may become stuck at the ileocecal valve. Serial examinations and radiographs can be appropriate for asymptomatic patients; however, increasing abdominal pain or tenderness may mandate further imaging and surgical consultation. Body packers represent an unusual exception to these rules. Patients who are discovered to be internally concealing large quantities of illicit drugs may require whole bowel irrigation to facilitate transit of colonic packets, and even emergency laparotomy for obstruction or suspected packet rupture in cases of cocaine or methamphetamine smuggling.[39]

SUMMARY

The GI tract is vulnerable to a wide variety of pathogenic agents with diverse physical, chemical, and biologic forms. Understanding the effects of such xenobiotics on the GI tract requires an appreciation of its normal anatomy and physiology. Because of its potential as a site of severe local or systemic effects, and the role that GI signs and symptoms play in various toxic syndromes, the GI tract is an important consideration in many toxicologic emergencies.

CHAPTER 26
HEPATIC PRINCIPLES

Kathleen A. Delaney

The liver plays an essential role in the maintenance of metabolic homeostasis. Hepatic functions include the synthesis, storage, and breakdown of glycogen. In addition, the liver is important in the metabolism of lipids; the synthesis of albumin, clotting factors, and other important proteins; the synthesis of the bile acids necessary for absorption of lipids and fat-soluble vitamins; and the metabolism of cholesterol.[20,54] Hepatocytes facilitate the excretion of metals, most importantly iron, copper, zinc, manganese, mercury, and aluminum; and the detoxification of products of metabolism, such as bilirubin and ammonia.[29,62] Generalized disruption of these important functions results in manifestations of liver failure: hyperbilirubinemia, coagulopathy, hypoalbuminemia, hyperammonemia, and hypoglycemia.[41,74] The hepatic functions can also be selectively altered by exposure to hepatotoxins.[54] Disturbances of more specific functions result in accumulation of fat, metals, and bilirubin, and the development of fat-soluble vitamin deficiencies.[20,54]

The liver is also the primary site of biotransformation and detoxification of xenobiotics.[46,133] Its interposition between the gut and systemic circulation makes it the first-pass recipient of xenobiotics absorbed from the gastrointestinal tract into the portal vein. The liver also receives blood from the systemic circulation and participates in the detoxification and elimination of xenobiotics that reach the bloodstream through other routes, such as inhalation or cutaneous absorption.[20,118]

Many xenobiotics are lipophilic inert substances that require chemical activation followed by conjugation to make them sufficiently soluble to be eliminated. The liver contains the highest concentration of enzymes involved in phase I oxidation-reduction reactions, the first stage of detoxification for many lipophilic xenobiotics.[46,133] Conjugation of the reactive products of phase I biotransformation with molecules such as glucuronide facilitates excretion.[133] (Chap. 12) Although many xenobiotics that are detoxified in the liver are subsequently excreted in the urine, the biliary tract provides a second essential route for the elimination of detoxified xenobiotics and products of metabolism.[20,29]

MORPHOLOGY AND FUNCTION OF THE LIVER

Two pathologic concepts are used to describe the appearance and function of the liver; a structural one represented by the hepatic lobule, and a functional one represented by the acinus. The basic structural unit of the liver characterized by light microscopy is the hepatic lobule, a hexagon with the central hepatic vein at the center and the portal triads at the angles. The portal triad consists of the portal vein, the common bile duct, and the hepatic artery. Cords of hepatocytes are oriented radially around the central hepatic vein, forming sinusoids. The acinus, or "metabolic lobule" is a functional unit of the liver. Located between two central hepatic veins, it is bisected by terminal branches of the hepatic artery and portal vein that extend from the bases of the acini toward hepatic venules at the apices. The acinus is subdivided into three metabolically distinct zones. Zone 1 lies near the portal triad, zone 3 near the central hepatic vein, and zone 2 is intermediate.[20,54] Figure 26–1 illustrates the relationship of the structural and functional concepts of the liver.

Approximately 75% of the blood supply to the liver is derived from the portal vein, which drains the alimentary tract, spleen, and pancreas. The blood is enriched with nutrients and other absorbed xenobiotics and is poor in oxygen. The remainder of the hepatic blood flow comes from the hepatic artery, which delivers well-oxygenated blood from the systemic circulation.[20] Blood from the hepatic artery and portal vein mixes in the sinusoids, coming in close contact with cords of hepatocytes before it exits through small holes in the wall of the vein. Oxygen content diminishes several fold as blood flows from the portal area to the central hepatic vein.[54,118]

There are six types of cells in the liver. Hepatocytes and bile duct epithelia make up the parenchyma. Cells found in the vicinity of the sinusoids include endothelial cells, fixed macrophages (Kupffer cells), hepatic stellate cells (Ito cells) that store fat, and large lymphocytic "pit cells" that roam the sinusoids.[118] The sinusoidal lining formed by endothelial cells is thin and fenestrated, allowing transfer of fluid, chylomicrons, and proteins across the space of Disse, an extrasinusoidal space filled with microvilli.[20,54,118] Kupffer cells scavenge particulate materials and cell debris within the sinusoids. When immunologically activated by xenobiotics, Kupffer cells contribute to the generation of oxygen free radicals[115,144] and may also participate in the production of autoimmune injury to hepatocytes.[33,61,115] Hepatic stellate cells (Ito cells) are primary sites for the storage of fat and vitamin A.[43] In a quiescent state they spread out between the sinusoidal endothelium and hepatic parenchymal cells. Filled with microtubules and microfilaments, they project cytoplasmic extensions that contact several cell types.[54,118] Activated stellate cells produce collagen, proteoglycans, and adhesive glycoproteins, which are crucial to the development of hepatic fibrosis.[118] Kupffer cells also contribute to the activation of hepatic stellate cells.[118] "Pit cells" are antigenically related to circulating natural killer cells. They actively lyse tumor cells and cells infected by virus[118] (Fig. 26–2).

Bile acids, organic anions, bilirubin, phospholipids, xenobiotics, and other molecules excreted in bile are actively transported across the hepatocyte plasma membrane into the bile canaliculi at sites that have specificity for acids, bases, and neutral compounds.[20,54] Tight junctions separate the contents of the bile canaliculi from the sinusoids and hepatocytes, maintaining a rigid and functionally necessary compartmentalization. Bile acids use three active transport systems: a sodium-dependent bile salt transporter in the sinusoidal membrane; an adenosine triphosphate (ATP)-dependent bile salt carrier in the canalicular membrane; and a canalicular membrane transport site driven by the membrane voltage potential.[54,67,118] Glucuronidated xenobiotics are substrates for the bile acid transport systems and are actively secreted into bile. Xenobiotics with molecular weights greater than 350 daltons are also preferentially secreted into bile. Like the transport and concentration of constituents from the sinusoids and hepatocytes, the flow of bile through the canaliculi is also an active process facilitated by ATP-dependent contractions of actin filaments that encircle the canaliculi.[67,139]

The enterohepatic circulation of bile acids and some vitamins plays a crucial role in their conservation. Unfortunately, this physiologically important process impedes the fecal elimination of some xenobiotics by reabsorbing and returning them back into the systemic circulation, prolonging their half lives and toxicity. Xenobiotics that have low molecular weights and are not ionized at intestinal pH, such as methyl mercury, phencyclidine, and nortriptyline, are most likely to be reabsorbed.[29,114]

The liver is especially vulnerable to toxic injury, due to its location at the end of the portal system and its substantial complement of biotransformation enzymes. Although phase I activation of xenobiotics is usually followed by phase II conjugation that results in detoxification, it can also lead to the production of xenobiotics with increased toxicity, which is often manifest at the site of their synthesis.[46,82,133]

	Zone 1	Zone 3

FIGURE 26–1. The acinus is defined by three functional zones. Specific contributions of each zone to the biotransformation of xenobiotics reflect various metabolic factors that include differences in oxygen content of blood as it flows from the oxygen-rich portal area to the central hepatic vein; differences in glutathione content; different capacities for glucuronidation and sulfation; and variations in content of metabolic enzymes such as CYP2E1.The hepatic lobule (not shown) is a structural concept, a hexagon with the central vein at the center surrounded by 6 portal areas that contain branches of the hepatic artery, bile duct, and portal vein. Injury to hepatocytes that is confined to zone 3 is called "centrilobular" because in the structure of the lobule, zone 3 encircles the central vein, which is the center of the hepatic lobule.

FACTORS THAT AFFECT THE ANATOMIC LOCALIZATION OF HEPATIC INJURY

Hepatocellular injury that occurs near the portal vein is called *periportal,* or *zone 1* necrosis. The terms *centrilobular* or *zone 3* necrosis refer to injury that surrounds the central hepatic vein.[20] Figure 26–3 shows centrilobular necrosis caused by exposure to bromobenzene. Metabolic characteristics of the zones of the acinus have important relevance to the anatomic distribution of toxic liver injury. Because of its location in the periportal area, zone 1 has a two-fold higher oxygen content than zone 3. Hepatic injury that results from the metabolic production of oxygen free radicals predominates in zone 1. Allyl alcohol, an industrial chemical that is metabolized to a highly reactive aldehyde, is associated with oxygen dependent lipid peroxidation injury to hepatocytes in zone 1.[8] The tendency for centrilobular or zone 3 accumulation of fat in patients with alcoholic steatosis is attributed to the effect of relative hypoxia in the central vein area on the oxidation potential of the hepatocyte.[80] The availability of substrates for detoxification and the localization of enzymes involved in biotransformation also affect the site of injury. Zone 1 has a higher concentration of glutathione, whereas zone 3 has a greater capacity for glucuronidation and sulfation.[134] Zone 3 has higher concentrations of alcohol dehydrogenase, which may lead to increased production of toxic acetaldehyde at centrilobular sites.[28,54,80,84] Zone 3 also has high concentrations of cytochrome oxidase CYP2E1, which converts many xenobiotics including acetaminophen, nitrosamines, benzene, and carbon tetrachloride (CCl_4) to reactive intermediates that may cause centrilobular injury. Although CCl_4 can be metabolized to a
FIGURE 26–2. Blood flowing through the hepatic sinusoids is separated from hepatocytes by fenestrated endothelium that allows passage of many substances across the Space of Disse. This figure shows 6 types of cells found in the liver and their localization in relation to the sinusoid. Stellate cells are fat storage cells that promote fibrosis when activated. Kupffer cells are fixed macrophages that participate in immune surveillance and are a source of free radicals when activated. Pit cells float freely in the sinusoids and have activities similar to natural killer (NK) cells. Hepatocytes and bile epithelial cells form the hepatic parenchyma.

highly reactive oxygen free radical in zone 1, it primarily injures zone 3 for the following reasons:[16] CCl_4 is metabolized by CYP2E1 in zone 3 to a trichloromethyl free radical ($\cdot CCl_3$) that can form covalent bonds with cellular proteins, cause lipid peroxidation, or spontaneously react with oxygen to form the more highly reactive trichloromethyl peroxy radical ($CCl_3OO\cdot$).[16,33,81] Higher oxygen tension in zone 1 fosters the formation of $CCl_3OO\cdot$ which is rapidly detoxified by glutathione. Since the less reactive $\cdot CCl_3$ that predominates in zone 3 is not readily detoxified by glutathione, zone 3 incurs the greater amount of injury. Hyperbaric oxygen increases the oxygen tension throughout the liver and decreases liver
FIGURE 26–3. Centrilobular necrosis in a rat liver caused by bromobenzene administration. Note the polymorphonuclear leukocyte infiltration surrounded by vacuolated hepatocytes in the necrotic area. injury caused by CCl_4, possibly by increasing the formation of $CCl_3OO\cdot$ in zone 3, which is then efficiently detoxified by glutathione.[16,133] The observed effects of isoniazid (an inhibitor of the enzyme CYP2E1) and chronic ethanol intake (an inducer of the CYP2E1 gene) on injury in cell cultures from periportal and centrilobular areas exposed to CCl_4 support the association of CCl_4 injury with the localization of CYP2E1 activity. Acute exposure to isoniazid significantly decreases the injury associated with exposure of zone 3 cells to CCl_4, whereas chronic treatment with ethanol significantly enhances it.[81]

HOST FACTORS THAT AFFECT THE DEVELOPMENT OF HEPATOTOXICITY

Xenobiotics that produce liver damage in all humans in a predictable and dose-dependent manner are called *intrinsic* hepatotoxins. They include acetaminophen, CCl_4, and yellow phosphorous. Those that cause liver damage in a small number of individuals and whose effect is not apparently dose dependent or predictable are called *idiosyncratic* hepatotoxins. Some idiosyncratic hepatotoxins cause hepatotoxicity very rarely, whereas others produce it commonly. The majority of hepatotoxins fall into the category of idiosyncratic xenobiotics.[75,82] The inhaled anesthetic halothane is both an intrinsic and an idiosyncratic hepatotoxin. A mild degree of hepatitis occurs in as great as 20% of patients exposed to halothane.[32] This form of halothane hepatitis, which can be reliably induced in animals, is likely caused by direct toxicity.[117] A more severe idiosyncratic form appears to be caused by an autoimmune response induced by halothane that targets liver proteins[13,127] (Chap. 67).

Sporadic unpredicted hepatotoxicity is not idiosyncratic, but is more likely a result of the combined effects of genetic and other factors that result in the overproduction or decreased clearance of toxic metabolites. Idiosyncratic toxicity may be related to individual variability in the capacity to metabolize a specific xenobiotic and would most likely be predictable, rather than "idiosyncratic," if the exposed individual's metabolic capabilities could be prospectively defined (Chap. 12). An individual's susceptibility to a hepatotoxin depends on numerous factors, including the activity of biotransformation enzymes, the availability of substrates such as glutathione, and the immune competence of the individual. In turn, these are affected by age, sex, diet, underlying diseases, concurrent exposure to other xenobiotics, and genetic factors. Many enzymes involved in biotransformation show genetic polymorphism.[46,51,75,82] The susceptibility to toxic effects of a xenobiotic may be determined by inherited variations in CYP enzymes. For example, approximately 8% of whites are deficient in CYP2D6, which is responsible for the metabolism of a number of xenobiotics, including debrisoquine (an antihypertensive first identified as the substrate of this enzyme), several antidepressants and antidysrhythmics, some opioids, and phenformin.[75,125] Perhexiline, an antianginal agent marketed in Europe in the 1980s, caused severe liver disease and peripheral neuropathy in persons with a demonstrated inability to metabolize debrisoquine.[125] The congenital disorder that results in Gilbert syndrome is characterized by impaired glucuronyltransferase. Patients demonstrate decreased glucuronidation and increased bioactivation of acetaminophen during chronic therapeutic dosing, suggesting an increased risk of hepatic injury following ingestions of acetaminophen.[25]

■ EFFECTS OF XENOBIOTICS ON ENZYME FUNCTION

Changes in the activities of biotransformation enzymes that result in increased formation of hepatotoxic metabolites increase susceptibility to hepatic injury. Chronic administration of isoniazid (INH) induces CYP2E1 activity.[145] During chronic ethanol exposure proliferation of the smooth endoplasmic reticulum in the centrilobular areas is associated with increased activity of CYP2E1.[23,65,81,83,99] In one rat study, the

administration of an average of 9.2 gm/kg of ethanol in increasing doses for 4 weeks resulted in a significant increase in the extent of injury to cultured zone 3 hepatocytes when exposed to CCl_4. This was associated with a higher expression of CYP 2E1 in the livers of ethanol treated rats.[81] Bromobenzene is a xenobiotic whose metabolism and hepatotoxicity are similar to that of acetaminophen. When administered to rats chronically exposed to ethanol, the onset of hepatotoxicity occurs more rapidly in study animals, with only a small increase in the extent of hepatic necrosis. The dose of bromobenzene required for hepatic injury to occur is not altered by pretreatment with ethanol.[48] Chronic administration of phenobarbital to rats results in a very significant increase in the hepatotoxic effects of bromobenzene.[98,109] Hepatic toxicity caused by solvents such as CCl_4, dimethylformamide, and bromobenzene may be exacerbated by chronic exposure to ethanol.[48,81,86,107] Whether ethanol increases the clinical risk of acetaminophen hepatotoxicity in humans is debated.[68,103,120,124,148] There is no evidence that the chronic use of ethanol increases the risk of liver injury due to therapeutic doses of acetaminophen.[54]

Some xenobiotic combinations increase the possibility of hepatotoxic reactions because one xenobiotic alters the metabolism of the other, leading to the production of toxic metabolites.[102] This is the case with combinations of rifampin and isoniazid;[55] amoxicillin and clavulanic acid;[72,106] and trimethoprim and sulfamethoxazole.[3]

Immune Mediated Hepatic Injury   Immune-mediated liver injury is an idiosyncratic and host-dependent hypersensitivity response to exposure to xenobiotics.[9,82] It is differentiated from liver injury caused by other autoimmune disorders by the absence of self-perpetuation, that is, there is a need for continuous exposure to the xenobiotic to perpetuate the injury.[82] Hypersensitivity reactions result in forms of liver injury that include hepatitis, cholestasis, and mixed disorders. Drugs with hypersensitivity reactions that typically present with hepatitis include halothane,[13,59,127] trimethoprim-sulfamethoxazole,[3,98] anticonvulsants,[77] and allopurinol.[4,126] Drugs that typically present with cholestatic signs and symptoms (pruritus, jaundice, insignificant elevations of aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) include chlorpromazine, erythromycin, penicillins, rifampin, and sulfonamides.[67,137] Signs of injury typically begin 1 to 8 weeks following the initiation of the drug, although they may begin as late as 20 weeks for drugs such as isoniazid or dantrolene. The onset of signs of injury associated with the oxypenicillins may occur as great as 2 weeks after the drug is stopped.[82] In all cases, the onset is earlier when the patient is rechallenged with the drug. Although eosinophilia, atypical lymphocytosis, fever, and rash are common clinical manifestations of hypersensitivity, their absence does not exclude an autoimmune mechanism of drug-associated liver injury.[64,82]

How the immune response ultimately leads to cell injury is not well defined. Damage to the hepatocyte may be mediated by complement- or antibody-directed lysis; by specific cell-mediated cytotoxicity; or by an inflammatory response stimulated by immune complexes and complement.[10,14,31,59,61,92] The covalent binding of a reactive electrophilic metabolite with a hepatocellular protein resulting in the formation of a neoantigen is a well-defined first step in the development of xenobiotic-related autoimmune liver injury. This covalent binding creates an "adduct" that is perceived as foreign by the immune system and induces an immune response. In cases where the metabolite is highly unstable, the electrophilic attack may be directed against the CYP enzyme at the site of formation of the metabolite.[13,77,82] Adducts and associated autoantibodies have been demonstrated for acetaminophen,[18] minocycline,[10] halothane,[13,31,127] dihydralazine,[14] phenytoin,[77] and germander.[71] The most severe form of idiosyncratic halothane liver injury is manifest as fulminant hepatic failure associated with formation of adducts of its trifluoroacetyl chloride (TFA) metabolite with numerous hepatoproteins that include CYP2E1 and pyruvate dehydrogenase.[9,31,59,127] Autoantibodies against the CYP2E1 enzyme have been demonstrated in halothane liver injury (Chap. 67).[13,59] Autoantibodies specifically directed against CYP

enzymes have also been demonstrated for dihydralazine,[14] and phenytoin.[77] A trifluoroacetyl protein adduct similar to that associated with halothane hepatitis was detected in workers who developed hepatic necrosis following exposure to hydrochlorofluorocarbons.[49] Whether autoantibodies stimulated by the xenobiotic-protein adducts are the actual mediators of cell injury is not clear.

Early reports of lymphocyte sensitization in cases of xenobiotic-mediated liver toxicity suggested that cell-mediated immunity may play a role.[137] Cell-mediated autoimmune mechanisms are implicated in the idiosyncratic type of halothane hepatitis and are suspected in an increasing number of models of experimental xenobiotic-mediated liver injury.[32] Polymorphonucleocyte (PMN) activation and infiltration appear to be important factors in the production of cholangitis in a rat model of α-naphthyl-isothiocyanate (ANIT) liver injury. ANIT stimulates the release of cytotoxic lysosomal enzymes and oxygen free radicals by activated PMNs.[92] Antibodies directed against circulating neutrophils to decrease the extent of liver damage caused by ANIT.[22] Natural killer T cells are ubiquitous in the liver and their possible role in the facilitation of cell-mediated autoimmune liver injury is being investigated.[21,45]

Availability of Substrates   The availability of substrates for detoxification may significantly affect both the likelihood and localization of hepatic injury.[73] The metabolism of acetaminophen illustrates the effect of glutathione concentration on the delicate balance between detoxification and the production of injurious metabolites. In healthy adults taking therapeutic amounts of acetaminophen, approximately 90% of hepatic metabolism results in formation of glucuronidated or sulfated metabolites.[25,133] Most of the remainder undergoes oxidative metabolism to the toxic electrophile *N*-acetyl-*p*-benzoquinoneimine (NAPQI) and is rapidly detoxified by conjugation with glutathione.[18,54] Glutathione may be depleted during the course of metabolism of acetaminophen by otherwise normal livers, or it may be decreased by inadequate nutrition or liver disease.[73,75] Excessive amounts of acetaminophen result in increased synthesis of NAPQI, which, in the absence of glutathione, reacts avidly with hepatocellular macromolecules. The cellular concentration of glutathione correlates inversely with the demonstrable covalent binding of NAPQI to liver cells.[18] Centrilobular (zone 3) necrosis predominates in acetaminophen induced hepatic injury, possibly related to the centrilobular localization of CYP2E1 and the relatively low glutathione concentrations compared to the periportal areas (zone 1).[54]

MORPHOLOGIC AND BIOCHEMICAL MANIFESTATIONS OF HEPATIC INJURY

The liver responds to injury in a limited number of ways.[57] Cells may swell (ballooning degeneration) and accumulate fat (steatosis) or biliary material. They may necrose and lyse or undergo the slower process of apoptosis, forming shrunken, nonfunctioning, eosinophilic bodies. Necrosis may be focal or bridging, linking the periportal or centrilobular areas; zonal or panacinar; or it may be massive. An inflammatory cell response may precede or follow necrosis.[20,75] Injury to the bile ducts results in cholestasis. Vascular injuries may cause obstruction to venous flow.[69,143] The vascular effects of cocaine may cause ischemic liver injury.[75,135] The variety and spectrum of injury caused by NSAIDS illustrates the difficulty in categorizing and characterizing all of the forms and causes of xenobiotic hepatic injury. These xenobiotics are associated with most forms of injury including asymptomatic aminotransferase elevations, simple cholestasis, hepatitis, bile duct injury, fulminant necrosis, and steatosis.[57] Both azathioprine[27] and ethanol[54,80,84] are associated with a multitude of histopathologic manifestations of hepatocellular injury. Table 26–1 lists characteristic morphologies of hepatic injury and associated xenobiotics.

Table 26–1. Morphology of Liver Injury by Selected Xenobiotics

Acute Hepatocellular Necrosis	Granulomatous Hepatitis	Fibrosis and Cirrhosis
Acetaminophen[a]	Allopurinol	Ethanol
Allopurinol	Aspirin	Methotrexate
Amatoxin[a]	Beryllium	Vitamin A
Arsenic	Carbamazepine	
Carbamazepine	Copper Salts	**Neoplasms**
Carbon tetrachloride[a]	Diltiazem	Androgens
Chlordecone (less severe)	Halothane	Contraceptive steroids
Hydralazine	Hydralazine	Vinyl chloride
Iron	Isoniazid	
Isoniazid	Metolazone	**Venoocclusive Disease**
Methotrexate[a]	Methyldopa	Cyclophosphamide
Methyldopa	Nitrofurantoin	Pyrrozolidine alkaloids
Nitrofurantoin	Penicillins	
Phenytoin	Phenytoin	**Cannicular Cholestasis**
Phosphorus (yellow)[a]	Procainamide	Chlorpromazine
Procainamide	Quinidine	Cyclosporine
Propythiouracil	Quinine	Estrogens
Quinine	Sulfonamides	Methylene dianiline
Propythiouracil	Sulfonylureas	
Quinine		**Bile Duct Damage**
Sulfonamides	**Cholestasis**	α-napthylisothiocyanate
Tetrachlorethane	Allopurinol	Amoxicillin
Tetracycline	Amoxicillin/clavulanic acid	Carbamazepine
Trinitrotoluene	Androgens	Nitrofurantoin
Troglitazone	Chlorpromazine	Oral contraceptives
Vinyl Chloride	Chlorpropamide	
	Erythromycin estolate	**Autoimmune Hepatitis**
Steatohepatitis	Hydralazine	Dantrolene
Amiodarone	Nitrofurantoin	Diclofenac
Dimethyl formamide	Oral contraceptives	Methyldopa
	Rifampin	Methyldopa
Microvesicular Steatosis	Tetracycline	Nafcillin
Aflatoxin	Trimethaprim-	Nitrofurantoin
Cerulide	sulfamethoxazole	Methyldopa
Fialuridine		Nafcillin
Hypoglycin		Nitrofurantoin
Margosa oil		Propylthiouracil
Nucleoside analogs		
(Antiretrovirals)		
Tetracycline		
Valproic acid		

[a] Intrinsic hepatotoxin.

■ ACUTE HEPATOCELLULAR NECROSIS

Numerous xenobiotics have been associated with hepatocellular necrosis (see Table 26–1). Acetaminophen is a common cause, as are herbal remedies, whose risks are increasingly recognized.[34,50,52,71,97] Many halogenated hydrocarbons that include carbon tetrachloride,[16,81] bromobenzene,[48,109] hydrochlorofluorocarbons,[49] halothane[13,59,127] and antituberculous drugs[93,94,101] also produce hepatocellular necrosis. A study of greater than 11,000 patients exposed to isoniazid during preventive treatment showed that hepatocellular necrosis occurred in 0.10% of those starting treatment, and in 0.15% of those completing treatment.[94] Risk factors for the development of hepatotoxicity from isoniazid exposure are female sex, increasing age, coadministration with rifampin, and alcoholism[101] (Chap. 57). The thiazolidinedione agents troglitazone and rosiglitazone, marketed for the treatment of type 2 diabetes, are associated with acute hepatocellular necrosis.[5,44] The much greater incidence of liver injury attributed to troglitazone led to its withdrawal from the market in March 2000.[79] Occupational exposure to solvents that include dimethylformamide and CCl$_4$ cause dose-related hepatocellular necrosis.[86,107,108]

Acute necrosis of a hepatocyte disrupts all aspects of its function. Because there is a great deal of functional reserve in the liver, hepatic function may be preserved despite the development of focal necrosis. Extensive necrosis results in functional liver failure. The processes that lead to cell necrosis are not well known. Cell lysis is preceded by the formation of blebs in the lipid membrane and leakage of cytosolic enzymes, primarily aminotransferases and lactate dehydrogenase. Coalescence of blebs leads to rupture of the cellular membrane and acute irreversible cell death, with disintegration of the nucleus and termination of all cellular function. Prior to membrane rupture, this injury is reversible by membrane repair processes.[92] The release of intracellular constituents attracts circulating leukocytes and results in an inflammatory response in the hepatic parenchyma. A proposed mechanism of rapid injury to the cell membrane is the initiation of a cascading lipid peroxidation reaction following attack by a free radical. The CYP2E1 enzyme has a significant potential to produce oxygen free radicals, as do activated PMNs and Kupffer cells.[23,33,92,115,144] Oxidant stress is an important cause of liver injury during the metabolism of ethanol by CYP2E1.[28] This results in cell death and the stimulation of stellate cells, which promotes fibrosis.[28] In addition to peroxidation of membrane lipids, the oxidation of proteins, phospholipid fatty acyl side chains, and nucleosides appear to be widespread. Mitochondrial injury and resultant ATP depletion may also be associated with necrosis.[58,85] Acetaminophen is the commonest xenobiotic cause of fulminant hepatic failure and NAPQI, its reactive metabolite of acetaminophen, may target mitochondrial enzymes.[79] Other xenobiotics known to cause mitochondrial injury include antiviral drugs,[19,24,79,88,90] tetracycline,[122] valproic acid,[11] hypoglycin, margosa oil, and cerulide.[85,119]

■ STEATOSIS

Steatosis is the abnormal accumulation of fat in hepatocytes. It reflects abnormal cellular metabolism in conditions that include responses to xenobiotics. Cell injury depends on the severity of the underlying metabolic disturbance, steatosis per se is normally well tolerated and reversible in many cases although approximately one-third of patients with nonalcoholic steatosis may develop steatohepatitis.[37,54,70] Nonalcoholic steatosis associated with obesity, insulin resistance, and the metabolic syndrome may account for many cases of cryptogenic cirrhosis.[37] Intracellular fat accumulation may occur as a result of any one or more of the following mechanisms: impaired synthesis of lipoproteins; increased mobilization of peripheral adipose stores;

increased uptake of circulating lipids; increased triglyceride production; decreased binding of triglycerides to lipoprotein; and decreased release of very-low-density lipoproteins from the hepatocytes.[7,54,70,80] There are two light microscopic manifestations of steatosis: macrovesicular steatosis, in which the nucleus is displaced by large droplets of intracellular fat, and microvesicular steatosis, which is characterized by tiny cytoplasmic fat droplets that do not displace the nucleus. Xenobiotics associated with macrovesicular steatosis include ethanol and amiodarone. Ethanol increases the uptake of fatty acids into hepatocytes and decreases lipoprotein secretion. In addition, the increased ratio of the reduced form of nicotinamide adenine dinucleotide (NADH) to the oxidized form of nicotinamide adenine dinucleotide (NAD$^+$), associated with hepatic metabolism of ethanol, decreases oxidation of fatty acids and promotes fatty acid synthesis.[54,80] An early pathologic lesion that occurs in alcoholic liver disease is reversible macrovesicular steatosis. Mallory bodies, eosinophilic cytoplasmic deposits of keratin filaments in degenerating hepatocytes, are also common microscopic findings in alcoholic liver disease.[20,54,80,84] Amiodarone hepatic toxicity resembles that of alcoholic hepatitis, with steatosis, Mallory bodies, and potential for progression to cirrhosis.[75] Lamellated intralysosomal phospholipid inclusion bodies are specific for amiodarone toxicity.[112] Figure 26–4 shows macrovesicular steatosis with Mallory bodies caused by amiodarone.

Steatosis Associated with Mitochondrial Dysfunction Microvesicular steatosis is caused by severe impairment of β-oxidation of fatty acids. The β-oxidation of fatty acids depends on a steady synthesis of cellular energy in the form of ATP and takes place in the mitochondia. Mechanisms of impaired β-oxidation of fatty acids include direct inhibition or sequestration of critical cofactors such as coenzyme-A and L-carnitine.[70] An association between deficiency of carnitine, microsteatosis, and the development of hyperammonemia is observed in children treated with valproic acid.[11,104,136] Valproic acid causes mild elevations of aminotransferases in approximately 11% of patients, usually during the first few months of therapy. The earliest pathologic
FIGURE 26–4. Macrovesicular steatosis associated with administration of amiodarone. The *small arrow* indicates the presence of Mallory bodies. The *large arrow* points to accumulated intracellular fat. (Note that the nuclei are displaced.) Polymorphonuclear leukocytes (*P*) are also present. (Reprinted, with permission, from Lee WM. Drug-induced hepatotoxicity. *N Engl J Med*. 1995;333:1118.)

lesion that signals progression of liver injury is microvesicular steatosis, which occurs in the absence of necrosis. A small percentage of patients progress to fulminant hepatic failure characterized by centrilobular necrosis.[146] The incidence of fatal hepatocellular injury is highest in children, approaching 1 in 800 children younger than age 2 years.[104] Other mechanisms of impairment of β-oxidation of fatty acids include processes that disrupt cellular ATP production, either directly by xenobiotics such as sodium azide or cyanide that inhibit electron transport in the respiratory chain; by xenobiotics that increase permeability of mitochondrial membranes and degrade the proton gradient that is critical to ATP synthesis; or by xenobiotics that uncouple oxidative ph osphorylation.[7,42,78,90,119,122] Nucleoside analogs that inhibit viral reverse transcriptase also inhibit mitochondrial DNA synthesis, leading to depletion of mitochondria.[19,70,90,119] Microvesicular steatosis is described in patients taking antiretrovirals such as zidovudine, zalcitabine, and didanosine.[24,88,128,131] Failure of the mitochondrial power supply may or may not be associated with hepatocyte necrosis and elevation of hepatocellular enzymes.[85,90,119] In all cases, metabolic acidosis with elevated lactate is a prominent biochemical feature.[24,42,119] The nucleoside analog fialuridine caused severe hepatotoxicity during a study of its use in the treatment of chronic hepatitis B infection. Microscopic examinations of liver specimens in these cases showed marked accumulation of fat with minimal necrosis or structural injury. Severe acidosis and failure of hepatic synthetic function suggested failure of cellular energy production. Mitochondria examined under the electron microscope were demonstrably abnormal.[90] Figure 26–5 demonstrates microvesicular steatosis in a patient with fialuridine hepatotoxicity. High doses of tetracycline produce microvesicular steatosis associated with moderate elevations of aminotransferases, markedly prolonged prothrombin time, and progression to fulminant hepatic failure.[122] Microvesicular steatosis attributed to failure of mitochondrial energy production was reported in a fatal case of *Bacillus cereus* food poisoning, where high concentrations of the bacterial emetic toxin cereulide were found in the bile and liver. In this case, microvesicular steatosis was associated with extensive hepatocellular necrosis.[85] Other xenobiotics that cause

mitochondrial failure are hypoglycin, the cause of Jamaican vomiting sickness, aflatoxin, and margosa oil.[119] Steatosis is also observed following exposure to the industrial solvent dimethylformamide. Liver biopsies in patients with acute illness show focal hepatocellular necrosis and microvesicular steatosis. More prolonged, less symptomatic exposures result in significant macrovesicular steatosis with mild aminotransferase elevations.[107,108]

■ CHOLESTASIS

Xenobiotics induce cholestasis by targeting specific mechanisms of bile synthesis and flow or by damaging canicular cells.[54,67] Cholestasis may occur with or without associated hepatitis. The development of jaundice following hepatic necrosis is a manifestation of general failure of liver function. More discrete mechanisms that result in intrahepatic cholestasis include (a) impairment of the integrity of tight membrane junctions that functionally isolate the canaliculus from the hepatocyte and sinusoids; (b) failure of transport of bile components across the hepatocytes; (c) blockade of specific membrane active transport sites; (d) decreased membrane fluidity resulting in altered transport; and (e) decreased canalicular contractility resulting in decreased bile flow.[12,54,67,121] Estrogens cause intrahepatic cholestasis by altering the composition of the lipid membrane and inhibiting the rate of secretion of bile into the canaliculi.[67,79,121] Rifampin impedes the uptake of bilirubin into hepatocytes. Methyltestosterone and C-17 alkylated anabolic steroids impair the secretion of bilirubin into canaliculi.[79] Exposure to chlorpromazine is associated with cholestasis and periductal inflammation. This may be caused by inhibition of Na+, K+-adenosine triphosphatase (ATPase), which results in decreased canalicular contractility.[116] Cyclosporine inhibits sodium-dependent uptake of bile salts across the sinusoidal membrane and blocks ATP-dependent bile salt transport across the canalicular membrane.[12] Floxacillin causes cholestasis with minimal inflammation or evidence of hepatocellular injury.[137] Exposure of rats to ANIT causes a specific injury localized to the tight junctions that separate the hepatocyte from the canaliculi. This results in reflux of bile constituents into the sinusoidal space and increased access of sinusoidal molecules to the biliary tree.[22,67,92]

■ VENOOCCLUSIVE DISEASE

Hepatic venoocclusive disease is caused by toxins that injure the endothelium of terminal hepatic venules, resulting in intimal thickening, edema, and nonthrombotic obstruction. Central and sublobular hepatic veins may also become edematous and fibrosed. There is intense sinusoidal dilation in the centrilobular areas that is associated with liver cell atrophy and necrosis.[142] The gross pathologic appearance is that of a "nutmeg" liver.[69,143] Massive hepatic congestion and ascites ensue.[69,111] Hepatic venoocclusive disease is rapidly fatal in 15% to 20% of cases. It is associated with exposure to pyrrolizidine alkaloids found in many plant species including *Symphytum* (comfrey tea),[140,143] *Heliotrope, Senecio,* and *Crotalaria*.[69] It has occurred in epidemic proportions; in South Africa after the ingestion of flour contaminated with ragwort (*Senecio*); in Jamaica after the ingestion of "bush teas" (*Crotalaria spp*); and in India and Afghanistan when food was contaminated with *Heliotropium lasiocarpine* and *Crotalaria*.[15,95,132] A rapidly progressive form has been reported in bone marrow transplant patients following high-dose treatment with cyclophosphamide.[89]

■ CHRONIC HEPATITIS

A form of hepatitis that clinically resembles nontoxic autoimmune hepatitis occurs with the chronic administration of drugs such as
FIGURE 26–5. This figure shows severe microvesicular steatosis in a patient treated with fialuridine. Note the central location of the nuclei. (Reprinted, with permission, from McKenzie R, Fried MW, Sallie R, et al. Hepatic failure and lactic acidosis due to fialuridine, an investigational nucleoside analogue for chronic hepatitis B. *N Engl J Med.* 1995;333:1099.)

methyldopa, nitrofurantoin, propylthiouracil, nafcillin, dantrolene, and diclofenac.[4,60,76,88,110,123,130] Many cases are associated with positive antinuclear antibody (ANA), smooth muscle antibody (SMA), and hyperglobulinemia. Jaundice is prominent and hepatocellular enzymes are elevated 5- to 60-fold. Liver biopsy commonly reveals intrahepatic cholestasis, as well as centrilobular inflammation.[82]

Granulomatous hepatitis is characterized by infiltration of the hepatic parenchyma with caseating granulomata. As great as 60 drugs are associated with this disorder. Fever and systemic symptoms are common, 25% have splenomegaly. Liver enzymes are mixed, reflecting variable degrees of cholestasis and hepatocellular injury. Eosinophilia occurs in 30% as an extrahepatic manifestation of drug hypersensitivity. Continued exposure may result in a more severe form of liver disease. Small vessel vasculitis, which may involve the skin, lungs, and kidney, is a disturbing sign associated with increased mortality.[75,91,147] Table 26–1 lists a number of the xenobiotics that have been implicated in this disorder.

■ CIRRHOSIS

Cirrhosis is caused by progressive fibrosis and scarring of the liver, which results in irreversible hepatic dysfunction and portal hypertension. This causes shunting of blood away from hepatocytes and subsequent hepatocellular dysfunction. Activated stellate cells produce collagen, proteoglycans, and adhesive glycoproteins, which are deposited in the space of Disse and are crucial to the development of hepatic fibrosis.[118] Kupffer cells contribute to the activation of hepatic stellate cells.[118] In alcoholic cirrhosis, acetaldehyde also stimulates collagen production by hepatic stellate cells, as do other aldehydes that are products of lipid peroxidation.[54,80] Alcoholic hepatitis generally precedes cirrhosis, although cirrhosis may develop in its absence.[84] Chronic ingestion of excessive amounts of vitamin A (25,000 U/d for 6 years or 100,000 U/d for 2.5 years) results in cirrhosis. An increase in the fat content of the sinusoidal stellate cells with increasing degrees of collagen formation are characteristic lesions that occur early in vitamin A toxicity (Chap. 41). Portal hypertension may be early and striking.[43] Like vitamin A, methyldopa and methotrexate also cause a slow progressive development of cirrhosis with few clinical symptoms.[76,141] Methotrexate-induced hepatic fibrosis is dose dependent. Risk factors include associated alcohol intake and preexisting liver disease. Reduced dosing has largely eliminated the risk of the development of cirrhosis in patients receiving methotrexate.[58,141]

■ HEPATIC TUMORS

There is persuasive evidence that the use of oral contraceptive steroids increases the risk of hepatic adenomas.[63] There is also evidence that oral contraceptives increase the overall risk of hepatocellular carcinoma; however, the number of cases associated with estrogen therapy is low.[53] Anabolic steroids are rarely associated with the development of both benign and malignant hepatic tumors.[38] Angiosarcoma is strongly associated with exposure to vinyl chloride, in addition to arsenic, thorium dioxide, and steroid hormones.[36]

■ HEPATIC INJURY ASSOCIATED WITH PLANTS AND HERBS

In addition to the venoocclusive disease associated with pyrrolizidine alkaloids described above, herbal remedies are increasingly recognized as a cause of acute hepatocellular injury. Numerous plants or plant products are known or suspected to cause hepatic injury (Chaps. 43 and 118).[30,34,50,52,71,97]

CLINICAL PRESENTATION OF TOXIC LIVER INJURY

Clinical presentations of toxic liver injury range from indolent, often asymptomatic progression of impairment of hepatic function to rapid development of hepatic failure. Jaundice and pruritis are due to increased concentrations of bile acids and bilirubin in the blood. Failure of hepatocellular synthetic function results in bleeding due to coagulopathy and edema due to hypoalbuminemia. Encephalopathy may be due to hypoglycemia, impaired neurotransmission, or accumulation of toxic products of metabolism such as ammonia. Fever may occur with autoimmune mediated liver injury. Impaired hepatic blood flow results in familiar manifestations of portal hypertension such as caput medusa, splenomegaly, ascites and varices. Spider angiomata and gynecomastia also occur due to altered estrogen metabolism.[20]

■ FULMINANT HEPATIC FAILURE

Fulminant hepatic failure (FHF) is defined as liver injury that progresses to coagulopathy and encephalopathy within 8 weeks of the onset of illness in a patient without preexisting liver disease.[41,74] Complications from FHF include encephalopathy, cerebral edema, coagulopathy, renal dysfunction, hypoglycemia, hypotension, acute lung injury, sepsis, and death. In some cases, a patient may progress from health to death in as little as 2-10 days.[17,39,40,41,74,85,100] Table 26–2 shows the clinical progression of encephalopathy as hepatic failure develops. The prognosis of FHF is related to the time that passes between the onset of jaundice and the onset of encephalopathy. Perhaps surprisingly, a better prognosis is associated with shorter (2-4 weeks) jaundice-to-encephalopathy intervals.[113] Most cases of FHF are caused by xenobiotics or viral hepatitis. FHF is usually associated with extensive necrosis,

TABLE 26–2. Stages of Hepatic Encephalopathy

Clinical Stage	Mental Status	Neuromotor Function
Subclinical	Normal physical examination	Subtle impairment of neuromotor function → driving or work injury hazard
I	Euphoric, irritable, depressed, fluctuating mild confusion, poor attention, sleep disturbance	Poor coordination; may have asterixis alone
II	Impaired memory, cognition, or simple mathematical tasks	Slurred speech, tremor, ataxia
III	Difficult to arouse, persistent confusion, incoherent	Hyperactive reflexes, clonus, nystagmus
IV	Coma; may respond to noxious stimuli	May have decerebrate posturing; Cheyne-Stokes respirations; pupils are reactive and the oculocephalic reflex is intact; may have signs of ↑ intracranial pressure

although it may occur in the absence of demonstrable necrosis following exposures to xenobiotics that injure mitochondria.[85,90,131] Some xenobiotics that are associated with fulminant hepatic necrosis are clove oil, amanitin cyclopeptides, acetaminophen, tetracycline, yellow phosphorus, halogenated hydrocarbons, isoniazid, methyldopa, and valproic acid.[30,74,96,107,108,113,122]

■ HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy (HE) is a severe manifestation of liver failure that is potentially fully reversible, even in cases of deep coma.[39,40,41] HE is associated with a fluctuating sensorium that ranges from barely discernible confusion to coma. Neuromotor signs such as asterixis and rigidity are common.[17] Table 26–2 lists the clinical stages of acute HE. Ammonia is produced in the colon by bacterial breakdown of ingested proteins then transported to the liver via the portal circulation where it is detoxified to glutamine and urea.[40] Ammonia concentrations are elevated in 60% to 80% of patients with HE.[40] Processes that raise CNS ammonia concentrations include infection, hypokalemia, alkalosis, increased muscle wasting, volume depletion, azotemia, or gastrointestinal bleeding.[40] Alkalosis and hypokalemia facilitate conversion of NH_4^+ to NH_3, which moves more easily across the blood–brain barrier. The demonstration that ammonia is not elevated in many cases suggests that there are other pathogenic etiologies and the etiology is multifactorial. Disruption of central neurotransmitter regulation including dopamine receptor binding may contribute.[138] There is evidence that liver failure is associated with the accumulation of substances that stimulate central benzodiazepine receptors, leading to inhibition of γ-aminobutyric acid (GABA) transmission.[6] Nonnitrogenous HE is precipitated by sedatives, especially benzodiazepines, hypoxia, hypoglycemia, hypothyroidism, and anemia.[40] Although it is clear that sedatives that depress GABAergic transmission can make encephalopathy worse, studies of the use of flumazenil to reverse encephalopathy show conflicting results.[6] Significant short-term improvement was demonstrated in some patients who already have a highly favorable prognosis. Although there is no clear evidence that all patients will benefit from flumazenil, some individuals may benefit for a short time. Certainly, the administration of benzodiazepines should be avoided.[6]

EVALUATION OF THE PATIENT WITH LIVER DISEASE

The history is critical in establishing the diagnosis of the patient with liver disease. A medication history should include careful investigation of nonprescription xenobiotics, especially acetaminophen and the possible use of alternative or complementary therapies including herbal therapies. Nearly all chronically used medications should be suspect. An occupational history may indicate exposure to vinyl chloride (plastics industry), dimethylformamide (leather industry), or other industrial solvents. Table 26–3 lists occupational exposures that result in liver injury. Alcohol abuse is a common cause of acute hepatitis and the most common cause of cirrhosis in this country.[80,84] A history of male homosexual contacts, healthcare occupation, or intravenous drug use indicates the possibility of hepatitis B and C. Recent travel to an underdeveloped country suggests the possibility of hepatitis A. In patients with significant pain, the possibility of cholelithiasis should be considered.

■ BIOCHEMICAL PATTERNS OF LIVER INJURY

There are two basic biochemical patterns associated with liver injury induced by xenobiotics. The hepatocellular pattern is characterized by elevation of liver transaminases due to the injury of hepatocytes

TABLE 26–3. Occupational Exposures Associated with Liver Injury

Xenobiotic	Type of Injury
Arsenic	Cirrhosis, angiosarcoma
Beryllium	Granulomatous hepatitis
Carbon tetrachloride	Acute necrosis
Chlordecone	Minor hepatocellular injury
Copper salts	Granulomatous hepatitis, angiosarcoma
Dimethylformamide	Steatohepatitis
Methylenedianiline	Acute cholestasis
Phosphorus	Acute necrosis
Tetrachloroethane	Acute, subacute necrosis
Tetrachloroethylene	Acute necrosis
Toluene	Steatosis, minor hepatocellular injury
Trichloroethane	Steatosis, minor hepatocellular injury
Trinitrotoluene	Acute necrosis
Vinyl chloride	Acute necrosis, fibrosis, angiosarcoma
Xylene	Steatosis, minor hepatocellular injury

by apoptosis or necrosis. The cholestatic pattern is characterized by elevation of the serum alkaline phosphatase concentration and usually results from injury or functional impairment of the bile ductules.[1] Processes associated with intrahepatic cholestasis in the absence of hepatitis may not lead to significant aminotransferase elevation.[98,106,147]

Aminotransferases Laboratory tests are helpful and certain patterns may be suggestive of specific etiologies (Table 26–4). Elevation of hepatocellular enzymes, especially the AST and ALT, indicates hepatocellular injury, and within a given clinical context, has useful diagnostic significance. Aminotransferases may be increased up to 500 times normal when hepatic necrosis is extensive, such as in severe acute viral or toxic hepatitis.[2,74] The degree of elevation does not always reflect the severity of injury as concentrations may decline as FHF progresses. Only moderately elevated, or occasionally normal aminotransferase concentrations occur in some patients with hepatic failure caused by mitochondrial failure, cirrhosis, or venoocclusive disease.[43,69,90,146] Aminotransferase concentrations may be normal or only slightly elevated in processes associated with intrahepatic cholestasis in the absence of hepatitis.[98,106,147] In alcoholic liver disease, in contrast to other forms of hepatitis, the AST concentration is typically two to three times greater than the ALT. This is attributed to impairment of ALT synthesis because of pyridine-5′-phosphate deficiency in alcoholics. This effect is reversed by pyridoxine supplementation. Elevation of either of these enzymes greater than 300 IU/L is inconsistent with injury caused by ethanol.[2] During acute extrahepatic obstruction of the biliary tract, the AST or ALT may be as high as 1000 IU/L, indicating inflammation caused by reflux of bile acids into the biliary tree.[2] The measurement of γ-glutamyl transpeptidase (GGTP) is not very useful as it is present throughout the liver and its elevation is often nonspecific.[2]

Alkaline Phosphatase In patients with cholestasis, bile acids stimulate the synthesis of alkaline phosphatase by hepatocytes and biliary epithelium in response to a number of pathologic processes in the liver. Elevations of the alkaline phosphatase as great as 10-fold may occur with infiltrative liver diseases, but are most commonly associated with extrahepatic obstruction.[2] Although the alkaline phosphatase may be normal or elevated only minimally in hepatocellular injury, it is

TABLE 26–4. Laboratory Tests that Evaluate the Liver

Disorder	Alkaline Phosphatase	AST, ALT	Albumin	Prothrombin Time	Bilirubin	Ammonia	Anion Gap
Hepatocellular necrosis, acute focal (hepatitis)	N or ↑	↑↑↑	N	N or ↑	↑↑	N	N
Hepatocellular necrosis, acute massive	N or ↑	↑↑↑	N	↑↑	↑↑↑	↑↑	↑
Chronic infiltrative disease (tumor, fatty liver)	↑↑↑	↑	N	N	N	N	N
Acute mitochondrial failure	N or ↑	N or ↑	N	↑↑	↑	↑↑	↑↑↑
Cholelithiasis	↑	N or ↑	N	N	N or ↑	N	N
Cholestasis	↑↑	N or ↑	N	N	↑	N	N
Chronic hepatitis	N or ↑	↑	N or ↓	N	N or ↑	N or ↑	N
Cirrhosis	N or ↑	↑	↓	N or ↑	N or ↑	N or ↑	N

↑ = increase; ↓ = decrease; N = normal.

unusual for obstruction to occur without some elevation of the alkaline phosphatase. Elevations of alkaline phosphatase and GGTP parallel each other in disease of the biliary tract.[2]

Bilirubin Elevation of conjugated, or direct, bilirubin implies impairment of secretion into bile while elevation of unconjugated, or indirect, bilirubin implies impairment of conjugation. Unconjugated hyperbilirubinemia also occurs during hemolysis and in rare disorders of hepatic conjugation such as Gilbert or Crigler-Najjar syndromes. Except in cases of pure unconjugated hyperbilirubinemia, the fractionation of bilirubin in the case of hepatobiliary disorders does not have any important diagnostic utility, and will not distinguish patients with parenchymal disorders of the liver from intrinsic or extrinsic cholestasis. The presence of bilirubin in the urine implies elevation of conjugated (direct) bilirubin which is water soluble and filtered by the glomerulus obviating the need for laboratory fractionation.[2]

Urobilinogen is produced by the bacterial metabolism of bilirubin in the bowel lumen. It is absorbed and excreted in the urine. Its presence in the urine indicates the normal excretion of bilirubin in bile, while its absence is associated with complete biliary obstruction. As a result of more modern methods of detection of complete obstruction of the biliary tract, this test is mainly of historical interest.

Serum Albumin Quantitatively, albumin is the most important protein that is made in the liver. With a half-life as great as 20 days, the albumin is usually normal in the previously healthy patient with acute liver injury. In the absence of disorders that affect albumin, such as nephrotic syndrome, protein-losing enteropathy, or starvation, a low serum albumin is a useful marker for the severity of chronic liver disease.[2]

Coagulation Factors Impairment of coagulation is a marker of the severity of hepatic dysfunction in both acute and chronic liver disease. Unlike the case with serum albumin, with its half-life of 20 days, the onset of coagulopathy as a consequence of impaired synthesis of the short-lived vitamin K-dependent clotting factors II, VII, IX, and X is rapid. Very acute changes in coagulation reflect the concentration of factor VII, which has the shortest half life.[56] The extrinsic coagulation pathway, as measured by the prothrombin time (PT) or the international normalized ratio (INR), is affected by reductions in factors II, VII, and X. Elevation of the INR or PT in acute hepatitis is associated with a higher risk of FHF.[47,74,90] In addition to failure of hepatic synthesis, inadequate levels of factors II, VII, IX, and X may also result from ingestion of warfarin anticoagulants or malabsorption of vitamin K (Chap. 59).[2]

Because different thromboplastin reagents give different PT values on the same sample, the INR was developed to normalize PT measurements in patients treated with warfarin, allowing comparisons of therapeutic outcomes across different care settings and across the literature. The INR uses the International Sensitivity Index (ISI) that is derived from a cohort of patients on stable anticoagulant therapy. It normalizes the responsiveness of a given thromboplastin reagent in comparison to a WHO reference standard that is assigned a value of 1.0.[66] There is little controversy regarding the value of the INR in comparison with the PT ratio for measuring the extent of warfarin-induced anticoagulation. Because factor deficiencies in patients with liver disease are different from those in patients on warfarin, there is considerable controversy regarding which measurement is best for patients with liver disease.[2,26,66] Although comparison of factor levels in warfarin-treated patients with those with liver disease showed no difference in factor VII, there are significant differences in factors II, V, X, and fibrinogen. Comparison of the PT with INR in the evaluation of test results with three different thromboplastin reagents showed consistency among the control groups of warfarin-treated patients, but no consistency among PT or INR measurements using the same thromboplastin reagents in patients with liver disease.[66] Because of a failure to demonstrate an advantage, liver specialists who have expressed an opinion support the continued use of the PT to describe the degree of liver injury, lacking the availability of a single reliable standard that would help predict operative risk.[2,26,66] In patients with liver disease, use of the INR implies a normalized correlation that does not exist and is therefore potentially misleading. The implication for toxicologists is that caution should be exercised in relying too heavily on published

INR values that purportedly predict the severity of illness in patients with acute liver failure.

Ammonia Severe generalized impairment of hepatic function leads to a rise in the serum ammonia concentration as a result of impairment of detoxification of ammonia produced during catabolism of proteins. The absolute concentration is not clearly associated with mental status alteration. Elevations of serum ammonia concentrations occur in 60% to 80% of patients with hepatic encephalopathy, suggesting that hyperammonemia is not the only cause of hepatic encephalopathy.[40]

Some patients treated with valproic acid have developed alterations in mental status associated with elevated ammonia concentrations, sometimes in the absence of other laboratory indicators of hepatic injury, and without demonstrable toxic concentrations of valproic acid. This has been attributed to selective impairment of urea cycle enzymes ornithine transcarbamylase or carbamyl phosphate synthetase by pentanoic acid metabolites (Chap. 47).[35,105] As noted above, an association between deficiency of carnitine, microsteatosis, and the development of hyperammonemia is observed in children treated with valproic acid. This is attributed to impairment of carnitine-dependent beta-oxidation of sodium valproate and free fatty acids in the mitochondria.[11,104,136]

■ OTHER LABORATORY TESTS

Serologic Studies for the Presence of Markers of Hepatitis A, B, and C Should be Done Routinely in Patients with Hepatitis. In the patient with severe liver injury, hypoglycemia is a major concern because of impairment of glycogen storage and gluconeogenesis. Hyperglycemia also occurs as a result of the liver's inability to handle a large glucose load. The arterial blood-gas value commonly shows a respiratory alkalosis. Severe metabolic acidosis with elevated lactate occurs in patients with hepatic failure caused by mitochondrial injury. Measurements of serum lactate concentration may be useful in identifying the cause of acidosis in a patient with suspected toxic liver injury.[85,90,119]

The CT and MRI scans are useful tests for evaluation of parenchymal disease of the liver. An ultrasound examination reliably demonstrates dilation of the extrahepatic bile ducts. Liver biopsy may be helpful but is not specifically diagnostic of xenobiotic-induced hepatic injury.

MANAGEMENT

In many patients, toxic liver injury resolves with simple withdrawal of the offending xenobiotic. In patients with severe injury, significant improvement in survival is associated with good supportive care in an intensive care environment.[74] Early referral to a transplant center for patients with evidence of severe or rapidly progressive toxic injury is indicated. For discussion of indications for the use of *N*-acetylcysteine and discussion of indications for transplantation, see Antidotes in Depth A4: *N*-Acetylcysteine.

SUMMARY

The primary role of the liver in the biotransformation of xenobiotics results in an increased risk of hepatotoxicity. Xenobiotic-induced liver injury can be dose-dependent and predictable or idiosyncratic and unpredictable. Idiosyncratic injury is affected by host characteristics that include genetic makeup, concomitant or previous exposure to drugs and toxins, and the underlying condition of the liver. The spectrum of liver injury includes combinations of cholestasis, steatosis, hepatocellular necrosis, apoptosis, and fibrosis. Injury may be a result of cellular or antibody-mediated immune mechanisms; free radical initiation of lipid peroxidation; mitochondrial injury; formation of adducts with critical cellular enzymes; and other, less-well-defined mechanisms.

CHAPTER 27
RENAL PRINCIPLES

Donald A. Feinfeld and Nikolas B. Harbord

OVERVIEW OF RENAL FUNCTION

■ ANATOMIC CONSIDERATIONS

The kidneys lie in the paravertebral grooves at the level of the T12-L3 vertebrae. The medial margin of each is concave whereas the lateral margins are convex, giving the organ a bean-shaped appearance. In the adult, each kidney measures 10 to 12 cm in length, 5 to 7.5 cm in width, and 2.5 to 3.0 cm in thickness. In an adult man, each kidney weighs 125 to 170 g; in an adult woman, each kidney weighs 115 to155 g.

On the concave surface of the kidney is the hilum, through which the renal artery, vein, renal pelvis, a nerve plexus, and numerous lymphatics pass. On the convex surface, the kidney is surrounded by a fibrous capsule, which protects it, and a fatty capsule with a fibroareolar capsule called the *renal fascia*, which offers further protection and serves to anchor it in place.

The arterial supply begins with the renal artery, which is a direct branch of the aorta. On entering the hilum, this artery subdivides into branches supplying the five major segments of each kidney: the apical pole, the anterosuperior segment, the anteroinferior segment, the posterior segment, and the inferior pole. These arteries subsequently divide within each segment to become lobar arteries. In turn, these vessels give rise to arcuate arteries that diverge into the sharply branching interlobular arteries, which directly supply the glomerular tufts.

The cut surface of the kidney reveals a pale outer rim and a dark inner region corresponding to the cortex and medulla, respectively. The cortex is 1 cm thick and surrounds the base of each medullary pyramid. The medulla consists of between 8 and 18 cone-shaped areas called *medullary pyramids;* the apex of each area forms a papilla containing the ends of the collecting ducts. Urine empties from these ducts into the renal pelvis, flows into the ureters, and, subsequently, into the urinary bladder.

The kidneys maintain the constancy of the extracellular fluid by creating an ultrafiltrate of the plasma that is virtually free of cells and larger macromolecules, and then processing that filtrate, reclaiming what the body needs and letting the rest escape as urine. Every 24 hours, an adult's kidneys filter nearly 180 L of water (total body water is ∼ 25–60 L), and 25,000 mEq of sodium (total body Na$^+$ is 1200–2800 mEq). Under normal circumstances, the kidneys regulate these two substances independent of each other, depending on the body's needs. Approximately 1% of the filtered water and 0.5% to 1% of the filtered Na$^+$ are excreted.

Renal function begins with filtration at the glomerulus, a highly permeable capillary network stretched between two arterioles in series. The relative constriction or dilation of these vessels normally controls the glomerular filtration rate (GFR). Under normal circumstances, approximately 20% of the plasma water in the blood entering the glomeruli goes through the filter, carrying with it electrolytes, small metabolites such as glucose, amino acids, lactate, and urea, and leaving behind the blood cells and nearly all the larger proteins, including albumin and globulins. The filtrate then enters a series of tubules that reabsorb and secrete certain substances, such as organic acids and bases, into the urinary space. The proximal tubule performs bulk reabsorption, isotonically reclaiming 65% to 70% of the filtrate. Distal to the proximal tubule is the loop of Henle, which controls concentration and dilution of the urine, and the distal nephron, which does the fine-tuning in the balance between excretion and reclamation. Reabsorption of sodium is controlled proximally by hydrostatic and oncotic pressures in the peritubular capillaries, and distally by hormones such as aldosterone. Control of water reclamation depends first on function of the ascending limb of the loop of Henle, which absorbs solute without water. This produces a dilute tubular fluid and at the same time makes the medullary interstitium hypertonic. Final regulation of water reabsorption is related to the concentration of antidiuretic hormone (ADH), which opens water-reabsorbing channels (aquaporins) into the membranes of the final nephron segments (collecting ducts). The kidneys also regulate balance for potassium and hydrogen ion (both of which are influenced by the effect of aldosterone on the distal nephron), and calcium and phosphate (both of which are influenced by the blood concentration of parathormone).

Injury to the vasculature, glomeruli, tubules, or interstitium can lead to renal dysfunction; that is, to a decrease in glomerular filtration. As the kidneys fail, serum concentrations of the marker substances urea and creatinine increase. However, the relationship between these concentrations and the level of GFR is hyperbolic, not linear, therefore a small initial elevation in serum concentrations of these substances denotes a large decrease in renal function. By the time blood urea nitrogen (BUN) or serum creatinine exceeds the upper limit of normal, GFR is reduced by more than 50%.

Many xenobiotics cause or aggravate renal dysfunction. The kidneys are particularly susceptible to toxic injury for four reasons:[151] (a) they receive 20% to 25% of cardiac output yet make up less than 1% of total body mass implying a relatively large renal exposure in almost all circumstances; (b) they are metabolically active, and thus vulnerable to xenobiotics that disrupt metabolism or are activated by metabolism such as acetaminophen; (c) they remove water from the filtrate and may build up a high concentration of xenobiotics; and (d) the glomeruli and interstitium are susceptible to attack by the immune system. Many factors, such as renal perfusion, can affect an individual's reaction to a particular nephrotoxin.[10] The clinician should be aware of these factors and, when possible, alter them to minimize the adverse effect after a toxic exposure.

■ FUNCTIONAL TOXIC RENAL DISORDERS

Although most toxic renal injury results in decreased renal function, there are three functional disorders that upset body balance despite normal GFR in anatomically normal kidneys: renal tubular acidosis, syndrome of inappropriate secretion of ADH, and nephrogenic diabetes insipidus.

Renal tubular acidosis (RTA) is a loss of ability to reclaim the filtered bicarbonate (proximal RTA) or a decreased ability to generate new bicarbonate to replace that lost in buffering the daily acid load (distal RTA). In either case, there is a nonaniongap metabolic acidosis, usually accompanied by hypokalemia.

The primary defect in distal RTA involves the decreased secretion of hydrogen (H$^+$) from the intercalated cells of the distal tubule. This most often denotes a defect in the H$^+$-translocating adenosine triphosphatase (ATPase) on the luminal surface of these cells. Less frequently occurring mechanisms include abnormalities of the chloride-bicarbonate exchanger, which is responsible for returning bicarbonate generated within the cell to the systemic circulation. Also, given the voltage dependence of hydrogen secretion, if there is a decrease in the degree of luminal electronegative charge, there will be a decrease in this secretion. Most of this voltage is created

by the activity of the Na$^+$-K$^+$-ATPase on the peritubular capillary side of the adjacent cell. (*Note:* Cells adjacent to the intercalated cells are called principal cells and primarily control K$^+$ secretion.) As this pump malfunctions, less sodium is returned to the capillaries, creating a decreased gradient from the lumen to the cell. Thus, the lumen becomes more electropositive, diminishing the transmembrane potential. Amphotericin causes distal RTA by allowing secreted H$^+$ to leak back into the tubular cells.[38]

The primary defect in proximal RTA is incompletely understood. Normally, the Na$^+$-H$^+$ exchanger in the luminal membrane, the Na$^+$-K$^+$-ATPase in the basolateral membrane, and the enzyme carbonic anhydrase, are the key systems necessary for proximal tubular bicarbonate reabsorption. If one or more of these mechanisms becomes disordered, the resorptive capacity of the proximal tubule is diminished. Proximal RTA often occurs as part of the Fanconi syndrome, a generalized failure of proximal tubular transport (proximal RTA plus aminoaciduria, renal glycosuria, and hyperphosphaturia), which may occur during treatment with some chemotherapy agents or antiretroviral drugs.

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) occurs when the body produces ADH despite a fall in plasma osmolality, which normally inhibits ADH secretion. ADH primarily affects the collecting tubule and causes increased water reabsorption by increasing the aquaporin channels in this segment. There are three common patterns of altered physiology: altered secretion of ADH; a resetting of the osmostat (ie, the threshold for ADH secretion); and the inability to decrease ADH secretion in the face of a water load. The increased hormonal effect of ADH serves to augment normal free water retention, which subsequently leads to the main clinical manifestations of SIADH: concentrated urine (as reflected in a relative increase in urine osmolality) and hyponatremia in the setting of euvolemia. Although this manifestation most often occurs as a complication of intracranial lesions or from ectopic ADH production by a tumor or in a diseased lung, many xenobiotics (eg, chlorpropamide, antidepressants, vincristine, opioids, and methylenedioxymethamphetamine [MDMA or Ecstasy]) can also cause inappropriate ADH release (Chap. 16).

Nephrogenic diabetes insipidus (NDI) is the reverse of SIADH and is the inability of the kidneys to respond to ADH stimulation despite severe losses of body water in urine. NDI will typically present with polyuria, or hypernatremia if water intake is limited or insufficient. Although genetic disorders, disease states, or electrolyte perturbations are usually implicated, several xenobiotics also cause NDI. Lithium, demeclocycline, foscarnet and clozapine are drugs that can cause this syndrome (Chap. 16). NDI from lithium toxicity is thought to result from impaired aquaporin-2 channel synthesis and transport despite normal ADH binding to vasopressin type-2 receptors at the collecting tubule.[199]

MAJOR TOXIC SYNDROMES OF THE KIDNEY

Most nephrotoxicity involves histologic renal injury. Although xenobiotics can affect any part of the nephron (Fig. 27–1), there are three major syndromes of toxic renal injury: (a) chronic kidney disease; (b) nephrotic syndrome; and, especially, (c) acute kidney injury (Table 27–1). For purposes of continuity, acute kidney injury is discussed last. Because nephrotoxins usually affect the tubules, the most metabolically active segment of the nephron, most nephrotoxicity involves either acute or chronic tubular injury, although glomerular injury sometimes results from xenobiotics. The processes are not mutually exclusive, and toxic nephropathy may impinge on more than one part of the nephron (eg, nonsteroidal antiinflammatory drug [NSAID]-induced acute kidney injury and nephrotic syndrome). When one of these patterns of renal injury occurs, the clinician should consider possible toxic etiologies.

Chronic kidney disease refers to a disease process that causes progressive decline of renal function over a period of months to years. There is usually a gradual rise in BUN and serum creatinine concentration as glomerular filtration falls; often there are no symptoms other than nocturia (indicating loss of urinary concentrating ability).

The most common lesion of nephrotoxic chronic kidney disease is chronic interstitial nephritis (Fig. 27–2), which involves destruction of tubules over a prolonged period,[75] with tubular atrophy, fibrosis, and a variable cellular infiltrate (see Fig. 27–2), sometimes accompanied by papillary necrosis. Acute interstitial nephritis may progress to chronic interstitial nephritis, if exposure to xenobiotics is prolonged.[217] The onset is usually insidious and relatively asymptomatic, often presenting as secondary hypertension or unexplained chronic azotemia. The major symptom is nonspecific nocturia. Papillary necrosis may lead to ureteral colic via papillary sloughing. There is mild to moderate proteinuria that remains well under the nephrotic range. Unlike other chronic renal disorders, interstitial nephritis is characterized by failure of the diseased tubules to adapt to the renal impairment, resulting in metabolic imbalances such as hyperchloremic metabolic acidosis, sodium wasting, and hyperkalemia early in the disease course.[71] Injury to erythropoietin-secreting cells may produce a disproportionate anemia.

Nephrotic syndrome is characterized by massive proteinuria (>3 g/d, in the adult), hypoalbuminemia, hyperlipidemia, and the edema that usually prompts the patient to seek medical attention. Although the relationships among these findings are not completely understood, the underlying event is injury to the glomerular barrier that normally prevents macromolecules from passing from the capillary lumen into the urinary space. Xenobiotics induce nephrotic syndrome (Table 27–2) in two ways. First, they may release hidden antigens into the blood, which leads to antigen–antibody complex formation after the immune response is elicited. These complexes subsequently deposit in the

TABLE 27–1. Major Nephrotoxic Syndromes

Chronic Renal Disease (slowly increasing azotemia)	Nephrotic Syndrome (proteinuria, hypoalbuminemia, edema)	Acute Renal Injury (rapidly increasing azotemia)
Chronic interstitial nephritis	Minimal glomerular change	Acute prerenal failure
Papillary necrosis	Membranous nephropathy	Acute urinary obstruction
Chronic glomerulosclerosis	Focal segmental glomerulosclerosis	Acute tubular necrosis

glomerular basement membrane, thereby changing its consistency (eg, gold) (Fig. 27–3). Second, they can upset the immunoregulatory balance (eg, NSAIDs). A less-common glomerular lesion is hypersensitivity vasculitis. The pathologic appearance of the glomeruli may be described as secondary minimal glomerular change, membranous glomerulopathy, or focal segmental glomerulosclerosis. Albumin loss usually exceeds urinary excretion as a result of renal tubular catabolism of filtered protein. The tubules also retain sodium, causing expansion of the extracellular space and edema. The glomerular lesion may progress to renal failure if the pathologic process continues.

Acute kidney injury (formerly called "acute renal failure") is defined as an abrupt decline in renal function that impairs the capacity of the kidney to maintain metabolic balance. The three main categories of acute kidney injury are prerenal, postrenal, and intrinsic renal failure.

Prerenal failure involves impaired renal perfusion, which can occur with volume depletion, systemic vasodilatation, heart failure, or preglomerular vasoconstriction. Hence, toxic events that cause bleeding (overdose of anticoagulants), volume depletion (diuretics, cathartics, or emetics), cardiac dysfunction (β-adrenergic antagonists), or hypotension from any cause can lead to acute prerenal failure.[67]

An example of vascular constriction is the hepatorenal syndrome, or renal hypoperfusion caused by liver failure. This syndrome is characterized by impaired renal function and marked constriction of the renal arterial vasculature associated with severe chronic or acute hepatic failure. Many neurohumoral disturbances lead to the renal and systemic hemodynamic changes that occur in the syndrome. Splanchnic and systemic vasodilation- likely secondary to portal hypertension decrease mean arterial pressure and compromise renal blood flow. Circulating mediators of vasoconstriction are subsequently increased, resulting in hepatorenal syndrome. Angiotensin, norepinephrine, vasopressin, endothelin, and isoprostane F_2 all contribute to an extreme cortical vasoconstriction. That this renal insufficiency is extrarenal is best illustrated by the fact that when a kidney from a patient with hepatorenal syndrome is transplanted into a uremic patient, the function of the graft promptly returns to normal.

Postrenal failure, such as urinary tract obstruction, may result from crystalluria (eg, oxalosis in ethylene glycol poisoning) or blocked urinary flow (eg, retroperitoneal fibrosis from methysergide; bladder dysfunction from anticholinergic drugs). Regardless of the cause of urinary tract obstruction, there are characteristic histologic and pathophysiologic alterations in the kidney. Microscopically, tubular dilation, predominantly in the distal nephron segments (ie, the collecting ducts and distal tubules), occurs initially and glomerular structure is preserved, subsequently dilation of the Bowman space occurs, and finally periglomerular fibrosis develops.

Pathophysiologically, GFR falls as tubule pressure counteracts the capillary hydraulic pressure gradient. Subsequently there is a fall in

renal perfusion leading to ischemic damage to nephrons. Tubular function is impaired such that concentrating ability, potassium secretory function, and urinary acidification mechanisms are all altered.

Acute tubular necrosis (Table 27–3), the most common nephrotoxic event,[4] is characterized pathologically by patchy necrosis of tubules, usually the proximal segments (Fig. 27–4). The lesion is associated with three different processes: direct toxic injury, ischemic injury from renal hypoperfusion, and pigmenturia.[181]

Direct toxicity accounts for approximately 35% of all cases of acute tubular necrosis.[130,235] Direct acting xenobiotics affect different segments of the renal tubules; for example, uranium attacks the proximal tubule and amphotericin the distal tubule (see Fig. 27–1). However, the clinical pattern of rapidly declining renal function, often accompanied by oliguria, is identical in all forms of tubular necrosis. Poisoning may also lead to ischemic tubular necrosis if hypotension or cardiac failure causes ischemia of nephron segments (proximal straight tubule and inner medullary collecting duct) that are particularly vulnerable to hypoxia.

Pigmenturia refers either to myoglobinuria from rhabdomyolysis (skeletal muscle necrosis) or to hemoglobinuria from massive hemolysis.[61] Either pigment may cause tubular injury and necrosis by precipitating in the tubular lumen.[73,181] Myoglobinuria follows necrosis of striated muscle. Alcohol and cocaine can be directly myotoxic in some individuals,[190] as can the β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) used to lower blood cholesterol.[107] Rhabdomyolysis causing myoglobinuric acute tubular necrosis can occur after extensive bee or wasp stings[128] or fire ant bites.[134] Xenobiotics that produce hypokalemia (eg, diuretics and laxatives) or predispose to hyperthermia (antipsychotics) can cause muscle necrosis on this basis. Most often, poisoning leads to muscle breakdown from pressure necrosis following prolonged unconsciousness (opioids and sedative-hypnotics), excessive muscle contraction (cocaine), or grand

mal seizures (alcohol withdrawal, theophylline).[82] Pigmenturic acute renal failure may also complicate poisoning with carbon monoxide, copper sulfate, and zinc phosphate.[34,130,259]

Myoglobin is normally excreted without causing toxicity. A study of patients with rhabdomyolysis suggests that the concentration of myoglobin in the urine may affect the development of renal failure.[73] If myoglobin inspissates in the tubular lumen because of renal hypoperfusion and high water absorption, it dissociates in the relatively acidic environment as H^+ is secreted, releasing tubulotoxic hematin.[61] This toxicity may stem from the iron-catalyzing production of oxygen free radicals.

Myoglobinuric acute tubular necrosis is diagnosed when acute kidney injury occurs following muscle breakdown. There is a simultaneous elevation of concentration of serum muscle enzymes such as creatinine kinase and aldolase. A positive urine orthotolidine test, with no erythrocytes in the sediment, and urine myoglobin may be measured. However, because primary renal failure may cause detectable myoglobinuria that does not worsen renal function,[71] finding myoglobin in the urine does not prove the diagnosis.

Myoglobinuric acute tubular necrosis can be prevented by early volume expansion if renal injury has not yet occurred.[200] Alkalinizing the urine may prevent dissociation of myoglobin and minimize tubular necrosis. However, massive rhabdomyolysis can lead to severe hypocalcemia resulting from the release of large amounts of phosphate into the blood. Alkalemia in this setting can cause tetany or seizures, worsening muscle injury.[130] Hence, the risk of alkalinization must be weighed against the benefit.

Hemoglobinuria follows hemolysis, which can be caused by a number of xenobiotics, including snake and spider venoms, cresol, phenol, aniline, arsine, stibine, naphthalene, dichromate, and methylene chloride. Sensitivity reactions to drugs (hydralazine, quinine) can also cause hemolysis.[61] The pathophysiology of hemoglobinuric acute tubular necrosis resembles that of myoglobinuria. The pigment deposits in the tubules and dissociates, causing necrosis to occur.[181] Volume depletion and acidosis precipitate the disorder, so volume expansion and alkalinization may help prevent kidney injury.

Although there is controversy about how a tubular lesion leads to glomerular shutdown, it is generally felt that tubular obstruction,

TABLE 27–4. Xenobiotics that Cause Acute Interstitial Nephritis

back-leak of filtrate across injured epithelium, renal hypoperfusion, and decreased glomerular filtering surface combine to impair glomerular filtration.[232] Additionally, filtration pressure is diminished by neutrophil infiltration and status in the vasa recta.[239] Recent evidence suggests that prolonged medullary ischemia, perhaps caused by an imbalance in the production of vasoconstrictors such as endothelin and vasodilators such as nitric oxide, is important in prolonging the renal dysfunction after the tubular injury develops.[142]

Clinically, acute tubular necrosis presents as a rapid deterioration of renal function, usually first noted as azotemia. Muddy brown casts or renal tubular cells may be seen in the urinary sediment, but hematuria and leukocyturia are unusual. Disorders of metabolic balance, such as hyperkalemia and metabolic acidosis, are also common. Although tubular sodium reabsorption is decreased, the fall in glomerular filtration usually leads to positive sodium and water balance, as renal output of these substances is fixed.[159]

Acute interstitial nephritis (Table 27–4) is clinically similar to acute tubular necrosis and often must be diagnosed by renal biopsy, which shows a cellular infiltrate separating tubular structures (Fig. 27–5). Nearly all acute interstitial nephritis is caused by hypersensitivity.[238] In many patients, the renal failure is accompanied by manifestations of systemic allergy such as fever, rash, or eosinophilia. Finding eosinophils in the urine is consistent with this disorder.[177] However, approximately 25% of patients with xenobiotic-induced interstitial nephritis have no signs of hypersensitivity. Unlike those with tubular necrosis, most patients with acute interstitial nephritis have hematuria and leukocyturia,[9] particularly eosinophiluria.[10] Secondary fever at the onset of azotemia is common, and flank pain or arthralgia may be present. The lesion usually improves after the xenobiotic is removed. Corticosteroids may hasten recovery;[89,147] many physicians use this treatment only if the renal failure does not improve promptly when the xenobiotic exposure is stopped.

DIFFERENTIAL DIAGNOSIS OF ACUTE KIDNEY INJURY

Patients who present with acutely deteriorating renal function often represent a difficult diagnostic challenge. Not only are there three major etiologic categories, but each category has several subdivisions; and more than one factor may be present. For example, a patient with an opioid overdose may have neurogenic hypotension (prerenal), together with muscle necrosis causing myoglobinuric renal failure (intrinsic renal), and opioid-induced urinary retention (postrenal). Because renal, prerenal, and postrenal processes are not mutually exclusive and require different interventions, all three should always be considered, even when one appears to be the most obvious cause of the renal failure.

Prerenal failure (renal hypoperfusion) initiates a sequence of events leading to renal salt and water retention.[12] Renin is released, causing
A   B

TABLE 27–5. Tests of Renal Function

Acute	Chronic
To differentiate prerenal failure from acute tubular necrosis: 1. BUN-to-creatinine ratio; usually > 20:1 in prerenal failure 2. Urine Na^+ usually < 20 mEq/L in prerenal failure; usually > 40 mEq/L in acute tubular necrosis 3. Fractional Na^+ excretion (FE_{Na}) is most reliable test: $$FE_{Na} = \frac{Urine[Na]/Plasma\,[Na^+]}{Urine[Creatinine]/Plasma\,[Creatinine]} \times 100$$ FE_{Na} < 1% (ie, normal) in prerenal failure, if the patient has not received diuretics or large infusions of sodium, which increase Na^+ excretion despite normal tubular function. In tubular necrosis or interstitial nephritis, renal Na^+ absorption is decreased, and FE_{Na} > 1%. This is useful except in pigmenturic or iodinated radiocontrast-associated renal failure, when the test is of no benefit.	Creatinine clearance (C_{cr}) = U × V/P (normal range 90–130 mL/min), where U is urine creatinine concentration, V is urine flow in mL/min, and P is plasma creatinine concentration. Urine collection must be complete (not necessarily 24 hours), and U and P must be in the same units. In steady states, C_{cr} in adults can be approximated by dividing the patient's weight in kilograms by the serum creatinine in mg/dL (multiply by 0.8 in women);[3] from the Cockroft-Gault equation,[44] $$C_{cr} = \frac{(140-age) \times ideal\,body\,weight\,(kg)}{72 \times serum\,creatinine} (\times 0.85\,for\,women)$$ or more formally, GFR can be estimated from the MDRD formula, 186 × serum creatinine$^{-1.154}$ × age$^{-0.203}$ (× 0.742 if female); × (1.21 if African-American).[140]

production of angiotensin, which enhances proximal tubular sodium reabsorption and stimulates adrenal aldosterone release, thus increasing distal sodium reabsorption. Prerenal failure is, therefore, accompanied by low urinary sodium excretion (Table 27–5). Release of ADH increases water and urea retention. Unresolving renal hypoperfusion may cause ischemic tubular necrosis.

Xenobiotics may decrease renal blood flow without causing intrinsic renal injury (see Fig. 27–1). Diuretics or cathartics can decrease blood volume and antihypertensive agents can excessively reduce blood pressure. Some xenobiotics (eg, cyclosporine, tacrolimus, amphotericin, methotrexate) cause prerenal vasoconstriction. NSAIDs lower filtration rate by inhibiting production of vasodilatory prostaglandins in the afferent arteriole. Finally, cardiotoxins, such as doxorubicin, can cause severe heart failure. Some xenobiotics cause a hypersensitivity vasculitis (see Fig. 27–1).

Although it is not a renal injury, the clinician should bear in mind that an estimated creatinine clearance (C_{cr}) or GFR < 40 carries the risk of nephrogenic systemic fibrosis in patients exposed to gadolinium for contrast MRI studies.[236]

Urinary tract obstruction should always be considered when the kidneys fail rapidly. Although complete obstruction leads to anuria, partial obstruction, which is more common, is usually associated with alternating oliguria and polyuria. Continued production of urine in the presence of obstruction leads to distension of the urinary tract above the blockage. Calyceal dilatation is common. Obstruction of the bladder outlet or urethra may distend the bladder.

Obstruction may be caused by xenobiotics (Table 27–6).[75] Most do so by impairing contraction of the bladder through anticholinergic action (atropine, antidepressants). Rarely, certain xenobiotics, particularly methysergide,[230] cause retroperitoneal fibrosis and ureteral constriction. Finally, a few xenobiotics lead to crystalluria and intratubular obstruction. Sometimes the xenobiotic itself forms precipitates (sulfonamides,[48] indinavir, or methotrexate) or causes excretion of a precipitating chemical such as oxalate (ethylene glycol and fluorinated anesthetics).

PATIENT EVALUATION

Evaluation of a patient with suspected toxic renal injury should include extrarenal as well as renal factors. The kidney's response to xenobiotics is affected by previous renal function, renal blood flow, and the presence of urinary tract obstruction that can exert back-pressure on the nephrons, all of which must be considered.

■ HISTORY

A past history of renal disease or conditions that can affect the kidney (eg, diabetes, hypertension, cardiovascular disease) should be noted. Flank pain, hematuria, or an abnormal pattern of urine output are important findings. The patient's intravascular volume status affects renal perfusion. Thus, a history of heart disease or a disorder that

lowers plasma volume such as vomiting or diarrhea is important. Prior cancer chemotherapy with drugs such as cisplatin or methyl-CCNU (methyl-1-[2-chloroethyl]-3-cyclohexyl-1-nitrosourea) should be noted. All current xenobiotics should be evaluated for potential renal effects, both those with direct and indirect nephrotoxic effects.[92] The patient's intake of alcohol and drugs of abuse should be explored. A careful occupational history and assessment of hobbies and lifestyle are crucial, with emphasis on exposure to nephrotoxic xenobiotics.

■ PHYSICAL EXAMINATION

The patient's hemodynamic status should be carefully assessed. Postural changes in pulse and blood pressure, and either engorgement or decreased filling of the neck veins, give important information about the intravascular volume. The skin should be examined for lesions. Funduscopy may reveal evidence of chronic hypertension or diabetes. All aspects of cardiac function should be noted, including presence or absence of edema. Injuries or scars in the suprapubic area or evidence of past urologic or retroperitoneal surgery may suggest obstruction, as may a palpable or percussible bladder.

■ LABORATORY EVALUATION

Nephrotoxic injury is not always apparent clinically, so the laboratory is exceedingly important. Acute loss of renal function may be suspected if urine output decreases, but oliguria is not universal. The most important parameter of renal function is glomerular filtration. Because urea and creatinine are largely excreted by this route, serum concentrations of these substances are used as markers of renal function. However, the concentration of any substance depends on both production and excretion. Azotemia—elevation of BUN or creatinine—is a standard

indication of renal insufficiency. However, BUN or creatinine in the normal range does not exclude a substantial degree of renal impairment because of the previously discussed hyperbolic relationship between these parameters and GFR. In addition, decreased production of urea (starvation or liver failure) or creatinine (amputation, muscle wasting) may result in a normal BUN or creatinine in the presence of significant renal impairment. Conversely, decreased renal perfusion (prerenal failure) is often associated with a disproportionate rise in BUN in comparison with the rise in creatinine, because urea is partially reabsorbed along with salt and water, whose reabsorption is increased when the kidneys are underperfused. Thus, a BUN-to-creatinine ratio > 20 is suggestive of prerenal failure (see Table 27–5). Because many

Nephrotic syndrome[31,76,252]
Penicillamine[202]
Probenecid[103]

nephrotoxic xenobiotics are associated with nonoliguric acute renal failure (urine volume > 400 mL/d), progressive azotemia without oliguria should always raise suspicion of a drug-related cause. Tubular injury, especially in lead poisoning and myoglobinuria, can cause hyperuricemia from decreased tubular secretion of uric acid.

Certain xenobiotics alter measured concentrations of urea and creatinine in the absence of any change in renal function.[171] The most obvious is exogenous creatine taken to build muscle mass. Cefoxitin, nitromethane, and ketones absorb light at the same frequency as the creatinine reaction product, thus artifactually increasing the measured level. Drugs that block renal creatinine secretion, such as cimetidine and trimethoprim, may also increase serum creatinine. BUN may be raised independently of renal function by tetracycline or corticosteroids, which increase protein catabolism.

In patients with chronic kidney disease it is necessary to assess the remaining renal function to manage the patient properly. Clearance measurements are generally used to determine glomerular filtration rate. The most common is endogenous Ccr (see Table 27–5).

Determining Ccr in acute kidney injury is not helpful, as the accuracy of a clearance implies a steady state. Changing GFR during a clearance time period distorts the resulting estimation. There is also a lag period between changes in kidney function and changes in BUN or creatinine concentrations. In general, a patient with acute kidney injury should be treated as if glomerular filtration were < 10 mL/min. In patients with acute kidney injury, a random sample of urine may be sent promptly to the laboratory for sodium and creatinine measurements to determine fractional sodium excretion, which may help discriminate prerenal azotemia from tubular necrosis (see Table 27–5).

Examination of the urine is essential in cases of poisoning. Although urine is sent to the laboratory, it can also be examined carefully by the physician. Standard dipsticks will detect albumin and glucose. The dipstick test for blood is useful for confirming the presence of small amounts of blood or myoglobin, but is not a substitute for careful microscopic examination of the sediment. Clinicians should look not only for red or white cells but also for crystals, tubular elements, casts, and bacteria. If acute interstitial nephritis is a consideration, a fresh urine sample should be stained for eosinophils.[164]

TABLE 27–11. Nephrotoxic Medications

Diuretics
Prerenal failure (volume depletion)
Acute interstitial nephritis[147,151,152]
Acute renal failure (mannitol)[28,93]
Hyperkalemia (K+-sparing diuretics)[72]
Hyponatremia

Antihypertensives
Prerenal failure (excessive dosage)
Acute interstitial nephritis
    Methyldopa[256]
    Captopril[233]
Nephrotic syndrome
    Captopril[196]
Obstruction (retroperitoneal fibrosis)
    Methyldopa[141]

Anticonvulsants
Acute interstitial nephritis
Carbamazepine[108]
Phenobarbital[182]
Phenytoin[9,112]
Nephrotic syndrome
    Trimethadione[15]
    Paramethadione

Anesthetics
Acute tubular necrosis
Methoxyflurane[185]
Halothane[86]
Enflurane[63]

Antineoplastics
Acute tubular necrosis
    Cisplatin[90,206]
    Methotrexate[46,99,193,116]
    Mithramycin[126]
    Ifosfamide[219]
    Streptozotocin[214]
Chronic interstitial nephritis
    Cisplatin[95]
    Nitrosoureas[64,217]
Thrombotic microangiopathy
    Mitomycin C[139,187]

Immunosuppressants
Acute tubular necrosis and/or
chronic interstitial nephritis
    Cyclosporine[74,110,158,172,189]
    Tacrolimus[173,235]
Acute interstitial nephritis
    Azathioprine[225]
Renal tubular acidosis
    Tacrolimus[97]

Radiocontrast agents
Acute renal failure, especially the
    high osmolal and ionic
    agents[11,28,68,123,165,166,179,195,249]
Osmotic nephropathy and renal
    vasoconstriction [gadolinium]

TABLE 27–12. Nephrotoxicity of Miscellaneous Xenobiotics

Acute glomerular injury
Focal segmental glomerulosclerosis
Pamidronate (collapsing type)[155]
Interferon alpha[176,257]

Acute tubular necrosis
Aluminum phosphide[127]
Deferoxamine[41]
Epinephrine (in neonate)[141]
Etidronate[183]
Mycotoxins[57]
Paraquat, diquat[248]

Acute interstitial nephritis
Cimetidine[147,157]
Clofibrate[51]
Phenylpropanolamine[26]
Proton-pump inhibitors[84A]
Ranitidine[79]
Ticlopidine[201]

Acute renal failure
Mushrooms
    Amanita (especially *A. smithiana*)[172]
    Cortinarius spp[136]
Pigments[67]
    Hemoglobin
    Myoglobin

Obstruction (retroperitoneal fibrosis)
Bromocriptine[29]

Renal stones and aminoaciduria
Worcestershire sauce[170]

Thrombotic microangiopathy
Clopidogrel[25]
Cyclosporine[246]
Mitomycin C[139]
Possible (IL-2, Interferon
    alpha, imatinib, gemcitabine)
Quinine[132]
Tacrolimus[144]
Ticlopidine[36]

TABLE 27–13. Nephrotoxicity of Drugs of Abuse

Nephrotic Syndrome	Amyloidosis	Obstruction (Retroperitoneal Fibrosis)	Acute Renal Failure (Myoglobinuria)	Chronic Renal Failure (Vasculitis)
Adulterated heroin[119,60,148,161] Adulterated cocaine[119]	Adulterated heroin (injection use)[49,117]	Lysergic acid diethylamide (LSD)[230]	Amphetamines[102,125] Cocaine[203]	Amphetamines[42]

TABLE 27–14. Nephrotoxicity of "Complementary" Medical Treatments

Acute Interstitial Nephritis	Acute Tubular Necrosis	Obstruction (Retroperitoneal Fibrosis)
Stephania tetrandra, Magnolia officinalis[69,247] (Chinese herbs, often irreversible) *Hypericum*[69] *Ledum*[69]	Grass carp gallbladder[143] Disodium edetate[45,183]	*Stephania tetrandra, Magnolia officinalis*[69,247]

Further evaluation of the patient with acute renal failure should include tests for obstruction, which can be caused by a number of substances (see Table 27–6). Renal ultrasonography should be performed to look for hydronephrosis. Postvoiding residual urine volume may be measured as appropriate by catheterization; if the volume is in excess of 75 to 100 mL, suspect bladder dysfunction or obstruction.

Nephrotoxic complications of specific xenobiotics are found in Tables 27–7 through 27–14.

SUMMARY

The kidneys are exposed to exogenous or endogenous xenobiotics in their role as primary defenders against harmful xenobiotics entering the bloodstream. The environment, the workplace, and, especially, the administration of medications, represent potential sources of nephrotoxicity. Consequently, it is important to determine, by history and observation, to which xenobiotics a patient may have been exposed and to be aware of their potential to harm the kidneys. It is equally crucial to work the other way when a patient presents with renal dysfunction: review all xenobiotics, both conventional and complementary, all xenobiotic exposures, and any conditions that can adversely affect the kidneys.

CHAPTER 28
GENITOURINARY PRINCIPLES

Jason Chu

The genitourinary system encompasses two major organ systems: the reproductive and the urinary systems. Successful reproduction requires interaction between two sexually mature individuals. Xenobiotic exposures to either individual can have an adverse impact on fertility, which is the successful production of children, and fecundity, which is an individual's or a couple's capacity to produce children. The role of occupational and environmental exposures in the development of infertility is difficult to define.[10,37,89,93] Well-designed and conclusive epidemiologic studies are lacking due to the following factors: laboratory tests used to evaluate fertility are relatively unreliable; clinical endpoints are unclear; xenobiotic exposure is difficult to monitor; and indicators of biologic effects are imprecise. The negative impact on fertility as an adverse effect of xenobiotics is often ignored, but the evaluation of infertility is incomplete without a thorough xenobiotics and occupational history. Differences in the toxicity of xenobiotics in individuals may be sex- and/or age-related. Xenobiotic-related, primary infertility may be the result of effects on the hypothalamic-pituitary-gonadal axis or of a direct toxic effect on the gonads.[78] Fertility is also affected by exposures that cause abnormal sexual performance. Table 28–1 lists xenobiotics associated with infertility.

Aphrodisiacs are used to heighten sexual desire and to counteract sexual dysfunction. Historically, humans have continued to search for the perfect aphrodisiac. Efficacy is variable, and toxic consequences occur commonly. Various treatments have been available for male sexual dysfunction, or erectile dysfunction.

Although many people search for a cure for impotence or infertility, others explore xenobiotics that can be used as abortifacients. Routes of administration used include oral, parenteral, and intravaginal, with an end result of pregnancy termination. Toxicity results not only in the termination of pregnancy but also from the systemic effects of the various xenobiotics.

This chapter examines these issues, as well as the impact of xenobiotics on the urinary system, specifically, urinary retention and incontinence, and abnormalities detected in urine specimens. Renal (Chap. 27), teratogenic, (Chap. 30), and carcinogenic principles are discussed elsewhere in this text.

MALE FERTILITY

Male fertility is dependent on a normal reproductive system and normal sexual function. The male reproductive system is comprised of the central nervous system (CNS) endocrine organs and the male gonads. The hypothalamus and the anterior pituitary gland form the CNS portion of the male reproductive system. Both organs begin low-level hormone secretion as early as in utero gestation. At puberty, the hypothalamus begins pulsatile secretion of gonadotropin-releasing hormone (GnRH). This stimulates the anterior pituitary gland to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in a pulsatile fashion. The hormones exert their effects on the male target organs, inducing spermatogenesis and secondary body sexual characteristics (Fig. 28–1).

Disruption of normal function at any part of the system affects fertility. There are a number of xenobiotics that can adversely affect the male reproductive system and sexual function.

■ SPERMATOGENESIS

Central to the male reproductive system is the process of spermatogenesis, which occurs in the testes. The bulk of the testes consist of seminiferous tubules with germinal spermatogonia and Sertoli cells. The remainder of the gonadal tissue is interstitium with blood vessels, lymphatics, supporting cells, and Leydig cells. Spermatogenesis begins with the maturation and differentiation of the germinal spermatogonia. The process is controlled by the secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus, which stimulates the pituitary to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Follicle-stimulating hormone stimulates the development of Sertoli cells in the testes, which are responsible for the maturation of spermatids to spermatozoa. Luteinizing hormone promotes production of testosterone by Leydig cells. Testosterone concentrations must be maintained to ensure the formation of spermatids.[19] Both FSH and testosterone are required for initiation of spermatogenesis, but testosterone alone is sufficient to maintain the process.

Testicular Xenobiotics Xenobiotics can affect any part of the male reproductive tract, but, invariably, the end result is decreased sperm production defined as oligospermia, or absent sperm production, azoospermia. In contrast to oogenesis in women, spermatogenesis is an ongoing process throughout life but can be inhibited by decreases in FSH and/or LH or Sertoli cell toxicity. Spermatogenic capacity is evaluated by semen analysis, including sperm count, motility, sperm morphology, and penetrating ability. Normal sperm count is greater than 40 million sperm/mL semen, and a count less than 20 million/mL is indicative of infertility.[19] Decreased motility (asthenospermia) less than 40% of normal or abnormal morphology (teratospermia) of greater than 40% of the total number of sperm also indicates infertility.[19,101]

Physiology of Erection The penis is composed of two corpus cavernosa and a central corpus spongiosum. The internal pudendal arteries supply blood to the penis via four branches. Blood outflow is via multiple emissary veins draining into the dorsal vein of the penis and plexus of Santorini. Within the penis, the corpora cavernosa share vascular supply and drainage due to extensive arteriolar, arteriovenous, and sinusoidal anastomoses.[120] When penile blood flow is greater than 20–50 mL/min, erection occurs. Maintenance of tumescence occurs with flow rates of 12 mL/min. The tunica albuginea limits the absolute size of erection.

In the flaccid state, sympathetic efferent nerves maintain helicine resistance arteriole constriction primarily through norepinephrine induced α-adrenergic agonism. α-Adrenergic receptor agonism in the erectile tissues decreases cAMP to produce flaccidity, while α-Adrenergic antagonism can result in pathologic erection (priapism) as a consequence of parasympathetic dominance.[120] Other vasoconstrictors, such as endothelin, prostaglandin F_{2a}, and thromboxane A_2 play a role in maintaining corpus cavernosal smooth muscle tone in contraction, which results in a flaccid state.[84]

Normal penile erection is a result of both neural and vascular effects. Psychogenic neural stimulation arising from the cerebral cortex inhibits norepinephrine release from thoracolumbar sympathetic pathways, stimulates nitric oxide (NO) and acetylcholine release from sacral parasympathetic tracts, and stimulates acetylcholine release from somatic pathways. In animals, dopamine and NO play a role in erection.[84] Reflex stimulation can also occur from the sacral spinal cord. The

TABLE 28–1. Xenobiotics Associated with Infertility

Men	
Xenobiotic	Effects
Anabolic steroids	↓ LH, oligospermia
Androgens	↓ testosterone production
Antineoplastics	Gonadal toxicity
Cyclophosphamide	Oligospermia
Chlorambucil	Oligospermia
Methotrexate	Oligospermia
Combination chemotherapy (COP, CVP, MOPP, MVPP)	Oligospermia
Carbon disulfide	↓ FSH, ↓ LH, ↓ spermatogenesis
Cimetidine	Oligospermia
Chlordecone	Asthenospermia, oligospermia
Dibromochloropropane (DBCP)	Azoospermia, oligospermia
Diethylstilbestrol	Testicular hypoplasia
Ethanol	↓ Testosterone production, Leydig cell damage, asthenospermia, oligospermia, teratospermia
Ethylene oxide	Asthenospermia (in monkeys), oligospermia
Glycol ethers	Azoospermia, oligospermia, testicular atrophy
Ionizing radiation	↓ Spermatogenesis
Opioids	↓ LH, ↓ testosterone
Lead	↓ Spermatogenesis, asthenospermia, teratospermia
Nitrofurantoin	↓ Spermatogenesis
Sulfasalazine	↓ Spermatogenesis
Tobacco	↓ Testosterone
Women	
Xenobiotic	Effects
Antineoplastics	Gonadal toxicity
Cyclophosphamide	Ovarian failure
Busulphan	Amenorrhea
Combination chemotherapy (MOPP, MVPP)	Amenorrhea
Diethylstilbestrol	Spontaneous abortions
Ethylene oxide	Spontaneous abortions
Lead	Spontaneous abortions, still births
Oral contraceptives	Affect hypothalamic-pituitary axis, end-organ resistance to hormones, amenorrhea
Thyroid hormone	↓ Ovulation

afferent limb of the reflex arc is supplied by the pudendal nerves and the efferent limb by the nervi erigentes (pelvic splanchnic nerves).

The central impulses stimulate various neurotransmitters to be released by peripheral nerves in the penis. Nonadrenergic-noncholinergic nerves and endothelial cells produce NO, which is the principal neurotransmitter mediating erection. Nitric oxide activates guanylate cyclase conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). Increasing concentrations of cGMP act as a second messenger, mediating arteriolar and trabecular smooth-muscle relaxation to enable increased cavernosal blood flow and penile erection.[84] Both cGMP and cyclic adenosine
FIGURE 28–2. A schematic of the erection and xenobiotics that cause sexual dysfunction. NE = norepinephrine; ACH = acetylcholine; NANC = nonadrenergic-noncholinergic; NO = nitric oxide; VIP = vasoactive intestinal peptide.

monophosphate (cAMP) pathways mediate smooth-muscle relaxation. Cholinergic nerves release acetylcholine, which stimulates endothelial cells via M_3 receptors to produce NO and prostaglandin E_2 (PGE). Prostaglandin E_2 and nerves containing vasoactive intestinal peptide (VIP) and calcitonin gene-related peptide (CGRP) increase cellular cAMP to potentiate smooth-muscle relaxation.

Penile corpus cavernosal smooth muscle relaxation allows increased blood flow into the corpus cavernosal sinusoids. Expansion of the sinusoids compresses the venous outflow and enables penile erection (Fig. 28–2).

■ SEXUAL DYSFUNCTION

Sexual dysfunction can result from decreased libido (sexual desire), impotence, diminished ejaculation, and erectile dysfunction. Dopamine, norepinephrine, oxytocin, and adrenocorticotrophic hormone (ACTH) are central neurotransmitters and hormones which facilitate sexual function. Serotonin, prolactin, endogenous opioids and GABA inhibit sexual function centrally.[6] Libido can be decreased by xenobiotics that block central dopaminergic or adrenergic pathways or by xenobiotics that increase serotonin or prolactin levels. Conversely, xenobiotics that increase dopamine can improve sexual function. Sexual dysfunction can also be caused by xenobiotics that decrease testosterone production and by xenobiotics that produce dysphoria. Xenobiotics that affect spinal reflexes can cause diminished ejaculation and erectile dysfunction.[118]

Approximately 30 million men in the United States suffer from erectile dysfunction, with an increased prevalence in older men.[53] Erectile dysfunction is defined as the inability to achieve and/or maintain an erection for a sufficiently long period of time to permit satisfactory sexual intercourse[3] and is divided into the following classifications: psychogenic, vasculogenic, neurologic, endocrinologic, and xenobiotic-induced. Xenobiotic-induced erectile dysfunction is associated with the following categories of xenobiotics: antidepressants, antipsychotics, centrally and peripherally-acting antihypertensives, CNS depressants, anticholinergics, exogenous hormones, antibiotics, and antineoplastics.[74,100,118] Treatment of this disorder is varied and includes vacuum-constriction devices, penile prostheses, vascular surgery, and medications (intracavernosal, transdermal, and oral agents).

Antihypertensives Erectile dysfunction is reported as an adverse effect with all antihypertensives and may be caused, in part, by a decrease in hypogastric artery pressure, which impairs blood flow to the pelvis.[117] Methyldopa and clonidine both are centrally acting α_2-adrenergic agonists that inhibit sympathetic outflow from the brain. Sexual dysfunction is reported in 26% of patients receiving methyldopa and in 24% of patients receiving clonidine.[14,87] Erectile dysfunction associated with thiazide diuretics may be related to decreased vascular resistance, diverting blood from the penis.[20] Spironolactone acts as an antiandrogen by inhibiting the binding of dihydrotestosterone to its receptors. Impotence related to use of β-adrenergic antagonists, is well documented[1,57,114] and may be caused by unopposed α-mediated vasoconstriction resulting in reduced penile blood flow.

Ethanol Ethanol is directly toxic to Leydig cells. Chronic alcohol abuse causes decreased libido, erectile dysfunction, and is associated with testicular atrophy. In alcoholics liver disease contributes to sexual dysfunction resulting from decreased testosterone and increased estrogen production. Alcoholics can have autonomic neuropathies affecting penile nerves and subsequent erection. Heavy drinkers suffer more from erectile dysfunction than episodic drinkers.[116]

Antipsychotics Individuals who take antipsychotics therapeutically have varying degrees of sexual dysfunction related to their underlying disease and their medications. All psychoactive medications are associated with sexual dysfunction to some degree. Monoamine oxidase inhibitors

α_1-Adrenergic antagonists	Diuretics
α_2-Adrenergic agonists	Ethanol
β-Adrenergic antagonists*	Lead
Anabolic Steroids	Lithium
Anticholinergics*	Methyldopa
Anticonvulsants	Monamine oxidase inhibitors*
Antiestrogens	Opioids
Benzodiazepines	Oral contraceptives
Calcium channel blockers	Phenothiazines
Cimetidine	Selective serotonin reuptake inhibitors
Clonidine	Spironolactone
Cyclic Antidepressants	

*Associated with erectile dysfunction

(MAOIs), cyclic antidepressants (CAs), antipsychotics, and selective serotonin reuptake inhibitors (SSRIs) are associated with decreased libido and erectile dysfunction in men.[31] Thioridazine is associated with significantly lower LH and testosterone levels in men in comparison with other antipsychotics.[19] Antidepressants such as bupropion, nefazodone, mirtazapine, and duloxetine have lower incidences of sexual dysfunction in comparison with other antidepressants.[102] Table 28–2 lists xenobiotics associated with sexual dysfunction.

■ XENOBIOTICS USED IN THE TREATMENT OF ERECTILE DYSFUNCTION

Intracavernosal Agents. The three most commonly used intracavernosal agents used for erectile dysfunction are papaverine, prostaglandin E_1, and phentolamine. Papaverine is a benzylisoquinoline alkaloid derived from the poppy plant *Papaver somniferum*. It exerts its effects through nonselective inhibition of phosphodiesterase, leading to increased cAMP and cGMP levels and subsequent cavernosal vasodilation. Papaverine was used for the treatment of cardiac and cerebral ischemia but had limited efficacy. Presently, it is used as intracavernosal therapy for erectile dysfunction alone or in conjunction with phentolamine. Systemic side effects include dizziness, nausea, vomiting, hepatotoxicity, lactic acidosis with oral administration, and cardiac dysrhythmias with intravenous use. Intracavernosal administration is associated with penile fibrosis which is usually dose-related phenomenon, although fibrosis can also occur with limited use.[33] More concerning is the development of priapism with papaverine use.

Prostaglandin E_1 (Alprostadil) is a nonspecific agonist of prostaglandin receptors resulting in increased concentrations of intracavernosal cAMP, cavernosal smooth muscle relaxation and penile erection. It is effective via intracavernosal administration as a single agent. Other preparations include an intraurethral preparation, which is less effective, and a topical gel formulation.[54] Penile fibrosis can occur but the incidence is lower compared to papaverine. Other adverse effects include penile pain, secondary to its effects as a nonspecific prostaglandin receptor agonist, and priapism.

Phentolamine is a competitive α-adrenergic antagonist at α_1 and α_2 receptors. It effects erection by inhibiting the normal resting adrenergic

tone in cavernosal smooth muscle, thus allowing increased arterial blood flow and erection. Intracavernosal use can cause systemic hypotension, reflex tachycardia, nasal congestion, and gastrointestinal upset. Penile fibrosis and priapism are also reported.

Oral Agents Since the development of the phosphodiesterase 5 inhibitors, oral therapy has replaced intracavernosal injections as the mainstay for treatment of erectile dysfunction. Sildenafil was the first agent developed, followed by vardenafil and tadalafil. These medications are pharmacodynamically similar but differ in their pharmacokinetics. Phosphodiesterase 5 inhibitors increase NO-induced cGMP concentrations by preventing phosphodiesterase breakdown of cGMP, enhancing NO-induced vasodilation to promote penile vascular relaxation and erection.[18]

After oral administration, sildenafil is rapidly absorbed with a bioavailability of 40% and a median peak serum concentration of 60 minutes. Its mean volume of distribution is 105 L, and its elimination half-life is 3 to 5 hours. Metabolism is primarily by the CYP3A4 pathway with some minor metabolic activity via the CYP2C9 pathway. Serum concentrations of sildenafil are increased in patients older than 65 years as well as those with hepatic dysfunction, severe renal dysfunction (creatinine clearance <30 mL/min), and when used with CYP3A4 inhibitors (macrolide antibiotics, cimetidine, antifungal agents, protease inhibitors).[26]

Vardenafil has more selective inhibition of phosphodiesterase 5 enzymes and less inhibition of phosphodiesterase 6 enzymes compared to sildenafil. After oral administration, it has a 14% bioavailability, a volume of distribution of 208 L, a median peak serum concentration of 60 minutes and an elimination half-life of 4 to 5 hours. The CYP3A4 pathway is the primary hepatic metabolic pathway with minor contributions from CYP3A5 and CYP2C9 enzymes.[13,15] The primary metabolite, M1, has phosphodiesterase 5 inhibitory activity but is four times less potent than vardenafil.[15] As with sildenafil, vardenafil concentrations are increased in patients older than 65 years, and those with hepatic dysfunction, severe renal dysfunction (creatinine clearance <30 mL/min), and when used with CYP3A4 inhibitors (macrolide antibiotics, cimetidine, antifungal agents, protease inhibitors).[62]

Tadalafil has a median peak serum concentration of 2 hours and a mean elimination half-life of 17.5 hours. It is predominantly metabolized by CYP3A4 enzymes. Unlike sildenafil and vardenafil, serum concentrations are not affected by age, hepatic dysfunction, renal dysfunction or CYP3A4 inhibitors. However, the FDA has issued recommendations to decrease the dosage of all phosphodiesterase 5 inhibitors if used in conjunction with atazanavir.[2]

The most common adverse effects of the phosphodiesterase 5 inhibitors are headache, flushing, dyspepsia, and rhinitis, which are related to phosphodiesterase 5 inhibitory effects on extracavernosal tissue.[53] Blurred vision, increased light perception and transient blue-green tinged vision are also reported and are related to the weak phosphodiesterase 6 inhibition of sildenafil in the retina.[53] Vardenafil and tadalafil are associated with infrequent abnormal vision, including blurred and abnormal color vision.[55]

More serious adverse effects of sildenafil include myocardial infarction, when used alone or with nitrates, subaortic obstruction, stroke, transient ischemic attack, priapism, and anterior optic ischemia.[9,41,61,103,106] Tadalafil use is associated with anterior ischemic optic neuropathy.[16]

When taken alone, the vasodilatory effects of phosphodiesterase 5 inhibitors cause a modest decrease in systemic blood pressure. However, because of their mechanism of action via cGMP inhibition and vascular vasodilation, phosphodiesterase 5 inhibitors can have synergistic interactions with the vasodilatory effects of nitrates resulting in profound hypotension.[18,63] A study of healthy male volunteers taking sildenafil demonstrated significantly less tolerance to a glyceryl trinitrate infusion in comparison with placebo.[115] Because of this interaction, patients with acute myocardial ischemic syndromes using phosphodiesterase 5 inhibitors should avoid taking organic nitrates as well.[26] α_1-Adrenergic antagonists are also contraindicated with concomitant phosphodiesterase 5 inhibitor use because of increased hypotensive effects.[63] Hypotension occurred in patients using vardenafil with terazosin and tamsulosin,[63] and in patients using tadalafil with doxazosin.[64] However, patients using tadalafil with tamsulosin did not develop hypotension.[64]

Yohimbine, an indole alkylamine alkaloid from the West African yohimbe tree (*Corynanthe yohimbe*), is an α_2-adrenergic antagonist with cholinergic activity used to treat erectile dysfunction and postural hypotension associated with anticholinergic drugs.[71] It is structurally similar to reserpine. Other names for yohimbine include Aphrodyne, corynine, hydroaergotocin, quebrachine, and the street name "yo-yo."[72] Its use in the treatment of impotence is based on the theory that erection is linked to cholinergic stimulation and α_2 antagonism, resulting in an increase inflow and decrease outflow of blood to the penis. Although the agent Aphrodex, which contained 5 mg yohimbine, 5 mg methyltestosterone, and 5 mg strychnine, improved performance in males with erectile failure,[75] its distribution was halted in 1973 because of safety concerns.[98]

Yohimbine can be obtained by prescription, but extracts are also available in "health food" products marketed as "vitalizing agents for men and women."[35] Yohimbine can also be extracted from the Rauwolfia root.[46] The "therapeutic" dose is 2 to 6 mg 3 times daily. The drug is rapidly absorbed, with peak serum concentrations occurring in 45 to 60 minutes. The half-life is 36 minutes, and clearance is by hepatic metabolism without renal excretion.[90] Maximum pharmacologic effects occur 1 to 2 hours after ingestion and effects persist for 3 to 4 hours.[72]

Because the erectile process involves various neurotransmitters, a single agent would be expected to only have a partial effect. In a double-blind study of 100 males with erectile failure treated with 18 mg/d of yohimbine, 42.6% of the treatment group and 27.6% of the placebo group reported some improvement in erectile function, which was not statistically significant.[83] Another study that compared a higher dose of yohimbine and placebo in 82 elderly males showed a statistically significant improvement with treatment.[108]

Adverse effects can occur with relatively low doses of yohimbine. Tachycardia, hypertension, mydriasis, diaphoresis, lacrimation, salivation, nausea, vomiting, and flushing can occur following intravenous administration.[58] Ten milligrams of yohimbine can elicit manic symptoms in patients with bipolar disorder,[95] and 15 mg/d is associated with bronchospasm[66] and a lupuslike syndrome.[99] A 16-year-old woman who ingested 250 mg of yohimbine powder, purchased for its purported aphrodisiac activity, developed an acute dissociative reaction with weakness, paresthesias, headache, nausea, palpitations, and chest pain. She also developed tachycardia, tachypnea, diaphoresis, tremors, and a rash. Her symptoms resolved after 36 hours without treatment.[72] Another report describes a 62-year-old man who ingested 200 mg of yohimbine and developed tachycardia, hypertension, and a brief period of anxiety that resolved without treatment.[46] Symptomatic patients who ingest yohimbine should receive activated charcoal and should be observed until asymptomatic. Clonidine has been recommended for treatment of yohimbine's central and peripheral effects.[72] β-Adrenergic antagonists may attenuate some of the peripheral toxicity, but may also result in unopposed α_1-adrenergic activity and worsening of hypertension, and should be avoided. Benzodiazepine administration may be sufficient for the treatment of agitation and sympathomimetic effects related to yohimbine.

Sublingual apomorphine effects erection through activation of central dopaminergic pathways; most likely D_2 receptors in the paraventricular nucleus of the hypothalamus.[56] It reaches maximum serum

concentrations within 40 to 60 minutes after sublingual administration and is metabolized hepatically with a half-life of 2 to 3 hours.[8] Common adverse effects are nausea, vomiting, headache, dizziness and syncope. Unlike the phosphodiesterase 5 inhibitors, apomorphine is not associated with hypotension when used with antihypertensive, such as nitrates.

Priapism Priapism is defined as prolonged involuntary erection, which is painful, unassociated with sexual stimulation, and can result in impotence. It most commonly occurs during the third and fourth decades of life and is caused by inflow of blood to the penis in excess of outflow. The corpora cavernosa become firm and the corpus spongiosum flaccid. Intracavernosal pressures can exceed arterial systolic pressure, resulting in cell death. Priapism can occur from an imbalance in neural stimuli, interference with venous outflow, or as a result of xenobiotic-induced inhibition of penile detumescence. α-Adrenergic antagonists prevent constriction of blood vessels supplying erectile tissue, resulting in priapism.[120] One out of 10,000 patients taking trazodone develop priapism, which is thought to be related to its α-adrenergic antagonist effects.[98] A common cause of priapism is iatrogenic, resulting from the injection of papaverine for the treatment of impotence.[109] Other xenobiotics associated with xenobiotic-induced priapism include prazosin, labetalol, guanethidine, hydralazine, phenothiazines, androgens, anticoagulants, ethanol, marijuana, and cantharidin[60,120] (Table 28–3).

The goal in the treatment of priapism is detumescence with retention of potency. Initial therapy includes sedation with benzodiazepines, analgesia with opioids, and ice packs, and early urologic consultation. Oral terbutaline (5–10 mg) was effective for prostaglandin E_1-induced priapism and may be effective for other xenobiotic-induced priapism.[73,96] Aspiration and normal saline irrigation of the corpora cavernosa may be effective. If priapism occurs secondary to α_1-adrenergic antagonism, an α_1-adrenergic agonist (0.02 mg norepinephrine or 0.2 mg phenylephrine) diluted with normal saline to 10 mL volume can be instilled by placing a 19-gauge butterfly needle into the corpora cavernosa. If the above measures fail, operative venous shunt placement may be required.[109,120]

FEMALE FERTILITY

The female reproductive system consists of the female gonadal organs and the respective hormonal system (Fig. 28–3). Fertility encompasses the reproductive system, the process of oocyte fertilization and gestation. Female infertility may result from changes in hormone concentrations, direct toxicity to the ovum, interference with the transport of the ovum, or inhibition of implantation of the ovum in the uterus. Women usually notice reproductive abnormalities more quickly than men, because menses may be affected; although infertility may occur while normal menses persists. Evaluation of female fertility is more difficult because of the complexity of the systems involved and the inaccessibility of the female germ cell, but it is feasible and involves investigations of the anatomy and hormonal concentrations. The following is a discussion of oogenesis, agents that disrupt oogenesis, and xenobiotics that affect early embryo gestation.

■ OOGENESIS

In contrast to men, women have a limited number of reproductive cells (ovarian follicles). Follicles are most numerous while the fetus is in utero, with the number decreasing to approximately 2 million at birth. By the time a woman reaches puberty, the majority of follicles have degenerated, leaving 300,000 to 400,000 ova, of which approximately 400 will eventually produce mature ova during a woman's reproductive years. In contrast, men produce millions of spermatozoa each day. The process of oogenesis requires secretion of GnRH from the hypothalamus, resulting in production of LH and FSH from the pituitary, which are required for ovarian follicle maturation.[19] FSH induces early maturation by stimulating granulosa and thecal cell proliferation and estrogen

TABLE 28–3. Xenobiotics Associated with Priapism

Androgens	**Antipsychotics**
Anticoagulants	Butyrophenones

TABLE 28–4. Xenobiotics Used as Abortifacients

Source	Common Name	Xenobiotic	Miscellaneous/Toxicity
Inhibit implantation			
Abrus precatorius	Jequirity pea	Abrin	Cytotoxic toxalbumin
Acanthospermum hispidum	Bristly starbur	*Acanthospermum hispidum*	Preimplantation effects
Aristolochia sp.	Birthwort	Aristolochic acid	Nephrotoxicity
Momordica charantia	Bitter melon	α-Momorcharin	Similar to trichosanthin
Cajanus cajan	Pigeon pea	*Cajanus cajan*	Preimplantation effects
Lagenaria breviflora	Wild colocynth	*Lagenaria breviflora*	Preimplantation effects
–	–	Mifepristone	Nausea, vomiting, abdominal pain, vaginal bleeding
Juniperus sabina	Savin	Oil of savin	Hepatotoxicity in mice
Ruta graveolens	Rue	Chalepesin	Hepatotoxicity, nephrotoxicity, photodermatitis
Abortive			
Ranunculus spp.	Buttercup	Devil's claw	Similar to pennyroyal oil
Angelica sinesis	Dong quai	Furanocoumarin, phytoestrogen	Anticoagulant effects, gynecomastia, photodermatitis
Daphne genkwa	Lilac daphne	Yuanhuacine	
–	–	Lysol disinfectant	Death after intrauterine administration
Mentha pulegium	Pennyroyal	Pulegone	Hepatotoxicity
–	–	Methotrexate	Cytotoxic effects
–	–	Mifepristone	Nausea, vomiting, abdominal pain, vaginal bleeding
Momordica charantia	Bitter melon	α-momorcharin	Similar to trichosanthin
Moringa oleifera	Horseradish tree	*Moringa oleifera*	100% abortifacient in rats
Podophyllum peltatum	Mayapple	Podophyllin	Podophyllum toxicity
Trichosanthes kirilowii	Snake gourd	Tricosanthin (compound Q)	Inhibits protein synthesis, ↓HCG, ↓progesterone
Oxytocic			
Aristolochia sp.	Birthwort	Aristolochic acid	Nephrotoxicity
Caulophyllum thalictroides	Blue cohosh	Methylcytisine	Toxicity similar to nicotine
Cimicifuga racemosa	Black cohosh	unknown	Nausea, vomiting, headache, rare hepatotoxicity
Cinchona spp.	Quinine bark	Quinine	Cinchonism
Claviceps purpurea	Ergot	Ergotamines	Vasospasm
Lagenaria breviflora Robert	Wild colocynth	*Lagenaria breviflora* Robert	Antiimplantation, oxytocic
Misoprostol		Prostaglandin E analogue	Marketed as Cytotec for gastric ulcers and arthrotec

production. LH is required for ovulation and for the formation of the corpus luteum. The corpus luteum continues estrogen production and produces progesterone, which stimulates the uterus to develop an endometrium receptive to any fertilized ovum. Successful ovulation requires not only hormone secretion but also appropriate cyclic secretion.

■ FEMALE SEXUAL DYSFUNCTION

The National Health and Social Life Survey found that 43% of women in the United States (in comparison with 31% of men) reported having sexual dysfunction.[67] In 1999, a consensus panel of the American Foundation for Urologic Disease revised the classification of female sexual dysfunction into the following four categories: a) sexual desire disorders, which include hypoactive sexual desire disorder and sexual aversion disorder; b) sexual arousal disorder; c) orgasmic disorder; and d) sexual pain disorders, which include dyspareunia, vaginismus, and noncoital sexual pain disorder.[11] The organic etiologies of female sexual dysfunction parallel those of male sexual and erectile dysfunction: vasculogenic, neurogenic, muscuologenic, psychogenic, endocrinologic, and xenobiotic-induced causes. The medications implicated in female sexual dysfunction are similar to the above-mentioned agents that decrease female fertility with antihypertensives, antidepressants and antipsychotics as the most frequent causes.[42]

Treatments for xenobiotic-induced female sexual dysfunction include decreasing medication dosages, switching to alternate medications with less adverse effects on sexual function (ie, bupropion and nefazodone), temporary cessation of the medication (drug holiday), or adding another medication to stimulate sexual function. Bupropion alone was as effective as fluoxetine for the treatment of depression but with less sexual dysfunction,[32] and when used in conjunction with SSRIs, bupropion improved

sexual function compared to SSRIs alone.[30] Sildenafil was successful for treating spinal cord-induced[105] and antidepressant-induced sexual dysfunction[88] whereas larger trials had mixed results with sildenafil for sexual arousal disorder.[12,22] Sublingual apomorphine improved sexual function in women with hypoactive sexual disorder.[21]

The majority of medical therapy for female sexual dysfunction is centered on hormonal agents; both estrogen and androgen supplementation. Estrogen replacement therapy is available in oral, dermal, vaginal ring, and topical cream formulations alone or in combination with progesterone.[113] Estrogen therapy is associated with a higher incidence of coronary disease, breast cancer, stroke, and venous thromboembolism. Androgen therapy includes testosterone, which is available in oral, dermal and topical preparations, and dehydroepiandrosterone.[4] Adverse effects are weight gain, increased cholesterol, and androgenization.

Abortifacients An abortifacient is defined as a xenobiotic that affects early embryonic gestation to induce abortion. Xenobiotics may act by flushing the zygote from the fallopian tube, blocking the uterine horn, inhibiting implantation, inducing fetal resorption, or by producing oxytocin like activity that results in uterine irritation and contraction. Abortifacients may also indirectly affect pregnancy by altering hormonal concentrations through placental inhibition of HCG or progesterone production or through interference with progesterone receptors.

The toxic effects of abortifacients are varied. Many produce gastrointestinal symptoms such as abdominal pain, nausea, and vomiting. Abdominal pain may be related to the oxytocic effects of the xenobiotic (eg, misoprostol and mifepristone) on the uterus, cytotoxic effects of the xenobiotic (eg, methotrexate) on the gastrointestinal lining leading to stomatitis and ulcers, or hepatoxicity (eg, pennyroyal).[27] Abortifacients that inhibit implantation or have abortive effects can have severe vaginal bleeding (eg, mifepristone). Other toxic effects are not necessarily related to their abortive mechanisms but due to the specific xenobiotic. Plant derived abortifacients can cause nephrotoxicity (eg, aristolochia), photosensitivity (eg, dong quai), seizures (eg, blue cohosh), or cardiac dysrhythmias (eg, quinine).[86] Congenital abnormalities (scalp and skull defects, cranial nerve palsies, limb defects such as talipes equinovarus) are also reported with misoprostol use that did not terminate pregnancy[28] (Table 28–4).

In a US poison center study, 5 of 43 pregnant women who intentionally overdosed used known abortifacients, including quinine, misoprostol, methylergonovine, and oral contraceptives. Four of these patients developed vaginal bleeding and cramping, but no short-term (1–3 days) fetal demise was reported.[94] The use of abortifacients is more common in underdeveloped countries and in people without access to safer methods for termination or prevention of pregnancy.

■ TOXICITY OF APHRODISIACS

Aphrodisiacs heighten sexual desire, pleasure, and/or performance and include xenobiotics from the plant, animal, and mineral kingdoms.[34] The search for an effective aphrodisiac has continued for thousands of years. Ancient fertility cults used *Datura,* belladonna, and henbane as aphrodisiacs. Yohimbine has been used by African cultures to enhance sexual prowess, and mandrake was used in medieval Europe. Other xenobiotics recommended include oysters, vitamin E, and ginseng. Because there are no measurable objective parameters, research in this area is lacking. Most published studies evaluating aphrodisiacs have been conducted in male rodents, and little information is available in humans. Toxicity can result from the aphrodisiac or adulterants[39] (Table 28–5).

Dopamine, NO, oxytocin, and ACTH facilitate sexual behavior. Dopamine stimulates the forebrain and midbrain and leads to an

TABLE 28–5. Xenobiotics Used as Aphrodisiacs

Xenobiotic	Toxicity
Oral	
Cantharidin	Vesicant actions–GI mucositis & hemorrhage, hematuria
Cathinone (hagigot)	Hypertension, tachycardia
Dapsone	Methemoglobinemia, hemolysis
Ginseng	Ginseng abuse syndrome, vaginal bleeding
Lead	Anemia, GI upset, abdominal pain
Nutmeg (myristicin)	Hallucinogen, GI upset
Tribulus terrestris (Puncturevine)	Gynecomastia
Yohimbine	Paresthesias
Topical	
Cantharidin	Vesicant actions–GI mucositis & hemorrhage, hematuria
Bufotoxin	Cardioactive steroid
Inhalation	
Alkyl nitrites (amyl, butyl, isobutyl nitrites)	Hemolytic anemia, methemoglobinemia

increase in sexual response and arousal. In animals, dopamine agonists, such as apomorphine and quinpirole, have proerectile effects through stimulation of dopamine pathways, increasing NO in the paraventricular nucleus in the hypothalamus, and releasing oxytocin.[84] Other preparations tested for the treatment of impotence include bromocriptine,[5,17] glyceryl trinitrate,[85] zinc,[7] oxytocin,[70] and LH.[69] Endogenous opioids, GABA, and norepinephrine are associated with decreased sexual behavior. Serotonin is generally inhibitory to sexual function but the effects are dependent on the receptor subclass. 5-HT$_{1A}$ receptor stimulation inhibits erection but facilitates ejaculation in rats, whereas 5-HT$_{2C}$ receptors facilitate male sexual behavior.[84] Various serotonergic drugs, including trazodone, nefazodone, bupropion, and clomipramine, are reported to improve sexual dysfunction.[98,119]

■ URINARY SYSTEM

The urinary system is composed of the kidneys, ureters, bladder, and urethra. Many xenobiotics are concentrated by the kidneys and eliminated in the urine. The following discusses the effect of xenobiotics on the bladder and urine (Chapter 27).

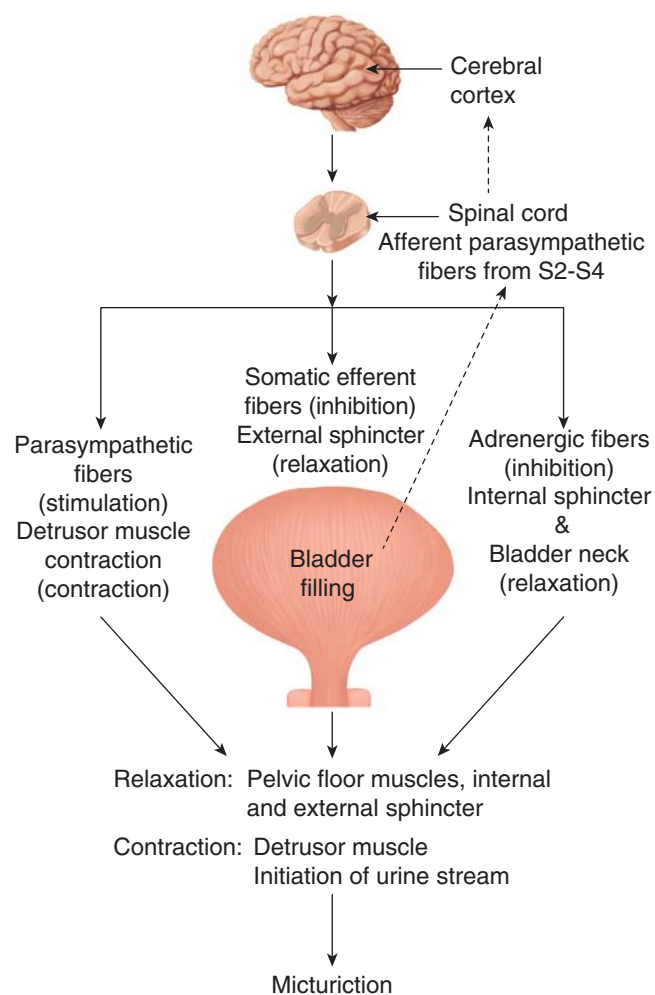
Bladder Anatomy and Physiology The bladder is a hollow, muscular reservoir composed of two parts— the body and the neck—and normally stores up to 350 to 450 mL of urine in adults. A smooth muscle, the detrusor muscle, makes up the bulk of the body and contracts during urination. Urine from the ureters enters the bladder at the uppermost part of the trigone, an area in the posterior wall of the bladder, and leaves via the neck and the posterior urethra. Surrounding the neck and posterior urethra is smooth muscle interlaced with elastic tissue to form the internal sphincter. Sympathetic innervation from the lumbar


FIGURE 28–4. A schematic description of the physiology of micturition. (The dotted lines show efferent pathway.)

spinal cord to the internal sphincter maintains smooth muscle contraction. Distal to the internal sphincter is an area with voluntary skeletal muscle that forms the external sphincter and is innervated by somatic pudendal nerves.

The nerve supply and neurophysiology of urination involves interplay between lumbar sympathetic nerves, sacral parasympathetic nerves and sacral somatic nerves. Figure 28–4 illustrates the physiology of micturition. With bladder filling, norepinephrine is released by sympathetic postganglionic fibers. α-adrenergic receptors predominate in the internal sphincter and the bladder neck while β-adrenergic receptors supply the detrusor wall of the bladder. Stimulation of α-adrenergic receptors results in internal sphincter contraction and increased bladder outlet resistance, and stimulation of β-adrenergic receptors leads to detrusor relaxation and bladder filling.[111] In micturition, parasympathetic pre- and post-ganglionic fibers release acetylcholine to M_2 and M_3 muscarinic receptors in the detrusor muscle. Stimulation of M_3 receptors is responsible for detrusor muscle contraction and bladder emptying.[25] Conversely, anticholinergics prevent bladder emptying and result in urinary retention.[23,24,29,45,50,82]

Urinary Abnormalities   Urinary incontinence is common in the elderly. As age increases, bladder size decreases, resulting in more frequent emptying. Early detrusor contraction, even with low bladder volumes, occurs more commonly in the elderly causing a sense of urgency. There

FIGURE 28–5. A graphic of the bladder and sites of xenobiotic effects.

are many etiologies for urinary incontinence, including various xenobiotic exposures (Fig. 28–5). General or regional anesthesia, bladder instrumentation, and medications may produce bladder atony leading to incontinence.[29] Functional incontinence can also result from use of

any medication that causes impaired cognition or decreased mobility (sedative/hypnotics, opioids, etc).[29] Pharmacologic agents used in the treatment of urinary incontinence include anticholinergics (tolterodine, oxybutynin, trospium chloride), imipramine, botulinum toxin A, and duloxetine. Duloxetine is a serotonin and norepinephrine reuptake inhibitor that acts centrally at the sacral cord pudendal motor nucleus to stimulate urethral rhabdosphincter contraction.[38] Urinary retention can be obstructive, neurogenic, psychogenic or pharmacologic in origin. Medications associated with urinary retention include sympathomimetics, anticholinergics, antidysrhythmics (quinidine, procainamide, disopyramide), antidepressants, antipsychotics, hormonal agents (progesterone, estrogen, testosterone), and muscle relaxants.[29,45] In men older than 50 years, benign prostatic hyperplasia is the most common cause of bladder outlet obstruction, leading to decreased urinary output and urinary retention. Treatment of benign prostatic hyperplasia consists of 5α-reductase inhibitors and α-adrenergic antagonists. 5α-reductase inhibitors (finasteride, dutasteride) block the conversion of testosterone to dihydrotestosterone in order to decrease prostate volume.[79] α_1-adrenergic antagonists (doxazosin, terazosin, alfuzosin, tamsulosin) decrease urethral α-adrenergic contraction.[47] Table 28–6 lists xenobiotics associated with urinary retention and incontinence.

TABLE 28–6. Xenobiotics that Cause Urinary Retention and Incontinence

Retention	Incontinence
α_1-Adrenergic agonists	α_1-Adrenergic antagonists
Amantadine	Antipsychotics
Antihistamines	Clozapine
Anticholinergics	Chlorpromazine
Atropine	Haloperidol
Dicyclomine	Thioridazine
Hyoscyamine	Cholinesterase inhibitors
Oxybutynin	Diuretics
Tolterodine	Naloxone (for opiate-induced retention)
Antipsychotics

Ampicillin	Nitrofurantoin
Amoxicillin	Primidone
Ascorbic acid	Sulfadiazine
Ciprofloxacin	Sulfamethoxazole
Ethylene glycol	Thiabendazole
Flucytosine	Triamterene

Abnormalities in Urinalysis Abnormalities of the urinalysis are often useful in identifying xenobiotic exposures. Crystalluria is a common finding and may be normal but the presence of crystals may aid in diagnosis. Crystal formation is dependent on supersaturation of the urine and changes in the urine temperature or pH. The most common crystals are calcium oxalate, uric acid, and phosphate. However, crystals of various xenobiotics alone or in combination with other crystals may be seen in ingestions.[43] The urinalysis in patients who ingest ethylene glycol often (but not always) reveals calcium oxalate or hippurate crystals. Calcium oxalate crystals are monohydrates (prism or needlelike) or dihydrates (envelope shaped). Hippurate crystals are needle shaped.[91] Crystalluria is present in 50% of cases of ethylene glycol poisoning. B irefringent single or conglomerates of hexagonal crystals are noted after massive primidone poisoning and result from precipitation of primidone in the urine.[110] Crystalluria is also described after therapeutic doses of salicylate, phenacetin, sulfonamide, and quinolones. After large ingestions, crystals can be seen with methotrexate, amoxicillin, cephalexin, ampicillin, and indinavir. (Table 28–7)

Urine color is dependent on several factors, including pH, concentration, natural pigments, and length of time exposed to air.[52] Normal urine specimens should be clear and yellow in coloration. Dilute urine secondary to diuretic use, diabetes mellitus, diabetes insipidus, or overhydration can appear colorless, whereas concentrated urine is usually orange. The presence of fluorescein, detected by illumination of the urine with a Wood lamp, suggests ethylene glycol (commercial antifreeze) ingestion, but this diagnostic test has poor sensitivity and specificity.[112] One study utilized urine samples from a group of unpoisoned children and three urine samples with added sodium fluorescein to examine physicians ability to detect urinary fluorescence with a Wood lamp against a fluorometer. The fluorometer reported fluorescence in 100% of the urine samples whereas the physicians reported fluorescence in 70% to 80% of the samples.[92] Urinary fluorescence, even when present, is not useful as a diagnostic test. Table 28–8 lists other causes of colored urine.

There are multiple causes of hematuria.[76] (Table 28–9). It can occur with xenobiotic interstitial nephritis, a condition distinguished by fever, rash, eosinophilia, azotemia, and oliguria.[36] Hemorrhagic cystitis is a more frequent cause of hematuria, and is associated with a number of xenobiotics. The clinical presentation of hemorrhagic cystitis includes hematuria, dysuria, and urinary frequency. Criteria for diagnosis include a history of gross hematuria, laboratory findings of gross hematuria (>5 RBC/HPF), platelet count above 50,000/mm,[7] and a negative urine culture.[97] When in doubt, the diagnosis may be confirmed by cystoscopy, which reveals an inflamed, hyperemic, and sometimes ulcerated bladder mucosa.

Cyclophosphamide-related hemorrhagic cystitis was first described in 1959,[81] and is the best-documented type of drug-induced hemorrhagic

cystitis.[48] As many as 46% of patients receiving cyclophosphamide will develop hemorrhagic cystitis.[40,59,65,68] Acrolein, the causative xenobiotic, is a metabolite of cyclophosphamide that damages the urothelium when excreted. (Chap. 54).[94,107]

An outbreak of hemorrhagic cystitis occurred in workers in a packaging plant after exposure to chlordimeform, a formamidine insecticide used to control mites and insects on cotton. Nine workers developed abdominal pain, dysuria, urgency, and hematuria, with biopsy-proven hemorrhagic cystitis.[44] Eight young adults developed painful hematuria after consuming "bootleg" methaqualone. The cause was orthotoluidine, a compound utilized in the synthesis of methaqualone, and the symptoms occurred within 6 hours of ingestion.[51] Cases of hemorrhagic cystitis have also been described with ticarcillin,[77] nafcillin, penicillin G, carbenicillin, piperacillin, isoniazid, indomethacin, tiaprofenic acid, and busulphan.[49,80,104]

SUMMARY

Toxicologic evaluation of the reproductive system is challenging because reproduction is an intermittent phenomenon. Adverse effects from xenobiotic exposures to both the male and female reproductive systems may not be noticed until fertility is desired. Xenobiotics can

affect the hormonal controls, the organs of gametogenesis or cause sexual dysfunction. Alternatively, patients with sexual dysfunction may take xenobiotics to treat their condition but can result in toxicity. Once pregnant, some patients may opt for abortifacients that also can have unexpected toxicity.

Xenobiotic effects on the urinary system can result in disorders of urination, either urinary retention or incontinence, and abnormalities of urine in terms of color, crystals, and hematuria. A thorough history including past and present medications, illicit drug use, occupational and environmental exposures, or the use of herbal or alternative therapies is mandatory in the evaluation of patients with genitourinary complaints.

CHAPTER 29
DERMATOLOGIC PRINCIPLES

Neal A. Lewin and Lewis S. Nelson

The skin shields the internal organs from harmful xenobiotics in the environment and maintains internal organ integrity. The adult skin covers an average surface area of 2 meters[2]. Despite its outwardly simple structure and function, the skin is extraordinarily complex. The skin can be affected by xenobiotic exposures that occur through any route. Dermal exposures account for a few percent of the cases and for approximately 1% of the fatalities reported to the American Association of Poison Control Centers (AAPCC) (Chap. 135). The principles of an adverse cutaneous reaction can be used to make relevant predictions, such as the physical and chemical properties of the xenobiotic and whether the effect of a response will be local or systemic. The clinician must obtain essential information as to the dose, timing, route, and location of exposure. The location of xenobiotic injury determines the histologic morphology, the severity of the reaction pattern, and the overall clinical findings. It should be noted, however, that different xenobiotics may produce clinically similar skin changes and conversely that many xenobiotics may produce diverse dermal lesions. The classical dermatologic lesions are defined in Table 29–1. The dermatology lexicon to assist the clinician is available at www.dermatologylexicon.org.

SKIN ANATOMY AND PHYSIOLOGY

The skin has three main components that interconnect anatomically and interact functionally: the epidermis, the dermis, and the subcutis or hypodermis (Figure 29–1). The three reactive units are the superficial reactive unit; the reticular layer of the dermis; and the subcutaneous tissue.[24] The primary physiologic role of the epidermis, the most external layer of the skin, is to maintain water homeostasis and to establish immunologic surveillance. It is composed of five layers: the horny, transitional, granular, spinous, and basal layers. The keratinocyte, which is an ectodermal derivative, represents the majority of the epidermis. The thin stratum corneum, or horny layer, is predominantly responsible for the protective function of the skin. Disruption or inadequate formation of the stratum corneum leads to a breakdown of this barrier function and many disease processes. The cells of the stratum corneum serve as a buffer to acidic and alkaline substances. Barrier function is also partly maintained by the granular layer. In this layer, there are Odland bodies, also known as membrane-coating granules, lamellar granules, and keratinosomes. The contents of these organelles provide a barrier to water loss while mediating stratum corneum cell cohesion.[10]

The stratum corneum is covered by a surface film composed of sebum emulsified with sweat and breakdown products from the horny layer.[22] The surface film functions as an external barrier to protect the entry of bacteria, viruses, and fungi. The role of the surface film, however, is limited with regard to percutaneous absorption. The major barrier molecules to percutaneous absorption in the skin are lipids called *ceramides*.[22] Diseases characterized by dry skin, such as eczema, atopic dermatitis, and psoriasis, are caused by decreased concentrations of ceramide in the stratum corneum, which allows increased xenobiotic penetration because of barrier degradation.[22] Similarly, hydrocarbon solvents, such

as gasoline or methanol, or detergents, commonly produce a "defatting dermatitis" by keratolysis or the dissolution of these surface lipids.

The degree of barrier function of the epidermis varies with its thickness as well. Differences in thickness are observed on different regions of the body. The epidermis varies from 1.5 mm on the glabrous surfaces (palms and soles) to 0.1 mm on the eyelids. The cells of the basal layer control the renewal of the epidermis. The basal layer contains stem cells and transient amplifying cells, which are the proliferative cells resulting in new epidermal formation that occurs every 59 to 75 days. As the basal cells migrate toward the skin surface they flatten, lose their nuclei, develop keratohyalin granules, and eventually develop into the horny layer. Patients with primary cutaneous diseases, such as psoriasis, have a significantly shortened epidermal renewal or turnover time resulting in a thicker epidermis (hyperkeratosis) and potentially less direct penetration of xenobiotics.[2] The basal layer is adjacent to the basement membrane zone and is also populated by melanocytes and Langerhans cells. Melanocytes contain melanin, which is the major chromophore in the skin that is responsible for absorbing ultraviolet and other light energies. Melanocytes are primarily responsible for producing skin pigmentation. The *Langerhans cells* are bone marrow–derived cells with a primary role in immunosurveillance. Langerhans cells function in the recognition, uptake, processing, and presentation of antigens to previously sensitized T lymphocytes. Langerhans cells may also carry antigens via dermal lymphatics to regional lymph nodes. The cells express chemokine CCR6 which allows tracking of peripatetic leukocytes to migrate from the dermis to the epidermis, and without CCR7 migration to lymph nodes is not possible.

The basement membrane zone, which consists of three layers—the lamina lucida, the lamina densa, and the sublamina densa—separates the epidermis from the dermis. It provides a site of attachment for keratinocytes and permits epidermal–dermal interaction.

The dermal-epidermal junction (DEJ) functions as a basement membrane to provide resistance against trauma, give support to the overlying structures, organize the cytoskeleton in the basal cells, and serve as a semipermeable barrier. The dermis, the second reactive unit, is deep to the epidermis and contains the adnexal structures, blood vessels, and nerves. It is arranged into two major regions, the upper papillary dermis and the deeper reticular dermis, which comprise the bulk of dermis. The dermis provides structural integrity and contains many important appendageal structures. The structural support is provided by both collagen and elastin fibers embedded in glycosaminoglycans, such as chondroitin A and hyaluronic acid. Mature dermis is predominantly composed of type I collagen (80%–90%); type III (8%–12%), type V (<5%); types VI, VII and IV collagen maintain a less important role. Collagen accounts for 70% of the dry weight of the skin, whereas elastic fibers are equivalent to 1% to 2% of the skin's dry weight. Several important cells, including fibroblasts, macrophages and mast cells, are transient circulating cells of the immune system present in the dermis. Traversing the dermis are venules, capillaries, arterioles, nerves, and glandular structures.

The arteriovenous framework of the skin consists of a deep plexus in the region of the subcutaneous dermal junction. From this deep plexus, smaller arterioles transverse upward to the junction of the reticular and papillary dermis, where they form the superficial plexus. Capillary-venules form superficial vascular loops that ascend into and descend from the dermal papillae. The communicating blood vessels provide channels in which xenobiotics exposed to the skin can be transported internally. In addition, they transport internally absorbed xenobiotics and cells of the immune system to the skin.

Parallel to the vasculature are cutaneous nerves, which serve the dual function of receiving sensory input and carrying sympathetically mediated autonomic stimuli that induce piloerection and sweating.[12]

TABLE 29–1. Dermatologic Diagnostic Descriptions of Lesions of the Skin

Primary Cutaneous Lesions	Secondary Cutaneous Lesions
Bulla: a circumscribed collection of free fluid > 0.5 cm in diameter	Erosion: a loss of the epidermis up to the full thickness of the epidermis but not through the basement membrane
Comedone: open and closed dilated pores (blackheads and whiteheads)	Hypertrophy: a thickening of the skin
Macule: a circumscribed flat variation of color that may be brown, blue, yellow, red, or hypopigmented (no thickness)	Lichenification: a secondary process with noted accentuation of skin surface markings
Nodule: a circumscribed elevation of ≥ 0.5 cm in diameter	Scale: flaking that is separate from the original surface of a lesion
Papule: an elevation of < 0.5 cm in diameter	Scar: a thickened, often discolored, surface
Plaque: a circumscribed elevation of > 0.5 cm in diameter	Ulcer: a loss of full-thickness epidermis and papillary dermis, reticular dermis, or subcutis
Pustule: a circumscribed collection of leukocytes and free fluid that vary in size	
Tumor: an elevation of > 0.5 cm in diameter	
Vesicle: a circumscribed collection of free fluid ≥ 0.5 cm in diameter	
Wheal: a firm edematous plaque resulting from infiltration of the dermis with fluid	

The apocrine glands consist of secretory coils and intradermal ducts ending in the follicular canal. The secretory coil is located in the subcutis and consists of a large lumen surrounded by columnar to cuboidal cells with eosinophilic cytoplasm.[12] Apocrine glands, which are located in select areas of the body such as the axilla, produce secretions that are rendered odoriferous by cutaneous bacterial flora.

The eccrine glands, in contrast, produce an isotonic to hypotonic secretion that is modified by the ducts and emerges on the skin surface as sweat. The eccrine unit consists of a secretory gland as well as intradermal and intraepidermal ducts. The coiled secretory gland is located in the area of the deep dermis and subcutis. Xenobiotics can be concentrated in the sweat and increase the intensity of the local skin reactions.
FIGURE 29–1. Skin histology and pathology. Intraepidermal cleavage sites in various xenobiotic-induced blistering diseases. In pemphigus foliaceous, the cleavage is below or within the granular layer, whereas in pemphigus vulgaris, it is suprabasilar. This accounts for the differing types of blisters found in the two diseases. HF = Hair Follicle

Certain antineoplastics, such as cytarabine or bleomycin, directly damage the eccrine sweat glands, resulting in anhidrosis.

Sebaceous glands also reside in the dermis. They produce an oily, lipid-rich secretion that functions as an emollient for the hair and skin, and can be a reservoir of noxious environmental xenobiotics. Pilosebaceous follicles, which are present all over the body, consist of a hair shaft, hair follicle, sebaceous gland, sensory end organ, and erector pili. Certain halogenated aromatic chemicals, such as polychlorinated biphenyls (PCBs), dioxin, and 2,4-dichlorophenoxyacetic acid, are excreted in the sebum and cause hyperkeratosis of the follicular canal. This produces a syndrome, chloracne, that looks like acne vulgaris, because of plugging of the ducts. Similar syndromes result from exposure to brominated and iodinated compounds, and are known as bromoderma and ioderma, respectively.[40]

The tissues of the hypodermis or subcutaneous tissue, serves to insulate, cushion, and allow for mobility of the overlying skin structures. Adipocytes represent the majority of cells found in this layer. Leptin, an adipose-derived hormone responsible for long-term feedback of appetite and satiety signaling, is synthesized and regulates fat mass (adiposity) in this layer.

The hair follicle is divided into three portions.[34] The deepest portion of the hair follicle contains the bulb with matrix cells. The matrix cells are highly mitotically active and often are the target of cytotoxic xenobiotics. The rate of growth and the type of hair are unique for different body sites. Hair growth proceeds through three distinct phases: the active prolonged growth phase (anagen phase) during which matrix cell mitotic activity is high; a short involutional phase (catagen phase); and a resting phase (telogen phase). Understanding the phases and biochemical structure of hair growth is important because hair growth can be used to identify clues regarding the timing and mechanism of action of a xenobiotic.

The nail, which is often considered analogous to the hair, is also a continuously growing structure. Fingernails grow at average of 0.1 mm/d and toenails grow at about one-third that rate. The mitotically active cells of the nail matrix are subject to both traumatic and xenobiotic injury that affects the appearance and growth of the nail plate. Because nail growth is consistent, location of an abnormality in the plate can predict the timing of exposure, such as Mees lines.

TOPICAL TOXICITY

■ TRANSDERMAL XENOBIOTIC ABSORPTION

Although there is no active uptake mechanism for xenobiotics by the skin, many undergo percutaneous absorption by passive diffusion. Lipid solubility, concentration gradient, molecular weight, and certain specific skin characteristics are important determinants of dermal absorption. Absorption is generally considered to occur though intercellular movement, requiring that the xenobiotic dissolve in the ceramides. This accounts for the importance of lipid solubility of the xenobiotic in transdermal absorption. However, excessive lipid solubility limits the partitioning of the xenobiotic from the stratum corneum into the aqueous dermis, a critical requirement since the blood vessels are in this deeper layer.[13,14,31,32] The relationship between lipid and water solubility is often described by the octanol-water partition coefficient. Xenobiotics with values between 10 and 1000 have sufficient lipid and water solubility to permit skin permeation.

For example, morphine sulfate, with an octanol water partition coefficient of approximately 1, is not absorbed when applied topically, whereas fentanyl, with a coefficient of approximately 700, is widely used as a transdermally delivered medication. The dermal toxicity of the various organic phosphorus compounds may be predicted based on this coefficient.[9] Although metal ions such as Hg+ have limited skin penetration, the addition of a methyl group, to form methylmercury, increases its lipophilicity and its systemic absorption. Dimethylmercury, has even better absorption and may produce life-threatening systemic effects with a minute amount applied to the skin (Chap. 96). Similarly, the nonionized component of the weakly acidic hydrofluoric (HF) acid is able to penetrate deeply through skin and even bone. The proton (H+) and fluoride ion (F−) are unable to penetrate the lipids of the skin individually because of their charged nature; however, once in the dermis, the HF acid may ionize and cause both acid-induced tissue necrosis and fluoride-induced toxicity (Chap. 105).[4]

Children appear particularly at risk for toxicity from percutaneous absorption because their skin is more penetrable than an adult's and specific anatomic sites, such as the face, often represent larger percentage of body surface areas than in the adult.[37] Furthermore, there is enhanced absorption on anatomic parts of the body with thinner skin, such as the mucous membranes, eyelids, and intertriginous areas (axillae, groin, inframammary, and intergluteal). Under certain circumstances, such as with more highly lipophilic xenobiotics, the stratum corneum may serve a depot function leading to slow onset and continued systemic exposure despite apparent removal of the xenobiotic. For example, applied topically in the form of a transdermal device, fentanyl does not result in peak concentration for 24 to 72 hours after initial application. When removed, the serum fentanyl concentrations fall with an average half-life of 17 hours, which is substantially longer than when administered intravenously.[18] The vehicle of a xenobiotic may also influence absorption; indeed, transdermal drug-delivery systems are based on their ability to alter the skin partition coefficient through the use of an optimized vehicle. Similarly, through localized dermal occlusion, transdermal systems hydrate the skin and raise its temperature to increase absorption. Despite these techniques to enhance drug delivery, transdermal systems require that large amounts of drug be present externally to maximize the transcutaneous gradient. Much of the drug typically remains in the patch when it is removed following its intended course of therapy, raising concerns for safe disposal, especially for children.[13,14,31,32]

Transdermal drug delivery has several therapeutic advantages, such as continuous dosing resulting in more stable pharmacokinetics, prolonged drug delivery resulting in a more convenient dosing schedule (eg, weekly device changes), and the avoidance of first pass hepatic metabolism. These delivery devices, familiarly called "patches," are highly developed and crafted to deliver their content at a specified rate. Some variability occurs related to skin thickness, dermal barrier damage (eg, dry skin, rashes), or external factors, such as ambient temperature. As with any route of administration, adverse effects and toxicity caused by excessive absorption following patch application may occur following therapeutic use and misuse. For example, this is reported with nicotine, fentanyl, NSAIDS, and lidocaine transdermal delivery devices. Other xenobiotics, topically applied without a specific delivery device, may be associated with systemic morbidity and mortality, including podophyllin, camphor, phenol, organic phosphorus compounds, ethanol, organochlorines, and nitrates.

■ CONTACT DERMATITIS

Allergic contact dermatitis from plants and dyes such as fragrances and paraphenylenediamine (henna) is increasing in frequency. Miconidin and miconidin methyl ester were isolated from *Primula obconica* (primrose). Parthenolide is an ingredient in feverfew and can cause an airborne contact dermatitis. Triethanolamine polyethylene glycol-3

(TEA-PEG-3) cocamide sulfate was identified recently to cause allergic reactions in coconut oil.

■ DIRECT DERMAL TOXICITY

Exposure to any of a myriad of industrial and environmental xenobiotics can result in dermal "burns." Although the majority of these xenobiotics injure the skin through chemical reactivity rather than thermal damage, the clinical appearances of the two are often identical. Injurious xenobiotics may act as oxidizing or reducing agents, corrosives, protoplasmic poisons, desiccants, or vesicants. Often an injury may initially appear to be mild or superficial with only faint erythema, blanching, or discoloration of the skin. Over the subsequent 24 to 36 hours there may be progression to extensive necrosis of the skin and its underlying tissues.

Acids are water soluble and many readily penetrate into the subcutaneous tissue. The damaged tissue coagulates and forms a thick leathery eschar that limits the spread of the xenobiotic. The histopathologic finding following acid injury is termed *coagulative necrosis*. Alkali exposures characteristically produce *a liquefactive necrosis*, which allows continued penetration of the corrosive xenobiotic; consequently, dermal injury following alkali exposure is typically more severe than after an acid exposure of an equivalent magnitude.[7]

Thermal damage can also be the result of a toxicologic exposure. For example, the exothermic reaction generated by the wetting of elemental phosphorus or sodium may result in a thermal burn. In these circumstances, the products of reactivity, phosphoric acid and sodium hydroxide respectively, may produce secondary chemical injury. Alternatively, skin exposure to a rapidly expanding gas, such as nitrous oxide from a whipped cream cartridge or compressed liquefied nitrogen, or to frozen substances, such as dry ice, can produce a freezing injury, or frostbite.

Hydrocarbon-based solvents are typically liquids that are capable of dissolving non–water-soluble solutes.[7] Although the most prominent effect is a dermatitis due to loss of ceramides from the stratum corneum, prolonged exposure can result in deeper dermal irritation and destruction.

PRINCIPLES OF DERMAL DECONTAMINATION

On contact with xenobiotics, the skin should be thoroughly cleansed to prevent direct effects and systemic absorption. In general, a copious amount of water is the decontamination agent of choice for skin irrigation. Soap should be used when adherent xenobiotics are involved. Following exposures to airborne xenobiotics, the mouth, nasal cavities, eyes, and ear canals should be irrigated with appropriate solutions such as water or a 0.9% NaCl solution. For nonambulatory patients, the decontamination process may need to be conducted using special collection stretchers if available.[6]

There are a few situations in which water should not be used for skin decontamination. The situations include contamination involving the reactive metallic forms of the alkali metals, sodium, potassium, lithium, cesium, and rubidium, which react with water to form strong bases. The dusts of pure magnesium, sulfur, strontium, titanium, uranium, yttrium, zinc, and zirconium will ignite or explode on contact with water. Following exposure to these metals, any residual metal should be removed mechanically with forceps, gauze, or towels and stored in mineral oil. Additionally, phenol has a tendency to thicken and become difficult to remove following exposure to water. Suggestions for phenol decontamination include high-flow water or low-molecular-weight polyethylene glycol solution. Lime, or CaO, thickens and forms $Ca(OH)_2$ following wetting, suggesting that mechanical removal is appropriate.[6]

DERMATOLOGIC SIGNS OF SYSTEMIC DISEASES

■ CYANOSIS

Normal cutaneous and mucosal pigmentation is caused by several factors, one of which is the visualization of the capillary beds through the translucent dermis and epidermis. Cyanosis manifests as a blue or violaceous appearance of the skin, mucous membranes, and nailbeds. It occurs when excessive concentrations of reduced hemoglobin (>5g/dL) are present, as in hypoxia or polycythemia, or when oxidation of the iron moiety of heme to the ferric state forms methemoglobin, which is deeply pigmented (Chap. 127). The presence of the more deeply colored hemoglobin moiety within the dermal plexus results in cyanosis that is most pronounced on the skin surfaces with the least overlying tissue, such as the mucous membranes or fingernails.

■ XANTHODERMA

Xanthoderma is a yellow to yellow-orange macular discoloration of skin.[16] Xanthoderma can be caused by xenobiotics such as carotenoids, which deposit in the stratum corneum, and causes carotenoderma. Carotenoids are lipid soluble and consist of α-carotene, β-carotene, β-cryptoxanthin, lycopene, lutein, and zeaxanthan, and serve as precursors of vitamin A (retinol). The carotenoids are excreted via sweat, sebum, urine, and GI secretions.

Jaundice is typically a sign of hepatocellular failure or hemolysis and is caused by hyperbilirubinemia either conjugated or unconjugated, a condition in which the yellow pigment deposits in the subcutaneous fat. True hyperbilirubinemia is differentiated from hypercarotenemia by the presence of scleral icterus in patients with the former which is absent in patients with the latter. In addition, the cutaneous discoloration seen in hypercarotenemia can be removed by wiping the skin with an alcohol swab. Lycopenemia, an entity similar to carotenemia, is caused by the excessive consumption of tomatoes. Additionally, topical exposure to dinitrophenol or picric acid or stains from cigarette use produces localized yellow discoloration of the skin.

■ URTICARIAL DRUG REACTIONS

Urticarial drug reactions are characterized by transient, pruritic, edematous, pink papules, or wheals that arise in the dermis, which blanch on palpation and are frequently associated with central clearing. Approximately 40% of patients with urticaria experience angioedema and anaphylactoid reactions as well.[1] The reaction pattern is representative of a type I, or IgE-dependent, immune reaction and commonly occurs as part of clinical anaphylaxis or anaphylactoid (non–IgE-mediated) reactions. Widespread urticaria may occur following systemic absorption of an allergen or following a minimal localized exposure in patients highly sensitized to the allergen. Following limited exposure, a localized form of urticaria also may occur. Regardless of the specific clinical presentation, the reaction occurs when immunologic recognition occurs between IgE molecules and a putative antigen triggering the immediate degranulation of mast cells, which are distributed along the dermal blood vessels, nerves, and appendages. The release of histamine, complements C3a and C5a, and other vasoactive mediators result in leakage of fluid from dermal capillaries as their endothelial cells contract. This produces the characteristic urticarial lesions described above. Activation of the nearby sensory neurons produces pruritus. Nonimmunologically mediated mast cell degranulation producing an identical urticarial syndrome may also occur, following exposure to any xenobiotic.[8]

Pruritus is a common manifestation of urticarial reactions, but it may also be of nonimmunologic origin. Patients with hepatocellular disease frequently suffer from pruritus, which is mediated by the release of bile acids. In addition, in patients with chronic liver disease and obstructive jaundice, pruritus can be caused by central mechanisms, as suggested by elevated central nervous system (CNS) endogenous opioid concentrations. Pruritus can also be caused by topical exposure to the urticating hairs of Tarantula spiders, spines of the stinging nettle plant (*Urtica spp*), or via stimulation of substance P by certain xenobiotics such as capsaicin.[15]

Xenobiotics can also evoke a type III immune reaction that causes mast cells to degranulate. The cellular inflammatory response to released chemotactic factors leads to increased vascular permeability.

■ FLUSHING

Vasodilation of the dermal arterioles leads to flushing. Flushing can occur following autonomically-mediated vasodilation, as occurs with stress, anger, or exposure to heat, or it can be chemically induced by vasoactive xenobiotics. Those xenobiotics that cause histamine release through a type I hypersensitivity reaction are the most frequent cause of xenobiotic-induced flush. Histamine and saurine poisoning can result from the consumption of scombrotoxic fish, and can produce flushing. Flushing after the consumption of ethanol is common in patients of Asian and Inuit descent and is similar to the reaction following ethanol consumption in patients exposed to disulfiram or similar agents (Chap. 79). The increased production of and inability to efficiently metabolize acetaldehyde, the initial metabolite of ethanol, results in the characteristic syndrome of vomiting, headache, and flushing. Niacin causes flushing through an arachidonic acid–mediated pathway that is generally prevented by aspirin.[5,38] Vancomycin if too rapidly infused causes a transient bright red flushing, mediated by histamine. This reaction typically occurs during and immediately after the infusion, and is termed "red man syndrome." Other nontoxicologic causes of flushing including carcinoid syndrome, pheochromocytoma, mastocytosis, anaphylaxis, medullary carcinoma of the thyroid, pancreatic cancer, and renal carcinoma must be entertained in the flushed patient.[17]

■ SKIN MOISTURE

Xenobiotic-induced diaphoresis may be part of a physiologic response to heat generation or may be pharmacologically mediated following parasympathetic or sympathomimetic xenobiotic use. Because the postsynaptic receptor on the eccrine glands is muscarinic, most muscarinic agonists stimulate sweat production. Sweat most commonly occurs following exposure to cholinesterase inhibitors, such as organic phosphorus compounds, but it may also occur with direct-acting muscarinic agonists such as pilocarpine. Alternatively, antimuscarinic agents, such as belladonna alkaloids or antihistamines, reduce sweating and produce dry skin.

■ METALLIC PIGMENTATION

Pigmentary changes can result from the deposition of fine metallic particles. The particles can be ingested and carried to the skin by the blood, or may permeate the skin from topical applications. Argyria, a slate-colored pigmentation of the skin resulting from the systemic deposition of silver particles in the skin, can be localized or widespread. The discoloration tends to be most prominent in areas exposed to sunlight, probably secondary to the fact that silver stimulates melanocyte proliferation. Histologically, fine black granules are found in the basement membrane zone of the sweat glands, blood

vessel walls, the dermoepidermal junction, and along the erector pili muscles (Chap. 99). Gold, which was historically used parenterally in the treatment of rheumatoid arthritis, caused a blue or slate-gray pigmentation known as *chrysiasis*. The pigmentation is also accentuated in light-exposed areas but, unlike in argyria, sun-protected areas do not histologically demonstrate gold. Also, melanin is not increased in the areas of hyperpigmentation. The hyperpigmentation is probably secondary to the gold itself, but the cause of its distribution pattern remains unknown. Histologically, the gold is distributed in a perivascular pattern in the dermis with granules accentuated at the basement membrane zone of sweat glands.

Bismuth produces a characteristic oral finding of the metallic deposition in the gums and tongue known as bismuth lines. Arsenic, which is found in certain pesticides and in contaminated well water, causes cutaneous hyperpigmentation with areas of scattered hypopigmentation. Chronic lead poisoning can produce a characteristic "lead hue" with pallor. Lead also deposits in the gums, causing the characteristic "lead line." Intramuscular injection of iron can cause staining of the skin, resulting in pigmentation similar to that seen in tattoos, and iron storage problems, known as *hemochromatosis,* can result in a bronze appearance of the skin.[11]

SPECIFIC SYNDROMES

Dermatology is a specialty whereby visual inspection may allow a rapid diagnosis. Some authors suggest a brief examination prior to a lengthy history due to some of the classic skin conditions with such obvious morphologies that a "doorway diagnosis" can be made. Irrespective of the initial complaint a total body examination with proper lighting needs to be accomplished on all patients. The tools the physician needs are readily available: magnifying glass, glass slide (diascopy), flashlight, alcohol pad to remove scale or makeup, scalpel, and at times a Wood lamp. Universal precautions should always be used.

The ability to describe lesions accurately is an important skill, as is the ability to recognize specific patterns. Such abilities help clinicians in their approach to the patient with a rash. Several cutaneous reaction patterns account for the majority of clinical presentations occurring in patients with xenobiotic-induced dermatotoxicity (Table 29–2).

Toxic epidermal necrolysis (TEN) and Stevens-Johnson syndrome (SJS) (Fig. 29–2) are considered to be related disorders that belong to a spectrum of increasingly severe skin failure.[27] Toxic epidermal necrosis is often considered to be the most severe manifestation of the spectrum of syndromes represented by erythema multiforme. Erythema multiforme is characterized by target-shaped, erythematous macules and patches on the palms and soles, as well as the trunk and extremities. The Nikolsky sign, consisting of sloughing of the epidermis when direct pressure is exerted on the skin lesion, is absent. Contact sensitization to sulfonamides, phenytoin, antihistamines, many antibiotics, dinitrochlorobenzene (DNCB), diphenylcyclopropenone (DPCP), isopropyl-*p*-phenylenediamine (IPPD), rosewood, and urushiol can elicit erythema multiforme. The Stevens-Johnson syndrome is considered to be an overlap reaction with erythema multiforme major when greater than 30% of body surface area is involved. However, although erythema multiforme shares many clinical characteristics with SJS/TEN, many now consider it as a distinct disease. It should also be noted that SJS occurs predominantly in children and TEN occurs in all age groups.

Toxic epidermal necrolysis is a rare, life-threatening dermatologic emergency with a 30% mortality. Its incidence is estimated at 0.4 to 1.2 cases per 1 million population, and xenobiotics are causally implicated in 80% to 95% of the cases. The cutaneous reaction pattern is characterized by tenderness and erythema of the skin and mucosa, followed by

FIGURE 29–2. Toxic Epidermal Necrolysis **(A)** Early eruption. Erythematous dusky red macules (flat atypical target lesions) that progressively coalesce and show epidermal detachment. **(B)** Advanced eruption. Blisters and epidermal detachment have led to large confluent erosions. **(C)** Full-blown epidermal necrolysis characterized by large erosive areas reminiscent of scalding. (Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, Gilchrest BA, Paller AS, Lefferell DJ. *Fitzpatrick's Dermatology in General Medicine.,* 7th ed. McGraw-Hill, 2008.)

extensive cutaneous and mucosal exfoliation. The incidence is higher in HIV-infected patients with advanced disease. [27,36] There is general agreement that the keratinocyte cell death in TEN is the result of *apoptosis* not *necrosis.* Furthermore, apoptosis is suggested based on electronic microscopic studies with DNA fragmentation analysis.[27]

Greater than 220 xenobiotics are implicated in causing TEN. Classically, the eruption is painful and occurs within days of the exposure to the implicated xenobiotic(s). The eruption is preceded by malaise, headache, abrupt onset of fever, myalgia, arthralgia, nausea, vomiting, diarrhea, chest pain, or cough. Initially, a macular erythema develops that subsequently becomes raised and morbilliform ("measles-like"). The face, neck, and central trunk are usually the initial areas affected. The disease generally progresses to involve the extremities and with the remainder of the body the lesions progress over a period of 2 to 15 days. Individual lesions are reminiscent of target lesions because of their dusky centers. The entire thickness of the epidermis, including the nails, becomes necrotic and may slough off. The mucosal surfaces of the lips, oropharynx, conjunctivae, vagina, urethra, and anus may show erythema and sloughing. This mucositis precedes the skin lesions by a few days.[30] A Nikolsky sign may occur,[3] and although suggestive, is not pathognomonic of TEN as it occurs in a variety of other dermatoses, including pemphigus vulgaris. If the diagnosis is suspected, a biopsy should be performed and treatment initiated immediately. The histopathology typically shows partial- or full-thickness epidermal necrosis, with subepidermal bullae with a sparse infiltrate, and vacuolization with numerous dyskeratotic keratinocytes along the dermoepidermal junction adjacent to the necrotic epidermis. Cytotoxic T lymphocytes are the main effector cells and experimental evidence points to involvement of both the Fas-Fas ligand and perforin/granzyme pathways. Anemia and lymphopenia are common, neutropenia portends a poor prognosis. Early stages consist mainly of CD8 lymphocytes in the epidermis and blisters containing CD4 lymphocytes in dermis.

Removal of the inciting xenobiotic as soon as possible is critical to survival. Patients with TEN related to a xenobiotic with a long half-life have poorer prognosis, and should be transferred to a burn or other specialized center for sterile wound care. The use of porcine xenografts or human skin allografts including amniotic membrane transplantation

has been utilized and is a widely accepted therapy.[29] Although glucocorticoids are not generally recommended, there is emerging support for the use of immunosuppressive or immunomodulatory agents, such as intravenous immunoglobulins, cyclophosphamide, and cyclosporine.[29] Reported mortality is as great as 30%, particularly in patients with gastrointestinal and tracheobronchial involvement.[36] The "acute skin failure" patients have metabolic abnormalities, sepsis, multiorgan failure, pulmonary emboli and gastrointestinal hemorrhages. The major causes of sepsis is *S. aureus* and *P. aerogenosa.* In a patient with SJS/TEN with ophthalmologic complications early ophthalmologic consultation is necessary because blindness is a potential complication.

Simulators of TEN include staphylococcal scalded skin syndrome; linear IgA dermatosis: paraneoplastic pemphigus; acute graft versus host disease; drug-induced pemphigoid and pemphigus vulgaris and acute generalized exanthematous pustulosis; discussion of these entities is beyond the scope of the chapter.

■ BLISTERING REACTIONS

Xenobiotic-related cutaneous blistering reactions may be clinically indistinguishable from autoimmune blistering reactions, such as pemphigus vulgaris or bullous pemphigoid (Fig. 29–3). Certain topically-applied xenobiotics cause blistering by disrupting the anchoring filaments of basal cell desmosomes at the dermal–epidermal junction. In high concentrations, the xenobiotics can lead to necrosis of both skin and mucous membranes. Other xenobiotics cause a similar reaction pattern mediated by the production of antibody directed against the cells at the dermal–epidermal junction (Table 29–3).

A number of medications, many of which contain a "thiol group" such as penicillamine and captopril, can induce either pemphigus, a superficial blistering disorder in which the blister is at the level of the stratum corneum, or pemphigus vulgaris, in which blistering occurs at the suprabasilar level (see Fig. 29–1). Other xenobiotics, such as diuretics, produce the tense bullae that resemble pemphigoid. Immunofluorescence studies might show epidermal intracellular immunoglobulin deposits at the dermal–epidermal junction. Treatment options include immunosuppressants. The reaction may persist for up to 6 months after the offending xenobiotic is withdrawn.

FIGURE 29–3. Pemphigus vulgaris. **(A)** Flaccid blisters. **(B)** Oral erosions. (Part **A,** contributed by Lawrence Lieblich, MD. Part **B,** reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, Gilchrest BA, Paller AS, Lefferell D. *Fitzpatrick's Dermatology in General Medicine,* 7th ed. McGraw-Hill, 2008.)

"Coma bullae" are flaccid bullae that occur occasionally in patients with sedative-hypnotic overdoses, particularly phenobarbital, or carbon monoxide poisoning. Although these blisters are thought to result predominantly from pressure-induced epidermal necrosis, they occasionally occur in non–pressure-dependent areas, suggesting a systemic mechanism. An intraepidermal or subepidermal blister may occur. There is accompanying eccrine duct and gland necrosis.

■ BULLOUS DRUG ERUPTIONS

Multiple, large, ill-defined, dull, purplish-livid patches sometimes accompanied by large flaccid blisters characterize these eruptions. Typical locations include acral extremities, genitals, and intertriginous sites, and this process may be confused with TEN if widely confluent. However, bullous drug eruptions spare the mucous membranes. This reaction pattern is generally not life-threatening. Bullous fixed-drug reactions result from exposure to diverse medications such as angiotensin converting enzyme inhibitors and a multitude of antibiotics.

The drug hypersensitivity syndrome known as drug rash with eosinophilia and systemic symptoms (DRESS) can be severe and potentially life threatening. The skin may be involved with systemic xenobiotic-induced immunologic diseases. The hypersensitivity syndromes are characterized by the triad of fever, skin eruption, and internal organ involvement.[20] The frequency has been estimated between 1 in 1000 to 1 in 10,000 with anticonvulsants or sulfonamide antibiotic exposures and usually begins within 2 to 6 weeks after the initial exposure.

TABLE 29–3. Differential Diagnosis of Xenobiotic-induced Blistering Disorders

Disease	Fever	Mucositis	Morphology	Onset	Miscellaneous
Xenobiotic-induced pemphigoid	No	Rare	Tense bullae (sometimes hemorrhagic)	Acute	Diuretics a common cause, especially spironolactone; often pruritic
Staphylococcal scalded skin syndrome	Yes	Absent	Erythema, skin tenderness, periorificial crusting	Acute	Affects children < 5 years, adults on dialysis, and those on immunosuppressive therapy
Xenobiotic-induced pemphigus	No	Usually absent	Erosions, crusts, patchy erythema (resembles pemphigus foliaceous)	Gradual	Commonly caused by penicillamine and other "thiol" drugs; resolves after inciting inciting agent is discontinued
Xenobiotic-triggered pemphigus	No	Present	Mucosal erosions, flaccid bullae	Gradual	Caused by "non-thiol" drugs; persists after discontinuation of drug; may require long-term immunosuppressive therapy
Paraneoplastic pemphigus	No	Present (usually severe)	Polymorphous skin lesions, flaccid bullae	Gradual	Resistant to treatment; associated with malignancy, especially lymphoma
Acute graft-versus host disease	Yes	Present	Morbilliform rash, bullae and erosions	Acute	Closely resembles TEN
Acute generalized exanthematous	Yes	Rare	Superficial pustules	Acute	Self-limiting on discontinuation of drug
Xenobiotic-induced linear IgA bullous dermatosis	No	Rare	Tense, subepidermal bullae	Acute	Vancomycin is most commonly implicated

FIGURE 29–4. A patient with a hypersensitivity syndrome associated with phenytoin. He has a symmetric, bright red, and exanthematous eruption, confluent in some sites. The patient had associated lymphadenopathy. (Reproduced with permission from Klaus Wolff; Richard Allen Johnson. *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology,* 6e, p. 22-10. McGraw-Hill, 2009.)

FIGURE 29–5. Leukocytoclastic vasculitis in a patient with mixed cryoglobulinemia manifested as palpable purpura and acrocyanosis. Patient with tuberculosis, positive antinuclear antibody, and hepatitis.(Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, Gilchrest BA, Paller AS, Lefferell DJ. *Fitzpatrick's Dermatology in General Medicine,* 7th ed. McGraw-Hill, 2008.)

Fever, malaise, pharyngitis and cervical lymphodenpathy are the usual presenting clinical findings. Atypical lymphocytes and eosinophilia, occur initially. The exanthem is generalized and conjunctivitis and angioedema may occur. One-half of these patients have hepatitis, interstitial nephritis, vasculitis, CNS manifestations (including encephalitis, aseptic meningitis), interstitial pneumonitis, ARDS, and autoimmune hypothyroidism. Colitis with bloody diarrhea and abdominal pain may occur. The aromatic anticonvulsants, allopurinol, sulfonamide antibiotics, and dapsone are the common xenobiotics that induce this syndrome. Treatment is supportive.[26,39] Although the role of systemic corticosteroids is controversial; most clinicians start prednisone at a dose of 1–2 mg/kg/d if symptoms are severe.

■ EXFOLIATIVE ERYTHRODERMAS

Exfoliative erythrodermic eruptions (Fig. 29–4) can result from any xenobiotic and are characterized by widespread erythema and scale with the potential for multisystem organ failure. The process may persist for months. Such patients require aggressive fluid and electrolyte repletion and nutritional support. Boric acid toxicity causes a bright red eruption ("lobster skin"), followed usually within 1 to 3 days by a generalized exfoliation.

■ VASCULITIS

Xenobiotic-induced vasculitis (Fig. 29–5) comprises 10% of acute cutaneous vasculitides. It generally occurs from 7 to 21 days after exposure to the xenobiotic and is a small vessel disease. Hypersensitivity vasculitis is characterized by purpuric, nonblanching macules that usually become raised and palpable. The purpura tends to occur predominantly on gravity-dependent areas, including the lower extremities, feet, and buttocks. Sometimes the reaction pattern can have edematous purpuric wheals (urticarial vasculitis), hemorrhagic bullae, or ulcerations. The underlying cytopathology consistently shows a leukocytoclastic vasculitis, which is characterized by fibrin deposition in the vessel walls. There is a perivascular infiltrate with intact and fragmented neutrophils that appear as black dots, known as "nuclear dust," visible only by electron microscopy. This reaction pattern may be limited to the skin, or may be more serious and involve other organ systems, particularly the kidneys, joints, liver, lungs, and brain. The purpura results from circulating immune complexes, which form as a result of a hypersensitivity to a xenobiotic. Treatment consists of withdrawing the putative agent and systemic corticosteroid therapy.

Purpura   Purpura is the multifocal extravasation of blood into the skin or mucous membranes (Fig. 29–6). Ecchymoses are, therefore, considered to be purpuric lesions. Cytotoxic medications that either diffusely suppress the bone marrow or specifically depress platelet counts below 30,000/mm³, predispose to purpuric macules. Xenobiotics that interfere with platelet aggregation, such as, aspirin, clopidogrel, ticlopidine, and valproic acid, may cause purpura, as may thrombolytics. Anticoagulants, such as heparin and warfarin, may also result in purpura (Chaps. 24 and 59).

Anticoagulant Skin Necrosis   Skin necrosis from warfarin, low molecular weight heparin, or unfractionated heparin usually begins 3 to 5 days after the initiation of treatment (Fig. 29–7). The estimated risk is 1 in 10,000 persons. It is four times higher in women especially if obese with peaks in sixth to seventh decades. The necrosis is secondary to thrombus formation in vessels of the dermis and subcutaneous fat. There may be blisters, ecchymosis, ulcers, and massive subcutaneous necrosis, usually in areas of abundant subcutaneous fat, such as the breasts, buttocks, abdomen, thighs, and calves. It may be associated with protein C or S deficiency, anticardiolipin antibody syndrome, as well as Factor V Leiden mutations.[28] Of note is acute generalized exanthematous pustulosis from dalteparin is reported.[21]

Treatment involves stopping the medication, administration of vitamin K and, if coumarin induced, changing to heparin. Treatment may include fresh frozen plasma and Protein C. Skin grafting may be necessary if full thickness necrosis occurs.

■ CONTACT DERMATITIS

When a xenobiotic comes in contact with the skin, it can result in either an allergic contact dermatitis or an irritant dermatitis. Contact dermatitis is characterized by inflammation of the skin with spongiosis (intercellular edema) of the epidermis that results from the interaction of a xenobiotic with the skin. Erythema, induration, pruritus, or blistering may be noted on areas in direct contact with the xenobiotic, while the remaining areas are spared.

Allergic contact dermatitis fits into the classic delayed hypersensitivity, or type IV, immunologic reaction. The development of this reaction requires prior sensitization to an allergen, which, in most cases, acts as a hapten by binding with an endogenous molecule that is then presented to an appropriate immunologic T cell. Upon reexposure, the hapten diffuses to the Langerhans cell, is chemically altered, bound to an HLA-DR, and the complex is expressed on the Langerhans cell surface. This complex interacts with primed T cells either in the skin or lymph nodes, causing the Langerhans cells to make interleukin-1 and the activated T cells to make interleukin-2 and interferon. This subsequently activates the keratinocytes to produce cytokines and eicosanoids that activate mast cells and macrophages, leading to an inflammatory response (Fig. 29–8).[19]

Many allergens are associated with contact dermatitis; a complete list is beyond the scope of this chapter. Among the most common plant-derived sensitizers are urushiol (poison ivy), sesquiterpene lactone (ragweed), and tuliposide A (tulip bulbs). Metals, particularly nickel, are commonly implicated in contact dermatitis. Several industrial chemicals, such as the thiurams (rubber) and urea formaldehyde resins (plastics), account for the majority of occupational contact dermatitis. Medications, particularly topical medications such as neomycin, commonly cause contact dermatitis. Management strategies commonly employed are outlined in Table 29–4.

Irritant dermatitis, although clinically indistinguishable, results from direct damage to the skin and does not require prior antigen sensitization. Still, the inflammatory response to the initial mild insult is the cause of the majority of the damage. Irritant xenobiotics include acids, bases, solvents, and detergents, many of which, in their concentrated form or following prolonged exposure, can cause direct cellular injury. The specific site of damage varies with the chemical nature of the xenobiotic. Many xenobiotics can affect the lipid membrane of the keratinocyte, whereas others can diffuse through the membrane, injuring the lysosomes, mitochondria, or nuclear components. When the cell membrane is injured, phospholipases are activated and affect the release of arachidonic acid and the synthesis of eicosanoids. The second-messenger system is then activated, leading to the expression of genes and the synthesis of various cell surface molecules and cytokines. Interleukin-1 is secreted, which can activate T cells directly and indirectly by stimulation of granulocyte-macrophage colony-stimulating factor production. Treatment is similar to contact dermatitis.

■ PHOTOSENSITIVITY REACTIONS

Photosensitivity may be caused by topical or systemic xenobiotics. Nonionizing radiation, particularly to ultraviolet A (320–400 nm) and less often to ultraviolet B (280–320 nm) are the wavelengths that commonly cause the photosensitivity diagnosis. There are generally two types of xenobiotic related reaction patterns: phototoxic and photoallergic.[25] *Phototoxic* drug reactions occur within 24 hours of the first dose and are dose-related. These reactions result from direct tissue injury caused by the absorption by the xenobiotics of activating
FIGURE 29–8. Contact dermatitis. **(1)** Causative xenobiotic, typically a hapten of < 500 daltons, diffuses through stratum corneum and binds to receptor on Langerhans cell (LC). **(2)** The antigen is processed with major histocompatibility complex II (MHC II) receptor site, presented to T-helper lymphocytes, and carried through the lymphatics to regional lymph nodes. **(3)** There it undergoes the sensitization phase by producing memory, effector, and suppressor T lymphocytes. **(4)** On reexposure to the same, or to a cross-reactive antigen, the LC represents the antigen to T lymphocytes (┄┄┄►), which are now sensitized. This initiates an inflammatory process that appears as indurated, scaly patches. NK, Natural Killer.

wavelengths of nonionizing radiation. The clinical findings include erythema, edema, and vesicles in a light-exposed distribution, and resemble an exaggerated sunburn that can last for days to weeks (Fig. 29–9). *Photoallergic reactions* occur less commonly, may occur following even small exposures, and are characterized by lichenoid papules or eczematous changes on exposed areas. These are type IV hypersensitivity reactions that develop in response to a xenobiotic that has been altered by absorption of nonionizing radiation, acting as a hapten and eliciting an immune response on first exposure. Only on recurrent exposure do to the lesions typically develop. Photoallergic reactions can be diagnosed by the use of patch tests. Both phototoxic and photoallergic reactions are managed with symptomatic

therapy, including topical or, if needed, systemic corticosteroids. The patient should be advised to avoid sun exposure or wear a sunscreen that blocks both ultraviolet A and ultraviolet B with a sun protection factor (SPF) of 15 or greater and is devoid of para-aminobenzoic acid (PABA), a sensitizing agent to many patients.

■ SCLERODERMA-LIKE REACTIONS

A number of environmental xenobiotics are associated with a localized or diffuse scleroderma-like reactions. Sclerodermatous changes refer to a tightened indurated surface change of the skin. These typically occur on the face, hands, forearms, and trunk and are three times more common in women. This may be accompanied by facial telangiectasias and Raynaud syndrome. Raynaud syndrome consists of skin color changes of white, blue, and red accompanied by intense pain with exposure to cold, and can cause acral ulcerations, if untreated. The fibrotic process usually does not remit with removal of the external stimulus. The association of scleroderma-like reactions with polyvinyl chloride manufacture is likely related to exposure to vinyl chloride monomer. Similar reports of this syndrome are associated with exposure to trichloroethylene and perchlorethylene, which are structurally similar to vinyl chloride. Epoxy resins, silica, and organic solvents have been implicated as environmental causes. The xenobiotics bleomycin, carbidopa, pentazocine are causative.

In Spain, patients exposed to imported rapeseed oil mixed with an aniline denaturant developed widespread cutaneous sclerosis. This became known as the "toxic oil syndrome." A similar syndrome, following ingestion of impure L-tryptophan as a dietary supplement, used as a sleeping aid resulted in the eosinophilia myalgia syndrome, which is characterized by myalgia, paralysis, edema, arthralgias, alopecia, urticaria, mucinous yellow papules, and erythematous plaques.[33]

■ HAIR LOSS

Anagen effluvium, hair loss during the anagen stage of the growth cycle, is caused by interruption of the rapidly dividing cells of the hair matrix producing rapid hair loss. *Telogen effluvium*, or toxicity during the resting stage of the cycle, might not produce hair loss for 2 to 4 weeks. Anagen toxicity is the most common mechanism and occurs with chemotherapeutics such as doxorubicin, cyclophosphamide, vincristine, and thallium exposures.[35] Many antineoplastics reduce the mitotic activity of the rapidly dividing hair matrix cells, leading to the formation of a thin shaft that breaks easily topical minoxidil may hasten resolution of the alopecia. Thallium, a toxin classically associated with hair loss, causes alopecia by two mechanisms. Thallium distributes intracellularly, like potassium, altering potassium-mediated processes and thereby disrupting protein synthesis. By binding sulfhydryl groups, thallium also inhibits the normal incorporation of cysteine into keratin. Selenium may produce alopecia by similar mechanisms. Thallium toxicity results in alopecia 1 to 4 weeks after exposure. Within 4 days of exposure a hair mount observed using light microscopy will demonstrate tapered or bayonet anagen hair with a characteristic

bandlike black pigmentation at the base. Seeing this anagen effect can reveal the timing of exposure (Chap. 100).

Soluble barium salts, such as barium sulfide, are applied topically as a depilatory to produce localized hair loss. The mechanism of hair loss is undefined.

■ NAILS

The nail consists of a horny layer the "nail plate" and four specialized epithelia: proximal nail fold, nail matrix, nail bed and hyponychium. The nail matrix consists of keratinocytes, melanocytes, Langerhans cells and Merkel cells.

Nail hyperpigmentation occurs for unclear reasons, but may be caused by focal stimulation of melanocytes in the nail matrix. The pigment deposition can be longitudinal, diffuse, or perilunar in orientation, and typically develop several weeks after chemotherapy.[35] Black dark-skinned patients are more commonly affected due to a higher concentration of melanocytes. Cyclophosphamide, doxorubicin, hydroxyurea, and bleomycin are most often implicated in nail hyperpigmentation, and the pigmentation generally resolves with cessation of therapy.

Nail findings may serve as important clues to xenobiotic exposures that have occurred in the recent past. Matrix keratinization in a programmed and scheduled pattern, leads to the formation of the nail plate. Certain changes in nails, such as Mees lines and Beau lines, result from a temporary arrest of the proximal nail matrix proliferation. These lines can be used to predict the timing of a toxic exposure because of the reliability of rate of growth of the nails at approximately 0.1 mm per day. Mees lines, first described in 1919 in the setting of arsenic poisoning, can be used to approximate the date of the insult by the position of growth of the Mees line a patterned leukonychia (not indentation) causing transverse white lines.[23] Multiple Mees lines suggests multiple exposures. Arsenic, thallium, doxorubicin, vincristine, cyclophosphamide, methotrexate, and 5 fluorouracil are examples of xenobiotics that cause Mees lines, but Mees lines may be noted after any period of critical illness such as sepsis or trauma. Beau lines, or onychodystrophy, are transverse grooves or indentations that are similar to Mees lines in origin and etiology (Fig. 29–10).

SUMMARY

The integument is constantly exposed to both topical and systemic xenobiotics and the exposure may result in reactive dermatoses. Prompt attention and diagnosis is imperative in treating such exposures. The skin, hair, and nails may provide invaluable clues about the route and nature of the xenobiotic. With a careful history, clinical examination, and appropriate biopsy when indicated the etiology and nature of the reaction can be ascertained and treatment initiated in a timely and an effective manner.

SPECIAL POPULATIONS

CHAPTER 30
REPRODUCTIVE AND PERINATAL PRINCIPLES

Jeffrey S. Fine

Reproductive and perinatal principles in toxicology are derived from many areas of basic science and are applied to many aspects of clinical practice. This chapter reviews several principles of reproductive medicine that have implications for toxicology: the physiology of pregnancy and placental xenobiotic transfer, the effects of xenobiotics on the developing fetus and the neonate, and the management of overdose in the pregnant woman.

One of the most dramatic effects of exposure to a xenobiotic during pregnancy is the birth of a child with congenital malformations. Teratology, the study of birth defects, has principally been concerned with the study of physical malformations. A broader view of teratology includes "developmental" teratoge ns—agents that induce structural malformations, metabolic or physiologic dysfunction, or psychological or behavioral alterations or deficits in the offspring, either at or after birth.[245] Only 4% to 6% of birth defects are related to known pharmaceuticals or occupational and environmental exposures.[41,245]

Reproductive effects of xenobiotics may occur before conception. Female germ cells are formed in utero; adverse effects from xenobiotic exposure can theoretically occur from the time of a woman's own intrauterine development to the end of her reproductive years. An example of a xenobiotic that had both teratogenic and reproductive effects is diethylstilbestrol (DES), which caused vaginal and/or cervical adenocarcinoma in some women who had been exposed to DES in utero and also had effects on fertility and pregnancy outcome.[23,31]

Men generally receive less attention with respect to reproductive risks. Male gametes are formed after puberty; only from that time on are they susceptible to xenobiotic injury. An example of a toxin affecting male reproduction is dibromochloropropane, which reduces spermatogenesis and, consequently, fertility. In general, much less is known about the paternal contribution to teratogenesis.[301]

Occupational exposures to xenobiotics are potentially important but are often poorly defined. In 2004, it was estimated that there were 41 million women of reproductive age in the workforce.[281] Although approximately 90,000 chemicals are used commercially in the United States, only a few thousand industrial and pharmaceutic agents have been specifically evaluated for reproductive toxicity. Many xenobiotics have teratogenic effects when tested in animal models, but relatively few well-defined human teratogens have been identified (Table 30–1).[256] Thus, most tested xenobiotics do not appear to present a human teratogenic risk, but most xenobiotics have not been tested.

Some of the presumed safe xenobiotics may have other reproductive, nonteratogenic toxicities. Several excellent reviews and online resources are available.[93,209,218,219,245,256]

Another type of xenobiotic exposure for a pregnant woman is intentional overdose. Although a xenobiotic taken in overdose may have direct toxicity to the fetus, fetal toxicity frequently results from maternal pulmonary and/or hemodynamic compromise, such as hypoxia or shock, further emphasizing the critical nature of the maternal–fetal dyad.

Xenobiotic exposures before and during pregnancy can have effects throughout gestation and may extend into and beyond the newborn period. In addition, the effects of xenobiotic administration in the perinatal period and the special case of delivering xenobiotics to an infant via breast milk deserve special consideration.

PHYSIOLOGIC CHANGES DURING PREGNANCY THAT AFFECT DRUG PHARMACOKINETICS

Many physical and physiologic changes that occur during pregnancy affect both absorption and distribution of xenobiotics in the pregnant woman and consequently affect the amount of xenobiotics delivered to the fetus.[278]

During pregnancy there is delayed gastric emptying, decreased gastrointestinal (GI) motility, and increased transit time through the GI tract. These changes result in delayed but more complete GI absorption of xenobiotics and, consequently, lower peak plasma concentrations. Because blood flow to the skin and mucous membranes is increased, absorption from dermal exposure may be increased. Similarly, absorption of inhaled xenobiotics may be increased because of increased tidal volume and decreased residual lung volume.

An increased free xenobiotic concentration in the pregnant woman can be caused by several factors, including decreased plasma albumin, increased binding competition, and decreased hepatic biotransformation, during the later stages of pregnancy. Fat stores increase during the early stages of pregnancy; free fatty acids are released during the later stages and, with them, xenobiotics that are lipophilic and may have accumulated in the lipid compartment. The increased concentration of free fatty acids can compete with circulating free xenobiotic for binding sites on albumin.

Other factors may lead to decreased free xenobiotic concentrations. Early in pregnancy, increased fat stores, as well as the increased plasma and extracellular fluid volume, lead to a greater volume of distribution. Increased renal blood flow and glomerular filtration may result in increased renal elimination.

Cardiac output increases throughout pregnancy, with the placenta receiving a gradually increasing proportion of total blood volume. Xenobiotic delivery to the placenta may therefore increase over the course of pregnancy.

These processes interact dynamically, and it is difficult to predict their net effect. The concentrations of many xenobiotics, such as

Table 30–1. Known and Probable Human Teratogens

Xenobiotic	Reported Effects	Comments
Amiodarone	Transient neonatal hypothyroidism, with or without goiter; hyperthyroidism	Amiodarone contains 39% iodine by weight. Small to moderate risk from 10 weeks to term for thyroid dysfunction.
Androgens (eg, methyltestosterone, danazol)	Virilization of the female external genitalia: clitoromegaly, labioscrotal fusion	Effects are dose dependent. Stimulates growth of sex-steroid-receptor–containing tissue.
Alkylating agents (eg, busulfan, chlorambucil, cyclophosphamide, mechlorethamine, nitrogen mustard)	Growth retardation, cleft palate, microphthalmia, hypoplastic ovaries, cloudy corneas, renal agenesis, malformations of digits, cardiac defects, other anomalies	A 10%–50% malformation rate, depending on the agent. Cyclophosphamide-induced damage requires cytochrome P450 oxidation.
Angiotensin converting enzyme inhibitors/angiotensin II type 1 receptor inhibitors (sartans)	Fetal/neonatal death, prematurity, oligohydramnios, neonatal anuria, IUGR, secondary skull hypoplasia, limb contractures, pulmonary hypoplasia	Do not interfere with organogenesis. Significant risk of effects related to chronic fetal hypotension during second/third trimester. If used during early pregnancy, can be switched during first trimester.[9,10,41]
Carbamazepine	Upslanting palpebral fissures, epicanthal folds, short nose with long philtrum, fingernail hypoplasia, developmental delay, NTD[128]	1% risk for NTD. Risk of other malformations is unquantified, but may be significant for minor anomalies. Risk is increased in setting of therapy with multiple anticonvulsants, particularly valproic acid. Mechanism may involve an epoxide intermediate. High-dose folate is recommended to prevent NTD.
Carbon monoxide	Cerebral atrophy, mental retardation, microcephaly, convulsions, spastic disorders, intrauterine/death	With severe maternal poisoning, high risk for neurologic sequelae; no increased risk in mild exposures.
Cocaine	IUGR, microcephaly, neurobehavioral abnormalities, vascular disruptive phenomenon (limb amputation, cerebral infarction, visceral/urinary tract abnormalities)	Vascular disruptive effects because of decreased uterine blood flow and fetal vascular effects from first trimester through the end of pregnancy. Risk for major disruptive effects is low (see text).
Corticosteroids	Cleft palate, decreased birth weight (up to 9%) and head circumference (up to 4%)	Low risk. Most information related to prednisone or methylprednisolone.
Coumadin (Warfarin)	Fetal warfarin syndrome: nasal hypoplasia, chondrodysplasia punctata, brachydactyly, skull defects, abnormal ears, malformed eyes, CNS malformations, microcephaly, hydrocephalus, skeletal deformities, mental retardation, spasticity	A 10%–25% risk of malformation for first-trimester exposure, 3% risk of hemorrhage, 8% risk of stillbirth. Bleeding is an unlikely explanation for effects produced in the first trimester. CNS defects may occur during second/third trimesters and may be related to bleeding.[128,289]
Diazepam	Cleft palate, other anomalies	Controversial association, probably low risk.[42,77,93] Risk may extend to other benzodiazepines. Also risk for neonatal sedation or withdrawal following maternal use near delivery.
Diethylstilbestrol (DES)	*Female offspring:* vaginal adenosis, clear cell carcinoma, irregular menses, reduced pregnancy rates, increased rate of preterm deliveries, increased perinatal mortality and spontaneous abortion *Male offspring:* epididymal cysts, cryptorchidism, hypogonadism, diminished spermatogenesis	A synthetic nonsteroidal estrogen that stimulates estrogen receptor–containing tissue and may cause misplaced genital tissue with propensity to develop cancer. A 40%–70% risk of morphologic changes in vaginal epithelium. Risk of carcinoma approximately 1/1000 for exposure before the 18th week. Most patients exposed to DES in utero can conceive and deliver normal children.
Ethanol	Fetal alcohol syndrome (FAS): pre-/postnatal growth retardation, mental retardation, fine motor dysfunction, hyperactivity, microcephaly, maxillary hypoplasia, short palpebral fissures, hypoplastic philtrum, thinned upper lips, joint, digit anomalies	FAS in 4% of offspring of alcoholic women consuming ethanol above 2 g/kg/d (6 oz/d) over the first trimester. There may be a threshold for effects, but a safe dose has not been identified. Can see partial expression or other congenital anomalies (see text). Other effects: increased incidence of spontaneous abortion, premature delivery, and stillbirth; neonatal withdrawal.
Fluconazole	Brachycephaly, abnormal facies, abnormal calvarial development, cleft palate, femoral bowing, thin ribs and long bones, arthrogryposis, and congenital heart disease	Risk related to high dose (400–800 mg/d), chronic, parenteral use. Single 150-mg oral dose probably safe.

Table 30–1. Known and Probable Human Teratogens (*Continued*)

Xenobiotic	Reported Effects	Comments
Indomethacin	Premature closure of the ductus arteriosus; in premature infants, oligohydramnios, anuria, intestinal ischemia	NSAIDs generally labeled as category B. However, there is concern when used after 34 weeks' gestation and for more than 48 hours and/or immediately prior to delivery. Risk may extend to other NSAIDs.
Iodine and iodine-containing products	Thyroid hypoplasia after the 8th week of development	High doses of radioiodine isotopes can additionally produce cell death and mitotic delay. Tissue and organ-specific damage is dependent on the specific radioisotope, dose, distribution, metabolism, and localization.
Lead	Lower scores on developmental tests	Higher risk when maternal lead is >10 µg/dL.
Lithium carbonate	Ebstein anomaly	Low risk.
Methimazole	Aplasia cutis, skull hypoplasia, dystrophic nails, nipple abnormalities, hypo- or hyperthyroidism	Small risk of anomalies or goiter with first-trimester exposure. Hypothyroidism risk after 10 weeks' gestation.
Methotrexate, Aminopterin (amethopterin)	Hydro-/microcephaly; meningoencephalocele; anencephaly; abnormal cranial ossification; cerebral hypoplasia; growth retardation; eye, ear, and nose malformations; cleft palate; malformed extremities/fingers; reduction in derivatives of first branchial arch; developmental delay[288]	These folate antagonists inhibit dihydrofolate reductase. High rate of malformations. Methotrexate is used to terminate ectopic pregnancies.
Methyl mercury, mercuric sulfide	Normal appearance at birth; cerebral palsy–like syndrome after several months; microcephaly, mental retardation, cerebellar symptoms, eye/dental anomalies	Inhibits enzymes, particularly those with sulfhydryl groups. Of 220 babies born following the Minamata Bay exposure, 13 had severe disease. Mothers of affected babies ingested 9–27 ppm mercury; greater risk with ingestion at 6–8 months' gestation. In acute poisoning, the fetus is 4–10 times more sensitive than an adult. Pathologically, there is atrophy and hypoplasia of the brain cortex and abnormalities in cytoarchitecture.[110,294]
Methylene blue (intraamniotic injection)	Intestinal atresia, hemolytic anemia, neonatal jaundice	This xenobiotic was used to identify twin amniotic sacs during amniocentesis.[63]
Misoprostol	Vascular disruptive phenomena (eg, limb reduction defects); Moebius syndrome (paralysis of 6th and 7th facial nerves)	Synthetic prostaglandin E_1 analog. Effects mostly observed in women after unsuccessful attempts to induce abortion.
Oxazolidine-2,4-diones (trimethadione, paramethadione)	Fetal trimethadione syndrome: V-shaped eyebrows; low-set ears with anteriorly folded helix; high-arched palate; irregular teeth; CNS anomalies; severe developmental delay; cardiovascular, genitourinary, and other anomalies	An 83% risk of at least one major malformation with any exposure; 32% die. Characteristic facial features are associated with chronic exposure.
Penicillamine	Cutis laxa, hyperflexibility of joints	Copper chelator–copper deficiency inhibits collagen synthesis/maturation. Few case reports; low risk.
Phenytoin	Fetal hydantoin syndrome: microcephaly, mental retardation, cleft lip/palate, hypoplastic nails/phalanges, characteristic facies–low nasal bridge, inner epicanthal folds, ptosis, strabismus, hypertelorism, low-set ears, wide mouth	Phenytoin has a direct effect on cell membranes and on folate and vitamin K metabolism. May reduce the availability of retinoic acid derivatives or alter the genetic expression of retinoic acid. Epoxide intermediate may play a role in teratogenesis. Effects seen with chronic exposure. A 5%–10% risk of typical syndrome, 30% risk of partial syndrome. Risks confounded by those associated with epilepsy itself and use of other anticonvulsants. Possible increased risk of developing tumors, in particular, neuroblastoma, although absolute risk is very low.
Polychlorinated biphenyls	Cola-colored children; pigmentation of gums, nails, and groin; hypoplastic, deformed nails; IUGR; abnormal skull calcifications	Cytotoxic agent. Body residue can affect subsequent offspring for up to 4 years after exposure. Most cases followed high consumption of PCB-contaminated rice oil; 4%–20% of offspring were affected.[125]

(Continued)

Table 30–1. Known and Probable Human Teratogens (*Continued*)

Xenobiotic	Reported Effects	Comments
Progestins (eg, ethisterone, norethindrone)	Masculinization of female external genitalia	Progestogens are converted into androgens or may have weak androgenic activity. Stimulates or interferes with sex-steroid receptors. Effects occur only after exposure to high doses of some testosterone-derived progestins and may be at the rate of <1% of those exposed. Oral contraceptives containing these agents are not thought to present teratogenic risk, despite their category X designation.
Quinine	Hypoplasia of 8th nerve, deafness, abortion	Effects related to high doses used as abortifacients.
Radiation, ionizing	Microcephaly, mental retardation, eye anomalies, growth retardation, visceral malformations	Significant doses of radiation from diagnostic or therapeutic sources produce cell death and mitotic delay. There is no measurable risk with X-ray exposures of 5 rads or less at any stage of pregnancy.[29,39]
Retinoids (isotretinoin, etretinate, high-dose vitamin A)	Spontaneous abortions; micro-/hydrocephalus; deformities of cranium, ears, face, heart, limbs, liver	Retinoids can cause direct cytotoxicity and alter apoptosis. Neural crest cells are particularly sensitive. For isotretinoin, 38% risk of malformations; 80% are CNS malformations. Effects are associated with vitamin A doses of 25,000–100,000 international units (IU)/day. Exposures below 10,000 IU/day present no risk to fetus. Topical retinoids are not considered a reproductive risk.[273]
Smoking	Placental lesions, IUGR, increased perinatal mortality, increased risk of SIDS, neurobehavioral effects such as learning deficits and hyperactivity.[121,230]	Possible mechanisms include vasoconstriction (nicotine effect); hypoxia secondary to hypoperfusion, CO, and CN; and altered development of neurons and neural pathways via stimulation of nicotinic acetylcholine receptors.[260,261]
Streptomycin	Hearing loss	Rare reports. A low-risk phenomenon that could be associated with long-duration maternal therapy during pregnancy.
Tetracycline	Yellow, gray-brown, or brown staining of deciduous teeth, hypoplastic tooth enamel	Effects seen after 4 months of gestation, because tetracyclines must interact with calcified tissue. Effects occur in 50% of fetuses exposed to tetracycline and in 12.5% of fetuses exposed to oxytetracycline.
Thalidomide	Limb phocomelia, amelia, hypoplasia, congenital heart defects, renal malformations, cryptorchidism, abducens paralysis, deafness, microtia, anotia	Approximately 20% risk for exposure during days 34–50 of gestation.
Trimethoprim	NTD, oral clefts, hypospadias, and cardiovascular defects	Approximately 1% risk of NTD for first-trimester exposure. Mechanism is folic acid inhibition.
Valproic acid	Lumbosacral spina bifida with meningomyelocele; CNS defects, microcephaly, cardiac defects; narrow face with high forehead, epicanthal folds, broad, low nasal bridge with short nose, long philtrum with a thin vermilion border; long, thin fingers and toes	Risk for spina bifida is approximately 1%, but the risk for dysmorphic facies may be greater. The mechanism of teratogenicity is unknown. Possible explanations include interference with glutathione, folate, or zinc metabolism, or regulation of intracellular pH. Risk is confounded by those risks associated with epilepsy itself or use of other anticonvulsants.
Vitamin D	Possible association with supravalvular aortic stenosis, elfin facies, and mental retardation	Large doses of vitamin D may disrupt cellular calcium regulation. Genetic susceptibility may play a role.

IUGR, intrauterine growth retardation; NSAID, nonsteroidal antiinflammatory drug; NTD, neural tube defect; SIDS, sudden infant death syndrome Data adapted from Brent RL: Environmental causes of human congenital malformations: The pediatrician's role in dealing with these complex clinical problems caused by a multiplicity of environmental and genetic factors. *Pediatrics*. 2004;113:957-968; Nulman I, Izmaylov Y, Staroselsky A, Koren G: Teratogenic drugs and chemicals in humans. In: Koren G, ed: *Medication Safety in Pregnancy and Breastfeeding*. New York, McGraw-Hill, 2007, pp. 21-30; and Polifka JE, Friedman JM: Medical genetics: 1. Clinical teratology in the age of genomics. *CMAJ*. 2002;167:265–273. .

lithium, gentamicin, and carbamazepine, decrease during pregnancy, even if the administered dose is not changed.[97]

Although not specifically related to the physiologic changes occurring during pregnancy, the fetus may be exposed to xenobiotics that accumulated in adipose tissue before pregnancy. For example, malformations typically ascribed to retinoid use were seen in a baby born to a woman whose pregnancy began 1 year after she discontinued use of the xenobiotic etretinate (retinoic acid).[148]

XENOBIOTIC EXPOSURE IN PREGNANT WOMEN

Exposure to xenobiotics during pregnancy is common. Between 30% and 80% of pregnant women take xenobiotics sometime during pregnancy—primarily analgesics, antipyretics, antimicrobials, and antiemetics, as well as vitamins, caffeine, ethanol, and nicotine.[34,47,60,71,179,236,237] Some pregnant women use xenobiotics to treat chronic disease; others unknowingly use various prescription and nonprescription xenobiotics prior to recognizing that they are pregnant.

Pharmaceutical manufacturers are required by law to label their products with respect to use in pregnancy, according to standards promulgated by the US Food and Drug Administration (FDA) (Table 30–2).[282] Similar classification systems have been developed in Sweden and Australia.[7,225,243] The original intent of the US regulations was to inform practitioners about the nature of the available evidence regarding risk in pregnancy. However, the general impression is that the categories refer to teratogenic risk—a hierarchy of harmful effects according to the letter categories and an equivalence of risk within each letter category.[76,146,225,249,250] For example, in the US system, a category C medication is generally considered more dangerous than a category B medication in pregnancy, even though category C is the default category for medications about which there is little or no specific information available, and for which the risk is unknown. Approximately 90% of medications are classified as category C.[160]

There is significant discordance between the use-in-pregnancy labeling and the teratogenic risk, as determined by clinical teratologists,[160] and the FDA system has been criticized for being too conservative.[92] Manufacturers may label certain medications as category X even when there is only limited information associating the medication with any adverse fetal or neonatal effects. For example, oral contraceptives generally carry a category X classification, even though they are not considered teratogenic; category X is assigned because there is no indication for use of oral contraceptives in pregnancy.[146] Certain agents with a category D classification may cause problems only at certain times during pregnancy. Even medications that are classified as category D or X may only have a very low risk of teratogenicity or other adverse effect, and exposure to these xenobiotics, even during the first trimester, may not be a sufficient indication to terminate a pregnancy.

The difficulty regarding appropriate drug labeling reflects many complex questions regarding the use of medications during pregnancy. How should animal data in general be evaluated? How should animal data be extrapolated to humans? How should the teratogenic risk be defined and quantified for any particular xenobiotic? How should the risk of not treating a particular disease be compared with the risk of using a particular medication to treat that disease? Finally, how should the answers to these questions be communicated to practitioners and the public?[250] In an attempt to address many of these problems, the FDA has proposed changes to the labeling of medications for use in pregnancy and lactation.[146,283]

Specific current information on individual xenobiotics can be obtained from local and regional teratogen information services[6] and published books,[42,93,245,255] some of which also have online versions.[191,218,219,276] Motherisk is a Canadian program that uses accumulated evidence and experience to advise women about the actual risk to them of using a particular medication or being exposed to a particular xenobiotic in a current or planned pregnancy.[190,191]

Although most women are concerned about the teratogenic effects of medications, in utero exposure to therapeutic medications can have

Table 30–2. FDA Use-in-Pregnancy Ratings

Category	Risk to Human Fetus	Example(s)	Basis
A	No known risk	Multiple vitamins	*Controlled studies show no risk*. Adequate, well-controlled studies in pregnant women do not demonstrate a risk to the fetus and if animal studies exist, they do not demonstrate a risk.
B	Unlikely risk	Acetaminophen, penicillin	*No evidence of risk in humans*. Either animal studies show risk but human studies do not, or if no adequate human studies have been done, animal studies show no risk.
C	Unknown risk	Albuterol	*Risk cannot be excluded*. Animal studies may or may not show risk, but human studies do not exist. However, benefits may justify the potential or unknown risk.
D	Known risk, but benefit may outweigh risk	Tetracycline	*Positive evidence of risk*. Investigational or postmarketing data or human studies show risk to the fetus. Nevertheless, potential benefits may outweigh the potential risk; for example, if the drug is needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.
X	Known risk but risk significantly outweighs benefit	Isotretinoin	*Contraindicated in pregnancy*. Studies in animals or humans or investigational or postmarketing reports have shown fetal risk that clearly outweighs any possible benefit to the patient.

other pharmacologic effects on the newborn infant, such as hyperbilirubinemia or withdrawal reactions.[42,73]

Estimates of substance use in pregnancy vary tremendously, depending on the geographic location, practice environment, patient population, and screening method.[54,150] Among a large national sample screened for xenobiotic use during pregnancy, 20% of pregnant women smoked, 20% drank ethanol, 3% used marijuana, 0.5% used cocaine, 0.1% used methadone, and fewer than 0.1% used heroin. Women tend to decrease their exposure to xenobiotics once they know they are pregnant.[35,124,127]

PLACENTAL REGULATION OF XENOBIOTIC TRANSFER TO THE FETUS

With respect to the transfer of xenobiotics from mother to fetus, the placenta functions in a manner similar to other lipoprotein membranes. Most xenobiotics enter the fetal circulation by passive diffusion down a concentration gradient across the placental membranes. The characteristics of a substance that favor this passive diffusion are low molecular weight (MW), lipid solubility, neutral polarity, and low protein binding.[212] Polar molecules and ions may be transported through interstitial pores.[279]

Xenobiotics with an MW greater than 1000 Da do not diffuse passively across the placenta, and this characteristic is used to therapeutic advantage. For example, warfarin (MW 1000 Da) easily crosses the placenta and causes specific fetal malformations.[289] However, heparin (MW 20,000 Da), which is too large to cross the placenta, is not teratogenic and, consequently, is the preferred anticoagulant during pregnancy. Most therapeutic medications have molecular weights between 250 and 400 Da and easily cross the placenta. For example, thiopental is highly lipid soluble and crosses the placenta rapidly. Fetal plasma concentrations reach maternal concentrations within a few minutes. Neuromuscular blockers such as vecuronium are more polar and cross the placenta slowly.[79]

Although the state of ionization is a limiting factor for diffusion, some highly charged compounds can still diffuse across the placenta. Valproic acid (pK_a 4.7) is nearly completely ionized at physiologic pH, yet there is rapid equilibration across the placental membrane. The small amount of xenobiotic that exists in the nonionized form rapidly crosses the placenta; as equilibrium is reestablished, a new, small amount of nonionized xenobiotic becomes available for diffusion.[195]

Fetal blood pH changes during gestation. Embryonic intracellular pH is high relative to the intracellular pH of the pregnant woman. During this developmental stage, weak acids will diffuse across the placenta to the embryo and remain there because of "ion trapping." Many teratogens, such as valproic acid, trimethadione, phenytoin, thalidomide, warfarin, and isotretinoin, are weak acids. Although ion trapping does not explain the mechanism of teratogenesis, it may explain how xenobiotics accumulate in an embryo. Late in gestation the fetal blood is 0.10 to 0.15 pH units more acidic than the mother's blood; this pH differential may permit weakly basic xenobiotics to concentrate in the fetus during this period.[212]

The relative concentrations of protein binding sites in the pregnant woman and fetus also have an impact on the extent of xenobiotic transfer to the fetus.[212] As maternal free fatty acid concentrations increase near term, these fatty acids can displace xenobiotics such as valproic acid or diazepam from maternal protein binding sites and make more free xenobiotic available for transfer to the fetus. Fetal albumin concentrations increase during gestation and exceed maternal albumin concentrations by term. Because the fetus does not have high concentrations of free fatty acids to compete for protein binding sites, these sites are available for binding the xenobiotics. At birth, when neonatal free fatty acid concentrations increase two- to threefold, they displace stored xenobiotic from the binding protein. In the cases of valproic acid and diazepam, the elevated concentrations of free xenobiotic have adverse effects on the newborn infant.[100,126,195,217]

The placenta may also affect xenobiotic presentation to the fetus by ion trapping and xenobiotic metabolism. The placenta blocks the transfer of some positively charged ions such as cadmium and mercury[110] and may even accumulate them. This barrier does not necessarily protect the fetus, however, because these heavy metal ions interfere with normal placental function and may lead to placental necrosis and subsequent fetal death.[189]

The placenta contains xenobiotic-metabolizing enzymes capable of performing both phase I and phase II reactions (Chaps. 12 and 26). However, the concentration of biotransforming enzymes in the placenta is significantly lower than that in the liver, and it is unlikely that the level of enzymatic activity is protective for the fetus. Moreover, the fetus may be exposed to reactive intermediates that form during these processes. On the other hand, glutathione may also be present in the placenta and detoxify some of these reactive intermediates.[130]

Placental transfer of xenobiotics can have a positive effect when it provides fetal therapy. For example, if a fetus is found to have a supraventricular tachycardia or atrial flutter, digoxin can be given to the mother in order to treat the tachydysrhythmia in the fetus.[142,233]

EFFECTS OF XENOBIOTICS ON THE DEVELOPING ORGANISM

A basic premise of teratogenicity is that the particular toxic effects of a xenobiotic are determined by the organism's stage of development.[40,251] Although the fertilized ovum is generally thought to be resistant to toxic insult before implantation,[40] xenobiotics in the fallopian or uterine secretions may prevent implantation of the embryo. Xenobiotic exposure leading to cell loss or chromosomal abnormalities may also lead to a spontaneous abortion, possibly even before pregnancy has been detected. If the preimplantation embryo survives a xenobiotic exposure, the functional cells usually proceed to normal development.[251] Teratogens that act in such a manner elicit an "all-or-none response"; that is, the exposed embryo will either die or go on to normal development.

Teratogens generally behave according to a dose–response curve; there is a threshold dose below which no effects occur and as the dose of the teratogen increases above the threshold, the magnitude of the effect increases. The effects might be the number of offspring that die or suffer malformations, or the extent or severity of malformations. A strict definition is teratogenic effects are those that occur at doses that do not cause maternal toxicity because maternal toxicity itself might be responsible for an observed adverse or teratogenic effect on the developing organism.[40]

Organogenesis occurs during the embryonic stage of development between days 18 and 60 of gestation. Most gross malformations are determined before day 36, although genitourinary and craniofacial anomalies occur later.[40] The period of susceptibility to teratogenic effects varies for each organ system (Fig. 30–1). For instance, the palate has a very short period of sensitivity, lasting approximately 3 weeks, whereas the central nervous system (CNS) remains susceptible throughout gestation.

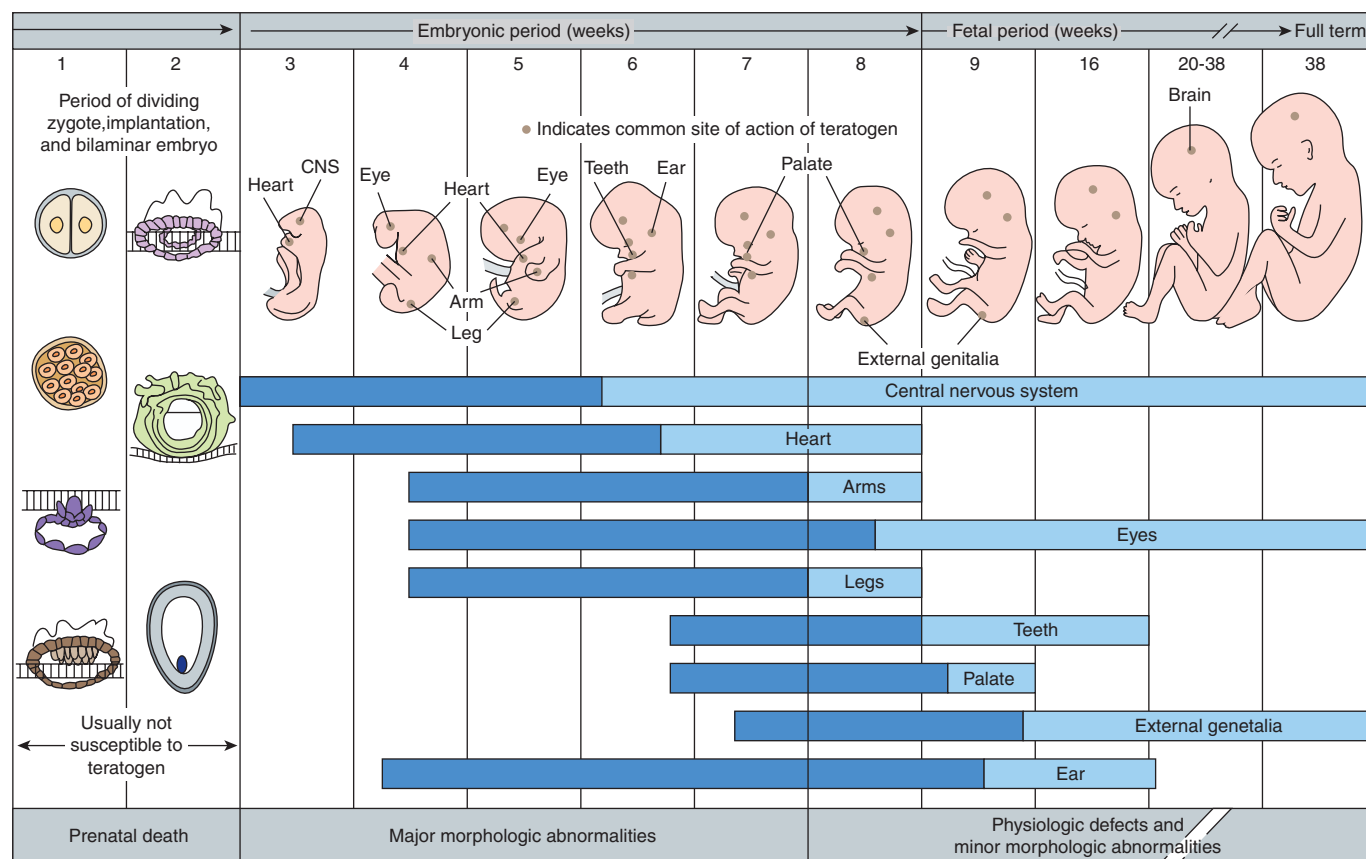
Theoretically, knowing the exact time of teratogen exposure during gestation would allow prediction of a teratogenic effect; this is true in animal models, where dose and time can be strictly controlled. It is also


FIGURE 30–1. Critical periods of fetal development. (Modified with permission from Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003, p. 520.)

true for thalidomide, where different limb anomalies are specifically related to exposures on particular days of gestation.[251] In many clinical situations, for xenobiotics administered either for a short course or chronically, relating teratogenicity to a particular xenobiotic exposure is difficult because the exact time of conception is unknown and the exact time of exposure is unknown. This is particularly true when the primary exposure precedes the pregnancy but there is secondary or ongoing exposure during pregnancy as xenobiotic is redistributed from tissue storage sites.[148]

During the fetal period, formed organs continue their cellular differentiation and grow to functional maturity. Exposure to xenobiotics such as cigarettes and their toxic constituents (for example, nicotine) during this period generally lead to growth retardation. Teratogenic malformations or death may still occur as a result of disruption or destruction of growing organs, as has been the result of exposure to angiotensin-converting enzyme inhibitors during the second and third trimesters.[27]

Another concern during the fetal period is the initiation of carcinogenesis. Significant cellular replication and proliferation lead to a dramatic growth in size of the organism. At the same time, when the fetus is exposed to xenobiotics, development of biotransformation systems may expose the organism to reactive metabolites that might initiate tumor formation. Some tumors, such as neuroblastoma, appear early in postnatal life, suggesting a prenatal origin. In pregnant rats given ethylnitrosourea during the embryonic period, lethal or teratogenic effects occur.[220] If ethylnitrosourea is administered during the fetal period,

there is an increased incidence of tumors in the offspring. Clear cell vaginal and cervical adenocarcinomas are seen in the female offspring of women exposed to DES during pregnancy.[31]

MECHANISMS OF TERATOGENESIS

Cytotoxicity is one mechanism of teratogenesis and is the characteristic result of exposure to alkylating or antineoplastic xenobiotics. Aminopterin, for example, inhibits dihydrofolate reductase activity and leads to suppression of mitosis and cell death. If exposure to a cytotoxic xenobiotic occurs very early in development, the conceptus may die, whereas sublethal exposure during organogenesis may result in maldevelopment of particular structures. There is evidence that following cell death, the remaining cells in an affected region may try to repair the damage caused by the missing cellular elements. This "restorative growth" may lead to uncoordinated growth and exacerbate the original malformation.

In the case of the cytotoxic xenobiotics, the mechanism of action is understood, although it is not always clear why particular xenobiotics affect particular structures. With other xenobiotics, the structural effects have a clearer relationship to the site of action. For instance, when glucocorticoids are administered in large doses to some experimental animals during the period of organogenesis, malformations of the palate occur. Glucocorticoid receptors are found in high concentrations in the palate of the developing mouse embryo.[213]

Corticosteroid exposure can also cause cleft palate in humans at a low frequency.[207,255]

Caloric deficiency is not considered teratogenic during the period of organogenesis. However, specific nutritional or vitamin deficiencies can be teratogenic; an increased incidence of neural tube defects occurs in the presence of folate deficiency, and the incidence has been reduced following the use of folate supplementation before and during pregnancy.[201] Ethanol affects the fetus both directly and indirectly. The craniofacial malformations seen in fetal alcohol syndrome probably result from the effects of ethanol during the period of organogenesis. Growth retardation may result from direct effects of ethanol on fetal growth, or from indirect effects resulting from ethanol-induced maternal nutritional deficiencies.

MANAGEMENT OF ACUTE POISONING IN THE PREGNANT WOMAN

For most women, pregnancy and the postpartum period are a period of emotional happiness. However, women have a lifetime prevalence of depression that is two to three times higher than men, and for some women psychiatric illness during pregnancy, particularly depression and anxiety, represents a significant complication. A new first episode or recurrence of major depression occurs in approximately 3% to 5% of pregnant women and 1% to 6% of postpartum women; an additional 5% to 6% of women in each period will have minor symptoms of depression.[96] Overall, these rates of depression are about the same in pregnant and nonpregnant women; however, during the postpartum period, the onset of new episodes of depression may be three times higher than for nonpregnant women. Pregnant teenagers may also be at higher risk of depression in pregnancy.[159]

Postpartum blues are common; typically involve relatively mild symptoms including mood swings, irritability, anxiety, and crying spells; and generally resolve by 2 weeks postpartum.[164] Postpartum blues do not include suicidal ideation. True depression is manifested by feelings of hopelessness or helplessness and may include suicidal ideation.[164] Postpartum psychosis, typically associated with bipolar disorder, is uncommon but it represents a true psychiatric emergency because there is a high risk of suicide and/or infanticide.[164]

Risk factors for perinatal depression include an unplanned pregnancy, ambivalence about the pregnancy, poor social support, marital difficulties, adverse life events, and chronic stressors such as financial problems.[164] Of particular importance is a personal or family history of depression, particularly previous perinatal depression. Discontinuation of antidepressant medications represents a significant risk for relapse of disease, although relapse is possible even while a woman is on antidepressant medication. Additional risk factors for depression include miscarriage, stillbirth, and preterm delivery.

Depression in pregnancy has adverse effects on both the mother and the fetus.[33] For the pregnant woman, adverse effects include noncompliance with prenatal care; self-medication with tobacco, alcohol, and drugs; poor sleep; poor appetite; and poor weight gain. In addition there may be increased risk of spontaneous abortion, preeclampsia, preterm delivery, and growth retardation. For many of these outcomes, it is difficult to separate out the contributions from multiple confounding and interacting factors including psychopathology, socioeconomic status, acute and chronic stressors, smoking, and the use of alcohol and other substances. Infants born to women being treated with antidepressant medications are also at risk for neonatal withdrawal symptoms.[139]

One of the most extreme outcomes of depression is suicide. Suicidal ideation occurs in about 5% of pregnant women in community samples and up to 20% in women with underlying psychiatric illness.[159,198]

Even so, suicide and suicide attempts during pregnancy are uncommon. Each year a small number of women die during pregnancy or the postpartum period; 1% to 5% of these pregnancy-related deaths may be the result of suicide.[52,69,202] Between 2% and 12% of women who attempt or commit suicide may be pregnant.[138,210,297] Overall, completed suicide occurs less frequently during pregnancy.[16,159,178] Psychiatric illness including previous suicide attempts predisposes to suicide attempts in pregnancy. Acute stressors leading to impulsive acts account for most of the uncompleted suicide attempts; these reasons include loss of a lover, economic crisis, prior loss of children, and unwanted pregnancy and desire for an abortion.[66,156,297] Fewer than half the suicide attempts are specifically related to a pregnancy-related problem.

Women who complete suicide typically have more severe psychiatric illness. In particular, these women are likely to use more violent means of suicide such as hanging or self-inflicted gunshot wounds, although poisonings are a significant contributor to these deaths.[202] In addition, substance and alcohol use is a significant contributing factor in many cases; additionally, some pregnancy-related deaths may be secondary to complications of substance use, such as overdose.[202] In one series, initiation of child-protection proceedings, particularly in the setting of maternal substance use, was a significant risk factor for postpartum suicide.[202]

Medication ingestion is a common method of attempting suicide during pregnancy. Analgesics, vitamins, iron, antibiotics, and antipsychotics account for 50% to 79% of the reported ingestions by pregnant women.[210,214] These xenobiotics are frequently prescribed for, and used by, pregnant women. Some of these xenobiotic exposures are attempts to terminate pregnancy (see Chap. 28).[210]

Although the focus of this section is on medical management, it goes without saying that any woman who attempts suicide during pregnancy should have a psychiatric evaluation after she is medically stabilized. In particular, there are a growing number of specialized units or teams that focus on pregnant or postpartum women and attempt to keep women and infants together in the postpartum period.[164,202]

Managing any acute overdose during pregnancy provokes discussion of several questions. Is the general management different? Do altered metabolism and pharmacokinetics increase or decrease the woman's risk of morbidity or mortality from a xenobiotic overdose? Is the fetus at risk of poisoning from a maternal overdose? Is there a teratogenic risk to the fetus from an acute overdose or poisoning? Is the use of an antidote contraindicated, or should use be modified? When should a potentially viable fetus be emergently delivered to prevent toxicity? When should termination of a pregnancy be recommended?

As described above, physiologic changes during pregnancy affect pharmacokinetics; xenobiotics taken in overdose also have unpredictable toxicokinetics. In any significant overdose during pregnancy, pregnancy-related alterations in pharmacokinetics are unlikely to protect the woman from significant morbidity or mortality.

Although a single high-dose exposure to a xenobiotic during the period of organogenesis might seem analogous to an experimental model to induce teratogenesis, most xenobiotics ingested as a single, acute overdose do not induce physical deformities.[67] Anticonvulsants are teratogenic and may be ingested in toxic doses, but their teratogenicity is probably related more to chronic exposure. Acute acetaminophen intoxication in the first trimester may lead to an increased risk of spontaneous abortion,[223] suggesting a teratogenic effect similar to the all-or-none response described earlier. In general, however, it is extremely difficult to ascribe teratogenicity to a particular xenobiotic exposure based on a single case report. There is, for example, a report of multiple severe congenital malformations in the stillborn fetus of a woman who overdosed on isoniazid during the 12th week of pregnancy.[154] However, because

the background incidence of congenital malformations is 3% to 6%, it is almost impossible to determine for a single individual whether a particular xenobiotic exposure is the etiology of any observed malformations.[68] Considering the successful outcome of most pregnancies that progressed following an acute overdose, it is very unlikely that the small risk of possible teratogenesis would ever lead to a recommendation for termination of pregnancy after an acute overdose of most xenobiotics.

In general, any condition that leads to a severe metabolic derangement in the pregnant woman is likely to have an adverse impact on the developing fetus. Therefore, the management of overdose in a pregnant woman usually follows the principles outlined in Chapter 4, with close attention paid to the airway, oxygenation, and hemodynamic stability. The use of naloxone or dextrose has not been specifically assessed in pregnancy, but should be guided by the same considerations raised in managing the nonpregnant patient with alterations in respiratory or neurologic function. Opioid-induced respiratory failure in the pregnant patient will lead to fetal hypoxia and adverse effects; opioid withdrawal in a pregnant woman, whether induced by abstinence or the use of naloxone, may adversely affect the fetus or the pregnancy. Consideration of the benefits and risks of the use of naloxone for an opioid-poisoned woman in respiratory distress or coma suggests that reduced morbidity, for both mother and fetus, may be achieved by the use of carefully titrated doses of naloxone to minimize the likelihood of maternal withdrawal (see Chap. 38 and Antidotes in Depth A–6: Opioid Antagonists).

Gastrointestinal decontamination is frequently a part of the early management of acute poisoning in the nonpregnant patient. Gastric lavage is not specifically contraindicated for the pregnant patient and the usual concerns about protecting the airway apply. Even though syrup of ipecac is no longer recommended as a standard therapy for the management of typical pediatric and adult ingestions, pregnancy was previously considered a relative contraindication to its use because vomiting increases both intrathoracic and intraabdominal pressure.

There is no specific contraindication to the use of activated charcoal in a pregnant woman. There may be a specific role for whole-bowel irrigation in the management of several xenobiotic exposures, particularly in the treatment of iron overdose in pregnancy.[284] The use of oral polyethylene glycol is safe in pregnant women.[196]

Almost all antidotes are designated as FDA pregnancy-risk category C; that is, there is little specific information to guide their use. Ethanol is labeled as category D (positive evidence of risk), although this is presumably related to chronic use throughout pregnancy. Fomepizole, which has replaced ethanol as the preferred antidote for toxic alcohol poisoning, is labeled as category C. Pyridoxine and thiamine are category A xenobiotics; N-acetylcysteine (NAC), magnesium, glucagon, and naloxone are category B xenobiotics.

Thus far, there are no reports of adverse effects on the fetus from antidotal treatment of a poisoned pregnant woman. Conversely, in at least one case, withholding deferoxamine therapy may have contributed to the death of both a woman and her fetus.[174,271]

■ ACETAMINOPHEN

Acetaminophen is the most common analgesic and antipyretic used during pregnancy and is one of the most common xenobiotics ingested in overdose during pregnancy.[185,223] There are two published series, as well as a number of individual reports, totaling more than 100 cases of acute acetaminophen overdose during all trimesters of pregnancy. In the two large series representing 112 acute and chronic overdoses, 33 patients had serum acetaminophen concentrations in the toxic range.[185,223] These studies, in addition to the case reports described below, demonstrate that most pregnant women recover from an acetaminophen ingestion without adverse effects to themselves or their babies.

In the two large series of acetaminophen overdose during pregnancy,[185,223] eight of 28 women who overdosed in the first trimester and continued their pregnancy experienced spontaneous abortions, most within 2 weeks of the ingestion. Of the eight women, five had toxic serum acetaminophen concentrations; one woman received NAC within 8 hours, and four received NAC between 12 and 17 hours after ingestion. In one of these cases both maternal and fetal death occurred. Five patients with toxic serum acetaminophen concentrations and 14 with nontoxic serum concentrations delivered healthy term newborns. Ten women had elective terminations of pregnancy.

The two large series included 32 second-trimester acute overdoses.[185,223] Two women who had nontoxic serum acetaminophen concentrations had spontaneous abortions—one had symptoms of a threatened abortion several days prior to the overdose, and the second was assaulted the day before the overdose and aborted the next day. Six women with toxic serum acetaminophen concentrations delivered full-term healthy infants; 19 women with nontoxic serum concentrations delivered full-term babies, and one woman with a nontoxic serum concentration delivered a premature infant 2 months after the overdose. Four women had elective terminations of pregnancy.

There are three case reports of women with acute overdoses in the second trimester. One woman who overdosed at 15.5 weeks of gestation had a toxic serum acetaminophen concentration, was treated with intravenous NAC beginning 20 hours after the ingestion, and developed hepatotoxicity. She had a spontaneous rupture of membranes at 31 weeks and delivered a male infant at 32 weeks.[163] One woman who overdosed at 16 weeks had a toxic serum acetaminophen concentration, was treated with NAC within 8 hours, and did not develop hepatotoxicity.[228] She delivered a normal female infant at term. One woman overdosed at 20 weeks, received intravenous NAC starting some time between 8 and 18 hours after ingestion, and developed hepatotoxicity. She had labor induced at 41 weeks because of weight loss and delivered a male infant.[268] The infant was irritable and developed hyperbilirubinemia, both of which resolved after phototherapy.

The two large series described above included 39 third-trimester overdoses.[185,223] Twelve women had toxic serum acetaminophen concentrations: eight delivered healthy term infants; two women who had no evidence of hepatotoxicity delivered premature infants 2 days after the overdose; one woman with hepatotoxicity delivered a moderately ill premature infant at 32 weeks of gestation; and one woman with severe hepatotoxicity delivered a stillborn infant with hepatic necrosis at 33 weeks of gestation (Table 30–3). Twenty-seven women had nontoxic serum acetaminophen concentrations: two delivered premature infants (one of whom had respiratory distress), and 25 delivered full-term infants. Of these full-term infants, one developed a withdrawal syndrome, one developed pyloric stenosis, and three had physical anomalies. Altogether, in these two series, six of 39 women with third-trimester overdoses had premature delivery, usually within 2 to 3 days of the overdose.

In addition to the large series described, there are 11 case reports of third-trimester acetaminophen overdoses (Table 30–3). Three additional third-trimester cases are briefly described: two women had an acute overdose and one had a chronic overdose. All three women had toxic serum acetaminophen concentrations, were treated with NAC, and delivered healthy infants while receiving NAC.[120] There are also several case reports of adverse pregnancy outcome in the setting of chronic use of acetaminophen, or acute overdose associated with chronic substance use.[53,120,145,165,223] It is difficult to interpret these

Table 30–3. Reported Cases of Third-Trimester Acetaminophen Overdose

| Gestational Age (Weeks) | Maternal | | Infant | | Comment | Ref |
	APAP Concentration (µg/mL) (Time[a])	AST Peak (IUnits/L) (Time[a])	APAP Concentration (µg/mL) (Time[a])	Hepatotoxicity (Yes/No)		
27	0 (36 h)	1226 (36 h)	ND	No	C/S for fetal distress. Infant: mild respiratory distress syndrome	94
27–28	56 (16 h)	6226 (96 h)	ND	Yes	Ingestion over 24 h. No fetal movements at presentation. PO NAC started at 20 h. Induced labor at 4 d. Infant: stillborn with diffuse hepatic necrosis. Hepatic APAP 250 µg/g.	107
29	160 (10 h)	4300 (50 h)	76 (16 h, cord)	No	Ingestion of aspirin, caffeine, and quinine, followed 17 h later by APAP. Presented in labor. Treated with oral methionine. Spontaneous delivery at 16 h. Infant: moderate hyaline membrane disease. Peak AST 86 (cord). Four whole-blood exchange transfusions. Discharged home at 54 d of life. Died at 106 d, no apparent cause.	153
31	40 (26)	13320 (60 h)	41 (27)	Yes	APAP only, C/S for fetal distress 1 h after initial maternal evaluation. Infant's birth weight was 1620 g. Apgars 0, 0, 1.[b] Infant died at 34 h of life. Mother died at 34 h post ingestion. No autopsy of mother or child.	286
32	448 (12 h)	5269 (48 h)	0 (84 h, cord)	No	IV NAC started at 12 h. Induced delivery at 84 h. Infant: transient hypoglycemia, mild respiratory distress, mild jaundice. Peak AST 56 (day 1 of life).	185,235
33	135 (28 h)	6237 (66 h)	330 (3 d, cord)	Yes	Oral NAC at 12 h. Fetal death at 2 d, spontaneous delivery at 3 d. Infant: stillborn with diffuse hepatic necrosis.	223
36	280 (3–4 h)	Normal	217 (6–7 h, cord)	No	Ingestion of APAP, ethanol, barbiturates. Elective C/S at 6–7 h. Infant: double volume exchange transfusion at 18 h. Discharge at 40 d, "cot death" at 157 d.	227
36	200 (5 h)	25 (24 h)	ND	No	Oral NAC (? time). Infant: spontaneous delivery 6 weeks after ingestion. Normal neonatal course.	48
38	216 (4 h)	Normal	13 (17 h, cord)	No	NAC (? route). Infant: normal neonatal course.	144,239
"Term"	147 (9 h)	28 (9 h)	133 (9 h, 4 h of life)	No	Infant PT 44 at 4 h of life. IV NAC. No problems. AST 86 at 4 h of life.	21
Term?	89 (11 h)	326 (35 h)	144 (11 h, 4 h of life)	No	Mother presented in labor at 6 h. Infant received IV NAC at 4 h of life. AST 55 at 4 h of life.	241

APAP, acetaminophen; AST, aspartate aminotransferase; C/S, cesarean section; IV, intravenous; NAC, *N*-acetylcysteine; ND, not done or not reported; PO, oral; PT, prothrombin time.

[b] Apgars are at 1, 5, and 10 minutes.

reports with respect to specific acetaminophen effect because of the confounders of chronic disease, chronic use, or use of additional medications or substances.

Acetaminophen is an FDA use-in-pregnancy category B medication; at recommended doses, it is considered safe for use during pregnancy. However, in overdose, it may put the developing fetus at risk. As the third-trimester cases described above demonstrate, acetaminophen crosses the placenta to reach the developing fetus. The clinical series[185,223] suggest that there may be some increased risk of spontaneous abortion after overdose during the first trimester, but not with therapeutic use.[157] There is also a question about whether overdose during the first trimester can lead to late sequelae, for instance, premature labor.

Some experimental work may help to explain early pregnancy loss after overdose. Acetaminophen prevented the development of preimplantation (two-cell stage) mouse embryos in culture, an effect that was not associated with alterations in glutathione concentrations,[151] and also led to abnormal neuropore development in cultured rat embryos.[267] These data suggest that acetaminophen may be directly toxic to the immature organism. However, other work reported that similar embryotoxic effects were associated with reductions in glutathione concentrations[293] and that *N*-acetyl-*p*-benzoquinoneimine (NAPQI) produced nonspecific toxicity when added to the rat embryo culture medium.[267]

The fetal liver has some ability to metabolize acetaminophen to a reactive intermediate in vitro. Cytochrome P450 (CYP) activity was detected in intact hepatocytes, as well as in microsomal fractions isolated from the livers of fetuses aborted between 18 and 23 weeks of gestation, although fetal CYP activity was only 10% of the activity of hepatocytes isolated from adults following brain death; fetal CYP activity increased with increasing gestational age.[231] In two clinical cases, cysteine and mercapturate conjugates were identified in newborns exposed to acetaminophen in utero, suggesting that the fetus and neonate can metabolize acetaminophen through the CYP system.[153,227] These data suggest that the fetus in utero and the neonate can generate a toxic metabolite; the clinical cases suggest that the fetal liver is susceptible to injury.

This CYP activity has not been further characterized. However, CYP2E1, one of the cytochromes responsible for acetaminophen metabolism, is present in human fetal tissues as early as 16 weeks of gestation.[187] CYP3A4 and CYP1A2 are also involved in acetaminophen metabolism, but are not present in fetal liver. CYP3A7 is a functional fetal form of the CYP3 family, but its metabolic activity with respect to acetaminophen has not been studied.[108]

The most difficult questions relate to management of overdose during the third trimester. Can acetaminophen overdose lead to premature labor even if a pregnant woman does not have a toxic serum concentration or develop hepatotoxicity? Should a woman be emergently delivered following overdose? Does NAC treatment of the mother help the fetus? What is the appropriate treatment of a neonate exposed to acetaminophen in utero?

The clinical cases may help address the last two questions (see Table 30–3). Six women, all less than 36 weeks of gestation, developed hepatotoxicity. Two infants died in utero with evidence of severe hepatotoxicity, although what effect in utero postmortem changes may have had on serum acetaminophen concentrations or liver pathology is unclear. One infant died on the second day of life with hepatotoxicity. The other three infants experienced problems associated with prematurity but did not develop obvious hepatotoxicity. One of these three had an exchange transfusion and an unexplained death at 3 months of age. Five women, all at 36 or more weeks of gestation, did not develop hepatotoxicity. One infant had an exchange transfusion and did not develop hepatotoxicity but died a "cot death"

at 5 months of age. One infant received IV NAC and had a transient elevation of aspartate aminotransferase (AST) and prothrombin time. Two infants were not treated; both did well, although one had a transient elevation of AST. One infant was born 6 weeks after the overdose and was normal.

Severe maternal hepatoxicity that is associated with any sign of fetal distress is an indication for urgent delivery. Although a fetus with prolonged exposure to acetaminophen in utero is at risk of developing severe hepatotoxicity, not all at-risk infants are affected. What role gestational age, maternal disease state, or other maternal factors may play is unknown. Although there are insufficient case data to suggest that acetaminophen overdose per se is an indication for urgent delivery, there may be an indication for urgent delivery when the maternal serum acetaminophen concentration is in the toxic range but hepatotoxicity has not yet developed.[275] Significant acetaminophen overdose with or without hepatotoxicity can precipitate premature spontaneous labor, and even women with nontoxic serum concentrations may be at a slightly increased risk.

In two cases, exchange transfusion was employed to treat the exposed neonate. In both cases, the acetaminophen half-life was prolonged, and in neither case was this affected by the transfusion. Disturbingly, these two infants had unexplained deaths at several months of age. There is insufficient information on which to base a recommendation regarding exchange transfusion as therapy for prenatal exposure.

The pregnant woman with acute toxic acetaminophen ingestion should be treated with *N*-acetylcysteine (see Chap. 34 and Antidotes in Depth A–4: *N*-Acetylcysteine). This is therapy to treat the mother. Although maternal hepatoxicity or delayed NAC therapy may be associated with fetal toxicity,[223] there is insufficient information to indicate that prevention of maternal toxicity will prevent fetal toxicity in either the first or the third trimester. NAC was found in cord blood after administration to four mothers before delivery,[120] although NAC did not cross the sheep placenta in vivo[252] or the perfused human placenta in vitro.[124] Even if NAC does cross the placenta, whether it prevents fetal hepatotoxicity is unknown because not all exposed fetuses develop hepatotoxicity.

In four third-trimester cases where the mothers overdosed at or after 36 weeks of gestation and did not develop hepatotoxicity, the infants did well. One infant received NAC. There are anecdotal reports of infants who received NAC soon after delivery and did well. Current theory suggests that infants and young children are less likely than teenagers or adults to develop hepatoxicity after acetaminophen overdose because of immature CYP activity and increased sulfation activity. It is intriguing to consider that this metabolic protection might extend to the newborn exposed to acetaminophen in utero. It also makes it difficult to know to what extent postnatal NAC therapy for the prenatally exposed newborn might prevent toxicity. Although there are no reported cases, it would seem that the premature newborn exposed in utero might be the best candidate for postnatal NAC therapy.

■ IRON

Iron is another common ingestant during pregnancy; maternal toxicity is generally greater than fetal toxicity. In two reported cases, normal babies were delivered although the mothers died.[206,221] In another case, the mother had severe iron toxicity with acidosis, shock, renal failure, and disseminated intravascular coagulation but was not treated with deferoxamine because of concerns about its teratogenic risks. Instead, the mother received an exchange transfusion followed 45 minutes later by a spontaneous abortion of the 16-week fetus.[174,271] Neonatal and cord blood iron concentrations were not elevated. In several cases, pregnant women who had signs and symptoms of iron poisoning and elevated

serum iron concentrations were treated with deferoxamine and subsequently delivered normal babies.[32,136,147,215,246,280]

Although the placenta transports iron to the fetus efficiently,[20] it also blocks the transfer of large quantities of iron. In a sheep model of iron poisoning, only a small amount of iron was transferred across the placenta despite significantly elevated serum iron concentrations.[65]

Deferoxamine is an effective antidote for iron poisoning (see Chap. 40 and Antidotes in Depth A–7: Deferoxamine), but it is reported to be an animal teratogen that causes skeletal deformities and abnormalities of ossification (FDA class C pregnancy risk). An animal model observed similar effects, but only with doses of deferoxamine that caused maternal toxicity.[36] Experimentally, in sheep, little transfer of deferoxamine across the placenta was demonstrated[65]; therefore, the reported fetal effects may be secondary to chelation of essential nutrients (such as trace metals) on the maternal side of the placenta.[275]

In clinical case reports of iron overdose for which deferoxamine was used, there have been no adverse effects on the fetus, although most have been either second- or third-trimester poisonings.[32,136,147,206,215,246,280] In a case series of 49 patients with iron poisoning during pregnancy, few of the patients exhibited any clinical toxicity other than vomiting and diarrhea; 25 received deferoxamine, most by the oral route.[184] One woman with a first-trimester overdose, eight women with second-trimester overdoses, and 12 women with third-trimester overdoses were treated with deferoxamine and subsequently delivered full-term infants. One infant whose mother overdosed at 30 weeks of gestation had webbed fingers on one hand. One woman overdosed at 20 weeks, had minimal clinical toxicity, received deferoxamine, and delivered a 2.5-kg male infant at 34 weeks. One woman with a first-trimester overdose and two women with second-trimester overdoses elected to terminate their pregnancies.

Further support for the safe use of deferoxamine in pregnancy is the experience with its use for pregnant women with thalassemia. For many years deferoxamine has been administered as part of the therapy for posttransfusion iron overload without adverse effects.[259]

Deferoxamine is probably safe for use in pregnant women. Considering the potentially fatal nature of severe iron poisoning, deferoxamine should be administered when signs and symptoms indicate significant poisoning.

Iron overdose may be one of the few specific indications for whole-bowel irrigation because iron is not adsorbed to activated charcoal (see Antidotes in Depth A–2: Activated Charcoal). A case report demonstrated elimination of pill fragments following treatment of a pregnant woman with whole-bowel irrigation.[284]

■ CARBON MONOXIDE

Carbon monoxide is the leading cause of poisoning fatalities in the United States. In contrast to iron and most other xenobiotics, when pregnant women are exposed to carbon monoxide, the fetus may be at greater risk of toxicity than the woman herself. There are reports of both the mother and fetus dying, the mother surviving but the fetus dying, and both the mother and fetus surviving but with adverse neonatal outcome, primarily brain damage resembling that seen following severe cerebral ischemia.[49,64,143,161,175,200,284,300] Similar clinical effects have also been observed in animal models.[78,101,162]

The case literature suggests increased risk of poor fetal outcome with clinically severe maternal poisoning or significantly elevated carboxyhemoglobin concentrations.[143,200] Women with minimal symptoms and/or low concentrations of carboxyhemoglobin have a low risk of fetal toxicity, but a lower limit of exposure without effect has not been specifically defined.[143]

In animal models, under physiologic conditions, the fetus has a carboxyhemoglobin concentration 10% to 15% higher than the mother. After exposure to carbon monoxide, the fetus achieves peak carboxyhemoglobin concentrations 58% higher than those achieved by the mother at steady state, and the time to peak concentration is also delayed compared to the mother. Similarly, the elimination of carbon monoxide occurs more slowly in the fetus than in the mother.[115,161,162] One case report describes such a phenomenon: after 1 hour of supplemental oxygen, the maternal carboxyhemoglobin was 7% and the fetal carboxyhemoglobin was 61% at the time of death in utero.[83]

Carbon monoxide leads to fetal hypoxia by several mechanisms: (1) maternal carboxyhemoglobin leads to a decrease in the oxygen content of maternal blood, and therefore less oxygen is delivered across the placenta to the fetus, which normally has an arterial PO_2 of only 20 to 30 mm Hg; (2) fetal carboxyhemoglobin causes a decrease in fetal PO_2; (3) carbon monoxide shifts the oxyhemoglobin dissociation curve to the left and decreases the release of oxygen to the fetal tissues (an exacerbation of the physiologic left shift found with normal fetal hemoglobin); and (4) carbon monoxide may inhibit cytochrome oxidase or other mitochondrial functions (Chap. 125).

The treatment for severe carbon monoxide poisoning is hyperbaric oxygen therapy (HBO) (see Chap. 125 and Antidotes in Depth A–37: Hyperbaric Oxygen). There are questions about the use of HBO in pregnant women because animal models suggest HBO adversely effects the embryo or fetus.[88,188,244,274] The applicability of the animal models to humans is difficult to assess; many of the animal models used hyperbaric conditions of greater pressures and duration than those clinically used for humans.

HBO has been used therapeutically for carbon monoxide poisoning in pregnancy with good results reported, although there are limited data on the long-term follow-up of the children.[44,87,95,105,116,143,285] One large series reported 44 women who were exposed to carbon monoxide during pregnancy and were treated with HBO, regardless of clinical severity or gestational age: 33 had term births; one had a premature delivery 22 weeks after HBO, during an episode of maternal fever; two had spontaneous miscarriages (one 12 hours after severe poisoning and one 15 days after mild poisoning); one delivered a child with Down syndrome; one had an elective abortion; and six were lost to follow-up.[83] Unfortunately, details regarding trimester of exposure, maternal carboxyhemoglobin level, and severity of symptoms are not available, making it difficult to interpret the reported outcomes. Although HBO appears safe for pregnant women and seems to present little risk to the fetus, it is not clear whether HBO prevents carbon monoxide–related fetal toxicity for those at risk. Carbon monoxide can have a severe impact on fetal health and development and, as noted above, the maternal carboxyhemoglobin concentration may not accurately reflect the fetal carboxyhemoglobin concentration.

HBO should be considered for any pregnant woman exposed to carbon monoxide, especially for a woman with an elevated serum carboxyhemoglobin concentration or any evidence of fetal distress. In order to allow the fetal carboxyhemoglobin to be eliminated, if HBO therapy is not available, 100% oxygen should be administered to a pregnant woman for five times as long as the time needed for her carboxyhemoglobin to return to the normal range. Thus if a pregnant woman's carboxyhemoglobin level returns to normal in 30 minutes she should continue to receive 100% oxygen for a total of 150 minutes.

SUBSTANCE USE DURING PREGNANCY

One of the most complex areas of toxicology deals with issues of substance use during pregnancy and its effects on the woman, on the pregnancy itself, and on fetal and postnatal development. This section reviews of some of the important aspects of this topic.

Clinical research in the area of substance use during pregnancy is very difficult to perform. With the increased use of cocaine during the latter half of the 1980s and 1990s, there was great interest in determining the effects of cocaine use during pregnancy. As research in this area progressed, many of the critical methodologic issues related to substance use research were highlighted.[89,123,155,197,303]

Substance-using women often have multiple risk factors for adverse pregnancy outcomes, such as low socioeconomic status, polysubstance use, ethanol and cigarette use, sexually transmitted diseases, AIDS, malnutrition, and lack of prenatal care. Lack of prenatal care is highly correlated with premature birth, and smoking is associated with spontaneous abortion, growth retardation, and sudden infant death syndrome (SIDS).[133,295] Other factors not specifically related to substance use such as age, race, gravidity, and prior pregnancies also affect pregnancy outcome. Each of these factors represents a significant potential confounding variable when the effects of a particular xenobiotic such as cocaine or marijuana are evaluated during pregnancy and must be controlled for in research design. Many of these factors are also significant confounders in evaluation of postnatal growth and development.

There may be bias in the selection of study subjects. For example, if all the patients are selected from an inner-city hospital obstetrics service, there is potential for overestimating the effects of the xenobiotic being studied. If cohorts are followed over a long time, study subjects are frequently lost to follow-up. Are the ones who continue more motivated, or do they have more problems that need attention?

Categorizing patients into substance-use groups is difficult. Self-reporting of substance use is frequently unreliable or inaccurate, and making determinations about the nature, frequency, quantity (dose), or timing (with respect to gestation) of xenobiotic exposure is difficult. Because substance users frequently use multiple xenobiotics, it may be difficult to categorize subjects into particular xenobiotic-use groups, and patients using different xenobiotics may be grouped together. In fact, there may be no actual xenobiotic-free control groups.

When urine drug screens are used to identify substance users, there is a high probability of false negatives because drug screens reflect only recent use. This factor is particularly important because substance use tends to decrease later in pregnancy, and a negative urine drug screen in the third trimester or at delivery may fail to identify a woman who was using xenobiotics early in pregnancy. Testing for xenobiotics in hair or meconium may improve the accuracy of the analysis with regard to the entire pregnancy.[37,140]

Another bias involves selection of infants who are exposed to xenobiotics. Evaluating newborns who are "at risk," show signs of withdrawal, or have positive urine drug screens will miss some exposed infants. When research concerns the neurobehavioral development of children exposed in utero to substances, it is important that the examiners performing the evaluation be blinded to the infants' xenobiotic exposure category.

Finally, there may be a bias against publishing research that shows a negative or no significant effect.[141]

■ ETHANOL

Chronic ethanol use during pregnancy produces a constellation of fetal effects. The most severe effects are seen in the fetal alcohol syndrome (FAS), which is characterized by (1) intrauterine or postnatal growth retardation, (2) mental retardation or behavioral abnormalities, and (3) facial dysmorphogenesis, particularly microcephaly, short palpebral fissures, epicanthal folds, maxillary hypoplasia, cleft palate, hypoplastic philtrum, and micrognathia.[30,173] A child can be diagnosed with FAS even when a history of regular gestational alcohol use cannot be confirmed.

In an attempt to formalize diagnostic criteria for FAS and other gestational-alcohol-related effects, the Institute of Medicine proposed some additional descriptors which are in common use.[269] *Partial FAS* is applied to a child with some of the characteristic facial features and with either growth retardation, neurodevelopmental abnormalities, or other behavioral problems. *Alcohol-related birth defects* are congenital anomalies other than the characteristic facial features described above, for example, cleft palate, which are sometimes seen with regular gestational alcohol use. *Alcohol-related neurodevelopmental disorder* describes neurodevelopmental abnormalities or other behavioral problems, which are sometimes seen with regular gestational alcohol use. Fetal alcohol spectrum disorders (FASD) is an umbrella term describing the range of effects that can occur in an individual whose mother drank alcohol during pregnancy.[30,263]

Differential expression of the syndrome may reflect the effects of varying quantities of ethanol ingested at critical periods specific for particular effects. The craniofacial anomalies probably represent teratogenic effects during organogenesis, whereas some central nervous system abnormalities and growth retardation may result from adverse effects later in gestation.

There is considerable controversy about what level of alcohol consumption can cause fetal alcohol spectrum disorder.[193,203] Approximately 10% of women consume some alcohol during pregnancy, 2% are frequent users and 2% binge. Of women who might become pregnant, about 50% drink some alcohol, 13% drink frequently, and 12% binge.[50] Some researchers believe that the fetal alcohol spectrum disorder is a result of alcoholism—chronic regular use or frequent binging—rather than to low levels of gestational ethanol exposure, no matter how little or how infrequent.[4,104] A high level of consumption would be in the range of 50 to 100 mL of 100% ethanol (four to six "standard" drinks of hard liquor) regularly throughout pregnancy[269] or binge drinking (at least five standard drinks per occasion), with a significantly elevated peak blood ethanol concentration.[3,170] On the other hand, some behavioral abnormalities have been associated with the reported consumption of as little as one drink per week.[264] In this regard, neither a no-effect amount nor a safe amount of ethanol use in pregnancy has been determined[129] and therefore the US Surgeon General recommends no alcohol consumption during pregnancy.[205]

The incidence of FAS is 0.5 to 3 per 1000 live births; 4% of women who drink heavily may give birth to children with FAS.[2,181] This means that several hundred children with FAS and several thousand with fetal alcohol effects will be born each year; ethanol use is considered the leading preventable cause of mental retardation in this country.[269] Although the primary determinant of FAS and its effects is the level of maternal ethanol consumption, there is some evidence that paternal ethanol exposure may play a contributing role.[1]

Ethanol use during pregnancy may lead to an increased incidence of spontaneous abortion, premature deliveries, stillbirths,[171] neonatal ethanol withdrawal,[25,199] and possibly carcinogenesis.[137] Infants may be irritable or hypertonic and may have problems with habituation and arousal. Long-term behavioral and intellectual effects include decreased IQ, learning disability, memory deficits, speech and language disorders, hyperactivity, and dysfunctional behavior in school.[180,264,270]

Brain autopsies of children with FAS demonstrate malformations of gray and white matter, a failure of certain regions such as the corpus callosum to develop, a failure of certain cells such as the cerebellar astrocytes to migrate, and a tendency for tissue in certain regions to die.[86] The mechanisms of ethanol-induced teratogenesis are not fully elucidated.[26,109] Much of the work in animals has focused on the developing nervous system, where ethanol adversely affects nerve cell

growth, differentiation, and migration, particularly in areas of the neocortex, hippocampus, sensory nucleus, and cerebellum.[106,272]

Several mechanisms are potential contributors to the effects of ethanol.[103] Ethanol interferes with a number of different growth factors, which may affect neuronal migration and development.[296] In addition, ethanol interferes with the development and function of both serotonin and *N*-methyl-D-aspartate (NMDA) receptors. Ethanol, or its metabolite acetaldehyde, may also cause necrosis of certain cells directly or through the generation of free radicals and excessive apoptosis.[59,86,113] In particular, craniofacial abnormalities may be related to apoptosis of neural crest cells through the formation of free radicals, a deficiency of retinoic acid, or the altered expression of homeobox genes which regulate growth and development.[272]

One integrative model of ethanol-induced teratogenesis proposes that sociobehavioral risk factors, such as drinking behavior, smoking behavior, low socioeconomic status, and cultural/ethnic influences, create provocative biologic conditions, such as high peak blood ethanol concentrations, circulating tobacco constituents, and undernutrition. These provocative factors exacerbate fetal vulnerability to potential teratogenic mechanisms, such as ethanol-related hypoxia or free radical–induced cell damage.[5]

■ OPIOIDS

Opioid use in pregnancy remains a significant cause of both maternal and neonatal morbidity. In past month surveys, heroin use is reported by approximately 0.1% of pregnant women,[204] and up to 75,000 babies per year may be exposed to methadone or heroin in utero.[194] Almost all clinical research regarding opioid toxicity during pregnancy relates to the use of heroin or methadone, although recent surveys indicate that approximately 0.1% of women use oxycodone (OxyContin) during pregnancy and the lay press has begun to report on fetal OxyContin exposure.[204,234]

Pregnant opioid users are at increased risk for many medical complications of pregnancy, such as hepatitis, sepsis, endocarditis, sexually transmitted diseases, and AIDS, and may be at increased risk for obstetric complications, such as miscarriage, premature delivery, or stillbirth.[89,102] Some of the obstetric complications may be related to associated risk factors in addition to the opioid use.

Maternal opioid use most commonly affects fetal growth.[89,102,303] There is an increased incidence of low birth weight in babies born to opioid-using mothers, compared to controls, and the effect is greater for heroin than for methadone. Women who receive low-dose methadone and good prenatal care have birth outcomes similar to nonusers, but they are at increased risk for pregnancy-related complications.[89]

The most significant acute neonatal complication of opioid use during pregnancy is the neonatal withdrawal syndrome (NWS), characterized by hyperirritability, gastrointestinal dysfunction, respiratory distress, and vague autonomic symptoms, including yawning, sneezing, mottling, and fever (Table 30–4).[13] Myoclonic jerks or seizures may also signify neurologic irritability. Withdrawing infants are recognizable by their extreme jitteriness, despite efforts at consolation; ecchymoses and contusions may be found on the tips of their fingers or toes, as a result of trauma from striking the sides of the bassinet. From 60% to 90% of methadone, heroin, and probably other chronic opioid-exposed offspring will show some signs of withdrawal.[89]

Some of the manifestations of the neonatal withdrawal syndrome may be caused by enhanced α-adrenergic activity in the locus coeruleus. Firing of neurons in this region of the brain leads to such NWS-like behaviors as wakefulness and tremors—effects that are inhibited by opioid agonists. Chronic opioid administration leads to tolerance, as well as an increased number of α_2-adrenergic receptors.

Table 30–4. Signs and Symptoms of Neonatal Opioid Withdrawal

Neurologic Excitability	Gastrointestinal Dysfunction	Autonomic Signs
Exaggerated Moro reflex	Dehydration	Fever
Frequent yawning and sneezing	Diarrhea	Increased sweating
High-pitched crying	Poor feeding	Mottling
Hyperactive deep tendon reflexes	Poor weight gain	Nasal stuffiness
Increased muscle tone	Uncoordinated and constant sucking	Temperature instability
Increased wakefulness		
Irritability	Vomiting	
Seizures		
Tremors		

Reproduced with permission from the Committee on Drugs. Neonatal drug withdrawal. *Pediatrics*. 1998;101:1079–1088.

Presumably, withdrawal of opioids causes increased stimulation of a large number of receptors in this region, leading to clinical signs of withdrawal.

Opioid withdrawal symptoms typically occur within 2 weeks of birth. Heroin withdrawal usually occurs within the first 24 hours; however, methadone withdrawal may be delayed because it has a larger volume of distribution and slower metabolism in the neonate, and therefore an increased half-life. In one study, methadone withdrawal occurred when the plasma concentration fell below 0.06 mg/mL.[232] The onset and severity of symptoms may be related to whether heroin, methadone, or both were used; how much was used chronically; how much was used near the time of delivery; the character of the labor; whether analgesics or anesthetics were used; and the maturity, nutrition, and medical condition of the neonate.[72] Acute neonatal withdrawal symptoms generally last from days to weeks, but some symptoms may persist for months.[13]

From 5% to 7% of babies showing signs of withdrawal experience seizures, generally by 10 days after birth.[114] Seizures may be more likely after methadone withdrawal than after heroin withdrawal.[302] These seizures do not necessarily predispose to idiopathic epilepsy; in one small study, children who had withdrawal seizures were normal at 1-year follow-up.[75]

Treatment of withdrawal begins by providing a comforting environment: swaddling or tightly wrapping the infant, minimal handling or stimulation, and demand feeding. More severe symptoms may require pharmacologic therapy. One way of determining the need for therapy is the application of a severity-scoring scale. In general, babies who are extremely irritable; have feeding difficulties, diarrhea, or significant tremors; or are crying continuously are candidates for pharmacologic therapy.[11,131]

Opioid agonists such as morphine, methadone, tincture of opium and paregoric, and sedative-hypnotic agents such as diazepam and phenobarbital have been used to treat withdrawal symptoms.[11,131] Tincture of opium, diluted to a final dose of 0.4 mg/mL of morphine equivalent, may be preferred because it is a pure opioid agonist, and the formulation has no additives. However, there are few well-controlled trials evaluating the relative efficacy of the different agents.[89]

Opioid agonists may be more effective at preventing withdrawal seizures from heroin or methadone than from phenobarbital or diazepam.[114,132] However, sedative-hypnotics are commonly used by

heroin users or adults maintained on methadone, and sedative-hypnotic withdrawal seizures may contribute to the overall neonatal abstinence symptomatology. In this setting there may be a role for phenobarbital. Because oral administration of phenobarbital may delay achieving a therapeutic concentration, parenteral administration may be required.

Infants of opioid-using mothers have a two to three times increased risk for SIDS compared to controls.[133,134] The mechanism may be related to a decreased medullary responsiveness to CO_2, or the effect may be related to some condition of the postnatal environment.[89]

Although young children born to opioid users do not seem to have significant differences in behavior compared to controls, older children have increased learning problems and school dysfunction particularly related to behavior difficulties.[303]

■ COCAINE

Approximately 1% of pregnant women in the United States use cocaine at some time during their pregnancy.[194] The rate may be as high as 15% in certain populations,[70] and it is estimated that more than 100,000 infants born in the United States each year may be exposed to cocaine in utero.[54] The consequences of cocaine use during pregnancy have been extensively reviewed.[118,211,253]

The incidence of abruptio placentae may be significant when related to acute cocaine use.[257] Some uncommon perinatal problems include seizures, cerebral infarctions, and other CNS effects.[57,211]

Cocaine use is significantly related to decreases in gestational age, birth weight, length, and head circumference, although these growth parameters generally correct by several years of age.[253] In addition, these growth effects are exacerbated by concomitant alcohol, tobacco, and opiate use.[253] Good prenatal care can mitigate many of these adverse effects of cocaine.[166,222,303]

Significant congenital malformations were reported among some infants who were exposed to cocaine in utero, specifically genitourinary malformations, cardiovascular malformations, and limb-reduction defects.[46,93] However, in one large population-based study, there was no increase in the incidence of malformations.[176]

Teratogenic effects have been observed in animal models of in utero cocaine exposure. Decreased maternal and fetal weight gain and an increased frequency of fetal resorption were demonstrated in rats[85]; sporadic physical anomalies have also been observed.[58] Teratogenic effects similar to those observed in humans were reported in mice: bony defects of the skull, cryptorchidism, hydronephrosis, ileal atresia, cardiac defects, limb deformities, and eye abnormalities.[90,167,168,186] Cocaine caused hemorrhage and edema of the extremities and, subsequently, limb-reduction defects in rats when administered during midgestation in the postorganogenic period.[290]

The perinatal effects of cocaine are probably mediated through a vascular mechanism. Cocaine administration in the pregnant ovine model causes increased uterine vascular resistance, decreased uterine blood flow, increased fetal heart rate and arterial blood pressure, and decreased fetal PO_2 and O_2 content.[19,298] Similar effects have been seen in rats.[208] Fetal hypoxia may cause rupture of fetal blood vessels and infarction in developing organ systems such as the genitourinary system[56,186,262] or the CNS.[55,74,291] Hyperthermia or direct effects of cocaine in the fetus may exacerbate these effects.[38] Limb-reduction defects similar to those attributed to cocaine have been produced after mechanical clamping of the uterine vessels.[38,292] A developing concept is that following vasospasm and ischemia, reperfusion occurs with the generation of oxygen free radicals and subsequent injury.[298,299]

Despite the reported malformations and a possible mechanism, neither the human epidemiology nor the effects observed in animal

models suggest a specific teratogenic syndrome. The risk of a significant malformation from prenatal cocaine exposure is low, but the effect, if one occurs, may be severe.[40,80,93]

One of the greatest concerns about prenatal cocaine exposure is the potential adverse effect on the developing child, and this is an intensive area of epidemiologic research. The most common findings in early infancy are lability of behavior and autonomic regulation, decreased alertness and orientation, and abnormal reflexes, tone, and motor maturity; however, many studies show no effect especially after controlling for confounding variables.[84,253] For some children, effects may manifest in later infancy as difficulty with information processing and learning. For school-age children, observed cognitive deficits may also be related to the home environment, even for those children who showed some of the typical neonatal behaviors.[91,253] Nonetheless, there is evidence of impairment in modulating attention and impulsivity, which makes handling unfamiliar, complex, and stressful tasks more difficult,[183,253] and these effects are also observed in animal models of prenatal cocaine exposure.[80,111,158,265]

The mechanism of neurotoxicity has not been specifically elucidated. As described above, for many of the maternal and fetal physical defects, cocaine may have direct toxicity or, alternatively, effects may be mediated through hypoxia or oxygen free radicals. Because cocaine interferes with neurotransmitter reuptake, it is likely that cocaine also disrupts normal neural ontogeny by interfering with the trophic functions of neurotransmitters on the developing brain, in particular dysfunction of signal transduction via the dopamine D1 receptor.[111,158,172,182] These mechanisms may be more important in the etiology of neurobehavioral effects.

BREAST-FEEDING

In the United States, breast-feeding is the recommended method of infant nutrition because it offers nutritional, immunologic, and psychological benefits. Many women use prescription and nonprescription xenobiotics while breast-feeding, and are concerned about the possible ill effects on the infant of these xenobiotics in the breast milk. This concern extends to the possible exposure of the infant to occupational and environmental xenobiotics via breast milk.[229,248] The response to many of these concerns can be determined by the answer to the following question: Does the risk to an infant from a xenobiotic exposure via breast milk exceed the benefit of being breast-fed?[152]

Pharmacokinetic factors determine the amount of xenobiotic available for transfer from maternal plasma into breast milk; only free xenobiotic can traverse the mammary alveolar membrane. Most xenobiotics are transported by passive diffusion. A few xenobiotics, such as ethanol and lithium, are transported through aqueous-filled pores. The factors that determine how well a xenobiotic diffuses across the membrane are similar to those for other biologic membranes such as the placenta: molecular weight, lipid solubility, and degree of ionization.

Large-molecular-weight xenobiotics, such as heparin or insulin, will not pass into breast milk. Lipid solubility is important not only for diffusion but also for xenobiotic accumulation in breast milk, because breast milk is rich in fat, especially breast milk that is produced in the postcolostral period (approximately 3 to 4 days postpartum). With a pH near 7.0, breast milk is slightly more acidic than plasma. Consequently, xenobiotics that are weak acids in plasma exist largely as ionized molecules and cannot be easily transported into milk. Conversely, xenobiotics that are weak bases exist in plasma largely as nonionized molecules and are available for transport into breast milk. Once in the breast milk, ionization of the weak base xenobiotics occurs, and the xenobiotic is concentrated as a result of ion trapping. In other words, xenobiotics that are weak bases may concentrate in breast milk.

Sulfacetamide (pK$_a$ 5.4, a weak acid) has a concentration in plasma 10 times its concentration in breast milk, whereas sulfanilamide (pK$_a$ 10.4, a weak base) is found in equal concentrations in both plasma and breast milk.[152]

The net effect of these physiologic processes is expressed in the milk-to-plasma (M/P) ratio. Xenobiotics with higher M/P ratios have relatively greater concentrations in breast milk. The M/P ratio does not, however, reflect the absolute concentration of a xenobiotic in the breast milk, and a xenobiotic with a high M/P *ratio* is not necessarily found at a high *concentration* in the breast milk. For example, morphine has an M/P ratio of 2.46 (is concentrated in breast milk), but only 0.4% of a maternal dose is excreted into the breast milk.[18] In general, for most pharmaceuticals, approximately 1% to 2% of the maternally administered dose is presented to the infant in breast milk.[152]

The M/P ratio has several limitations. It does not account for differences in xenobiotic concentration that may result from (1) repeat or chronic dosing, (2) breast-feeding at different times relative to maternal xenobiotic dosing, (3) differences in milk production during the day or even during a particular breast-feeding session, (4) the time postpartum (days, weeks, or months) when the measurement is made, and (5) maternal disease.

While being cognizant of the limitations, a spot breast milk xenobiotic concentration or a concentration estimate based on the M/P ratio allows a simplistic estimation of the quantity of xenobiotic to which an infant is exposed, assuming a constant breast-milk concentration:

Infant dose = Breast-milk concentration × amount consumed

The effect of this dose on the infant depends on the bioavailability of the xenobiotic in breast milk, the pharmacokinetic parameters that determine xenobiotic concentrations in the infant, and the infant's receptor sensitivity to the xenobiotic. These parameters are often different in neonates than in adults and may lead to xenobiotic accumulation; generally, absorption is greater, but metabolism and clearance are reduced.[17] These effects are exaggerated in premature infants.[216,226] The amount of most xenobiotics delivered to infants in breast milk is usually adequately metabolized and eliminated.[152]

Many of the considerations above are theoretical, and the number of specifically contraindicated xenobiotics is quite small.[14] Published guidelines on the advisability of breast-feeding during periods of maternal therapy are generally based on the expected effects of full doses in the infant or on case reports of adverse occurrences. Interestingly, when the reports of adverse effects were reviewed, 37% of cases were in infants younger than 2 weeks old, 63% were in infants younger than 1 month old, and 78% were in infants younger than 2 months old; 18% were in infants 2 to 6 months old; and only 4% were in infants older than 6 months.[15] It seems, therefore, that adverse effects are most likely to be observed in the first few weeks of life, when an infant's metabolic capacity is only 20% to 40% that of an adult.[8]

Every few years the American Academy of Pediatrics (AAP) publishes recommendations regarding breast-feeding in the setting of xenobiotic exposure. In the latest revision, the AAP continues to discourage the use of xenobiotics such as cocaine or heroin during the breast-feeding period because of direct effects on the baby, as well as detrimental effects on the physical and emotional health of the mother and on the caregiving environment.[14] Although ethanol is not specifically contraindicated for the breast-feeding mother, decreased milk production and adverse effects in the infant are noted with maternal consumption of large amounts of ethanol.[152]

The AAP recommends the temporary cessation of breast-feeding when the mother is exposed to metronidazole, an in vitro mutagen, or to certain radiopharmaceuticals, specifically isotopes of copper, gallium, indium, iodine, sodium, and technetium. In these cases,

breast milk can be collected and stored before medication use for later feeding to the baby. Breast-feeding is resumed when the milk is no longer radioactive, generally 1 to 3 days for most of the isotopes mentioned except gallium, after which radioactivity may be present for 2 weeks. Metronidazole can be administered as a single 2-g dose, allowing breast-feeding to be discontinued for only 12 to 24 hours.[152]

Although there are few data demonstrating specific effects, the AAP suggests caution with regard to breast-feeding while using sedative-hypnotics, antidepressants, and antipsychotics. These medications modulate neurotransmitters in the CNS, which can adversely affect the developing nervous system.

For most xenobiotics, a risk-to-benefit analysis must be made. For example, lithium is transferred in breast milk and may lead to measurable, although subtherapeutic, serum concentrations in the breast-fed infant. Although the effects of such exposure to lithium are unknown, many practitioners believe that the benefit of treating a mother's bipolar illness outweighs the potential risk to the infant.[152,247]

Similarly, the breast-fed infant of a woman who smokes is exposed to nicotine and other tobacco constituents, both by inhalation and via breast milk. Although this child may be at increased risk for respiratory illness as a result of exposure to tobacco smoke, some of the risk may be reduced by breast feeding.[14,224]

Many xenobiotics, including pharmaceuticals, foods, and environmental xenobiotics, have been found in breast milk, and Table 30–5 lists some of their effects. In addition to the effects listed, there may be a small increased risk of carcinogenicity associated with exposure to some environmental xenobiotics through breast milk.[229]

In most cases, women do not need to stop breast-feeding while using pharmaceuticals, such as most common antibiotics. However, "compatibility" with breast-feeding is generally based on a lack of reported adverse effects, which may reflect limited clinical experience with a particular xenobiotic in breast-feeding patients. Therefore, in the setting of limited information, exposure to a xenobiotic through breast milk should be regarded as a small potential risk, and the infant should receive appropriate medical follow-up. Not all "compatible" medications are safe in all situations. For instance, phenobarbital can produce CNS depression in an infant if the mother's serum concentration is in the high therapeutic or supratherapeutic range, which often occurs while dosage adjustments are being made. Such a concentration may or may not produce CNS depression in the mother. Nalidixic acid, nitrofurantoin, sulfapyridine, and sulfisoxazole, although generally safe, can cause hemolysis in a breast-fed infant with glucose-6-phosphate dehydrogenase deficiency.

Decisions on breast-feeding should be made with the informed involvement of the woman, her physicians and, when necessary, a consultant with special expertise in this field. Guidelines are available from several sources.[28,42,152,190]

TOXICOLOGIC PROBLEMS IN THE NEONATE

Physiologic differences between adults and newborn infants affect xenobiotic absorption, distribution, and metabolism.[17,135,287] Appropriate administration of xenobiotics to newborn infants therefore requires an understanding of the appropriate developmental state for medication dosing and pharmacokinetics. Even so, approximately 8% of all medication doses administered in neonatal intensive care units (NICUs) may be up to 10 times greater or lesser than the dose ordered,[62] and as many as 30% of newborns in NICUs may sustain adverse drug effects, some of which may be life threatening or fatal.[18] Pharmacokinetic differences between adults and newborns may account for some cases of unanticipated xenobiotic toxicity seen in the newborn infant.

Table 30–5. Xenobiotics Associated With Effects on Some Nursing Infants

Xenobiotic	Effect
Use With Caution	
5-Aminosalicylic acid	Diarrhea
Acebutolol, atenolol, nadolol, sotalol, timolol	Hypotension, bradycardia, tachypnea, cyanosis
Amiodarone	Possible hypothyroidism
Antineoplastics: Cyclophosphamide, cyclosporine, doxorubicin, methotrexate	Neutropenia, thrombocytopenia, ? immune suppression; ? effect on growth or carcinogenesis
Aspirin	Metabolic acidosis; may affect platelet function; rash
Bromocriptine	Suppresses lactation
Chloramphenicol	Potential risk for aplastic anemia or gray-baby syndrome[131]
Chlorpromazine	Galactorrhea in mother; drowsiness and lethargy in infant; decline in developmental scores
Cimetidine	Possible antiandrogenic effects[152]
Clemastine	Drowsiness, irritability, refusal to feed, high-pitched cry, meningismus
Clofazimine	Possible increased skin pigmentation
Codeine	CNS and respiratory depression
Ergotamine	Vomiting, diarrhea, seizures; may inhibit prolactin secretion and lactation
Fluoxetine	Colic, irritability, feeding and sleeping disorders, slow weight gain
Haloperidol	Decline in developmental scores
Lamotrigine	Potential therapeutic serum concentrations in infant
Lithium	Subtherapeutic concentrations in infant
Metronidazole, tinidazole	In vitro mutagen
Phenindione	Risk of hemorrhage
Phenobarbital	Sedation, withdrawal after weaning from phenobarbital-containing milk; methemoglobinemia
Primidone	Sedation, feeding problems
Propylthiouracil, methimazole	May cause thyroid suppression and goiter[152]
Salicylates	Metabolic acidosis; may affect platelet function; rash
Sulfapyridine, sulfisoxazole	Caution in infant with jaundice or G6PD deficiency and in ill, stressed, or premature infant
Sulfasalazine	Bloody diarrhea
Tetracycline	May cause staining of infant teeth after prolonged maternal use[131]
Use Is Compatible With Breast-Feeding Despite Known Effect	
Ethanol	Large doses: ↓ milk ejection reflex. Infant: drowsiness, diaphoresis, ↓ growth and weight gain
Bendroflumethiazide	Suppresses lactation
Caffeine	Irritability, poor sleeping pattern (no effect with usual amount of caffeinated beverages)
Carbimazole	Goiter
Chloral hydrate	Sleepiness
Chlorthalidone	Excreted slowly
Contraceptive pills with estrogen/progesterone	Rare breast enlargement; decrease in milk production and protein content (unconfirmed)
Danthron	Increased bowel activity
Dexbrompheniramine maleate with *d*-isoephedrine	Crying, irritability, poor sleeping pattern
Estradiol	Withdrawal vaginal bleeding
Indomethacin	Seizure
Iodine topical	Odor of iodine on infant's skin
Iodine, iodides	Goiter
Methyprylon	Drowsiness
Nalidixic acid	Hemolysis in infant with G6PD deficiency
Nitrofurantoin	Hemolysis in infant with G6PD deficiency
Phenytoin	Methemoglobinemia
Theophylline	Irritability
Specific Risk Categories	
Aspartame	Caution if mother has phenylketonuria
Chocolate (theobromine)	Irritability or increased bowel activity if mother consumes large amounts
Fava beans	Hemolysis in infant with G6PD deficiency
Hexachlorobenzene	Skin rash, diarrhea, vomiting, dark urine, neurotoxicity, death
Lead	Possible neurotoxicity
Methylmercury, mercury	Possible neurodevelopmental toxicity
Polyhalogenated biphenyls	Lack of endurance, hypotonia, sullen expressionless facies
Silicone	Esophageal dysmotility
Tetrachloroethylene	Obstructive jaundice, dark urine
Vegetarian diet	Vitamin B_{12} deficiency

GI absorption of xenobiotics in the neonate is generally slower than in adults.[17,135,287] This delay may be related to decreased gastric acid secretion, decreased gastric emptying and transit time, and decreased pancreatic enzyme activity. The GI environment of the newborn and young infant may allow the growth of *Clostridium botulinum* and the subsequent development of infantile botulism (see Chap. 46). Infantile botulism has been reported in infants several weeks of age.[122,277]

Although it is uncommon, cutaneous absorption of xenobiotics may be a route of toxic exposure in the newborn.[82,240] Aniline dyes used for marking diapers are absorbed, causing methemoglobinemia,[240] and contaminated diapers were responsible for one epidemic of mercury poisoning.[22] The absorption of hexachlorophene antiseptic wash has led to neurotoxicity with marked vacuolization of myelin seen microscopically.[149,177,258] The dermal application of antiseptic ethanol has caused hemorrhagic necrosis of the skin of some premature infants. Iodine antiseptics have led to hypothyroidism in mature newborns.[51] Increased potential for absorption and toxicity has followed the application of corticosteroids[98,238] and boric acid[81] to the skin of children with cutaneous disorders.

Other routes of exposure have led to clinical poisoning. Several children aspirated talcum powder and died.[43,192] Inhalation of mercury from incubator thermometers may be a potential risk.[12] One child died following the ophthalmic instillation of cyclopentolate hydrochloride.[24]

Because of differences in total body water and fat compared to the adult, the distribution of absorbed xenobiotics may differ in neonates.[17,135,287] Water represents 80% of body weight in a full-term baby, compared to 60% in an adult. Approximately 20% of a term baby's body weight is fat, compared to only 3% in a premature baby. The increased volume of water means that the volume of distribution for some water-soluble xenobiotics, such as theophylline or phenobarbital, is increased.

Protein binding of xenobiotics is reduced in newborns compared to adults: the serum concentration of proteins is lower, there are fewer receptor sites that become saturated at lower xenobiotic concentrations, and binding sites have decreased binding affinity.[17,135,287] Protein binding has potential relevance with respect to bilirubin, an endogenous metabolite that at very high concentrations can cause kernicterus; bilirubin competes with exogenously administered xenobiotics for protein binding sites. In vitro, certain xenobiotics, such as sulfonamides and ceftriaxone, displace bilirubin from protein receptor sites, which might increase the risk of kernicterus, although this has not been clinically demonstrated. Conversely, bilirubin may itself displace other xenobiotics, such as phenobarbital or phenytoin, leading to increased plasma xenobiotic concentrations.

Newborn infants have decreased hepatic metabolic capacity compared with adults, which may lead to xenobiotic toxicity.[17,135] For example, caffeine, used in the treatment of neonatal apnea, has an extremely prolonged half-life in newborns because CYP1A2 has only 5% of the normal adult activity.[17] Except for CYP1A2, most of the CYP enzymes reach approximately 25% of adult activity in newborns by about 1 month of age.

Two syndromes related to immature metabolic function have been described. The "gasping baby syndrome," characterized by gasping respirations, metabolic acidosis, hypotension, central nervous system depression, convulsions, renal failure, and occasionally death, is attributed to high concentrations of benzyl alcohol and benzoic acid in the plasma of affected infants.[11,45,99] Benzyl alcohol, a bacteriostatic agent, was added to intravenous flush solutions and accumulated in newborns after repetitive doses. The high concentrations of benzoic acid could not be further metabolized to hippuric acid by the immature liver. Immature glucuronidation in the neonate is responsible for the "gray-baby syndrome" following high doses of chloramphenicol (Chaps. 31 and 55).[117]

The umbilical vessels are a common site of vascular access in sick neonates. Because blood drains into the portal vein, it is possible that IV medications experience a "first-pass" effect, although whether this route of xenobiotic administration affects metabolism or clearance has not been well studied. Most renal functions, including glomerular filtration rate and tubular secretion, are relatively immature at birth[17]; the glomerular filtration rate of the newborn is approximately 30% of that of an adult. Xenobiotics such as aminoglycosides and digoxin are excreted unchanged by the kidney and, therefore, depend on glomerular filtration for clearance. Dosing of these xenobiotics in the newborn must account for these differences.

An interesting association has been made periodically over the years between the use of erythromycin, particularly in the first 2 weeks of life, and idiopathic hypertrophic pyloric stenosis.[61,119,169,242,266] Although erythromycin is known to interact with motilin receptors in the antrum of the stomach, no specific etiology has been defined.[112]

Very little information is available to guide the clinician in the management of xenobiotic poisoning in the newborn infant. Cutaneous absorption is probably already complete by the time toxicity is noted, although further exposure may be prevented. Gastrointestinal decontamination is not generally performed in neonates, and the neonate may be at increased risk of fluid, electrolyte, and thermoregulatory problems following gastric lavage or the use of cathartic agents. Multiple-dose activated charcoal was used in a 1.4-kg 2-week-old premature infant to treat theophylline poisoning.[254] Hemodialysis, hemoperfusion, and exchange transfusion are used in neonates to treat xenobiotic toxicity (Chaps. 9 and 31).

SUMMARY

The use of xenobiotics in the pregnant or breast-feeding woman is a complex area of medical practice and presents the clinician with potentially difficult management decisions. This chapter highlights some of the important principles of xenobiotic effects in both the pregnant woman and the fetus. Appropriate management of many of the potential problems will be facilitated by the coordinated efforts of obstetricians, perinatologists, neonatologists, pediatricians, and toxicologists.

CHAPTER 31
PEDIATRIC PRINCIPLES

Jeffrey S. Fine

Phone calls to poison centers regarding childhood exposures to potential xenobiotics are more frequent than those regarding any other age group. Because of this and the frequent role of poisoning as a cause of pediatric injury, pediatricians have been active for many years in helping to establish and promote the study of medical toxicology, as well as in establishing and supporting the use of regional poison centers. Although the basic approaches to the medical management of toxicologic problems outlined in Chapters 3 and 4 are generally applicable to both children and adults, issues, such as abuse by poisoning, are of particular concern in children. This chapter provides a pediatric perspective to the application of generally accepted toxicologic principles.

EPIDEMIOLOGY

To analyze the problem of pediatric poisoning, it is necessary to understand the magnitude of the problem. When assessing the impact of a particular type of injury such as poisoning, epidemiologists examine multiple parameters, such as exposure, morbidity, mortality, and cost, to measure the effect of the injury; however, these parameters are difficult to measure accurately. An important source for information on the extent and effects of poisoning exposures in the United States is the American Association of Poison Control Centers (AAPCC). Every year, the AAPCC compiles standardized data collected from poison centers throughout the United States; the 2007 annual review includes information submitted by 61 poison centers. In the following discussion, comments on AAPCC data refer to cumulative information from the previous five published reports covering the years 2003 to 2007 (see Chap. 135)

Each year, the AAPCC reports approximately 1.6 million potentially toxic exposures in children and adolescents ages 0 to 19 years, which account for 65% of all reported exposures. In fact, children younger than age 6 years account for 52% of all reported exposures. Of the reported exposures in children and adolescents, children younger than age 6 years account for 79%, children between 6 and 12 years of age account for 10%, and adolescents between 13 and 19 years of age account for 11%. Girls represent 47% of the reported poisoning exposures in young children and 55% of the reported exposures among adolescents.

Among the AAPCC-reported xenobiotic exposures in children younger than age 6 years, 99% are labeled unintentional. In contrast, only 48% of the reported adolescent exposures are unintentional; 47% exposures in adolescents are labeled intentional, mostly resulting from substance use or suicide attempts. The high frequency of intentional poisoning in adolescents has been reported by others.[35,150,199] The remaining 5% of adolescent exposures include adverse drug events and other miscellaneous or unknown causes. Differences in the reasons for exposure between young children and adolescents account for differences in the outcomes of these exposures.

Approximately 118,000 xenobiotic exposures each year are classified by the AAPCC as therapeutic errors, accounting for approximately 6% of exposures in children younger than 6 years of age, 21% in children 6 to 12 years of age, and 9% in adolescents. An additional 13,000 exposures each year are classified as adverse drug reactions, which account for approximately 0.4% of exposures in children younger than 6 years of age, 2% in children 6 to 12 years of age, and 3% in adolescents.

Table 31–1 shows the leading causes of reported exposures in children and adolescents. According to the AAPCC, approximately 55% of childhood exposures are to xenobiotics that are commonly found around the house, such as cleaning products, cosmetics, plants, hydrocarbons, and insecticides; approximately 45% are to pharmaceuticals. In older children and adolescents, approximately 47% of exposures are to nonpharmaceutical xenobiotics, and approximately 53% are to pharmaceuticals. Most hospitalizations and deaths in both groups are caused by pharmaceuticals.

Table 31–1 lists the most common reported *exposures*, but not all of these xenobiotics lead to serious morbidity and mortality (Table 31–2). For example, children frequently ingest cosmetic products, so the number of reported exposures is large, but most cosmetics manufactured in the United States are nontoxic. Poisoning is unusual in children younger than age 6 months but may result from the inadvertent administration of an incorrect drug or drug dose by a parent,[38,61] intentional administration of a drug by a parent or sibling,[46,79] or passive exposure (eg, to the smoke of "crack" cocaine or phencyclidine).[16,78,133,173,208] Any poisoning in a child younger than 1 year of age should be carefully evaluated for possible child abuse or neglect (see below).[79]

Several typical characteristics associated with ingestions by toddlers differentiate them from ingestions by adolescents or adults: (1) they are without suicidal intent; (2) there is usually only one xenobiotic involved; (3) the xenobiotics are usually nontoxic; (4) the amount is usually small; and (5) toddlers usually present for evaluation relatively soon after the ingestion is discovered, generally within 1 to 2 hours. As many as 30% of children who experience one ingestion will experience a repeat ingestion; adolescents may be particularly prone to recidivism.[62,89] Children who ingest poisons may also be at a greater risk for other types of injuries.[14,52]

The peak age for childhood poisoning is between 1 and 3 years.[30] Unintentional ingestion is unusual after age 5 years, although when it occurs it can be the result of mistaken consumption of a xenobiotic from a mislabeled container.[26] Between the ages of 5 and 9 years, poisoning may result from intrafamilial stress or suicidal intent. After age 9 years and through adolescence overdose or poisoning frequently results from either suicidal gestures and attempts, or from the adverse effects of alcohol or substance use. Unintentional poisonings are largely preventable. (see Chap. 135)

Because many children are exposed to nontoxic xenobiotics or to only small amounts of potentially toxic xenobiotics, the proportion of children and adolescents who suffer significant morbidity is small (Table 31–3). However, because there are millions of such exposures each year, the number of children and adolescents who experience at least moderate effects is large.

Another source of data related to poisoning morbidity is the National Injury Surveillance database maintained by the United States Centers for Disease Control and Prevention (CDC), which provides information on emergency department (ED) visits and hospitalizations.[31] For the period 2001 to 2007, the CDC estimates approximately 66,000 ED visits (274 per 100,000) and 6300 hospitalizations (10%) per year for children 0 to 5 years who were exposed to a xenobiotic. Children 6 to 12 years accounted for 12,000 ED visits (38 per 100,000) and 1900 hospitalizations (16%), and adolescents 13 to 19 years old account for 103,000 ED visits (198 per 100,000) and 36,000 hospitalizations (35%). Approximately 80% of the patients hospitalized were adolescents, and approximately 75% of those cases were intentional poisonings.

These numbers are consistent with estimates of 100,000 to 170,000 ED visits for poisoning and overdose per year, or approximately 300 to 840

TABLE 31–1. Average Annual Xenobiotic Exposures Reported to the American Association of Poison Control Centers (2003–2007)[a]

Age <6 Years		Age 6–19 Years	
Category	Number of Exposures	Category	Number of Exposures
Cosmetics and personal care items	165,637	Analgesics	46,047
Cleaning substances	119,500	Cough and cold preparations	20,510
Analgesics	98,743	Cosmetics and personal care items	17,412

[a] Data from Litovitz T, Manoguerra A: Comparison of pediatric poisoning hazards: an analysis of 3.8 million exposure incidents. *Pediatrics.* 1992;89:999–1106.

[b] Major effect is defined as life-threatening signs and symptoms or significant residual disability or disfigurement.

[c] Data from American Association of Poison Control Centers (AAPCC),2003–2007.

[d] The AAPCC does not report specific outcomes other than death, by age, for individual xenobiotics; consequently, the number of major effects cannot be calculated from annual reports.

TABLE 31–3. Outcome of Reported Pediatric Xenobiotic Exposures (2003–2007)[a]				
	Effects (% of Reported Exposures)[b]			
Age (years)	Minor or None	Moderate	Major	Death
0–5	99	1	0.05	0.003
6–12	97	3	0.15	0.008
13–19	88	11	1	0.04
All children and adolescents 0–19	97	2	0.19	0.008

[a] See Chap. 135 for references and discussion.

[b] Minor = minimal signs and symptoms often not requiring therapy; moderate = more pronounced, prolonged, or systemic signs and symptoms often requiring therapy; major = life-threatening signs and symptoms.

visits per 100,000 for children younger than 5 years of age and 290 to 360 per 100,000 visits for adolescents. Hospitalization rates are 10% to 20%.[29,30,53,60,125,196]

As mentioned, adolescents are more frequently hospitalized than children after exposure to xenobiotics.[62] However, it is unclear whether this reflects medical hospitalization for management of the xenobiotic exposure or for patients' psychiatric problems. The peak age for hospitalizing young children exposed to xenobiotics is between 1 and 3 years, reflecting the peak age of exposure. Whereas among hospitalized children younger than age 2 years, exposure to nonpharmaceutical xenobiotics is more common; children older than age 2 years and adolescents are more commonly exposed to pharmaceuticals.[53,62,199]

Although the AAPCC reports overall outcome related to age, it does not generally stratify outcome of exposure to individual xenobiotics by age. In a multiyear review published in 1992, the AAPCC reported the xenobiotics that caused the greatest number of major and fatal effects in children younger than 6 years old.[116] Table 31–2 lists the xenobiotics that caused significant morbidity and mortality. Other reports of hospitalized patients include a similar distribution of xenobiotics that cause significant morbidity.[8,32,85,213] However, in rural areas of many developing countries, kerosene and pesticides are the leading causes of poison-related hospitalizations, and the spectrum of pharmaceutical exposures is often different[2,72,74,140,142] (see Chap. 136).

Poisoning accounts for approximately 2% of childhood and 6% of adolescent injury-related deaths in the United States.[31] Based on information from death certificates filed in state vital statistics offices as well as demographic information provided by funeral directors, the CDC reports 593 deaths in children younger than 6 years of age from 1999 to 2005 for an average of about 85 per year. These deaths represent 10% of the reported poisoning fatalities for all age groups for those years and an 81% decrease from the 456 deaths reported by the CDC in 1959.[30] This dramatic decrease in childhood poisoning mortality may be the result of improved poisoning prevention such as child-resistant closures and improved medical care or may reflect a decrease in reporting (see Chap. 135).

Thirty-seven percent of the AAPCC-reported childhood fatalities result from unintentional ingestions; 20% are from environmental exposures, mostly carbon monoxide poisoning; 16% are caused by therapeutic errors and adverse reactions; and 11% are malicious or related to abuse. The remaining 16% have miscellaneous causes or are

unknown. In contrast, 42% of AAPCC-reported adolescent fatalities are the result of suicide and 37% follow abuse or misuse of substances; only 5% are related to environmental exposures, and only 3% are caused by medication errors and adverse reactions; the remaining 13% have miscellaneous or unknown causes.

Although the AAPCC data provide a remarkable amount of epidemiologic information, there are questions about the accuracy of the data.[75,77,206] For example, as mentioned above, whereas the CDC reported 593 poisoning-related deaths in children younger than 6 years of age from 1999 to 2005, the AAPCC reported 184 for those same years based on voluntary calls. Thus, there is a recognition that many significant poisonings are not reported to poison centers. Physicians managing "common" toxicologic problems may not feel the need for the assistance of a local or regional poison center and may not feel compelled to participate in the reporting process. Therapeutic misadventures may also go unreported. In Rhode Island, only 45 of 369 poisoning deaths were reported to the regional poison center[114] (see Chap. 135).

The most notable difference between the xenobiotics listed in Table 31–2 and studies from the 1960s and 1970s is that salicylates are no longer a leading cause of reported poisoning morbidity and mortality.[40,45] This change may be related to federal regulations requiring child-resistant closures as well as to the decreased availability of aspirin at home for use in children after the recognition of its association with Reye syndrome (see Chap. 35).[19,37,86,134,160]

There are some significant etiologic differences between children and adolescents (see Table 31–1), particularly with regard to the lethality of xenobiotics. For 2003 to 2007, the xenobiotics causing the greatest number of childhood deaths were analgesics, carbon monoxide, and antihistamines and cough and cold preparations, which together account for 58% of all reported poisoning deaths. The xenobiotics causing the greatest number of adolescent deaths were analgesics, antidepressants, and stimulants and street drugs, which together account for 64% of reported poisoning deaths.

With respect to AAPCC-reported analgesic-related deaths, there are significant differences between children and adolescents for this population of possibly exposed individuals. For children younger than 6 years, opioids are suggested to account for 69% of the deaths (methadone, 39%; oxycodone or hydrocodone, 23%), and acetaminophen-containing products accounted for 28%. The high frequency of childhood exposures to these xenobiotics has been identified as a significant consequence of both the therapeutic and illicit use of prescription opioid analgesics.[11] These fatalities were related to unintentional exposures in 43% of the children (mostly opioids), malicious exposures in 18% (all opioids), and therapeutic errors in 13% (mostly acetaminophen); the reasons in the rest of the cases were unknown. In adolescents, opioids accounted for 60% of the deaths (methadone, 31%; oxycodone or hydrocodone,15%), and acetaminophen-containing products accounted for 38%. Forty-four percent of the fatalities were the result of abuse or misuse, and 40% were suicides.

Hydrocarbon-related fatalities occur in both children and adolescents; whereas the hydrocarbon deaths of young children generally result from unintentional aspiration, almost all of the hydrocarbon-related deaths in adolescents are related to inhalational abuse of hydrocarbons such as trichloroethanes or chlorofluorocarbons.

Poisoning also has an economic cost. Charges for hospitalized patients range from $2000 to $10,000, depending on the length of stay and outcome.[98,192,213] In a large-scale economic analysis of the cost of injury in the United States in 1985, the estimated average lifetime cost was $495 per child and $10,839 per adolescent or young adult injured or killed by poisoning for a total lifetime cost of approximately $140 million for children and $1.5 billion for adolescents and young adults.[152]

BEHAVIORAL, ENVIRONMENTAL, AND PHYSICAL ISSUES

An oversimplification of the etiology of childhood poisonings would be the formulation that unobserved toddlers exploring their environment inadvertently ingest xenobiotics. However, this approach ignores the complex interplay of factors that may contribute to some ingestions in children.

One approach to understanding injury causation that can be applied to poisoning uses an infectious disease–like model.[73] According to this model, there are three interacting factors: host, agent, and environment. These factors interact during three phases: preinjury, injury, and postinjury. The factors themselves contribute to the likelihood, nature, magnitude of, and host response to an injury.

During the preinjury phase, there is an interaction of the host, agent, and environment. Under the proper circumstances, an injury may occur. Modification of these factors may help to prevent an injury. For example, if a 2-year-old child finds two pills on a bedside table, there is a fair chance the child will ingest the tablets. However, storing the pills out of reach of the child can prevent the ingestion.

The injury phase covers both the ingestion and the initial pathophysiologic host response. Again particular factors determine the nature and extent of injury. Continuing the above example, if the two pills are 325-mg acetaminophen tablets, the ingestion will not lead to injury. However, if the pills are 0.2-mg clonidine tablets, there is a high likelihood of toxicity.

The postinjury phase is concerned both with the ongoing host response and the medical management of the patient who has been poisoned. In this phase, it would be determined whether the 2-year-old child with a clonidine ingestion manifests signs of toxicity, such as coma or hypotension; whether the child requires treatment with activated charcoal (AC), intravenous fluid, or naloxone; and whether the child requires hospital admission.

This paradigm is only a model; in reality, it is often difficult to examine any individual factor independently, and the relative contributions of these factors are not well defined. Nonetheless, consideration of the individual factors of host, agent, and environment allows us to focus on several relevant aspects of poisoning in children.

Childhood and adolescence are times of tremendous growth and development.[215] Some of these physical and social changes place children and teenagers at increased risk for poisonings. By 7 months of age, an infant sitting up can pivot in order to grab an object; by 9 to 10 months of age, most infants can creep and crawl; by 15 months of age, most toddlers are walking quite competently and eagerly exploring. Between 9 and 12 months of age, a skillful pincer grasp with the thumb and forefinger develops that allows the child to pick up small objects. Throughout this period, one of the child's primary sensory experiences is sucking on or gumming objects that are placed in the mouth. Thus, the combination of three developmental skills—the ability to move around the home and go beyond the immediate view of a guardian, the ability to pick up and manipulate small objects, and the tendency of children to put things in their mouths—places them at risk for poisoning.

As children develop socially, they desire to become more like their parents, and they tend to imitate behaviors, such as taking medicine or using mouthwash. Children are taught that medicine is good for them when they are sick. Many children's medicines are sweetened and flavored to make them more palatable, and many parents inappropriately encourage their children to take medicines by telling them "it tastes like candy." Children have been observed "making tea" from plants or "making pizza" with mushrooms from the yard.[26]

As children become more mobile, agile, and curious, xenobiotics that were previously outside their reach become accessible, even when stored in some difficult-to-reach places. There is some evidence suggesting that parents underestimate the developmental skills of their children.[52] The meaning of the term *unintentional* with respect to childhood poisoning should also be reconsidered—the toddler quite purposefully intends to get to a pill and eat it, but the child does *not* intend to injure him- or herself.

Some of the reasons why a child wants to ingest a pill are because it is there, it looks and maybe tastes like candy or food, or that the child is mimicking the behavior of a parent who ingests medicines or vitamins to cure illness and improve health. However, these reasons may not be sufficient to explain why xenobiotic exposures occur. Another aspect of poisoning that must be considered is the interaction between the child's temperament and the social environment.

Many authors have tried to identify psychosocial predictors for childhood poisoning in general and for repeat poisoning in particular.[22,54,91,94,186] As many as 30% of children repeatedly ingest xenobiotics, frequently the same xenobiotic. Certain risk factors have been identified for single and repeat episodes of childhood poisoning, such as hyperactivity, impulsive risk-taking behavior, rebelliousness, and negativistic attitude. Other factors seem to be associated more with the quality of supervision by parents or guardians, who themselves are experiencing medical illnesses, depression, or social isolation.[94] Finally, a stressful environment or a major social problem may also contribute.[181,187] It is not difficult to imagine a situation of a parent who is depressed, uses antidepressant medication that is kept at the bedside, and cannot give adequate attention to a demanding child. In a bid for attention, or as an expression of anger or frustration, the child ingests some of the parent's medication.

With regard to the agent, a number of issues affect the preinjury and injury phases, and modification of any one of the interacting factors of host, agent, or environment may potentially prevent or reduce the severity of injury. When household products of lower toxicity are available around the house, the likelihood of injury is reduced if one of these products is ingested. For example, less-toxic rodenticides such as warfarin have replaced more toxic ones such as thallium or sodium monofluoroacetate, and relatively nontoxic paradichlorobenzene mothballs have largely replaced the relatively more toxic camphor-containing mothballs.

It may also be possible to reduce the likelihood of ingestion by making a xenobiotic unpalatable. Denatonium benzoate is an aversive bittering xenobiotic that is added to some liquids such as windshield washer fluid and antifreeze to prevent unintentional poisoning.[87] However, some trials show that whereas older children may respond negatively to these xenobiotics with the first taste, younger children may ingest 1 to 2 teaspoonfuls before being deterred by the bitter flavor.[20,180] This is an important consideration because even a small amount of a xenobiotic such as methanol can be toxic (see below). The actual usefulness of denatonium benzoate in poison prevention is largely unstudied.[161]

The problem of unintentional ingestions is compounded by poison "look-alikes," that is, xenobiotics that resemble candy or food products.[55] Some common examples are ferrous sulfate tablets and vitamins that look like common candies and fuel oils that come in cans resembling soft drink containers. Many shampoos and dishwashing detergents are given lemon or strawberry scents and have pictures of fruits on the labels. Children are not always able to distinguish poison "look-alikes" from real candies, fruits, and sodas, and they may be attracted to bright colors, pleasant smells, and appealing packages. Eliminating these "look-alikes" might prevent some unintentional ingestions.

Probably the most significant changes have occurred in the physical characteristics with regard to packaging and dispensing of pharmaceuticals and some other xenobiotics with child-resistant closures mandated

by the Poison Prevention Packaging Act of 1972 (see Chap. 134). This legislation is credited with causing a significant reduction in morbidity and mortality due to poisoning from aspirin and other regulated products, although this analysis has been challenged.[37,159,201] Child-resistant closures have also been credited with reducing the number of toxic exposures to kerosene.[107]

Nonetheless, problems with child-resistant closures include the dispensing of pharmaceuticals in nonresistant containers, not properly closing child-resistant containers, and leaving pharmaceuticals out of the child-resistant container.[29,184] Seventy percent of potentially toxic pharmaceuticals may be in non–child-resistant or in improperly functioning child-resistant containers. Several studies have identified poor functioning of the closures when there is sticky liquid or pill residue around the top or in the screw threads of the child-resistant container.[89,98,212]

Although child-resistant containers are a significant deterrent to unintentional ingestions in toddlers, they are not completely effective, and even without the problems noted, some children can open them. A false sense of security associated with these closures may lead some parents to be less compulsive regarding safe storage of the containers. A double barrier, such as a unit-dose dispenser within a child-resistant container or a blister pack, has been recommended for a few pharmaceuticals associated with a large number of significant poisonings such as iron and antidepressants.[98]

In fact, in 1997, the Food and Drug Administration (FDA) issued a regulation to package products with 30 mg or more of elemental iron per tablet in unit-dose packages such as blister packs.[66] The intent of this regulation was to reduce the likelihood of iron poisoning in children. Even before this regulation was instituted, the number of fatal childhood iron ingestions had declined significantly; therefore, it is not known how much if any of the decrease is related to the mandated packaging changes. In any case, the rule was overturned in 2003, when it was determined that the FDA did not have the statutory authority to regulate a drug for the purpose of poison prevention.[139] As yet there is no evidence of an resurgence of iron-related fatalities.

A discussion of containers and storage naturally leads to a consideration of the third factor in the injury-causation model discussed above, the environment, which is particularly important in the preinjury and the injury phases. Approximately 80% of childhood pharmaceutical ingestions occur at home; the remainder occurs at the homes of grandparents, other relatives, and friends. At home, the medicine usually belongs either to the child or to a parent, although a significant number of medications, both at home and away from home, belong to a grandparent.[89,115] Grandparents, other relatives, and family friends without children at home may not obtain or retain medications in child-resistant containers and may not be as attentive to safe storage practices. Poison prevention education directed to these groups may be particularly helpful.[128]

Medications are frequently kept in the kitchen or bedroom while they are being used.[89,212] In the kitchen, medications are stored in the refrigerator, on the table, or on the counter, and in the bedroom, medications are left on a dresser or bedside table. A mother's or grandmother's purse is another location where medications are commonly found. Interestingly, there are no significant differences in the storage practices in the homes of children who ingest and those who do not ingest medicines, so storage practices alone cannot predict the likelihood of childhood poisoning.[186,212]

One important caveat relates to the storage of nonpharmaceutical xenobiotics, particularly those in liquid form. These types of xenobiotics should never be transferred for storage to familiar household containers, such as food jars or wine or soda bottles, stored in areas low to the ground such as beneath sinks, or kept in cabinets that do not have child-resistant locks. Both children and adults have been unintentionally exposed to xenobiotics, such as sodium hydroxide, pesticides, hydrocarbons, and potassium cyanide that was stored in bottles in the refrigerator.[197] Many of the kerosene exposures reported from developing countries occur because the kerosene is stored in water bottles, jugs, or other containers in easily accessible locations. When the weather is hot, children may mistake the clear liquid kerosene for water.[1,2,179]

HISTORY OF THE INGESTION

The appropriate management of any poisoned patient is influenced by the history of the exposure. Except in rare cases of child abuse–related poisoning, parents or guardians will generally provide information to the fullest extent possible. As a rule, in the case of children, the xenobiotic and time of ingestion are known. However, the reported number of pills or volume of liquid ingested may not be as accurate. Clues to the amount ingested are the number of pills or volume of liquid in a bottle before and after an ingestion, the number of pills set out on the night table, or the area of a spot of liquid after a spill. When symptoms are suggestive of poisoning but the history is inadequate, information about possible exposure outside of the home, such as with a babysitter, grandparent, friend, or other relative, should be obtained because approximately 15% of childhood poisonings occur outside the home.[89,145]

In contrast, adolescents may not be forthcoming when relating the history of an intentional ingestion, especially when they are depressed, suicidal, or concerned about the response of their guardian or parent. When caring for these patients, the clinician must use the history provided but should remain skeptical about the reported type and number of xenobiotics ingested, as well as the time of ingestion.

When a child may be the victim of abuse or intentionally poisoned by a parent or guardian, the healthcare provider must ensure that (1) the history of the poisoning remains consistent over time and among people providing the details of the event, (2) the child's clinical presentation is consistent with the history of the poisoning, and (3) the reported actions are consistent with the child's developmental level.

GASTROINTESTINAL DECONTAMINATION

Chapter 7 is devoted to a complete discussion of gastrointestinal (GI) decontamination. This section reiterates and emphasizes only a few important points.

As described above, children generally ingest small quantities of single xenobiotics. For most of these ingestions, gastric emptying is unnecessary. Some examples of nontoxic ingestions are eating a crayon or the leaf of a jade plant, licking the cap of a household bleach container, or swallowing two adult-strength acetaminophen tablets.

Orogastric lavage is the preferred method of gastric emptying when indicated for most serious ingestions. Small children can generally tolerate orogastric lavage with a large-bore 28- or 34-French tube; however, the smaller "large-bore" tubes may not be effective for removing large pills or fragments from the stomach of a small child. Placement of an orogastric tube is an unpleasant and frightening procedure for an infant or small child to undergo. Some local trauma may result from tube placement and, rarely, there may be more serious injury, such as esophageal perforation. Also, many children vomit during placement of an orogastric tube. Therefore, the use of orogastric lavage should be limited to cases in which the risk of significant morbidity or mortality is high, the likelihood of benefit is at least moderate, and the likely risk of injury to the child from the procedure is small. Orogastric lavage should never be used as a form of punishment. The patient should be intubated

to protect the airway before orogastric lavage is used in a child with a diminished gag reflex or a depressed level of consciousness.

Previously, administration of syrup of ipecac to poisoned patients was considered a primary emergency intervention, and the availability of ipecac in the home was a primary tenet of pediatric anticipatory guidance. The AAPCC reports that the use of syrup of ipecac for case management declined from 13% in 1983 to 0.1% by 2005. This is not surprising because syrup of ipecac is contraindicated in cases associated with hemodynamic instability, seizures, or a depressed level of consciousness. Although syrup of ipecac is highly effective at making children vomit, the efficacy of preventing morbidity after an ingestion is questionable.

Even before the use of syrup of ipecac was abandoned, it had been used only infrequently in the ED management of poisonings, with lavage favored when evacuation of the stomach was considered important. However, it was, until recently, still advocated for use at home at the direction of a poison center to avoid an unnecessary evaluation in an ED. However, in 2003, the American Academy of Pediatrics recommended against the use of ipecac at home, and in 2004, the American Academy of Clinical Toxicology and the European Association of Poison Control Centres and Clinical Toxicologists recommended against the general use of syrup of ipecac for the management of poisoning.[4,6] The reasons for the new recommendations include its unproven benefit, its adverse effects, its interference with and complication of subsequent ED evaluation, its abuse potential, and its administration in cases in which there is no indication or there is a contraindication because of lack of consultation with a poison center.

Notwithstanding these position statements, some toxicologists believe there may still be a role for home use of ipecac syrup in very specific limited circumstances.[158] Thus, there may still be a very limited role for the use of syrup of ipecac in the management of some cases (see Chap. 7 and Antidotes in Depth A1: Syrup of Ipecac).

AC is a current mainstay of poison treatment in the ED.[3,36] Children generally will not drink AC willingly, although some children can be coaxed to do so if the AC is disguised in a baby bottle or soft drink container or sweetened with juice or sorbitol.[209] A nasogastric or orogastric tube may have to be inserted to administer AC. This can be a small-bore tube because it is not intended for lavage, although the smaller the bore, the more difficult it is to administer the thick slurry of AC. Placement of the tube, the presence of AC in the stomach, the effects of the xenobiotic, or the previous use of an emetic all may make the child vomit, making aspiration of AC or stomach contents a risk. For AC to be used safely in a patient who is comatose and who does not have a gag reflex, the patient should be intubated and the airway protected. Because of this risk, AC alone is unnecessary for a nontoxic or minimally toxic ingestion.

AC is available for home use.[108,190] Administration of AC at home or by prehospital personnel allows for administration significantly earlier than can be achieved after arrival and evaluation in the ED.[41,190] Although it would seem to have potential benefit as home therapy, AC is unpalatable, quite messy, and not always available; as a result, it has not achieved widespread use in the home.[138,158] It is also unclear how well parents can administer AC at home.[169,170,191] Whether the earlier administration of AC would affect outcome is unknown. If AC is to replace syrup of ipecac for home therapy, it will require a substantial reeducation effort on the part of pediatricians, toxicologists, and pharmacists.

METHODS OF ENHANCED ELIMINATION

For consequential poisoning with xenobiotics such as methanol, ethylene glycol, salicylates, lithium, and theophylline, either hemodialysis or charcoal hemoperfusion is the optimal technique to enhance elimination,

depending on the particular xenobiotic. These extracorporeal techniques can be performed on newborns or small infants in specially equipped centers with dedicated personnel. The primary limiting factor is the ability to obtain vascular access.[18,49,51,198] However, even large centers that routinely do hemodialysis in children may not be able to manage very small infants. There has been a report of the use of peritoneal dialysis for the treatment of alcohol intoxication in a child,[71] but this technique is not generally recommended.

Exchange transfusion is occasionally used to enhance xenobiotic elimination. This technique might be useful when multiple-dose AC cannot be administered, the xenobiotic is poorly adsorbed to charcoal, or access to specialized hemodialysis or hemoperfusion is not readily available. Exchange transfusion has been used successfully for poisoning by salicylates[50,124] and theophylline.[15,141,176]Another xenobiotic for which exchange transfusion may be a therapeutic alternative is chloral hydrate.[9]

XENOBIOTICS THAT MAY BE TOXIC OR FATAL IN SMALL QUANTITIES

When children ingest even small quantities of toxic xenobiotics, they are potentially ingesting large relative doses because of their small size. There are a number of xenobiotics that may cause significant toxicity or even death with as little as one pill or one teaspoonful.[13,113] Table 31–4 lists these xenobiotics.

XENOBIOTICS THAT MAY CAUSE DELAYED TOXICITY IN CHILDREN

Several xenobiotics warrant particular concern because their effects may be significantly delayed. Classic examples are atropine-diphenoxylate (Lomotil)[23,43,126] and sulfonylureas such as glipizide.[69,148,194] Both of these xenobiotics may cause serious morbidity with initial symptoms or recurrence of symptoms delayed by as much as 24 hours after ingestion.

TABLE 31–4. Xenobiotics that May Cause Severe Toxicity to an Infant After a Small Adult Dose, a Single pill or a Small Volume

Benzocaine

β-Adrenergic antagonists (sustained release)

Calcium channel blockers (sustained release)

Camphor

Clonidine

Cyclic antidepressants

Diphenoxylate and atropine (Lomotil)

Methanol or ethylene glycol

Methylsalicylate

Monoamine oxidase inhibitors

Opioids (methadone, codeine, OxyContin)

Phenothiazines

Quinine or chloroquine

Sulfonylureas

Theophylline

Children with real or possible ingestions of Lomotil or a sulfonylurea should be admitted for observation and monitoring, even if they are asymptomatic, because effects may not become apparent for 24 hours (see Chaps. 38 and 48).

With the advent of new modified-release formulations of calcium channel blockers and β-adrenergic antagonists, concern for delayed toxicity and possibly death has become even greater and has been extended to other xenobiotics.

XENOBIOTICS THAT CAUSE UNUSUAL OR IDIOSYNCRATIC REACTIONS IN CHILDREN

■ BENZYL ALCOHOL: GASPING SYNDROME

Benzyl alcohol is a preservative added to liquid pharmaceutical preparations; for small-volume medications administered to adults, the benzyl alcohol additive is quite safe (Chap. 55). At toxic doses, benzyl alcohol may cause respiratory failure, vasodilation, hypotension, convulsions, and paralysis. Intravenous flush solutions containing benzyl alcohol were implicated as the cause of the "gasping syndrome" in sick newborns; the syndrome includes severe metabolic acidosis, encephalopathy, respiratory depression, and gasping.[5] The association was made when infants with this syndrome were found to have elevated concentrations of benzoic acid and hippuric acid, metabolites of benzyl alcohol.[28,63] Benzyl alcohol is metabolized by the conjugation of benzoic acid with glycine to form hippuric acid; this pathway may not be functional in premature infants. Benzyl alcohol administration has also been associated with kernicterus and intraventricular hemorrhage in premature infants.[81,90] Although benzyl alcohol has been removed from many of the medications used for neonates, some preparations may still contain this agent.[207]

■ IMIDAZOLINES AND CLONIDINE: CENTRAL NERVOUS SYSTEM EFFECTS

Imidazolines such as tetrahydrozoline, oxymetazoline, xylometazoline, and naphazoline are nonprescription sympathomimetics used as nasal decongestants and conjunctival vasoconstrictors (see Chap. 50). Clonidine is an imidazoline derivative used as an antihypertensive (see Chap. 62). In small children, these xenobiotics can cause central nervous system (CNS) depression, respiratory depression, bradycardia, miosis, and hypotension.[12,123,210] The presumed mechanism of action is by stimulation of central alpha$_2$-adrenergic and imidazole receptors. Although naloxone has been reported to reverse some of the CNS effects of clonidine, there have been no reports of its successful use with the other imidazolines (see Chap. 62).

■ ETHANOL: HYPOGLYCEMIA

Ethanol is the primary component of alcoholic beverages, as well as a major constituent of many liquid preparations, such as mouthwash, vanilla flavoring, and perfume. Besides its well-known sedative–hypnotic effects, ethanol poisoning in children is associated with hypoglycemia because of reduced hepatic glycogen stores in children.[42,112,121,202] Ethanol-induced hypoglycemia may cause seizures and may exacerbate the other CNS effects induced by ethanol poisoning. Hypoglycemia results from the inhibition of gluconeogenesis in the setting of alcohol poisoning. There does not seem to be a blood alcohol concentration threshold for the development of hypoglycemia, which has been reported with blood alcohol concentrations as low as 20 mg/dL[42] (see Chap. 77).

■ CHLORAMPHENICOL: GRAY BABY SYNDROME

Chloramphenicol is a broad-spectrum antibiotic that has been used in pediatrics because of its activity against *Haemophilus influenzae.* It has largely been replaced by other antibiotics in the United States because of its association with aplastic anemia. When administered at high doses, chloramphenicol can produce the "gray baby syndrome," which includes abdominal distension, vomiting, metabolic acidosis, progressive pallid cyanosis, irregular respirations, hypothermia, hypotension, and vasomotor collapse. Although these effects occur primarily in premature newborn infants, they may also occur in older children and adults (see Chap. 56).

Gray baby syndrome is associated with serum concentrations greater than 100 mg/L. Increased chloramphenicol concentrations may result from (1) inadequate conjugation of chloramphenicol with glucuronic acid because of inadequate activity of glucuronyl transferase in the newborn liver and (2) decreased renal elimination of unconjugated chloramphenicol. The exact mechanism of toxicity is unknown; there is speculation that free radicals produced during the metabolism of chloramphenicol may interfere with mitochondrial function.[84]

MEDICATION ERRORS

Ever since the publication of the Institute of Medicine's report titled *To Err is Human* in 1999, increasing attention has been paid to the issue of medical errors in medicine.[100] Although most of the research regarding medication errors has focused on adults (see Chap. 139), this problem also affects children. Remarks in this section are generally limited to the pediatric literature.

Approximately 113,000 exposures each year are classified as therapeutic errors, accounting for approximately 6% of exposures in children younger than 6 years of age, 21% in children 6 to 12 years of age, and 9% in adolescents. For 2003 to 2007, there were a total of 26 deaths attributed to therapeutic errors, representing 5% of all reported deaths in children and adolescents. Although only 6% of the AAPCC-reported exposures in young children were related to therapeutic errors, approximately 12% of the reported deaths were related to therapeutic errors. This is in contrast to adolescents, for whom 9% of the calls but only 2% of the reported deaths were related to therapeutic errors.

Medication errors may occur at any phase of a process that includes ordering, order transcription, pharmacy dispensing, preparation and administration of the medication, and monitoring of medication effects. In fact, the same types of errors can usually occur at different points in the process. Table 31–5 lists the types of errors that can occur, and Table 31–6 provides some examples of errors.

Most of the analyses of medication errors have occurred in inpatient settings. The reported frequencies of medication errors vary widely—from 0.47% to 5.7% of written orders and from 0.51 to 157 per 1000 patient-days.[56,82,92,96,167] The variance largely depends on whether the definition of "error" does or does not include prescribing errors, regardless of whether or not they are corrected, and whether potential, or only actual, adverse drug events are included. The reported frequencies also vary depending on whether there is active case finding or whether there is only voluntary reporting.

In a 2001 study of pediatric inpatients in which orders were actively monitored for a 6-week period, 5.7% of 10,778 prescriptions had errors in the order for the medication, transcription of the order, dispensing or administration of the medication, or monitoring of medication effects (56 per 100 admissions, 157 per 1000 patient-days);[96] 1.1% could have *potentially* caused an adverse effect (10 per 100 admissions, 29 per 1000 patient-days). Eighty-four percent of the errors occurred during the ordering or transcription phase, so most of the errors were intercepted

TABLE 31–5. Types of Medication Errors

1. Wrong patient–someone else's drug
2. Wrong drug
   a. Wrong individual drug
   b. Wrong formulation
   c. Known allergy
   d. Known drug–drug interactions
   e. Wrong indication
   f. Contraindication
   g. Expired
   h. Deteriorated
3. Wrong dose
   a. Miscalculation
      i. Decimal point error
      ii. Wrong formula
      iii. Right formula using wrong dose, frequency, units, weight
      iv. Pound/kilogram confusion
      v. Mg/g units confusion
      vi. Dilution error
   b. Appropriate individual dose divided into multiple doses
   c. Total daily dose for an individual dose
   d. Wrong IV infusion rate
   e. Measuring error
4. Wrong route
5. Wrong frequency
   a. Increased or decreased dosing interval
   b. Omitted, delayed, or added dose
   c. Delay or failure to supply
6. Transcription errors
7. Documentation (order, prescription, transcription, logs)
   a. Illegible
   b. Incomplete or missing information (weight, signature, maximum daily dose, stop date)
8. Monitoring
9. Miscellaneous
   a. Wrong label
   b. Wrong information or advice
   c. Failure to detect error
   d. Breast milk exposure

TABLE 31–6. Examples of Medication Errors

1. **Wrong drug.** In one nursery, an epidemic mimicking neonatal sepsis was caused when racemic epinephrine was inadvertently administered instead of vitamin E because both drugs were manufactured by the same company, distributed in nearly identical bottles, and stored near each other inside the nursery refrigerator.[189]
2. **Wrong drug formulation.** Acetaminophen suppositories (120 mg) were ordered for a toddler, but adult-strength suppositories (650 mg) were distributed and administered every 4 hours. The child developed hepatotoxicity requiring hospitalization and therapy (see Chap. 34).
3. **Wrong dose.** A 1-kg premature infant required sedation for a diagnostic study. A high dose of chloral hydrate, 100 mg/kg, was miscalculated to be 1 g (1000 mg) instead of 100 mg. The child had a cardiopulmonary arrest and died. When drugs require milligram per kilogram dosing, it is easy to make decimal mistakes in the calculation or in the transcription.
4. **Wrong dose/wrong route.** A recommendation was made to treat a baby with penicillin G benzathine, 50,000 U/kg intramuscularly (IM). The recommendation was transcribed as "penicillin G 50,000 units/kg." The order was handwritten as "Benzathine Pen G 150,000 U IM" but was misread or misinterpreted as 1,500,000 U intravenously. The patient had a cardiopulmonary arrest and died.[185]
5. **Wrong dose.** A patient had the dose of cyclosporine changed from 10 mg to 7 mg twice daily. The child received 70 mg (0.7 mL of solution) instead of 7 mg (0.07 mL). When the prescription was refilled, the parents received a 5-mL syringe to use instead of a 1-mL syringe they had used previously.[47]

---

similar to those from inpatient settings have been reported in pediatric EDs.[105,109,135,156,174]

The studies cited above suggest that the frequency of significant errors leading to significant adverse drug events is low; however, even a low frequency applied to a large population of patients could result in a large number of patients being harmed. The most important outcome of the analysis would be to try to reduce the overall number of errors to reduce the number of potential and actual adverse drug events.

The causes of medication errors are numerous, varied, and complex; they are organizational, environmental, and personal, which includes factors such as the level of training, knowledge and competence, the time of day, workload, staff interactions, communications, number of distractions or interruptions, ambient noise, and drug formulation and drug packaging[44,58,65,100,205] (see Chap. 139).

Children may be placed at increased risk of a medication error for several reasons: (1) someone other than the child administers the medication, so there is little opportunity to prevent or limit drug administration; (2) a young child cannot warn practitioners about possible problems such as allergies; (3) a young child cannot inform practitioners when he or she is experiencing an adverse event; (4) medication ordering and administration in children frequently requires dose calculations; (5) inexperienced practitioners may be uncomfortable with pediatric dosing or related calculations; and (6) incorrect measurement or dilution of concentrated stock solutions may yield a small volume, which is not perceived as containing a relatively large dose of medication.[33,47,65]

The most common error attributed to physicians is prescription of an incorrect dose, particularly in children, in whom almost every prescription requires a determination of weight and calculation of the

---

and corrected before drug administration. There were 26 true adverse drug events, but only five were considered preventable errors (0.05%, 0.52 per 100 admissions, 1.8 per 1000 patient-days). Although the overall error rate was similar to that reported by the same group in a study of adults, the rate of errors that could *potentially* have caused harm was three times greater; 41% of the potentially harmful errors were not intercepted.

Generally, error rates are higher in intensive care units, where the sickest patients are cared for; such patients often receive multiple medications with complex administration regimens[56,82,96,149,167,200,211] Results

dose.[96,106,111] In addition, even the milligram per kilogram dose may vary depending on the age of the patient or the diagnosis. Although pediatric doses are generally determined on a milligram per kilogram basis, if the weight is recorded in pounds and this weight is used in the calculation, there will be a built-in twofold error. Calculation errors also occur when drug preparation requires dilution of a concentrated stock solution or special compounding. Further confusion can arise when *mg* is written or interpreted as *mL* or *mcg* in a calculation.

When an extra zero is added or a required zero is omitted from calculations, written or verbal prescriptions, or in dispensed and administered medications, a 10-fold error occurs. These large errors are common and result in significant under- or overdosing; 10-fold errors have been reported in testing scenarios, case series, and case reports.[27,47,68,102,103,106,136,149,154,163,167,183,185] These errors are of particular concern because the risk of toxicity generally increases with significant overdose.

Because the causes of medication error are numerous and complex, the solutions must be multifaceted and interdisciplinary. The approach to the problem is contained within the field of human factors research and potentially requires changes in individual factors such as knowledge; environmental factors such as interruptions; and system problems such as how medications are ordered, stocked, and dispensed[100,193,205] (see Chap. 139).

The most commonly recommended solutions to reduce the frequency of medication errors are computerized physician order entry (CPOE) with clinical decision support systems; ward-based clinical pharmacists; and improved communication among physicians, nurses, and pharmacists.[95,110,157,193] In one of the studies cited above, it was estimated that these three solutions together could have prevented more than 90% of the potential errors,[57] although the effect of interventions other than CPOE have generally not been studied.

In its simplest form, CPOE eliminates errors related to legibility. Decision support adds the ability to check a prescription against age, weight, dose, allergies, and drug–drug interactions, but it may not prevent ordering the wrong drug or dose, so there is still a need for education and human oversight in additional to other safeguards. The implementation of CPOE is generally associated with at least some reduction in errors related to medication ordering,[39,83,99,146,204] although in one controversial study, CPOE was associated with an increase in mortality,[76] and this may have been related to the method of implementation.[88,117,166] Occasionally, other problems are associated with computerized systems.[101,127,203]

Some years from now, all inpatient medication orders and outpatient prescriptions may be transmitted electronically, but until that time, it will be necessary to ensure that prescriptions are written legibly and correctly. The Joint Commission and many other groups have issued a number of recommendations to reduce errors in medication ordering (see chapter 139).

Standardized tests of the math skills necessary to calculate doses and administer medications have demonstrated deficiencies in both nursing and physician groups.[17,21,137,143,147,162,168] These kinds of tests may be a way to identify practitioners at risk for making calculation errors, highlight areas in need of remediation, and serve as an ongoing educational tool.

As described above, there may be an increased risk of medication errors in critical care areas because of severity of illness and intensity of medication therapy. In many cases, such as during resuscitations, critically ill patients require immediate therapy, verbal orders are common, and there is often insufficient time to carefully review all of the particulars related to medication ordering and administration.[106,109,119,144]

Critical care areas, including the ED, benefit from having precalculated dosing charts available for resuscitation medications and for other commonly prescribed medications; this is a recommendation of the American Heart Association.[7] Many clinical units have developed their own dosing schemes. Commercial products, such as the Broselow-Luten system, are also available and have been shown to reduce the number of medication errors in simulated [118,120,175] and real resuscitations.[93]

The previous discussion has been almost exclusively related to hospital-based medication use, but significant errors also may occur in outpatient settings.

Antipyretics are among the most frequently recommended medications for children. Although significant toxicity after unintentional ingestions in toddlers is now rare, administration of multiple supratherapeutic doses of acetaminophen is common and may cause significant hepatotoxicity.[104]

In fact, many parents have difficulty calculating the appropriate dose of acetaminophen and measuring out the appropriate amount after it is calculated despite having received appropriate instructions and graduated cups or oral-dosing syringes.[70,122,130,182,188] The most commonly used measuring device is also the most inaccurate; the household teaspoon is not standardized for volume and can easily be confused with a household tablespoon.[122] Although graduated syringes are considered the most accurate of the measuring instruments available and are recommended by the American Academy of Pediatrics for young children, acetaminophen and ibuprofen elixirs are typically packaged with a graduated cup for administration. Visual cues using pictograms in the discharge instructions or color-coded or premarked syringes may be one way to improve the accuracy of parental medication dosing.[59,214]

INTENTIONAL POISONING AND CHILD ABUSE

Intentional poisoning of children is an unusual, though significant, form of child abuse. There are several types of intentional poisoning, some of which define pathologic characteristics of the parent or guardian: (1) undifferentiated child abuse, neglect, or impulsive acts under stress; (2) factitious illness (Munchausen syndrome by proxy [MSBP]); (3) overt parental psychosis; (4) altruistic motivation or bizarre childrearing practices; and (5) the Medea complex, or the vengeful killing of a child out of spite for one's spouse.[79,165,195]

Intentional poisoning is rarely suspected unless the patient dies and an autopsy is performed, a wide-ranging drug screen is ordered, or the history is bizarre enough to raise suspicions. In many cases in which children are later found to be poisoned, the initial diagnoses were sepsis, meningitis, seizures, intracranial hemorrhage, gastroenteritis, apnea, apparent life-threatening events, or metabolic derangements.[79] In addition to many pharmaceuticals, salt, pepper, water, caffeine, ethylene glycol, herbs, plants, and traditional remedies have been used to poison children.[48,79] Although the death rate from unintentional poisoning in children is much less than 1%, the death rate from inflicted poisoning may be as high as 20% to 30%.[48,79,195]

Intentional poisoning may be associated with other forms of abuse; approximately 20% of poisoned children may have evidence of physical abuse.[48,79] Of children presenting to the ED after presumed unintentional poisoning, 36% had previous ED visits for trauma, 7% for poisoning, 6% for both trauma and poisoning, and 1.4% for failure to thrive. At the time of the visit, only 7% were evaluated for possible abuse, and 2.7% were considered neglected.[79] These data do not prove an association between poisoning and physical trauma; however, in some children, repeat episodes of trauma or poisoning may be a manifestation of significant intrafamilial stress. Healthcare providers must remain vigilant to the possibility that a presumed unintentional

poisoning may have been inflicted, especially in the setting of a repeat ingestion or when there have been previous evaluations for trauma.

Substance abuse by a parent or guardian may play a role in unintentional or intentional poisoning of children. Children have been intoxicated with cocaine or phencyclidine by passive inhalation,[16,78,133,172,208] unintentional ingestion,[97,155] and rectal adminstration,[151] as well as through breast milk.[34] Children have been given doses of alcohol, methadone, and other xenobiotics to quiet them or to prevent withdrawal.[45,80,153] There have also been reports of babysitters blowing marijuana smoke into babies' faces to "get them high" or to quiet them.[173]

In 1977, the term *Munchausen syndrome by proxy* was used to describe a condition in which a parent or guardian, typically the mother, fabricates a history of nonexistent disease(s) in a child or creates the signs and symptoms of disease in a child (factitious illness).[131,132,165] This is usually a manifestation of the parent's complex psychiatric illness, which may include Munchausen syndrome itself.[24,67,171] There may be only a fine line separating MSBP from an intentional poisoning with intent to harm or kill a child. However, regardless of the specific intent, this condition is considered a form of child abuse.

Over the years, child protection experts have tried to develop more specific terminology than MSBP. In light of the fact that this entity involves two individuals—the child victim and the adult perpetrator—the American Professional Society on the Abuse of Children recommends that the child victim be diagnosed with "pediatric condition falsification" and that the psychiatric diagnosis of "factitious disorder by proxy" be applied to the adult perpetrator. The diagnosis of MSBP requires that both criteria be met.[10,171]

A child's fabricated illness may lead to multiple medical evaluations by several different physicians, frequent hospitalizations, unnecessary surgeries and diagnostic testing, unneeded prescribing and administration of medication, and at times even the death of the child. Administration of medications to the child by the adult perpetrator is frequently how a particular set of signs and symptoms is created. Xenobiotics used to create factitious illness have included analgesics, antidepressants, insulin, syrup of ipecac, Lomotil, phenothiazines, sedative–hypnotics, warfarin, phenolphthalein, and hydrocarbons.[164] Several warning signals may suggest a diagnosis of MSBP (Table 31–7).

In one illustrative case of MSBP, a 29-month-old boy who had undergone a previous appendectomy was hospitalized multiple times for vomiting, diarrhea, and dehydration.[64] Evaluation included multiple blood and stool analyses, a gastric pH probe, computed tomography, magnetic resonance imaging, endoscopy, and upper GI series. On the fourth admission, a small bowel obstruction was identified, and the child had lysis of adhesions. Nonetheless, symptoms recurred every 2 to 4 months, necessitating hospitalization. The child failed to thrive and required a nasoduodenal tube for feeding, which frequently became dislodged. The child went on to have a jejunostomy tube and a permanent central venous catheter placed. Eighteen months after his initial presentation, the child presented in congestive heart failure with evidence of cardiomyopathy. A urine screen identified emetine and cephaline, components of syrup of ipecac. The child was removed from his home to protective custody after which he recovered and remained asymptomatic on a regular diet.

Siblings of children evaluated and treated for poisoning may also have suffered from factitious illness. In addition, significant psychiatric problems may be manifested by the victim, parents, and siblings.[25,129,171,177]

Child abuse or neglect must be part of the differential diagnosis of any case of childhood poisoning. Intentional poisoning should be considered for

1. An "ingestion" in a child younger than 1 year of age

2. A case with a confusing history or presentation

TABLE 31–7. Factitious Illness (Munchausen Syndrome by Proxy): Suggestive Characteristics in Clinical Situations

1. The child has a persistent or recurrent illness that cannot be explained.
2. The history of disease or results of diagnostic tests are inconsistent with the general health and appearance of the child.
3. The signs and symptoms cause the clinician to remark, "I've never seen anything like this before!"
4. The signs and symptoms do not occur when the child is separated from the parent.
5. The parent is particularly attentive and refuses to leave the child's bedside, even for a few minutes.
6. The parent develops particularly close relations with hospital staff.
7. The parent seems less worried than the physician about the child's condition.
8. Treatments are not tolerated (eg, intravenous lines fall out frequently, prescribed medications lead to vomiting).
9. The proposed diagnosis is a rare disease.
10. "Seizures" are unwitnessed by medical staff and reportedly do not respond to any treatment.
11. The parent has a complicated medical or psychiatric history.
12. The parent is or was associated with the healthcare field.

---

3. A child with a previous poisoning or a child whose siblings have previously been evaluated for poisoning

4. A child with a previous presentation for a rare or unexplained medical condition

5. A child with apnea, unexplained seizures, or an apparent life-threatening event

6. A massive ingestion by a small child

7. An ingestion of multiple xenobiotics by a small child

8. An exposure to substances of abuse

9. An intoxication with a xenobiotic to which a child could or would not typically have access

10. "Accidental ingestions" in a school-age child

11. A history of previous trauma, child abuse, or neglect

12. Sudden infant death syndrome or an unexplained death[79,80]

These considerations of child abuse notwithstanding, rare diseases do occur. One child's rare, inherited metabolic disorder, methyl malonic acidemia, was misdiagnosed as ethylene glycol poisoning because of the chromatographic appearance of the metabolite propionic acid, which was similar to that of ethylene glycol.[178]

SUMMARY

Children are frequently exposed to potentially toxic xenobiotics; fortunately, most childhood exposures are ingestions of nonpoisonous xenobiotics or small nontoxic quantities of potentially toxic xenobiotics. When a child sustains a significant toxic exposure, management follows general toxicologic principles. Although most childhood exposures are unintentional, the clinician should be alert to the possibility of intentional poisoning of a child with pharmaceutical or household products.

The normal development of children places them at risk for unintentional ingestions. A chaotic home environment or a disorganized social structure may compound these risks. Small size puts children at increased risk for medication dosing and dispensing errors, and their immature metabolic processes may lead to unexpected toxicity from pharmaceutical agents.

Toxicologists should encourage parents to provide as safe a home environment as possible to prevent unintentional ingestions and must encourage practitioners to exercise special vigilance when administering medications to children.

CHAPTER 32
GERIATRIC PRINCIPLES

Judith C. Ahronheim and Mary Ann Howland

PREVALENCE, LETHALITY, AND UNDERRECOGNITION OF TOXIC EXPOSURE

In developed countries, the population is aging steadily. In the United States, those older than 65 years of age comprise not only an increasing proportion of the population at large (12%) but also an increasing proportion of patients seen in medical practices. Compared with all other age groups, patients older than 65 years of age account for one-third of emergency department (ED) ambulance arrivals and the highest proportion of patients in EDs triaged as emergent.[80]

Although the elderly account for only a small minority of toxicologic exposures, after they have been exposed, they have a high mortality rate. Among exposures reported to the American Association of Poison Control Centers (AAPCC) in 2006, the fatality ratio (ie, number of cases divided by number of deaths) increased with age in a bimodal pattern, with peaks in the middle and latest decades of life (see Chap. 135). Previous AAPCC surveys had shown a steady increase in fatality ratio. In addition to possible methodologic changes and smaller numbers of exposures in the latest decades of life, potential explanations for the current change to a bimodal pattern may include an increase in intentional exposures in midlife and physiologic vulnerability in the later decades. However, this only accounts for part of the difference because suicide fatality ratios increase steadily with age (see Suicide and Intentional Poisonings below). In a separate study, seven specific pharmaceuticals were selected from the AAPCC database for analysis based on their prevalent use and potential toxicity from 1995 through 2002. These pharmaceuticals were theophylline, digoxin, benzodiazepines, tricyclic antidepressants (TCAs), calcium channel blockers, acetaminophen, and salicylate.[97] The death rate from intentional or unintentional exposure to these pharmaceuticals was found to increase by 35% for each decade of life after age 19 years.[97]

Toxic exposures reported to the AAPCC may underestimate the serious consequences for elderly people exposed to toxic substances. Data from the National Electronic Injury Surveillance System—Cooperative Adverse Drug Event Surveillance Project (NEISS-CADES) indicate that patients aged 65 years and older accounted for 25% of estimated visits related to adverse drug events (ADEs) and almost 50% of such visits requiring hospitalization or prolonged monitoring in the ED.[10] The problem may be even greater because the NEISS-CADES study did not capture recognized or unrecognized ADEs in patients treated or dying outside of EDs.

Underrecognition of toxic exposures in the elderly may occur for several reasons. First, because of pharmacokinetic and pharmacodynamic changes that occur as one ages,[31] a "standard" therapeutic dose may produce an unexpected serious effect. Second, the presentation of disease, including drug toxicity, is often atypical in the elderly.[59] For example, falls in the elderly may be a presenting sign of xenobiotic toxicity and are commonly due to prescribed xenobiotics, with sedative–hypnotics, antipsychotics, antidepressants, and class Ia antidysrhythmics (quinidine and procainamide) most often associated with an increased risk of falling.[108] If the patient is cognitively impaired and

the fall is unwitnessed, the immediate consequences of the fall may be adequately addressed, but the xenobiotic causing it may not.[67] Likewise, the toxicologic etiology of neurologic deficits may not be recognized. For example, severe hypoglycemia can produce signs of classic stroke,[116] which could be attributed to other etiologies, particularly in someone who is elderly and otherwise predisposed (see Chap. 48). Another important syndrome in older patients is delirium, which may be caused by many factors but is a common presentation of xenobiotic toxicity[87] (see Chap. 18).[87] A large variety of xenobiotics may cause mental status changes, which may mistakenly be attributed to for nonxenobiotic-related causes in the elderly.[104] Conversely, altered mental status may be unrecognized[75] and, even when obvious, misdiagnosed—for example, as Alzheimer's disease.

A striking case of drug-induced mental status changes is represented by a previously normal 66-year-old man who developed psychosis and attempted suicide after taking increasing doses of dextromethorphan-containing cough syrup for a respiratory infection. The patient was treated with psychiatric medications, and several months elapsed before providers realized that his behavior had been xenobiotic induced rather than due to a primary psychiatric condition.[79]

Finally, the presentation of drug toxicity may be delayed in elderly individuals. Drugs with long half-lives may not reach a steady state and hence not achieve peak action until days after the drug therapy is initiated. In some older patients, the active metabolite of flurazepam, desalkylflurazepam, has a half-life of up to 100 hours or longer, which requires days to achieve a steady state.[47] When peak effects are delayed in this way, drug toxicities may easily be mistaken for nondrug-related illnesses.

Table 32–1 lists xenobiotics commonly responsible for toxicity in the elderly.

SUICIDE AND INTENTIONAL POISONINGS

The risk of suicide by all methods increases steadily with age, particularly among men. Although data for individual ethnic groups are limited, white men have a substantially higher risk of suicide than age-matched cohorts among the African American population.[20] Another high-risk group appears to be Native American and Alaskan Native men,[61] although the number of deaths from all causes among elderly men in those groups is too low to make meaningful comparisons.[20] Although less likely than men to complete suicide, women are more likely to attempt it.[20] The male-to-female ratio of suicide attempts narrows with increasing age, and in the oldest age groups, men attempt suicide slightly more often than women, when all methods of attempted suicide are considered (Chap. 17).[20,102]

Data published in 2000 from eight states reveal that for all attempted and successful suicides combined, the case fatality rate increases with age and is highest for those aged 65 years and older compared with all other age groups (30.7% compared with 14.8% in the next highest group, which is those between 45 and 64 years old).[102] Although the elderly are more likely to select a highly lethal method, the fatality rate is highest among the elderly regardless of method used. In the United States, firearms are the most frequent means of death by suicide. Among men older than age 65 years, xenobiotic overdose accounts for only 3% of completed suicides, and firearms account for 73%. In contrast, xenobiotic overdose and firearms each account for approximately 25% of successful suicides in women. When death by toxic inhalation is included, poison exposure may surpass gunshot wounds as a cause of death among elderly women.[82] Xenobiotic overdose is an important factor in suicide *attempts* by the elderly of both genders.[41]

Geographic and cultural factors also determine the method of suicide. In countries other than the United States, firearms are only

rarely used to commit suicide at any age; suicide by oral overdose and toxic inhalation consequently comprise a much greater proportion.[106] A study of medical examiner–certified suicides in New York City between 1990 and 1998 revealed that falls from a height was the most common method used by people 65 years of age and older and accounted for 33.6% of suicides by people 85 years and older.[2] These data likely represent a local phenomenon because they are inconsistent with national statistics.[20] Falls from a substantial height in Manhattan, with its skyscrapers, landmarks, and bridges, accounts for 34% of suicides among residents and 43% of suicides among visitors.[61]

Among the elderly, the pattern of medications responsible for suicidal deaths may be changing because selective serotonin reuptake inhibitors (SSRIs) are increasingly prescribed for depression instead of TCAs.[15] In the United States, higher suicide rates have been associated with greater use of TCAs than non-TCA antidepressants,[45] which could be related to greater lethality of TCAs in overdose or poorer tolerability of TCAs, leading to nonadherence and enhanced suicide risk. In a Swedish study examining autopsy-confirmed suicides that included analysis of legal xenobiotics, the incidence of suicidal fatalities attributed to benzodiazepines was reported to be increasing despite a marked decrease in benzodiazepine prescriptions.[15] Overdose of benzodiazepines is rarely fatal unless it is accompanied by alcohol or another toxic ingestion or occurs in the presence of serious medical conditions.[35] However, the likelihood of fatality from an overdose of benzodiazepine taken alone increases markedly with each decade of life,[97] perhaps because benzodiazepines in frail elderly people commonly lead to secondary morbidity and mortality from aspiration pneumonia, falls including hip fracture, and other medical complications that may be only the proximate cause of death in the case of overdose.

Notably, flunitrazepam and nitrazepam, the two most frequently implicated in single benzodiazepine suicides in Sweden,[16] are not available in the United States. However, single-drug suicides have been reported with other benzodiazepines that are available, such as flurazepam, triazolam, diazepam, and oxazepam.[16,28,81]

UNINTENTIONAL POISONING, ADVERSE DRUG EVENTS, AND THERAPEUTIC ERRORS

Although poisoning exposures are much less frequent in the elderly than in other age groups, the incidence of ADEs among adults increases steadily with age and increases steeply from age 65 years through the tenth decade of life (Fig. 32–1).[10] An ADE is defined as "one that occurs with normal, prescribed, labeled or recommended use of the [drug]."[9] ADEs are more likely to be serious in the elderly than in younger adults. Serious ADEs are those resulting in death, hospitalization, life-threatening outcome, disability, or other serious outcome[18] and are most prevalent among people 85 years of age and older.[13]

It may be challenging for a clinician to distinguish an intentional or unintentional overdose from an ADE in an elderly patient. The history, if available, must be explored carefully to identify and prevent recurrent problems. However, exposures in persons older than age 60 years are more likely the result of therapeutic errors and "misuse" than in younger adults.[24,29] A therapeutic error is defined as "an unintentional deviation from a proper therapeutic regimen that results in the wrong dose, incorrect route of administration, administration to the wrong person, or administration of the wrong substance" and includes "unintentional administration of xenobiotics or foods which are known to interact."[9] These age-related differences may be because of physiologic changes that affect xenobiotic disposition or effect, patient errors caused by cognitive or visual impairment, or lack of provider proficiency in geriatric prescribing principles.

In contrast to serious consequences of therapeutic errors, reactions such as the serotonin syndrome and neuroleptic malignant syndrome (NMS), which are potentially life threatening, may occur with correctly prescribed therapeutic doses or drug interactions.[5] Although abnormalities in thermoregulation are more common in late life,[8] the risk of developing NMS has not been linked to advanced age per se.[17] However, these syndromes can be overlooked in a patient with comorbidities that could obscure a precise diagnosis. For example, NMS must be distinguished from such geriatric syndromes as cerebrovascular events, heat stroke, or neuroleptic sensitivity syndrome seen in Lewy body dementia.[17]

Both serotonin syndrome and NMS, which are relatively unpredictable, and can occur at any age, are relatively rare. Among elderly

TABLE 32–2. Pharmacokinetic Considerations in the Elderly

	Young	Elderly	Effect on Kinetics
Fat (% of body weight)	15	↑30	↑Vd for xenobiotics distributing to fat (amitriptyline, diazepam)
Intracellular water (% of body weight)	42	↓30	↓Vd for water-soluble xenobiotics
Muscle (% of body weight)	17	↓12	↓Vd for xenobiotics distributing into lean tissue (acetaminophen, caffeine, digoxin, ethanol)
Albumin (g/dL)	4	↓With acute or chronic illness	↑Free concentrations of xenobiotics if > 90% bound to albumin, especially in overdose; interpretation of serum concentration altered
Liver	Normal	↓Size ↓Hepatic blood flow	Liver enzymes not predictive of compromise; concentrations of xenobiotics with high extraction (propranolol, triazolam) may increase; ↓hepatic oxidation (diazepam, chlordiazepoxide)
Kidney	Normal	↓Renal blood flow ↓GFR ↓Tubular secretion	↑Accumulation (lithium, aminoglycosides, *N*-acetyl procainamide, ACE inhibitors, cimetidine, digoxin, opioid metabolites

ACE, angiotensin-converting enzyme; GFR, glomerular filtration rate; Vd, volume of distribution.

patients, serious or life-threatening ADEs are more typically caused by commonly prescribed drugs, such as anticoagulants; insulin and oral hypoglycemics; and drugs that cause delirium, such as sedative–hypnotics, opioids, and anticholinergic agents (see Table 32–1).

As many as 42% of serious ADEs reported in elderly patients are potentially preventable.[4,51] National data from the NEISS-CADES study revealed that drugs requiring careful outpatient monitoring were disproportionately represented among ED visits attributed to unintentional drug overdose. Data gathered as recently as 2004 and 2005 show that hypoglycemics, warfarin, certain anticonvulsants, lithium, digitalis glycosides, and perhaps surprisingly, theophylline account for more than 50% of unintentional overdoses among all age groups and 42% of all estimated hospitalizations.[10] These xenobiotics pose a particular problem for patients 65 years of age and older, being implicated in 85% of visits attributed to unintentional overdose, 87% of overdoses requiring hospitalizations, and 54% of hospitalizations overall.[10] Insulin, warfarin, and digoxin were the most common specific xenobiotics implicated in such events.

The above-mentioned xenobiotics are generally monitored with routine blood testing. Other drugs that commonly cause ADEs in the elderly must be monitored clinically, and these ADEs are often best prevented by not prescribing these xenobiotics to vulnerable patients or by cautioning against their use when they are available without prescription. Criteria have been developed to guide clinicians regarding "inappropriate" medications in elderly patients.[38] Xenobiotics deemed inappropriate in the elderly cause numerically fewer ADEs than more frequently prescribed xenobiotics.[11] However, there is consensus as well as evidence that these xenobiotics pose great risk to older adults, especially those who are frail.[42,72] For example, the elderly are at enhanced risk of severe upper gastrointestinal (GI) bleeding from nonsteroidal antiinflammatory drugs (NSAIDS).[119] Although this could be partly explained by increased exposure to and regular use of these drugs, for chronic conditions, older adults are more vulnerable to their effects because of underlying atrophic gastritis. There is controversy as to cause of age-related gastric mucosal changes, but they may partly be caused by underlying *Helicobacter pylori* infection, which appears to increase with age.[3,33] The elderly are also at greater risk of prolonged hypoglycemia from certain sulfonylureas, particularly glyburide.[100] Age-related mechanisms to explain this vulnerability to glyburide may include a

decreased counterregulatory hormonal response to xenobiotic-induced hypoglycemia,[84] inappropriate stimulation of insulin in response to hypoglycemia,[105] or reduced excretion of a renally eliminated active metabolite of glyburide.[60] Other age-related factors involved in enhanced susceptibility to ADEs are given in Tables 32–2 and 32–3.

SUBSTANCE ABUSE IN THE ELDERLY

Substance abuse declines with age[39] but is important to consider in older adults under relevant clinical circumstances. Alcohol is the most common substance of abuse in people older than age 65 years. Abuse of alcohol or other xenobiotics may be a continuation of long-term habits, but some individuals may first begin to use and abuse xenobiotics late in life.[63]

Substance abuse in late life is probably underrecognized and underreported.[96] In one Illinois study of patients presenting to a trauma facility, only 5% of those aged 65 years and older were tested for alcohol or other substances, but among those younger than age 65 years, 22% were tested for alcohol and 29% for other xenobiotics.[122] However, almost half of the elderly patients tested for alcohol were positive and 72% of those had a blood alcohol level of 80 mg/dL (the legal limit in Illinois) or above, results that were comparable to those of younger patients who were studied, 75% of whom tested positive. For a comparable amount of alcohol ingested, the blood alcohol concentration of an elderly person will be higher than that of a younger adult because changes in body composition reduce the volume of distribution (Vd) of ethanol.[109,113] Moreover, because of an age-associated diminished tolerance to alcohol, the impact on cognitive or motor function tends to be greater.

In the Illinois study noted above, 11% of elderly patients who were tested had positive urine toxicology screening results compared with 43% of tested younger adults.[122] The most common xenobiotics detected in the elderly were benzodiazepines, opioids, and barbiturates, which, like alcohol, are more likely to impair older than younger adults. The failure to consider use of these xenobiotics, whether illicit or by prescription, may have serious consequences. When admitted to hospitals, if a careful history is not elicited, withdrawal from these xenobiotics may be missed, be misdiagnosed, and as a result be inappropriately managed.

TABLE 32–3. Pathophysiologic Disorders Exacerbated or Unmasked by Xenobiotics in the Elderly[a]

Disorder or Alteration	Drug	Possible Outcome
ADH secretion (increased)	Antipsychotics, SSRIs	Hyponatremia
Androgenic hormones (decreased in men)	Digoxin, spironolactone	Gynecomastia
Baroreceptor dysfunction, venous insufficiency	Antipsychotics, diuretics, CAs, α_1-adrenergic antagonists	Orthostatic hypotension
Bladder dysfunction	Diuretics	Incontinence
Cardiac disease	Thiazolidinediones	Congestive heart failure
Dementia	Sedatives, anticholinergics, many others	Confusion
Gastritis (atrophic)	NSAIDs, salicylates	Gastric hemorrhage
Immobility, cathartic bowel	Anticholinergics, opioids, CCBs	Constipation; fecal impaction
Nodal disease (sinus or AV)	β-Adrenergic antagonists, digoxin, CCBs	Bradycardia
Parkinson's disease; Lewy body dementia	Antipsychotics, metoclopramide	Parkinsonism
Prostatic hyperplasia	Anticholinergics, CAs, disopyramide	Urinary retention
Thermoregulation, disordered	Antipsychotics	Hypo- or hyperthermia
Venous insufficiency	CCBs, gabapentin, others	Edema

[a] Disorder may be preclinical.

ADH, antidiuretic hormone; AV, atrioventricular; CCB, calcium channel blocker; SSRI, serotonin reuptake inhibitor; CA, cyclic antidepressant.

PHARMACOKINETICS

Age-related pharmacokinetic changes have important clinical implications for elderly patients. The most consistent pharmacokinetic change that occurs with aging is a decrease in renal function. Glomerular filtration rate (GFR) declines, on the average, by 50% between the ages of 30 and 80 years[32,98] and cannot be accurately predicted by serum creatinine, which does not increase significantly with age,[98] because muscle mass, the source of serum creatinine, declines with age.[68,89]

Because it is impractical and often difficult to measure 24-hour creatinine clearance before instituting therapy with a renally excreted xenobiotic, clinicians commonly estimate creatinine clearance using age-adjusted formulas or nomograms. Frequently applied formulas are fairly predictive of renal function when renal function is stable.[88] However, age-related declines in GFR are not universal, and limited data from longitudinal studies suggest that as many as 33% of elderly individuals do not experience this age-related decline.[77] Conversely, predictive formulas could significantly overestimate actual creatinine clearance in chronically ill, debilitated elderly people, especially those with renal insufficiency.[71] Modifications to the Cockcroft-Gault equation to correct for body surface area[58,99] have been proposed to better reflect renal function (see Table 27–5 for details). However, anthropomorphic measurements are unreliable in the elderly,[66,101] and physiologic variability is great. Alternative measurements, such as the Modification of Diet in Renal Disease(MDRD) Study Group equation, serum cystatin C, and others have also been proposed, but no current method of estimating renal function in the elderly appears to be superior for use in the clinical setting.[111] For all of these reasons, it is difficult to accurately predict the renal elimination of xenobiotics or their metabolites in the elderly. A practical solution is to assume that renal function has declined significantly and to exercise caution when prescribing maintenance doses of drugs with a narrow therapeutic-to-toxic ratio (Table 32–4). Failure to do so is an important cause of toxicity.[74]

The nature and degree of impact of age-related hepatic changes on drug elimination is controversial. Liver mass decreases with an associated decrease in hepatic blood flow,[120] which results in decreased efficiency of hepatic extraction. Enzymatic processes are often unpredictable,[65] and although hepatic oxidation appears to decline with age,[31] this change is difficult to demonstrate. There is substantial genetic variability among cytochrome P450 isoenzymes, making it difficult to interpret studies of age-related alterations in oxidative metabolism. Some studies that consider cofactors that could affect hepatic enzymes, such as concurrent

medications or cigarette smoking, or that determine isoenzyme genotype may demonstrate that there is no age-related change in hepatic oxidative enzyme function.[7]

Hepatic conjugation does not decline significantly with age, so xenobiotics such as temazepam and oxazepam that are metabolized by these processes do not have prolonged elimination half-lives. In contrast, xenobiotics such as diazepam and flurazepam, which are metabolized by hepatic oxidative enzymes, are eliminated more slowly with age.[47] Similar to many oxidized xenobiotics, metabolites of diazepam and flurazepam are active, undergo further metabolism, and remain in circulation after the parent xenobiotic has been metabolized. The active metabolites of some drugs, such as opioids, are renally eliminated, and excretion may be prolonged because of an age-related decline in renal function (see Table 32–4).

Other changes in enzyme systems may occur late in life. For example, a decline in gastric alcohol dehydrogenase level increases the bioavailability of ingested ethanol in the elderly.[93] The decline in this enzyme is attributed to the increased incidence of gastric atrophy with age (see below). Whether age-related changes occur in metabolic enzymes that are present in the intestines, brain, kidneys, and other organ systems and what impact such changes have on drug disposition and drug interactions are likely to become active areas of research. Studies to date have not demonstrated a substantial effect of age on P-glycoprotein, a transmembrane transport protein involved in xenobiotic interactions in the kidneys, intestines, and other organs.[7]

Age-related alterations in body composition may affect xenobiotic disposition in later life (see Table 32–2). For example, lean muscle mass and total body water decline, and the fat-to-lean ratio increases with advancing age.[68,89] Thus, highly lipid-soluble xenobiotics tend to have an increased volume of distribution. As a result, there may be a delay before steady state is reached, and peak effect and toxicity may occur later than expected. This mechanism may be an additional reason xenobiotics such as diazepam and flurazepam have prolonged half-lives in otherwise healthy elderly patients. In contrast, xenobiotics that distribute in water, such as ethanol, have a smaller Vd, leading to higher peak concentrations, accounting at least in part for the more pronounced peak effect of ethanol in the elderly. This may also account for the increased blood alcohol concentration attained in an older adult drinking an equivalent amount of alcohol as a younger person, as noted above.[109,113]

Protein reserve diminishes with age as a consequence of decreased muscle mass and decreased protein synthesis.[95] Although serum albumin concentration remains in the normal range in healthy elderly individuals,[14] people in this age group are more likely to experience a rapid decrease in albumin concentrations when experiencing acute or chronic illness or when their protein intake diminishes.[27,121] A decline in serum protein level increases the free or active fraction of xenobiotics that are otherwise highly protein bound. Free xenobiotic is able to travel more readily to the liver and kidney for metabolism or excretion, so a gradual change in the serum protein concentration is unlikely to lead to a change in the patient's response to the xenobiotic. However, these changes may be clinically important for interpreting serum concentrations of highly protein bound xenobiotics. Clinical laboratories typically measure total xenobiotic concentrations, which include both free and bound xenobiotic. Because most xenobiotic is bound, the reported value reflects mostly bound xenobiotic; therefore, the total xenobiotic concentration may be in the therapeutic range even though the active unbound fraction is actually elevated. Phenytoin, which is highly bound to albumin, serves as an illustrative example. If the serum concentration of phenytoin is reported as subtherapeutic, the physician might order a dose increase even though the free fraction of phenytoin actually is in the therapeutic range. With a dose increase, the free or

active fraction may increase to toxic concentrations. Basic xenobiotics are not bound to albumin but to α-1-acid glycoprotein (AAG), an acute-phase reactant that tends to increase, rather than decrease, with age.[1] However, the increase attributed to age is most likely related to underlying disease. These unpredictable changes would be expected to have the reverse effect on the ratio of bound to unbound xenobiotic in any laboratory report. However, the correlation between clinical effect and free xenobiotic concentrations requires further study because there may be complex factors involved, for example, alterations in Vd, tissue-specific xenobiotic concentrations, and the contribution of other serum proteins to xenobiotic binding.

The precise contributions of gastric and intestinal tract mechanisms to toxicity have not been adequately determined. Changes in gastric absorption with age are not substantial enough to have an important clinical impact, and if anything, there is a modest decline, partly because of delayed gastric emptying, which could cause a delay in absorption of certain xenobiotics. However, age-associated changes in the gastric mucosa may account for enzymatic changes, as demonstrated in the case of alcohol dehydrogenase, noted above.

PHARMACODYNAMICS

Pharmacodynamic factors may also affect a patient's response to a particular xenobiotic. In general, age-related physiologic changes in target or nontarget organs lead to increased sensitivity to most xenobiotics, although sensitivity to some xenobiotics may also be decreased. For example, there is evidence that β-adrenergic receptor sensitivity declines with aging, leading to a diminished response to both β-adrenergic agonists and antagonists, although this is not necessarily demonstrated clinically.[26,40,114]

The observation of enhanced sensitivity to xenobiotics is probably due to altered pharmacokinetics in many, if not most, cases.[50] Proving that enhanced sensitivity is related to altered pharmacodynamics would require demonstrating that the concentration of drug at the tissue site was not increased as the result of diminished elimination. Regardless of the mechanism, it is important to recognize that the response to a given xenobiotic might be altered in specific ways among the elderly. These altered responses are probably caused less by chronologic aging and more by an increased prevalence of disease.[23,50] Table 32–3 provides examples of pathologic or physiologic changes that frequently occur in the elderly and disorders that are worsened or unmasked by xenobiotics.

ADVERSE DRUG EVENTS: RECOGNIZING RISK AND AVOIDING PITFALLS

A complicated xenobiotic regimen reduces adherence,[86] increases medication errors, and increases the risk of clinically important drug interactions. The likelihood of experiencing an ADE increases with the increasing number of xenobiotics taken.[55] Geriatric patients take more prescription and nonprescription xenobiotics than any other patient group.[62] ADEs may occur as a consequence of xenobiotic–xenobiotic interactions, but the exact relationship between the two phenomena is sometimes difficult to quantitate.[55]

Concurrent disease in target or nontarget organs may also alter the patient's sensitivity to a xenobiotic,[87] resulting in a serious ADE even when the patient is given a standard or previously used xenobiotic dose. Coexistent disease is often subclinical, and the patient's enhanced sensitivity may not be anticipated. A patient with subclinical Alzheimer's disease whose cognitive function is overtly normal may acutely develop

delirium or symptoms of dementia when given standard doses of drugs such as sedative–hypnotics and CAs. Delirium is a medical emergency and an important cause of ED visits by the elderly.[57]

Another contributing factor to an ADE is physician lack of knowledge with regard to the principles of geriatric prescribing.[37,52,91] New xenobiotics are sometimes promoted as being safer than older ones, but problems often become apparent after marketing and use by large numbers of patients. For example, the hypnotic agent zolpidem was marketed as a safe alternative to benzodiazepines for the elderly. However, similar to benzodiazepines, zolpidem may also cause confusion, global amnesia, memory loss, and falls.[115,117] Low-molecular-weight heparins (LMWHs), such as enoxaparin and dalteparin, are other examples. LMWHs have more predictable pharmacokinetics than unfractionated heparin and are associated with a lower rate of overall bleeding. However, because therapeutic monitoring requires measurement of antifactor Xa activity, which is not as readily available as standard tests such as activated partial thromboplastin time (aPTT), they have not been recommended for routine use.[54] LMWHs such as enoxaparin and dalteparin are eliminated by the kidneys, and repeated doses lead to progressive increases in antifactor Xa activity when creatinine clearance is 30 mL/min or below,[21,76] a degree of renal insufficiency that is common in frail elderly patients. Less severe levels of renal impairment may also result in reduced enoxaparin clearance that might be avoided with lowered doses.[56] Most reported cases of serious, unexpected enoxaparin-induced bleeding, occur in elderly patients who are receiving "standard," not age-appropriate, dosing.[83,110,112]

In addition to dosing incautiously, clinicians often prescribe drugs considered inappropriate for the elderly at any dose,[30] drugs such as CAs, long-acting benzodiazepines, and anticholinergics.[22] In all of these cases, attention to geriatric risk factors might prevent ADEs.

Compounding the problem of lack of knowledge is the common practice of not adequately studying the effects of new xenobiotics in the elderly (see Chap. 138 for further details).[12,73] Reactions occurring in a small percentage of patients in a special subgroup can easily be missed during the initial drug evaluations. Even when a substantial number of subjects older than age 60 years are studied, a much smaller proportion of patients older than age 70 years may be included in clinical trials.[73] Thus, the adults at highest risk for many forms of xenobiotic toxicity are in a population that is often the least studied. Xenobiotic testing is typically carried out in subjects who are young adults and disease free, so pharmacokinetic profiles do not reflect patterns of xenobiotic disposition characteristic of geriatric patients. Pharmacokinetic testing may be limited to a one-time dose, and frequently the evaluation takes place over a short period of time. On average, approximately 5 half-lives of a xenobiotic are necessary to achieve steady-state xenobiotic concentrations. Thus, a xenobiotic with a half-life of 24 hours might not reach a steady state for 5 days, and in the presence of prolonged elimination associated with age-related factors, a steady state might not be reached for substantially longer. As a result, even if elderly subjects are included in a xenobiotic trial, the ultimate effect of that xenobiotic might not be appreciated during testing intervals designed for younger patients.

Morbidity and mortality in elderly patients as a result of specific xenobiotics might be avoided if the responsible xenobiotics were studied under the predictably high-risk conditions typically present in the elderly. For example, xenobiotics eliminated by the kidney need to be evaluated after repeated dosing in elderly subjects. Gatifloxacin was removed from the market only after several years of use when it was finally linked to both hypoglycemia and hyperglycemia in large numbers of elderly subjects.[49,92] Adverse events from xenobiotics that are studied in the elderly or others with chronic illness may be less obvious in the presence of comorbidity in the population at risk. The cyclooxygenase-2 (COX-2) inhibitor rofecoxib (Vioxx) was withdrawn from the market in 2004 after it was shown to increase the risk of myocardial infarction and stroke, especially in older adults.[34] Based on the complex actions of COX-1 and COX-2 in many tissues, the possibility existed that COX-2 inhibition might increase cardiovascular morbidity, for example, by leaving COX-1–mediated platelet aggregation unopposed while inhibiting prostacyclin-induced vasodilation or by leading to fluid retention and increased blood pressure via renal mechanisms.[53,94] Because elderly individuals typically have one or more chronic illnesses[23] as well as occult disease, extra vigilance is required when new xenobiotics are given, and clinicians and clinical investigators must be very mindful of the theoretical possibilities of adverse outcomes. In view of the vulnerability of older patients to many medications, the Food and Drug Administration (FDA) now requires that sponsors of new drug applications present effectiveness and safety data for important demographic subgroups, including the elderly, in their FDA submission data.[19] However, exceptions to the rule are allowed, for example, when studies have included insufficient numbers of subjects older than age 65 years to determine whether the elderly respond differently to the drug, the labeling must state this, but the statement is a poor substitute for providing actual efficacy and safety data.[25] Also, unfortunately, geriatric recommendations in the package insert may thus be insufficiently specific to provide guidance for drugs commonly used in this population.[103]

Xenobiotics, such as digoxin, warfarin, and diuretics, commonly prescribed in the elderly population, are frequently involved in serious drug interactions. This situation is complicated by the frequency with which elderly patients who often have multisystem disease visit multiple physicians, who prescribe medications without specific knowledge of, or attention to, the remainder of the patient's xenobiotic regimen, thereby increasing the risk of inappropriate xenobiotic combinations.[46,107] Problems can also arise when patients obtain prescriptions from more than one pharmacy or mail order service.

Herbal preparations used by the elderly also may interact with prescription medications.[43,85] The use of herbal preparations has increased substantially in recent years, particularly among patients with illnesses such as cancer, dementia, and depression that commonly affect the elderly. Very few patients voluntarily report use of these or other nonprescribed therapies to their physicians, and too often the physician fails to inquire specifically about such "alternative" or "complementary" therapies. Poisonings, herb–drug interactions, and other problems related to herbal preparations are discussed further in Chap. 43.

The use of nonprescription pharmaceuticals may also cause serious adverse effects. For example, excessive use of magnesium-containing preparations frequently causes severe toxicity in older individuals. Impaired renal clearance, decreased GI motility, and other medical comorbidities are just three risk factors that potentiate magnesium toxicity in the elderly. The source of magnesium in these cases may include the cathartics that contain magnesium hydroxide (Milk of Magnesia) and magnesium citrate, antacid preparations, and magnesium sulfate (Epsom salts).[44] Magnesium-containing laxatives are still sometimes used in hospital settings with serious outcomes.[90] Likewise, oral sodium phosphate formulations, frequently used to cleanse the large intestine before endoscopy, may harm renal function in certain elderly patients despite normal baseline creatinine.[64] Virtually all of the most popular nonprescription medications[62] are more likely to produce problems in the elderly than in younger patients, including GI bleeding (aspirin and other NSAIDs), enhanced warfarin sensitivity (cimetidine), confusion and urinary retention (anticholinergic antihistamines), and cardiovascular symptoms (pseudoephedrine).

Outdated and discontinued xenobiotics are an additional problem for the elderly, who often retain unused or partially used products

in their homes for decades or may continue to request prescription renewals when safer or more effective alternatives are available. Patients may be unwilling to change or physicians may continue to renew the prescription without sufficiently reevaluating the patient. Potential examples include digoxin and theophylline, which are still responsible for large numbers of adverse events diagnosed in EDs,[10] as well as diazepam, propoxyphene, and sedating antihistamines and other anticholinergics.

Other age-related factors may increase the risk of unintentional poisonings in geriatric patients; impaired vision, hearing, and memory may lead to misunderstanding or an inability to follow directions concerning the use of prescription and nonprescription drugs. Dementia is another important risk factor in unintentional poisonings. In addition to cognitive impairment, patients with dementia sometimes exhibit abnormal feeding behaviors, which may lead to ingestion of toxic substances.[118]

MANAGEMENT

Management decisions must be made with the foregoing principles in mind. GI decontamination should proceed as in younger patients. Because constipation is a more frequent problem in the elderly, when multiple-dose activated charcoal is used, particular attention must be paid to GI function and motility. The specific precautions and contraindications in the basic management and GI decontamination detailed in Chapter 7 are particularly pertinent for the geriatric population.

The presence of clinical or subclinical heart failure or renal failure may increase the risk of fluid overload when sodium bicarbonate is used. In the elderly, hemodialysis or hemoperfusion may be indicated earlier in cases of aspirin, lithium, or theophylline poisoning, in which elimination may be hampered by a decreased creatinine clearance or reduced endogenous clearance.

A problem that may go unrecognized in geriatric patients is the development of alcohol or xenobiotic withdrawal symptoms. Because elderly patients are typically not perceived as xenobiotic users, a physician evaluating an unfamiliar patient may not be aware of the patient's chronic use of prescribed benzodiazepines or opioids and consequently might fail to consider the possibility of substance withdrawal when unanticipated complications occur during hospitalization.

Strategies to limit unintentional toxic exposures in elderly patients with cognitive or sensory impairment should be similar to those used in young children, who are also at high risk of ingesting toxic substances or pharmaceuticals prescribed for others in the household. The strategies should include the removal of potentially dangerous substances and unnecessary xenobiotics from the patient's environment. The physician should request that the patient or caregiver bring all medications to the office in the original bottles and then make an effort to limit the number of medications prescribed or to seek alternative medications with a safer therapeutic index or appropriate geriatric safety profile. Administration and control of the medications by directly observed therapy may, of necessity, become the responsibility of the caregiver rather than the patient.

ADMISSION CRITERIA

When geriatric patients are evaluated in the ED for poisonings or serious ADEs, the need for hospital admission should be guided by concerns about the patient's frailty weighed carefully against the known hazards of hospitalization for the elderly.[28] The physician should be particularly alert to certain situations that might mandate admission, including elder abuse or neglect, unexplained mental status changes,

inadequate home care manifested by unexplained falls, and overdose of xenobiotics with prolonged durations of action.

When there is concern that the established caregivers at home may be abusing or neglecting the patient, the patient requires further observation, removal from the environment, and possibly hospitalization. Signs of actual physical abuse may be more obvious than signs of neglect.[69] Vulnerable elderly who are physically disabled or cognitively impaired may be brought to the hospital because of presumed illness, but the source of the problem may actually be the caregiver. The caregiver, frequently a family member, may be depleting the patient's funds for personal use. Patients may become ill because funds were diverted from the purchase of food or because the patient's prescription drugs were sold on the street. More direct abuse may take the form of intentional poisoning of the patient by overdose of the patient's own prescription drugs. Provision for follow-up care, such as an alternative place to live and guardian appointment, is essential because abuse and neglect are associated with serious outcomes.[70]

Unresolved mental status changes may require close observation and hospitalization. Elderly patients who are confused or unable to walk are sometimes mistakenly assumed to be chronically impaired. However, incomplete explanation of an altered mental status or physical impairment should prompt careful inquiry into the patient's baseline functional status. Functional deterioration should never be assumed to be age related. Many very elderly patients are cognitively normal, physically robust, and independent in all activities of daily living.

Patients with overdoses with long-acting medications require careful monitoring. Because the durations of action of certain xenobiotics may be markedly prolonged among geriatric patients, a higher degree of vigilance is required. A classic example is associated with the use of the long-acting benzodiazepine flurazepam, mentioned above. Although this drug has been less often used in the United States in recent years, other long-acting benzodiazepines, such as flunitrazepam and nitrazepam, are still widely used in other countries.[36] The ultra-long-acting sulfonylurea chlorpropamide is rarely used today, but glyburide may cause relatively prolonged hypoglycemia compared with other hypoglycemics, as noted above.

SUMMARY

Older patients may account for only a small fraction of total poisoning victims, but when poisoned, they have a high mortality rate. More importantly, the elderly are much more likely to experience serious ADEs as a consequence of both appropriate and inappropriate use of medications. Attention to risk factors is essential in this vulnerable population. Important risk factors include pharmacokinetic and pharmacodynamic changes; the presence of overt or subclinical disease, including dementia; patient and provider error; suicide risk; complex therapeutic drug regimens; and a general lack of knowledge about the principles of prescribing for the geriatric population.

CHAPTER 33

POSTMORTEM TOXICOLOGY

Rama B. Rao and Mark A. Flomenbaum

Postmortem toxicology is the study of the presence, distribution, and quantification of a xenobiotic after death. This information is used to account for physiologic effects of a xenobiotic at the time of death through its quantification and distribution in the body at the time of autopsy. Several variables may cause changes in xenobiotic concentrations during the interval between the time of death and subsequent autopsy and the storage interval between the time of sampling and the time of testing. Toxicologists and forensic pathologists are frequently asked to interpret postmortem xenobiotic concentrations and decide whether the reported values are meaningful and, if so, whether these substances were incidental or contributory to the cause of death.

The development of the field of forensic toxicology and the improvement of laboratory technology now permit more refined identification and quantification of xenobiotics. The interpretation of postmortem xenobiotic concentrations and their significance, however, continues to evolve.

This chapter reviews factors that affect xenobiotic concentrations identified at autopsy and discusses an approach for interpreting postmortem toxicologic reports as they relate to the cause and manner of death.[37,40,42,48,49,50,58,68,78,96]

HISTORY AND ROLE OF MEDICAL EXAMINERS

The relationship between antemortem xenobiotic exposures and death has been a subject of investigation for centuries. In 12th-century England, an appointee of the royal court, eventually named the *coroner*, was designated to record and identify causes of death.[72] In suspicious circumstances, coroners investigated poisonings, but scientific methods were primitive, and conclusions regarding such deaths were conjecture at best.

By the mid-19th century however, techniques for detecting certain compounds in postmortem tissue were developed and focused generally on identifying heavy metals as a cause of death in homicides.[43,72,76,93,98] At that time, coroners were still elected or appointed individuals with little or no medical training. However, with better laboratory techniques and autopsies performed by trained pathologists, the specialty of forensic medicine continued to develop. In late 19th-century Massachusetts, trained pathologists, referred to as *medical examiners*, ultimately replaced the coroner system and were eventually empowered by the state to investigate deaths (medicolegal autopsies).[72] Currently in the United States, legal jurisdiction of death investigations is the responsibility of either a coroner or a medical examiner depending upon the state or county, with 19 states using medical examiner systems almost exclusively.[47]

The medicolegal autopsy is performed by a forensic pathologist who attempts to establish the cause and manner of death (Table 33–1). The *cause of death* is the physiologic agent or event necessary for death to occur. For example, the presence of cyanide in the toxicologic evaluation may be sufficient to establish cardiorespiratory arrest from cyanide poisoning. The *manner of death* is an explanation of how the death occurred and broadly distinguishes natural from nonnatural (or violent) deaths. Nonnatural deaths, depending on the jurisdiction, may be divided into several categories (Table 33–2). With the identification of cyanide, the manner of death cannot be considered natural because a poisoning is a "chemically traumatic" (violent) event. The medical examiner must make the best determination of the manner of death based on the available evidence.[98,105] An unintentional exposure may be classified as an *accident* (a legal term for some unintentional nonnatural deaths), and intentional self-exposure may be classified as a *suicide*. If the circumstances indicate an exposure due to the acts of another person, the manner of death is classified as a *homicide*.

Determination of the manner of death has important consequences. Homicide necessitates involvement of law enforcement officials for further investigation. Cases deemed suicide not only impact survivors psychologically but also may nullify life insurance payments. Conversely, a case deemed an "accident" may have a double-indemnity insurance clause. Assignment of financial responsibility for workplace disasters may be similarly affected when illicit drugs are identified in the postmortem specimens of involved workers.

Recognition of xenobiotic-related deaths also has significant public health consequences. The forensic pathologist may be the first to identify and report critical information regarding fatal drug reactions, medication errors, or rapidly fatal epidemics associated with illicit drug use or malicious intent activities. In cases of occupational and environmental xenobiotic-related fatalities, interventions can be implemented to prevent subsequent morbidity and mortality. In addition, the pathologist describes gross and microscopic autopsy findings that may elucidate mechanisms of xenobiotic toxicity.

Postmortem toxicologic techniques may be used in other types of investigations as well. For example, when carboxyhemoglobin is identified in the burned human remains from an airplane crash, a cabin fire before descent is more probable than a fire on impact. This type of postmortem analysis is useful in the reconstruction of events leading to the crash.[8,54,63,97]

THE TOXICOLOGIC INVESTIGATION

Ordinarily, toxicologic samples are collected as part of a complete autopsy. In the hospital, when a death is assumed to be from natural causes, the hospital pathologist may perform an autopsy with the consent of the family. In a medicolegal investigation, however, the forensic pathologist determines the need for a complete or partial autopsy and has statutory authority to act on that determination independent of familial consent. Occasionally, only fluid samples may need to be obtained along with an external inspection of the body if a complete autopsy is either unnecessary or the family has legal or religious grounds for objection. The precise list of xenobiotics screened in postmortem samples varies greatly by jurisdiction. Large cities may routinely screen for hundreds of illicit, therapeutic, and environmental xenobiotics. Occasionally, the suspicions of the medical examiner or death scene investigator warrant special assays that are performed only upon request.

The sampling of fluid and tissue may be obtained minutes to years after death. The *postmortem interval*, defined by the degree of bodily decomposition, varies depending on environmental conditions such as ambient temperature, humidity, and immersion under water.[64] Samples may be collected from a body during advanced stages of decomposition, after exhumation from graves, or even after embalming.[8,36,37,44,61,77] Knowing the condition of the body at the time of sampling assists in interpreting the toxicologic findings. These postmortem changes are reviewed below.

DECOMPOSITION AND POSTMORTEM BIOCHEMICAL CHANGES

The first stage of decomposition is autolysis during which endogenous enzymes are released and normal mechanisms maintaining cellular integrity fail.[57] Chemicals move across leaky cellular membranes down relative concentration gradients. Glycolysis continues in the red blood cells until intracellular glucose is depleted, and then lactate is produced. Ultimately, intracellular ions and proteins are released into the blood, and tissue and blood acidemia develops (Table 33–3).[98]

The next stage of decomposition is putrefaction. This stage involves digestion of tissue by bacterial organisms, which typically colonize the bowel or respiratory system. Later, other organisms may be introduced by insects or other external sources. As the putrefactive process advances, the colors of the skin and organ change; epithelial blebs may form and separate from the underlying dermis; and gases may accumulate, forming foul odors and bloating.[98]

If death occurs in a very warm, dry climate, such as a desert or comparably arid environment, the body may desiccate so rapidly that putrefactive changes may not occur. This results in mummification and produces a lightweight cadaver with a tight, dry skin enveloping a prominent bony skeleton.[98]

If the environment is very cold and devoid of oxygen, such as at great depths under water, putrefaction will be slowed. Anoxic decomposition of fatty tissues occurs, forming a white, cheesy material known as adipocere.

Another phase of decomposition, anthropophagia, occurs in unprotected environments where insects or other animals feed on the remains.[98]

Because most postmortem changes are driven by chemical reactions, they are temperature dependent, with increased temperatures accelerating the process and cooler temperatures retarding it. In general, morgue refrigerators achieve low enough temperatures (40°F; 4°C) to prevent further gross decomposition and many associated postmortem changes.

Another process that alters natural decomposition is embalming, a process of chemically preserving tissues that may be performed in a variety of ways.[45,46] Typically, blood is drained through large vessel pumps, and an embalming fluid is injected intravascularly to perfuse and preserve the face or other tissues. Intracavitary spaces may be injected with the preserving substances, and solid organs may or may not be removed.

SAMPLES USED FOR TOXICOLOGIC ANALYSIS

Unless the medical examiner is suspicious about a death, only standard autopsy samples will be available in an otherwise intact body.[23,37,52,59,81,96] These typically include samples of blood, gastric contents, bile, urine, and occasionally solid organs such as the liver or brain. Less commonly, vitreous humor is obtained for analysis (Table 33–4). If the decedent was hospitalized before death, antemortem specimens may also be available for evaluation and comparison. These specimen analyses are reviewed in greater detail below.

■ BLOOD

Postmortem cell lysis prevents the reporting of plasma concentrations, and "blood" concentrations are reported instead. Intravascular blood

Gastric contents	Kidneys	Pupae casings
Vitreous humor	Muscle	
	Nails	
	Skin	

CSF, cerebrospinal fluid.

from the subclavian or femoral vessels is a common source for toxicologic examination. In patients with a prolonged postmortem interval and in cases where intravascular blood is coagulated, right heart blood may serve as a sample site. Just one site is usually sampled unless an unusual xenobiotic with nonuniform distribution is suspected of causing the death. Ideally, femoral blood is obtained.

Other sources of blood may sometimes be available to the forensic pathologist. These frequently include antemortem samples and occasionally extravasated blood, which is unlikely to undergo extensive metabolism. Intracranial clots, in particular, serve as useful comparative samples in patients with a prolonged survival period after exposure to a xenobiotic.[65]

In advanced states of decomposition, blood from the abdominal or thoracic cavities is less useful because it may be contaminated by bacteria or other substances that may affect xenobiotic recovery or analysis.

■ VITREOUS HUMOR

Because of the relatively avascular and acellular nature of the fluid, the vitreous humor is well protected from the early decompositional changes that typically occur in blood.[16,18,19,20,24] When bodies are immediately refrigerated, creatinine, blood urea nitrogen, and sodium can be reliably approximated from vitreous humor samples for up to 3 or 4 days. Potassium concentrations are less reliable as cell lysis causes intracellular release. When vitreous glucose is elevated, hyperglycemia at the time of death can be assumed. A low vitreous glucose level, however, is inconclusive with regard to the antemortem serum glucose concentration. A low vitreous glucose level may be attributable to either antemortem hypoglycemia or postmortem glycolysis (even in the relatively avascular vitreous).

The aqueous content of the vitreous is normally higher than that of blood and may affect the partitioning of certain water-soluble xenobiotics.

■ URINE

Urine may be available during the autopsy and may reveal renally eliminated substances or their metabolites. Because the bladder serves as a reservoir in which metabolism is unlikely to occur, the concentrations of xenobiotics obtained during the autopsy reflect antemortem urine concentrations. An isolated urine sample is of limited quantitative value but may be useful when compared with other sample sites.

■ GASTRIC CONTENTS

The gross contents of the stomach are inspected for color; odor; and the presence or absence of pill fragments, food particles, activated charcoal, and other foreign materials.[96] Typically, gastric concentrations of xenobiotics are reported as milligrams of substance per gram of total gastric contents. Xenobiotic-induced pylorospasm, diminished intestinal motility, or decreased splanchnic blood flow may all decrease gastric emptying and affect the quantitive values obtained from sampling different parts of the gastrointestinal tract.

■ SOLID ORGANS AND OTHER SOURCES

Xenobiotic concentrations in solid organs, such as the liver and brain, are usually reported as milligrams of substance per kilogram of tissue. Other tissue samples, including hair and nails, are used for thiol-avid agents such as metals. Rarely, tracheal aspirates of gases may be analyzed to confirm inhalational exposures. Pleural fluid analysis of postmortem xenobiotics typically yields qualitative results in decomposed bodies because redistribution of xenobiotics from the stomach and intestines may occur.[31,88]

OTHER SAMPLING SOURCES

In an embalmed body, either the organs or tissues that remain relatively unembalmed, such as deep leg muscle,[67] or the embalming fluid itself may be used for analysis. Some authorities regulate the contents of embalming fluid to specifically avoid confounding postmortem analysis. Most embalming fluid in the United States consists of formaldehyde, sodium borate, sodium nitrate, glycerin and water. When a body is disinterred, soil samples are usually obtained from above and below the coffin to permit identification of chemicals that may have leeched into or out from the body.[77]

On rare occasions, cremated remains, often referred to as *cremains*, are the only source of sampling available. Most metallic implants, such as pacemakers, are removed before cremation, and only dental remains, particulate matter, and occasionally calcified blood vessels are available for analysis.[4,104] In most cremations performed in the United States, the incineration process is followed by mechanical grinding to yield a fine particulate matter.[104] The ability to extract xenobiotics from such samples is markedly limited at best, and little published data are available on the subject. A new technique to identify heavy metals such as lead from cremains has been described but is not routinely used at present.[4,104]

ENTOMOTOXICOLOGY

In putrefied bodies or bodies that have undergone anthropophagy, fluids and even insect parts can be analyzed. Forensic entomologists can collect samples of these insects from the remains. After taking into account the stage of insect life, environmental conditions, and the season, the approximate time of death can be extrapolated. The species *Calliphoridae*, or the bluebottle fly, is attracted to unprotected remains by a very fine scent that develops in the cadaver within hours of death. The adult fly lays eggs on mucosal surfaces or in open wounds. After the eggs hatch, the larvae feed on the decomposing tissue. Larval samples can then be examined for the presence of xenobiotics. To achieve accurate analysis, these samples must be preserved immediately after collection because living larvae can continue to metabolize certain xenobiotics. In another phase of their life cycle, the larvae undergo pupation, secreting a substance that encloses them into pupal casings until they hatch as adults. These pupal casings are often found in the soil beneath the body. Some xenobiotics have been identified in the casings long after the adult fly has emerged[86] (Table 33–5). A variety of other anthropophagic insect species may also demonstrate the presence

of toxicological substances.[1,41,61,62] This process of analysis is termed *entomotoxicology*.

INTERPRETATION OF POSTMORTEM TOXICOLOGY RESULTS

After fluid and tissue samples have been collected and analyzed for the presence of xenobiotics, the process of interpreting these results begins. This complex task attempts to account for the clinical effects of a xenobiotic at the time of death by integrating medical history, autopsy and crime scene findings, and toxicologic reports. Multiple confounding variables may affect the sample concentrations of xenobiotics from the time of death to the time of testing after the autopsy. Variables include the nature, metabolism, and distribution of the xenobiotic; the state of health of the decedent; physical and environmental variables during the postmortem interval; the techniques of analysis; and other findings of the autopsy (Tables 33–6, 33–7).

■ VARIABLES RELATING TO THE XENOBIOTIC

Postmortem Redistribution The xenobiotic blood concentration may be higher during the autopsy than at the time of death if the agent undergoes significant postmortem redistribution.[53,80,103–110] Redistribution occurs most often with substances that have large volumes of distribution and when decomposition results in release of intracellular xenobiotic into the extracellular compartment.[84] For example, amitriptyline may be released from tissue stores into the blood as autolysis progresses, resulting in a higher blood concentration during the autopsy than at the time of death. If postmortem redistribution is not considered, xenobiotic concentrations obtained during the autopsy may be misinterpreted as being supratherapeutic or even toxic, and the cause of death may be inappropriately attributed to this agent.

Postmortem Metabolism Less commonly, xenobiotic concentration may decrease secondary to postmortem metabolism. For example, cocaine continues to be degraded after death by endogenous enzymes such as cholinesterases in the blood, which are stable in postmortem tissue and in vitro. Unless blood is collected immediately after death and placed in tubes containing enzyme inhibitors such as sodium fluoride, the concentration of cocaine will continue to decrease, and the analysis will not accurately reflect the concentration of the drug at the time of death.[58,70,97,101] All available information regarding postmortem redistribution or metabolism of a specific xenobiotic must be considered for the proper interpretation of the toxicologic results.

State of Absorption and Distribution Both in the living and deceased, the state of absorption, distribution, and other toxicokinetic principles affect the apparent concentration of a sampled xenobiotic. For a xenobiotic with minimal postmortem metabolism or redistribution, the phase of absorption is suggested by the relative quantity of the agent in different fluids and solid organs. For example, a high concentration of xenobiotic pill fragments in the gastric contents, with progressively lower concentrations in the liver, blood, vitreous, and brain, suggests an early phase of absorption at the time of death. When an agent is orally administered and the tissue concentration is highest in the liver, the relationship suggests a postabsorption phase but a predistribution concentration. A concentration found to be highest in the urine suggests that the xenobiotic was in an elimination phase at the time of death. Although this approach has limitations, it may be important for correlating the state of absorption and the expected clinical course of the xenobiotic. Unfortunately, multiple samples may not always be available at the time of autopsy or the interpretation of reports, and opportunities for subsequent sampling are often limited.

Xenobiotic Stability Xenobiotic stability refers to the ability of an agent to maintain its molecular integrity despite postmortem changes such as decomposition of the body, adverse storage conditions, or the lack of preservatives.[5,13,15,55,56,61,91,99,106,108,109] Postmortem xenobiotic stability was assessed in homogenized liver tissue infused with various concentrations of xenobiotics.[99] The samples were allowed to putrefy outdoors, and sequential sampling of xenobiotic concentrations was performed. The xenobiotics that decreased in concentration as putrefaction progressed were considered labile, but samples with a constant concentration were considered stable. The authors proposed that the chemical moieties of a xenobiotic determine its stability. For example, labile agents share the molecular configuration of an oxygen–nitrogen bond, thiono groups, or aminophenols. Conversely, chemical structures that enhance stability include single-bonded sulfur groups, carbon–oxygen and carbon–nitrogen bonds, and sulfur–oxygen and hydrogen–nitrogen bonds. Although not explicitly studied in otherwise intact but putrefying bodies, logically, a less stable xenobiotic may be recovered in a lower concentration than the actual concentration at the time of death. This must be considered when information regarding stability is available and the body of a decedent is in an advanced stage of decomposition.

TABLE 33–6. Considerations in Interpreting Postmortem Xenobiotic Concentrations

Xenobiotic Chemical Interactions An artifact may result from a chemical interaction with a xenobiotic added during the postmortem interval, such as embalming fluid.[38] In a study of xenobiotic-spiked blood and formalin in test tubes, amitriptyline was formed by the methylation of nortriptyline.[26,109] Identification of amitriptyline, which was not present at the time of death, could confuse the interpretation of toxicologic analyses.

Expected Clinical Effects of the Xenobiotic For a fatality to be attributed to a xenobiotic, the expected clinical course from the exposure should be consistent with the autopsy findings. For example, what are the implications of a person found dead[90] minutes after having been seen ingesting pills, if a large concentration of acetaminophen is identified in both the gastric contents and blood but not in other tissues of at autopsy? Although suicidal intent may be supported by this finding, the onset of death within minutes is inconsistent with a fatality due to an acetaminophen overdose. Thus, another cause of death must be sought. Interpretation of postmortem toxicology must also incorporate clinically relevant consequences of xenobiotic interactions. For example, the combined ingestion of phenobarbital and ethanol can cause fatal respiratory depression. Although neither may be fatal alone, their clinical synergy must be acknowledged during toxicological interpretation.

■ VARIABLES RELATED TO THE DECEDENT

Comorbid Conditions The clinical response to a xenobiotic may be affected by acquired and inherited physiologic conditions that are not always identified or identifiable on autopsy. A thorough medical history is important, and may assist in interpreting the clinical effects of a xenobiotic exposure. Similarly, certain clinical conditions may produce substances that interfere with postmortem laboratory assays. For example, an individual with a critical illness may produce digoxin-like immunoreactive substances (DLIS), which may cross-react with the postmortem digoxin assay.[6] Without knowledge of DLIS production, the results may confound toxicologic analysis.

Tolerance Tolerance is an acquired condition in which increasingly higher xenobiotic concentrations are required to produce a given clinical effect. It is an important consideration for deaths in the presence of opioids, ethanol, and sedative–hypnotic agents. For example, respiratory depression and death from methadone may be easily diagnosed in an opioid-naive individual with a history of methadone exposure and methadone-positive postmortem samples. However, the same methadone concentrations in a patient on chronic methadone maintenance therapy will not produce the same outcome. Unfortunately, no autopsy markers are available to indicate tolerance, and no biochemical or histologic markers are available during autopsy that may be used to predict clinically dangerous xenobiotic concentrations in tolerant individual.[27] Complex postmortem assays analyzing opioid receptors are not routinely used.[35] Postmortem assessment of tolerance ultimately depends on knowledge of the patient, pharmacokinetics of the agent, and the best judgment of the investigator.

Pharmacogenetics There is genetic variability in the expression of certain metabolic enzymes. For example, pharmacogenetic differences in metabolic enzymes, such as CYP2D6, predispose some individuals to fatal hypotension from an inability to metabolize debrisoquine. Such distinctions are not routinely identifiable on autopsy.[28]

■ VARIABLES RELATING TO THE AUTOPSY

State of Decomposition In decedents in advanced stages of decomposition, xenobiotics may diffuse from depot compartments such as the stomach or bladder into adjacent tissues and blood vessels or secondarily affecting their sample concentrations.[22,37,65,75–77,83–85]

During putrefaction, bacteria cause fermentation of endogenous carbohydrates, resulting in ethanol formation. In decedents without gross evidence of putrefaction, especially those in cool, dry environments, endogenous ethanol production is minimal.[17,21] With a longer postmortem interval or in an environment that is more conducive to ethanol production, the distinction between endogenous and exogenous sources of ethanol becomes more difficult. Sampling from multiple sites is often useful in making the distinction.[100] A comprehensive review of interpreting postmortem ethanol concentrations is available elsewhere.[65]

Handling of the Body or Samples   Inappropriate handling of the body may result in artifacts.[90,92] In one reported case, methanol was detected in the vitreous humor of a decedent after embalming.[12] The methanol was subsequently traced to a spray cleanser that likely settled on the surface of open eyes during washing of the body.

In addition, inappropriate handling of samples may affect xenobiotic concentrations. In one study, autopsy blood was obtained from a diabetic man who died of bronchopneumonia. The samples were stored at 4°C and tested at 2 and 5 days postmortem. The blood ethanol increased from 0.4g/L to 3.5 g/L because of an inadequate addition of fluoride preservative to the samples. The combination of inadequate preservation, hyperglycemia (vitreous glucose of 996 mg/dL), and bacterial sepsis created an ideal environment for ethanol production.[65]

In the United States, preservatives containing metals are currently banned for use in embalming because they may contaminate subsequent evaluation for metal poisoning. Formalin may also affect stability or quantitative identification of some xenobiotics. When necessary, an analysis of embalming fluid used by the mortician or soil sampling around disinterred bodies may facilitate the toxicologic investigation.[19,33]

Autopsy Findings   In many xenobiotic-related deaths, the anatomic findings are nonspecific.[107] In some cases, the autopsy reveals confirmatory or supportive findings. A large quantity of undigested pills in the stomach is consistent with an intentional overdose, and suicide should be considered. Centrilobular hepatic necrosis may be found in decedents with a history of acetaminophen overdose. The autopsy may also reveal other findings such as coronary artery narrowing, chronic hypertension, renal abnormalities, or a clinically silent myocardial injury. Such information may be useful to assess the potential effects of a xenobiotic in a patient with previously undiagnosed conditions. In other cases, the absence of a chronic condition may be strongly suggestive of a xenobiotic-related death. For example, a decedent with an autopsy finding of aortic dissection in the absence of chronic hypertensive findings or other predisposing conditions may suggest a xenobiotic-induced hypertensive crisis as may occur from use of cocaine or other sympathomimetics.

Artifacts Related to Sampling Sites   Site-specific differences in postmortem xenobiotic blood concentrations are common.[34] For example, blood drawn from femoral vessels may have low glucose levels because of postmortem glycolysis, but the blood glucose concentration removed from the right heart chambers may be high as a result of perimortem release of liver glycogen stores. Hyperglycemic states are more reliably assessed from sampling the vitreous humor. An elevated vitreous glucose concentration suggests antemortem hyperglycemia. The individual interpreting the toxicologic report must know the exact site from which the sample was taken.[19,59]

Ideally, samples from more than one site would be available for comparison; unfortunately, multiple blood samples are not often routinely obtained. Comparison of concentrations from different sites may reveal important information regarding the state of xenobiotic absorption at the time of death and acute versus chronic exposure.[9–11,19,25,29,51,66,71,79,81,83,87–89,94,95,100,102]

Other Considerations   Published therapeutic, toxic, and fatal postmortem xenobiotic concentrations are available to aid in the interpretation of postmortem specimens.[3,69] However, the conditions associated with reported concentrations do not necessarily permit comparisons with the concentrations of the particular case under investigation. Thus, these resources are valuable but should be used mainly as guidelines and not accepted as absolute values that define either toxic or therapeutic concentrations. Similarly, formulas available for assessing xenobiotic doses or concentrations in the living are not usually applicable when analyzing postmortem samples.

■ OTHER LIMITATIONS

Although there are generalized standards of practice in forensic investigations, specimen collection and laboratory methodology may vary.[2,3] Some xenobiotic concentrations may be falsely elevated or depressed depending on the chosen methodology.[31,71] Descriptions of specific toxicology laboratory techniques are beyond the scope of this chapter, but these variables must also be given consideration in the interpretations of results. Other limitations may include a lack of information relating to the circumstances of death and possible compromises in specimen handling because of the required protocols for the maintenance of proper chain of custody (often of paramount importance in forensic autopsies).[36,37]

SUMMARY

To accurately interpret postmortem toxicologic reports, it is essential to understand potential biochemical changes and other artifacts that affect postmortem testing. Unfortunately, because of the complexity and variety of all possible circumstances, no single resource can absolutely correlate postmortem xenobiotic blood and tissue concentrations to those at the actual time of death. Postmortem toxicology is an evolving discipline that may permit only the most likely truths associated with the xenobiotic identified and the circumstances in question.[14,32,73] Progress in this field will depend on the continued collaboration between the treating physicians, medical and forensic toxicologists, and forensic pathologists.

SPECIAL CONSIDERATIONS (SC1)

ORGAN PROCUREMENT FROM POISONED PATIENTS

Rama B. Rao

Xenobiotics can cause brain death due to the unique vulnerabilities of the central nervous system. With supportive care however, such patients may be suitable candidates for organ donation.[7,8,11,27,33] Early identification of donors is critical as the viability of transplantable tissue diminishes as duration of brain death progresses.[24,33] Timely identification may be further complicated by the presence of xenobiotics that mimic brain death.[3,8,31]

A variety of protocols to establish brain death are reviewed elsewhere.[3,8,31] Once brain death is established, organ procurement personnel assist in: obtaining familial consent, deciding which organs are most suitable for transplant, and maximizing physiological support and perfusion until organ procurement occurs.[33]

Successful transplantation of organs is reported from poisoned donors associated with a multitude of xenobiotics[1,2,4,6-8,10,14,23,25-30]

(Tables SC1-1, SC1-2). Although some xenobiotics are highly toxic, such as cyanide and carbon monoxide (CO), transfer of clinical poisoning to the organ recipient is not reported. This is likely caused by several factors including xenobiotic metabolism, tissue redistribution or binding prior to procurement, as well as the means of handling organs during the transplantation process. For example, some xenobiotic clearance may occur in the myocardium during organ rinsing and cardiopulmonary bypass.[25] Furthermore, individual organs may not uniformly manifest toxicity in response to xenobiotic insults. For example, the heart of a CO poisoned donor was examined after a transplantation failed for technical reasons. The myocardium did not demonstrate histological signs of CO poisoning.[30]

Probably more critical to transplantation success is adequate tissue perfusion and well maintained cellular morphology. For example, patients suffering brain death from acetaminophen poisoning are not suitable liver donors given the hepatoxicity. Alternatively, xenobiotics considered toxic to organ function by impairing enzymes have resulted in successful transplantation if the cellular structure is otherwise maintained. For example, a death from cardioactive steroid poisoning did not preclude successful heart transplantation even when the donor had a bradydysrhythmia, an elevated serum digoxin concentration,

Table SC–1. Organs Transplanted After Donor Poisonings

Organ	Poisons Identified in Donors
Cornea*[1,23,25,26,29]	brodifacoum, cyanide
Heart[8,14,25,28,30]	acetaminophen, alkylphosphate, benzodiazepine, beta-adrenergic antagonists, brodifacoum, carbamazepine, carbon monoxide, chlormethiazole, cyanide, digitalis, digoxin, ethanol, flurazepam, glibenclamide, insulin, meprobamate, methanol, propoxyphene, thiocyanide
Kidney*[2,4,6,10,25,26,29]	acetaminophen, brodifacoum, carbon monoxide, *Conium maculatum*, cyanide, ethylene glycol, Insulin, malathion, methanol, tricyclic antidepressants
Liver[4,6,7,10,14]	brodifacoum, carbon monoxide, *Conium maculatum*, cyanide, ethylene glycol, insulin, malathion, methanol, Methaqualone, tricylic antidepressants
Lung[5,7,14,25,27,29]	brodifacoum, carbon monoxide, methanol
Pancreas[6,7,10,25]	acetaminophen, brodifacoum, carbon monoxide, *Conium maculatum*, cyanide, ethylene glycol, methanol, tricyclic antidepressants
Skin[7,27]	cyanide, methanol

*Can be cadaveric procurement.

Table SC–2. Xenobiotic Related Deaths Resulting in Successful Organ Donation

Alkylphosphate

Barbiturates

Benzodiazepines

Beta-adrenergic antagonists

Brodifacoum

Carbamazepine

Carbon monoxide

Cardioactive steroids

Chlormethiazole

Conium maculatum

Cyanide

Ethanol

Ethylene glycol

Glibenclamide

Ibuprofen

Insulin

Malathion

Methaqualone

Meprobamate

Methanol

Propoxyphene

Tricyclic antidepressants

and required cardiopulmonary resuscitation.[30] Similarly, the liver of a patient poisoned with brodifacoum was transplanted after administration of fresh frozen plasma and vitamin K_1. The recipient's INR post-transplant was 2 and corrected rapidly with supportive care. Recipient concentrations of brodifacoum were not reported and not clearly causative of the elevated INR.[25] In both examples the target of toxicity was enzymatic and the tissue morphology was otherwise minimally affected. Organs from a patient who suffered hypoxic brain death after malathion poisoning were procured 2 weeks after the exposure at which time which no further evidence of acute cholinergic toxicity was present and[4] successfully transplanted. Most transplant failures from poisoned donors, are due to rejection, sepsis, or technical reasons. The 1-year survival in recipients from poisoned donors approximates that from nonpoisoned donors, one series reported at 75% survival.[10] In another review 5-year survival was between 33% and 100% with heart transplant recipients the lowest.[7]

Ideally, a comprehensive international registry of transplants from poisoned donors will be established to improve understanding of transplants from such patients. It appears that patients who suffer brain death from poisoning are potentially suitable donors when cellular infrastructure is preserved.[20,22,24,33] Consideration for organ procurement should not be limited by the xenobiotic.

Therapeutic serum concentration	=	10–30 µg/mL	
	=	66–199 µmol/L	

HISTORY AND EPIDEMIOLOGY

Acetaminophen (*N*-acetyl-*p*-aminophenol [APAP]), a metabolite of phenacetin, was first used clinically in the United States in 1955.[137,154,161] The well-known toxicity of phenacetin led to unfounded concerns about acetaminophen safety that delayed widespread acceptance of acetaminophen until the 1970s. Acetaminophen has since proved to be a remarkably safe drug at appropriate dosage, which has led to its popularity, as evidenced by sales of more than 90 million tablets per year.[70] Acetaminophen is available alone in myriad single-agent dose formulations and delivery systems, and in a variety of combinations with opioids, other analgesics, sedatives, decongestants, expectorants, and antihistamines.[161]

The diversity and wide availability of acetaminophen products dictate that acetaminophen toxicity be considered not only after identified ingestions but also after exposure to unknown or multiple drugs in settings of intentional drug overdose, drug abuse, and therapeutic misadventures.

Despite enormous experience with acetaminophen toxicity, many controversies and challenges are unresolved. New formulations and new analogs will be introduced in the future, which will require reassessments of the knowledge in this area.[303] To best understand the continuing evolution in approach to acetaminophen toxicity, it is critical to start with an analysis of certain fundamental principles and then to apply these principles to both typical and atypical presentations in which acetaminophen toxicity must be considered.

PHARMACOLOGY

Acetaminophen (APAP) is an analgesic and antipyretic with weak peripheral antiinflammatory and antiplatelet properties. Analgesic activity is reported at a serum acetaminophen concentration of 10 µg/mL and antipyretic activity at 4 to 18 µg/mL.[323]

APAP has a unique mechanism of action among the analgesic antipyretics. Most of the nonsteroidal antiinflammatory drugs (NSAIDs) occupy the cyclooxygenase (COX) binding site on the enzyme prostaglandin H_2 synthase (PGH_2) and prevent arachidonic acid from physically entering the site and being converted to prostaglandin H_2. APAP also inhibits prostaglandin H_2 production but does so indirectly by reducing a heme on the peroxidase (POX) portion of the PGH_2,[177] and indirectly inhibiting COX activation.[9,138,173] In this way, APAP function is highly dependent on cellular location and intracellular conditions.[8,102,211] APAP strongly inhibits prostaglandin synthesis where concentrations of POX and arachidonic acid ("peroxide tone") are low, such as the brain.[92] In conditions of high peroxide tone, such as inflammatory cells (macrophages) and platelets, prostaglandin synthesis is less affected by APAP.[9,34,102,110,173,203,211] This explains APAP's strong central antipyretic and analgesic effect but weak peripheral antiinflammatory and antiplatelet effects. Functionally, APAP predominantly acts as a central indirect inhibitor of COX-2 enzymes,[121,201,203] with some mild peripheral COX-2 inhibition[164] and minimal COX-1 inhibition (see chap. 36).[53]

Antipyresis and analgesia are predominantly mediated by this central indirect COX-2 inhibition and the resulting decrease in prostaglandin E_2 (PGE_2) synthesis.[89,102,150,168,203] Additional analgesic effects may be mediated by APAP's centrally mediated indirect stimulation of serotonergic and opioid descending pathways or activation of the cannabinoid system. Stimulation of descending serotonergic pathways has been demonstrated in rats[32] and humans,[102,216] and the analgesic effect of APAP may be inhibited by several serotonin antagonists or serotonin depletion.[2,216,218,219,252] In rats, the analgesic effect of APAP is attenuated by opioid receptor antagonists.[47,253] However, APAP poorly binds to opioid receptors,[230,231,232] and the exact mechanism of opioid stimulation remains unexplained.[254] Finally, activation of the central or peripheral endogenous cannabinoid system, potentially from an APAP metabolite,[123] has been theorized but remains controversial.[22,67,109,210]

PHARMACOKINETICS

After oral (PO) ingestion of a therapeutic dose immediate-release acetaminophen is rapidly absorbed from the small intestine with a time to peak [APAP] of approximately 30 minutes for liquids and 45 minutes for tablets.[4,77,95] Extended-release acetaminophen has a time to peak of 1 to 2 hours but is almost entirely absorbed by 4 hours.[79] The time to peak may be delayed by food[77] and coingestion of opioids or anticholinergics.[108,200] The oral bioavailability is 60% to 98%,[234] and the volume of distribution is 1 L/kg.[4,95] Peak [APAP] after recommended doses typically ranges from 8 to 20 µg/mL.[4,7,163] After administration of 20 to 25 mg/kg rectal suppositories, the peak [APAP] ranges from 4.1 to 13.6 µg/mL, the time to peak [APAP] is 2 to 4 hours (range, 0.4–8 hours), and the bioavailability is 30% to 40%.[15,28,107] Acetaminophen is available in several countries in the intravenous (IV) form as an acetaminophen solution and as a pro-drug (eg, propacetamol) and is currently in Phase lll trials in the United States. The time to peak of the

IV formulations are immediate (<15 min), and peak [APAP] after a 2-g infusion of IV APAP is approximately 75 µg/mL with a large range of 31 to 161 µg/mL.[93,104,215] Acetaminophen has total protein binding of 10% to 30% that does not change in overdose.[186] APAP crosses the placenta; the blood–brain barrier; and in small amounts (<2% of ingested dose), into breast milk.[100,167,207]

After it has been absorbed, approximately 90% of acetaminophen normally undergoes hepatic conjugation with glucuronide (40%–67%) and sulfate (20%–46%) to form inactive metabolites, which are eliminated in the urine.[256] A small fraction of unchanged acetaminophen (<5%) and other minor metabolites reach the urine.[192,253] The remaining fraction, which usually ranges from 5% to 15%, is oxidized by CYP2E1 (and, to a lesser extent, CYP3A4, CYP2A6 and CYP1A2),[116,176] resulting in the formation N-acetyl-p-benzoquinoneimine (NAPQI).[62] Glutathione quickly combines with NAPQI,[191] and the resulting complex is converted to nontoxic cysteine or mercaptate conjugates, which are eliminated in the urine (Fig. 34–1).[185,192] The elimination half-life of

FIGURE 34–1. Important routes of acetaminophen metabolism in humans and mechanisms of N-acetylcysteine (NAC) hepatoprotection. NAC[1] augments sulfation, NAC[2] is a glutathione (GSH) precursor, NAC[3] is a GSH substitute, and NAC[4] improves multiorgan function during hepatic failure and possibly limits the extent of hepatocyte injury. APAP = N-acetyl-p-aminophenol = acetaminophen.

acetaminophen is approximately 2 to 3 hours after a nontoxic dose[4,228] but may become prolonged in patients who develop hepatotoxicity.[227]

TOXICOKINETICS

Even after overdose, the majority of acetaminophen absorption occurs within 2 hours. Peak plasma concentrations generally occur within 4 hours, although later peaks or double peaks are rarely documented in overdoses.[298] Evidence suggests that NAPQI production is largely the result of activity of the CYP2E1 enzyme after both therapeutic and supratherapeutic doses of APAP.[116] Contributions of CYP1A2, CYP3A4, and CYP2A6 to the production of NAPQI in humans are small and insignificant in most cases, but they may be variable, depending on individual host factors and dosage.[116,213,233,295] After clinically significant overdose, nontoxic sulfation metabolism of APAP may become saturated,[147] and the amount of NAPQI formed is increased out of proportion to the acetaminophen dose. Glucuronidation rates are likely not saturatable in humans (see Fig. 34–1).[73,147,224]

PATHOPHYSIOLOGY

The safety of appropriate acetaminophen dosing results from the availability of electron donors such as reduced glutathione (GSH) and other thiol (S-H)-containing compounds. After therapeutic acetaminophen dosing, GSH supply and turnover far exceed that required to detoxify NAPQI, and no toxicity occurs. After overdose, the rate and quantity of NAPQI formation outstrip supply and turnover of GSH, resulting in free NAPQI rapidly binding to hepatocyte constituents. In animal experiments of acetaminophen overdose, hepatotoxicity becomes evident only when hepatic [GSH] decreases to 30% of baseline or below.[190] This affords acetaminophen a remarkably safe therapeutic index. Whereas a therapeutic acetaminophen dose is 10 to 15 mg/kg, significant toxicity after a single acute overdose generally involves doses that are higher than 150 mg/kg.[225]

When NAPQI formation overwhelms the supply of thiol-containing compounds, it covalently binds[86,221] and arylates proteins throughout the cell,[61,133,137] inducing a series of events that result in cell death.[135] Covalent binding and arylation occur rapidly after glutathione depletion and within hours of ingestion.[27,133,135,236] Both covalent binding and glutathione deficiency are necessary for hepatotoxicity; however, the selective arylation of specific cellular proteins is more predictive of toxicity than total covalent binding.[61,128]

After covalent protein binding and glutathione depletion occur, a cascade of events follows that alters normal cell function and impairs cell defenses against endogenous reactive oxygen species.[137,236,299] This cascade can be ameliorated with N-acetylcysteine (NAC) even after covalent binding occurs.[43,75,98,133,236] These events include mitochondrial dysfunction,[48,78] an increase in mitochondrial permeability,[236] mitochondrial oxidant stress or peroxynitrite formation,[63,120,144] hepatocellular hypoxia,[249] DNA fragmentation[63] resulting from interactions with topoisomerase 2-α,[18,267] calcium dyshomeostasis,[196,300] lipid peroxidation,[105,318] nitric oxide release,[250] inflammatory cell mobilization and activation,[125,156,169] inflammatory cytokine release,[132,133,156,169] and up- or downregulation of protein expression.[25,128,129,249] Which specific event is critical and irreversibly commits the cell to death is not known and is an active area of research.

The final pathway of hepatic cell death is predominantly cellular necrosis,[106] although evidence suggests that apoptosis may occur early in APAP toxicity.[175,235] Macrophages, neutrophils, and inflammatory cells infiltrate after necrosis[125,159,169] followed by a cascade of inflammatory cytokines such as IL-6, IL-8, and MCP-1.[125,132,133,169]

Hepatocellular destruction caused by secondary inflammation, impairment of microcirculation,[188] and hepatic nitric oxide release[133,250] are all demonstrated, although none appear to be necessary for hepatic injury.[63,129,130,159] The exact mechanism and sequence of events involved in hepatocellular damage remains controversial.[127,128,133]

Hepatotoxicity initially and most profoundly occurs in hepatic zone III (centrilobular) because this zone is the area with the largest concentration of oxidative metabolism (CYP2E1)[23] (see Fig. 26-1). In more severe hepatotoxicity, necrosis may extend into zones I and II, destroying the entire liver parenchyma.

Renal injury after acute overdose is typically acute tubular necrosis (ATN) that may be caused by local production of NAPQI by renal CYP2E1 enzymes.[40,84,124] However, several other nephrotoxic mechanisms have been proposed.[113] Conversion of acetaminophen and hepatically derived acetaminophen–glutathione[195] to nephrotoxic *p*-aminophenol[52] are both demonstrated in selected animal models.[80,85,182] NAPQI formation via renal prostaglandin synthetase[308] and prostaglandin-mediated renal medullary ischemia[227] are also suspected of contributing to chronic analgesic nephropathy from acetaminophen alone or in combination with other analgesics.[94,165,251] In patients with hepatic failure, volume depletion and hepatorenal syndrome may be the most important contributory cofactors because the rate of renal failure is similar regardless of the cause of hepatic failure.[322] Dose-related renal potassium wasting[212,315] after acute APAP overdose may be related to APAP-induced renal vasoconstriction due to COX inhibition or a NAC effect, or both.[99,212]

Direct injury to organs other than the liver and kidney is rarely reported. The mechanism of early central nervous system (CNS) depression after APAP ingestion is undefined, but theoretical mechanisms include serotonin and opioid effects as well as CNS glutathione depletion.[26,54] Acidosis and hyperlactatemia early after massive APAP ingestion may be the result of alterations in mitochondrial respiratory function, but the exact mechanism is unknown.[46,88,287] Rare cases of metabolic acidosis with 5-oxoprolinemia and 5-oxoprolinuria are reported and appear to be more likely in women with chronic APAP use and renal insufficiency.[42,90,122] In this rare condition, it is theorized that chronic APAP use combined with acute oxidative stress and inflammatory mediators may lead to an alteration of the γ-glutamyl cycle and elevations of γ-glutamylcysteine and 5-oxoproline.[42,90,122]

The remaining sequelae of severe toxicity are secondary effects of fulminant hepatic failure rather than direct acetaminophen effects, and the pathophysiology of these complex multisystem problems is well described.[162] For example, myocardial injury and pancreatitis have both been reported in patients with acetaminophen-induced fulminant hepatic failure. The ability of NAC to ameliorate secondary multiorgan failure via extrahepatic mechanisms suggests that the oxidation of vital thiols and the loss of normal microvascular function are important components of secondary organ failure.[89,112]

CLINICAL MANIFESTATIONS

Early recognition and treatment of patients with acetaminophen poisoning are essential to minimize morbidity and mortality. This task is made difficult by the lack of early predictive clinical findings, and clinicians should not be reassured by the absence of clinical symptoms shortly after ingestion. The first symptoms after acetaminophen overdose may be those of hepatic injury, which develop many hours after the ingestion, when antidotal therapy will have diminished efficacy.

The clinical course of acute acetaminophen toxicity can be divided into four stages.[247] During stage I, hepatic injury has not yet occurred, and even patients who ultimately develop severe hepatotoxicity may be asymptomatic. Clinical findings, when present, are nonspecific

and may include nausea, vomiting, malaise, pallor, and diaphoresis. Laboratory indices of liver function are normal. In rare cases of massive overdose, a decreased level of consciousness,[91,103,149,242,285] metabolic acidosis,[103,149,184,242] and even death[33,296] may occur during this stage in the absence of signs or symptoms of hepatotoxicity.[33,91,149,242,285,328] These clinical findings should never be attributed to acetaminophen alone without thorough evaluation of other possible causes.

Stage II represents the onset of liver injury, which occurs in fewer than 5% of those who overdose.[276] Aspartate aminotransferase (AST) is the most sensitive, widely available measure to detect the onset of hepatotoxicity, and AST abnormalities always precede evidence of actual liver dysfunction (prolonged prothrombin time (PT), international normalized ratio (INR), elevated bilirubin concentration, hypoglycemia, and metabolic acidosis). When stage II occurs, onset of AST elevation is most common within 24 hours after ingestion but is nearly universal by 36 hours.[268] In the most severely poisoned patients, AST concentrations may increase as early as 12 hours after ingestion.[268] Symptoms and signs during stage II vary with the severity of liver injury. By convention, acetaminophen-induced *hepatotoxicity* is defined as a peak AST concentration above 1000 IU/L. Although lower peak concentrations of AST represent some injury to hepatic tissue, they rarely have any clinical relevance.

Stage III, defined as the time of maximal hepatotoxicity, most commonly occurs between 72 and 96 hours after ingestion. The clinical manifestations of stage III include fulminant hepatic failure with encephalopathy, coma, or rarely exsanguinating hemorrhage. Results of laboratory studies are variable; AST and alanine aminotransferase (ALT) concentrations above 10,000 IU/L are common, even in patients without other evidence of liver failure. Much more important than the degree of aminotransferase concentration elevation, abnormalities of PT and INR, glucose, lactate, creatinine and pH are essential determinants of prognosis and treatment.

Renal function abnormalities are rare overall[225] but occur in as many as 25% of patients with significant hepatotoxicity[225] and in more than 50% of those with hepatic failure.[155,322] Renal abnormalities may be more common after sustained, repeated excessive dosing[155] and in adolescents and young adults.[35,180,197] After acute ingestions, elevations of serum creatinine typically occur between 2 and 5 days after ingestion, peak on day 7 (range, 3–16 days), and normalize over a month.[180] When overt renal failure necessitating hemodialysis occurs, it nearly always does so among patients with marked hepatic injury.[50] Infrequently, mild renal insufficiency occurs without elevations in aminotransferase concentrations.[1,35,60]

Fatalities from fulminant hepatic failure generally occur between 3 and 5 days after an acute overdose. Death results from either single or combined complications of multiorgan failure, including hemorrhage, acute respiratory distress syndrome, sepsis, and cerebral edema. Patients who survive this period reach stage IV, defined as the recovery phase. Survivors have complete hepatic regeneration, and no cases of chronic hepatic dysfunction have been reported. The rate of recovery varies; in most cases, AST, pH, PT and INR, and lactate are normal by 7 days in survivors of acute overdoses. ALT may remain elevated longer than AST, and creatinine may be elevated for more than 1 month. The recovery time is much longer in severely poisoned patients, and histologic abnormalities may persist for months.[166,178,220]

DIAGNOSTIC TESTING

■ ASSESSING THE RISK OF TOXICITY

Principles That Guide the Diagnostic Approach The majority of acetaminophen exposures result in no toxicity, and the overall mortality

rate after acute APAP ingestion is less 0.5%.[276] However, APAP is commonly ingested and is now the leading cause of acute liver failure in the United States, United Kingdom, and much of Europe.[155,161] To maintain the seemingly divergent goals of avoiding the enormous cost of overtreatment while eliminating patient risk, clinicians must understand the basis for and sensitivity of current toxicity screening methods. A discussion of the diagnostic approach follows.

When considering risk determination, it is useful to separate different categories of acetaminophen exposure. There is an extensive body of experience and literature on acute overdose in typical circumstances, permitting a more systematic approach with demonstrated efficacy. For issues related to repeated excessive acetaminophen dosing, uncertain circumstances, patients with possible predispositions to toxicity, new acetaminophen formulations, and many other permutations, there is an important conceptual framework for decision making but little in the way of validated strategies. For these challenges, the central concepts and one approach are presented here, with the understanding that they are dynamic and that more than one approach may have validity.

The clinician must rely solely on the often unreliable ingestion history and measurement of [APAP] in the patient to assess the risk for subsequent toxicity and thus the need for treatment. The ideal model for determining risk after acetaminophen overdose would assess the individual's metabolic enzyme activity (CYP2E1, UDP-glucuronosyl transferase, and sulfotransferase activity), the amount and rate of NAPQI formation, the availability of hepatic GSH, and the balance of NAPQI formation and hepatic GSH turnover.[189,243] At present, none of these measures is available to clinicians.

Protein adducts, which indicate binding of NAPQI to hepatocyte proteins[71,131,199,229,317] and the profile of urinary APAP metabolism[73] can be determined but have been inadequately studied to be useful in risk assessment. Plasma GSH concentration can be measured or approximated using the plasma γ-glutamyl transferase (GGT) concentration but have an uncertain relationship to hepatic GSH availability.[265,279]

Risk Determination After Acute Overdose Determining risk in a patient with acute overdose consists of determining the initial risk based on dosing history and then potentially further risk stratifying with serum [APAP].

Acute overdose usually is considered a single ingestion, although many patients actually overdose incrementally over a brief period of time. For purposes of this discussion, an *acute overdose* is arbitrarily defined as one in which the entire ingestion occurs within a single 8-hour period.[69] Figures of 7.5 g in an adult or 150 mg/kg in a child are widely disseminated as the lowest acute dose capable of causing toxicity.[226] These standards are likely quite conservative but have stood the test of time as sensitive markers and have been corroborated with some data in humans.[313] However, it is more likely that doses of at least 12 g in an adult or 200 mg/kg in a child are necessary to cause hepatotoxicity in most patients.[193,313]

Higher dose cutoffs for consideration of risk would improve specificity; however, the value of improving specificity has not been weighed against the current sensitive lower cutoff. In the face of an enormous variety of potential outliers, the near absence of screening failures almost certainly results from the use of these standards and of a very sensitive screening nomogram. The adult standard may be considered less controversial than that for children because massive ingestions, unreliable histories, and factors that might predispose to toxicity occur primarily in adults, justifying continued use of 7.5 g as a screening amount to avoid missing serious toxicity. In patients younger than 6 years old, with unintentional ingestions, use of a higher 200-mg/kg cutoff has been suggested[51,193,290] and may be appropriate but has been incompletely studied.

The dose history should be used in the assessment of risk only if there is reliable corroboration or direct evidence of validity. Although the amount ingested by history roughly correlates with risk of toxicity and an [APAP] over the treatment line,[313] historical information is not

Acetaminophen nomogram
FIGURE 34–2. The Rumack-Matthew nomogram (reconstructed) for determining the risk of acetaminophen-induced hepatoxicity after a single acute ingestion. Serum concentrations above the treatment line on the nomogram indicate the need for *N*-acetylcysteine therapy.

sufficiently reliable in all patients to exclude significant ingestion, particularly in patients with self-harm or drug abuse. In fact, patients with suicidal ingestions who do not confirm an ingestion of acetaminophen may have a measurable concentration of it in 1.4% to 8.4% of cases[10,172] and a concentration over the treatment line in up to 0.2% to 2.2%.[10,172] Therefore, when the history suggests possible risk, the patient should be further assessed using determination of [APAP].

Interpretation of [APAP] after acute exposures is based on adaptation of the Rumack-Matthew nomogram (Fig. 34–2).[243] The original nomogram was based on the observation that untreated patients who subsequently developed AST or ALT concentrations above 1000 IU/L could be separated from those who did not on the basis of the initial [APAP]. A nomogram was constructed that plotted the initial concentration versus time since ingestion, and a discriminatory line was drawn to separate patients who developed hepatotoxicity from those who did not. The initial discriminatory line stretched from [APAP] of 300 μg/mL at 4 hours to 50 μg/mL at 12 hours but was lowered to between 200 μg/mL at 4 hours and 50 μg/mL at 12 hours after evaluation of additional patients.[243] The half-life of acetaminophen was not a factor in the development of the nomogram, and the slope of the treatment line does not reflect any discriminatory APAP half-life or acetaminophen kinetics.[243] The nomogram is designed and validated using a single value obtained at or greater than 4 hours after ingestion to allow for complete APAP absorption. Although patients who develop hepatotoxicity may have acetaminophen half-lives greater than 4 hours,[228] plotting multiple points on the nomogram or using an APAP half-life to determine risk has not been adequately studied and has significant limitations.[145,278] The nomogram was later extrapolated to 24 hours using the same slope of the original nomogram line.[243]

It is important to realize that the line was based on aminotransferase concentration elevation rather than on hepatic failure or death, and it was chosen to be very sensitive, with little regard to specificity. Without antidotal

therapy, only 60% of those with an initial [APAP] above this original line will develop hepatotoxicity as defined by aminotransferase concentrations above 1000 IU/L, but the risk of hepatotoxicity is not the same for all such patients. Elevated aminotransferase concentration develops in virtually all untreated patients with [APAP] far above the line, and serious hepatic dysfunction occurs frequently; the incidence of hepatotoxicity among untreated people with [APAP] immediately above the line is very low, and the risk of hepatic failure or death is far less.[225,270]

The original line ("200-line") is used in the United Kingdom, Canada, Europe, Australia, and other locations throughout the world. The line used in the United States runs parallel to the original but was arbitrarily lowered by 25% to add even greater sensitivity.[243,247] The lower line, subsequently referred to as the *treatment line* or *150-line,* starts at a concentration of 150 µg/mL at 4 hours after ingestion; declines with a 4-hour half-life, and ends at 4.7 µg/mL 24 hours after the overdose. The treatment line is one of the most sensitive screening tools used in medicine. The incidence of nomogram failures in the United States using this line is only 1% to 3% (depending on time to treatment) and most likely results predominately from inaccurate ingestion histories.[243] A vanishingly small number of anecdotal cases of nomogram failure involve special circumstances of increased risk,[56,181,202] questionable facts, or both.[274]

The higher line ("200-line") has had reported nomogram failures, although they are likely rare. Several authors have recommended that the 200-line is not sensitive enough for patients with comorbid factors that potentially predispose them to hepatotoxicity, and a lower line starting at 100 µg/mL ("100-line") is used in some countries.[39,41,56,72,274,304] In retrospective series, six patients developed hepatotoxicity with [APAP] between the 150-line and the 200-line, and one died of liver failure.[17,41] It has been estimated that of all patients with [APAP] between the 150-line and 200-line, if untreated 3% to 10% develop hepatotoxicity (AST >1000 IU/L),[243,276] and 0.08% develop hepatic failure.[17]

Based on these observations and more than 20 years of use, the 150-line should be considered adequate in nearly all cases and is reliable when rigorously followed. When using the acetaminophen nomogram, it is essential to precisely define the time window during which acetaminophen exposure occurred and, if the time is unknown, to use the earliest possible time as the time of ingestion. Using this approach, patients with [APAP] below the treatment line, even if only slightly so, do not require further evaluation or treatment for acute acetaminophen overdose. This also applies to most patients with factors that may predispose them to acetaminophen-induced hepatotoxicity. There appears to be adequate experience with acute acetaminophen overdose in the settings of potentially predisposing factors such as chronic alcohol abuse, chronic medication with CYP-inducing drugs, and inadequate nutrition to recommend that no special approach is required in such cases. Further study is needed to determine if rare events, such as acute APAP ingestion in the setting of chronic INH use,[202] may uniquely predispose patients to toxicity[87,327] and require alteration of this approach.

The goal should be to determine [APAP] at the earliest point at which it will be meaningful in decision making. Measurement of [APAP] 4 hours after ingestion or as soon as possible thereafter is used to confirm the patient's risk of toxicity and thus the need to initiate NAC. No established guidelines are available for the use of determinations made less than 4 hours after ingestion, and because of variability in absorption, such values have less predictive value. Although it is optimal to start NAC therapy as soon as possible after confirmation of risk, most patients have excellent outcomes if therapy is started earlier than 6 to 8 hours after the overdose.[270,276] This allows clinicians some leeway to wait for the laboratory results before starting therapy in patients in whom the history of ingestion suggests that the 4 hour concentration will fall below the treatment line. It should be noted, however, that delaying NAC therapy longer than 6 to 8 hours after

ingestion may increase the patient's risk. If there is any concern about the availability of an acetaminophen concentration before this time, treatment with NAC should be initiated. Only if the results cannot be obtained within 6 to 8 hours of the overdose should history alone be considered adequate to consider the patient at risk and as an indication to start NAC. In such cases, [APAP] still should be determined as soon as possible. The results, when they become available, should be interpreted according to the treatment line on the acetaminophen nomogram and NAC either continued or discontinued on the basis of this result. In the unusual circumstance in which no determination of [APAP] can ever be obtained, evidence of possible risk by history alone is sufficient to initiate and complete a course of NAC therapy post ingestion.

Early Measurement of [APAP] Measurement of [APAP] between 1 and 4 hours after ingestion may be helpful only to exclude ingestion of APAP. If [APAP] is below 10 µg/mL in this time frame, significant APAP overdose can likely be excluded. However, a concentration that is detectable between 1 and 4 hours cannot be definitively interpreted and mandates repeat testing at 4 hours.

■ DETERMINATION OF RISK WHEN THE ACETAMINOPHEN NOMOGRAM IS NOT APPLICABLE

Risk Determination When the Time of Ingestion Is Unknown With careful questioning of the patient, family, and others, it is almost always possible to establish a time window during which the APAP ingestion must have occurred. The *earliest possible time* of ingestion ("worst-case scenario") is used for risk-determination purposes. If this time window cannot be established or is so broad that it encompasses a span of more than 24 hours, the following approach is suggested. Determine both [APAP] and AST concentrations. If the AST concentration is elevated, regardless of [APAP], treat the patient with NAC. If the time of ingestion is completely unknown and [APAP] is detectable, it is prudent to assume that the patient is at risk and to initiate treatment with NAC. If [APAP] is below the lower level of detection and the AST concentration is normal, there is little evidence that subsequent consequential hepatic injury is possible; NAC is unnecessary.

Risk Assessment After Extended-Release Acetaminophen An extended-release formulation of acetaminophen (Extended Relief Tylenol, Tylenol 8 Hour, Tylenol Arthritis Pain) was released in the United States in 1994, and others exist worldwide. The pill available in the United States consists of a 325-mg immediate-release acetaminophen dose and an additional 325-mg dose designed for delayed dissolution.[70] This results in the immediate release of acetaminophen with delayed release of an additional dose. Pharmacokinetic analysis of the product reveals that the majority of acetaminophen is absorbed within 4 hours,[79,305] the peak [APAP] is within 4 hours,[55,79,286] and a small number of patients may have an initial [APAP] below the treatment line, but then have a subsequent [APAP] above the treatment line ("nomogram crossing").[55,305] This "nomogram crossing" is not unique to the extended-release product and occurs in up to 10% of acute ingestions of immediate-release APAP.[44] There is little evidence that nomogram crossing effects outcome[70] and no evidence that an alternate approach to extended-release products should be used. In a 9-year review of isolated extended-release acetaminophen overdoses, no deaths were reported from acute overdose.[70] Therefore, a single [APAP] can reliably be plotted on the treatment nomogram after APAP extended-release ingestion. The validity of this approach, of course, is specific to the current product, and any new type of extended-release acetaminophen formulation must be evaluated individually.

Patients with Signs or Symptoms of Hepatic Injury After Acute Ingestion Patients who present with signs or symptoms of hepatic

injury after acute acetaminophen ingestion should be immediately started on NAC and measurements of AST and acetaminophen concentrations should be obtained. In patients with elevated AST and acetaminophen concentrations below the treatment line, the history should be reviewed with respect to the timing of ingestion and repeat excessive acetaminophen dosing. The patients should be thoroughly evaluated for causes of hepatic failure and for other causes of elevated AST concentration.

Risk Determination After Chronic Overdose Exposure No well-established guidelines are available for determining risk after chronic exposure to APAP. Conceptually, several factors must be considered before assessing and determining an individual's risk of toxicity. It has been well established that therapeutic dosing of APAP is safe; however, some risk factors may put individual patients at risk for toxicity at supratherapeutic doses.

The chronic ingestion of "maximal therapeutic" doses (4 g/d) in normal adults without special circumstances appears to be safe. Several randomized, controlled trials have used maximal therapeutic doses of APAP (4 g/d) in hundreds of patients over periods from 4 weeks to 2 years with no reported increase in adverse events or hepatic injury.[38,96,152,217] A transient increase in transaminases up to 10 times the normal concentration has been detected in some patients taking therapeutic doses,[316] but these abnormalities resolve spontaneously despite continued use and have not led to hepatic dysfunction.[152,316] Finally, several studies have evaluated abstaining chronic alcoholics administered APAP 4 g/d for up to 10 days with no evidence of hepatic damage, although elevations in transaminases were detected in both APAP and control groups.[66,153]

Although therapeutic dosing appears to be safe, repeated supratherapeutic ingestions (RSTIs) may lead to toxicity. Given the amount of APAP use, the incidence of serious acetaminophen toxicity after repeated doses is small, and hepatotoxicity appears to occur only after massive dosing[66,165,179,312] or prolonged excessive dosing.[36,66] The risk of hepatotoxicity is likely proportional to both the total amount of APAP ingested and the duration of the exposure; however, exact cutoffs for safe dosing are difficult to determine and are likely subject to factors of the individual. In an ideal setting, the interaction of an individual's CYP2E1 activity and therefore NAPQI production with the rate of hepatic glutathione turnover would be determined and considered, but these evaluation tools are currently not available.

Although short-term prospective studies of supratherapeutic dosing (6–8 g/d) have not identified alterations in APAP kinetics or hepatotoxicity,[97] several series and case reports have identified patients with hepatotoxicity who retrospectively report therapeutic or slightly supratherapeutic doses. Retrospective dosage reporting is prone to significant errors, and a substantial portion of these cases involve parental dosing errors, iatrogenic errors, alcoholic patients, or other issues in which those giving the history may be unable or unwilling to report accurately. Furthermore, because APAP is commonly used in patients with alcoholism and viral infections, it is unclear in which cases APAP was causative, contributory, or unrelated to hepatotoxicity.

Conceptually, the groups that are at "high risk" for hepatotoxicity after RSTI of APAP have either potentially increased activity of CYP2E1 and therefore additional NAPQI formation or have decreased glutathione stores and turnover rate. In fact, nearly all reported cases of APAP toxicity from RSTI involve patients who have a factor that influences their glutathione supply or turnover, NAPQI production, or both, including infants with febrile illness who have received excessive dosing,[49,59,74,80,118,206,289,388] chronic alcohol users,[194,264,330] and patients chronically taking CYP-inducing medications.[36,39] The interplay of NAPQI and glutathione may also be an important factor. For example, malnutrition has been theorized to increase the risk of APAP

toxicity[320]; however, both CYP2E1 activity[58] and glutathione supply[143] are decreased in malnourished patients, and their relative impact on risk is unknown.

When there is concern about toxicity risk after RSTI dosing, several approaches are suggested. The goal should be to select patients at risk based on dosing history and other risk factors and to then use limited laboratory testing to determine the need for NAC. A logical screening laboratory evaluation consists of determination of [APAP] and AST concentrations, with additional testing as indicated by these results and other clinical features. The objective is to identify the two conditions that warrant NAC therapy—remaining acetaminophen yet to be metabolized and potentially serious liver injury.

Role of History and Physical Examination in Chronic Overdose The first consideration when evaluating a patient with a history of repeated supratherapeutic acetaminophen dosing is the presence or absence of signs or symptoms of hepatotoxicity. Regardless of risk factors or dosing history, such findings should prompt treatment with NAC and laboratory evaluation. This is particularly important because most reported cases of serious toxicity after repeated dosing are symptomatic for more than 24 hours before diagnosis, and earlier diagnosis should improve outcome.

In asymptomatic patients, a reasonable approach is to perform laboratory evaluation for those who have ingested more than 200 mg/kg/d (or 10 g/d, whichever is less) in a 24-hour period or more than 150 mg/kg/d (or 6 g/d, whichever is less) in a 48-hour period.[66,69,174] In children younger than age 6 years, laboratory evaluation should be performed if the reported ingestion is more than 100 mg/kg/d over a 72-hour period or greater.

Several factors or characteristics place patients at higher risk for chronic APAP toxicity. High-risk factors that have been theorized include chronic alcoholism; chronic ingestion of isoniazid; febrile illnesses in infants and young children; and malnutrition, AIDS, or anorexia. In some cases, animal or basic science studies show evidence of increased risk, and in most cases, there have been multiple anecdotal reports of toxicity at therapeutic or slightly supratherapeutic doses. Whether these patients require a lower threshold for laboratory screening is unknown and controversial.

Role of Laboratory Evaluation in Chronic Overdose After a patient is determined to be at risk, an [APAP] and AST concentrations should be determined. These should be interpreted using the concept that a patient may be at risk of hepatotoxicity if there is evidence of hepatic injury (elevation of AST) or there remains enough APAP to produce further hepatic damage.

Using the strategy described here, patients with elevated AST concentrations are considered at risk, regardless of [APAP]. An [APAP] is useful in patients with normal AST concentrations as a tool to determine only whether sufficient acetaminophen remains to lead to subsequent NAPQI formation and delayed hepatotoxicity. In many cases, AST concentration is normal and [APAP] is below 10 μg/mL, obviating the need for NAC. If the AST concentration is normal, the patient should be considered at risk if [APAP] is 10 μg/mL or above.

Patients who develop highly elevated AST after chronic acetaminophen overdose should be treated and further evaluated with laboratory tests to assess hepatotoxicity and prognosis (creatinine, PT and INR, and pH; phosphate; lactate).

The measurement of APAP protein adducts in urine has been described and theoretically could quantify NAPQI production in the liver. Although this test has promise as an early detection tool, it remains largely unavailable and has been insufficiently studied for clinical use.[71,133,199]

Patients who are identified as at risk, with an elevated AST or a normal AST and an elevated [APAP], should be treated with NAC.

RISK DETERMINATION AFTER ACETAMINOPHEN EXPOSURE IN CHILDREN

Serious hepatotoxicity or death after acute acetaminophen overdose is extremely rare in children.[30,245,290] Predominant theories[5] for resistance to toxicity include a relative hepatoprotection in children because of increased sulfation capacity[185] or differences in the characteristics of children's poisonings, including smaller ingested doses, overestimation of liquid doses, and unique formulations.[293] This has led some to suggest higher screening values and a higher nomogram line for children.[6,31,301] However, no significant change in NAPQI production has been demonstrated in children,[307] and a more liberal approach to children's acute APAP ingestions has been inadequately studied and is not recommended. After repeated supratherapeutic acetaminophen dosing, there is no evidence that children are relatively protected. In fact, infants and children with acute febrile illnesses comprise one of the few groups in which toxicity after repeated excessive dosing is well described.[49,59,74,80,119,120,206,239,280,288] Common sources of dosing errors include substitution of adult for pediatric preparations; substitution of drops (100 mg/mL) for elixir (32 mg/mL), overzealous dosing by amount or frequency in attempts to maximize effect, and failure to read the label and dose carefully.[5] Age younger than 2 years is an independent risk factor for development of toxicity.[139] These rare cases of toxicity in febrile children with repeated supratherapeutic dosing may simply reflect that these children constitute the most common setting for pediatric acetaminophen use and that children are at greater relative risk for excessive dosing because of their size. Although logically one can argue that inflammatory oxidant stress and short-term fasting during febrile infectious illnesses affect oxidative drug metabolism and decrease glutathione supply, these relationships are complex and not well defined. Of the reported cases of repeated supratherapeutic APAP dosing in children with hepatic injury, the cause was likely an isolated infectious illness in some, acetaminophen in others, and a combination of the two in still others.

RISK DETERMINATION AFTER ACETAMINOPHEN EXPOSURE IN PREGNANCY

The initial risk of toxicity of a pregnant patient is similar to that of a nonpregnant patient with a few exceptions. Little evidence suggests that any alteration of the treatment line is necessary. In fact, there have been no reported cases of fetal or maternal toxicity in women with [APAP] below the treatment line[183] or in those treated with NAC within 10 hours of an acute ingestion.[238] However, there is controversy in assessing the risk of fetal toxicity after the mother has been determined to be at risk. To better understand the issues, a review of maternal–fetal physiology and pharmacokinetics related to APAP and NAC is necessary.

Acetaminophen is capable of crossing the human placenta,[11,167,205,240] and APAP may be present in concentrations that are similar to maternal serum concentrations within hours after ingestion.[11,205,240] Fetal metabolism of APAP probably is inefficient but is not completely understood. Fetal sulfation and oxidative metabolism of APAP are slower than in adults, and glucuronidation is undetectable until 23 weeks of gestation.[241] CYP450 enzymes that are capable of oxidizing APAP are present in the fetus as early as 18 weeks gestation.[241] However, the activity of these enzymes is less than 10% that of adult enzymes at 18 weeks gestation and increases to only 20% activity at 23 weeks.[241] How the opposing forces of decreased overall metabolism of APAP and decreased NAPQI formation impact fetal risk is unclear.

The mechanism of fetal risk in patients with [APAP] over the treatment line remains controversial. The degree of fetal toxicity that is attributable to fetal metabolism of APAP or to maternal illness is

unclear. In clinical case series, the majority of pregnant women who overdose on APAP have uneventful pregnancies.[183,238] Pregnant women who develop APAP toxicity in the first trimester have an increased risk of spontaneous abortion,[238] and those who develop APAP toxicity in the third trimester have a potential risk of fetal hepatotoxicity because of fetal metabolism. However, reports of third-trimester fetal hepatotoxicity are rare[183,238] and are only associated with severe maternal toxicity.[238,310] The factors associated with poor fetal outcome after a large APAP overdose are delayed treatment with NAC and young gestational age.

The decision to treat a pregnant woman with NAC requires consideration of what is known about the efficacy and beneficial effects as well as the adverse effects of NAC for both the fetus and the mother. Every indication suggests that NAC is both safe and effective in treating the mother,[238] but there are inadequate data to evaluate efficacy in the fetus, although fetal outcome has generally been excellent after maternal treatment with NAC.[238] Given that NAC has been safely used in many pregnancies[183,238] and fetal mortality is linked to delays to treatment, NAC should be initiated in pregnant women whose [APAP] is over the treatment line. The necessary length of NAC therapy is difficult to determine. The 20-hour IV protocol probably is the most commonly recommended NAC protocol used for pregnant women worldwide, with *published* experience supporting NAC treatment courses shorter than the PO 72-hour protocol (see chap. 30).[183,238]

ETHANOL AND RISK DETERMINATION

The effects of ethanol on acetaminophen toxicity are complex and are best described by clearly separating experimental animal data from actual human overdose experience, acute from chronic ethanol abuse, and single from repeated supratherapeutic acetaminophen dosing. Although not entirely consistent, both animal and human data suggest that acute ethanol coingestion with APAP may be hepatoprotective. Ethanol coingestion decreases NAPQI formation presumably by inhibiting CYP2E1 in both humans[3,13,296,297] and animals.[255,296,302] In large retrospective evaluations of human overdoses, acute ethanol ingestion independently decreases the risk of severe hepatotoxicity in chronic alcoholics[260] and in nonalcoholics,[270] but does not significantly decrease the risk of hepatotoxicity (ALT >1000 IU/L) in a smaller prospective study.[314]

Chronic ethanol administration however, increases the risk of hepatotoxicity from acetaminophen dosing in animals[302,329] and increases human NAPQI formation[294] on the basis of induced CYP2E1 metabolism or decreased mitochondrial glutathione supply or regeneration.[158,329]

After acute acetaminophen overdose, alcoholics may be at a slightly increased risk; however, this elevated risk appears to be of little clinical importance given the sensitivity of the treatment line.[244,275,297] There is no credible evidence that chronic ethanol use should alter the approach after an APAP acute overdose using the treatment line. Given the paucity of data linking alcoholism to nomogram failures, it appears that the treatment line is adequately sensitive for screening after an acute APAP overdose, regardless of the patient's pattern of ethanol use.

The relationship between chronic ethanol use and chronic APAP use is complex. Hepatotoxicity has been sporadically reported in patients with chronic ethanol abuse after repeated supratherapeutic acetaminophen dosing.[194,264,323] Complicating these reports are the clinical challenges of obtaining accurate histories in alcoholics, failure to exclude non-APAP causes of hepatotoxicity, and other factors. Alcoholics commonly use supratherapeutic doses both chronically and acutely and use combinations of multiple APAP-containing products.[265] In contrast, prospective evidence demonstrates minimal risk of hepatotoxicity in alcoholic patients who ingest therapeutic doses of APAP.[14,117,151,153] In prospective trials of ingestion of 4g/d of APAP in moderate to heavy

ethanol drinkers for up to 10 days, no clinically relevant increases in AST versus placebo have been identified.[14,117,151,153] It should be noted, however, that in studies involving alcoholics, mild AST elevations (<120 IU/L) were noted in 40% of both study and control subjects, and more significant increases (>120 IU/L or three times normal) were noted in 4% of 6% of subjects.[151,153] In addition, in all studies, a small group of patients developed significant increases in transaminases, but most were unchanged. Patients who develop elevated transaminases after therapeutic dosing who are then rechallenged with additional APAP develop similar AST increases,[117] implying that individual factors are likely more important than the chronic ethanol use itself.

■ CYP INDUCERS AND RISK DETERMINATION

Inducers of the CYP enzymes have long been theorized to increase the risk of toxicity from APAP because of a proportionally increased production of NAPQI.[246] It is now clear that APAP is metabolized to NAPQI largely by CYP2E1[116,176] and that only induction of this specific enzyme is likely to increase the risk of hepatotoxicity.

Although ethanol and isoniazid are known inducers of CYP2E1, there is no evidence that the clinical approach to these patients should be altered. Similarly, several other medications, including phenytoin, carbamazepine, and phenobarbital, have been theorized to increase APAP toxicity because of nonspecific CYP induction activity. None of these anticonvulsants induces CYP2E1, although there is some evidence that they increase NAPQI formation in cultured human hepatocyte and animal models, possibly through inhibition of glucuronidation.[29,81,190,222] Clinical experience, however, suggests that there is no need to change the clinical approach to these patients.[301]

■ ASSESSING ACTUAL TOXICITY: CRITICAL COMPONENTS OF THE DIAGNOSTIC APPROACH

Earlier protocols and guidelines recommended extensive and ongoing laboratory assessment after acetaminophen overdose.[247] Based on the pathophysiology and time course of toxicity, a simplified and far more cost-effective approach is logical.

Initial Testing   The acetaminophen concentration should be measured in patients with acute acetaminophen overdose and no evident hepatotoxicity, but no other initial laboratory assessment is required. AST concentration should be measured in patients considered to be at risk for APAP toxicity according to the nomogram or history (in the case of repeated supratherapeutic dosing) or in those suspected of already having mild hepatotoxicity by history and physical examination.

Unless evidence of serious hepatotoxicity is present, AST concentration is sufficient indication of hepatic conditions, and no additional testing is initially needed. Death of hepatocytes, resulting in release of measurable hepatic enzymes, precedes all cases of serious liver dysfunction. Even if abnormalities of other markers precede elevation of AST concentration, there is no evidence that their detection benefits the patient.[16] Mild renal toxicity may rarely occur without hepatotoxicity[35]; however, at least minimal elevation of AST concentration generally precedes evidence of clinically significant nephrotoxicity.[1,50] Exceptions are rare,[35,54,142,] and routine screening of renal function in the absence of elevated AST concentration is probably unnecessary.

Acetaminophen overdose may lead to minor prolongation of PT even without causing hepatotoxicity.[321] This most commonly occurs between 4 and 24 hours after ingestion and may be a result of NAPQI-related inhibition of vitamin K–dependent γ-carboxylation of factors II, VII, IX, and X.[292,321] These minor prolongations (resulting in PT that usually is less than twice control) are rarely clinically relevant, are not evidence of hepatotoxicity, and should not be used as

prognostic factors or indications for NAC treatment. In fact, treatment with NAC may prolong PT[134,148] by interfering with the PT assay, by reversing an APAP/NAPQI effect,[292] or by direct NAC effects.[292] Clinical interpretation of these minor prolongations of PT is clouded by preexisting conditions, treatment with NAC, and laboratory error. Even in cases in which PT and INR are prolonged, if consequential liver injury does develop, elevation of AST concentration precedes serious liver dysfunction.

Ongoing Monitoring and Testing   If no initial elevation of AST concentration is noted, repeated AST determination alone—without other biochemical testing—is sufficient to exclude the development of hepatotoxicity. AST should be determined at the end of the protocol (eg, at 21 hours if using the 21-hour protocol) or every 24 hours if using a longer protocol. If elevated AST concentration is noted, then PT and INR and creatinine concentration should be measured and repeated every 24 hours or more frequently if clinically indicated. Results of other liver tests, such as γ-glutamyltransferase, alkaline phosphatase, lactate dehydrogenase, and bilirubin, which are useful when determining the cause of liver abnormalities, will be abnormal in cases of serious acetaminophen-induced hepatotoxicity but provide little additional useful information if the cause is certain.

If evidence of actual liver failure is noted, then careful monitoring of blood glucose, pH, PT and INR, creatinine, lactate, and phosphate concentrations are important in assessing extrahepatic organ toxicity and are vital in assessing hepatic function and the patient's potential need for transplant (see Assessing Prognosis). In addition, meticulous bedside evaluation is necessary to detect and document vital signs, neurologic status, and evidence of bleeding. Many additional tests may be useful in the setting of liver failure based on clinical condition and local protocols. Testing for other rare acetaminophen-associated conditions by electrocardiography, lipase determination, or other studies should be performed on a case-by-case basis only.

MANAGEMENT

■ GASTROINTESTINAL DECONTAMINATION

In cases of very early presentation or coingestion of agents that delay gastrointestinal (GI) absorption, gastric emptying may be appropriate for some patients. In general, however, gastric emptying is not a consideration for patients with isolated acetaminophen overdose because of the very rapid GI absorption of acetaminophen and the availability of an effective antidote.

Administration of activated charcoal (AC) shortly after APAP ingestion may decrease the number of patients who have an [APAP] above the treatment line.[45] Although activated charcoal is most effective when given within the first 1 to 2 hours after APAP ingestion, it may be reasonable to consider AC at later times provided there are no contraindications.[283]

Interactions between AC and PO administered NAC are likely clinically unimportant. In the majority of cases, there should be no interaction because GI absorption of APAP, and therefore the necessity to give AC, is complete by 4 hours after ingestion, and NAC typically is administered between 4 and 8 hours after ingestion. As a result, there is generally no difficulty separating the doses.

If delayed or repeated AC dosing is indicated because of suspected delayed absorption or coingestants, then a strategy using an IV NAC protocol should be considered. Alternatively, PO NAC and AC doses may be separated by 1 to 2 hours, with NAC given the priority for the first dose because time to administration of NAC correlates with risk of hepatotoxicity.[270,276] NAC is absorbed high in the GI tract and is not likely to interact with AC if they are not administered simultaneously.

In unusual cases, as a result of coingestants, timing of presentation, and unavailability of IV NAC, PO NAC and AC may be administered simultaneously. Although there is clear in vitro evidence of binding between AC and NAC[57,248,291] and volunteer data suggest that AC causes statistically significant decreases in NAC absorption,[83] there is no evidence that this interaction is clinically significant or that a dose adjustment is necessary.[282]

■ SUPPORTIVE CARE

General supportive care consists primarily of controlling nausea and vomiting and managing the hepatic injury, renal dysfunction, and other manifestations. Treatment of these problems is based on general principles and is not acetaminophen dependent. Discussion of the management of liver failure is clearly beyond the scope of this chapter, but certain aspects deserve mention. Monitoring for and treatment of hypoglycemia as a result of liver failure are critical because hypoglycemia is one of the most readily treatable of the life-threatening effects of liver failure. If adequate viable hepatocytes are present, vitamin K may produce some improvement in coagulopathy; thus, trial dosing is logical as liver injury develops and as it resolves. Administration of fresh-frozen plasma (FFP) should be based on specific indications rather than PT and INR alone.

One of the most important advances is use of prolonged NAC for treatment of fulminant hepatic failure. Parenteral NAC, other advances in supportive care, and successful liver transplantation programs appear to have substantially improved survival from APAP-related liver failure.[101,174,259]

Antidotal Therapy with N-acetylcysteine

Mechanism of Action of N-acetylcysteine Conceptually, it is helpful to think of NAC as serving three distinct roles. During the metabolism of acetaminophen to NAPQI, NAC *prevents toxicity* by limiting the formation of NAPQI. More importantly, it *increases the capacity to detoxify* NAPQI that is formed (see Fig. 34–1). In fulminant hepatic failure, NAC *treats toxicity* through nonspecific mechanisms that preserve multiorgan function. A complete discussion of NAC can be found in Antidotes in Depth A4: *N*-Acetylcysteine. A brief review follows.

NAC prevents toxicity by serving as a glutathione precursor[157] and as a glutathione substitute, combining with NAPQI, and being converted to cysteine and mercaptate conjugates.[46] NAC may also lead to increased substrate for nontoxic sulfation, allowing less metabolism by oxidation to NAPQI.[271] Each of these preventive mechanisms must be in place early, and none is of benefit after NAPQI has initiated cell injury. Time is required to saturate nontoxic metabolism from excessive NAPQI, deplete GSH, and overcome GSH production; thus there is a window of opportunity after exposure to an APAP overdose during which NAC can be initiated before the onset of liver injury without any loss of efficacy. Based on large clinical trials, it appears that NAC efficacy is nearly complete as long as it is initiated within 6 to 8 hours of an acute overdose.[141,270,276,277] However, the relationship between the time to administration of NAC and the risk of hepatotoxicity should be considered a continuous variable, with the risk of hepatotoxicity beginning to increase at 6 hours for patients with very high [APAP] and closer to 8 hours for patients with [APAP] just over the treatment line.[270,284] For this reason, NAC therapy should not be unnecessarily delayed past 6 hours if it can be safely administered earlier.

Several observations illustrate the effectiveness of NAC by other mechanisms of action even after NAPQI formation and binding. NAC actually reverses NAPQI oxidation in both a mouse model[62] and an in vitro human hepatocyte model,[175] and even after cell injury is initiated, NAC may diminish hepatocyte injury.[43] Most significantly, a prospective, randomized trial found that even after fulminant hepatic failure

was evident, starting IV NAC diminished the need for vasopressors and the incidences of cerebral edema and death.[140] In this study, despite improved organ function and survival in the NAC-treated group, there was no apparent difference in the degree of hepatic injury, implying that much of the benefit of NAC in this setting may not be derived from hepatic effects. Whether based on its nonspecific antioxidant effects, its increase in oxygen delivery and utilization,[76,112,136,281,309,310] its ability to enhance glutathione supply, or its role in mediating microvascular tone, NAC improves function in several organs affected by multisystem failure.[64,76,306] In fact, NAC may preserve cerebral blood flow and perfusion in the setting of cerebral edema[319] more effectively than traditional therapies such as mannitol and hyperventilation, which may actually be detrimental.

Although NAC has a defined role in preventing and treating APAP-induced hepatic injury, its role in treating APAP-induced renal injury is less clear. When used early after ingestion in animals, NAC produces a small reduction in renal injury.[195,272] In retrospective reviews of human data, NAC has had little effect on renal injury[82] but does not appear to be harmful.[197] However, little data is available to recommend NAC therapy in treating isolated renal injury or renal injury after resolution of hepatic injury.

N-acetylcysteine administration NAC may be administered via the PO or IV routes and in protocols that vary in length. The two most common regimens are a 21-hour IV infusion and a 72-hour PO dosing protocol. These are described at length in Antidotes in Depth A4: *N*-Acetylcysteine.

With the exception of established liver failure, for which only the IV route has been investigated,[140] the IV and PO routes of NAC are equally efficacious in preventing or treating acetaminophen toxicity.[44,223] The decision to treat with IV or PO dosing is complex and is described in Antidotes in Depth A4: *N*-Acetylcysteine. In brief, whereas IV NAC has been associated with rare but severe anaphylactoid reactions and medication errors.[115] PO NAC is associated with a greater than 50% risk of vomiting. There are three scenarios in which IV NAC is generally recommended: APAP toxicity in pregnant women, APAP-induced liver failure, and intractable vomiting preventing PO treatment.

Duration of N-acetylcysteine Treatment Known mechanisms of action and the observation that all studied durations of NAC are effective when started within 8 hours[44] suggest that all courses of treatment currently published are effective when NAC is used for its early preventive actions. Results from use of the traditional 20-hour IV NAC protocol, the 48- and 36-hour IV NAC protocols studied in the United States,[273] one 20-hour PO protocol,[325] and other "short-course" dosing protocols[24,324] indicate that all therapies are safe and effective in this scenario.[289,326]

It is important to realize that even in low-risk patients (those treated within 8 hours), regardless of the protocol (20, 36, 48, or 72 hour) or formulation of NAC (IV, PO) initiated, that NAC therapy should be continued until APAP metabolism is complete (the [APAP] is below detection) and there are no signs of hepatotoxicity.[85,180] With this concept in mind, it may seem reasonable to *shorten* a set course of NAC if the patient is low risk and the above criteria are met [APAP] undetectable, AST normal, PT/INR normal, and no encephalopathy).[24,68,270] This approach is conceptually reasonable; however, adequate studies have not definitively confirmed its safety.[266,270] For that reason, shortened courses cannot currently be recommended until additional studies are completed.

However, NAC therapy should be continued *beyond* the prescribed protocol length if there is evidence of significant liver injury (AST concentration above normal or INR elevated or encephalopathy is present) or acetaminophen metabolism is incomplete ([APAP] detectable). This likely will not be an issue in the vast majority of cases because the

aminotransferases of approximately half of all NAC-treated patients with [APAP] above the treatment line will remain below 100 IU/L.[277] The IV NAC dosing protocol that has proved beneficial in patients with liver failure is the same initial dosing as the 1-hour IV protocol but with the third IV infusion continued until resolution of liver failure. These observations suggest that rather than a single duration of therapy for all patients, it is appropriate to extend treatment protocols based on the clinical course of the patient.[68]

After NAC therapy is extended beyond a set-length protocol, the decision to discontinue therapy should be entirely based on the patient's condition. For patients who develop liver failure, IV NAC is continued until the PT or INR is near normal and encephalopathy, if present, is resolved.[174] For patients without liver failure but with elevated AST concentration, NAC is often continued until all liver abnormalities resolve (AST concentration is decreasing and <1000 IU/L).

Hepatic Transplantation Liver transplantation may increase survival for a select group of severely ill patients who have acetaminophen-induced fulminant hepatic failure.[174,208] Tremendous improvements in transplantation and supportive hepatic care have increased immediate survival rates after hepatic transplantation to 75% to 78% with 3-year survival rates of 56% to 66%.[21,174] Patients who meet criteria for transplant but do not receive an organ have had survival rates ranging from 5% to 17%,[19,20,155,174,187,209] but survival rates have recently been reported as high as 66%.[259]

Concerns that patients who receive transplants for acetaminophen-induced fulminant hepatic failure will have lower survival rates and be unable to maintain posttransplant medication regimens have resulted in the majority of patients not being listed for transplant.[21] However, those who meet psychosocial criteria for transplantation have high rates of survival,[21,174] and only 12% later die from intentional rejection or suicide attempts.[21] Techniques that allow subtotal hepatectomy with transplantation and eventual weaning of immunosuppressants are promising and may allow for higher rates of transplantation.[171]

Assessing Prognosis Determining a patient's prognosis and predicting patients who require transplantation early in the course of the disease is an important area of current research.

The most commonly used indicator of the need for immediate transplantation is the King's College Criteria (KCC), which was developed and validated on patients with acetaminophen-induced fulminant hepatic failure. The criteria include a serum pH below 7.30 after fluid resuscitation or the combination of creatinine above 3.3 mg/dL, PT above 100 seconds (INR > 5 is commonly used), and grade III or IV encephalopathy. The survival rate of patients who meet the KCC but do not receive an organ remains below 20% in most centers.[12,21,209] Significantly higher survival rates in patients meeting transplant criteria have recently been reported and may be due to improved supportive care for patients with acute liver failure.[101,259]

When determining the KCC, interpretation of PT and INR must include awareness of therapy with vitamin K or FFP and/or NAC. The use of vitamin K, if effective, implies that transplant may be unnecessary because viable liver remains. If vitamin K is ineffective, PT and INR can be used as discussed in the previous paragraph. Transfusion of exogenous clotting factors, such as FFP, alters interpretation because improvement in PT and INR may not indicate improvement in liver function. The prognostic importance of monitoring PT and INR in this setting suggests that FFP should be given only with evidence of bleeding, with risk of bleeding from known concomitant trauma, or before invasive procedures and not based merely on the PT and INR value.

A blood lactate concentration above 3.5 mmol/L at a median of 55 hours after APAP ingestion or blood lactate concentration above 3.0 mmol/L after fluid resuscitation are shown to be both sensitive and a specific predictor of patient death without transplant.[20,65] Additional

studies confirmed lactate as an independent predictor of prognosis but suggest that it does not add significantly to the KCC .[263] Others have confirmed a lower specificity than initially reported[101,263] and suggested that a higher cutoff (4 mmol/L) may be more specific.[263]

Unfortunately, patients often meet the KCC and lactate criteria quite late in their course of disease, so these criteria are not useful as early predictors or as standards for transfer to a facility that performs hepatic transplant. Several attempts at determining early predictors of death or the need for transplant have proven to be no more effective than the KCC, including serum phosphate (day 2),[19,261] Model for Endstage Liver Disease score,[170,262] serum Gc-globulin,[160,257] factor V concentration,[126,214] Factor VIII:V ratio,[37,214] worsening day 4 PT and INR,[111] and PT (in seconds) larger than the number of hours since ingestion.[204]

An Acute Physiology and Chronic Health Evaluation (APACHE) II score above 15 in isolated APAP ingestions may be as specific as the above KCC criteria and slightly more sensitive.[187] These criteria may be beneficial in determining whether to transfer a patient to a transplant center because the score is easily calculated, is sensitive, and is available within the first day of admission; however, confounders such as coingestants may decrease its utility. Furthermore, an APACHE III score above 60 may be helpful in identifying additional patients with multiorgan dysfunction who may require transplantation.[21]

Several early factors may be useful in identifying patients at high risk of hepatotoxicity but not necessarily patients who require transplantation or who may die. The time from ingestion to the initiation of NAC and serum APAP concentration are directly proportional to the patient's risk of developing hepatotoxicity and hepatic failure.[258,270,276] Using these principles, a nomogram has been produced that may be used to determine the risk of hepatotoxicity on patient arrival. Unfortunately, this only predicts the risk of a peak aminotransferase above 1000 IU/L and has not been studied to determine the risk of death or transplant.

SUMMARY

Several key concepts will help clinicians effectively manage patients with acetaminophen exposures. For patients with intentional over-doses, measurement of [APAP] should be considered part of the initial evaluation. In cases in which risk assessment for acetaminophen toxicity is merited, treatment with NAC should be initiated as soon as possible and ideally within 6-8 hours from the time of ingestion. IV NAC should be preferentially used in cases of fulminant hepatic failure or intractable vomiting and in pregnant patients. Otherwise, the efficacy of the PO and IV formulations should be considered the same. Patients who present after repeated excessive APAP dosing should be assessed for evidence of hepatic injury and for the possibility of ongoing production of NAPQI. Factors that potentially predispose patients to hepatotoxicity after repeated dosing should be taken into account when deciding which patients to assess further for hepatic injury.

Patients showing evidence of severe hepatotoxicity or hepatic encephalopathy and those at risk for fulminant hepatic failure may require admittance to the ICU. All of these patients require frequent neurologic checks, monitoring of vital signs, and additional and repeated laboratory studies. Consultations with a regional poison center, gastroenterologist (or hepatologist) consultant, and regional transplant center are important to guide treatment strategies and to coordinate transplantation when needed. Early psychiatric consultation may be helpful in assessing transplant eligibility. Absolute indications for transplantation vary and should be discussed early with the appropriate local transplant center, poison control center, medical toxicologist(s) and hepatologist(s).

Although our understanding of acetaminophen toxicity has advanced significantly and additional therapeutic modalities (primarily IV NAC)

have become more widely available, many important challenges remain. Development of an entirely new method of toxicity screening to accurately determine the risk of toxicity in atypical patients, high-risk patients, and those who present after repeated excessive dosing of APAP is needed. Ongoing study of antidotal therapy dosing protocols is needed to assess the validity of many assumptions. Most importantly, improved methods to determine the indication for liver transplantation early after APAP ingestion are desperately needed. These and other issues predict that further changes are likely. Hopefully, the principles and current strategies presented in this chapter will serve as a strong foundation for these important future advances.

N-ACETYLCYSTEINE

Mary Ann Howland and Robert G. Hendrickson

N-acetylcysteine

Glutathione

Methionine

Cysteamine
N-acetylcysteine (NAC) is the cornerstone of therapy for patients with potentially lethal acetaminophen (APAP) overdoses. If administered early in the course of exposure, NAC can prevent APAP-induced hepatotoxicity. Administered after the onset of hepatotoxicity, NAC can improve outcome and decrease mortality. NAC also has a role in limiting hepatotoxicity caused by other xenobiotics that cause glutathione depletion and free radical formation, such as cyclopeptide-containing mushrooms, carbon tetrachloride, chloroform, pennyroyal oil, clove oil, and possibly liver failure from chronic valproic acid use.[27,47,48,145] Finally, NAC is useful in the management of patients with fulminant hepatic failure caused by other nontoxicologic etiologies.[17,70,76,127] Its beneficial effects are also under investigation in critically ill patients with a variety of stress-induced disorders,[79,124,139] in the prevention of further renal impairment in patients with chronic renal insufficiency administered a radiographic contrast agent,[46,55,71,114] and in those with hepatorenal syndrome.[57] Furthermore, NAC may enhance the elimination of boron, cobalt, cadmium, chromium, gold, and methylmercury, although this evidence is limited.[27,78]

HISTORY

Shortly after the first case of APAP hepatotoxicity was reported, Mitchell and coworkers described the protective effect of glutathione.[87,111] Prescott et al.[99] first suggested the use of NAC for APAP poisoning in 1974. Early experiments demonstrated that NAC could prevent APAP-induced hepatotoxicity in mice and that the oral (PO) and intravenous (IV) routes were equally efficacious when treatment was initiated early after ingestion.[94] Mitchell et al.,[87] Prescott et al.,[98,99] and Rumack and Peterson[112] performed human research with PO and IV NAC in the 1970s. The United States Food and Drug Administration (FDA) approved NAC for PO use in 1985 and for IV administration in 2004.

Cysteamine, methionine, and NAC, which are all glutathione precursors or substitutes, have been used successfully to prevent hepatotoxicity, but cysteamine and methionine both produce more adverse effects than NAC, and methionine is less effective than NAC. Therefore, NAC has emerged as the preferred treatment.[96,118,138]

MECHANISM OF ACTION IN ACETAMINOPHEN POISONING

NAC has several distinct roles in the treatment of APAP poisoning. Early after ingestion and during the metabolism of APAP to *N*-acetyl benzoquinoneimine (NAPQI), NAC prevents toxicity by rapidly detoxifying NAPQI that has formed. After hepatotoxicity is evident, NAC decreases toxicity through several nonspecific mechanisms, including free radical scavenging, increasing oxygen delivery, antioxidant effects, and alteration of microvascular tone.

NAC effectively prevents APAP-induced hepatotoxicity if it is administered before glutathione stores are depleted to 30% of normal. This level of depletion occurs approximately 6 to 8 hours after toxic APAP ingestion.[98,107,121] In this preventive role, NAC acts primarily as a precursor for the synthesis of glutathione.[73] NAC is a thiol-containing compound that is deacetylated to cysteine, an amino acid that is used intracellularly. Cysteine is then used with the amino acids glycine and glutamate to synthesize glutathione.[110] The availability of cysteine is the rate-limiting step in the synthesis of glutathione, and NAC is effective in replenishing diminished supplies of both cysteine and glutathione. Additional minor mechanisms of NAC in preventing hepatotoxicity include acting as a substrate for sulfation,[120] as an intracellular glutathione substitute by directly binding to NAPQI,[25] and by enhancing the reduction of NAPQI to *N*-acetyl-*p*-aminophenol (APAP).[73]

After NAPQI covalently binds to hepatocytes and other tissues,[107] NAC modulates the subsequent cascade of inflammatory events in a variety of ways.[51] NAC may act directly as an antioxidant or as a precursor to glutathione. Glutathione protects cells against electrophilic compounds by acting as both a reducing agent and an antioxidant.[110] NAC improves oxygen delivery[34,51,62,126,139,140] and utilization in extrahepatic organs such as the brain, heart, and kidney, probably by improving blood flow in the microvasculature, although the exact mechanism is unclear.[79,114,123] In addition, in vitro studies demonstrate a suppressive action on macrophages, neutrophils, leukocyte endothelial cell adhesion, and cytokines.[70]

CLINICAL USE

In acute overdose, treatment with NAC should be initiated if the serum APAP is plotted on or above the treatment line on the Rumack-Matthew nomogram or the patient's history suggests an acute APAP ingestion of 150 mg/kg or above and the results of blood tests will not be available within 8 hours of ingestion. In chronic APAP ingestions, treatment with NAC should be initiated if either aspartate aminotransferase (AST) is above normal or the APAP concentration is above 10 μg/mL (see Chap. 34 for details).

PHARMACOKINETICS

Administered NAC is present in plasma in the reduced or oxidized state and is either free or bound to plasma proteins or with other thiols and SH groups to form mixed disulfides such as NAC–cysteine.[97] NAC has a relatively small volume of distribution (Vd) (0.5 L/kg), and protein binding is 83%. NAC is metabolized to many sulfur-containing compounds such as cysteine, glutathione, methionine, cystine, and disulfides, as well as conjugates of electrophilic compounds, which are not measured.[42,93,97] Thus, the pharmacodynamic study of NAC is complex. In addition, the pharmacokinetics of NAC are complicated based on whether total or free NAC is being measured.[97]

■ PHARMACOKINETICS OF ORAL *N*-ACETYLCYSTEINE

PO NAC is rapidly absorbed, but the bioavailability is low (10%–30%) because of significant first-pass metabolism.[42,93,97] The mean time to maximum peak concentration is 1.4 ± 0.7 hours. The mean elimination half-life is 2.5 ± 0.6 hours and is linear with increasing dose up to 3200 mg/m^2/d given as a single daily dose. Intersubject plasma NAC concentrations vary 10-fold.[93] Chronic administration leads to a decrease in plasma concentrations from a C_{max} of 8.9 mg/L (55 μmol/L) at the end of 1 month to 5.1 mg/L (31 μmol/L) at the end of 6 months.[93]

Conflicting in vitro[26,68,113] and in vivo[24,40,90,103] data regarding the concomitant use of PO NAC and activated charcoal suggest that the resultant bioavailability of NAC is either decreased or unchanged. This interaction is likely of limited clinical importance, and either PO or IV NAC can be initiated without concern for charcoal interaction (see Chap. 34).

■ PHARMACOKINETICS OF INTRAVENOUS *N*-ACETYLCYSTEINE

When only free NAC was measured and analyzed, 600 mg of IV NAC given to healthy volunteers resulted in a peak serum NAC concentration of (300 μmol/L) 49 mg/L with a half-life of 2.27 hours compared with a peak serum concentration of (16 μmol/L) 2.6 mg/L after 600 mg PO.[20] Serum concentrations after IV administration of an initial loading dose of 150 mg/kg over 15 minutes reach approximately 500 mg/L (3075 μmol/L).[97] A steady-state plasma concentration of 35 mg/L (10–90 mg/L) is reached in approximately 12 hours with the standard IV protocol.[97] Approximately 30% is eliminated renally. Although an early study suggested that severe liver damage did not appear to affect NAC elimination,[97] a more recent study suggests that the half-life is increased because of a reduction in clearance, while the Vd did not change.[62]

ORAL VERSUS INTRAVENOUS *N*-ACETYLCYSTEINE

■ INTRAVENOUS VERSUS ORAL ADMINISTRATION

As with many issues related to APAP toxicity, the choice of PO versus IV NAC is complex. The available information suggests that each has advantages and disadvantages, and each may be more appropriate than the other in certain settings. Because no controlled studies have compared IV with PO NAC, conclusions about the relative benefit of each are largely speculative.

With the exception of fulminant hepatic failure, for which only the IV route has been investigated, IV and PO NAC administration are equally efficacious in treating patients with APAP toxicity.[100] Initial concerns about the apparent superiority of PO NAC over IV NAC when started 16 to 24 hours after overdose have been resolved by data showing equivalent results between the two protocols.[100] Any difference in outcome for these patients almost certainly is related to the *duration* and *dose* of NAC therapy rather than the route itself. The decision of which route to use should depend on the rate of side effects, safety, availability, and ease of use. Efficacy should not be a consideration.

Safety is the best understood of these issues. Nausea and vomiting may occur in more than 50% of patients treated with PO NAC,[86] and diarrhea is prevalent, but there is no credible evidence of more serious complications resulting from PO NAC. Reports of skin rash and unusual complications are rare.[88] In contrast, IV NAC is associated with a 2% to 6% rate of anaphylactoid reactions,[58,63,144,148] although rates of up to 14% to 18% have been reported in prospective trials.[67] Most of these reactions are mild and include rash, flushing, vomiting, and bronchospasm.[9,67,121] Anaphylactoid reactions may be severe in 1% of cases[67,85] and in rare instances may lead to hypotension and death.[5,15,30,63,83,85,121,148] Anaphylactoid reactions are attributed to both the dose and concentration of NAC. Reaction rate may be decreased by using a more dilute NAC solution[63,67,148] and slowing NAC infusions in some studies.[24] In one prospective study, prolongation of the loading infusion from 15 to 60 minutes did not decrease the anaphylactoid rate significantly (from 18% to 14%).[67] Unfortunately, this study lacked blinding; was underpowered; and had insufficient comparisons of coingestions, medical histories, and APAP concentration, so its generalizability is limited.[43,82]

Minor reactions, such as rash, generally do not require treatment, rarely recur, and do not preclude administration of subsequent NAC doses.[9,121,148] Even when urticaria, angioedema, and respiratory symptoms develop, they usually are easily treated, and NAC can be subsequently restarted with a very low incidence of recurrence.[9,95] Although proper dosing of IV NAC is very safe, it nevertheless must be considered less safe than PO NAC because of the possibility of severe anaphylactoid reactions, the risk of dosing errors,[52] and the possibility of nontreatment because of anaphylactoid reactions.[58,95]

Additional safety concerns have involved dosing for both small infants and obese adults. The IV NAC dosing regimen includes a milligrams per kilograms dose in a fixed water volume, leading to variability of IV NAC concentration.[23,58] This leads to a large free water dose for children, with one case of hyponatremic seizures,[128] and high concentration NAC for obese adults, with concern for anaphylactoid reactions. This has led to alternative dosing for both children (constant 3% concentration)[23] and obese adults (ceiling weight of 100 kg) (see Dosing below).[37]

The main disadvantage of the PO formulation of NAC is the high rate of vomiting and the concern that vomiting may delay therapy.[100] Delays in administration of NAC are correlated with an increased risk of hepatotoxicity.[122] The IV route avoids an increased rate of vomiting in patients who typically are already nauseated and avoids the use of high-dose antiemetics that may alter mental status.[86] Another potential disadvantage of PO NAC is that its absorption may be delayed up to 1 hour compared with IV NAC.[56] However, although short delays in delivery of NAC to the liver are probable in some instances, the equivalent rates of hepatotoxicity in patients treated with PO and IV NAC early after APAP ingestion suggest the delays associated with the

PO route may not be clinically relevant. PO NAC doses may be difficult to administer to patients with alterations of mental status because of the risk of aspiration, so IV NAC offers a distinct advantage in these instances.

One theoretical, albeit unproven, advantage of PO NAC early in the course of toxicity is that direct delivery via the portal circulation yields a higher concentration of NAC in the liver. Because of this first-pass clearance, PO NAC results in circulating NAC 20- to 30-fold lower than after IV dosing, suggesting that most PO NAC ended up in the liver.[20,56] However, elevated serum NAC may be an advantage of IV NAC administration when the liver is not the target organ of NAC, as with cerebral edema or in pregnancy. Lower costs of care are emphasized as an advantage of PO NAC, particularly in the United States, where the IV formulation is more expensive than the generic PO formulation.[74] However, the shorter length of stay for most patients treated with IV NAC (21 vs. 72 hours) may negate or reverse this difference. With the increasing use of "patient-tailored" NAC therapy, whether a major cost difference remains is unknown.[16,29]

Historically, before the current IV formulation in the United States, the PO formulation was used intravenously for years with an excellent safety profile[36,63,148] and without published evidence of infectious or febrile consequences.[36,63] This IV use of the PO formulation for this purpose is not generally recommended but is historically effective and may be necessary in cases in which only the PO formulation is available and the patient has intractable vomiting or APAP-induced hepatic failure.[74]

■ SPECIFIC INDICATIONS FOR IV NAC

In addition to decisions based on cost, duration, safety, and ease of use, three situations exist for which the available information suggests IV NAC is preferable to PO NAC: fulminant hepatic failure, inability to tolerate PO NAC, and APAP poisoning in pregnancy. Each of these requires further study for validation, but all three seem well supported by current information.

Fulminant hepatic failure is an important indication for IV NAC. The choice of IV over PO NAC is based on several observations. Most importantly, IV is the only route that has been studied in liver failure.[66] PO NAC may prove effective but has not yet been demonstrated. Second, evidence that (some or all of) the benefit of NAC in liver failure is extrahepatic suggests that IV NAC is preferable.[51] IV NAC results in higher blood NAC concentrations, which presumably leads to more NAC delivery to critical organs. Finally, concomitant gastrointestinal bleeding, use of lactulose, and other factors make IV NAC more practical.

A more common indication for IV NAC use is for patients with very high APAP concentrations who are approaching or are more than 6 to 8 hours from the time of ingestion and who are unable to tolerate PO NAC after a brief aggressive trial of antiemetic therapy. Use of IV NAC is logical to prevent further delays and resultant loss of NAC efficacy, even without proof that continued vomiting significantly limits NAC absorption.

The most controversial indication for IV NAC use is during pregnancy. Administration of IV NAC to the mother has the theoretical advantage of increased delivery to the fetus over PO NAC use. IV administration circumvents first-pass metabolism, presumably exposing the fetal circulation to higher maternal serum concentrations with IV dosing. Some studies have suggested that placental transfer of NAC to the fetus is limited.[61,116] However, one case series found that the NAC concentration in cord or neonatal blood after PO maternal NAC administration equaled the NAC concentration seen in patients treated with PO NAC.[59] Of course, an equivalent serum NAC concentration does not prove adequacy of therapy. Unlike the neonates studied, patients treated with PO NAC have extensive first-pass hepatic

uptake before NAC entry into the serum, where NAC concentration was measured.[20,56] Whether serum NAC concentration in the neonates studied reflects any significant hepatic NAC delivery is uncertain.

SAFETY IN PREGNANCY AND NEONATES

Untreated APAP toxicity is a far greater threat to fetuses than is NAC treatment.[28,105] NAC traverses the human placenta and produces cord blood concentrations comparable to maternal blood concentrations.[59] NAC is FDA Pregnancy Category B.

Limited data exist with regard to the management of neonatal APAP toxicity,[7,75,108,117] although IV and PO NAC have been used safely.[1,7] No adverse effects were observed when preterm newborns were treated with IV NAC[1] (see Chaps. 30 and 34). The elimination half-life of NAC in preterm neonates was 11 hours compared with 5.6 hours in adults.[1] IV administration has the advantage of assuring adequate antidotal delivery. PO administration in general is associated with necrotizing enterocolitis in neonates, although NAC has been orally administered safely in neonates.

OTHER USES (NON-ACETAMINOPHEN)

Diverse investigations of NAC as a treatment for a number of xenobiotics associated with free radical or reactive metabolite toxicity have been reported. Some of these xenobiotics include acrylonitrile, amatoxins, cadmium, chloroform, carbon tetrachloride, cyclophosphamide, 1,2-dichloropropane, doxorubicin, eugenol, pulegone, ricin, and zidovudine.[27,39,42,138,145] NAC has not been adequately studied for any of these xenobiotics in humans to definitively recommend it as a therapeutic intervention. However, the best evidence supports the use of NAC in cases of acute exposures to cyclopeptide-containing mushrooms (see below) and carbon tetrachloride.[27,42,138] NAC has also decreased cisplatin-induced nephrotoxicity in both rats and human cell cultures, but little human data exist.[6,109] NAC may be considered in cases of acute pennyroyal oil (ie, pulegone) or clove oil (eg, eugenol) ingestions based on their similarities to APAP-induced hepatotoxicity in which NAC has been proven beneficial and preventative. Both pulegone and eugenol are converted to reactive metabolites and induce glutathione depletion, leading to centrilobular necrosis.[131-134] NAC may be effective in treating patients with hepatotoxicity from chronic valproate use given the evidence that the 2,4-diene valproic acid metabolite acts as an electrophile and reduces hepatic glutathione.[47,48] However, there is no evidence that NAC is effective in treating patients with acute valproate toxicity and no evidence or theoretical efficacy in treating valproate-induced hyperammonemia. NAC has been demonstrated to increase excretion of several metals and other elements in animal studies, including boron, cadmium, chromium, cobalt, gold, and methylmercury.[11,13,27,53] The clinical usefulness of this effect remains unclear.

NAC has been studied as a chemopreventive agent[32,79,110] against cancer,[2] lung injury,[31,33] cardiac injury,[123,124] multiorgan failure from trauma and sepsis,[49,101,115,125,] traumatic brain injury,[12,130,147] and malnutrition. NAC has extracellular antimutagenic effects, enhances repair of nuclear DNA damaged by carcinogens, and inhibits malignant cell invasion and metastases.[32,92,102] PO NAC added to prednisone and azathioprine preserves vital capacity in patients with idiopathic pulmonary fibrosis.[33] Rescue NAC therapy has been studied with high-dose APAP (>20 g/m^2) in patients with specific advanced malignancies.[69]

NAC has been extensively studied to determine its effect on the risk of contrast-induced nephropathy in procedures requiring IV contrast. Both PO[3,18,21,35,45,65,119] and IV[10,38,84] formulations have been studied

before angiography with mixed results, with some small studies showing large reductions in nephropathy rates, but several studies showing no advantage over placebo. Absolute creatinine change in the positive studies remains quite small and are typically below 0.2 mg/dL.[46,71] Studies using higher IV NAC doses[10,84] have shown greater reductions in nephropathy rates and will likely be further studied. One recent study showed a dose-related effect on both nephropathy and in-hospital mortality when comparing 600 mg to 1200 mg IV with placebo.[84] Routes and doses have varied in these studies, and understanding of the appropriate dose continues to evolve. Most studies use 400 to 600 mg PO NAC 2-3 times a day for 1 to 2 days before and 1 to 2 days after cardiac catheterization.[3,18,21,35,45,65,119,129] Other studies have used IV NAC boluses of 600 mg, 1200 mg,[38,84] and 150 mg/kg over 30 minutes.[10]

NAC has been used for decades in cases of cyclopeptide-containing mushroom poisoning, particularly poisoning with amanita phalloides. NAC therapy for amatoxin poisoning is largely based on the similarity of toxicity of amatoxin and APAP, including delayed onset of centrilobular hepatic necrosis. Decreases in intracellular glutathione stores have been identified in isolated rat hepatocytes that were exposed by amanita extracts,[64] leading to the reasonable conclusion that supplying the tissue with thiols may decrease toxicity. In retrospective studies, patients treated with NAC have lower mortality rates than those treated with supportive care[41]; however, in animal studies, NAC has little effect on hepatotoxicity.[135]

ADVERSE EFFECTS AND SAFETY ISSUES

PO NAC may cause nausea, vomiting, flatus, diarrhea, gastroesophageal reflux, and dysgeusia; generalized urticaria occurs rarely. Generalized anaphylactoid reactions described after IV NAC dosing[4,15,19,30,44,54,81,83,97,104,137,141] are not noted after PO therapy and may be related to rate, concentration, or high serum NAC concentrations.[14,97]

The IV route ensures delivery, but rate-related anaphylactoid reactions are possible. The manufacturer of IV NAC categorizes the number of anaphylactoid reactions occurring in 109 patients receiving the previously recommended 15-minute loading dose as mild (6%), moderate (10%), and severe (1%).[1] Of the adverse events occurring in more than 2000 patients who received IV NAC over 15 minutes, vasodilation, rash, and pruritus account for approximately 10%, hypotension 4%, bronchospasm 6%, and angioedema 8%.[1] An interesting yet unexplainable observation demonstrated a 25% incidence of anaphylactoid reactions to IV NAC administered over 15 minutes when the APAP 4-hour plasma concentration was less than 150 µg/mL compared with a 3% incidence when the serum concentration was 300 µg/mL.[142]

If angioedema or an anaphylactoid reaction characterized by hypotension; shortness of breath; or wheezing, flushing, or erythema occurs, NAC should be stopped and standard symptomatic therapy instituted. After the reaction resolves, NAC can be carefully readministered at a slower rate after 1 hour, assuming NAC is still indicated. If the reaction persists or worsens, IV NAC should be discontinued and a switch to PO NAC should be considered. Adverse reactions confined to flushing and erythema are usually transient, and NAC can be continued with meticulous monitoring for systemic symptoms that indicate the need to stop the NAC. Urticaria can be managed with diphenhydramine with the same precautions.[9] Iatrogenic overdoses with IV NAC have resulted in severe reactions and even death in children.[1,9,83]

IV NAC decreases clotting factors and increases the prothrombin time (PT) in healthy volunteers and overdose patients without hepatic damage.[60,80,89,143] This effect occurs within the first hour, stabilizes after 16 hours of continuous IV NAC, and rapidly returns to normal when the infusion is stopped.[60] Because the INR is used as a marker of the severity of toxicity and is one of the criteria for transplantation, this adverse effect of NAC should always be considered when evaluating the patient's condition. An elevated INR without other indicators of hepatic damage is probably related to the NAC.

DOSING

The standard 21-hour IV NAC protocol is a loading dose of 150 mg/kg up to a maximum of 15 g in 200 mL of 5% dextrose in water (D_5W) (for adults) infused over 60 minutes followed by a first maintenance dose of 50 mg/kg up to a maximum of 5 g in 500 mL D_5W (for adults) infused over 4 hours followed by a second maintenance dose of 100 mg/kg up to a maximum of 10 g in 1000 mL D_5W (for adults) infused over 16 hours. The loading dose was changed to a 60-minute infusion rate from a previously recommended 15-minute infusion rate.

When NAC is administered orally, the patient should receive a 140-mg/kg loading dose either orally or by enteral tube. Starting 4 hours after the loading dose, 70 mg/kg should be given every 4 hours for an additional 17 doses, for a total dose of 1330 mg/kg. The solution should be diluted to 5% and can be mixed with a soft drink to enhance palatability. If any dose is vomited within 1 hour of administration, the dose should be repeated[77] or IV delivery used. Antiemetics (eg, metoclopramide or a serotonin receptor antagonist) should be used to ensure absorption.

Several other regimens, including a 48-hour IV, 36-hour IV, 36-hour PO, and 20-hour PO protocols, have been described; however, none of these has been adequately studied for general use[29,121,146,149] (see Chap. 34).

Regardless of the protocol initiated, NAC should be continued beyond the protocol length if the serum APAP concentration is detectable or the AST is elevated. A NAC infusion should be continued until the APAP concentration is undetectable, the serum AST is normal or has significantly improved (eg, two consecutive decreasing values and AST <1000 IU/L), and any evidence of hepatic failure (international normalized ratio [INR] >2, encephalopathy) has resolved.[29]

There are no specific dosing guidelines for obese patients. However, it may be reasonable to limit PO and IV NAC dosing using a maximum weight of 100 kg. This maximum limit is not based on experimental evidence; however, patients who are larger than 100 kg have an equivalent hepatic volume and similar ingestion amounts as patients who weight less than 100 kg. The current NAC dosing is sufficient for a patient of any weight with an APAP dose of 16 g, postulating that 4% is converted to the toxic metabolite, NAPQI. Although dosing with a maximum weight is logical, it has not yet been adequately studied in obese humans.

For the rare patient who ingests exceptionally large doses of APAP, or who has prolonged and significantly elevated APAP concentrations, consideration should be given to treating with greater amounts of NAC once prolonged, massive APAP concentrations are evident.[122a,115a] No data exists to determine which, if any, alternative NAC dosing strategy is superior, however it seems reasonable to increase NAC dosing if the hepatic exposure to APAP is prolonged and massive. Several strategies have been theorized, but none studied, including: 1) increasing the maintenance IV dose to 200 mg/kg over 16 hours (12.5 mg/kg/h) (in 1000 mL D5W for patients >40 kg) possibly preceded by a repeat of the IV loading dose or 2) adding the standard oral protocol (140 mg/kg oral loading dose followed by 70 mg/kg orally every 4 hours) to the standard IV regimen (6.25 mg/kg/h).

Previously dosing information for IV NAC was not available for patients weighing less than 40 kg, and problems with osmolarity, sodium concentrations and fluid requirements became apparent when improper dilutions were used. The package insert now gives specific information for dosing in these patients.

The IV dosing of NAC is complicated because three different preparations must be prepared with each based on weight. A recent

TABLE A4–1. Three-Bag Method Dosage Guide[1] by Weight for Patients Weighing 40 kg or Above [a]

Body Weight		Loading Dose (150 mg/kg in 200 mL D_5W over 60 min)	Second Dose (50 mg/kg in 500 mL D_5W over 4 h)	Third Dose (100 mg/kg in 1000 mL D_5W over 16 h)
(kg)	(lb)	Acetadote (mL)[b]	Acetadote (mL)[b]	Acetadote (mL)[b]
100	220	75	25	50
90	198	67.5	22.5	45
80	176	60	20	40
70	154	52.5	17.5	35
60	132	45	15	30
50	110	37.5	12.5	25
40	88	30	10	20

[a] The total volume administered should be adjusted for patients weighing less than 40 kg and for those requiring fluid restriction.

[b] Acetadote is available in 30 mL 200-mg/mL single-dose glass vials.

D_5W, 5% dextrose in water.

TABLE A4–2. Three-Bag Method Dosage Guide[1] by Weight for Patients Weighing Less Than 40 kg[1a]

Body Weight		Loading Dose (150 mg/kg over 60 min)		Second Dose (50 mg/kg over 4 h)		Third Dose (100 mg/kg over 16 h)	
(kg)	(lb)	Acetadote(mL)	D_5W (mL)[b]	Acetadote(mL)[b]	D_5W (mL)	Acetadote(mL)[b]	D_5W (mL)
30	66	22.5	100	7.5	250	15	500
25	55	18.75	100	6.25	250	12.5	500
20	44	15	60	5	140	10	280
15	33	11.25	45	3.75	105	7.5	210
10	22	7.5	30	2.5	70	5	140

[a] Acetadote is hyperosmolar (2600 mOsm/L) and is compatible with D_5W, ½ normal saline (0.45% sodium chloride injection), and water for injection.

[b] Acetadote is available in 30 mL 200-mg/mL single-dose glass vials.

D_5W, 5% dextrose in water.

retrospective study estimated that there was a 33% medication error rate in the preparation and delivery of IV NAC.[52] To limit these errors, the Tables A4–1 and A4–2 from the package insert give the appropriate doses and dilutions for adults and patients weighing less than 40 kg.[1] In addition, the following web site has a dosage calculator: http://acetadote.net/dosecalc.shtml.

If hepatic failure intervenes, IV NAC should be administered at a dose of 150 mg/kg in D_5W infused over 24 hours and continued until the patient has a normal mental status (or recovers from hepatic encephalopathy)[51] and the patient's INR becomes below 2.0[106] or until the patient receives a liver transplant.[22,50,66]

AVAILABILITY

NAC (Acetadote) is available as a 20% concentration in 30-mL single-dose vials designed for dilution before IV administration. NAC for PO administration is available in 10-mL vials of 10% and 20% for PO administration and should also be diluted before administration.

CHAPTER 35
SALICYLATES

Neal E. Flomenbaum
Acetylsalicylic acid   Methylsalicylic acid

Salicylic Acid

MW   =   138 daltons
Therapeutic serum concentration   =   15–30 mg/dL
                                            =   1.1–2.2 mmol/L

Salicylate overdose remains a consequential concern for clinicians. Unintentional salicylate toxicity may occur in patients who are unaware that fixed-dose cold preparations may contain aspirin and who concomitantly take aspirin, seeking further relief of their symptoms. Serious adolescent and adult salicylate poisonings frequently result from suicide attempts. Even in this setting, rapid diagnosis and appropriate therapy initiated quickly can reduce mortality. Salicylism should be considered in patients who have tachypnea, acid–base disorders, and acute lung injury (ALI), particularly anyone using salicylates. Unexplained neurologic abnormalities should also raise concern, particularly in patients in the aforementioned groups.[4]

HISTORY AND EPIDEMIOLOGY

Hippocrates may have been among the first to use willow bark and leaves to relieve fever, but it was not until 1829 that the glycoside salicin was extracted from the willow bark and used as an antipyretic. Seven years later, salicylic acid was isolated, and by the late 1800s, it was being used to treat gout, rheumatic fever, and elevated temperatures. The less irritating acetylated compound was first synthesized in 1833, and in 1899 acetylsalicylic acid was commercially introduced as aspirin by Bayer.[19] With that, the modern era of aspirin therapy and salicylate toxicity began.

Since 2000, the category of analgesics, which includes both aspirin and acetaminophen, has consistently ranked first among the xenobiotics most frequently reported in human exposures. In 2007, the American Association of Poison Control Centers (AAPCC) National Poison Data System (NPDS) reported 309,431 analgesic exposures in the United States. Of the 1239 deaths judged to be poison-related fatalities, aspirin alone accounted for 63. Isolated aspirin poisoning is the 14th most common cause of death from toxic exposures recorded by AAPCC NPDS (see Chap. 135).

Safety packaging, together with the increased use of nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, and other alternatives to aspirin have contributed to the decreased incidence of unintentional salicylate poisoning. On the other hand, the widespread availability of salicylate preparations without prescription and the toxicity caused by small increments in salicylate dosage when used chronically have contributed to its continued implication in poisoning.[79]

Over the past 2 decades, popular brand and product names previously associated exclusively with salicylates or acetaminophen have been applied to other analgesic-containing products. For example, the names Alka-Seltzer, Anacin, and Excedrin, which once were used exclusively for salicylate-containing products, are now used as brand names for products containing aspirin, acetaminophen, or both. Bayer, a company once associated exclusively with aspirin, now also markets a line of products called Bayer Select, which contain ibuprofen or acetaminophen. Clinicians should be vigilant for parents and healthcare providers who, while seeking to give acetaminophen to avoid Reye syndrome,[10,72] may inadvertently give their children a product containing aspirin.[27] Intentional or unintentional overdose of nonprescription brands or products might involve aspirin.[27] Salicylate toxicity may also result from confusion regarding the correct dosage: Terms such as *grains* and *milligrams* and *baby*, *children's*, *junior*, and *adult aspirin* are often misunderstood.

PHARMACOLOGY AND TOXICOLOGY OF SALICYLATES

There are two types of salicylic acid esters: phenolic esters such as aspirin and carboxylic acid esters, including methyl salicylate, phenyl salicylate, and glycosalicylate.[34] Most of the studies of salicylate metabolism involve aspirin.[34] The implicit assumption is that all members of the salicylate class have similar properties after they are converted to salicylic acid.

Aspirin and other salicylates are analgesics, antiinflammatories, and antipyretics, a combination of traits shared by all medications of varying structures known as NSAIDs. Most of the beneficial effects of NSAIDs result from the inhibition of cyclooxygenase (COX). This enzyme enables the synthesis of prostaglandins, which in turn mediate inflammation and fever.[116,136] Contributing to the antiinflammatory effects and independent of the effects on prostaglandins, salicylates and other NSAIDs may also directly inhibit neutrophils.[12]

Salicylates and NSAIDs are purportedly most effective in treating the pain accompanying inflammation and tissue injury. Such pain is elicited by prostaglandins liberated by bradykinin and other cytokines. Fever is also mediated by cytokines such as interleukin (IL)-1β, IL-6, α and β interferons, and tumor necrosis factor-α, all of which increase synthesis of prostaglandin E2.[19] In turn, this inflammatory mediatory increases cyclic AMP, triggering the hypothalamus to elevate the body temperature set point, resulting in increased heat generation and decreased heat loss.[26]

Because platelets cannot regenerate COX-1, a daily dose of as little as 30 mg of aspirin inhibits COX-1 for the 8- to 12-day life of the platelet.[19] Adverse effects of aspirin and some NSAIDs related to alteration of COX include gastrointestinal (GI) ulcerations and bleeding, interference with platelet adherence,[119] and a variety of metabolic and organ-specific effects described below under Gastrointestinal Effects.

To achieve an antiinflammatory effect for patients with chronic conditions such as rheumatoid arthritis, salicylates typically have been prescribed in doses sufficient to achieve serum salicylate concentrations of 15 to 30 mg/dL, which is considered the therapeutic range. Concentrations higher than 30 mg/dL are associated with signs and symptoms of toxicity.

Salicylate is rapidly absorbed from aspirin tablets in the stomach. The pK_a of aspirin is 3.5, and the majority of salicylate is nonionized (ie, salicylic acid) in the acidic stomach (pH, 1–2).[34,67] Although absorption of salicylate may be less efficient in the small bowel because of its higher pH, it is substantial and rapid due to the large surface area and the increase in pH increases the solubility of salicylate.[19,97,98] The dosage form of salicylates (eg, effervescent, enteric coated) influences the absorption rate.[118,121,145] Delayed absorption of aspirin may result from salicylate-induced pylorospasm or pharmacobezoar formation.[14,118]

After ingestion of therapeutic doses of immediate-release salicylate, significant serum concentrations are achieved in 30 minutes, and maximum concentrations are often attained in less than 1 hour.[34] The apparent volume of distribution (Vd) increases from 0.2 L/kg at low concentrations to more than 0.3 L/kg (possibly as high as 0.5 L/kg) at higher concentrations.[87,88,130] There is a decrease in protein (albumin) binding from 90% at therapeutic concentrations to less than 75% at toxic concentrations caused by saturation of protein binding sites.[2,15,41]

Salicylates have substantially longer apparent half-lives at toxic concentrations than at therapeutic concentrations, varying from 2 to 4 hours at therapeutic concentrations to as long as 20 hours at high concentrations.[37,89] Salicylates are conjugated with glycine and glucuronides in the liver and are eliminated by the kidneys. Approximately 10% of salicylates are excreted in the urine as free salicylic acid, 75% as salicyluric acid, 10% as salicylic phenolic glucuronides, 5% as acylglucuronides, and 1% as gentisic acid.[19] As the concentration of salicylates increases, two of the five pathways of elimination—those for salicyluric acid and the salicylic phenolic glucuronide—become saturated and exhibit zero-order kinetics. As a result of this saturation, overall salicylate elimination changes from first-order kinetics to zero-order kinetics.[87] When administered chronically, a small increase in dosage or a small decrease in metabolism or renal function may result in substantial increases in serum salicylate concentrations and toxicity.[79] At very high serum concentrations, first-order elimination may become more prominent because of an increasing fraction of renal clearance. Figure 35–1 illustrates the main features of salicylate metabolism (see Chap. 8).

Free salicylic acid is filtered through the glomerulus and both passively reabsorbed and secreted from the proximal tubules. More than 30% of ingested salicylate may be eliminated in alkaline urine and as little as 2% in acidic urine.[139] Salicylate conjugates (glycine and glucuronides) are filtered and secreted by the proximal tubules; salicylate conjugates are not reabsorbed across renal tubular cells because of poor lipid solubility, and the amount eliminated is dependent on glomerular filtration rate and proximal tubule secretion but not urine pH. Protein-binding abnormalities, urine and plasma pH variations, and delayed absorption all influence the maximum salicylate concentrations and the rates of decline.[98,118]

PATHOPHYSIOLOGY

ACID–BASE DISTURBANCES CAUSED BY SALICYLATE POISONING

Salicylate stimulates the respiratory center in the brainstem, leading to hyperventilation and respiratory alkalosis.[134] In addition, salicylates are weak acids, and in toxic concentrations, they titrate approximately 2 to 3 mEq/L of plasma bicarbonate. Toxic concentrations of salicylate impair renal hemodynamics, leading to the accumulation of inorganic acids. Salicylate interferes with the Krebs cycle, which limits production of adenosine triphosphate (ATP).[77] It also uncouples oxidative phosphorylation, causing accumulation of pyruvic and lactic acids
FIGURE 35–1. Salicylic acid metabolism. At excessive doses, the 4 mechanisms of salicylic acid metabolism are overloaded, leading to increased tissue binding, decreased protein binding, and increased excretion of unconjugated salicylic acid.* = Michaelis-Menten kinetics; ** = first-order kinetics.

and releasing energy as heat[83] (see Chap. 12). Salicylate-induced increased fatty acid metabolism generates ketone bodies, including β-hydroxybutyric acid, acetoacetic acid, and acetone. The net result of all of these metabolic processes is an anion gap metabolic acidosis (see Chap. 16), in which the unmeasured anions include salicylate and its metabolites, lactate, ketoacids, and inorganic acids.

Neurologic Effects   The central nervous system (CNS) effects are the most visible and most consequential clinical effects in salicylate-poisoned patients. With increasing CNS salicylate concentrations, neuronal energy depletion likely develops as salicylate uncouples neuronal and glial oxidative phosphorylation,[96] resulting in neuronal dysfunction and ultimately cerebral edema.

Correlation Between Cerebrospinal Fluid and Serum Salicylate Concentrations. Salicylate concentrations in the cerebrospinal fluid (CSF) directly correlate with death in primates.[64] Inhalation of carbon dioxide in a dog resulted in a precipitous decrease in serum salicylate concentrations, which returned to baseline rapidly after the discontinuation of CO_2.[65] This suggests that the salicylate redistributed into tissue during the period of induced respiratory acidosis and reequilibrated after its correction. Autoradiographs of cat brain after administration of radiolabeled salicylate visually and objectively document the profound effect that acidosis has on the distribution of salicylate into the brain.[56] However, even if CSF salicylate concentrations in humans are more accurate predictors of toxicity than serum concentrations, their use in clinical management is currently impractical. Furthermore, serum salicylate concentrations in the presence of acidemia may have little or no correlation with the CSF salicylate concentration.

Glucose Metabolism   Salicylate poisoning may produce a discordance between serum and CSF glucose concentrations.[117] Despite normal serum glucose concentrations, CSF glucose concentration decreased 33% in salicylate-poisoned mice compared with controls.[135] In other words, the rate of CSF glucose use exceeded the rate of supply, even in the presence of a normal serum glucose concentration. There was also a marked increase in oxygen consumption in mice, even with low salicylate concentrations, highlighting the importance of salicylate-induced uncoupling of oxidative phosphorylation.[64]

Hepatic Effects   Salicylate-poisoned mice had a marked decrease in hepatic glycogen and a dramatic increase in serum lactate concentration compared with control subjects.[65] This is likely because of increased glycogenolysis and glycolysis to compensate partly for the energy loss caused by uncoupling of oxidative phosphorylation.[96] Salicylates reduce lipogenesis by blocking the incorporation of acetate into free fatty acids and increase peripheral fatty acid metabolism as an energy source, resulting in ketone formation.

Through the depletion of intrahepatocyte coenzyme A (Co-A), fatty acids entering the hepatocyte cytoplasm cannot be transported into the mitochondria for beta-oxidation. The buildup of fatty acids in the hepatocyte results in microvesicular steatosis, which is characteristic of Reye syndrome.

Otolaryngologic Effects   The molecular mechanism of salicylate ototoxicity is not completely understood but appears to be multifactorial. Inhibition of cochlear COX by salicylate increases arachidonate, enabling calcium flux and neural excitatory effects of *N*-methyl-D-aspartic acid (NMDA) on cochlear spinal ganglion neurons.[112,123] Also, the prevention of prostaglandin synthesis interferes with the Na^+-K^+-adenosine triphosphatase (ATPase) pump in the stria vascularis, and the vasoconstriction decreases cochlear blood flow.[16,21,45,74] Membrane permeability changes cause a loss of outer hair cell turgor in the organ of Corti, which may impair otoacoustic emissions.[113,115] See Chapter 20 for a more complete description of the pathophysiology of salicylate-induced ototoxicity and sensorineural alterations as well as comparisons with the patterns of other ototoxic xenobiotics.

Pulmonary Effects   ALI results from increased pulmonary capillary permeability and subsequent exudation of high-protein edema fluid into the interstitial or alveolar spaces.[69] Hypothalamic insults from increased intracranial pressure or salicylate CNS poisoning may be the critical factor, with resultant adrenergic overactivity. This "central" ALI shifts blood from the systemic to the pulmonary circulation because of a loss of left ventricular compliance with left atrial and pulmonary capillary hypertension (see Chap. 21). Additionally, the resulting hypoxia results in pulmonary arterial hypertension and a local release of vasoactive substances, worsening ALI.[70]

Gastrointestinal Effects   GI manifestations result from local gastric irritation at lower doses and from stimulation of the medullary chemoreceptor trigger zone at higher doses. Hemorrhagic gastritis, decreased gastric motility, and pylorospasm also result from the direct gastric irritant effects of salicylates.[121]

Renal Effects   The kidneys clearly play a major role in the handling and excretion of salicylate and its metabolites. Although some believe that salicylates are nephrotoxic, the majority of studies and experimental evidence do not strongly support this notion.[32,43,106] Most of the adverse renal effects historically associated with salicylates occurred with use of combination products such as aspirin–phenacetin–caffeine (APC) tablets and appear to have been mostly caused by the phenacetin.[43] Renal papillary necrosis and chronic interstitial nephritis, initially characterized by reduced tubular function and reduced concentrating ability, rarely occur in adults using salicylates unless they have chronic illnesses that already compromise renal function.

Chronic nephrotoxicity from long-term use of aspirin alone has been demonstrated in humans in only one case-control series. In adults with preexisting glomerulonephritis, cirrhosis, or chronic renal insufficiency and in children with congestive heart failure, short-term therapeutic doses of aspirin may precipitate reversible acute renal failure, possibly because of inhibition of the vasodilatory prostaglandins necessary to maintain renal blood flow in people with these conditions.[32] In healthy adults, however, short-term therapeutic doses of aspirin do not adversely affect creatinine clearance, urine volume, or sodium and potassium clearance. Aspirin doses above 300 mg/kg may cause acute renal failure, and chronic aspirin poisoning may cause reversible or irreversible acute renal failure.[32]

Hematologic Effects   The hematologic effects of salicylate poisoning include hypoprothrombinemia and platelet dysfunction.[105] The platelet dysfunction, caused by irreversible acetylation of COX-1 and -2, prevents the formation thromboxane A_2, which is normally responsible for platelet aggregation. The platelets themselves are numerically and morphologically intact but are unresponsive to thrombogenic stimulation. Hypoprothrombinemia is the result of interruption of vitamin K cycling, similar to that of warfarin.[103] Anemia in patients who chronically abuse salicylates may be a result of the effects of both platelet dysfunction and GI bleeding.[105] Hemolysis is unusual, and alterations in leukocyte function are of no apparent clinical significance.[122]

Musculoskeletal Effects   Rhabdomyolysis after salicylate overdose probably results from uncoupling of muscular oxidative phosphorylation.[86,96,97] Paratonia, characterized by extreme muscle postmortem rigidity, was present in three of the 51 salicylate deaths reviewed in Ontario between 1983 and 1984.[95] Rapid rigor mortis and paratonia (which are not unique to salicylate poisoning) are probably related to the extreme depletion of myocyte ATP and the inability of the muscle fibers to relax.

CLINICAL MANIFESTATIONS OF SALICYLATE POISONING

■ ACUTE SALICYLATE TOXICITY

The earliest signs and symptoms of salicylate toxicity, which include nausea, vomiting, diaphoresis, and tinnitus, typically develop within 1 to 2 hours of acute exposure.[16,53,131] As CNS salicylate concentrations increase, tinnitus is rapidly followed by diminished auditory acuity that sometimes leads to deafness.[16] Other early CNS effects may include vertigo and hyperventilation manifested as hyperpnea or tachypnea (see Chap. 3), hyperactivity, agitation, delirium, hallucinations, convulsions, lethargy, and stupor. Coma is rare and generally occurs only with severe acute poisoning or mixed overdoses (Table 35–1).[53] A marked elevation in temperature resulting from the uncoupling of oxidative phosphorylation caused by salicylate poisoning [96] is one indication of severe toxicity and is typically a preterminal condition.

TABLE 35–1. Clinical Manifestations and Diagnostic Testing Results of Salicylate Toxicity

Acid–Base and Electrolyte Disturbances
- Anion gap increased
- Respiratory alkalosis (predominates early)
- Metabolic acidosis
- Respiratory acidosis (late, grave prognosis)
- Metabolic alkalosis (vomiting)
- Hyponatremia or hypernatremia
- Hypokalemia

Central Nervous System
- Tinnitus
- Diminished auditory acuity
- Vertigo
- Hallucinations
- Agitation
- Hyperactivity
- Delirium
- Stupor
- Coma
- Lethargy
- Convulsions
- Cerebral edema
- Syndrome of inappropriate antidiuretic hormone

Coagulation Abnormalities
- Hypoprothrombinemia
- Inhibition of factors V, VII, and X
- Platelet dysfunction

Gastrointestinal
- Nausea
- Vomiting
- Hemorrhagic gastritis
- Decreased motility
- Pylorospasm

Hepatic
- Abnormal liver enzymes
- Altered glucose metabolism

Metabolic
- Diaphoresis
- Hyperthermia
- Hypoglycemia
- Hyperglycemia
- Hypoglycorrhachia
- Ketonemia
- Ketonuria

Pulmonary
- Hyperpnea
- Tachypnea
- Respiratory alkalosis
- Acute lung injury

Renal
- Tubular damage
- Proteinuria
- NaCl and water retention
- Hypouricemia

Unfortunately, many of the signs and symptoms of salicylate toxicity are vague and may be mistakenly attributed to another illness with disastrous consequences.[28,131] In the review of all salicylate deaths in Ontario, Canada, in 1983 and 1984, the author noted that in six of the 23 (26%) patients who arrived alert, no salicylate determination appears to have been made and that probably neither the diagnosis nor the severity of the salicylate poisoning was recognized.[95]

Acid–Base Disturbances Caused by Salicylate Poisoning A primary respiratory alkalosis predominates initially, although a metabolic acidosis begins to develop early in the course of consequential salicylate toxicity. By the time a symptomatic adult patient presents to the hospital after a substantial acute or chronic salicylate overdose, a mixed acid–base disturbance is often prominent.[54] This latter finding includes two primary processes, a respiratory alkalosis and a metabolic acidosis, and is discernible by arterial blood gas (ABG) and serum electrolyte analyses. In one study of 66 salicylate-poisoned adults, 22% had respiratory alkalosis and 56% had mixed respiratory alkalosis and metabolic acidosis.[54]

The predominant primary respiratory alkalosis that initially characterizes salicylate poisoning in adults may be missed in young children.[55,131] Possible reasons for this include the limited ventilatory reserve of small children that prevents the same degree of sustained hyperpnea as occurs in adults, the fact that children may present later for healthcare, or the exposure to salicylates per body weight may be much larger. The typical acidemic presentation of a seriously poisoned child led some investigators in the past to incorrectly suggest that pediatric salicylate poisoning produces only metabolic acidosis. Although after a significant salicylate exposure, some children present with a mixed acid–base disturbance and a normal or high pH, most present with acidemia.[55]

The mixed acid–base pattern is so characteristic of adult salicylate poisoning that any salicylate-poisoned adult who presents with respiratory acidosis almost certainly has salicylate-induced ALI, severe fatigue from the strenuous exercise of hyperventilating for a prolonged period, or CNS depression (eg, mixed overdose). Mixed xenobiotic overdoses in adult populations are fairly common, as demonstrated by the findings of one study that one-third of patients with a presumed primary salicylate overdose had taken other xenobiotics.[54] Benzodiazepines, barbiturates, alcohol, and cyclic antidepressants all blunt the centrally induced hyperventilatory response to salicylates, resulting in either actual respiratory acidosis (PCO_2 >40 mm Hg) or metabolic acidosis without an apparently appropriate degree of respiratory compensation (PCO_2 <40 mm Hg but inappropriately high for the concomitant degree of metabolic acidosis). In both adults and children, the development of respiratory acidosis may occur as salicylate poisoning progresses. The combination of metabolic and respiratory acidosis in a salicylate-poisoned adult resulting in severe and worsening acidemia indicates an exceedingly grave situation and almost invariably is a preterminal event.[109]

Neurologic Effects Hyperventilation is centrally mediated, and detection requires an assessment of both the ventilatory rate and depth. Patients may develop a spectrum of CNS abnormalities that includes confusion, agitation, lethargy, and then ultimately seizures and coma. The most severe clinical findings are likely associated with the development of cerebral edema and portend a poor prognosis.

Otolaryngologic Effects The pattern of salicylate-induced auditory sensorineural alterations is different than the pattern characterizing other ototoxic drugs.[20] Tinnitus, which is a subjective sensation of ringing or hissing, with or without hearing loss as well as loss of absolute acoustic sensitivity, and alterations of perceived sounds are the three effects resulting from exposure to large doses of salicylates.[20] Tinnitus and subsequent reversible hearing loss typically occurs with

serum salicylate concentrations of 20 to 45 mg/dL or higher.[16,20,100] Occasionally, investigators have questioned whether salicylate ototoxicity may be used as an indicator of serum salicylate concentration, only to note that whereas some patients with therapeutic concentrations of salicylates complained of tinnitus, many with higher or toxic concentrations had no tinnitus. In a study of 94 patients with salicylate concentrations above 30 mg/dL on one or more occasions, tinnitus only correlated with serum salicylate concentrations in 30%; 55% had no tinnitus, although audiologic testing results were usually abnormal regardless of the presence or absence of tinnitus.[59] Thus, symptomatic ototoxicity is too nonspecific and too insensitive to serve as an indicator of serum salicylate concentrations.

Pulmonary Effects When a patient with salicylate poisoning presents with the clinical and radiographic manifestations of pulmonary edema or ALI, major causes that must be considered include aspiration pneumonitis, viral and bacterial infections, neurogenic ALI, and salicylate-induced ALI[70,78] (see Chap. 21). In 111 consecutive patients with peak salicylate concentrations above 30 mg/dL, ALI occurred in 35% of patients older than 30 years of age and none of the 55 patients younger than 16 years of age. Risk factors for developing ALI included cigarette smoking, chronic salicylate ingestion, and the presence of neurologic symptoms on admission. The average arterial blood pH was 7.37 in the six adult patients with ALI and 7.46 in the 30 adults without ALI. There was no significant difference in salicylate concentrations, which were approximately 57 mg/dL in both groups.[141] In a 2-year review of all salicylate deaths in Ontario, Canada, 59% of 39 autopsies revealed pulmonary pathology, mostly "pulmonary edema" (ALI).[95]

Hepatic Effects Salicylate-induced hepatitis occurred in children who were being treated with high (average concentration, 30.9 mg/dL) chronic doses of salicylates for rheumatic fever and juvenile rheumatoid arthritis.[60,93,124] Another form of liver disease associated with salicylates that also occurs primarily in children is Reye syndrome, which is characterized by nausea, vomiting, hypoglycemia, elevated concentrations of liver enzymes (aspartate aminotransferase [AST], alanine aminotransferase [ALT], fatty infiltration of the liver, and coma after a viral illness, usually influenza or varicella.[7,10] Although the link between Reye syndrome and salicylates has never been fully proven, the existence of such a link is fairly mechanistically certain, and the decreasing incidence that has occurred concomitantly with the decreased use of salicylates in children is highly suggestive.[10,22,140] Apart from the few cases still attributable to salicylate use, Reye or "Reye-like" syndromes may occur from other etiologies, including possible biochemical disturbances induced by viral or bacterial infections; microbial toxins; hypoglycin from unripe Ackee fruit; and valproic acid, tetracycline, zidovudine, diclofenac sodium, as well as a variety of antineoplastics.[114]

■ CHRONIC SALICYLATE TOXICITY

Chronic salicylate poisoning most typically occurs in elderly individuals as a result of unintentional overdosing on salicylates used to treat chronic conditions such as rheumatoid arthritis and osteoarthritis[5,39,79] (Table 35–2). Presenting signs and symptoms of chronic salicylate poisoning include hearing loss and tinnitus; nausea; vomiting; dyspnea and hyperventilation; tachycardia; hyperthermia; and neurologic manifestations such as confusion, delirium, agitation, hyperactivity, slurred speech, hallucinations, seizures, and coma.[4,40,53,85] Although there is considerable overlap with some of the presenting signs and symptoms of acute salicylate poisoning, the slow onset and less severe appearance of some of these signs of chronic poisoning in elderly individuals frequently cause delayed recognition of the true cause of the patient's presentation.[54]

TABLE 35–2. Differential Characteristics of Acute and Chronic Salicylate Poisoning

	Acute	Chronic
Age	Younger	Older
Etiology	Overdose usually intentional	Therapeutic misadventures; iatrogenic
Diagnosis	Easily recognized	Frequently unrecognized
Other diseases	None	Underlying disorders (especially chronic pain conditions)
Suicidal ideation	Typical	Usually absent
Serum concentrations	Marked elevation	Intermediate elevation
Mortality	Uncommon when recognized and properly treated	More common because of missed diagnosis

Typically, ill patients who have chronic salicylate poisoning may be misdiagnosed as having delirium, dementia, encephalopathy of undetermined origin, diseases such as sepsis (fever of unknown origin), alcoholic ketoacidosis, respiratory failure, or cardiopulmonary disease.[4,8,28,44,53] Unfortunately, many of the signs and symptoms of chronic salicylate toxicity may be mistakenly attributed to the illness for which the salicylates were administered, with serious consequences.[28,131] In a study of 73 consecutive adults hospitalized with salicylate poisoning, 27% were not correctly diagnosed for as long as 72 hours after admission.[4] These patients manifested toxicity with standard or excessive therapeutic regimens and had significant associated diseases without a history of previous overdoses. In this group, 60% of the patients had a previous neurologic consultation before the diagnosis of salicylism was established. When diagnosis is delayed in elderly individuals, the morbidity and mortality associated with salicylate poisoning are high. Mortality was reported to be as high as 25% in the 1970s,[4] and there are no data to suggest that survival after delayed diagnosis is substantially better today (see Table 35–2).

Underrecognition or misdiagnosis of chronic salicylate poisoning is not confined to elderly patients and may be a problem at the other end of the age spectrum as well. In one study of all children admitted to a district hospital in Kenya over a 3-month period with the primary diagnosis of severe malaria, 90% had detectable blood salicylate concentrations, and six of 143 had serum concentrations 20 mg/dL or above. All six of the children with serum salicylate concentrations of 20 mg/dL or above had neurologic impairment and metabolic acidosis, and four had hypoglycemia, suggesting that salicylates may be associated with the complications of malaria that have substantial morbidity and mortality.[44]

DIAGNOSTIC TESTING

Careful observation of the patient, correlation of the serum salicylate concentrations with blood pH, and repeat determinations of serum salicylate concentrations every 2 to 4 hours are essential until the patient is clinically improving and has a low serum salicylate concentration in the presence of a normal or high blood pH. In all cases, after

Prior to alkalinization

Tissues pH 6.8	Plasma pH 7.1	Urine pH 6.5
HA	HA	HA
$H^+ + A^-$	$H^+ + A^-$	$H^+ + A^-$

After alkalinization

Tissues pH 6.8	Plasma pH 7.4	Urine pH 8.0
HA	HA	HA
$H^+ + A^-$	$H^+ + A^-$	$H^+ + A^-$

FIGURE 35–2. Rationale for alkalinization.[131] Alkalinization of the plasma with respect to the tissues and alkalinization of the urine with respect to plasma shifts the equilibrium to the plasma and urine and away from the tissues, including the brain. This equilibrium shift results in "ion trapping."[131] (From Temple AR. Acute and chronic effects of aspirin toxicity and their treatment. *Arch Intern Med*. 1981;141:364-369.)

a presumed peak serum salicylate concentration has been reached, at least one additional serum concentration should be obtained several hours later. Analyses should be obtained more frequently in managing seriously ill patients to assess the efficacy of treatment and the possible need for hemodialysis (HD).

Serum salicylate concentrations may provide useful clinical correlations at a normal or high blood pH, but they should not be used as the sole determinant of the degree of toxicity. A concurrent arterial or venous blood pH should be determined when a serum salicylate concentration is obtained because in the presence of acidemia, more salicylic acid leaves the blood and enters the CSF and other tissues (Fig. 35–2), increasing the toxicity. In other words, meaningful interpretation of serum salicylate concentrations must take into account the effect of blood pH on salicylate distribution unless the serum salicylate concentration is so high that HD is indicated regardless of the pH. A decreasing serum salicylate concentration may be difficult to interpret because it may reflect either an increased tissue distribution with increasing toxicity or an increased clearance with decreasing toxicity. A decreasing serum salicylate concentration accompanied by a decreasing or low blood pH should be presumed to reflect a serious or worsening situation, not a benign or improving one.

In summary, when the patient's clinical signs and symptoms are given the highest priority and the serum salicylate concentration is interpreted in conjunction with a simultaneously obtained blood pH, the severity of toxicity usually can be predicted and the need for HD most accurately assessed.

■ RAPID CONFIRMATION OF SALICYLATE EXPOSURE

Rapid "point-of-care" determinations that may suggest salicylate poisoning in the proper clinical setting are (1) a positive urine ketone determination reflecting ketogenesis from increased fatty acid metabolism[66] or (2) a whole-blood electrolyte determination performed on a hand-held analyzer, which can quickly demonstrate acid–base disturbance(s) characteristic of salicylate poisoning.

Serum salicylate concentrations are relatively easy to obtain in most hospital laboratories, and with proper attention to the units reported (mg/dL vs. mg/L) and concomitant arterial or venous blood pH values,

clinicians can quickly confirm or exclude toxic salicylate concentrations. The historical bedside urine qualitative tests for the presence of salicylate (not for poisoning per se) using either ferric chloride or mercuric chloride (Trinder assay) can no longer be performed outside of a certified laboratory as they are not permissible under the federal Clinical Laboratory Improvement Amendments (CLIA) in the United States.

■ SERUM SALICYLATE CONCENTRATIONS AND CORRELATION WITH TOXICITY

Serum salicylate concentrations should be requested when clinically significant salicylate exposures are suspected and not as part of a general toxicologic screen. There is often confusion in correctly identifying aspirin and acetaminophen products, and the possibility that either or both may be used in a suicide attempt may suggest the need for determinations of both. Four studies, including one in the United States,[127] one in Hong Kong,[25] and two in the United Kingdom,[57,144] concluded that universal salicylate screening is not indicated for all patients with acute self-poisonings. The lack of initial symptoms after acetaminophen ingestion highlights the importance in routine laboratory screening for acetaminophen. The London, UK study of 596 patients concluded that routine measurements of serum salicylate concentration are not required in the absence of a positive history of salicylate ingestion, an inability to obtain a valid history (because of reduced level of consciousness, for example) and the absence of clinical features of salicylate poisoning. A prospective study in Glasgow, UK, considering routine testing for serum paracetamol and salicylate concentrations in 134 alert overdose patients found that no patient who had denied taking salicylate or paracetamol subsequently tested positive. In the absence of any clinical indications of toxicity, routine ASA testing may not be necessary for fully conscious patients. [57] In current practice, insufficient information is often obtained from patients to identify the clinical features of toxicity, and there is a need for focused clinical investigation for signs and symptoms of salicylate poisoning in at-risk groups.[144]

■ ERRORS IN THE INTERPRETATION OF SERUM SALICYLATE CONCENTRATIONS

Laboratory reporting errors for serum salicylate concentrations are relatively common due partly to the use of several different units. Analyzing and reporting salicylate concentrations as milligrams per liter when the clinician is accustomed to receiving results as milligrams per deciliter or inadvertently reporting actual milligrams per liter (before internal laboratory conversion) results erroneously because "mg/dL" provides the true salicylate concentration multiplied by 10.[58] These may suggest a toxic salicylate concentration in a patient whose serum salicylate concentration is actually within the therapeutic range (eg, "165 mg/L" instead of "16.5 mg/dL"). Most errors can be eliminated before initiation of aggressive therapy, such as HD, by determining whether the reported salicylate concentration is consistent with the clinical presentation and ABG or venous blood gas results and, when time permits, repeating the salicylate determination with appropriate consideration for methodology and conversion calculations.[58] Using the above example, a patient with a serum salicylate concentration of 165 mg/dL would undoubtedly show clinical signs of salicylate toxicity and have a profound acid–base abnormality.

The Done nomogram for classifying aspirin poisoning,[37] which was first published in 1960, was based on data predominantly from children, intended to be applied at only 6 hours or more after a single acute ingestion of nonenteric-coated, orally ingested aspirin and in patients with a blood pH of approximately 7.4 or higher. Such conditions rarely

apply to patients with serious salicylate poisoning, explaining why the Done nomogram showed poor predictive value when applied to a group of 55 predominantly adults with salicylate poisoning.[39]

MANAGEMENT

Evidence-based consensus guidelines were developed to assist poison center staff with appropriate out-of-hospital triage decisions of patients with suspected salicylate exposures.[29] Management recommendations for in-hospital use may contain inadequate, misleading, or dangerous advice for managing patients with salicylate overdoses, as demonstrated by a 2001 report from Canada.[18] Additionally, there is significant discordance among medical directors of poison centers regarding the optimal method of GI decontamination of a patient who ingested a large quantity of enteric-coated aspirin.[75,76]

For a salicylate-poisoned patient who presents severely ill and requires mechanical ventilation for airway stabilization or sedation, maintenance of hyperventilation requires an extremely careful approach if death is to be avoided.[11,128] The complexity of the decision-making process and practical implementation of this common practice is highlighted in patients with salicylate poisoning. Airway protection is the reason often invoked when a patient with altered mental status undergoes endotracheal intubation. Although this is often appropriate, it must be performed efficiently because death has occurred after sedation during initial airway management.[11] Additionally, the postintubation ventilator settings must be properly chosen to avoid the development of hypoventilation relative to the preintubation degree of spontaneous ventilation. This is discussed further below under Alkalemia by Hyperventilation versus Sodium Bicarbonate and Risks Associated with Assisted Ventilation.

Frequent blood gas monitoring is required for all salicylate-poisoned patients. Although maintaining alkalemia clearly is essential for treatment, blood pH probably should not be allowed to increase above 7.55 because alkalemia shifts the oxyhemoglobin dissociation curve to the left and may be otherwise detrimental. Note, however, that even with a blood pH of 7.45 to 7.50 in patients with moderately severe salicylism, boluses of bicarbonate have been given without necessarily further increasing the pH. Frequent reassessment of blood pH, fluid status, and urinary pH almost always allows administration of more sodium bicarbonate than was initially thought possible.

■ GASTRIC DECONTAMINATION AND USE OF ACTIVATED CHARCOAL

The use of orogastric lavage and activated charcoal (AC) is discussed throughout this text. Their effects on the absorption and elimination of salicylates have been extensively studied. In vitro studies suggest that each gram of AC can adsorb approximately 550 mg of salicylic acid.[90,101] In humans, AC reduces the absorption of therapeutic doses of aspirin by 50% to 80%, effectively adsorbing aspirin from enteric-coated and sustained-release preparations in addition to immediate-release tablets.[90] Presumably, the sooner AC is given after salicylate ingestion, the more effective it will be in reducing absorption. A 10:1 ratio of AC to ingested salicylate appears to result in maximal efficacy. Although peak serum concentrations are markedly decreased from predicted concentrations, aspirin desorption from the aspirin–AC complex may diminish the impact of AC on total absorption.[49,94,101] The addition of a cathartic to the initial dose of AC has been questioned and largely abandoned for most xenobiotics, but a benefit of adding sorbitol to AC in preventing salicylate absorption was demonstrated in one study.[80]

Repetitive or multiple-dose AC (MDAC) probably limits desorption, which may reduce the concentration of initially absorbed salicylate

to only 15% to 20%.[49] MDAC appears to increase the elimination of unabsorbed salicylates over that achieved by single-dose AC.[9,66] Thus, the use of MDAC to decrease GI absorption of salicylate overdoses is warranted, particularly if a pharmacobezoar or extended-release preparation is suspected (see Antidotes in Depth A2: Activated Charcoal).

The value of MDAC in enhancing salicylate elimination through GI dialysis is controversial and is not generally warranted.[3,73] In one volunteer study of 2800 mg of aspirin followed by 25 g of AC at 4, 6, 8, and 10 hours after ingestion, the total amount of salicylate excreted from the body increased by 9% to 18% but was not considered statistically significant.[82] The efficacy will likely be greater in the overdose situation, when more unbound salicylate is available because of decreased protein binding. However, in another study of the effects of MDAC on the clearance of high-dose intravenous (IV) aspirin in a porcine model, MDAC did not enhance the clearance of salicylates under alkaline conditions when the venous bicarbonate was kept at ≥15 mEq/L and urine pH kept at ≥7.5.[73] In contrast to the findings of both of these studies, two children with salicylate overdoses were successfully treated with MDAC given every 4 hours for 36 hours.[138] Overall, extensive use of MDAC is currently discouraged, but the administration of two to four properly timed doses is reasonable (see Chap. 7).

Theoretical support may be found for the use of whole-bowel irrigation (WBI) consisting of polyethylene glycol electrolyte lavage solution (PEG-ELS) in addition to AC to reduce systemic absorption, particularly for enteric-coated aspirin preparations.[133] Moreover, WBI alone may be effective in preventing absorption of other xenobiotics. However, the addition of WBI to MDAC does not increase the clearance of absorbed salicylate.[94]

■ FLUID REPLACEMENT

There is a need to differentiate between restoration of fluid and electrolyte balance in salicylate-poisoned patients as opposed to increasing the fluid load presented to the kidneys in an attempt to achieve "forced diuresis." Fluid losses from salicylate poisoning are prominent, especially in children, and can be attributed to tachypnea, hyperpnea, vomiting, fever, a hypermetabolic state, and insensible perspiration.[132] The kidneys also respond to salicylate poisoning by excreting an increased solute load, including large quantities of bicarbonate, sodium, potassium, and organic acids.[5] For all of these reasons, the patient's volume status must be adequately assessed and corrected if necessary, along with any glucose and electrolyte abnormalities. As in other cases, accurate management of volume status in poisoned patients may require invasive monitoring with a central venous pressure monitor or, preferably, a pulmonary artery catheter, especially in patients with cardiac disease, ALI, or renal compromise.

Increasing fluids beyond restoration of fluid balance to achieve forced diuresis is a practice that was inappropriately promoted in the past. Although forced diuresis theoretically increases renal tubular flow and reduces the urine tubular cell diffusion gradient for reabsorption, renal excretion of salicylate depends much more on urine pH than on flow rate, and use of forced diuresis alone is not effective regardless of whether diuretics, osmotic agents, or fluid volumes are used to achieve the diuresis.[108] Although renal salicylate clearance varies in direct proportion to flow rate, its relation to pH is logarithmic.[84] In summary, although fluid imbalance must be corrected, forced saline diuresis does little more than oral fluids to enhance elimination over a 24-hour period[108] and subjects the patient to the hazards of fluid overload.

■ ALKALEMIA BY HYPERVENTILATION VERSUS SODIUM BICARBONATE

Alkalinization of the serum by a substance that does not easily cross the blood–brain barrier such as intravenously administered sodium

bicarbonate reduces the fraction of salicylate in the nonionized form and increases the pH gradient with the CSF. This both prevents entry and helps remove salicylate from the CNS[56,62,64,65,131] (see Fig. 35–2). Hyperventilation alone should not be relied upon, and NaHCO$_3$ should be used for alkalinization.

Alkalinization with IV sodium bicarbonate should be considered for symptomatic patients whose serum salicylate concentrations exceed the therapeutic range and for clinically suspected cases of salicylism until a salicylate concentration and simultaneously obtained blood pH are available to guide treatment. Patients on therapeutic regimens of salicylates who feel well with salicylate concentrations of 30 to 40 mg/dL and who do not manifest toxicity do not require intervention. Oral bicarbonate administration should never be substituted for IV bicarbonate to achieve alkalinization because the oral route may increase salicylate absorption from the GI tract by enhancing dissolution.

Alkalinization may be achieved with a bolus of 1 to 2 mEq/kg IV followed by an infusion of 3 ampules of sodium bicarbonate (132 mEq) in 1 L of 5% dextrose in water (D$_5$W), administered at 1.5 to 2.0 times the maintenance fluid range. Urine pH should be maintained at 7.5 to 8.0, and hypokalemia must be corrected (see below) to achieve maximum urinary alkalinization. Calcium concentrations should be monitored because decreases in both ionized[38] and total serum calcium[52] are also complications of bicarbonate therapy. Volume load should remain modest while repleting previous losses. Early HD must be considered when a patient cannot tolerate the increased solute load that results from alkalinization because of ALI, congestive heart failure, renal failure, or cerebral edema. However, even when the decision for HD has been made, alkalinization (when possible) helps to achieve a more rapid initial reduction in blood concentrations.[63]

■ RISKS ASSOCIATED WITH ASSISTED VENTILATION

Although induced hyperventilation may effectively increase the blood pH in certain patients, endotracheal intubation followed by assisted ventilation of a salicylate-poisoned patient poses particular risks if it is not meticulously performed. Although early endotracheal intubation to maintain hyperventilation may aid in the management of patients whose respiratory efforts are faltering, healthcare providers must maintain appropriate hypocarbia through hyperventilation. Ventilator settings that result in an increase in the patient's PCO$_2$ relative to pre-mechanical ventilation (p-MV) will produce a relative respiratory acidosis, even if serum pH remains in the alkalemic range.

In a search of a poison center database of patients with salicylate poisoning between 2001 and 2007, seven patients were identified with salicylate concentrations above 50 mg/dL, who had both pre-MV and post-MV data. All seven had a post-MV pH values below 7.4, and five of the six for whom recorded PCO$_2$ values were available had post-MV PCO$_2$ above 50 mm Hg, suggesting substantial underventilation. Two of the seven patients died after intubation, and one sustained neurologic injury. Inadequate MV of patients with salicylate poisoning was associated with respiratory acidosis, a decrease in the serum pH, and clinical deterioration.[128] Even when achieved, however, respiratory alkalosis sustained by hyperventilation (assisted or unassisted) alone should never be considered a substitute for use of either sodium bicarbonate (to achieve both alkalemia and alkalinuria) or HD (when indicated).

■ ENHANCED SALICYLATE ELIMINATION BY URINE ALKALINIZATION

Because salicylic acid is a weak acid (pK$_a$ 3.5), it will be ionized in an alkaline milieu and theoretically can be "trapped" there. This occurs because there is no specific uptake mechanism in the kidney for salicylate, and passive reabsorption of a charged molecule is very limited.

Thus, alkalinization of the urine (defined as pH ≥7.5) with sodium bicarbonate results in enhanced excretion of the ionized salicylate ion.

Alkalinization of the urine should be considered as first-line treatment for patients with moderately severe salicylate poisoning who do not meet the criteria for HD.[111] It should also be administered to salicylate-poisoned patients who require HD as long as it is thought clinically safe to do so. Although salicylic acid is almost completely ionized within physiologic pH limits, small changes in pH obtained by alkalinization may have substantial changes in the relative amount of salicylate in the charged form. Regardless of the reason for the change in serum PH, renal excretion of salicylate is very dependent on urinary pH[108,139] (see Fig. 35–2 and Antidotes in Depth A5: Sodium Bicarbonate).

Alkalinization increases free salicylate secretion from the proximal tubule but does not affect renal elimination of salicylate conjugates. The percentage of a single dose of 1.5 g of sodium salicylate administered to volunteers that was excreted unchanged increased from 2.3% ± 1.5% under acidic conditions to 30.5% ± 9.1% under alkaline conditions. When urine acidity was maintained using ammonium chloride, salicylic acid had a terminal t$_{1/2}$ value of 3.29 ± 0.52 hours, which was significantly reduced to 2.50 ± 0.41 hours when an alkaline urine was maintained with sodium bicarbonate treatment. The total body clearance of salicylic acid was significantly less under acidic urine conditions (1.38 ± 0.43 L/h) than under alkaline urine conditions (2.27 ± 0.83 L/h).[139]

Alkalinizing the urine from a pH of 5 to 8 logarithmically increased renal salicylate clearance from 1.3 to 100 mL/min.[99] Assuming an overdose Vd of 0.5 L/kg, this increased clearance would decrease salicylate half-life from 310 to 4 hours. However, alkalinizing the urine from a pH of 5 to 8 has a more modest effect on serum salicylate clearance.[108] The apparent serum half-life decreased from 48 to 6 hours. This difference between serum and renal half-lives reflects the fact that renal clearance only applies to free salicylate, but serum clearance applies to both free and protein-bound salicylate.

Although the administration of acetazolamide, a noncompetitive carbonic anhydrase inhibitor, results in the formation of bicarbonate-rich alkaline urine, it also causes a systemic metabolic acidosis and acidemia.[48,62,65] The effect of acetazolamide is usually self-limited and mild but nevertheless increases the concentration of freely diffusible nonionized molecules of salicylic acid, thereby increasing the Vd and most probably enhancing the penetrance of salicylate into the CNS.[65,89]

■ HYPOKALEMIA

Hypokalemia is a common complication of salicylate poisoning and prevents urinary alkalinization unless corrected. Hypokalemia results from the movement of potassium into cells in exchange for hydrogen ions in the presence of alkalemia, potassium losses in the urine or feces, and vomiting with subsequent metabolic alkalosis and bicarbonaturia.[53] Furthermore, in the presence of hypokalemia, the renal tubules reabsorb potassium ions in exchange for hydrogen ions, preventing urinary alkalinization. If urinary alkalinization cannot be achieved easily, hypokalemia, excretion of organic acids, and salt and water depletion should be considered possible reasons.

■ EXTRACORPOREAL REMOVAL

Unfortunately, delays in initiating HD remain a potentially preventable cause of death despite repeated calls over many years for prompt HD for patients with salicylate poisoning.[47] Extracorporeal measures are indicated if the patient has severe signs or symptoms, a very high serum salicylate concentration regardless of clinical findings, severe fluid or electrolyte disturbances, or ALI or is unable to eliminate the salicylates (Table 35–3). In most instances of severe salicylate poisoning, HD is the extracorporeal technique of choice, not only to clear the

TABLE 35–3. Indications for Hemodialysis in Salicylate-Poisoned Patients

Renal failure

Congestive heart failure (relative)

Acute lung injury

Persistent CNS disturbances

Progressive deterioration in vital signs

Severe acid–base or electrolyte imbalance despite appropriate treatment

Hepatic compromise with coagulopathy

Salicylate concentration (acute) >100 mg/dL (in the absence of the above)[a]

[a] Hemodialysis for patients with chronic poisoning is indicated for those with concerning symptoms regardless of salicylate concentrations.

salicylate but also to rapidly correct fluid, electrolyte, and acid–base disorders that will not be corrected by hemoperfusion (HP) alone. The combination of HD and HP in series is feasible and theoretically may be useful for treating patients with severe or mixed overdoses,[35] but it is rarely used. Rapid reduction of serum salicylate concentrations in severely poisoned patients has been described with the use of continuous venovenous hemodiafiltration, a technique that may be especially valuable for patients who are too unstable to undergo HD or when HD is unavailable[146] (see Chap. 9).

A combination of therapies that is both useful and practical is to ensure effective alkalinization with sodium bicarbonate while the patient is waiting for and then while undergoing HD. In one unique case report, a patient who overdosed twice on salicylates within a 2-month period was treated in the first instance with 4 hours of HD but no effective alkalinization and in the second instance with sodium bicarbonate alkalinization but no HD. In both instances, blood concentrations of salicylates were above 65 mg/dL. Although similar decreases in salicylate concentrations were achieved with each technique, the rate of decline during the first 4 hours was faster with alkalinization and HD.[63] Combining the two therapies makes sense even if part of the reason for the increased early effectiveness of sodium bicarbonate treatment is related to the rapidity with which it can be achieved compared with the 2 to 4 hours required to institute HD after a patient presents under even the most favorable circumstances.[63]

Peritoneal dialysis (PD) was sometimes suggested in the past as a simpler extracorporeal procedure for eliminating salicylates in the setting of hemodynamic compromise, coagulopathy, or inability to perform HP or HD. However, PD is only 10% to 25% as efficient as HP or HD and not even as efficient as renal excretion itself. The 24-hour clearance of salicylates with PD is less than the 4-hour clearance of salicylates by HP or HD; therefore, PD is not recommended (see Chap. 9).

In a recent animal model of salicylate poisoning, IV infusion of 1.25 g/kg of albumin was accompanied by a 14% decline in median brain salicylate concentration.[31] If this effect is achievable in humans, it could (along with rapid NaHCO$_3$ infusions) allow additional time for HD to be instituted.

◼ OTHER FORMS OF SALICYLATE

Topical Salicylate Methyl Salicylate (Oil of Wintergreen) and Salicylic Acid Topical salicylates, which are used as keratolytics (salicylic acid) or as rubifacients (≤30% methyl salicylate) are rarely responsible for salicylate poisoning when used in their intended manner because absorption through normal skin is very slow. However, particularly in children, extensive application of topical preparations containing methyl salicylate may result in consequential poisoning.[17,143] After 30 minutes of contact time, only 1.5% to 2.0% of a dose is absorbed, and even after 10 hours of contact with methyl salicylate, only 12% to 20% of the salicylates is systemically absorbed.[18,120] Heat, occlusive dressings, young age, inflammation, and psoriasis all increase topical salicylate absorption.[24]

Ingestion of methyl salicylate may be disastrous, but its highly irritating characteristics probably limit most ingestions. When ingested, 1 mL of 98% oil of wintergreen contains an equivalent quantity of salicylate as 1.4 g of aspirin. In a 10-kg child, the minimum toxic salicylate dose of approximately 150 mg/kg body weight can almost be achieved with 1 mL of oil of wintergreen, which contains 140 mg/kg of salicylates for the child (see Chap. 42). In Hong Kong, medicated oils containing methyl salicylate accounted for 48% of acute salicylate poisoning cases treated in one hospital.[23] Methyl salicylate is rapidly absorbed from the GI tract and much, but not all, of the ester is rapidly hydrolyzed to free salicylates. Despite rapid and complete absorption, serum concentrations of salicylates are much less than predicted after ingestion of methyl salicylate containing liniment compared with oil of wintergreen.[143] Vomiting is common, along with abdominal discomfort. Onset of symptoms usually occurs within 2 hours of ingestion.[24] Patients with methyl salicylate exposure have died in less than 6 hours, emphasizing the need for early determinations of salicylate concentrations in addition to frequent testing after such exposures.

Bismuth Subsalicylate Bismuth subsalicylate, which is found in the popular medication Pepto Bismol, releases the salicylate moiety in the GI tract, which is subsequently absorbed. Each milliliter of bismuth subsalicylate contains 8.7 mg of salicylic acid.[46] After a large therapeutic dose (60 mL), peak salicylate concentrations may reach 4 mg/dL at 1.8 hours after ingestion.[46] Patients with diarrhea and infants with colic using large quantities of this antidiarrheal agent may develop salicylate toxicity.[91,137] Chronic use should raise concerns for bismuth toxicity (see Chap. 89).

◼ PREGNANCY

Considered a rare event, salicylate poisoning during pregnancy poses a particular hazard to the fetus because of the acid–base and hematologic characteristics of the fetus and placental circulation. Salicylates cross the placenta and are present in higher concentrations in the fetus than in the mother. The respiratory stimulation that occurs in the mother after toxic exposures does not occur in the fetus, which has a decreased capacity to buffer acid. The ability of the fetus to metabolize and excrete salicylates is also less than in the mother. In addition to its toxic effects on the mother, including coagulation abnormalities, acid–base disturbances, tachypnea, and hypoglycemia, repeated exposure to salicylates late in gestation displaces bilirubin from protein-binding sites in the fetus, causing kernicterus.

A case report described fetal demise in a woman who claimed to ingest 50 aspirin tablets per day for several weeks during the third trimester of pregnancy. This raises concerns that the fetus is at greater risk from salicylate exposures than is the mother. Emergent delivery of near-term fetuses of salicylate-poisoned mothers should be considered on a case-by-case basis[102] (see Chap. 30).

SUMMARY

The initial assessment of a patient who has ingested excessive amounts of salicylates includes a determination of the vital signs, particularly

the depth and frequency of respiration as well as the temperature. The clinical presentation of a patient with a salicylate overdose may be characterized by an early onset of nausea, vomiting, abdominal pain, blood-tinged vomitus or gross hematemesis, tinnitus, and lethargy. The presence of hyperventilation, hyperthermia, confusion, coma, seizures, and any other nonspecific neurologic presentation should heighten suspicion of salicylate poisoning (see Tables 35–1 and 35–2). Using a combination of symptoms, signs, and characteristic ABG findings along with the results of point-of-care testing and laboratory studies, the clinician can rapidly confirm a significant salicylate ingestion and then institute immediate alkalinization with sodium bicarbonate; achieve gastric decontamination by orogastric lavage (if indicated), AC, or MDAC (if indicated); and consider the need for HD (or perhaps hemodiafiltration) early in the course of management.

In patients with pulmonary and CNS manifestations of salicylate toxicity, the protective nature of hyperventilation in maintaining alkalemia may be disastrously compromised by assisted ventilation unless the clinician is extremely skilled at adjusting the ventilator to ensure hyperventilation, decreased PCO_2, and high pH (7.5) at all times. Moreover, any unnecessary delays to HD places the patient at greater risk for morbidity or mortality. Serum and urinary alkalinization with sodium bicarbonate to eliminate salicylates is important even though use of sodium bicarbonate may further complicate electrolyte abnormalities. Maintenance of eukalemia is important to ensure success, and fluid and electrolyte replacement is essential.

ANTIDOTES IN DEPTH (A5)

SODIUM BICARBONATE

Paul M. Wax

Sodium bicarbonate is a nonspecific antidote effective in the treatment of a variety of poisonings by means of a number of distinct mechanisms (Table A5–1). However, the support for its use in these settings is predominantly based on animal evidence, case reports, and consensus.[9] It is most commonly used in the treatment of patients with cyclic antidepressant (CA) and salicylate poisonings. Sodium bicarbonate also has a role in the treatment of phenobarbital, chlorpropamide, and chlorophenoxy herbicide poisonings and wide-complex tachydysrhythmias induced by type IA and IC antidysrhythmics and cocaine. Correcting the life-threatening acidosis generated by methanol and ethylene glycol poisoning and enhancing formate elimination are other important indications for sodium bicarbonate. Use of sodium bicarbonate in the treatment of rhabdomyolysis, metabolic acidosis with elevated lactate, cardiac resuscitation, and diabetic ketoacidosis is controversial and is not addressed in this Antidote in Depth.[1,4,15,45,91,92]

ALTERED XENOBIOTIC IONIZATION RESULTING IN ALTERED XENOBIOTIC DISTRIBUTION

■ CYCLIC ANTIDEPRESSANTS

The most important role of sodium bicarbonate in toxicology appears to be its ability to reverse potentially fatal cardiotoxic effects of the CAs and other type IA and IC antidysrhythmics. Use of sodium bicarbonate for CA overdose developed as an extension of sodium bicarbonate use in the treatment of patients with other cardiotoxic exposures. Noting similarities in electrocardiographic (ECG) findings between hyperkalemia and quinidine toxicity (ie, QRS widening), investigators in the 1950s began to use sodium lactate (which is rapidly metabolized in the liver to sodium bicarbonate) for the treatment of quinidine toxicity.[3,8,95] In a canine model, quinidine-induced ECG changes and hypotension were consistently reversed by infusion of sodium lactate.[7] Clinical experience confirmed this benefit.[8] Similar efficacy in the treatment of patients with procainamide cardiotoxicity was also reported.[95]

With the introduction of the CAs during the late 1950s, conduction disturbances, dysrhythmias, and hypotension occurring after overdose were soon reported. Extending the use of sodium lactate from the type I antidysrhythmics to the CAs, uncontrolled observations in the early 1970s showed a decrease in mortality from 15% to less than 3% when sodium lactate was administered to patients with CA poisoning.[29] In 1976, the first report of successful use of sodium bicarbonate in the treatment of a series of CA-induced dysrhythmias in children was reported.[17] In this series, nine of 12 children who had developed multifocal premature ventricular contractions (PVCs), ventricular tachycardia, or heart block reverted to normal sinus rhythm

with sodium bicarbonate therapy alone. An early canine experiment of amitriptyline-poisoning demonstrated resolution of dysrhythmias upon alkalinization of the blood to a pH above 7.40.[17] Other methods of alkalinization, including hyperventilation and administration of the nonsodium buffer tris (hydroxymethyl) aminomethane (THAM), were also effective in reversing the dysrhythmias.[18,42]

A better understanding of the mechanism and utility of sodium bicarbonate has come from a series of animal experiments during the 1980s. In amitriptyline-poisoned dogs, sodium bicarbonate reversed conduction slowing and ventricular dysrhythmias and suppressed ventricular ectopy.[62] When comparing sodium bicarbonate, hyperventilation, hypertonic sodium chloride, and lidocaine, sodium bicarbonate and hyperventilation proved most efficacious in reversing ventricular dysrhythmias and narrowing QRS prolongation. Although lidocaine transiently antagonized dysrhythmias, this antagonism was demonstrable only at nearly toxic lidocaine concentrations and was associated with hypotension. Furthermore, prophylactic alkalinization protected against the development of dysrhythmias in a pH-dependent manner.

In desipramine-poisoned rats, the isolated use of either sodium chloride or sodium bicarbonate was effective in decreasing QRS duration.[69] Both sodium bicarbonate and sodium chloride also increased mean arterial pressure, but hyperventilation or direct intravascular volume repletion with mannitol did not. In further studies both in vivo and on isolated cardiac tissue, alkalinization and increased sodium concentration improved CA effects on cardiac conduction.[79,80] Although respiratory alkalosis and sodium chloride each independently improved conduction velocity, this effect was greater when sodium bicarbonate was administered.

Another study on amitriptyline-poisoned rats demonstrated that treatment with sodium bicarbonate was associated with shorter QRS interval, longer duration of sinus rhythm, and increased survival rates.[44] Sodium bicarbonate seems to work independently of initial blood pH. Animal studies show that cardiac conduction improves after treatment with sodium bicarbonate or sodium chloride in both normal pH and acidemic animals.[69] Clinically, TCA-poisoned patients who already were alkalemic also responded to repeat doses of sodium bicarbonate.[59]

Although several authors suggest that the efficacy of sodium bicarbonate is modulated via a pH-dependent change in plasma protein binding that decreases the proportion of free drug,[18,49] further study failed to support this hypothesis.[72] The administration of large doses of a binding protein α_1-acid glycoprotein (AAG) (to which CAs show great affinity) to desipramine-poisoned rats only minimally decreased cardiotoxicity. Although the addition of AAG increased the concentrations of total desipramine and protein-bound desipramine in the serum, the concentration of active free desipramine did not decline significantly. A redistribution of CA from peripheral sites may have prevented lowering of free desipramine concentration. The persistence of other CA-associated toxicity, such as the anticholinergic effects and seizures, also argues against changes in protein-binding modulating toxicity. In vitro studies performed in plasma protein-free bath further support that the efficacy of sodium bicarbonate is independent of plasma protein binding.[79]

Sodium bicarbonate has a crucial antidotal role in CA poisoning by increasing the number of open sodium channels, thereby partially

TABLE A5–1. Sodium Bicarbonate: Mechanisms, Site of Action, and Uses in Toxicology

Mechanism	Site of Action	Uses
Altered interaction between xenobiotic and sodium channel	Heart	Amantadine Carbamazepine Cocaine Diphenhydramine Flecainide Mesoridazine Procainamide Propoxyphene Quinidine Quinine Thioridazine cyclic antidepressants
Altered xenobiotic ionization leads to altered tissue distribution	Brain	Formic acid Phenobarbital Salicylates

Neutralization	Lungs	Chlorine gas, HCl
Maintenance of chelator effect	Kidneys	Dimercaprol (BAL)–metal
Reduce free radical formation	Kidneys	Contrast media

BAL, British anti-Lewisite.

reversing fast sodium channel blockade. This decreases QRS prolongation and reduces life-threatening cardiovascular toxicity such as ventricular dysrhythmias and hypotension.[62,69,79] The animal evidence supports two distinct and additive mechanisms for this effect: a pH-dependent effect and a sodium-dependent effect. The pH-dependent effect increases the fraction of the more freely diffusible nonionized xenobiotic. Both the ionized xenobiotic and the nonionized forms are able to bind to the sodium channel, but assuming CAs act like local anesthetics, it is estimated that 90% of the block results from the ionized form. By increasing the nonionized fraction, less xenobiotic is available to bind to the sodium channel binding site. The sodium-dependent effect increases the availability of sodium ions to pass through the open channels. Decreased ionization should not significantly decrease the rate of CA elimination because of the small contribution of renal pathways to overall CA elimination (<5%).

Although many anecdotal accounts support the efficacy of sodium bicarbonate in treating CA cardiotoxicity in humans,[36] these reports are all uncontrolled observations; controlled studies are not available. In one of the largest retrospective observational studies involving

91 patients who received sodium bicarbonate after CA overdose, QRS prolongation corrected in 39 of 49 patients who had QRS durations above 0.12 seconds, and hypotension corrected within 1 hour in 20 of 21 patients who had systolic blood pressures below 90 mm Hg.[37] Use of sodium bicarbonate was not associated with any complications in this study.

Prospective validation of treatment criteria for use of sodium bicarbonate after CA overdose has not been performed. The most common indications are conduction delays manifested by QRS above 0.10 seconds or right bundle-branch block, wide-complex tachydysrhythmias, and hypotension.[45] Because studies show that there is a critical threshold QRS duration at which ventricular dysrhythmias may occur (≥ 0.16 seconds),[12] it seems reasonable that narrowing the QRS interval through use of sodium bicarbonate or hyperventilation may prophylactically prevent against development of dysrhythmias. Practice patterns vary considerably with regard to the use of sodium bicarbonate when the QRS interval is below 0.16 seconds.[83] Although sodium bicarbonate has no proven efficacy in either the treatment or prophylaxis of TCA-induced seizures, seizures often cause acidemia, which rapidly increases the risks of conduction disturbances and ventricular dysrhythmias. Administering sodium bicarbonate when the QRS duration is 0.10 seconds or above may establish a theoretical margin of safety in the event the patient suddenly deteriorates, without adding significant demonstrable risk. When the QRS duration is below 0.10 seconds (given the negligible risk of seizures or dysrhythmias), prophylactic use of sodium bicarbonate is not indicated. In patients exhibiting a Brugada ECG pattern (right bundle branch block with downsloping ST segment elevation in V1–V3) and QRS widening after CA ingestion, sodium bicarbonate administration may narrow the QRS without reversing the Brugada pattern[5] (see Chap. 22).

Because cardiotoxicity may worsen during the first few hours after ingestion, we recommend starting sodium bicarbonate immediately if the QRS interval widens to greater than 0.10 seconds. Because CA-induced hypotension also responds to sodium bicarbonate, hypotension is another indication for sodium bicarbonate. However, no evidence supports a role for sodium bicarbonate in CA-poisoned patients who present with altered mental status or seizures without QRS widening or hypotension.

Because the potential benefits of alkalinization in CA overdose usually outweigh the risks, sodium bicarbonate should be administered regardless of whether the patient has an acidemic or normal pH. The most commonly used preparations are an 8.4% solution (1 M) containing 1 mEq each of sodium and bicarbonate ions per milliliter (calculated osmolarity of 2000 mOsm/L) and a 7.5% solution containing 0.892 mEq each of sodium and bicarbonate ions per milliliter (calculated osmolarity of 1786 mOsm/L). Fifty-milliliter ampules of the 8.4% and 7.5% solutions contain 50 and 44.6 mEq of $NaHCO_3$, respectively. One to two milliequivalents of sodium bicarbonate per kilogram body weight should be administered intravenously (IV) as a bolus over a period of 1 to 2 minutes.[70] Greater amounts may be required to treat patients with unstable ventricular dysrhythmias. Sodium bicarbonate can be repeated as needed to achieve a blood pH of 7.50 to 7.55.[71,85] The end point of treatment is narrowing of the QRS interval. Excessive alkalemia (pH >7.55) and hypernatremia should be avoided. Because sodium bicarbonate has a brief duration of effect, a continuous infusion usually is required after the IV bolus. Three 50-mL ampules should be placed in 1 L of 5% dextrose in water (D_5W) and run at twice maintenance with frequent checks of QRS and pH depending on the fluid requirements and blood pressure of the patient. Frequent evaluation of the fluid status should be performed to avoid precipitating pulmonary edema. An optimal duration of therapy has not been established. The time to resolution of conduction abnormalities during

continuous bicarbonate infusion varies significantly, ranging from several hours to several days.[50] In a case of prolonged clinical effects from modified-release amitriptyline poisoning, sodium bicarbonate was administered on multiple occasions over 110 hours after the initial ingestion to reverse ongoing sodium channel conduction disturbances.[64] Sodium bicarbonate infusion usually is discontinued as soon as there is improvement in hemodynamics and cardiac conduction and resolution in altered mental status, although controlled data supporting such an approach are lacking.

■ OTHER SODIUM CHANNEL BLOCKING XENOBIOTICS

Sodium bicarbonate is useful in treating patients with cardiotoxicity from other xenobiotics, with sodium channel blocking effects manifested by widened QRS complexes, dysrhythmias, and hypotension. Isolated case reports provide the bulk of the evidence in these situations. The utility of sodium bicarbonate in treating patients with type IA and IC antidysrhythmics, diphenhydramine, propoxyphene, and quinine has been demonstrated.[7,11,77,84,88,95]

Use of sodium bicarbonate in the treatment of patients with amantadine overdose manifested by prolongation of the QRS and QT intervals was associated with narrowing of the QT but not the QRS interval.[25] Although the usefulness of sodium bicarbonate in reversing QT prolongation occasionally observed during fluoxetine and citalopram overdose has been reported,[19,24,30] sodium channel disturbances are uncommon in most cases of selective serotonin reuptake inhibitor (SSRI) overdose, and routine use of alkalinization therapy in this setting is unwarranted. Sodium bicarbonate may help in the management of patients with other ingestions associated with type IA-like cardiac conduction abnormalities and dysrhythmias, such as carbamazepine and the phenothiazines thioridazine and mesoridazine, but documentation of such benefit is lacking.

The role of sodium bicarbonate as an antidote has been studied in experimental models of calcium channel blocker toxicity and β-adrenergic antagonist toxicity. In the calcium channel blocker study, hypertonic sodium bicarbonate increased mean arterial pressure and cardiac output in verapamil-poisoned swine.[89] Possible explanations for this beneficial effect include the increase in serum pH, reversal of a sodium channel effect, lowering of serum potassium concentration, or volume expansion. In a canine model of propranolol toxicity, sodium bicarbonate failed to increase heart rate or blood pressure.[51]

Cocaine, a local anesthetic with membrane-stabilizing properties resembling other type I antidysrhythmics may cause similar conduction disturbances. In several canine models of cocaine toxicity, 2 mEq/kg of sodium bicarbonate successfully reversed cocaine-induced QRS prolongation[6,68] and improved myocardial function.[97] Of interest, sodium loading by itself (2 mEq/kg of sodium chloride) failed to produce a benefit. Similar findings were demonstrated in cocaine-treated guinea pig hearts.[98] Patients with cocaine-induced cardiotoxicity responded to treatment with sodium bicarbonate.[41,66,94] In many of these cases, simultaneous treatment with sedation, active cooling, and hyperventilation confounds the contribution of the sodium bicarbonate to overall recovery.

ALTERED XENOBIOTIC IONIZATION RESULTING IN ENHANCED ELIMINATION

■ SALICYLATES

Although there is no known specific antidote for salicylate toxicity, judicious use of sodium bicarbonate is an essential treatment modality of salicylism. Through its ability to change the concentration gradient of the ionized and nonionized fractions of salicylates, sodium bicarbonate is useful in decreasing tissue (eg, brain) concentrations of salicylates and enhancing urinary elimination of salicylates.[74] This therapy may limit the need for more invasive treatment modalities, such as hemodialysis.

Salicylate is a weak acid with a pK_a of 3.0. As pH increases, more of the xenobiotic is in the ionized form. Ionized molecules penetrate lipid-soluble membranes less rapidly than do nonionized molecules because of the presence of polar groups on the ionized form. Consequently, when the ionized forms predominate weak acids, such as salicylates, may accumulate in an alkaline milieu, such as an alkaline urine.[56,86]

Although alkalinizing the urine to increase salicylate elimination is an important intervention in the treatment of patients with salicylate poisoning, increasing the serum pH in patients with severe salicylism may prove even more consequential by protecting the brain from a lethal central nervous system (CNS) salicylate burden. Using sodium bicarbonate to "trap" salicylate in the blood (ie, keeping it out of the brain) may prevent clinical deterioration of salicylate-poisoned patients. Salicylate lethality is directly related to primary CNS dysfunction, which, in turn, corresponds to a "critical brain salicylate level."[35] At physiologic pH, at which a very small proportion of the salicylate is in the nonionized form, a small change in pH is associated with a significant change in amount of nonionized molecules (eg, at a pH of 7.4, 0.004% of the salicylate molecules is in the nonionized form; at a pH of 7.2, 0.008% of the salicylate is in the nonionized form). In experimental models, lowering the blood pH produces a shift of salicylate into the tissues.[20] Hence, acidemia that is observed in significant salicylate poisonings can be devastating. In salicylate-poisoned rats, increasing the blood pH with sodium bicarbonate produced a shift in salicylate out of the tissues and into the blood.[34] This change in salicylate distribution did not result from enhanced urinary excretion because occlusion of the renal pedicles failed to alter these results.

Enhancing the urinary elimination of salicylate by trapping ionized salicylate in the urine also provides great benefit. Salicylate elimination at low therapeutic concentrations consists predominantly of first-order hepatic metabolism. At these low concentrations, without alkalinization, only approximately 10% to 20% of salicylate is eliminated unchanged in the urine. With increasing concentrations, enzyme saturation occurs (Michaelis-Menten kinetics); thus, a larger percentage of elimination occurs as unchanged free salicylate. Under these conditions, in an alkaline urine, urinary excretion of free salicylate becomes even more significant, accounting for 60% to 85% of total elimination.[31,75]

The exact mechanism of pH-dependent salicylate elimination has generated controversy. The pH-dependent increase in urinary elimination initially was ascribed to "ion trapping," which is the filtering of both ionized and nonionized salicylate while reabsorbing only the nonionized salicylate.[82] However, limiting reabsorption of the ionizable fraction of filtered salicylate cannot be the primary mechanism responsible for enhanced elimination produced by sodium bicarbonate.[52] Because the quantitative difference between the percentage of molecules trapped in the ionized form at a pH of 5.0 (99% ionized) and a pH of 8.0 (99.999% ionized) is small, decreases in tubular reabsorption cannot fully explain the rapid increase in urinary elimination seen at a pH above 7.0.

"Diffusion theory" offers a reasonable alternative explanation. Fick's law of diffusion states that the rate of flow of a diffusing substance is proportional to its concentration gradient. A large concentration gradient between the nonionized salicylate in the peritubular fluid (and blood) and the tubular luminal fluid is found in alkaline urine. Because at a higher urinary pH, a greater proportion of secreted nonionized molecules quickly becomes ionized upon entering the alkaline environment, more salicylate (ie, nonionized salicylate) must

pass from the peritubular fluid into the urine in an attempt to reach equilibrium with the nonionized fraction. In fact, as long as nonionized molecules are rapidly converted to ionized molecules in the urine, equilibrium in the alkaline milieu will never be achieved. The concentration gradient of peritubular nonionized salicylates to urinary nonionized salicylates continues to increase with increasing urinary pH. Hence, increased tubular diffusion, not decreased reabsorption, probably accounts for most of the increase in salicylate elimination observed in the alkaline urine.[52]

Controversies regarding the indications for alkalinization in the treatment of patients with salicylism persist. Although urinary alkalinization undoubtedly works to lower serum salicylate concentrations and enhance urinary elimination, the risks associated with alkalinization in the management of salicylism are of concern. Concerns regarding excessive alkalemia, hypernatremia, fluid overload, hypokalemia, and hypocalcemia, as well as the potential delay in achieving alkalinization with sodium bicarbonate (as opposed to more rapid response achieved with hyperventilation), have all been raised.[27,48,70,75,82] Early on, patients with pure respiratory alkalosis often have alkaluria, as well as alkalemia, and do not require urinary alkalinization. In the more common scenario in which patients present with a mixed respiratory alkalosis and metabolic acidosis, sodium bicarbonate must be administered cautiously. Young children who rapidly develop metabolic acidosis often require alkalinization but should be at less risk for complications of this therapy.[65]

Sodium bicarbonate is indicated in the treatment of salicylate poisoning for most patients with evidence of significant systemic toxicity. Although some authors have suggested alkali therapy for asymptomatic patients with concentrations above 30 mg/dL,[96] limited data support this approach. For patients with chronic poisoning, concentrations are not as helpful and may be misleading; clinical criteria remain the best indicators for therapy. Patients with contraindications to sodium bicarbonate use, such as renal failure and acute lung injury, should be considered candidates for intubation and subsequent hyperventilation, but extracorporeal removal is often required because of the difficulty and danger of intubation.

Dosing recommendations depend on the acid–base status of the patient. For patients with acidemia, rapid correction is indicated with IV administration of 1 to 2 mEq of sodium bicarbonate per kilogram of body weight.[90] After the blood is alkalinized or if the patient has already presented with an alkalemia, continued titration with sodium bicarbonate over 4 to 8 hours is recommended until the urinary pH reaches 7.5 to 8.0.[87,90] Alkalinization can be maintained with a continuous sodium bicarbonate infusion of 100 to 150 mEq in 1 L of D_5W at 150 to 200 mL/hr (or about twice the maintenance requirements in a child). Obtaining a urinary pH of 8.0 is difficult but is considered to be the goal. Fastidious attention to the patient's changing acid–base status is required. Systemic pH should not go above 7.55 to prevent complications of alkalemia.

Hypokalemia can make urinary alkalinization particularly problematic.[48,81] In hypokalemic patients, the kidneys preferentially reabsorb potassium in exchange for hydrogen ions. Urinary alkalinization will be unsuccessful as long as hydrogen ions are excreted into the urine. Thus, appropriate potassium supplementation to achieve normokalemia may be required to alkalinize the urine.[99]

In the past, proper urinary alkalinization was thought to require forced diuresis to maximize salicylate elimination.[23,48] Suggestions included administering enough fluid (2 L/h) to produce a urine output of 500 mL/h. Because forced alkaline diuresis appears unnecessary and is potentially harmful as a result of its unnecessarily large fluid load, the goal is alkalinization at a rate of approximately twice maintenance requirements to achieve a urine output of 3 to 5 mL/kg/h.

■ PHENOBARBITAL

Although cardiopulmonary support is the most critical intervention in the treatment of patients with severe phenobarbital overdose, sodium bicarbonate may be a useful adjunct to general supportive care. The utility of sodium bicarbonate is particularly important considering the long plasma half-life (~100 hours) of phenobarbital. Phenobarbital is a weak acid (pK$_a$, 7.24) that undergoes significant renal elimination. As in the case of salicylates, alkalinization of the blood and urine may reduce the severity and duration of toxicity. In a study of mice, the median anesthetic dose for mice receiving phenobarbital increased by 20% with the addition of 1 g/kg of sodium bicarbonate (increasing the blood pH from 7.23 to 7.41), demonstrating decreased tissue concentrations associated with increased pH.[93] Extrapolating the animal evidence to humans has suggested that phenobarbital-poisoned patients in deep coma might develop a respiratory acidosis secondary to hypoventilation, with the acidemia enhancing the entrance of phenobarbital into the brain, thus worsening CNS and respiratory depression. Alternatively, increasing the pH with bicarbonate, ventilatory support, or both would enhance the passage of phenobarbital out of the brain, thus lessening toxicity. Given the relatively high pK$_a$ of phenobarbital, significant phenobarbital accumulation in the urine is evident only when urinary pH is increased above 7.5.[10] As the pH approaches 8.0, a threefold increase in urinary elimination occurs. The urine-to-serum ratio of phenobarbital, although much higher in alkaline urine than in acidic urine, remains less than unity, thereby suggesting less of a role for tubular secretion than in salicylate poisoning.

Clinical studies examining the role of alkalinization in phenobarbital poisoning have been inadequately designed. Many are poorly controlled and fail to examine the effects of alkalinization, independent of coadministered diuretic therapy. In one uncontrolled study, a 59% to 67% decrease in the duration of unconsciousness in patients with phenobarbital overdoses occurred in patients administered alkali compared with nonrandomized control subjects.[58] In other older studies, treatment with sodium lactate and urea reduced mortality and frequency of tracheotomy to 50% of control subjects, enhanced elimination, and shortened coma.[47,61] In a later human volunteer study, urinary alkalinization with sodium bicarbonate was associated with a decrease in phenobarbital elimination half-life from 148 to 47 hours.[28] However, this beneficial effect was less than the effect achieved by multiple-dose activated charcoal (MDAC), which reduced the half-life to 19 hours.[28] In a nonrandomized study of phenobarbital-poisoned patients comparing urinary alkalinization alone, MDAC alone, and both methods together, both the phenobarbital half-life decreased most rapidly and the clinical course improved most rapidly in the group of patients who received MDAC alone.[57] Interesting, the combination approach proved inferior to MDAC alone but was better than alkalinization alone. The authors speculated that when both treatments were used together, the increased ionization of phenobarbital resulting from sodium bicarbonate infusion may have decreased the efficacy of MDAC. These studies suggest that MDAC is more efficacious than urinary alkalinization in the treatment of phenobarbital-poisoned patients, although both approaches are beneficial and indicated.

Sodium bicarbonate therapy does not appear warranted in the treatment of patients with ingestions of other barbiturates, such as pentobarbital and secobarbital, most of which have a pK$_a$ above 8.0 or are predominantly eliminated by the liver.

■ CHLORPROPAMIDE

Chlorpropamide is a weak acid (pK$_a$, 4.8) and has a long half-life (30–50 hours). In a human study using therapeutic doses of chlorpropamide, urinary alkalinization with sodium bicarbonate significantly increased

renal clearance of the drug.[63] This study showed that whereas nonrenal clearance was the more significant route of elimination at a urinary pH of 5 to 6 (only slightly above pK$_a$), at a pH of 8.0, renal clearance was 10 times that of nonrenal clearance. Alkalinization reduced the area under the curve (AUC) almost fourfold and shortened the elimination half-life from 50 to 13 hours. Acidification increased the AUC by 41% and increased the half-life to 69 hours. Although not a study in overdose patients, this report suggests that sodium bicarbonate may be useful in the management of patients with chlorpropamide overdose. The effect of urinary alkalinization on elimination of other sulfonylureas is unnecessary because the benefit presumably is limited as these agents are largely metabolized in the liver.

■ CHLOROPHENOXY HERBICIDES

Alkalinization is indicated in the treatment of patients with poisonings from weed killers that contain chlorophenoxy compounds, such as 2,4-dichlorophenoxyacetic acid (2,4-D) or 2-(4-chloro-2-methylphenoxy) propionic acid (MCPP).[73] Poisoning results in muscle weakness, peripheral neuropathy, coma, hyperthermia, and acidemia. These compounds are weak acids (pK$_a$ 2.6 and 3.8 for 2,4-D and MCPP, respectively) that are excreted largely unchanged in the urine. In an uncontrolled case series of 41 patients poisoned with a variety of chlorophenoxy herbicides, 19 of whom received sodium bicarbonate, alkaline diuresis significantly reduced the half-life of each by enhancing renal elimination.[26] In one patient, resolution of hyperthermia and metabolic acidosis and improvement in mental status were associated with a transient elevation of serum concentration, perhaps reflecting chlorophenoxy compound redistribution from the tissues into the more alkalemic blood. The limited data suggest that the increased ionized fractions of the weak-acid chlorophenoxy compounds produced by alkalinization is trapped in both the blood and the urine (as demonstrated with salicylates and phenobarbital); thus, its use ameliorates toxicity and shortens the duration of effect.

CORRECTING METABOLIC ACIDOSIS

■ TOXIC ALCOHOLS

Sodium bicarbonate has two important roles in treating patients with toxic alcohol ingestions. As an immediate temporizing measure, administration of sodium bicarbonate may reverse the life-threatening acidemia associated with methanol and ethylene glycol ingestions. In rats poisoned with ethylene glycol, the administration of sodium bicarbonate alone resulted in a fourfold increase in the median lethal dose.[13] Clinically, titrating the endogenous acid with bicarbonate greatly assists in reversing the consequences of severe acidemia, such as hemodynamic instability and multiorgan dysfunction.

The second role of bicarbonate in the treatment of toxic alcohol poisoning involves its ability to favorably alter the distribution and elimination of certain toxic metabolites.[76] In cases of methanol poisoning, the proportion of ionized formic acid can be increased by administering bicarbonate, thereby trapping formate in the blood compartment.[40,53] Consequently, decreased visual toxicity results from removal of the toxic metabolite from the eyes. In cases of formic acid (pK$_a$ of 3.7) ingestion, sodium bicarbonate decreases tissue penetration of the formic acid and enhances urinary elimination.[60] Further investigation is required to delineate the beneficial effects of sodium bicarbonate in the treatment of patients with toxic alcohol ingestions.

Early treatment of acidemia with sodium bicarbonate is strongly recommended in cases of methanol and ethylene glycol poisoning.[33] Sodium bicarbonate should be administered to toxic alcohol-poisoned patients with an arterial pH below 7.30.[46] More than 400 to 600 mEq of

sodium bicarbonate may be required in the first few hours.[39] In cases of ethylene glycol toxicity, sodium bicarbonate administration may worsen hypocalcemia, so the serum calcium concentration should be monitored. Combating the acidemia, however, is not the mainstay of therapy, and concurrent administration of IV fomepizole or ethanol and preparation for possible hemodialysis are almost always indicated.

■ METFORMIN

Metformin toxicity, either from overdose or therapeutic use in the setting of renal failure, may cause severe, life-threatening lactic acidosis. The use of high-dose sodium bicarbonate to correct the metabolic acidosis, as well as extracorporeal removal of the metformin, has been recommended in these cases.[32]

INCREASING XENOBIOTIC SOLUBILITY: METHOTREXATE

Urinary alkalinization with sodium bicarbonate is routinely used during high-dose methotrexate cancer chemotherapy therapy. Methotrexate is predominantly eliminated unchanged in the urine. Unfortunately, it is poorly water soluble in acidic urine. Under these conditions, tubular precipitation of the methotrexate may occur, leading to nephrotoxicity and decreased elimination, increasing the likelihood of methotrexate toxicity. Administration of sodium bicarbonate (as well as intensive hydration) during high-dose methotrexate infusions increases methotrexate solubility and the elimination of methotrexate.[22,78]

NEUTRALIZATION: CHLORINE GAS

Nebulized sodium bicarbonate serves as a useful adjunct in the treatment of patients with pulmonary injuries resulting from chlorine gas inhalation.[2,21] Inhaled sodium bicarbonate neutralizes the hydrochloric acid that is formed when the chlorine gas reacts with the water in the respiratory tree. Although oral sodium bicarbonate is not recommended for neutralizing acid ingestions because of the problems associated with the exothermic reaction and production of carbon dioxide in the relatively closed gastrointestinal tract, the rapid exchange in the lungs of air with the environment facilitates heat dissipation. In a chlorine-inhalation sheep model, animals treated with 4% nebulized sodium bicarbonate solution demonstrated higher PO$_2$ and lower PCO$_2$ than did the normal, saline-treated animals.[21] There was no difference, however, in 24-hour mortality or pulmonary histopathology. In a retrospective review, 86 patients with chlorine gas inhalation were treated with nebulized sodium bicarbonate.[14] Sixty-nine patients were sent home from the emergency department, 53 of whom had clearly improved. In a more recent study, 44 patients who were diagnosed with reactive airway dysfunction syndrome after an acute exposure to chlorine gas were randomized to receive either nebulized sodium bicarbonate (4 mL of 4.2% NaHCO$_3$ solution) or nebulized placebo.[2] Both groups also received IV corticosteroids and inhaled β$_2$ agonists. Compared with the placebo group, the nebulized sodium bicarbonate group had significantly higher forced expiratory volume in 1 second (FEV$_1$) values at 120 and 240 minutes and scored significantly higher on a posttreatment quality of life questionnaire.

MAINTENANCE OF CHELATION EFFECT: DIMERCAPROL–METAL CHELATION

Adverse effects and safety concerns may be associated with the dissociation of the dimercaprol (British anti-Lewisite [BAL]) metal binding

that occurs in acid urine. Because dissociation of the BAL-metal chelate occurs in acidic urine, the urine of patients receiving BAL should be alkalinized with hypertonic $NaHCO_3$ to a pH of 7.5 to 8.0 to prevent renal liberation of the metal.[43]

REDUCTION IN FREE RADICAL FORMATION: CONTRAST MEDIA

Recent studies have suggested that sodium bicarbonate may be beneficial in preventing contrast-induced nephropathy (CIN).[55] A randomized trial of 119 patients compared an infusion of 154 mEq/L of either sodium bicarbonate or sodium chloride before (3 mL/kg for 1 hour) and after (1 mL/kg/h for 6 hours) iopamidol administration. CIN, defined as a 25% or greater increase in serum creatinine concentration within 2 days of contrast, occurred in eight patients in the sodium chloride group and one patient in the sodium bicarbonate group. In another study comparing sodium bicarbonate with sodium chloride before emergency coronary angiography or intervention, the incidence of CIN was also significantly lower in the sodium bicarbonate group than in the sodium chloride group (7% vs. 35%).[54] It is suggested that increasing medullary pH with sodium bicarbonate infusion might protect the kidneys from oxidant injury by slowing free radical production. The addition of *N*-acetylcysteine to a sodium bicarbonate hydration regimen to prevent CIN does not appear to offer any benefit compared with the use of only sodium bicarbonate hydration.[67] Further study to define the optimal hydration strategy is recommended.[38]

SUMMARY

Despite the increasing tendency to avoid sodium bicarbonate administration in critically ill acidemic patients, sodium bicarbonate remains an important antidote in the treatment of a wide variety of xenobiotic exposures. In fact, its utility in poisoned patients continues to expand. Sodium bicarbonate is effective in the treatment of patients with poisonings by CAs[16] and other sodium channel blockers through its effects on drug ionization and subsequent diffusion from the sodium channel binding site. Sodium bicarbonate is effective for salicylates, phenobarbital, and other weak acids because of its ability to ion trap in the blood or brain and keep toxins away from the target organ.[68] Sodium bicarbonate is effective as a neutralizing agent for inhaled acids such as chlorine gas. In the more common causes of metabolic acidosis with elevated lactate, specific therapy such as antibiotics, volume resuscitation, and inotropic support usually takes precedence over bicarbonate administration.

CHAPTER 36
NONSTEROIDAL ANTIINFLAMMATORY DRUGS

William J. Holubek

Nonsteroidal antiinflammatory drugs (NSAIDs) comprise a class of xenobiotics with analgesic, antipyretic, and antiinflammatory properties. These desirable clinical effects account for the extensive list of approved clinical uses, including the treatment of pain, inflammation, and fever, as well as the management of connective tissue, immunologic, and rheumatologic diseases.[55] In addition to the countless benefits of NSAIDs, some deleterious and life-threatening effects are associated with both their therapeutic use and overdose. In an attempt to circumvent some of these adverse effects, selective cyclooxygenase-2 (COX-2) inhibitors were introduced to the market but one was withdrawn because of their own toxicity profiles. The term *NSAID* used in this chapter does not refer to salicylates, which are unique members of the NSAID class and are covered in Chapter 35.

HISTORY AND EPIDEMIOLOGY

The discovery of NSAIDs began with the creation of acetyl salicylic acid (aspirin) by Felix Hoffman in 1897.[59] Searching for an antirheumatic xenobiotic with less adverse gastrointestinal (GI) effect than aspirin, Stewart Adams and John Nicholson discovered and developed 2-(4-isobutylphenyl) propionic acid, now known as ibuprofen, in 1961. Ibuprofen was initially marketed under the trade name Brufen in the United Kingdom in 1969 and was introduced to the U.S. market in 1974. Ibuprofen became available without a prescription in the United States by 1984. More than a decade later, in 1999, the first selective COX-2 inhibitor, rofecoxib, was approved by the U.S. Food and Drug Administration (FDA), but it was withdrawn in 2004 after increased myocardial infarctions and cerebrovascular accidents were associated with its use.

The American Association of Poison Control Centers (AAPCC) compiles data from participating poison centers throughout the United States using the National Poison Data System (NPDS), formerly known as the Toxic Exposure Surveillance System (TESS). Approximately 4% of all human exposures reported to the AAPCC from 2003 to 2007 were to NSAIDs (including COX-2 inhibitors, ibuprofen, ibuprofen with hydrocodone, indomethacin, ketoprofen, naproxen, and others), which translates to about 90,000 to 100,000 calls annually. In 2006, the AAPCC introduced a Fatality Review Team, which attempts to determine the relationship between exposure and death. The 2006 and 2007 annual reports assigned five deaths and 107 life-threatening manifestations to NSAID exposure (see Chap. 135).

Ibuprofen, naproxen, and ketoprofen are currently the only nonprescription NSAIDs in the United States. NSAIDs are also contained in cough and cold preparations and in prescription combination drugs (eg, ibuprofen with hydrocodone) and have occasionally been found as adulterants in herbal preparations.[64]

NSAIDs are considered among the most commonly used and prescribed medications in the world.[10,75] An estimated one in seven patients with rheumatologic diseases is given a prescription for NSAIDs, and another one in five U.S. citizens uses NSAIDs for acute common complaints.[99]

PHARMACOLOGY

These chemically heterogeneous compounds can be divided into carboxylic acid and enolic acid derivatives and COX-2 selective inhibition (Table 36–1). They all share the ability to inhibit prostaglandin (PG) synthesis. PG synthesis begins with the activation of phospholipases (commonly, phospholipase A_2 or PLR) that cleave phospholipids in the cell membrane to form arachidonic acid (AA). AA is metabolized by PG endoperoxide G/H synthase, otherwise known as COX, to form many eicosanoids, including PGs and the prostanoids, prostacyclin (PGI_2) and thromboxane (TXA_2). AA can also be metabolized by lipoxygenase (LOX) to form hydroperoxy eicosatetraenoic acid (HPETE), which is converted to many different leukotrienes (LTs) that are involved in creating a proinflammatory environment (Fig. 36–1).

The COX enzyme responsible for PG production exists in two isoforms termed *COX-1* and *COX-2*. COX-1 is constitutively expressed by virtually all cells throughout the body but is the only isoform found within platelets. This enzyme produces eicosanoids that govern "housekeeping" functions, including vascular homeostasis and hemostasis, gastric cytoprotection, and renal blood flow and function.[11,79] COX-2, on the other hand, is rapidly induced (within 1 to 3 hours) in inflammatory tissue by laminar shear (or mechanical) forces and cytokines, producing PGs involved in the inflammatory response. COX-2 is also upregulated by several cytokines, growth factors, and tumor promoters involved with cellular differentiation and mitogenesis, suggesting a role in cancer development.[11,31,85]

Glucocorticoids can both inhibit PLA and downregulate the induced expression of COX-2, which decreases the production of eicosanoids and PGs, respectively. Most NSAIDs nonselectively inhibit the COX enzymes in a competitive or time-dependent, reversible manner, unlike salicylates which irreversibly acetylate COX (see Chap. 35). Inhibiting COX-1 can interrupt tissue homeostasis, leading to deleterious clinical effects. In what may seem advantageous, some NSAIDs (eg, etodolac, meloxicam, and nimesulide) preferentially inhibit COX-2 over COX-1; others were specifically designed to selectively inhibit COX-2 (eg, celecoxib).[97] As will be discussed later in this chapter, many of the selective COX-2 inhibitors (sometimes referred to as *coxibs*) were removed from the market in the United States because of their increased risk of adverse cardiovascular events.

NSAIDs do not directly affect the LOX enzyme and the production of LTs; however, some data suggest that blocking the COX enzymes allows AA to be shunted toward the LOX pathway, increasing the production of proinflammatory and chemotactic-vasoactive LTs.[55,99]

PHARMACOKINETICS AND TOXICOKINETICS

Most NSAIDs are organic acids with extensive protein binding (>90%) and small volumes of distribution of approximately 0.1 to 0.2 L/kg. Oral absorption of most NSAIDs occurs rapidly, resulting in bioavailabilities above 80%. Time to peak plasma concentrations achieved by NSAIDs can differ widely (see Table 36–1).[17]

NSAIDs differ with regard to their sites of both action and accumulation within the body. For example, significant synovial concentrations are attained by indomethacin, tolmetin, diclofenac, ibuprofen, and piroxicam.[17] Some NSAIDs cross the blood–brain barrier, achieving significant cerebrospinal fluid (CSF) concentrations. The mechanism and chemical properties related to these properties are not well defined, but evidence suggests that NSAIDs with either very high or very low lipophilicity do

TABLE 36–1. Classes and Pharmacology of Selected Nonsteroidal Antiinflammatory Drugs[8,17,18,29,56,65]

	Time to Peak Plasma Concentration (h)	Half-Life (h)	Pharmacokinetics	Unique Features
CARBOXYLIC ACIDS				
Acetic Acids				
Diclofenac[a,e]	2–3	1–2	First-pass effect; hepatic metabolism (CYP2C9)	Decreases leukocyte AA concentration; topical activity; hepatotoxic
Etodolac	1	7	Hepatic metabolism	Inhibits PMN motility; coronary vasoconstrictor effect
Indomethacin	1–2	2.5	Demethylation (50%)	Poor antiinflammatory effect; topical activity
Ketorolac	< 1	4–6	Urinary excretion	
Sulindac	1–2	7	Active metabolite with a half-life of 18 hr	Prodrug; hepatotoxic
Tolmetin	< 1	5	Hepatic metabolism	Accumulates in synovia
Fenamates				
Meclofenamate	0.5–2.0	2–3		Seizures; GI inflammation
Mefenamic acid	2–4	3–4	Urinary excretion (50%)	Seizures; PG antagonist
Propionic Acids				
Fenoprofen	2	2–3	Decreased oral absorption (~85%)	Increased C_{CSF}
Flurbiprofen	1–2	6		Increased C_{CSF}
Ibuprofen[b,f]	<0.5	2–4	Hepatic metabolism; urinary excretion	Also formulated as IV caldolor
Indobufen[c]	2	6–7	Urinary excretion (70%–80%)	In Europe, used as prophylaxis for thrombus formation
Ketoprofen[b]	1–2	2	Hepatic metabolism; urinary excretion	Bradykinin antagonist; stabilizes lysosomal membranes
Naproxen[b]	1	14	Increased half-life with renal dysfunction	Inhibitory effect on leukocytes; prolonged platelet inhibition
Oxaprozin	3–6	40–60		Once-daily administration
Salicylates (see Chapter 35)				
ENOLIC ACIDS				
Oxicams				
Meloxicam[a]	5–10	15–20		High COX-2 selectivity
Nabumetone	3–6	24	Hepatic metabolism; active metabolites	Prodrug
Piroxicam	3–5	45–50	Hepatic metabolism (CYP2C9)	Inhibits neutrophil activation
Pyrazolone				
Phenylbutazone[c]	2	54–99	Hepatic metabolism; active metabolites	Irreversible agranulocytosis; aplastic anemia
COX-2 SELECTIVE INHIBITORS[d]				
Celecoxib	2–4	6–12	Hepatic metabolism (CYP2C9)	Inhibits CYP2D6
Nimesulide[c]	1–3	2–5	Urinary excretion (60%); active metabolites	Inhibits neutrophil activation

AA, arachidonic acid; C_{CSF}, cerebrospinal fluid concentration; COX, cyclooxygenase; GI, gastrointestinal; PMN, polymorphonuclear leukocytes; PG, prostaglandin.

[a] COX-2 preferential.

[b] Nonprescription.

[c] Not available in the United States.

[d] Rofecoxib (Vioxx) and valdecoxib (Bextra) are no longer available.

[e] Available in combination with misoprostol.

[f] Available in combination with oxycodone and hydrocodone.
FIGURE 36–1. Arachidonic acid (AA) metabolism. This figure also illustrates some of the major differences between cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). Phospholipase A is stimulated by physical, chemical, inflammatory, and mitogenic stimuli and releases AA from cell membranes. The COX-1 enzyme synthesizes prostaglandins (PGs) that maintain cellular and vascular homeostasis. The COX-2 enzyme produces PGs within activated macrophages and endothelial cells that accompany inflammation. Whereas nonsteroidal antiinflammatory drugs reversibly inhibit both COX isoforms, selective COX-2 inhibitors inhibit the COX-2 isoform. Some authors suggest that inhibiting the COX enzymes shunts AA metabolism toward the production of chemotactic-vasoactive leukotrienes. Glucocorticoids inhibit PLA and downregulate induced expression of COX-2. 5-HPETE, hydroperoxy eicosatetraenoic acid; PLA, phospholipase A; PGI_2, prostacyclin; PGE_2, prostaglandin E_2; PLT, platelet; RBF, renal blood flow; TXA_2, thromboxane.

not cross the blood–brain barrier well.[3,56] Ketorolac and diclofenac have topical activity and are used in ophthalmologic solutions.[17]

Serum half-lives with therapeutic dosing vary from as short as 1 to 2 hours for diclofenac and ibuprofen to 50 to 60 hours for oxaprozin and piroxicam (see Table 36–1). Most NSAIDS undergo hepatic metabolism with renal excretion of metabolites. Whereas diclofenac undergoes extensive first-pass metabolism, 10% to 20% of indomethacin and ketorolac are excreted unchanged in the urine. Variable amounts of NSAIDs are recovered in the feces.[17]

The kinetics of NSAIDs may change in overdose, depending on the particular xenobiotic. Therapeutic and supratherapeutic doses of naproxen (250 mg–4 g) result in the same half-life and time to peak plasma concentration, but the clearance and volume of distribution increase proportionately.[67,78] When plasma protein binding of naproxen becomes saturated, the free drug concentration increases more rapidly than the total drug concentration, resulting in increased urinary excretion.[78] Overdoses of ibuprofen do not appear to prolong its elimination half-life.[36,57,101]

PATHOPHYSIOLOGY

GI toxicity is the most common adverse effect from NSAID use (Table 36–2). Normally, the COX-1 enzyme expressed in the gastric epithelial cells leads to the production of PGs (PGE_2 and PGI_2), which are responsible for maintaining GI mucosal integrity by increasing mucous production and decreasing acid production. NSAIDs not only inhibit the production of these cytoprotective PGs and platelet aggregatory TXA_2 but also have a direct cytotoxic effect, increasing the risk of gastric and duodenal ulcers, perforations, and hemorrhage.[24,70,75] Esophageal and small intestinal ulcers and strictures are also associated with NSAID use. Small intestinal diaphragms (or webs) are concentric web-like septa arising from submucosal fibrosis that can eventually cause a small bowel obstruction. These diaphragms rarely occur but are considered pathognomonic for NSAID use.[24]

Selective COX-2 inhibitors to decreased the incidence of significant GI toxicity compared with some nonselective NSAIDs, a benefit that is lost in patients concomitantly taking warfarin or low-dose aspirin.[4,12,31,98] Although *Helicobacter pylori* and NSAID use both individually increase the risk of gastroduodenal ulcers, there are conflicting

data regarding the relationship between the two, given the wide array of study designs, individual responses to infection and treatments, and different gastric acid suppressants. Current evidence suggests that eradicating *H. pylori* before initiating NSAID therapy in NSAID-naïve patients may decrease this risk.[10,19,24,75]

Locally, the kidney produces homeostatic PGs largely via COX-1, including PGI_2, PGE_2, and PGD_2 which cause renal vasodilation and maintain renal blood flow and function.[31,99] Patients with volume contraction (dehydration) or poor cardiac output (congestive heart failure) have elevated concentrations of renal vasoconstrictor substances from stimulation of both the renin–angiotensin–aldosterone axis and the sympathetic nervous system. In these patients, NSAIDs inhibit the synthesis of the compensatory vasodilatory PGs, resulting in unopposed renal vasoconstriction and causing decreased renal blood flow and glomerular filtration rate (GFR). This effect may lead to medullary ischemia and possibly acute renal failure, particularly in elderly individuals.[72] This vasoconstrictive effect appears to be reversible upon discontinuation of therapy. This same effect is associated with COX-2 selective inhibitors.[63,72,99]

Some PGs mediate natriuretic and diuretic effects by maintaining adequate GFR by renal vasodilation, inhibiting sodium chloride absorption, and antagonizing the action of antidiuretic hormone (vasopressin). In addition to opposing homeostatic renal vasodilation, NSAIDs also augment sodium reabsorption, blunting the antihypertensive effect of thiazide and loop diuretics. NSAIDs also decrease renin synthesis, a mechanism shared by beta-adrenergic antagonists, rendering this antihypertensive therapy less effective.[99]

Normal platelet function depends partly on endothelial-derived PGI_2 (largely via COX-1), which blocks platelet activation and causes vasodilation, allowing blood to flow freely within vessels. At the site of vascular injury, platelets are activated by binding to collagen-bound von Willebrand factor and synthesize and release TXA_2, a potent platelet stimulator and vasoconstrictor. The antiplatelet activity of NSAIDs stems from their ability to inhibit COX-1 which is necessary for platelet-stimulating TXA_2 synthesis. Some in vitro evidence suggests that PGI_2 synthesis is largely dependent on COX-2.[16] Inhibiting the antiaggregatory PGI_2 may counter the antiplatelet effect, creating a prothrombotic environment. This is the predominant theory of how selective COX-2 inhibitors increase the risk of adverse cardiovascular events (see below for further discussion).[79]

PGs play a major role during the initiation of parturition. Exogenous administration of $PGF_{2\alpha}$ and PGE_2 has been used to induce uterine activity, and indomethacin has been used successfully as a tocolytic agent blunting PG-mediated uterine stimulation. However, a major clinical drawback in using NSAIDs as a tocolytic agent is the potential to cause premature constriction or closure of the ductus arteriosus in utero. Vasodilatory PGs are required to keep the fetal ductus arteriosus open and patent, and inhibiting these PGs has been shown to cause fetal ductal constriction, leading to pulmonary hypertension and persistent fetal circulation after birth.[61]

TABLE 36–2. Selected Adverse Effects of Nonsteroidal Antiinflammatory Drugs

Gastrointestinal

Chronic: dyspepsia, ulceration, perforation, hemorrhage, elevated hepatic aminotransferases, hepatocellular injury (rare)

Acute: same as above

Renal

Chronic: acute renal failure, fluid and electrolyte retention, hyperkalemia, interstitial nephritis, nephrotic syndrome, papillary necrosis, azotemia

Acute: same as above

Hypersensitivity or Pulmonary

Chronic: angioedema, drug-induced lupus

Acute: asthma exacerbation, anaphylactoid and anaphylactic reactions, urticaria, angioedema, acute lung injury, drug-induced lupus

Hematologic

Chronic: increased bleeding time, agranulocytosis, aplastic anemia, thrombocytopenia, neutropenia, hemolytic anemia

Acute: same as above

Central Nervous System

Chronic: headache, dizziness, lethargy, coma, aseptic meningitis, delirium, cognitive dysfunction, hallucinations, psychosis

Acute: same as above

Drug Interactions

Aminoglycosides: increased risk of aminoglycoside toxicity[80]

Anticoagulants (eg, warfarin): increased risk of GI bleeding[11,79]

Antihypertensives (especially diuretics, β-adrenergic antagonists, and ACE inhibitors): reduced antihypertensive effects[99]

Digoxin: increased risk of digoxin toxicity[89]

Ethanol: increased bleeding time[79]

Lithium: increased risk of lithium toxicity[69]

Methotrexate: increased risk of methotrexate toxicity[69]

Sulfonylureas: increased hypoglycemic effect[87]

CARDIOVASCULAR RISK OF SELECTIVE CYCLOOXYGENASE-2 INHIBITORS AND NONSELECTIVE NSAIDs

Atherosclerosis is a dynamic process of thrombus formation and inflammation involving numerous tissue factors and inflammatory mediators.[32] Given the ability to inhibit synthesis of proinflammatory PGs, selective COX-2 inhibitors would be expected to be antithrombotic; however, their ability to inhibit endothelial-derived PGI_2 combined with their relative inability to inhibit platelet-activating TXA_2 (a predominantly COX-1 effect) may shift the balance toward thrombus formation.[62]

In 2000, the Vioxx Gastrointestinal Outcomes Research (VIGOR) study reported a slightly higher incidence of myocardial infarction in patients taking rofecoxib compared with those taking naproxen (0.4% vs. 0.1%). This was thought to be because of a substantial number of patients who were not taking daily aspirin but should have been (based on FDA criteria) and that naproxen may have had a cardioprotective effect.[12,58,62]

In 2004, Merck pharmaceutical company withdrew rofecoxib from the worldwide market given the prepublication results of a study demonstrating an undisputed elevated cardiovascular risk.[14] Results from a meta-analysis[44] spawned controversy within the medical literature regarding the extent of delay before the withdrawal of rofecoxib from the market.[27,42,48,91] Several other studies addressing selective COX-2 inhibitors have shown similar results of increased risk of adverse cardiovascular events, suggesting this to be a class effect.[27,68,86] Valdecoxib has subsequently been removed from the market, leaving celecoxib as the only selective COX-2 inhibitor available; however, it carries a U.S. FDA alert on a possible increased cardiovascular risk.[86]

The data on nonselective NSAID use and cardiovascular risk remain controversial. Many of the currently published studies and meta-analyses use large databases and are unable to exclude significant confounding factors, including smoking, body mass index, chronic disease, concurrent aspirin use, and socioeconomic status.[96] Some of the nonselective NSAIDs that show a trend toward elevated cardiovascular risk include diclofenac, meloxicam, indomethacin, and (to a lesser extent) ibuprofen.[34,58,81,96] In 2005, the U.S. FDA asked manufacturers of all nonprescription NSAIDs to revise their package inserts to provide more information on the potential cardiovascular risks pending further investigation.

CLINICAL MANIFESTATIONS OF TOXICITY

NSAIDs are a heterogeneous class of drugs, some carrying a unique toxicity profile or effect. Fortunately, most nonselective NSAIDs behave similarly in overdose, although much of the medical literature specifically describes ibuprofen. Regardless of the particular NSAID ingested, symptoms, if they develop, typically manifest within 4 hours after ingestion.[36,37,38,53,57,95,100]

Initial clinical manifestations are usually mild and predominantly include GI symptoms such as nausea, vomiting, abdominal pain, or neurologic symptoms such as drowsiness, headache, tinnitus, blurred vision, diplopia, and dizziness. More moderate and severe findings are rare and include coma, seizures, central nervous system (CNS) depression, metabolic acidosis, hypotension, hypothermia, rhabdomyolysis, electrolyte imbalances, cardiac dysrhythmias, and acute oliguric renal failure.[20,36,37,53,57,60,76,95] Massive NSAID ingestions may lead to multisystem organ failure and death.[22,41,84,93,101]

■ NEUROLOGIC EFFECTS

The neurologic effects of NSAID use vary from the mild drowsiness, headache, and dizziness with therapeutic dosing to the more life-threatening CNS depression, coma, and seizures in overdose. The mechanism associated with the depressed level of consciousness is unknown; however, several animal studies suggest a relationship with opioid receptors, and a human case report documents a dramatic return of consciousness in a child after IV administration of high-dose naloxone.[28] Other miscellaneous neurologic manifestations reported include optic neuritis, toxic amblyopia, color blindness, transient diplopia, other visual disturbances, transient loss of hearing, acute psychosis, and cognitive dysfunction.[39,54,69]

Drug-induced aseptic meningitis has been reported with several NSAIDs, including tolmetin, rofecoxib, naproxen, sulindac, piroxicam, and diclofenac, but ibuprofen is more commonly implicated perhaps because of its widespread use.[66] Clinical findings include fever and chills, headache, meningeal signs, nausea, vomiting, and altered mental status, as well as CSF pleocytosis, elevated protein, and normal glucose.[66] Recent studies suggest an immunologic mechanism because NSAID-induced aseptic meningitis appears to be more common in patients with systemic lupus erythematosus or mixed connective tissue disease.[39,66,69]

Muscle twitching and generalized tonic-clonic seizures are described with mefenamic acid overdose and usually occur within 7 hours after ingestion.[2] Seizures are also associated with ibuprofen overdose.[71] The specific mechanism for NSAID-induced seizures is unknown.

■ RENAL AND ELECTROLYTE EFFECTS

Both acute overdose and chronic therapeutic dosing of NSAIDs may have deleterious effects of renal function, most of which are reversible but in rare cases permanent. These include sodium retention and edema, hyperkalemia, acute renal failure, membranous nephropathy, nephrotic syndrome, interstitial nephritis, and both acute and chronic renal papillary necrosis.[39,74,99] General risk factors for NSAID-induced renal dysfunction include congestive heart failure, volume depletion, diabetes mellitus, underlying renal disease, systemic lupus erythematosus, cirrhosis, diuretic therapy, and advanced age.[55]

Acute tubulointerstitial nephritis (ATIN) is one of the more common forms of NSAID-induced renal impairment, and it may occur with short-term therapeutic dosing.[25,55] Many cases of ATIN probably go undiagnosed because clinical symptoms usually do not appear until significant renal impairment occurs.[25,77] Significant elevations in blood urea nitrogen (azotemia) may occur in elderly patients within 5 to 7 days of initiating NSAID therapy but return to baseline within 2 weeks of discontinuation.[35]

Analgesic abuse nephropathy is a condition whose pathogenesis is not well defined, but it develops from excessive, chronic therapeutic consumption of NSAIDs. This results in acute renal failure manifested by renal papillary necrosis, often requiring hemodialysis.[82,99] Analgesic abuse nephropathy was originally described with the use of analgesic combinations including phenacetin and aspirin in addition to caffeine and has decreased in prevalence after the removal of phenacetin from many world markets.

Anion gap metabolic acidosis, with and without acute renal failure, complicates many acute, massive ibuprofen ingestions and may be profound.[26,41,52,73,101,102] The cause of the acidosis in this setting is most likely multifactorial, involving elevated lactate concentrations from profound hypotension and tissue hypoperfusion, as well as the accumulation of ibuprofen and its two major metabolites, all weak acids.[53] An elevated anion gap metabolic acidosis with elevated lactate concentrations is also described after naproxen overdose, suggesting this to be a class effect given that all NSAIDs are acid derivatives.[13]

Use of NSAIDs by pregnant women is associated with reversible oligohydramnios and is used therapeutically as a treatment modality for polyhydramnios. Decreased fetal urine output and neonatal acute and chronic renal failure, including transient oligoanuria, have been associated with gestational NSAID use, commonly indomethacin.[5,30,45]

■ GASTROINTESTINAL EFFECTS

Numerous studies have reported an increased risk in serious, adverse GI effects with therapeutic use of NSAIDs.[33,50,70] The relative risk of developing gastroduodenal perforation, ulcer, or hemorrhage during chronic NSAID therapy ranges from 2.7 to 5.4, with ketorolac posing the greatest risk.[70,92] Acute NSAID overdoses are reported to cause bloody emesis,[100] fecal occult blood,[20]; and severe, life-threatening GI hemorrhage.[52]

NSAID-induced hepatotoxicity is a well known adverse effect that has prompted the removal of several NSAIDs from the market. Hepatotoxicity occurs with an incidence less than 0.1% and can be quite difficult to diagnose because many patients on chronic NSAID therapy have underlying conditions, such as systemic lupus or rheumatoid arthritis, which may cause hepatotoxicity. NSAID-induced hepatotoxicity is an idiosyncratic reaction primarily causing hepatocellular injury and does not depend on the chemical class. Diclofenac and sulindac are most commonly implicated.[90]

■ IMMUNOLOGIC AND DERMATOLOGIC EFFECTS

The non-immunologic anaphylactoid and IgE-mediated anaphylactic reactions that are reported with the use of NSAIDs are clinically indistinguishable from one another, producing flushing, urticaria, bronchospasm, edema, and hypotension.[7] Evidence for anaphylactic reactions includes the presence of NSAID-specific IgE antibodies, positive wheal-and-flare skin reactions, and lack of cross-reactivity with oral challenges of aspirin and other NSAIDs.[7] The proposed mechanism of NSAID-induced anaphylactoid reactions involves the inhibition of COX-1, which not only inhibits the production of PGE_2 (which causes bronchodilation and inhibits the release of histamine from mast cells and basophils) but also shunts the AA metabolism to increased production of bronchoconstricting LTs.

The term *aspirin-sensitive asthmatic* is a bit of a misnomer because it refers to anaphylactoid reactions that may occur with any COX-1 inhibiting NSAID, not only aspirin.[7,88] Selective COX-2 inhibitors cause similar clinical reactions but with an unclear mechanism. There appears to be very little cross-reactivity between NSAIDs and selective COX-2 inhibitors, and reports of reactions to one COX-2 inhibitor and not another suggest a predominant IgE-mediated mechanism.[7,47,88]

The most common skin reactions include angioedema and facial swelling, urticaria and pruritus, bullous eruptions, and photosensitivity.[39] Although rare, toxic epidermal necrolysis and Stevens-Johnson syndrome have been reported.[39]

■ HEMATOLOGIC EFFECTS

As a class, NSAIDs are frequently implicated as a cause of thrombocytopenia and are reported to have caused adverse effects on most other cell lines and function, including agranulocytosis, aplastic anemia, hemolytic anemia, methemoglobinemia, neutropenia, and pancytopenia.[23,39,46,65,94] Specifically, phenylbutazone in chronic, therapeutic doses is associated with agranulocytosis and aplastic anemia,[84] prompting its removal from the U.S. market in the 1970s. The inhibitory effect of NSAIDs on granulocyte adherence, activation, and phagocytosis has been suggested as the mechanism responsible for the association between NSAID use and necrotizing fasciitis, causing a delay in the onset of symptoms.[40]

The ability of a particular type of NSAID to inhibit platelet aggregation and affect bleeding time depends on the dose and half-life because NSAIDs reversibly inhibit COX. One dose of ibuprofen prolongs the bleeding time within 2 hours and persists for up to 12 hours; however, this increase in bleeding time usually remains within the upper limit of normal range. This is in contrast to aspirin, which irreversibly inhibits COX, and typically doubles the bleeding time within 12 hours, returning to normal within 24 to 48 hours.[79] Compared with placebo, flurbiprofen and indobufen have been shown to clinically inhibit platelet function, thereby decreasing vascular reocclusion after angioplasty and preventing thromboembolic complications.[9,15] The concern for ketorolac to potentiate postoperative bleeding remains controversial, but many studies support its safety and efficacy.[1,21]

Furthermore, NSAID use may potentiate bleeding risk in patients already at higher risk. These patients include those with thrombocytopenia, coagulation factor deficiencies, or von Willebrand disease and those ingesting alcohol or on warfarin therapy.[79]

■ CARDIOVASCULAR EFFECTS

Although no evidence supports a direct cardiotoxic effect of NSAIDs or their metabolites, acute and massive NSAID overdoses may be complicated by persistent, severe hypotension; myocardial ischemia; and cardiac conduction abnormalities and dysrhythmias, including bradycardia, ventricular tachycardia or fibrillation, and prolonged QT interval.[26,41,76,83,101] The cause of these findings is yet to be elucidated, although these effects are reported only in severely ill patients with acid–base abnormalities and multisystem organ involvement (see Cardiovascular Risk above).

■ PULMONARY EFFECTS

Although there is no evidence of direct pulmonary toxicity, some case reports describe the development of acute lung injury with[51,60] and without[26,41] hypoxia. Because this is described with salicylate toxicity, it may be mechanism based. Although chest radiographic findings such as bilateral pulmonary infiltrates appear to resolve rapidly, one study reported persistent clinical abnormalities associated with exertional dyspnea 1 month later (see Immunologic Effects above).[60]

DIAGNOSTIC TESTING

Serum concentrations of most NSAIDs can be determined but usually only by a specialty laboratory requiring several days to report results. Although ibuprofen nomograms were constructed in an attempt to correlate serum concentrations with clinical toxicity,[36,43] the utility of these nomograms proved limited because serum concentrations do not reliably correlate with clinical toxicity.[38,57,83]

Laboratory measurements, including complete blood count, serum electrolytes, blood urea nitrogen, and creatinine should be obtained for all symptomatic patients, patients with intentional ingestion, ibuprofen ingestion of greater than 400 mg/kg in a child, or ibuprofen ingestion of greater than 6 g in an adult.[38] For patients presenting with significant neurologic effects, such as CNS depression, further evaluation of acid–base and ventilatory status by blood gas, hepatic aminotransferases, and prothrombin time should be obtained. Additionally, one must always be cognizant of other potential medical and infectious causes (eg, encephalitis and meningitis) and consider the utility of a lumbar puncture. An acetaminophen concentration should always be determined in patients with intentional ingestions and in patients presenting with an unclear history because many people mistake acetaminophen for NSAIDs because of confusing labeling and packaging or unawareness that they are completely different types of analgesics. For similar reasons, one may also consider obtaining a salicylate concentration.

MANAGEMENT

Management of a patient with an NSAID overdose is largely supportive and guided by the clinical signs and symptoms. Most asymptomatic patients with intentional overdose and those with normal vital signs require observation for 4 to 6 hours and a serum acetaminophen concentration before being medically cleared. Children with ibuprofen ingestions of less than 100 mg/kg can be observed at home, but those who ingest greater than 400 mg/kg are at high risk for toxicity and require medical evaluation.[38] GI decontamination with activated charcoal (AC) should be considered for an asymptomatic patient with the potential

for a large ingestion, symptomatic patients, and children with a history of ibuprofen ingestion greater than 400 mg/kg.[38,49] Serum concentrations of ibuprofen have been demonstrated to increase after the time of emergency department arrival,[101] so gastric lavage for massive overdose followed by AC should be considered. Multiple-dose AC may be useful for patients with massive overdoses of sustained-release preparations.[101]

Patients who develop severe, life-threatening manifestations usually present with lethargy or unresponsiveness.[26,41,60,71,83,101] Aggressive, supportive care is indicated in these patients, including stabilization of the airway and intravenous (IV) fluid therapy. An early electrocardiogram is essential to detect any significant electrolyte abnormalities or conduction disturbances. Electrolyte imbalances should be corrected and sodium bicarbonate therapy considered for severe metabolic acidosis. Hypotension should be treated initially with IV fluid therapy followed by direct-acting vasopressors if necessary. Electrocardiograms should be monitored for the development of any life-threatening electrolyte imbalances or cardiac conduction abnormalities.

Given their high protein binding, NSAIDs do not appear to be amenable to extracorporeal removal methods; however, in cases of persistent metabolic acidosis or renal failure, hemodialysis or continuous renal replacement therapies may be useful to correct the acid–base status.[6,51] Patients with seizures, which are characteristic of mefenamic acid overdose,[2] should be treated with IV benzodiazepines. Phenylbutazone overdose, in particular, carries a high morbidity and mortality rate and requires early and aggressive treatment.[22,65]

The most common adverse effect of therapeutic NSAID use is dyspepsia, and the most serious GI effect is ulcer formation, which has the potential for perforation and hemorrhage. Most patients with dyspepsia do not have ulcers.[24] To help prevent the development of ulcers, concomitant use of misoprostol (a PGE_1 analog), an H_2-blocker, or a proton pump inhibitor (PPI) is often used; however, PPIs may be superior for both preventing and healing gastroduodenal ulcers resulting from chronic NSAID therapy.[75]

SUMMARY

NSAIDs are among the most commonly used drugs in the world. Each NSAID is unique in its chemical structure, but they all share the ability, among other properties, of inhibiting COX-1. Most NSAID overdoses produce nonspecific symptoms, including nausea and abdominal discomfort, requiring very little management, if any. Although the management of patients with larger ingestions involves administration of AC and general supportive care, all patients with intentional NSAID overdoses require the exclusion of acetaminophen coingestion. Massive ingestions may cause life-threatening complications, including coma, metabolic acidosis, renal failure, GI hemorrhage, seizures, and cardiovascular collapse. In these rare cases, therapy depends on hemodynamic monitoring, appropriate resuscitation, and supportive care.

CHAPTER 37

COLCHICINE, PODOPHYLLIN AND THE VINCA ALKALOIDS

Joshua G. Schier

Colchicine

Podophyllotoxin

Vinblastine: R₁ = CH₃
Vincristine: R₁ = CHO
Colchicine, podophyllotoxin, and the vinca alkaloids exert their primary toxicity by binding to tubulin and interfering with microtubule structure and function. The ubiquitous nature of microtubules within human cells and the heavy reliance on them for maintenance of normal cell functions present numerous opportunities for these xenobiotics to cause dysfunction at a cellular, organ, and organ system level in a dose-dependent fashion.

COLCHICINE

■ HISTORY AND EPIDEMIOLOGY

The origins of colchicine and its history in poisoning can be traced back to Greek mythology. Medea was the evil daughter (and a known poisoner) of the king of Colchis, a country that lay east of the Black Sea in Asia Minor. After being betrayed by her husband Jason (of Jason and the Argonauts), she killed their children and her husband's lover. Medea often used plants of the Liliaceae family, of which *Colchicum autumnale* is a member, to poison her victims.[17,134,176] The use of colchicum for medicinal purposes is also reported in *Pedanius Dioscorides De Materia Medica*, an ancient medical text, written in the first century A.D.[17,134,176] and subsequently in the 6th century A.D. by Alexander of Trallis, who recommended it for arthritic conditions.[17,30,110,176] However,

colchicum fell out of favor, perhaps because of its pronounced gastrointestinal (GI) effects, until it was introduced for dropsy and various other nonrheumatic conditions in 1763.[17,176] In the late 18th century, a colchicum-containing product known as *Eau Medicinale* appeared, which reportedly had strong anti-gout effects.[176] Colchicine, the active alkaloidal component in colchicum, was isolated in 1820 and rapidly became popular as an anti-gout medication.[134,176] Benjamin Franklin reportedly had gout and is credited with introducing colchicine in the United States.[134] Colchicine is still used in the treatment of gout and has been used in a multitude of other disorders, including amyloidosis, Behçet 's syndrome, familial Mediterranean fever, pericarditis, arthritis, pulmonary fibrosis, vasculitis, biliary cirrhosis, pseudogout, certain spondyloarthropathies, calcinosis, and scleroderma.[7,17,122,127] Systematic data supporting the efficacy of colchicine therapy in many of these other diseases are lacking.

Colchicine is derived from two plants of the Liliaceae family, *C. autumnale* (autumn crocus, meadow saffron, wild saffron, naked lady, son-before-the-father) and *Gloriosa superba* (glory lily).[176] The autumn crocus may contain different amounts of colchicine by weight, depending on the plant part (bulb, 0.8%; flowers, 0.1%; seeds, 0.8%; and the corm or underground stem, 0.6%).[110,134,159] Colchicine concentrations within the plant peak during the summer months.[134] The leaves of *C. autumnale* closely resemble those of the *Allium ursinum* or wild garlic and have been mistaken for them.[33,34,98] The tubers of *G. superba* may be confused with *Ipomoea batatas* (sweet potatoes).[176]

There is a lack of good epidemiologic data on colchicine poisoning. The American Association of Poison Control Centers records several hundred overall exposures annually. The majority of these exposures are in adults and are categorized as unintentional. Of the cases with a recorded outcome, approximately 10% reportedly to have major toxicity or resulted in death (see Chap. 135). At least 50 adverse events (23 of which were fatalities) have been linked to the use of intravenous (IV) colchicine.[216] The United States Food and Drug Administration recently announced its intent to stop the marketing of injectable compounds containing colchicine,[216] and serious questions remain about the utility of colchicine in light of its extremely narrow therapeutic index.

■ PHARMACOLOGY

Colchicine is a potent inhibitor of microtubule formation and function, which interferes with cellular mitosis, intracellular transport mechanisms, and maintenance of cell structure and shape.[127,176] The ubiquitous presence of microtubules in cells throughout the body presents a wide variety of targets for colchicine in poisoning.[127,176] Colchicine accumulates in leukocytes and has inhibitory effects on leukocyte adhesiveness, ameboid motility, mobilization, lysosome degranulation, and chemotaxis.[17,40,49,74,81,127,136,137,171-173,177] At doses used clinically, colchicine inhibits neutrophil and synovial cell release of chemotactic glycoproteins.[180,202] Colchicine also inhibits microtubule polymerization, which disrupts inflammatory cell-mediated chemotaxis and phagocytosis.[184] It reduces expression of adhesion molecules on endothelial and white blood cells and affects polymorphonuclear cell cytokine production.[5,18,152] Colchicine also acts as a competitive antagonist at GABA_A receptors.[226]

■ PHARMACOKINETICS AND TOXICOKINETICS

Colchicine is rapidly absorbed in the jejunum and ileum and has a bioavailability generally between 25% and 50%.[17,123,176,188] It is highly lipid soluble[12,17,176] with a volume of distribution that ranges from 2.2 to 12 L/kg and that may increase to 21 L/kg in overdose.[158,164,176,181,182,214,223] Colchicine binding to plasma proteins approaches 50%.[17,127,153,176] Protein binding is principally to albumin, although some binding to

α-1-glycoprotein acid and other lipoproteins is reported.[188] During the first several hours after acute overdose, colchicine is sequestered in white and red blood cells in concentrations 5-10 times higher than serum.[188] Peak serum concentrations after ingestion occur between 1 to 3 hours.[127] Toxic effects usually do not occur with concentrations less than 3 ng/mL.[75,153,222]

Colchicine is primarily metabolized through the liver with up to 20% of the ingested dose excreted unchanged in the urine.[108,176,214] Colchicine undergoes demethylation by the cytochrome P450 3A4.[108,127,164,213] Detoxification mainly occurs through deacetylation, demethylation, biliary secretion, and excretion in the stool.[108,127,150,186,188,213] Enterohepatic recirculation of colchicine occurs.[1,164,176]

Serum elimination half-lives ranging from 9 to 108 minutes have been reported.[10,95,176,188,223] On closer examination, however, these times probably more accurately reflect a rapid initial distribution phase. The drug undergoes a more delayed terminal elimination phase, which ranges from 1.7 to 30 hours, depending on the individual compartment model used to estimate elimination and the amount of colchicine absorbed.[1,79,176,182,186,188,214] These values are on the same order as and probably reflect the tubulin—colchicine complex disassociation time.[164] Individuals with renal failure and liver cirrhosis may have elimination half-lives that are prolonged up to 10-fold.[127] Colchicine can remain in measurable tissue quantities for a long time, as evidenced by its detection in white blood cells after 10 days and in urine 7 to 10 days after exposure.[74,176] Colchicine can cross the placenta and is secreted in breast milk, but it is not dialyzable.[127] Postmortem examination of colchicine-poisoned patients reveals high concentrations within the bone marrow, testicles, spleen, kidney, lung, brain, and heart.[181]

Drug Interactions Colchicine metabolism is susceptible to drug interactions. Because colchicine is detoxified through CYP3A4, blood concentrations are susceptible to xenobiotics that alter the function of this enzyme, such as erythromycin, clarithromycin, and grapefruit juice.[42,67,87,127] In particular, coadministration of clarithromycin and colchicine, especially in patients with renal insufficiency, increases the risk of fatal interaction.[107] P-glycoprotein (PGP) expels and clears colchicine, and drugs that inhibit PGP may directly affect the amount of colchicine eliminated and hence, toxicity.[164] For example, cyclosporine increases colchicine toxicity.[127,200,201]

PATHOPHYSIOLOGY

Microtubules play a vital role in cellular mitosis and possess a high amount of dynamic instability.[14,73,116,194] Microtubules are made up of tubulin protein subunits, of which three are known to exist: α, β, and γ.[116,146,194] These structures are highly dynamic with α-β tubulin heterodimers, constantly being added at one end and removed at the other.[116,117] Microtubules undergo two forms of dynamic behavior: dynamic instability, in which microtubule ends switch between growth and shortening phases, and treadmilling, in which there is a net growth (addition of heterodimers) at one end and a shortening (loss) at the other.[20] Assembly and polymerization dynamics are regulated by additional proteins known as stabilizing microtubule-associated proteins (MAPs) and destabilizing MAPs.[20] These dynamic behaviors and a resultant equilibrium are needed for multiple cell functions, including cell support, transport, and mitotic spindle formation for cell replication.[116] Xenobiotics that bind to specific regions on tubulin can interfere with microtubule structure and function, thereby causing mitotic dysfunction and arrest.[146,194] This leads to cellular dysfunction and death.[194] Xenobiotics that target microtubules can be generally divided into two categories: polymerization inhibitors (ie, vinca alkaloids, colchicine) and polymerization promoters (ie, taxanes, laulimalides).[20]

Colchicine binds to a tubulin dimer at a specific region known as the *colchicine-binding domain*, which is located at the interphase of the α and β subunits of the tubulin heterodimer.[20,99,116,167,194,217] This binding is relatively slow, temperature dependent, and generally irreversible, resulting in an alteration of the protein's secondary structure.[99,116,167,189] Colchicine binds at a second reversible but lower-affinity site on tubulin.[116,133] Current evidence suggests that the colchicine—tubulin complex binds to the microtubule ends and prevents further growth by sterically blocking further addition of dimers.[20] Conformational changes in the tubulin and colchicine complex also result as colchicine concentrations increase, which weakens the lateral bonds at the microtubule end.[20,146,194] Lateral and longitudinal interactions between dimers within a microtubule help stabilize the structure. The number of tubulin—colchicine dimers incorporated into the microtubule determines the stability of the microtubule ends.[20] All of these processes may prevent adequate binding of the next tubulin subunit and result in cessation of microtubule growth.[146,194] At low concentrations, colchicine arrests microtubule growth, where as at high concentrations, colchicine can actually cause microtubule depolymerization through disassociation of tubulin dimers.[20]

These conformational changes ultimately result in disassembly of the microtubule spindle in metaphase of cellular mitosis, cellular dysfunction, and death.[77,99,116,167,189,194] The effects of colchicine are dose dependent, with high concentrations inhibiting further microtubule polymerization, as well as inducing depolymerization of already formed microtubules.[130] Low concentrations can simply affect new microtubule formation and have no effect on preestablished polymer mass.[130] Colchicine also inhibits microtubule-mediated intracellular granule transport.[17,127] Some in vitro animal studies have also shown that colchicine might inhibit DNA synthesis by changing cell regulatory events at a critical time during the mitotic cycle.[72,78,101,130]

◼ TOXIC DOSE

The toxic dose for colchicine is not well established. An early case series suggested that patients with ingestions of greater than 0.8 mg/kg uniformly died and those with ingestions above 0.5 mg/kg but less than 0.8 mg/kg would survive if given supportive care.[23] This information was based on a limited series of patients and is likely not generalizable.[156] More recent literature suggests that severe toxicity and even death may occur with smaller doses, and patients may survive ingestions in excess of 0.8 mg/kg.[63,81,88,94,156,204] This inability to accurately quantify the toxic dose in humans is likely due in great part to difficulty in dose estimation from the patient's history and significant advances in supportive care.

◼ CLINICAL PRESENTATION

The clinical findings in poisoned patients is commonly described as triphasic (Table 37–1).[103,142,158,204] GI irritant effects, such as nausea, vomiting, abdominal distress, and diarrhea, occur initially within several hours after an overdose[3,32,34,59,66,118,142,147,219] and may lead to severe volume depletion.[87,106,137,156,158,160,204,225] This first stage usually persists for the first 12 to 24 hours after ingestion.[106,142] The second stage is characterized by widespread organ system dysfunction, particularly the bone marrow, and lasts for several days.[34,63,156,158,204] The final phase is characterized by recovery or death, and the progression can usually be defined within 1 week.[103,106,142,204]

After overdose, the hematopoietic effects of colchicine are characterized by an initial peripheral leukocytosis, which may be as high as 30,000/mm³. This is followed by a profound leukopenia, which may be lower than 1000/mm³. It is commonly accompanied by pancytopenia, usually beginning 48 to 72 hours after overdose.[17,32,79,87,102,142,161] The hematopoietic manifestations occur as a result of colchicine's effects

TABLE 37–1. Colchicine Poisoning: Common Clinical Findings, Timing of Onset, and Treatment

Phase	Time[a]	Signs and Symptoms	Therapy/Followup
I	0–24 hours	Nausea, vomiting, diarrhea	Antiemetics Consider GI decontamination
		Dehydration	IV fluids
		Leukocytosis	Close observation for leukopenia
II	1–7 days	Possible risk of sudden cardiac death (24–36 hours)	ICU admission and appropriate resuscitation
		Pancytopenia	G-CSF
		Renal failure	Hemodialysis
		Sepsis	Antibiotics
		Acute respiratory distress syndrome	Oxygen, mechanical ventilation
		Electrolyte imbalances	Repletion as needed
		Rhabdomyolysis	IV fluids, hemodialysis
III	>7 days	Alopecia	Follow-up within 1–2 months
		Myopathy, neuropathy, or myoneuropathy	EMG testing, biopsy and neurological follow-up as needed

[a] The interval time course is not absolute, and overlap of symptom presentation may occur.
EMG, electromyography; G-CSF, granulocyte-colony stimulating factor.

on bone marrow cell division.[30,106,145,181,225] A rebound leukocytosis and recovery of all cell lines occur if the patient survives.

Colchicine toxicity is associated with the development of dysrhythmias and cardiac arrest.[30,103,106,142,158] Sudden cardiovascular collapse from colchicine typically occurs between 24 to 36 hours after ingestion.[30,41,142,145,156] Profound hypovolemia and shock may contribute to this collapse,[17,87,156,158,204] but colchicine has direct toxic effects on skeletal and cardiac muscle, causing rhabdomyolysis.[26,50,140,148,157,220,225]

Myopathy,[35,36,193,229] neuropathy,[8,130] and a combined myoneuropathy[6,52,61,70,125,126,178,199,233] are described as a result of both long-term therapy and acute poisoning.[130] A combined myoneuropathy is reported more often, with myopathy dominating the clinical picture.[6,52,61,70,125,126,178,199,233] The myoneuropathy is often initially misdiagnosed as polymyositis or uremic neuropathy (caused by coexistent renal insufficiency).[6,126] Myoneuropathy usually develops in the context of chronic, therapeutic dosing in patients with some baseline renal impairment,[6,52,61,70,125,126,178,199,233] although it may also occur in the presence of normal renal function.[175] Patients may present with proximal limb weakness, distal sensory abnormalities, distal areflexia, and nerve conduction problems consistent with an axonal neuropathy.[126,169] A small amount of myelin degeneration is reported on autopsy, which suggests a myelinopathic component.[31] The myopathy is characterized by vacuolar changes on biopsy and accompanied by lysosome accumulation.[6,70,126,233] Elevated serum creatine kinase activity is present concurrently with symptoms.[126,158] Weakness usually resolves within several weeks of drug discontinuation.[126] Myopathy may also

occur when concomitant use of hydroxymethylglutaryl—coenzyme A reductase inhibitors are used in patients with renal insufficiency.[2] Myopathy symptoms typically resolve within 4 to 6 weeks, although it may take up to 6 to 8 months in some patients.[229]

Acute respiratory distress syndrome occurs with colchicine toxicity.[11,59,102,150,191,195] The etiology is not well understood but may result from several factors, including respiratory muscle weakness, multisystem organ failure, and possibly direct pulmonary toxicity.[59,142,150,191,212] Other indirect effects of colchicine include renal failure and various electrolyte abnormalities resulting from fluid loss and impaired kidney function.[17,63,87,130,158]

Alopecia, which is usually reversible, is a well-described complication that occurs 2 to 3 weeks after poisoning in survivors.[17,79,87,88,106,133,211] Dermatologic complications range in severity from epithelial cell atypia to toxic epidermal necrolysis.[4,9,77,86,185]

Neurologic effects, including delirium, stupor, coma, and seizures, might be at least partly attributable to the multisystem disease caused by poisoning and not necessarily a direct effect of colchicine.[35,161,176,195] The cause of seizures is unclear but it might be partly attributable to antagonism of GABA$_A$ receptors.[226]

Other reported complications of colchicine poisoning include bilateral adrenal hemorrhage,[54,208] disseminated intravascular coagulation,[106,176,195] pancreatitis,[161] and liver dysfunction.[35,158,176]

■ DIAGNOSTIC TESTING

Colchicine concentrations in body fluids are not available in a clinically relevant fashion and have no well-established correlation with severity of illness. However, effective steady-state serum concentrations for treatment of patients with various illnesses are reported as 0.5 to 3.0 ng/mL.[153] Concentrations greater than 3.0 ng/mL are generally associated with toxicity.[75,153,222] Serum concentrations do not correlate well with the amount of xenobiotic ingested in massive oral overdose settings.[62] Initial laboratory monitoring should include a complete blood count (CBC), serum electrolytes, renal and liver function tests, creatine kinase, phosphate, calcium, magnesium, prothrombin time, activated partial thromboplastin time, and urinalysis. The need for other laboratory studies, such as a troponin, arterial blood gases, lactate, fibrinogen, and fibrin split products, should be considered, depending on the clinical situation. If cardiac toxicity is present or suspected, serial troponins (every 6–12 hours) should be performed because increasing concentrations may be predictive of cardiovascular collapse.[84,220] An electrocardiogram and chest radiograph should also be obtained. Serial CBCs are indicated (at least every 12 hours) to evaluate for the development of depression in cell lines.

■ MANAGEMENT

Treatment for patients with colchicine toxicity is mainly supportive, which includes IV fluid replacement, vasopressor use, hemodialysis (for renal failure), antibiotics for suspected secondary infection, colony-stimulating factors and adjunctive respiratory therapy (endotracheal intubation, positive end-expiratory pressure), as indicated. Consultation with nephrology and hematology specialists should be obtained in the case of impaired renal function or evidence of hematotoxicity.

Gastrointestinal Decontamination Because most patients with an acute oral colchicine overdose present several hours after their ingestion, vomiting has already begun, and the utility of GI decontamination is inadequately defined. However, given the extensive morbidity and mortality associated with colchicine overdose, orogastric lavage probably should be performed in patients who present within 1 to 2 hours of ingestion and are not vomiting.[25,218] A dose of activated charcoal (AC) should be administered after lavage, or in its place, and

multiple-dose AC (MDAC) should be considered because of enterohepatic recirculation.[1,176] The delay in presentation to a health care facility coupled with the presence of GI symptoms such as vomiting significantly complicates using MDAC. However, antiemetic medications can be given to control emesis and facilitate AC administration.

Antidotal Therapy Experimental colchicine-specific antibodies can restore colchicine-affected tubulin activity in vitro and were successfully used in a single case of severe colchicine poisoning.[13] The administration of Fab fragments was temporally associated with a dramatic improvement in clinical and hemodynamic status. This improvement was also associated with a significant increase in serum colchicine concentrations, which suggests a redistribution of drug into the intravascular space.[13] Unfortunately, this therapy is not commercially available.

Granulocyte-colony stimulating factor (G-CSF) has been useful in the treatment of patients with colchicine-induced leukopenia and thrombocytopenia.[57,97,120,232] The dose of G-CSF, the dosing frequency, and the route of administration were variable in the reported cases.[57,97,120,232] G-CSF should be started if the patient begins to manifest evidence of leukopenia. Dosing should be in accordance with the manufacturer's instructions.

Extracorporeal Elimination Hemodialysis and hemoperfusion are not viable options for patients with colchicine poisoning based on its large volume of distribution, but hemodialysis may be required if renal failure is present.[16,21,22,181,182,214,223]

Disposition Because of the significant morbidity and mortality associated with colchicine toxicity, all symptomatic patients with suspected or known overdoses should be admitted to the hospital for observation. Because these patients have a risk of sudden cardiovascular collapse within the first 24 to 48 hours[156] intensive care unit monitoring is recommended for at least this initial time period. Troponin should be ordered every 6 to 12 hours during this period because increasing results may suggest an increased risk of cardiotoxicity and cardiovascular collapse.[84,220] Poisoned patients manifest GI signs and symptoms within several hours of ingestion and should be observed for at least 8 to 12 hours. Patients who do not manifest GI signs and symptoms within that time period after ingestion are unlikely to be significantly poisoned.

PODOPHYLLUM RESIN OR PODOPHYLLIN

■ HISTORY AND EPIDEMIOLOGY

Podophyllin is the name often used to refer to a resin extract from the rhizomes and roots of certain plants of the genus *Podophyllum*.[64,91] Examples include the North American perennial *Podophyllum peltatum* (mayapple or mandrake), the related Indian species *Podophyllum emodi*, and the Taiwanese *Podophyllum pleianthum*.[64] It is more descriptive to refer to it as podophyllum resin.[64,91] Podophyllum resin, or podophyllin, contains at least 16 active compounds.[45,64,91] These include a variety of lignins and flavonols, including podophyllotoxin, picropodophyllin, α- and β-pellatins, desoxypodophyllotoxin, and quercetin.[43,45,64,91] Podophyllotoxin, a component of podophyllin, is a potent microtubular poison, similar to colchicine, and causes similar effects in overdose.[64]

The first reported modern era medicinal use of podophyllin preparations was as a laxative in the 19th century.[43,45,173] Its cathartic properties, as well as its potential toxicity, were noted as early as 1890, when the first fatality from podophyllin was recorded.[69,196] Podophyllin was used to treat individuals with a variety of other health issues, including liver disease, scrofula, syphilis, warts, and cancer.[64] Etoposide and teniposide are semisynthetic derivatives of podophyllotoxin used as chemotherapeutics.[64]

Poisoning usually is caused by systemic absorption after topical application, after ingestion of the resin or plant, and after consumption of a commercial preparation of the extract. Systemic toxicity is described after unintentional dispensing of the incorrect herb, as well as after ingestion of herbal preparations containing podophyllin.[46,48,65]

■ PHARMACOLOGY

Podophyllin is primarily used in modern pharmacopeia as a topical treatment for patients with verruca vulgaris and condyloma acuminatum.[43,76,129] The active ingredient is believed to be podophyllotoxin.[12,64,119,196,210,221,230] Podophyllotoxin exists in the plant as a β-D-glucoside.[76,119,196] Numerous synthetic and semisynthetic derivatives of podophyllotoxin exist; however, the most important are probably the chemotherapeutics etoposide and teniopside.[64] The antitumor effect of etoposide and teniposide results from their interaction with topoisomerase II and free radical production, leading to DNA strand breakage, an effect not shared by podophyllin and colchicine.[39,64] Use of etoposide and teniposide may also lead to a cessation of cell growth in the late S or early G2 phase of the cell cycle.[39,64,85] Further discussion of these xenobiotics can be found in the Chapter 52.

■ PHARMACOKINETICS AND TOXICOKINETICS

Very limited information exists regarding the pharmacokinetics (absorption, distribution, metabolism, and elimination) of podophyllin as a preparation or for its major active ingredient, podophyllotoxin. Podophyllotoxin is highly lipid soluble and can easily cross cell membranes.[76,89,163,196] It can be eliminated through the bile with a half-life of 48 hours.[43,53] However, review of the referenced articles failed to adequately support this elimination and may have been based solely on clinical course.[53]

Absorption of podophyllotoxin was measured in seven men after application of various amounts of a 0.5% ethanol podophyllotoxin preparation for condylomata acuminata.[221] Peak serum concentrations of 1 to 17 ng/mL were achieved within 1 to 2 hours after administration of doses ranging from 0.1 to 1.5 mL (0.5—7.5 mg).[221] Patients treated with less than or equal to 0.05 mL had no detectable podophyllotoxin in their serum. Administration of 0.1 mL yielded peak serum concentrations up to 5 ng/mL within 1 to 2 hours and up to 3 ng/mL at 4 hours. Administration of 1.5 mL yielded peak serum levels ranging from 5 to 9 ng/mL within 1 to 2 hours, levels of 5 to 7 ng/mL at 4 hours, 3 to 4.5 ng/mL at 8 hours, and 3.5 ng/mL at 12 hours.[221]

■ PATHOPHYSIOLOGY

The components of podophyllin have numerous actions within the cell, including inhibition of purine synthesis, inhibition of purine incorporation into RNA, reduction of cytochrome oxidase and succinoxidase activity, and inhibition of microtubule structure and function.[43,85,224] Podophyllotoxin causes its toxicity similar to colchicine[64,230] because it is able to bind to tubulin subunits and interfere with subsequent microtubule structure and function.[64,230] Interestingly, radiolabeled podophyllotoxin can inhibit colchicine binding to tubulin, suggesting that their binding sites overlap.[64] Podophyllotoxin binds more rapidly than colchicine, and binding is reversible in contrast to colchicine.[64] Podophyllotoxin also inhibits fast axoplasmic transport similar to colchicine by interference with microtubule structure and function.[170] Many other compounds, such as the vinca alkaloids, cryptophycins, and halichondrins, also inhibit microtubule polymerization in a similar manner.[117]

■ CLINICAL PRESENTATION

Poisoning is described after ingestion,[38,48,65,80,104,143,187,228] as well as after absorption from topical application of podophyllin.[83,144,151,154,168,205,207] Toxicity also is reported after IV administration of podophyllotoxin[192] and ingestion of mandrake root or herbal remedies containing

podophyllin.[65,69,80] Nausea, vomiting, abdominal pain, and diarrhea usually begin within several hours after ingestion.[53,69,83,89,104,144,149,151,187,192,196,205,228] Symptoms of poisoning might be delayed for 12 hours or more after topical exposure to podophyllin and are often caused by improper usage (excessive topical exposure, interruption in skin integrity, or failure to remove the preparation after a short time period).[144,149,154,196] Initial clinical findings are not necessarily dictated by the route of exposure.[144]

Alterations in central and peripheral nervous system function tend to predominate in podophyllin toxicity. Patients might present with, or rapidly progress to confusion, obtundation, and coma.[38,53,65,83,143,149,151,154,187,205,207,210,228]

Delirium and both auditory and visual hallucinations occur during the initial presentation.[55,76,207] Patients develop paresthesias, lose deep tendon reflexes, and might develop a Babinski sign.[38,45,48,53,65,83,143,151,154,166,196,207] Cranial nerve involvement, including diploplia,[45] nystagmus,[53] dysmetria,[48] dysconjugate gaze,[207] and facial nerve paralysis,[55] are all reported. Patients who recover from the initial event are at risk of developing a peripheral sensorimotor axonopathy.[48,53,76,83,143,151,163,166,196,207] The reported duration for recovery from podophyllin-induced axonopathy is variable but can take several months.[53,65,83,151,163] Dorsal radiculopathy[89] and autonomic neuropathy have also been reported.[129] There may be a mild myelopathic component in the neuropathy.[47]

Hematologic toxicity from podophyllin most likely results from its antimitotic effects. A review of the limited literature suggests that it is similar to colchicine but is not nearly as consistent in its pattern, severity, and frequency. An initial leukocytosis[83,151,154,196] may occur after poisoning, which can be followed by leukopenia, thrombocytopenia, or generalized pancytopenia.[104,129,149,151,196,205] In patients who recover, cell lines tend to reach their nadir within 4 to 7 days after exposure.[76,83,104,151,205]

Other complications of poisoning include fever,[149] ileus,[76,149,207] elevated liver function tests,[65,104,151,205,228] and hyperbilirubinemia,[104] coagulopathy,[104] seizures,[55,187] and renal insufficiency or failure.[149,228] Teratogenic effects resulting from exposure during pregnancy may also occur.[45,119]

DIAGNOSTIC TESTING

Podophyllin or podophyllotoxin concentrations are not readily available. Routine testing for suspected or known podophyllin poisoning should include routine laboratory tests and other targeted testing, as needed. Serial cell blood counts should be obtained in cases of poisoning to evaluate for pancytopenia.

MANAGEMENT

Management primarily consists of supportive and symptomatic care. Orogastric lavage may be considered in patients with serious ingestions if presentation occurs within several hours of ingestion based on its high toxicity profile.[25,218] If the patient presents within the first several hours of ingestion, a dose of AC should be given. Any topically applied podophyllin should be removed and the area thoroughly cleansed. Supportive and symptomatic care should be instituted as needed. Patients either progress to multisystem organ dysfunction and death or recover with supportive care.

A few case reports of treatment with extracorporeal elimination techniques exist. These reports include resin hemoperfusion[100] and charcoal hemperfusion.[151,196] The role these procedures played in the patients' clinical courses is unclear. As a result, firm recommendations regarding the use of these techniques cannot be made at this time.

DISPOSITION

Patients with significant ingestions of podophyllin develop GI symptoms within a few hours,[48,69,80,104,166,228] but patients may also present with primarily neurologic symptoms, such as confusion or obtundation.[38,43,76,144] An isolated number of cases suggest the onset of toxicity can be delayed for as long as 12 hours.[38,43,53,65] Dermal exposure might result in even further delayed toxicity because systemic absorption is delayed and symptom onset is more insidious.[76,83,129,154,196,205,207] Patients probably should be observed for toxicity for at least 12 hours after ingestion and perhaps even longer after a significant dermal exposure.

VINCRISTINE AND VINBLASTINE

PHARMACOLOGY

Vincristine and vinblastine are derived from the periwinkle plant (*Catharanthus roseus*) and used for the treatment of patients with leukemias, lymphomas, and certain solid tumors. Their mechanism of activity is similar to that of colchicine, podophyllotoxin, and the taxoids (eg, paclitaxel, docetaxel).[60,71] These chemotherapeutics disrupt microtubule assembly from tubulin subunits by either preventing their formation or depolymerization, both of which are necessary for routine cell maintenance. Vinblastine binds to the β-subunit of the tubulin heterodimer at a specific region known as the *vinblastine binding site*.[20] Microtubules are responsible for several basic cellular functions, including cell division, axonal transport of nutrients and organelles, and cellular movement. Mitotic metaphase arrest is commonly observed because of the inability to form spindle fibers from the microtubules. Cell death quickly ensues as a result of the interruption of these homeostatic functions, accounting for the clinical manifestations.

PHARMACOKINETICS

After IV administration, vincristine is rapidly distributed to tissue stores and highly bound to proteins and red blood cells.[37] The capacity of vincristine to be bound by plasma proteins ranges from 50% to 80%.[174] In more than 50% of children given IV vincristine, serum concentrations were not detected 4 hours after administration.[155] The vinca alkaloids are primarily eliminated through the liver. Patients with hepatic dysfunction are susceptible to toxicity. Elimination of vincristine occurs via the hepatobiliary system,[37] and it has a terminal plasma half-life of about 24 hours.[162] Vincristine overdose is the most frequently reported antineoplastic overdose in the literature. This is because there are at least four different potential inappropriate ways to dose and administer vincristine, including confusing it with vinblastine, misinterpreting the dose, administering it by the wrong route, and confusing two different-strength vials. The normal dose of vincristine is 0.06 mg/kg, and a single dose is not to exceed 2 mg for either an adult or child.

CLINICAL MANIFESTATIONS

Despite their similarity in structure, vincristine and vinblastine differ in their clinical toxicity. Vincristine produces less bone marrow suppression and more neurotoxicity than does vinblastine. During the therapeutic use of vincristine, myelosuppression occurs in only 5% to 10% of patients.[105] However, this effect is common in the overdose setting, and when it occurs, the need for replacement blood products and concern for overwhelming infection is apparent.[132] The decrease in cell counts begins within the first week and may last for up to 3 weeks. Other manifestations of acute vincristine toxicity are mucositis, central nervous system (CNS) disorders, and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) (see Chap. 16).

CNS disorders are varied and unusual during therapeutic vincristine therapy because of its poor penetrance of the blood—brain barrier. They are, however, more common when there is delayed elimination, damage

to the blood brain—barrier, overdose, or inadvertent intrathecal administration. Generalized seizures from toxicity or secondary effects may occur from 1 to 7 days after exposure.[109,115,121,206] Other manifestations are depression, agitation, insomnia, and hallucinations. Vincristine stimulation of the hypothalamus may be responsible for the fevers and SIADH noted in overdosed patients.[183] The fevers begin 24 hours after exposure and last 6 to 96 hours. Serum electrolytes need to be monitored, typically for 10 days.

Autonomic dysfunction is observed, and it commonly includes ileus, constipation, and abdominal pain. Atony of the bladder, hypertension, and hypotension may also occur.[121]

Ascending peripheral neuropathies occur during vincristine therapy and can be limited by keeping the total for a single dose below 2 mg.[197] Neuropathy may appear after an overdose, starting at about 2 weeks and lasting for 6 to 7 weeks. Paresthesias, neuritic pain, ataxia, bone pain, wrist drop, foot drop, involvement of cranial nerves III to VII and X, and diminished reflexes may be observed.[227] The incidence of paresthesia increases with dose and is reported to be 56% in patients treated at doses between 12.5 and 25 µg/kg.[105] At a dose of 75 µg/kg, the incidence of patients with a sensory disorder increased by sixfold. The loss of reflexes, the earliest and most consistent sign of vincristine neuropathy, is maximal at 17 days after a single massive dose. Muscular weakness is a limiting point in therapy and typically involves the distal dorsiflexors of the extremities, although laryngeal involvement is also reported.[128,190] These severe neurologic symptoms may be reversed by either withholding therapy or reducing dosage upon manifestation of these findings.[128] The mechanism of toxicity is not well understood but appears to be related to inhibition of microtubular synthesis, which leads to axonal degeneration.[90,165] A brain biopsy of a patient suffering a vincristine-related death showed neurotubular dissociation, which is characteristic of vincristine damage in experimental animals.[28,51] Unlike the vinca alkaloids, Taxol-induced peripheral neuropathy is predominantly sensory and resolves faster with discontinuation.[131] This is because of the different effects on microtubule assembly by these agents. Nerve conduction studies and the Achilles tendon reflex are useful in monitoring patients for toxicity after exposure.

Vincristine-induced myocardial infarctions have been reported, but their cause is not understood.[138,198,209,231] They may be related to vinca alkaloid—induced platelet aggregation, coronary artery spasm, or increased sensitivity of myocardium to hypoxia.

■ MANAGEMENT

Patients receiving an inadvertent amount of an IV dose of vincristine should be admitted to a cardiac-monitored bed and observed for 24 to 72 hours.[135] Treatment of generalized seizures with benzodiazepines or phenobarbital is usually successful, and phenytoin was used successfully in a patient with barbiturate hypersensitivity.[121] Prophylactic phenobarbital and benzodiazepine agents were used to prevent seizures in two patients.[44,124] Dysrhythmias and alterations in blood pressure may also be expectantly managed. Calcium channel blockers (nifedipine and amlodipine) were used to control hypertension in a patient with vincristine overdose.[44] Blood counts must be monitored daily, and G-CSF may be used to treat neutropenia.[44,132,206] However, the red blood cell response from the use of erythropoietin may be limited because of the induction of metaphase arrest in the erythroblasts.[141]

If patients remain asymptomatic during the observation period, they can be discharged with follow-up for bone marrow suppression and SIADH; otherwise, depending on the patient's clinical condition, continual observation for progression of neurologic symptoms is warranted.[19] The symptoms of acute toxicity usually last for 3 to 7 days, and the neurologic sequelae may last for months before some resolution is observed.

In a controlled clinical trial for vincristine-induced peripheral neuropathy, glutamic acid therapy had limited efficacy. Patients receiving vincristine therapy were given glutamic acid as 500 mg orally 3 times a

day.[114] There was a decreased incidence in loss of the Achilles tendon reflex and a delayed onset of paresthesias in the glutamic acid—treated group. No reported adverse effects with glutamic acid were observed in this investigation. Animal studies involving the administration of glutamic and aspartic acid to mice poisoned with either vinblastine or vincristine demonstrate increased survival and decreased sensorimotor peripheral neuropathy.[27,58,112] The mechanisms of these observed effects with glutamic acid remain unclear, but several authors have suggested the ability of glutamic acid to competitively inhibit a common cellular transport mechanism for vincristine,[24,56] its ability to assist in the stabilization of tubulin and promote its polymerization into microtubules,[29,96] and the ability of glutamic acid to improve cellular metabolism by overcoming the inhibition in the Krebs cycle.[68,179] Although the role of glutamic acid in acute toxicity needs further study, it is not harmful and should be considered. Glutamic acid may be initiated as 500 mg orally three times a day and continued until the serum vincristine concentration is below toxicity.[114] L-Glutamic acid is the preferred stereoisomer because it is biologically active, and this product is available as a powder from various distributors in the United States.

Leucovorin may shorten the course of vincristine-induced peripheral neuropathy[92] and myelosuppression.[124] The mechanism is attributed to leucovorin's ability to overcome a vincristine-mediated block of dihydrofolate reductase and thymidine synthetase.[92] However, neither leucovorin[15,111,215] nor pyridoxine[113] has been definitely shown to be effective. An initial experimental investigation evaluating the efficacy of antibody therapy to limit vinca alkaloid toxicity shows promise.[93]

One case of vinblastine overdose was reported to be successfully managed with plasma exchange procedures performed at 4 hours and 18 hours after vinblastine administration.[203]

■ ENHANCED ELIMINATION

Vincristine's rapid distribution and high protein binding characteristics favor early intervention and methods other than hemodialysis. Double-volume exchange transfusion was performed at 6 hours postexposure in 3 children who were overdosed with 7.5 mg/m² of IV vincristine.[124] This procedure replaced approximately 90% of the circulating blood volume by exchanging twice the patient's blood volume. Of the two survivors, their respective postexchange serum vincristine concentrations were 57% and 71% lower than their preexchange concentrations. The amount of vincristine removed was not determined. Although these patients developed peripheral neuropathies, myelosuppression, and autonomic instability, the author noted that the duration of illness was shorter than previously reported. Thus, based on the pharmacokinetic profile of vincristine and these two reports, exchange transfusion in children is the preferred method of enhanced elimination when the patient presents soon after the administration of the drug, and plasmapheresis is the preferred method in adults.

Plasmapheresis was attempted with vinca alkaloid overdoses.[132,174] In an 18-year-old patient who received two 8-mg IV doses of vincristine at 12-hour intervals, the procedure was performed 6 hours after the second dose, and 1.5 times the plasma volume was plasmapheresed.[174] Postplasmapheresis serum vincristine concentration was 23% lower than the starting concentration. The patient survived with myelosuppression, neurotoxicity, and SIADH. Additional information on the toxicity of intrathecal administration of the vinca alkaloids can be found in Special Considerations SC2: Intrathecal Administration of xenobiotics.

SUMMARY

Colchicine toxicity may be evident several hours after ingestion and consists of severe nausea, vomiting, diarrhea and abdominal pain followed by pancytopenia several days later. Colchicine-poisoned patients

TABLE 37–2. Comparison of General Antimitotic Xenobiotics in Overdose

	Colchicine	Podophyllum Resin	Vincristine	Vinblastine
Route of exposure	PO	PO and topical	IV	IV
Initial symptoms	GI[a]	GI[a] and/or neurologic effects (obtundation, confusion, delirium)	GI effects,[a] fever, neurologic effects	GI effects,[a] fever, myalgias, neurologic effects
Initial symptom onset	Several hours after ingestion; delayed presentation beyond 12 hours is very unlikely	Several hours after ingestion; delayed presentation (past 12 h) is possible, especially in those with a cutaneous route of exposure	Usually within 24–48 hours	Usually within 24–48 hours
Hematotoxic effects	Leukocytosis (24–48 hours after ingestion); pancytopenia (beginning 48–72 h after ingestion)	Similar to colchicine; however, not well characterized and reported less frequently	Hematotoxicity may occur; *less* toxicity compared with vinblastine	Hematotoxicity may occur; *more* toxicity compared with vincristine
CNS effects	Late (after 48–72 h after ingestion); obtundation, confusion, and lethargy secondary to progression of MSD	Can be early (<12 h after ingestion); CNS toxicity may occur later or secondary to progression of MSD	Variable; cranial neuropathies; seizures; obtundation, confusion, and lethargy may occur because of progression of MSD	Variable; cranial neuropathies; obtundation, confusion, and lethargy may occur because of progression of MSD[b]
Delayed PNS effects	Myoneuropathy most common; reported most often in chronic colchicine users with renal insufficiency	Peripheral sensorimotor axonopathy	Autonomic and ascending peripheral neuropathy; *increased* severity compared with vinblastine	Can see autonomic and peripheral neuropathy; *decreased* severity compared with vincristine
Clinical course	Recovery or MSD and death	Recovery or MSD and death	Recovery or MSD and death; May develop SIADH	Recovery or MSD and death; may develop SIADH
Management	Supportive; GI decontamination; G-CSF for neutropenia	Supportive; consider GI decontamination for oral exposures and skin decontamination for topical exposures	Primarily supportive; G-CSF for neutropenia; see Special Considerations: Intrathecal Administration of Xenobiotics	Primarily supportive; G-CSF[c] for neutropenia; treatment of intrathecal overdoses; Special Considerations SC2: Intrathecal Administration of Xenobiotics

[a] Nausea, vomiting, diarrhea, abdominal discomfort.

MSD, multi-system organ dysfunction; PNS, peripheral nervous system.

may have a higher risk of sudden cardiac death, especially during the period between 24 and 36 hours after ingestion; increasing serial troponin levels in these patients may suggest a higher risk of cardiovascular complications. Podophyllum toxicity may be less pronounced but may occur after dermal application (Table 37–2).

Management of patients with toxicity from colchicine, podophyllotoxin, and the vinca alkaloids is generally similar after oral exposure. Serial blood counts should be done to identify the development of cytopenias. G-CSF may be of benefit in patients with colchicine-induced neutropenia. Early GI decontamination and supportive treatment are the hallmarks of therapy for all colchicine and podophyllin exposure because there are no commercially available and proven antidotes. The particular aspects and complications of unintentional or excessive IV or intrathecal exposure are described in detail in this chapter, and experimental antidotes for vincristine and vinblastine exposure were discussed.

The findings and conclusions in this article are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention or the Agency for Toxic Substances and Disease Registry.

INTRATHECAL ADMINISTRATION OF XENOBIOTICS

Rama B. Rao

Cerebrospinal fluid (CSF) is produced by the choroid plexus lining the ventricles at a rate of 15–30 mL/h, or approximately 500 mL/d in adults.[46] Cerebrospinal fluid flows in a rostral to caudal direction and is resorbed through the arachnoid villi directly into the venous circulation. The estimated total volume of CSF in a healthy adult is between 130–150 mL, and 35 mL in infants.[46,62,82]

For over 100 years, a variety of experimental and therapeutic xenobiotics have been delivered directly into the CSF.[53,109] The most common current indications for intrathecal xenobiotic administration include analgesia, anesthesia, and treatment of spasticity or CNS neoplasms. The clinical advantages of this route of administration include targeted delivery and lower medication dosages with fewer systemic effects. Medications are usually administered via a spinal needle or an indwelling intrathecal catheter. Catheters may be attached to either an external or subcutaneous pump. Less commonly, substances are administered into a reservoir of an intraventricular shunt (Table SC2–1). The distribution of intrathecal xenobiotics is determined by a variety of factors. Some authors speculate that the xenobiotic movement is often attributed to both diffusion and convection, and that the dilution of xenobiotics administered via a lumbar catheter is attributed to the outflow of CSF from the fourth ventricle.[79] In a radiolabelled tracer study of 5 patients with lumbar catheters, individuals received intrathecally the hydrophilic radiolabeled diethylene triamine pentaacetic acid (^{111}In- DTPA). Neuroimaging revealed a drop in concentration of the tracer as the fluid moved rostrally.[55] The steady state lumbar to cervical concentration for hydrophilic xenobiotics is 4:1 with marked interindividual variability.[79] Depending on the lipophilicity the xenobiotic reaches the brain within a few minutes to 1 hour. Patient position, and interindividual variations in lumbosacral CSF fluid volume may affect xenobiotic distribution and may account for the differences in the level of spinal anesthesia among patients administered the same local anesthetic dosages.[44] Baricity which is the ratio of the specific gravity of the xenobiotic to the specific gravity of CSF at 98.6° F (37° C) is also a consequential variable. Hyperbaric xenobiotics typically distribute in accordance with gravitational forces.[44] In overdose or administration of xenobiotics unintended for intrathecal administration, distribution, resorption, and clinical effects may not follow predictable models.

Complications can occur from preparation and dosing errors or inadvertent penetration of the dura and admixture with the CSF during epidural anesthesia or analgesia.[24,43,44] Medications intended for intrathecal delivery may be administered into the wrong port of a pump delivery system resulting in a massive overdose. Another potentially fatal error involves inadvertent administration of the wrong medication into the CSF.[49] This error occurs with misidentification or mislabeling of medications during pharmacy preparation, or at the bedside. For patients with indwelling devices, medications intended for intravenous delivery may be misconnected to the intrathecal catheter which also operates via Luer lock system.

Several factors affect the clinical toxicity of intrathecal medication errors.[110] The properties of the xenobiotic are important. Ionized xenobiotics are likely to disrupt normal neurotransmission and cause toxicity, as may hyperosmolar or lipophilic xenobiotics. The site of administration may be important as well. Patients administered the wrong xenobiotic into an Ommaya reservoir may suffer more immediate alterations in mental status depending upon the agent administered. While intrathecal administration of preservatives and excipients are investigated in animal models, the characteristics of these adjuvants in medication errors is not likely to be of value in predicting clinical effect.[45]

Patients may present with exaggerated symptoms typically associated with the xenobiotic. For example, patients with intrathecal morphine overdose may present with symptoms of opioid toxicity.[51] Other manifestations of intrathecal errors, regardless of the xenobiotic, include pain and paresthesias, often ascending in nature, autonomic instability especially with extremes of blood pressure, and hyperreflexic myoclonic spasms similar to those seen in patients with tetanus. Seizures, or a depressed level of consciousness may also occur. The time of onset of these life-threatening symptoms may be determined by the dose and characteristics of the xenobiotic. For example, a woman inadvertently administered intrathecal potassium chloride complained immediately of severe back pain.[67] Myoclonic spasms, seizures, and coma followed and the patient died within 3 hours despite a normal serum potassium concentration. Patients with inadvertent vincristine exposures may be asymptomatic for many hours and die within a few days to a few weeks.

Once a medication delivery error is identified, rapid intervention is mandatory especially for ionic agents, chemotherapeutics, or iodinated water soluble contrast agents as these xenobiotics usually reach the brain within an hour. In cases in which outcome is uncertain or not previously described, the exposure should be treated as potentially fatal. Any existing access to the CSF, ideally in the lumbosacral area, should be maintained.[103] Immediate withdrawal of CSF, in volumes as high as 75 mL in adults is indicated. This can be replaced with isotonic solutions: lactated ringers 0.9% salineplasma-lyte or a combination of these. Some older cases utilized Elliot B solution. Some authors recommend the initial large volume removal be performed in 20–30 mL aliquots. For children, multiple aliquots of between 5–10 mL can be removed and replaced with isotonic fluid. If the patient can tolerate an upright position, this may limit cephalad movement of xenobiotics, but positioning for any critical life support measures should take precedence.

Delays to initial CSF drainage should be minimized as the interval between the exposure and CSF drainage may also affect the total xenobiotic recovered (see below). In the interim, a neurosurgical consultation should be obtained to consider the placement of ventricular access for the performance of continuous CSF lavage. This procedure, also known as ventriculolumbar perfusion, involves continuous ventricular instillation of an isotonic solution with CSF drainage through a lumbar site. Another intervention involves placement of an epidural catheter into the intrathecal space at a space above the lumbar drainage site.

TABLE SC2–1. Xenobiotics Administered Intrathecally*

Analgesics/anesthetics	Antiinflammatory
Anesthetics (local)	Corticosteroids
Clonidine[20]	**Antispasmodic**
Ketamine[42]	Baclofen
Midazolam[112]	**Chemotherapeutics**
Morphine[59]	Liposomal cytarabine[15]
Neostigmine[59]	Methotrexate
Octreotide[72,77]	**Vasoactive**
Opioids[65]	Epinephrine
Zinconitide[16]	Papaverine[99]
Antibiotics	Phenylephrine
Amikacin[13,25]	**Other**
Amphotericin B	Bethanecol[76]
Arbekacin[36]	Colistin[105]
Cefotetan	Somatostatin
Ceftriaxone[21]	Tetanus immunoglobulin[2]
Gentamicin[94]	
Levofloxacin[13]	
Penicillin	
Polymixin E[12]	
Vancomycin[1,66]	

*Few of these xenobiotics are FDA approved for intrathecal administration. Most were utilized in clinical trials or as rescue xenobiotics for refractory CNS infections.

An isotonic solution can be perfused through the catheter and drained caudally. This serves as a readily available, rapid intervention for patients awaiting placement of an emergent ventriculostomy.[69,96]

For ventriculolumbar perfusion, lavage flow rates can be as great as 150 mL/h. Fresh frozen plasma can be added to the lavage fluid after several hours to increase the CSF protein content. The ideal lavage fluid, protein components, and infusion rates are not known.[40] Some protocols previously utilized are listed in Table SC2–2. Although artificial CSF formulations exist, their role in the treatment of such medication errors is not evaluated.[70]

Depending on the xenobiotic exposure, specific antidotes or rescue agents can be employed. With most intrathecal exposures, these rescue agents will be administered via oral, intramuscular or intravenous routes. Extreme caution should be under taken to avoid delivery of antidotes directly into the CSF, unless specific data supports their use.

XENOBIOTIC RECOVERY FROM CSF

Immediate, aggressive CSF removal and lavage resulted in nearly 95% recovery of vincristine in the lavage fluid of a patient with inadvertent exposure. Of the published cases in which xenobiotic recovery is reported, percentages relate to both the lavage method and quantity of CSF removed. For example, withdrawal of 10 mL of CSF 45 minutes after a methotrexate overdose in a 4-year-old patient recovered 20% of the initial dose.[3] Withdrawal of 200 mL of CSF in aliquots, 45 minutes after methotrexate overdose in a 9-year-old patient recovered 78% of the initial dose.[30] The specific xenobiotic may affect recovery as well.

For example a patient underwent withdrawal of 30 mL of CSF at 18 minutes after an overdose of simultaneously administered lidocaine, epinephrine, and fentanyl. Approximately 39% of lidocaine was recovered, whereas the recovery of fentanyl was only 7%.[95]

SPECIFIC EXPOSURES

■ IONIC CONTRAST AGENTS

Several xenobiotics have been utilized historically for contrast myelography. Many of these agents were abandoned because of their propensity to cause adhesive arachnoiditis chronic pain syndromes or other complications (Thorotrast). Low osmolar, nonionic contrast media are currently utilized, but unfortunately, other hyperosmolar ionic media are readily available in radiographic suites and sometimes inadvertently administered. Some patients develop cranial neuropathies.[34] Exposed patients become symptomatic within 30 minutes to 6 hours after administration with hyperreflexia and myoclonic spasms following minimal stimulation.[84,86,100] Clinical symptoms typically begin in the lower extremities and move in a cephalad direction, sometimes progressing to opisthotonos. This is likely due to alterations in inhibitory neurotransmission as occur in patients with tetanus, and has been termed ascending tonic-clonic syndrome (ATCS). In one review, nearly one-third of patients died as a result of their exposures.[104] Immediate large volume CSF drainage should be performed in 20 mL aliquots with isotonic fluid replacement. Ventriculolumbar perfusion should be considered in severe cases.

■ CHEMOTHERAPEUTICS

Methotrexate is administered intrathecally for the prevention and treatment of leukemic meningitis or other CNS neoplasms.[8] Errors are generally dose related.[3,28-30,41,47,58,83,101] In most reported cases, aggressive drainage of CSF as great as 250 mL in aliquots with isotonic fluid replacement was utilized without ventriculolumbar perfusion. Experimental treatment of patients with intrathecal carboxypeptidase G_2 (CPDG$_2$) has been described without obvious adverse events.[71,107] The patients underwent lumbar drainage followed by intrathecal CPDG$_2$. Drainage removed between 32% and 58% of the methotrexte, and the antidote reduced the methotrexte concentrations by 98%. The patients received 2000 U of intrathecal CPDG$_2$ in 12mL of normal saline over 5 minutes (Antidote in Depth A14: Carboxypeptidase).

Intrathecal leucovorin is *absolutely contraindicated* as its use results in fatalities. Following intrathecal methotrexate overdose, the intravenous administration of leucovorin is appropriate[48,102] (Antidote in Depth: Leucovorin).

Vincristine is typically administered intravenously and does not cross the blood brain barrier. There are no therapeutic indications for intrathecal vincristine, and such errors are almost always fatal.[4-6,14,26,33,37,38,56] As soon as the exposure is identified, immediate CSF drainage should be instituted and rapid neurosurgical consultation should be obtained. The few known survivors with cognitive function underwent early neurosurgical intervention for ventriculolumbar perfusion.[6,69,80] One of the patients had an epidural catheter placed intrathecally above the drainage site for lumbolumbar perfusion while awaiting ventriculostomy. This method of intrathecal perfusion should be considered in all patients with intrathecal vincristine exposures until definitive ventriculolumbar perfusion can be established. Ideally tubing systems would be readily available to prevent intrathecal medication errors.[73,98] Other rescue medications are covered in Chap. 53.

TABLE SC2–2. Adverse Intrathecal Exposures

Agent	Age (y) Sex (M,F)	Mechanism	Symptoms	Intervention	Outcome
Baclofen[114]	8/M	Probable pump malfunction	Coma, vomiting, bradycardia	20 mL CSF removed at undetermined time	Survived
Bupivcaine[32]	34/M	Inadvertent dural puncture	Hypotension, ascending paralysis at 10 minutes	Not described	Survived
Cefotetan[17]	66/M	Catheter misconnection	Dyspnea, hypotension, myoclonic spasm, pain at 2 hours	10 mL CSF removed at 20 hours	Rhabdomyolysis Survived
Ceftriaxone[21]	74/F	Overdose	Bilateral lower extremity pain	240 mL CSF removed in 20 mL aliquots, with 0.9% NaCl replacement. Started at unknown time.	Survived
Cytarabine[57]	4	Overdose	Mydriasis, delayed onset, gait impairment, tremor	50 mL CSF removed in 5 mL aliquots, with 0.9% NaCl replacement. Started at 65 minutes. Estimated 27%–36% cytarabine recovery	Died of unknown cause
Dactinomycin[54]	5/F	Medication error	Hypotonia, fasciculations, hyperreflexia at 2 hours	50 mL CSF removed with 0.9% NaCl replacement at 1 hour, then ventriculolumbar perfusion started at 1.5 hours using 0.9% NaCl 100 mL/h with 2.5 mg/mL hydrocortisone for 26 hours Other adjuncts	Ascending paraplegia, obstructive hydrocephalus, Survived
Doxorubicin[7]	12/F	Medication error	Fever, headache, vomiting at 12 hours, seizures, hydrocephalus	No attempt at removal	Survived without sequelae at 56 days
Doxorubicin[50]	31/F	Medication error 14.5 mg	Hypoesthesia, paraparesis, incontinence over 7 days, T8 sensory level, bowel and bladder incontinence, meningismus, adhesive arachnoiditis at 3 weeks	CSF exchange at 20 cm³/h for 500 cm³ per publication. Methyl predinsolone 500 mg/d and immunoglobulin 22 g/d initiated at 1 week. Treatment of arachnoiditis with ventriculoperitoneal shunt placement.	Lower extremity weakness 3/5 at 8 months, eventual ambulation with resolution of incontinence at 14 months
Furosemide[19]	36/M	Medication error	None	No attempt at removal	Survived
Gadolinium[8]	64/M	Medication error: gadopentetate dimeglumine	Confusion, nausea, vomiting, ataxia, nystagmus, hallucinations, blurred vision, depressed mental status	Not described	Survived
Gallamine[39]	48/M	Medication error	Hyperreflexic nyoclonic spasm, onset 1 hour 45 minutes; fever, hypertension, tachycardia, miosis, coma at 3 hours	15 mL CSF drainage Started at 6 hours	Survived
Iohexol[34]	–	Medication error	Cranial neuropathy	Not described	Survived
Iohexol[85]	52/M	Dural perforation	ATCS at 30 minutes Coma, hypoxia, fever	Not described	Survived

TABLE SC2–2. Adverse Intrathecal Exposures (*Continued*)

Agent	Age (y) Sex (M,F)	Mechanism	Symptoms	Intervention	Outcome
Ioxitalmate Contrast[104]	48/M	Medication error	ATCS, opisthotonos	Sitting position, intubation 145 mL CSF removal in 10–20 mL aliquots Other adjuncts	Survived
Leucovorin[48]	11/M	Therapeutic error	Seizures	Not described	Died on day 5
Lidocaine, epinephrine, fentanyl[95]					
Patient 1	28/F	Dural perforation	Hypotension, numbness at 5 minutes	20 mL CSF drained within 5 minutes 51% lidocaine recovery, 4% fentanyl recovery	Survived
Patient 2	68/F	Dural perforation	C_5-C_6 sensory impairment at 18 minutes	30 mL CSF drained at 18 minutes 39% lidocaine recovery, 7% fentanyl recovery	Survived
Magnesium sulfate[61]	23/F	Misidentification; 2 mL of 50% magnesium sulfate	Backache, lower extremity motor, weakness sensation intact, normotension	Fowlers position	Recovery within 7 h
Meglumine diatrizoate[86] (ionic contrast)	67/M	Medication error	ATCS at 30 minutes	None	Survived
Mercury antiseptic[97]	69/F	Inadvertent Mercurochrome Injection into CSF fistula	Local pain, nuchal rigidity; coma at 24 hours	Lumbar drain Parenteral chelation	Sensorimotor polyneuropathy Survived
Methotrexate[29]	2/F	Overdose	Headaches	Not specified	Survived
Methotrexate[35]	34/M	Overdose	Confusion, seizures, ARDS; coma at 2 hours	200 mL CSF drained and replaced with 0.9% NaCl. Started at 6 hours in aliquots over 48 hours, then another 150 mL CSF exchange over 36 hours (patient also received intrathecal leucovorin)	Cognitive and motor deficits
Methotrexate[30]	9/M	Overdose	Lower extremity numbness, seizures, flaccid paralysis, cranial neuropathy, posturing	200 mL CSF drained in 30–40 mL aliquots Started at 45 minutes 78% drug recovery	Died
Methotrexate Series I[3]		Overdose			
Patient 1	12/M		Headache, vomiting at 45 minutes	30 mL CSF drained Started at 2 hours. 28% drug recovery	Survived until relapse leukemia
Patient 2	4/M		Not described	10 mL CSF drained at 45 minutes 20% drug recovery	Survived

TABLE SC2–2. Adverse Intrathecal Exposures (*Continued*)

Agent	Age (y) Sex (M,F)	Mechanism	Symptoms	Intervention	Outcome
Methotrexate Series II[47]					
Patient 1	4/M	Not described	Not described	250 mL CSF drained in 20 mL aliquots. Replacement with 0.9% NaCl. Started at 5 hours.	Survived
Patient 2	11/M	Not described	Not described	20 mL CSF withdrawn then 210 mL CSF drained in 5 mL aliquots. Replacement with 0.9% NaCl. Started at 3 hours. 31% drug recovery	Survived
Methotrexate[60]	3/F	Medication error: 125 mg	Seizures at 3 hours	No CSF exchange; IV folinic acid rescue and dexamethasone	Survived
Methotrexate[96]	26/M	Medication error: 62 5mg	Immediate pain in leg; coma and flaccid paralysis followed; renal failure	70 mL CSF drained at 2 hours; Ventriculolumbar perfusion with 240 mL 0.9% NaCl over 3 hours; intrathecal administration of 1000 U glucarpidase at 8.5 hours 32% recovery in initial drainage fluid, 58% recovery from perfusion drainage	Survived
Methotrexate[107]	Case series n = 7	Medication errors 155–600 mg	5/7 patients with seizures, some with headache, nausea, vomiting	Various interventions including ventriculolumbar perfusion started within 1 hour with 500 mL 0.9% NaCl over 4 hours	All survived
Methylene blue[31]	Case series n = 14	10–100 mg	Pain headache, paralysis	Not described	11/14 residual paraplegia or weakness
Methylene blue[91]	59/M	6 mL of 1% solution	Vomiting, hypotension day 1; paralysis and urinary retention.	Not described	Paraplegia and death at 5 years
Morphine[87]	45/F	Inadvertent filling wrong port of subcutaneous infusion pump. 450 mg	Seizures, hypertension, subarachnoid hemorrhage	12 mL CSF withdrawn then 550 mL CSF drained at 10 mL/h by gravity over 2–3 days. Other adjuncts.	Survived
Morphine[51]	81/M	5 mg	Coma at 4 hours	50 mL CSF drained over 6 minutes, replacement with 50 mL 0.9% NaCl	Survived
Morphine[115]	47/F	510 mg into wrong port of pump	Myoclonic spasms, coma, seizures, cranial neuropathy, hypertension then hypotension	No CSF interventions	Survived
Neostigmine[63]	26/M	Medication error	Not described	None	Survived
Penicillin[18]	22/M	Dosing error into Ommaya reservoir	Coma, hyporeflexia, tonic-clonic seizures, absence seizures, hypotension at 30 minutes	10 mL CSF withdrawal then ventriculolumbar CSF drainage. Replacement with Ringer lactate over 30 minutes.	Survived

TABLE SC2–2. Adverse Intrathecal Exposures (*Continued*)

Agent	Age (y) Sex (M,F)	Mechanism	Symptoms	Intervention	Outcome
Potassium chloride[67]	42/F	Medication error during labor	Immediate cramps, pain, seizures, normal serum potassium	None	Maternal-fetal death at 3 hours
Rifampin[90]	41/M	Medication error 600 mg	None reported	None	Survived
Tramadol[10]	75/F	Connection error	Diaphoresis, hypotension at 10 minutes. Myoclonic spasms, opisthotonos		Died at 48 hours
Tranexamic acid[113]	49/F	Medication error, wrong route	Immediate back pain, hypertension; seizure at 2 minutes; ventricular fibrillation	None	Died at 1.5 h
Vincristine[64]	5/F	0.9 mg	Headache at 10 hours, opisthotonos, nystagmus, flaccidity	Not described	Died on day 18
Vincristine[88]	2.5/F	3 mg error	Opisthotonos day 2	200 mL CSF drainage in 10 mL aliquots. Replacement with 0.9% NaCl	Died on day 3
Vincristine[58]	27/F	Medication error into Ommaya reservoir	Ascending paralysis	Detail limited- CNS"washout" FFP and "lactate solution" in undefined quantities. Timing not described	Died on day 10
Vincristine[108]	16/M	Mislabeled	Ascending paralysis at 2 hours, fever, coma	None	Died
Vincristine[28]	Adult	Medication error	Ascending paralysis	CSF drainage unreported quantity and replacement with Ringer lactate immediately. Ventriculolumbar perfusion 150 mL/h for > 24 hours then 25 mL FFP in 1L isotonic solution at 75 mL/h for undefined time. 95% recovery of vincristine	Lower extremity neuropathy
Vincristine[33]	4/F	Medication error 1.5 mg	Nystagmus, encephalopathy, ascending paralysis, transient improvement	Immediate drainage 18 mL CSF in 3 mL aliquots. Replacement 0.9% NaCl. An additional 30–40 mL drained over 30 minutes, starting at 10 minutes. Ventriculolumbar perfusion using Plasmalyte to replace 200 mL CSF over at unknown rate. Then 6 mL FFP in 250 mL Plasmalyte at 50 mL/h for 4 hours.	Died on day 13
Vincristine[4]	1.25/M	0.7mg	Febrile and irritable at 10 hours then lower ext pain, nuchal rigidity, opisthotonos, ileus, hypotonia at day 2; ascending paralysis, encephalopathy by day 5; respiratory arrest at day 7	Intrathecal corticosteroids at 10 hours	Died on day 75 (withdrawal of life support)

(*Continued*)

TABLE SC2–2. Adverse Intrathecal Exposures (*Continued*)

Agent	Age (y) Sex (M,F)	Mechanism	Symptoms	Intervention	Outcome
Vincristine[5]	7/F	0.5 mg	Ascending weakness, pain, paraplegia	Upright position; immediate drainage 75 mL CSF within 15 minutes, replaced with Ringer lactate; ventriculolumbar perfusion started within 2 hours with 150 mL/h of Ringer lactate for 10 hours then FFP l15 mL in 1L Ringer lactate as irrigant at 55 mL/h for 24 hours. Other adjuncts	Paraplegia, neurogenic bladder; survived
Vincristine[6]	12/F	Medication error: 2 mg	Asymptomatic for 48 hours, then ascending paralysis, hiccup, cranial neuropathy, coma	35 mL CSF drained at 30 minutes then additional drainage of 15 mL CSF replaced with Ringer lactate; ventriculolumbar perfusion at 3 hours using FFP 15 mL in 1L Ringer lactate for total drainage of 615 mL CSF over 10 h; 0.785 mg recovered	Died on day 83
Vincristine[14]	23/M	Error: 2 mg	Headache day 1; leg weakness at day 2–3; ascending myeloencephalopathy with coma at day 10; seizures	Drainage of 100 mL CSF at 10 minutes, "large volume lumbar punctures" day 2 and 3	Prolonged coma, died at 11 months
Vincristine series[26]		Medication error			
	5/F		Ascending paralysis, opisthotonos, coma	Not described	Died on day 7
	57/M		Ascending paralysis	"Flushing the subarachnoid space"	Died at 4 weeks
Vincristine[56]	3/M	Medication error	Leg pain day 1; headache, nuchal rigidity at day 2; bladder dysfunction, fever, lower extremity paralysis, opisthotonos at day 3, coma	Not described	Died on day 6
Vincristine[68]	59/F	Medication error into ommaya reservoir; 2 mg	Nausea, vomiting day 1; altered mental status, tremor, chills, hiccups, nystagmus, coma over 1 week.	50 mL CSF drainage at 10 minutes followed by 75 mL CSF drainage at 30 mintes; ventriculolumbar perfusion with Ringer lactate and FFP over 24 hours	Died on day 40
Vincristine[69]	10/F	Medication error	Asymptomatic for 6 days, then ascending paralysis with incontinence	Immediate drainage of CSF for 15 minutes; epidural catheter above the lumbar drainage site with lumbolumbar irrigation using 12.5 mL FFP in 500 mL Ringer lactate with 96 mL drained; ventriculolumbar perfusion within 90 minutes for 24 hours	Survived with sensory-motor deficits of the extremities and urinary incontinence

TABLE SC2–2. Adverse Intrathecal Exposures (*Continued*)

Agent	Age (y) Sex (M,F)	Mechanism	Symptoms	Intervention	Outcome
Vindesine[101]	25/F	Medication error	Ascending parethesia, paraplegia, coma	40 mL drainage immediately. Subsequent irrigation delayed by 24 hours	Died at 6 weeks
Vincristine[92]	5.5/	1.2 mg	Headache, vomiting and backache at 3 h, nystagmus, extremity weakness at 72 h, autinoimic instability, hiccups, encephalopathy	Drainage of 20 mL CSF at 30 min, repeated on day 2, intrathecal corticosteroids, 23% recovery of dose	Died on day 12
Vincristine[93]	29/F	2 mg	Headache, ascending paraplegia, cranial neuropathy, coma	Intrathecal infusion 5mL 0.9% NaCl with drainage of 10 mL CSF, positioned upright, additional 60 mL CSF drained at 3 hours	Died on day 14, pulmonary embolus at autopsy
Zinconitide series[78]		Overtitration of therapeutic dosage in each case			
	47/M		Nystagmus, auditory and visual hallucinations, dysmetria, ataxia	Not described	Resolution with discontinuation of medication
	62/M (for pain of multiple sclerosis)		Agitation, disorientation, waxing and waning mental status, hallucinations, allodynia, bradycardia	Not described	Resolution with discontinuation of medication. Worsening MS at 1 year
	45/M		Nausea, lightheadedness, nystagmus, bradycardia, agitation	Not described	Resolution with discontinuation

CSF = cerebrospinal fluid

ARDS = adult respiratory distress syndrome; ATCS = ascending tonic clonic syndrome- myoclonus, hyperreflexia on minimal stimulation, beginning in the lower extremities.

CSF = cerebrospinal fluid; FFP = fresh frozen plasma

PUMP MALFUNCTIONS AND ERRORS

Some implantable pumps contain two access sites, one of which is contiguous with the intrathecal space and allows for CSF withdrawal or injection of nonionic contrast media for imaging. The other pump is a depot port that is intermittently filled with concentrated amounts of drug (usually an opioid analgesic or baclofen) to be delivered through a programmable pump. In some patients a template must be placed on the skin overlying subcutaneous pumps to ascertain the proper medication port. Errors occur when a concentrated bolus is inadvertently injected into the wrong port resulting in a massive, sometimes fatal, overdose.[49,111] Massive intrathecal morphine overdose can have severe rapid symptoms, including hypertensive crises. Either reaccessing the CSF port immediately or placing spinal needle into the intrathecal space at another site is critical for the withdrawal of CSF. Large volume

drainage with isotonic fluid replacement is required, as well as other supportive measures such as intravenous naloxone. The patients usually require intubation and care in an intensive care unit. The clinical service that placed the pump should be consulted to assist in further CSF access and perform interrogation of the pump in cases where malfunction is suspected.[27] If the consultant is not readily available, emptying the deport port will automatically cause the pump motor to stop.

The other pump problem encountered is sudden, insufficient delivery of either baclofen or opioid pain medication.[81] This may occur because of pump malfunction. Alternatively the intrathecal catheter may kink, migrate, or become obstructed by an inflammatory mass.[22,23,49,74] Patients with chronic use of baclofen or morphine may suffer severe withdrawal symptoms when intrathecal delivery is disrupted.[106] Intrathecal doses are 100 to 1000 times more potent than the equivalent dose administered intravenously.[52] The patients

may therefore require very high oral or intravenous doses to treat withdrawal until intrathecal delivery can be reestablished. The clinical service that implanted the pump should be consulted, and a thorough neurologic examination should be performed to evaluate for spinal cord compression symptoms.[49] An anteroposterior and lateral radiograph can be obtained to assess for kinking or fracture of the catheter.

SUMMARY

Intrathecal medication errors can be life threatening. Rapid intervention with CSF drainage should be considered when a dosing or medication error occurs. More aggressive therapies may be required for chemotherapeutic medications, depending on the administered agent.

CHAPTER 38
OPIOIDS

Lewis S. Nelson and Dean Olsen

Morphine
Opioids are among the oldest therapies in our armamentarium, and clinicians recognize their universal utility to limit human distress from pain. Although opioids enjoy widespread use as potent analgesics, they have the potential for abuse because of their psychoactive properties. Although the therapeutic and toxic doses are difficult to predict because of the development of tolerance with chronic use, the primary adverse event from excessive dosing is respiratory depression.

HISTORY AND EPIDEMIOLOGY

The medicinal value of opium, the dried extract of the poppy plant *Papaver somniferum*, was first recorded around 1500 B.C. in the Ebers papyrus. Raw opium is typically composed of at least 10% morphine, but extensive variability exists depending on the environment in which the poppy is grown.[82] Although reformulated as laudanum (deodorized tincture of opium; 10 mg morphine/mL) by Paracelsus, paregoric (camphorated tincture of opium; 0.4 mg morphine/mL), Dover's powder (pulvis Doveri), and Godfrey's cordial in later centuries, the contents remained largely the same: phenanthrene poppy derivatives, such as morphine and codeine. Over the centuries since the Ebers papyrus, opium and its components have been exploited in two distinct manners: medically to produce profound analgesia and nonmedically to produce psychoactive effects.

Currently, the widest clinical application of opioids is for acute or chronic pain relief. Opioids are available in various formulations that allow administration by virtually any route: epidural, inhalational, intranasal, intrathecal, oral, parenteral (ie, subcutaneous [SC], intravenous [IV], intramuscular [IM]), rectal, transdermal, and transmucosal. Patients also may benefit from several of the nonanalgesic effects engendered by certain opioids. For example, codeine and hydrocodone are widely used as antitussives, and diphenoxylate as an antidiarrheal.

Unfortunately, the history of opium and its derivatives is marred by humankind's endless quest for xenobiotics that produce pleasurable effects. Opium smoking was so problematic in China by the 1830s that the Chinese government attempted to prohibit the importation of opium by the British East India Company. This act led to the Opium Wars between China and Britain. China eventually accepted the importation and sale of the drug and was forced to turn over Hong Kong to British rule. The euphoric and addictive potential of the opioids is immortalized in the works of several famous writers, such as Thomas de Quincey (*Confessions of an English Opium Eater*, 1821), Samuel Coleridge (*The Rime of the Ancient Mariner*, 1798), and Elizabeth Barrett Browning (*Aurora Leigh*, 1856).

Because of mounting concerns of addiction and toxicity in the United States, the Harrison Narcotic Act, enacted in 1914, made nonmedicinal use of opioids illegal. Since that time, recreational and habitual use of heroin and other opioids have remained epidemic in the United States and worldwide despite extensive and diverse attempts to curb their availability.

Morphine was isolated from opium by Armand Séquin in 1804. Charles Alder Wright synthesized heroin from morphine in 1874. Ironically, the development and marketing of heroin as an antitussive agent by Bayer, the German pharmaceutical company, in 1898 legitimized the medicinal role of heroin.[153] Subsequently, various xenobiotics with opioidlike effects were marketed, each promoted for its presumed advantages over morphine. This assertion proved true for fentanyl because of its pharmacokinetic profile. However, in general, the advantages of such medications have fallen short of expectations, particularly with regard to their potential for abuse.

The terminology used in this chapter recognizes the broad range of xenobiotics commonly considered to be opiumlike. The term *opiate* specifically refers to the relevant alkaloids naturally derived directly from the opium poppy: morphine; codeine; and, to some extent, thebaine and noscapine. *Opioids* are a much broader class of xenobiotics that are capable of either producing opiumlike effects or binding to opioid receptors. A *semisynthetic opioid*, such as heroin or oxycodone, is created by chemical modification of an opiate. A *synthetic opioid* is a chemical, not derived from an opiate, that is capable of binding to an opioid receptor and producing opioid effects clinically. Synthetic opioids, such as methadone and meperidine, bear little structural similarity to the opiates. Opioids also include the naturally occurring animal-derived opioid peptides such as endorphin and nociceptin/orphanin FQ. The term *narcotic* refers to sleep-inducing xenobiotics and initially was used to connote the opioids. However, law enforcement and the public currently use the term to indicate any illicit psychoactive substance. The term *opioid* as used hereafter encompasses the opioids and the opiates.

PHARMACOLOGY

■ OPIOID-RECEPTOR SUBTYPES

Despite nearly a century of opioid studies, the existence of specific opioid receptors was not proposed until the mid-20th century. Beckett and Casy noted a pronounced stereospecificity of existing opioids (only the L-isomer is active) and postulated that the drug needed to "fit" into a receptor.[7] In 1963, after studies on the clinical interactions of nalorphine and morphine, the theory of receptor dualism[155] postulated the existence of two classes of opioid receptors. Such opioid binding sites were not demonstrated experimentally until 1973.[126] Intensive experimental scrutiny using selective agonists and antagonists continues to permit refinement of receptor classification. The current, widely accepted schema postulates the coexistence of three major classes of opioid receptors, each with multiple subtypes, and several poorly defined minor classes.

Initially, the reason such an elaborate system of receptors existed was unclear because no endogenous ligand could be identified. However, evidence for the existence of such endogenous ligands was uncovered in 1975 with the discovery of metenkephalin and leuenkephalin[102] and the subsequent identification of β-endorphin and dynorphin. As a group, these endogenous ligands for the opioid receptors are called *endorphins* (*endo*genous mor*phine*). Each is a five–amino acid peptide cleaved from a larger precursor peptide: proenkephalin, proopiomelanocortin, and prodynorphin, respectively. More recently, a minor related endogenous opioid (nociceptin/orphanin FQ) and its receptor ORL have been described.

All three major opioid receptors have been cloned and sequenced. Each consists of seven transmembrane segments, an amino terminus, and a carboxy terminus. Significant sequence homology exists

between the transmembrane regions of opioid receptors and those of other members of the guanosine triphosphate (GTP)–binding protein (G-protein)–binding receptor superfamily. However, the extracellular and intracellular segments differ from one another. These nonhomologous segments probably represent the ligand-binding and signal transduction regions, respectively, which would be expected to differ among the three classes of receptors. The individual receptors have distinct distribution patterns within the central nervous system (CNS) and peripherally on nerve endings within various tissues, mediating unique but not entirely understood clinical effects. Until recently, researchers used varying combinations of agonists and antagonists to pharmacologically distinguish between the different receptor subtypes. However, knockout mice (ie, mutant mice lacking the genes for an individual opioid receptor) promise new insights into this complex subject.[51]

Because multiple opioid receptors exist and each elicits a different effect, determining the receptor to which an opioid preferentially binds should allow prediction of the clinical effect of the opioid. However, binding typically is not limited to one receptor type, and the relative affinity of an opioid for differing receptors accounts for the clinical effects (Table 38-1). Even the endogenous opioid peptides exhibit substantial crossover among the receptors.

Although the familiar pharmacologic nomenclature derived from the Greek alphabet is used throughout this textbook, the International Union of Pharmacology (IUPHAR) Committee on Receptor Nomenclature has twice recommended a nomenclature change from

the original Greek symbol system to make opioid receptor names more consistent with those of other neurotransmitter systems.[173] In the first new schema, the receptors were denoted by their endogenous ligand (*o*pioid *p*eptide [OP]), with a subscript identifying their chronologic order of discovery.[37] The δ receptor was renamed OP_1, the κ receptor was renamed OP_2, and the μ receptor was renamed OP_3. However, adoption of this nomenclature met with significant resistance, presumably because of problems that would arise when merging previously published work that had used the Greek symbol nomenclature. The currently proposed nomenclature suggests the addition of a single letter in front of the OP designation and the elimination of the number. In this schema, the μ receptor is identified as MOP. In addition, the latest iteration formally recognizes the nociceptin/orphanin FQ or NOP receptor as a fourth receptor family.

Mu Receptor (μ, MOP, OP₃) The early identification of the μ receptor as the *m*orphine binding site gave this receptor its designation.[109] Although many exogenous xenobiotics produce supraspinal analgesia via μ receptors, the endogenous ligand is elusive. Nearly all of the recognized endogenous opioids have some affinity for the μ receptor, although none is selective for the receptor. Endomorphin-1 and -2 are nonpeptide ligands present in brain that may represent the endogenous ligand.

Experimentally, two subtypes ($μ_1$ and $μ_2$) are well defined, although currently no xenobiotics have sufficient selectivity to make this dichotomy clinically relevant. Experiments with knockout mice suggest that both subtypes derive from the same gene and that either posttranslational changes or local cellular effects subsequently differentiate them. The $μ_1$ subtype appears to be responsible for supraspinal (brain) analgesia and for the euphoria sometimes engendered by these xenobiotics. Although stimulation of the $μ_2$ subtype produces spinal-level analgesia, it also produces respiratory depression. All of the currently available μ agonists have some activity at the $μ_2$ receptor and therefore produce some degree of respiratory compromise. Localization of μ receptors to regions of the brain involved in analgesia (periaqueductal gray, nucleus raphe magnus, medial thalamus), euphoria and reward (mesolimbic system), and respiratory function (medulla) is not unexpected.[69] Predictably, μ receptors are found in the medullary cough center, peripherally in the gastrointestinal (GI) tract, and on various sensory nerve endings, including the articular surfaces (see analgesia under Clinical Manifestations below).

Kappa Receptor (κ, KOP, OP₂) Although dynorphins now are known to be the endogenous ligands for these receptors, originally they were identified by their ability to bind ketocyclazocine and thus were labeled κ.[109] κ receptors exist predominantly in the spinal cords of higher animals, but they also are found in the antinociceptive regions of the brain and the substantia nigra. Stimulation is responsible for spinal analgesia, miosis, and diuresis (via inhibition of antidiuretic hormone release). Unlike μ-receptor stimulation, κ-receptor stimulation is not associated with significant respiratory depression or constipation. The receptor currently is subclassified into three subtypes. The $κ_1$ receptor subtype is responsible for spinal analgesia. This analgesia is not reversed by μ-selective antagonists,[116] supporting the role of κ receptors as independent mediators of analgesia. Although the function of the $κ_2$ receptor subtype is largely unknown, stimulation of cerebral $κ_2$ receptors by xenobiotics such as pentazocine and salvinorin A produces psychotomimesis in distinction to the euphoria evoked by μ agonists.[144] The $κ_3$ receptor subtype is found throughout the brain and participates in supraspinal analgesia. This receptor is primarily responsible for the action of nalorphine, an agonist–antagonist opioid. Nalbuphine, another agonist–antagonist, exerts its analgesic effect via both $κ_1$ and $κ_3$ agonism, although both nalorphine and nalbuphine are antagonists to morphine at the μ receptor.[128]

Delta Receptor (δ, DOP, OP₁) Little is known about δ receptors, although the enkephalins are known to be their endogenous ligands.

TABLE 38–1. Clinical Effects Related to Opioid Receptors

1996 Conventional Name	Proposed IUPHAR Name	IUPHAR Name	Important Clinical Effects of Receptor Agonists
$μ_1$	OP_{3a}	MOP	Supraspinal analgesia
			Peripheral analgesia
			Sedation
			Euphoria
			Prolactin release
$μ_2$	OP_{3b}		Spinal analgesia
			Respiratory depression
			Physical dependence
			GI dysmotility
			Pruritus
			Bradycardia
			Growth hormone release
$κ_1$	OP_{2a}	KOP	Spinal analgesia
			Miosis
			Diuresis
$κ_2$	OP_{2b}		Psychotomimesis
			Dysphoria
$κ_3$	OP_{2b}		Supraspinal analgesia
δ	OP_1	DOP	Spinal and supraspinal analgesia
			Modulation of μ-receptor function
			Inhibit release of dopamine
Nociceptin/ orphanin FQ	OP_4	NOP	Anxiolysis
			Analgesia

GI, gastrointestinal; IUPHAR, International Union of Pharmacology Committee on Receptor Nomenclature.

Opioid peptides identified in the skin and brain of *Phyllomedusa* frogs, termed *dermorphin* and *deltorphin*, respectively, are potent agonists at the δ receptor. δ receptors may be important in spinal and supraspinal analgesia (probably via a noncompetitive interaction with the μ receptor) and in cough suppression. δ receptors may mediate dopamine release from the nigrostriatal pathway, where they modulate the motor activity associated with amphetamine.[69] δ receptors do not modulate dopamine in the mesolimbic tracts and have only a slight behavioral reinforcing role. Subpopulations, specifically δ_1 and δ_2, are postulated based on in vitro studies but presently are not confirmed in vivo.[173]

Nociceptin/Orphanin FQ Receptor (ORL$_1$, NOP, OP$_4$) The ORL$_1$ receptor was identified in 1994 based on sequence homology during screening for opioid-receptor genes with DNA libraries. It has a similar distribution pattern in the brain and uses similar transduction mechanisms as the other opioid-receptor subtypes. It binds many different opioid agonists and antagonists. Its insensitivity to antagonism by naloxone, often considered the sine qua non of opioid character, delayed its acceptance as an opioid-receptor subtype. Simultaneous identification of an endogenous ligand, called *nociceptin* by the French discoverers and *orphanin* FQ by the Swiss investigators, allowed the designation OP$_4$. A clinical role has not yet been defined, but anxiolytic and analgesic properties are described.[25]

Sigma Receptor (σ) Although originally conceived as an opioid subtype, the σ receptor is no longer considered opioid in character, and it has not been given an IUPHAR OP designation. Investigation of this receptor revealed that it is insensitive to antagonism by naloxone, prefers ligands with a dextrorotatory stereochemistry, and has no endogenous ligand, all features in contradistinction to the other opioid receptors. Nonetheless, the effects of the σ receptor are relevant to opioid pharmacology because certain opioids, such as dextromethorphan and pentazocine, are σ-receptor agonists. Stimulation of the σ receptor is implicated in psychotomimesis and movement disorders, effects that are reported with both dextromethorphan and pentazocine independently.[65] Hallucinogens, such as ibogaine, and antipsychotics, such as haloperidol, are known σ-receptor antagonists.

Other Receptors (Epsilon [ε], Zeta [ζ]) Two other opioid receptor subtypes are largely uncharacterized in humans. The ε receptor is postulated based on in vivo binding assays and has no known clinical role. The ζ receptor has been proposed and may serve as an opioid growth factor receptor.

■ OPIOID-RECEPTOR SIGNAL TRANSDUCTION MECHANISMS

Figure 38–1 illustrates opioid-receptor signal transduction mechanisms. Continuing research on the mechanisms by which an opioid receptor induces an effect has produced confusing and often contradictory results. Despite the initial theory that each receptor subtype is linked to a specific transduction mechanism, individual receptor subtypes may use one or more mechanisms, depending on several factors, including receptor localization (eg, presynaptic vs postsynaptic). As noted, all opioid-receptor subtypes are members of a superfamily of membrane-bound receptors that are coupled to G proteins.[173] The G proteins are responsible for signaling the cell that the receptor has been activated and for initiating the desired cellular effects. The G proteins are generally of the pertussis toxin-sensitive, inhibitory subtype known as G_i or G_o, although coupling to a cholera toxin-sensitive, excitatory G_s subtype has been described. Regardless of subsequent effect, the G proteins consist of three conjoined subunits, α, β, and γ. The βγ subunit is liberated upon GTP binding to the subunit. When the α subunit dissociates from the βγ subunit, it modifies specific effector systems, such as phospholipase C or adenylate cyclase, or it may directly affect

a channel or transport protein. GTP subsequently is hydrolyzed by a GTPase intrinsic to the α subunit, which prompts its reassociation with the βγ subunit and termination of the receptor-mediated effect.

CLINICAL MANIFESTATIONS

Table 38–2 outlines the clinical effects of opioids.

■ THERAPEUTIC EFFECTS

Analgesia Although classic teaching attributes opioid analgesia solely to the brain, opioids actually appear to modulate cerebral cortical pain perception at supraspinal, spinal, and peripheral levels. The regional distribution of the opioid receptors confirms that μ receptors are responsible for most of the analgesic effects of morphine within the brain. They are found in highest concentration within areas of the brain classically associated with analgesia—the periaqueductal gray, nucleus raphe magnus, locus ceruleus, and medial thalamus. Microelectrode-induced electrical stimulation of these areas[130] or iontophoretic application of agonists into these regions results in profound analgesia.[9] Specifically, enhancement of inhibitory outflow from these supraspinal areas to the sensory nuclei of the spinal cord (dorsal roots) dampens nociceptive neurotransmission. Additionally, inactivation of the μ-opioid–receptor gene in embryonic mouse cells results in offspring that are insensitive to morphine analgesia.[110]

Interestingly, blockade of the *N*-methyl-D-aspartate (NMDA) receptor, a mediator of excitatory neurotransmission, enhances the analgesic effects of μ-opioid agonists and may reduce the development of tolerance (see Dextromethorphan below).[1] Even more intriguing is the finding that low-dose naloxone (0.25 μg/kg/h) actually improves the efficacy of morphine analgesia.[48] Administration of higher-dose, but still low-dose, naloxone (1 μg/kg/h) obliterated its opioid-sparing effect. Although undefined, the mechanism may be related to selective inhibition of G_s-coupled excitatory opioid receptors by extremely low concentrations of opioid-receptor antagonist.[28,27]

δ and κ receptors also are responsible for mediation of analgesia, but they exert their analgesic effect predominantly in the spinal cord. Conceptually, these receptors modulate nociceptive impulses in transit to the thalamus via the spinothalamic tract, reducing the perception of pain by the brain. Xenobiotics with strong binding affinity for δ receptors in humans produce significantly more analgesia than morphine administered intrathecally. Indeed, the use of spinal and epidural opioid analgesia is predicated on the direct administration of opioid near the κ and δ receptors in the spinal cord. Agonist–antagonist opioids, with agonist affinity for the κ receptor and antagonist effects at the μ receptor, maintain analgesic efficacy.

Interestingly, communication between the immune system and the peripheral sensory nerves occurs in areas of tissue inflammation. In response to inflammatory mediators, such as interleukin-1, immune cells locally release opioid peptides, which bind and activate peripheral opioid receptors on sensory nerve terminals.[174] Agonism at these receptors reduces afferent pain neurotransmission and may inhibit the release of other proinflammatory compounds, such as substance P.[157] Of note, intraarticular morphine (1 mg) administered to patients after arthroscopic knee surgery produces significant, long-lasting analgesia that can be prevented with intraarticular naloxone.[156] The clinical analgesic effect of 5 mg of intraarticular morphine is equivalent to 5 mg of morphine given IM.[22] Intraarticular analgesia is locally mediated by μ receptors.[44]

Despite their well-defined analgesic properties and their recommendation by many clinical practice guidelines, opioids continue to be underprescribed for patients with acute and chronic pain. Reluctance often stems from the fear that patients may become addicted or abuse the opioid. However, despite extensive investigation, this is of limited
FIGURE 38–1. Opioid-receptor signal transduction mechanisms. Upon binding of an opioid agonist to an opioid receptor, the respective G protein is activated. G proteins may (**A**) reduce the capacity of adenylate cyclase to produce cAMP; (**B**) close calcium channels that reduce the signal to release neurotransmitters; or (**C**) open potassium channels and hyperpolarize the cell, which indirectly reduces cell activity. Each mechanism has been found coupled to each receptor subtype, depending on the location of the receptor (pre- or postsynaptic), and the neuron within the brain (see text). Note that α_2 receptors (**D**) mediate similar effects, using a different G protein (G_z).

Adenylate cyclase/cAMP (**A**). Inhibition of adenylate cyclase activity by G_i or G_o is the classic mechanism for postsynaptic signal transduction invoked by the inhibitory μ receptors. However, this same mechanism also has been identified in cells bearing either δ or κ receptors. Activation of cAMP production by adenylate cyclase, with subsequent activation of protein kinase A, occurs after exposure to very-low-dose opioid agonists and produces excitatory, antianalgesic effects.[39]

Calcium (Ca^{2+}) channels (**B**). Presynaptic μ receptors inhibit norepinephrine release from the nerve terminals of cells of the rat cerebral cortex. Adenylate cyclase does not appear to be the modulator for these receptors because inhibition of norepinephrine release is not enhanced by increasing intracellular cAMP levels by various methods.[208] Opioid-induced blockade is, however, prevented by increased intracellular calcium levels that are induced either by calcium ionophores, which increase membrane permeability to calcium, or by increasing the extracellular calcium concentration.[208] This implies a role for opioid-induced closure of N-type calcium channels, presumably via a G_o protein. Reduced intraterminal concentrations of calcium prevent the neurotransmitter-laden vesicles from binding to the terminal membrane and releasing their contents. Nerve terminals containing dopamine appear to have an analogous relationship with inhibitory κ receptors, as do acetylcholine-bearing neurons with opioid receptors.[208]

Potassium(K$^+$) channels (**C**). Increased conductance through a potassium channel, generally mediated by G_i or G_o, results in membrane hyperpolarization with reduced neuronal excitability. Alternatively, protein kinase A–mediated reduction in membrane potassium conductance enhances neuronal excitability.

concern.[80,89] Furthermore, opioid analgesics often are better tolerated, safer, and less expensive than the alternatives, such as the nonsteroidal antiinflammatory drugs.

Euphoria The pleasurable effects of many xenobiotics used by humans are mediated by the release of dopamine in the mesolimbic system. This final common pathway is shared by all opioids that activate the μ–δ receptor complex in the ventral tegmental area, which, in turn, indirectly promotes dopamine release in the mesolimbic region. Opioids also may

have a direct reinforcing effect on their self-administration through μ receptors within the mesolimbic system.[67]

The sense of well-being and euphoria associated with strenuous exercise appears to be mediated by endogenous opioid peptides and μ receptors. This so-called "runner's high" is reversible with naloxone.[143] Naloxone may also reverse euphoria or even produce dysphoria in nonexercising, highly trained athletes. Even in normal individuals, high-dose naloxone ($\leq$4 mg/kg) may produce dysphoria.[23]

TABLE 38–2. Clinical Effects of Opioids	
Cardiovascular	Bradycardia
	Orthostatic hypotension
	Peripheral vasodilation
Dermatologic	Flushing (histamine)
	Pruritus
Endocrinologic	Reduced antidiuretic hormone (ADH) release
	Prolactin release
	Reduced gonadotrophin release
Gastrointestinal	Increased anal sphincter tone
	Increased biliary tract pressure
	Reduced gastric acid secretion
	Reduced motility
Neurologic	Analgesia
	Antitussive
	Euphoria
	Sedation, coma
	Seizures (meperidine, propoxyphene)
Ophthalmic	Miosis
Pulmonary	Acute lung injury
	Bronchospasm (histamine)
	Respiratory depression

Exogenous opioids do not induce uniform psychological effects. Some of the exogenous opioids, particularly those that are highly lipophilic such as heroin, are euphorigenic, but morphine is largely devoid of such pleasurable effects.[150] However, morphine administration results in analgesia, anxiolysis, and sedation. Because heroin has little affinity for opioid receptors and must be deacetylated to morphine for effect, these seemingly incompatible properties likely are related to pharmacokinetic differences in blood–brain barrier penetration.[123] Chronic users note that fentanyl produces effects that are subjectively similar to those of heroin.[94] This effect may explain the higher prevalence of fentanyl, as opposed to other accessible opioids, as an abused drug by anesthesiologists.[11,177] In distinction, certain opioids, such as pentazocine, produce dysphoria, an effect that is related to their affinity for κ or σ receptors.

Antitussive Codeine and dextromethorphan are two opioids with cough-suppressant activity. Cough suppression is not likely mediated via the μ_1 opioid receptor because the ability of other opioids to suppress the medullary cough centers is not correlated with their analgesic effect. Various models suggest that cough suppression occurs via agonism of the μ_2 or κ opioid receptors or antagonism of the δ opioid receptor and that the σ or NMDA receptors also are involved.[163]

■ TOXIC EFFECTS

When used appropriately for medical purposes, opioids are remarkably safe and effective. However, excessive dosing for any reason may result in serious toxicity. Most adverse or toxic effects are predictable based on "opioid" pharmacodynamics (eg, respiratory depression), although several xenobiotics produce unexpected "nonopioid" or xenobiotic-specific responses. Determining that a patient is suffering from opioid toxicity is generally more important than identifying the specific opioid

involved. Notwithstanding some minor variations, patients poisoned by all available opioids predictably develop a constellation of signs, known as the *opioid syndrome* (see Chap. 3). Mental status depression, hypoventilation, miosis, and hypoperistalsis are the classic elements.

Respiratory Depression Experimental use of various opioid agonists and antagonists consistently implicates μ_2 receptors in the respiratory depressant effects of morphine.[144] Through these receptors, opioid agonists reduce ventilation by diminishing the sensitivity of the medullary chemoreceptors to hypercapnea.[180] In addition to loss of hypercarbic stimulation, opioids depress the ventilatory response to hypoxia.[95] The combined loss of hypercarbic and hypoxic drive leaves virtually no stimulus to breathe, and apnea ensues. Equianalgesic doses of the available opioid agonists produce approximately the same degree of respiratory depression.[42,145] This reasoning is supported by experiments in MOR-deficient knockout mice.[134] Patients chronically exposed to opioid agonists, such as those on methadone maintenance, experience chronic hypoventilation, although tolerance to loss of hypercarbic drive may develop over several months.[106] However, such patients never develop complete tolerance to loss of hypoxic stimulation.[136] Although some opioids, notably the agonist–antagonists and partial agonists, demonstrate a ceiling effect on respiratory depression, such sparing generally occurs at the expense of analgesic potency. The different activity profiles likely are a result of differential activities at the opioid-receptor subtypes; that is, agonist–antagonists are predominantly κ-receptor agonists and either partial agonists or antagonists at μ sites.

It is important to recognize that ventilatory depression may be secondary to a reduction in either respiratory rate or tidal volume. Thus, although respiratory rate is more accessible for clinical measurement, it is not an ideal index of ventilatory depression. In fact, morphine-induced respiratory depression in humans initially is related more closely to changes in tidal volume.[145] Large doses of opioids also result in a reduction of respiratory rate.

Acute Lung Injury Reports linking opioids with the development of acute pulmonary abnormalities became common in the 1960s, although the first report was made by William Osler in 1880.[125] Almost all opioids are implicated, and opioid-related acute lung injury (ALI) is reported in diverse clinical situations. Typically, the patient regains normal ventilation after a period of profound respiratory depression, either spontaneously or after the administration of an opioid antagonist, and over the subsequent several minutes to hours develops hypoxemia and pulmonary crackles. Occasionally, classic frothy, pink sputum is present in the patient's airway or in the endotracheal tube of an intubated patient. Acute lung injury was described in 71 (48%) of 149 hospitalized heroin overdose patients in New York City.[40] The outcome generally depends on comorbid conditions and the delay to adequate care. ALI may be an isolated finding or may occur in the setting of multisystem organ damage.

No single mechanism can be consistently invoked in the genesis of opioid-associated ALI. However, several prominent theories are each well supported by experimental data. Although several authors ascribe ALI to naloxone, the majority of affected patients had already experienced respiratory arrest and had been given naloxone to reestablish spontaneous breathing. In these patients, naloxone likely "uncovered" the clinical findings of ALI that were not evident because an adequate examination could not be performed. Other evidentiary cases involve surgical patients given naloxone postoperatively who subsequently awoke with clinical signs of pulmonary edema. In addition to presumably receiving the naloxone for ventilatory compromise or hypoxia, these patients received multiple intraoperative medications, further obscuring the etiology.[129] Although naloxone ordinarily is safe when appropriately administered to nonopioid-tolerant individuals, the production of acute opioid withdrawal may be responsible for "naloxone-induced" ALI. In this situation, as in patients with "neurogenic" pulmonary edema,

massive sympathetic discharge from the CNS occurs and produces "cardiogenic" pulmonary edema from the acute effects of catecholamines on the myocardium. In an interesting series of experiments, precipitated opioid withdrawal in nontolerant dogs was associated with dramatic cardiovascular changes and abrupt elevation of serum catecholamine concentrations.[117,118] The effects were more dramatic in dogs with an elevated PCO_2 than in those with a normal or low PCO_2, suggesting the potential benefit of adequately ventilating patients before opioid reversal with naloxone. Similar effects occur in humans undergoing ultrarapid opioid detoxification (UROD; see below).[43]

Even though abrupt precipitation of withdrawal by naloxone may contribute to the development of ALI, it cannot be the sole etiology. Alveolar filling was noted in 50% to 90% of the postmortem examinations performed on heroin overdose patients, many of whom were declared dead before arrival to medical care and thus never received naloxone.[66,70] In addition, neither naloxone nor any other opioid antagonist was available when Osler and others described their initial cases of pulmonary edema. Alternatively, the negative intrathoracic pressure generated by attempted inspiration against a closed glottis creates a large pressure gradient across the alveolar membrane and draws fluid into the alveolar space. This mechanical effect, also known as the *Müller maneuver*, was invoked as the cause of ventilator-associated ALI before the advent of demand ventilators and neuromuscular blockers. In the setting of opioid poisoning, glottic laxity may prevent adequate air entry during inspiration. This effect may be especially prominent at the time of naloxone administration, in which case breathing may be reinstituted before the return of adequate upper airway function.

Cardiovascular Arteriolar and venous dilation secondary to opioid use may result in a mild reduction in blood pressure.[178] This effect is clinically useful for treatment of patients with acute cardiogenic pulmonary edema. However, although patients typically do not develop significant supine hypotension, orthostatic changes in blood pressure and pulse routinely occur. Bradycardia is unusual, although a reduction in heart rate is common as a result of the associated reduction in CNS stimulation. Opioid-induced hypotension appears to be mediated by histamine release, although induction of histamine release does not appear to occur through interaction with an opioid receptor. It may be related to the nonspecific ability of certain xenobiotics to activate mast cell G proteins,[6] which induce degranulation of histamine-containing vesicles. Many opioids share this ability, which seems to be conferred by the presence of a positive charge on a hydrophobic molecule. Accordingly, not all opioids are equivalent in their ability to release histamine.[6] After administration of one of four different opioids to 60 healthy patients, meperidine produced the most hypotension and elevation of serum histamine concentrations; fentanyl produced the least.[47] The combination of H_1 and H_2 antagonists is effective in ameliorating the hemodynamic effects of opioids in humans.[127]

Cardiovascular toxicity may occur with use of propoxyphene, which causes wide-complex dysrhythmias and negative contractility through sodium channel antagonism similar to that of type IA antidysrhythmics (see Propoxyphene below). Adulterants or coingestants may also produce significant cardiovascular toxicity. For example, quinine-adulterated heroin is associated with dysrhythmias. Cocaine, surreptitiously added to heroin, may cause significant myocardial ischemia or infarction. Similarly, concern that naloxone administration may "unmask" cocaine toxicity in patients simultaneously using cocaine and heroin ("speedball") probably is warranted but rarely is demonstrated unequivocally.

Certain opioids at therapeutic concentrations, particularly methadone, may interfere with normal cardiac repolarization and produce QT interval prolongation, an effect that predisposes to the development of torsades de pointes.[92,121] Many patients who receive methadone experience minor increases in QT interval, although a small percentage of patients experience a substantial increase to more than 500 msec.[92] Methadone and levo-α-acetylmethadol (LAAM) both prolong the QT interval via interactions with cardiac K^+ channels.[85] Additionally, certain opioids, primarily propoxyphene, may alter the function of myocardial Na^+ channels in a manner similar to that of the antidysrhythmics (see Chap. 63).

Miosis The mechanisms by which opioids induce miosis remain controversial. Support for each of several mechanisms can be found in the literature. Stimulation of parasympathetic pupilloconstrictor neurons in the Edinger-Westphal nucleus of the oculomotor nerve by morphine produces miosis. Additionally, morphine increases firing of pupilloconstrictor neurons to light,[98] which increases the sensitivity of the light reflex through central reinforcement.[181] Although sectioning of the optic nerve may blunt morphine-induced miosis, the consensual reflex in the denervated eye is enhanced by morphine. Because opioids classically mediate inhibitory neurotransmission, hyperpolarization of sympathetic nerves or of inhibitory neurons to the parasympathetic neurons (removal of inhibition) ultimately may be found to mediate the classic "pinpoint pupil" associated with opioid use.

Not all patients using opioids present with miosis. Meperidine has a lesser miotic effect than other conventional opioids, and propoxyphene use does not result in miosis.[54] Use of opioids with predominantly κ-agonist effects, such as pentazocine, may not result in miosis. Mydriasis may occur in severely poisoned patients secondary to hypoxic brain insult. Additionally, concomitant drug abuse or the presence of adulterants may alter pupillary findings. For example, the combination of heroin and cocaine ("speedball") may produce virtually any size pupil, depending on the relative contribution by each xenobiotic. Similarly, patients ingesting diphenoxylate and atropine (Lomotil) or those using scopolamine-adulterated heroin typically develop mydriasis.[61]

Seizures Seizures are a rare complication of therapeutic use of most opioids. In patients with acute opioid overdose, seizures most likely are caused by hypoxia. However, experimental models demonstrate a proconvulsant effect of morphine in that it potentiates the convulsant effect of other xenobiotics.[185] These effects are variably inhibited by naloxone, suggesting the involvement of a mechanism other than opioid receptor binding. In humans, morphine-induced seizures are reported in neonates and are reversed by naloxone,[30] although opioid withdrawal seizures in neonates are more common.

Seizures should be anticipated in patients with meperidine, propoxyphene, tapentadol or tramadol toxicity. Naloxone antagonizes the convulsant effects of propoxyphene in mice, although it is only moderately effective in preventing seizures resulting from meperidine or its metabolite normeperidine.[55] Interestingly, naloxone potentiates the anticonvulsant effects of benzodiazepines and barbiturates, but in a single study, it antagonized the effects of phenytoin.[78] The ability of fentanyl and its analogs to induce seizures is controversial. They are used to activate epileptiform activity for localization in patients with temporal lobe epilepsy who are undergoing surgical exploration.[113] However, electroencephalography (EEG) performed on patients undergoing fentanyl anesthesia did not identify seizure activity even though the clinical assessment suggested that approximately one-third of them had seizures.[152] It appears likely that the rigidity and myoclonus associated with fentanyl use are readily misinterpreted as a seizure.

Movement Disorders Patients may experience acute muscular rigidity with rapid IV injection of certain high-potency opioids, especially fentanyl and its derivatives.[161] This condition is particularly prominent during induction of anesthesia and in neonates.[46] The rigidity primarily involves the trunk and may impair chest wall movement sufficiently to exacerbate hypoventilation. Chest wall rigidity may have contributed

to the lethality associated with epidemics of fentanyl-adulterated or fentanyl-substituted heroin. Although the mechanism of muscle rigidity is unclear, it may be related to blockade of dopamine receptors in the basal ganglia. Other postulated mechanisms include γ-aminobutyric acid (GABA) antagonism and NMDA agonism. Opioid antagonists generally are therapeutic but may produce adverse hemodynamic effects, withdrawal phenomena, or uncontrollable pain, depending on the situation.[46] Although not a problem for patients taking stable doses of methadone, rapid escalation of methadone doses may produce choreoathetoid movements.[10]

Gastrointestinal Effects Historically, the morphine analog apomorphine was used as a rapidly acting emetic whose clinical use was limited by its tendency to depress the patient's level of consciousness. Emesis induced by apomorphine is mediated through agonism at D_2 receptor subtypes within the chemoreceptor trigger zone of the medulla. Many opioids, particularly morphine, produce significant nausea and vomiting when used therapeutically.[20] Whether these effects are inhibited by naloxone is not clearly established, but they likely are not.

Although diphenoxylate and loperamide are widely used therapeutically to manage diarrhea, opioid-induced constipation is most frequently a bothersome side effect of both medical and nonmedical use of opioids. Constipation, mediated by μ_2 receptors within the smooth muscle of the intestinal wall,[73] is ameliorated by oral naloxone. Provided the first pass hepatic glucuronidative capacity is not exceeded (at doses of ~6 mg), enteral naloxone is poorly bioavailable and thus induces few, if any, opioid withdrawal symptoms.[115] Methylnaltrexone and alvimopan are bioavailable, peripherally acting opioids that antagonize the effects of other opioids on the GI tract opioid receptors.[187] Opioid withdrawal does not occur because methylnaltrexone and alvimopan cannot cross the blood–brain barrier.[114] (see Antidote in Depth A6: Opioid Antagonists)

DIAGNOSTIC TESTING

■ LABORATORY CONSIDERATIONS

Although it is always tempting to seek laboratory confirmation of an ingested xenobiotic in acutely poisoned patients, current laboratory methodology suffers from several important limitations and the potential for many confounding variables. The most apparent impediment to use of laboratory testing in the acute care setting is the lack of timely reporting of results. Patients may experience grave consequences if therapy is withheld pending test results. Opioid poisoned patients are particularly appropriate for a rapid clinical diagnosis because of the unique characteristics of the opioid syndrome. Additionally, even in situations where the assay results are available rapidly, the fact that several distinct classes of opioids and nonopioids can produce similar opioid effects limits the use of laboratory tests, such as immunoassays, that rely on structural features to identify xenobiotics. Furthermore, because opioids may be chemically detectable long after their clinical effects have dissipated, assay results cannot be considered in isolation but rather viewed in the clinical context. Several well-described problems with laboratory testing of opioids are described below and in Chapter 6.

Cross-Reactivity Many opioids share remarkable structural similarities, such as methadone and propoxyphene, but they do not necessarily share the same clinical characteristics (Fig. 38–2). Because most clinical assays depend on structural features for identification, structurally similar xenobiotics may be detected in lieu of the desired one. Whether a similar xenobiotic is noted by the assay depends on the sensitivity and specificity of the assay and the serum concentration of the xenobiotic. Some cross-reactivities are predictable, such as that of codeine with
FIGURE 38–2. Structural similarity between methadone and propoxyphene and between phencyclidine and dextromethorphan.

morphine, on a variety of screening tests. Other cross-reactivities are less predictable, as in the case of the cross-reaction of dextromethorphan and the phencyclidine (PCP) component of the fluorescence polarization immunoassay (Abbott TDx),[138] a widely used drug abuse screening test (see Chap. 6).[158]

Congeners and Adulterants Commercial opioid assays, which are specific for morphine, likely will not detect most of the semisynthetic and synthetic opioids. In some cases, epidemic fatalities involving fentanyl derivatives remained unexplained despite obvious opioid toxicity until the ultrapotent fentanyl derivative α-methylfentanyl (although initially misidentified as 3-methylfentanyl) was identified by more sophisticated testing.[91,108] Oxycodone, hydrocodone, and other common morphine derivatives have variable detectability by different opioid screens.[100,151]

Drug Metabolism A fascinating dilemma may arise in patients who ingest moderate to large amounts of poppy seeds.[87] These seeds, which are widely used for culinary purposes, are derived from poppy plants and contain both morphine and codeine. After ingestion of a single poppy seed bagel, patients may develop elevated serum morphine and codeine concentrations and test positive for morphine.[119,133] Because the presence of morphine on a drug abuse screen may suggest illicit

heroin use, the implications are substantial. Federal workplace testing regulations thus require corroboration of a positive morphine assay with assessment of another heroin metabolite, 6-monoacetylmorphine, before reporting a positive result.[120,172] Humans cannot acetylate morphine and therefore cannot synthesize 6-monoacetylmorphine, but humans can readily deacetylate heroin, which is diacetylmorphine.

A similar problem may occur in patients taking therapeutic doses of codeine. Because codeine is demethylated to morphine by CYP2D6, a morphine screen may be positive as a result of metabolism and not structural cross-reactivity.[50] Thus, determination of the serum codeine or 6-monoacetylmorphine concentration is necessary in these patients. Determination of the serum codeine concentration is not foolproof, however, because codeine is present in the opium preparation used to synthesize heroin.

Forensic Testing Decision making regarding the cause of death in the presence of systemic opioids often is complex.[32] Variables that often are incompletely defined contribute substantially to the difficulty in attributing or not attributing the cause of death to the opioid. These variables include the specifics regarding the timing of exposure, the preexisting degree of sensitivity or tolerance, the role of cointoxicants (including parent opioid metabolites), and postmortem redistribution and metabolism.[39,84] Interesting techniques to help further elucidate the likely cause of death that have been studied include the application of postmortem pharmacogenetic principles[79] and the use of alternative specimens (see Chap. 33).

MANAGEMENT

The consequential effects of acute opioid poisoning are CNS and respiratory depression. Although early support of ventilation and oxygenation is generally sufficient to prevent death, prolonged use of bag-valve-mask ventilation and endotracheal intubation may be avoided by cautious administration of an opioid antagonist. Opioid antagonists, such as naloxone, competitively inhibit binding of opioid agonists to opioid receptors, allowing the patient to resume spontaneous respiration. Naloxone competes at all receptor subtypes, although not equally, and is effective at reversing almost all adverse effects mediated through opioid receptors. (Antidotes in Depth A6: Opioid Antagonists contains a complete discussion of naloxone and other opioid antagonists.)

Because many clinical findings associated with opioid poisoning are nonspecific, the diagnosis requires clinical acumen. Differentiating acute opioid poisoning from other etiologies with similar clinical presentations may be challenging. Patients manifesting opioid toxicity, those found in an appropriate environment, or those with characteristic physical clues such as fresh needle marks require little corroborating evidence. However, subtle presentations of opioid poisoning may be encountered, and other entities superficially resembling opioid poisoning may occur. Hypoglycemia, hypoxia, and hypothermia may result in clinical manifestations that share features with opioid poisoning and may exist concomitantly. Each can be rapidly diagnosed with routinely available, point-of-care testing, but their existence does not exclude opioid toxicity. Other xenobiotics responsible for similar clinical presentations include clonidine, PCP, phenothiazines, and sedative–hypnotics (primarily benzodiazepines). In such patients, clinical evidence usually is available to assist in diagnosis. For example, nystagmus nearly always is noted in PCP-intoxicated patients, hypotension or electrocardiographic (ECG) abnormalities in phenothiazine-poisoned patients, and coma with virtually normal vital signs in patients poisoned by benzodiazepines. Most difficult to differentiate on clinical grounds may be toxicity produced by the centrally

acting antihypertensive agents such as clonidine (see Clonidine below and Chap. 62). Additionally, myriad traumatic, metabolic, and infectious etiologies may occur simultaneously and must always be considered and evaluated appropriately.

■ ANTIDOTE ADMINISTRATION

The goal of naloxone therapy is not necessarily complete arousal; rather, the goal is reinstitution of adequate spontaneous ventilation. Because precipitation of withdrawal is potentially detrimental and often unpredictable, the lowest practical naloxone dose should be administered initially, with rapid escalation as warranted by the clinical situation. Most patients respond to 0.04 to 0.05 mg of naloxone administered IV, although the requirement for ventilatory assistance may be slightly prolonged because the onset may be slower than with larger doses. Administration in this fashion effectively avoids endotracheal intubation and allows timely identification of patients with nonopioid causes of their clinical condition yet diminishes the risk of precipitation of acute opioid withdrawal. SC administration may allow for smoother arousal than the high-dose IV route but is unpredictable in onset and likely prolonged in offset.[176] Prolonged effectiveness of naloxone by the SC route can be a considerable disadvantage if the therapeutic goal is exceeded and the withdrawal syndrome develops.

In the absence of a confirmatory history or diagnostic clinical findings, the cautious empiric administration of naloxone may be both diagnostic and therapeutic. Naloxone, even at extremely high doses, has an excellent safety profile in opioid-naïve patients receiving the medication for nonopioid-related indications, such as spinal cord injury or acute ischemic stroke. However, administration of naloxone to opioid-dependent patients may result in adverse effects; specifically, precipitation of an acute withdrawal syndrome should be anticipated. The resultant agitation, hypertension, and tachycardia may produce significant distress for the patient and complicate management for the clinical staff and occasionally may be life threatening. Additionally, emesis, a common feature of acute opioid withdrawal, may be particularly hazardous in patients who do not rapidly regain consciousness after naloxone administration. For example, patients with concomitant ethanol or sedative–hypnotic exposure and those with head trauma are at substantial risk for pulmonary aspiration of vomitus if their airways are unprotected.

Identification of patients likely to respond to naloxone conceivably would reduce the unnecessary and potentially dangerous precipitation of withdrawal in opioid-dependent patients. Routine prehospital administration of naloxone to all patients with subjectively assessed altered mental status or respiratory depression was not beneficial in 92% of patients.[186] Alternatively, although not perfectly sensitive, a respiratory rate of 12 breaths/min or less in an unconscious patient presenting via Emergency Medical Services best predicted a response to naloxone.[71] Interestingly, neither respiratory rate below 8 breaths/min nor coma was able to predict a response to naloxone in hospitalized patients.[183] It is unclear whether the discrepancy between the latter two studies is a result of the demographics of the patient groups or whether patients with prehospital opioid overdose present differently than patients with iatrogenic poisoning. Regardless, relying on the respiratory rate to assess the need for ventilatory support or naloxone administration is not ideal because hypoventilation secondary to hypopnea may precede that caused by bradypnea.[131,147]

The decision to discharge a patient who awakens appropriately after naloxone administration is based on practical considerations. Patients presenting with profound hypoventilation or hypoxia are at risk for development of ALI or posthypoxic encephalopathy. Thus, it seems prudent to observe these patients for at least 24 hours in a medical setting. Patients manifesting only moderate signs of poisoning who remain normal for at least several hours after parenteral naloxone likely

TABLE 38–3. How to Use a Naloxone Infusion

1. If a naloxone bolus (start with 0.04 mg IV and titrate) is successful, administer two-thirds of the effective bolus dose per hour by IV infusion; frequently reassess the patient's respiratory status.

2. If respiratory depression is not reversed after the bolus dose:

   Intubate the patient, as clinically indicated.

   Administer up to 10 mg of naloxone as an IV bolus. If the patient does not respond, do not initiate an infusion.

3. If the patient develops withdrawal after the bolus dose:

   Allow the effects of the bolus to abate.

   If respiratory depression recurs, administer half of this new bolus dose and begin an IV infusion at two-thirds of the initial bolus dose per hour. Frequently reassess the patient's respiratory status.

4. If the patient develops withdrawal signs or symptoms during the infusion:

   Stop the infusion until the withdrawal symptoms abate.

   Restart the infusion at half the initial rate; frequently reassess the patient's respiratory status.

   Exclude withdrawal from other xenobiotics.

5. If the patient develops respiratory depression during the infusion:

   Readminister half of the initial bolus and repeat until reversal occurs.

   Increase the infusion by half of the initial rate; frequently reassess the patient's respiratory status.

   Exclude continued absorption, readministration of opioid, and other etiologies as the cause of the respiratory depression..

---

are safe to discharge. However, the need for psychosocial intervention in patients with uncontrolled drug use or after a suicide attempt may prevent discharge from the emergency department (ED).

Patients with recurrent or profound poisoning by long-acting opioids, such as methadone, or patients with large GI burdens (eg, "body packers" or those taking sustained-release preparations), may require continuous infusion of naloxone to ensure continued adequate ventilation (Table 38–3). An hourly infusion rate of two-thirds of the initial reversal dose of naloxone is sufficient to prevent recurrence.[57] Titration of the dose may be necessary as indicated by the clinical situation. Although repetitive bolus dosing of naloxone may be effective, it is labor intensive and subject to error.

Despite the availability of long-acting opioid antagonists (eg, naltrexone and nalmefene) that theoretically permit single-dose reversal of methadone poisoning, the attendant risk of precipitating an unrelenting withdrawal syndrome hinders their use as antidotes for initial opioid reversal. However, these opioid antagonists may have a clinical role in the maintenance of consciousness and ventilation in opioid-poisoned patients already awakened by naloxone. Prolonged observation and perhaps antidote readministration may be required to match the pharmacokinetic parameters of the two antagonists. Otherwise, well children who ingest short-acting opioids may be given a long-acting opioid antagonist initially because they are not expected to develop a prolonged, potentially hazardous withdrawal. However, the same caveats remain regarding the need for extended hospital observation periods if ingestion of methadone or other long-acting opioids is suspected.

■ RAPID AND ULTRARAPID OPIOID DETOXIFICATION

The concept of antagonist-precipitated opioid withdrawal is promoted extensively as a "cure" for opioid dependency, particularly heroin and

oxycodone, but has fallen out of favor in recent years. Rather than slow, deliberate withdrawal or detoxification from opioids over several weeks, antagonist-precipitated withdrawal occurs over several hours or days.[59] The purported advantage of this technique is a reduced risk of relapse to opioid use because the duration of discomfort is reduced and a more rapid transition to naltrexone maintenance can be achieved. Although most studies find excellent short-term results, relapse to drug use is very common.[112] Rapid opioid detoxification techniques are usually offered by outpatient clinics and typically consist of naloxone- or naltrexone-precipitated opioid withdrawal tempered with varying amounts of clonidine, benzodiazepines, antiemetics, or other drugs. UROD uses a similar concept but involves the use of deep sedation or general anesthesia for greater patient control and comfort. The risks of these techniques are not fully defined but are of substantial concern. Massive catecholamine release, ALI, renal insufficiency, and thyroid hormone suppression have been reported after UROD, and many patients still manifest opioid withdrawal 48 hours after the procedure. As with other forms of opioid detoxification, the loss of tolerance after successful completion of the program paradoxically increases the likelihood of death from heroin overdose if these individuals relapse. That is, recrudescence of opioid use in pre-detoxification quantities is likely to result in overdose.[160] Both techniques are costly; UROD under anesthesia commonly costs thousands of dollars.

SPECIFIC OPIOIDS

The vast majority of opioid-poisoned patients follow predictable clinical courses that can be anticipated based on our understanding of opioid receptor pharmacology. However, certain opioids taken in overdose may produce atypical manifestations. Therefore, careful clinical assessment and institution of empiric therapy usually are necessary to ensure proper management (Table 38–4).

■ MORPHINE AND CODEINE

Morphine is poorly bioavailable by the oral route because of extensive first-pass elimination. Morphine is hepatically metabolized primarily to morphine-3-glucuronide (M3G) and, to a lesser extent, to morphine-6-glucuronide (M6G), both of which are cleared renally. Unlike M3G, which is essentially devoid of activity, M6G has μ-agonist effects in the CNS.[2] However, M6G administered peripherally is significantly less potent as an analgesic than is morphine.[146] The polar glucuronide has a limited ability to cross the blood–brain barrier, and P-glycoprotein is capable of expelling M6G from the cerebrospinal fluid. The relative potency of morphine and M6G in the brain is incompletely defined, but the metabolite is generally considered to be several-fold more potent.[2]

Codeine itself is an inactive opioid agonist, and it requires metabolic activation by O-demethylation to morphine by CYP2D6 (Fig. 38–3). This typically represents a minor metabolic pathway for codeine metabolism. N-demethylation into norcodeine by CYP3A4 and glucuronidation are more prevalent but produce inactive metabolites. The need for conversion to morphine explains why approximately 5% to 7% of white patients, who are devoid of CYP2D6 function, cannot derive an analgesic response from codeine.[76,104] Rarely, ultrarapid CYP2D6 metabolizers produce unexpectedly large amounts of morphine, with resulting life-threatening opioid toxicity.[49]

■ HEROIN

Heroin is 3,6-diacetylmorphine, and its exogenous synthesis is performed relatively easily from morphine and acetic anhydride. Heroin has a lower affinity for the receptor than does morphine, but it is

TABLE 38–4. Classification, Potency, and Characteristics of Opioids

Opioid (Representative Trade Name)	Type[a]	Derivation	Analgesic Dose (mg) (via route, equivalent to 10 mg morphine SC[b])	Comments[a,c]
Alvimopan (Entereg)	Ant	Synthetic	Nonanalgesic (12mg PO)	Peripherally acting antagonist; reverses opioid constipation
Buprenorphine (Buprenex)	P/AA	Semisynthetic	0.4 IM	Opioid substitution therapy requires 6–16 mg/d
Butorphanol (Stadol)	AA	Semisynthetic	2 IM	
Codeine	Ag	Natural	120 PO	Often combined with acetaminophen; requires demethylation to morphine by CYP2D6
Dextromethorphan (Robitussin DM)	NEC	Semisynthetic	Nonanalgesic (10–30 PO)	Antitussive; psychotomimetic via or NMDA receptor
Diphenoxylate (Lomotil)	Ag	Synthetic	Nonanalgesic (2.5 PO)	Antidiarrheal, combined with atropine; difenoxin is potent metabolite
Fentanyl (Sublimaze)	Ag	Synthetic	0.125 IM	Very short acting (<1 h)
Heroin (Diamorph)	Ag	Semisynthetic	5 SC	Diacetylmorphine, used therapeutically in some countries, Schedule I medication in the United States
Hydrocodone (Vicodin, Hycodan)	Ag	Semisynthetic	10 PO	
Hydromorphone (Dilaudid)	Ag	Semisynthetic	1.3 SC	
LAAM (Orlaam)	Ag	Synthetic	(Flexible oral dosing[d])	Long acting, potent metabolites; no longer distributed in US because of QTc interval prolongation
Levorphanol (Levodromoran)	Ag	Semisynthetic	2 SC/IM	
Loperamide (Imodium)	Ag	Synthetic	Nonanalgesic (2 PO)	Antidiarrheal
Meperidine, pethidine (Demerol)	Ag	Synthetic	75 SC/IM	Seizures caused by metabolite accumulation
Methadone (Dolophine)	Ag	Synthetic	10 IM	Very long acting (24 h)
Methylnaltrexone (Relistor)	Ant	Synthetic	Nonanalgesic (8-12mg SC)	Peripherally acting antagonist; reverses opioid constipation
Morphine	Ag	Natural	10 SC/IM	
Nalbuphine (Nubain)	AA	Semisynthetic	10 IM	
Nalmefene (Revex)	Ant	Semisynthetic	Nonanalgesic (0.1 IM)	Long-acting antagonist (4–6 h)
Nalorphine	AA	Semisynthetic	15 IM	Historically used as an opioid antagonist[a]
Naloxone (Narcan)	Ant	Semisynthetic	Nonanalgesic (0.1–0.4 IV/IM)	Short-acting antagonist (0.5 h)
Naltrexone (Trexan, Revia)	Ant	Semisynthetic	Nonanalgesic (50 PO)	Very long-acting antagonist (24 h)
Oxycodone (Percocet, OxyContin)	Ag	Semisynthetic	10 PO	Often combined with acetaminophen; OxyContin is sustained release
Oxymorphone (Numorphan)	Ag	Semisynthetic	1 SC	
Paregoric (Parapectolin)	Ag	Natural	25 mL PO	Tincture of opium (0.4 mg/mL)
Pentazocine (Talwin)	AA	Semisynthetic	50 SC	Psychotomimetic via receptor
Propoxyphene (Darvon)	Ag	Synthetic	65 PO	Seizures, dysrhythmias; combined with acetaminophen
Tapentadol (Nucynta)	Ag	Synthetic	50-100mg PO	Seizures
Tramadol (Ultram)	Ag	Synthetic	50–100 PO	Seizures possible with therapeutic dosing

[a] Agonist–antagonists, partial agonists, and antagonists may cause withdrawal in tolerant individuals.

[b] Typical dose (mg) for agents without analgesic effects is given in parentheses.

[c] Duration of therapeutic clinical effect 3–6 hours unless noted; likely to be exaggerated in overdose.

[d] Although approximately equipotent with methadone, LAAM is not used as an analgesic.

AA, agonist antagonist (κ agonist, μ antagonist); Ag, full agonist (μ_1, μ_2, κ); Ant, full antagonist (μ_1, μ_2, κ antagonist); NEC, not easily classified; NMDA, *N*-methyl-D-aspartate; P, partial agonist (μ_1, μ_2 agonist, κ antagonist).

rapidly metabolized by plasma cholinesterase and liver human carboxylesterase (hCE)-2 to 6-monoacetylmorphine, a more potent μ agonist than morphine (see Fig. 38–3).[142] Users claim that heroin has an enhanced euphorigenic effect, often described as a "rush." This effect likely is related to the enhanced blood–brain barrier penetration occasioned by the additional organic functional groups of heroin and its subsequent metabolic activation within the CNS. Interestingly, cocaine and heroin compete for metabolism by plasma cholinesterase and the
FIGURE 38–3. Opiate/opioid metabolism. Codeine can be *O*-methylated to morphine, *N*-demethylated to norcodeine, or glucuronidated to codeine-6-glucuronide (codeine-6-G). Morphine can be *N*-demethylated to normorphine or glucuronidated to either morphine-3-glucuronide (morphine-3-G) or morphine-6-glucuronide (morphine-6-G). Heroin is converted to morphine by a two-step process involving plasma cholinesterase and two human liver carboxylesterases known as human carboxylesterase-1 and human carboxylesterase-2.

two human liver carboxylesterases hCE-1 and hCE-2. This interaction may have pharmacokinetic and clinical consequences in patients who "speedball."[8,83]

Heroin can be obtained in two distinct chemical forms: base or salt. The hydrochloride salt form typically is a white or beige powder and was the common form of heroin available before the 1980s.[81] Its high water solubility allows simple IV administration. Heroin base, on the other hand, now is the more prevalent form of heroin in most regions of the world. It often is brown or black. "Black tar heroin" is one appellation referring to an impure South American import available in the United States. Because heroin base is virtually insoluble in water, IV administration requires either heating the heroin until it liquefies or mixing it with acid. Alternatively, because the alkaloidal form is heat stable, smoking or "chasing the dragon" is sometimes used as an alternative route. Street-level heroin base frequently contains caffeine or barbiturates,[81] which improves the sublimation of heroin and enhances the yield.[74]

Widespread IV use has led to many significant direct and indirect medical complications, particularly endocarditis and AIDS, in addition to fatal and nonfatal overdose. Nearly two-thirds of all long-term (>10 years) heroin users in Australia had overdosed on heroin.[34] Among recent-onset heroin users, 23% had overdosed on heroin, and 48% had been present when someone else overdosed.[58] Risk factors for fatality after heroin use include the concomitant use of other drugs of abuse, particularly ethanol; recent abstinence, as occurs during incarceration[141];

and perhaps unanticipated fluctuations in the purity of available heroin.[33,132] Because most overdoses occur in seasoned heroin users and about half occur in the company of other users,[34] a trial distribution of naloxone to heroin users was initiated. Although earlier administration of antidote could be beneficial, certain issues make this approach controversial. For example, despite the acknowledged injection skills of the other users in the "shooting gallery," their judgment likely is impaired. In one survey, summoning an ambulance was the initial response to overdose of a companion in only 14% of cases.[35] A survey of heroin users suggested they lacked an understanding of the pharmacology of naloxone, which might lead to inappropriate behaviors regarding both heroin and naloxone administration.[140]

Recognition of the efficacy of intranasal heroin administration, or snorting, has fostered a resurgence of heroin use, particularly in suburban communities. The reasons for this trend are unclear, although it is widely suggested that the increasing purity of the available heroin has rendered it more suitable for intranasal use. However, because intranasal administration of a mixture of 3% heroin in lactose produces clinical and pharmacokinetic effects similar to an equivalent dose administered IM, the relationship between heroin purity and price and intranasal use is uncertain.[24,135] Needle avoidance certainly is important, reducing the risk of transmission of various infectious diseases, including HIV. Heroin smoking has also increased in popularity in the United States, albeit not to the extent in other countries (see "Chasing the Dragon" below).

Celebrities and musicians have popularized intranasal heroin use as a "safe" alternative to IV use. This usage is occurring despite a concomitantly reported rise in heroin deaths in regions of the country where its use is prevalent. Although intranasal use may be less dangerous than IV use from an infectious disease perspective, it is clear that both fatal overdose and drug dependency remain common.[166]

Adulterants, Contaminants, and "Heroin" Substitutes The history of heroin adulteration and contamination has been extensively described. Retail (street-level) heroin almost always contains adulterants or contaminants. What differentiates the two is the intent of their admixture. Adulterants typically are benign because inflicting harm on the consumer with their addition would be economically and socially unwise, although adulterants occasionally are responsible for epidemic death. Interestingly, most heroin overdose fatalities do not have serum morphine concentrations that substantially differ from those of living users, raising the possibility that the individual death is related to an adulterant or contaminant.[36]

Historically, alkaloids, such as quinine and strychnine, were used to adulterate heroin to mimic the bitter taste of heroin and to mislead clients. Quinine may have first been added in a poorly reasoned attempt to quell an epidemic of malaria among IV heroin users in New York City in the 1930s.[66] That quinine adulteration was common is demonstrated by the common practice of urine screening for quinine as a surrogate marker for heroin use. However, quinine was implicated as a causative factor in an epidemic of heroin-related deaths in the District of Columbia between 1979 and 1982. Toxicity attributed to quinine in heroin users includes cardiac dysrhythmias (see Chap. 23), amblyopia, and thrombocytopenia. Quinine adulteration currently is much less common than it was in the past. Trend analysis of illicit wholesale and street-level heroin adulteration over a 12-year period in Denmark revealed that although caffeine, acetaminophen, methaqualone, and phenobarbital all were prevalent adulterants, quinine was not found.[81] Recent data on adulteration in the United States are unavailable. Many other adulterants or contaminants, including thallium, lead, cocaine, and amphetamines, have been reported.

Poisoning by scopolamine-tainted heroin reached epidemic levels in the northeastern United States in 1995.[61] Exposed patients presented

with acute psychosis and anticholinergic signs. Several patients were treated with physostigmine, with excellent therapeutic results.

Clenbuterol, a β-2 adrenergic agonist with a rapid onset and long duration of action, was found to be a contaminant in street heroin in the Eastern United States in early 2005. Users had, in most cases, insufflated what they believed to be unadulterated street heroin, but they rapidly developed nausea, chest pain, palpitations, dyspnea, and tremor. Physical findings included significant tachycardia and hypotension, as well as hyperglycemia, hypokalemia, and increased lactate concentrations on laboratory evaluation, and a few fatalities occurred.[72,184] Although the patients were initially thought to be cyanide poisoned, laboratory investigation uncovered clenbuterol. Several patients were treated with β-adrenergic antagonists or calcium channel blockers and potassium supplementation with good results (see Chaps. 39 and 44).

"Chasing the Dragon" IV injection and insufflation are the preferred means of heroin self-administration in the United States. In other countries, including the Netherlands, the United Kingdom, and Spain, a prevalent method is "chasing the dragon" whereby users inhale the white pyrolysate that is generated by heating heroin base on aluminum foil using a hand-held flame. This means of administration produces heroin pharmacokinetics similar to those observed after IV administration.[68] Chasing the dragon is not a new phenomenon, but it has gained acceptance recently among both IV heroin users and drug-naïve individuals.[235] The reasons for this shift are diverse but probably are related to the avoidance of injection drug use with its concomitant infectious risks. The increasing availability of the smokable base form of heroin is associated, but whether it is a cause or an effect of this trend is unknown.

In the early 1980s, a group of individuals who smoked heroin in the Netherlands developed spongiform leukoencephalopathy. Other causes of this rare clinicopathologic entity include prion-related infections such as bovine spongiform leukoencephalopathy, hexachlorophene, pentachlorophenol, and metal poisoning, although none appeared responsible for this phenomenon. Since the initial report, similar cases have been reported in other parts of Europe and in the United States.[93,103] Initial findings may occur within 2 weeks of use and include bradykinesia, ataxia, abulia, and speech abnormalities. Of those whose symptoms do not progress, half may recover. However, in others, progression to spastic paraparesis, pseudobulbar palsy, or hypotonia may occur over several weeks. Approximately half of individuals in this group do not develop further deficits or improve, but death occurs in approximately 25% of reported cases. The prominent symmetric cerebellar and cerebral white matter destruction noted on brain computed tomography and magnetic resonance imaging corresponds to that noted at necropsy.[86,122]

The syndrome has the characteristics of a point-source toxic exposure, but no culpable contaminants have been identified, although aluminum concentrations may be elevated.[45] A component or pyrolysis product unique to certain batches of "heroin" is possible.[15] Treatment is largely supportive. Based on the finding of regional mitochondrial dysfunction on functional brain imaging and an elevated brain lactate concentration, supplementation with 300 mg QID of coenzyme Q has purported benefit but has not undergone controlled study.[93]

■ OTHER OPIOIDS

Fentanyl and Its Analogs Fentanyl is a short-acting, highly potent opioid agonist that is widely used in clinical medicine. Fentanyl has approximately 50 to 100 times the potency of morphine. It is well absorbed by the transmucosal route, accounting for its use in the form of a "lollipop." Fentanyl is widely abused as a heroin substitute and is the controlled substance most often abused by anesthesiologists.[11]

Transdermal fentanyl in the form of a patch (Duragesic) was approved in 1991 and is widely used by patients with chronic pain

syndromes. Fentanyl has adequate solubility in both lipid and water for transdermal delivery. The transdermal pharmacokinetics differ markedly from those of the more conventional routes.[90] A single patch contains an amount of drug to provide a transdermal gradient sufficient to maintain a steady-state plasma concentration for approximately 3 days (eg, a 50 μg/h patch contains 5 mg). However, even after the patch is considered exhausted, approximately 50% of the total initial fentanyl dose remains. Interindividual variation in dermal drug penetration and errors in proper use, such as use of excessive patches or warming of the skin, may lead to an iatrogenic fentanyl overdose. Fentanyl patch misuse and abuse occur either by application of one or more patches to the skin or by withdrawal or extraction of the fentanyl from the reservoir for subsequent administration.[165]

Regional epidemics of heroin substitutes with "superpotent" activity occasionally produce a dramatic increase in "heroin-related" fatalities. Epidemic deaths among heroin users first appeared in Orange County, California, in 1979 and were traced to α-methylfentanyl sold under the brand name China White.[91] Similar epidemics of China White poisoning occurred in Pittsburgh in 1988 and in Philadelphia in 1992, although the adulterant in these cases was 3-methylfentanyl, another potent analog. A later epidemic in New York City marked the reappearance of 3-methylfentanyl under the brand name Tango and Cash. Typically, patients present comatose and apneic, with no opioids detected on routine blood and urine analysis. In such cases, unsuspecting users had administered their usual "dose of heroin," measured in 25-mg "bags" that contained variable amounts of the fentanyl analog. Because of the exceptional potency of this fentanyl analog (as much as 6000 times greater than that of morphine), users rapidly developed apnea.

The largest epidemic of more than 1000 fentanyl-related deaths occurred between 2005 and 2007 primarily in the Philadelphia, Chicago, and Detroit regions because of surreptitiously adulterated or substituted heroin. Fentanyl use was identified by postmortem urine and blood testing or through analysis of unused drug found on either the decedent or persons with whom the decedent shared drugs. In response to this large epidemic, drug users and others were counseled in overdose prevention and cardiopulmonary resuscitation and even provided with "take-home" parenteral or intranasal naloxone.[19]

Sufentanil and alfentanil are anesthetic opioids with increased potency compared to fentanyl. In some regions of the country, fentanyl and both licit and illicit fentanyl analogs (eg, 3-methylfentanyl and para-fluorofentanyl) are common drugs of abuse. Experienced heroin users could not easily differentiate fentanyl from heroin, although in one study, heroin was noted to provide a more intense "rush."[94] Although unconfirmed, the xenobiotic used by Russian authorities to overcome terrorists and subdue a hostage situation in Moscow in October 2002 may have been carfentanil,[179] a potent μ-receptor agonist that is commonly used as a positron emission tomography scan radioligand.

Although fentanyl is a more potent opioid agonist than heroin, the dose of naloxone required to reverse respiratory depression appears to be similar to that of other common opioids.[164] This is because the binding affinity (K_d) of fentanyl at the μ opioid receptor is similar to that of both morphine and naloxone.[171] In a typical overdose, the quantity of fentanyl is likely to be equipotent to typical heroin. However, if large quantities of fentanyl are involved in the poisoning, higher than normal doses of naloxone may be required for reversal. Use of other opioids, such as sufentanil and buprenorphine, which have higher affinity for opioid receptors (lower K_d') may lead to the need for larger doses of naloxone to reverse the patient's respiratory depression[101] (see Antidotes in Depth A6: Opioid Antagonists).

Oxycodone and Hydrocodone Although media reports highlight the abuse of these and other prescription opioids by sports figures and

other personalities, this trend has reached epidemic levels in regions of the country where heroin is difficult to obtain (thus the term "hillbilly heroin"). The abuse liabilities of these semisynthetic opioids based on their subjective profile are similar.[175] Although many users initially receive oxycodone or hydrocodone as analgesics, the majority of abusers obtain the drugs illicitly or from friends.[13,105] Regulatory agencies, law enforcement, and the drug manufacturer have made tremendous efforts to control drug diversion to illicit use.[52,170] Physicians have been charged criminally with complicity for inappropriate prescriptions for patients with the intent to sell or abuse these drugs.[52] Many of these opioids are sold in fixed combination with acetaminophen (eg, Percocet [oxycodone 5 mg], Vicodin [hydrocodone]), raising concerns about the complications of acetaminophen hepatotoxicity. Unlike most immediate-release prescription opioids, oxycodone can be obtained in a controlled-release form (OxyContin) that contains as much as 80 mg. Abusers typically crush the tablet, which destroys the sustained-release matrix and liberates large amounts of insufflatable or injectable oxycodone. The psychoactive effects of these opioids are similar to other μ-receptor agonists[189] and often are used as a substitute for heroin. Opioid dependence, overdose, and death are common sequelae of oxycodone abuse.

Body Packers In an attempt to transport illicit drugs from one country to another, "mules," or body packers, ingest large numbers of multiple-wrapped packages of concentrated cocaine or heroin. When the authorities discover such individuals or when individuals in custody become ill, they may be brought to a hospital for evaluation and management. Although these patients generally are asymptomatic on arrival, they are at risk for delayed, prolonged, or lethal poisoning as a consequence of packet rupture.[168] In the past, determining the country of origin of the current journey was nearly diagnostic of packet content. However, because most of the heroin imported into the United States now originates from South America, which is also the major source of imported cocaine, the discernment from cocaine on this basis is impossible. Given the current greater revenue potential of heroin, the majority of body packers carry heroin.[56] Details of diagnosis and management are discussed in Special Considerations SC4: Internal Concealment of Xenobiotics.

Agonist–Antagonists The opioid agonists in common clinical use tend to have specific binding affinity toward the μ-opioid–receptor subtype. The agonist–antagonists differ in that they interact with multiple receptor types and may have different effects at each receptor. Thus, although most opioids typically produce either agonist or antagonist effects, the agonist–antagonists generally have agonist effects at the κ-receptor subtype and antagonistic effects at the μ-receptor subtype. Therefore, opioids such as pentazocine (Talwin) may elicit a withdrawal syndrome in a μ-opioid–tolerant individual because of antagonist effects at the μ receptor. This effect forms the basis of the claim offered by many methadone-dependent patients that they are "allergic to Talwin." However, this same drug may act as an analgesic in nonopioid-using patients through its agonist effects at the κ₁-receptor subtype. Although the clinical effects of agonist–antagonists after overdose resemble those of the other opioids, including lethal respiratory depression,[124] they are less likely than the full agonists to produce severe morbidity or mortality because of their ceiling effect on respiratory depression (see Respiratory Depression above).

Pentazocine. Historically, patients abusing pentazocine (Talwin) administered it with tripelennamine, a blue capsule, accounting for the appellation "T's and Blues." Although this mixture has largely fallen out of favor, pentazocine abuse occurs occasionally. The psychotomimetic effects noted with high doses of pentazocine likely are mediated by κ_2 or perhaps σ receptors. Because pentazocine can be

readily dissolved, IV injection was a preferred route for its abuse until the commercial formulation was altered to include 0.5 mg naloxone (Talwin NX). When ingested, the naloxone is eliminated by first-pass hepatic metabolism; if injected, naloxone prevents the euphoria sought by users.

■ AGENTS USED IN OPIOID SUBSTITUTION THERAPY: METHADONE, LAAM, AND BUPRENORPHINE

Two contrasting approaches to the management of patients with chronic opioid use exist: detoxification and maintenance therapy. Detoxification probably is most appropriate for patients motivated or compelled to discontinue opioid use. It can be performed either by tapered withdrawal of an opioid agonist or with the assistance of opioid antagonists. Maintenance therapy may include use of a long-acting opioid antagonist, such as naltrexone, to pharmacologically block the effects of additional opioid use. Alternatively, and more commonly, maintenance therapy involves opioid substitution therapy.[17]

Methadone Methadone is a synthetic μ-opioid–receptor agonist used both for treatment of chronic pain and as a maintenance substitute for opioid dependence. Methadone has been available for the latter use for more than 40 years through methadone maintenance treatment programs (MMTPs).[38] In MMTPs, the opioid in use is replaced by methadone, which is legal, oral, and long acting. This opioid allows patients to abstain from activities associated with procurement and administration of the abused opioid and eliminates much of the morbidity and mortality associated with illicit drug use. Although often successful in achieving opioid abstinence, some methadone users continue to use heroin, other opioids, and other xenobiotics. [84]

Methadone is administered as a chiral mixture of (R,S)-methadone. In humans, methadone metabolism is mediated by several cytochrome P450 (CYP) isozymes, mainly CYP3A4 andCYP2B6, and to a lesser extent CYP2D6. CYP2B6 demonstrates stereoselectivity toward (S)-methadone,[53] and in vivo data show that CYP2B6 slow metabolizer status is associated with high (S)- but not serum (R)-methadone concentrations.[29] In clinical trials, QT prolongation was exacerbated in individuals who were CYP2B6 slow metabolizers, and this population had higher (S)-methadone concentrations.[41] (R)-methadone is used in Germany and is both more effective and safer than the chiral mixture or the (S) enantiomer, but it is not available in the United States at the present time.

Methadone predictably produces QT interval prolongation because of blockade of the hERG (human *ether-a-gogo* related gene) channel. In the human heart, the hERG voltage-gated potassium channel mediates the rapidly activating delayed rectifier current (see Chap 22). Blocking potassium efflux from the cardiac myocyte prolongs cellular repolarization, prolonging the QT interval. Syncope and sudden death caused by ventricular dysrhythmias (such as torsades de pointes) are the result. Initially described in case reports of patients on high doses of methadone, clinical trials now reveal that methadone can prolong the QT interval in a concentration-dependent fashion.[107] Genetic factors in the metabolism of methadone[41] and probably baseline QT status at the initiation of methadone therapy may underlie and potentially predict adverse effects. (S)-methadone binding to hERG is greater than twofold than that of (R)-methadone and is primarily responsible for the drug's cardiotoxicity.[77]

A major difficulty is identification of individuals who are at risk for life threatening dysrhythmias from methadone-induced QT interval prolongation. Expert-derived guidelines recommend questioning patients about intrinsic heart disease or dysrhythmias, counseling patients initiating methadone therapy, and obtaining a pretreatment ECG and a follow-up ECG at 30 days and yearly.[92] Patients who receive methadone doses of greater than 100 mg/day might warrant more

frequent ECGs, particularly after dose escalation or change in comorbid disease staus.[92] Although these guidelines are disputed by some and limited data exist on the utility of the ECG as a screening test for persons at risk for torsades de pointes from methadone, given its low cost, easy availability, and minimal invasiveness, the guideline recommendations seem practical and appropriate.

Although therapeutic methadone is generally safe, rapid dose escalation during induction in the treatment program may unintentionally produce toxicity and, rarely, fatal respiratory depression.[17] This adverse effect is generally the result of the long duration of effect of methadone and the time lag for the development of tolerance.

Acute methadone overdose results in clinical findings typical of opioid poisoning, although the duration is substantially longer than expected after overdose of prototypical therapeutic opioids. After a successful therapeutic response to the administration of naloxone, recurrence should be expected because the duration of effect of naloxone is approximately 1 hour. In many cases, continuous infusion of naloxone or possibly administration of a long-acting opioid antagonist is indicated to maintain adequate ventilation.

Unintentional methadone overdosage ironically may be related to the manner in which MMTPs dispense the drug. Most patients attending MMTPs are given doses of methadone greater than needed to simply prevent withdrawal and to prevent surreptitious heroin or other opioid use.[159] Additionally, many MMTPs provide their established patients with sufficient methadone to last through a weekend or holiday without the need to revisit the program. This combination of dose and quantity may allow diversion of portions of the dose without the attendant risk of opioid withdrawal. Furthermore, home storage of this surplus drug in inappropriate containers, such as juice containers or baby bottles,[63] is a cause of unintentional methadone ingestion by children. Such events can be anticipated because methadone is frequently formulated as a palatable liquid and may not be distributed in child-resistant containers. The primary reason for distribution as a liquid, as opposed to the pill form given to patients with chronic pain syndromes, is to ensure dosing compliance at the MMTP. Unfortunately, death is frequent in children who overdose.[102]

Buprenorphine Because prescription of methadone for maintenance therapy is restricted to federally licensed programs, it is inaccessible and inconvenient for many patients. Buprenorphine was approved in 2000 as a schedule III medication for office-based prescription, administered thrice weekly, providing an attractive alternative for patients with substantially broader potential for obtaining outpatient therapy. However, because of the initial limitations on patient volume (subsequently expanded), the requirement for physician certification, and possibly the hesitation on the part of community physicians to welcome patients with substance use problems into their practices, many of the purported benefits of buprenorphine therapy over methadone have not been realized.

Buprenorphine (Subutex), a partial μ-opioid agonist, in doses of 8 to 16 mg sublingually, is effective at suppressing both opioid withdrawal symptoms and the covert use of illicit drugs. Buprenorphine for opioid substitution therapy may be preferred as an alternative to methadone because it has a better safety profile. That is, buprenorphine overdose is associated with markedly less respiratory depression than full agonists such as methadone, and there is no reported effect on the QT interval.

Buprenorphine competes with the extant opioid for the μ receptor; thus, administration of initial doses of buprenorphine in patients taking methadone for opioid substitution therapy can be complicated by opioid withdrawal, particularly in patients on higher doses of methadone. For this reason, the initial dose of buprenorphine typically is administered in the presence of a physician. The use of buprenorphine to assist opioid maintenance is limited in that many patients have difficulty stopping or decreasing their methadone dose. In patients in whom transfer from methadone to buprenorphine is indicated, dose reduction of methadone to 30 mg/day or less can reduce withdrawal symptoms precipitated by buprenorphine.[14] Buprenorphine use has been reported to result in only a mild withdrawal syndrome when abruptly discontinued and for this reason may prove efficacious in opioid detoxification programs.[3] After the initial doses of buprenorphine, sublingual tablets containing both buprenorphine and naloxone (Suboxone) are prescribed to prevent their IV use.

Buprenorphine at therapeutic doses produces nearly complete occupancy of the μ opioid receptors, where it prevents other opioids from binding.[60] Interestingly, naloxone may prevent the clinical effects of buprenorphine, but the reversal of respiratory effects by naloxone appear to be related in a nonlinear fashion. Relatively low bolus doses of IV naloxone had no effect on the respiratory depression induced by buprenorphine, but high doses (5–10 mg) caused only partial reversal of the respiratory effects of buprenorphine. More recently, data in healthy volunteers suggest a bell-shaped dose response to naloxone,[137,169] with a midrange dose of naloxone that is most effective at reversing respiratory depression. Although doses that would reverse other opioids were ineffective (0.2–0.4 mg), increasing the dose of naloxone to 2 to 4 mg caused full reversal of buprenorphine respiratory depression. However, the onset of reversal is usually slower than occurs when antagonizing other opioids.[169] Further increasing the naloxone dose to 5 to 7 mg caused a decline in reversal activity and actually increased the degree of respiratory depression. Although life-threatening respiratory depression from buprenorphine overdose appears to be rare, reversal of respiratory depression should be treated with a starting dose that is slightly higher than used to reverse other opioids and increased slowly and titrate to reversal of respiratory depression. For example, a starting dose of naloxone of 0.02 mg/kg, or between 1 and 2 mg, is reasonable, and upward titration should not provide doses in excess of about 5 mg without careful consideration and monitoring. Furthermore, because respiratory depression from buprenorphine may outlast the reversal effects of naloxone boluses or short infusions, a continuous infusion of naloxone may be required to maintain respiratory function.

As a partial agonist, buprenorphine has a ceiling effect on respiratory depression in healthy volunteers, with minimal plateau in analgesic effect.[31] However, in some patients, despite the ceiling effect, clinically consequential respiratory depression may occur.[167] Data from multiple case series indicate that most buprenorphine-related deaths are associated with concomitant use of other drugs, most often benzodiazepines, or to the IV injection of crushed tablets.[167]

The higher affinity (lower K_d) and partial agonism of buprenorphine should allow it to function as an antagonist to the respiratory depressant effects of heroin and improve spontaneous respiration. Although administration of sublingual buprenorphine for opioid overdose is reportedly successful in some case reports,[182] this practice is largely unstudied. Interestingly, some reported deaths involved patients given buprenorphine tablets intravenously by fellow drug users for the treatment of heroin-induced respiratory depression.[12]

Clonidine Clonidine, a presynaptic α_2-adrenergic agonist of the imidazoline class, is widely used by both clinicians and patients to reduce the disturbing autonomic effects of opioid withdrawal. Although clonidine is not structurally related to any opioid, in overdose, clonidine produces a clinical syndrome identical to that produced by the μ-active opioids. Mechanistically, there is functional overlap between α_2 and μ receptors within the brain (see Fig. 38–1). For these reasons, clonidine is commonly used to ameliorate the autonomic effects of opioid withdrawal. Although the autonomic abnormalities can be normalized with this approach, the psychological aspects of withdrawal, including drug craving and poor judgment, may not be alleviated.

■ UNIQUE OPIOIDS

Meperidine Meperidine, also called pethidine outside of the United States, is widely used for treatment of chronic and acute pain syndromes. Meperidine produces clinical manifestations typical of the other opioids and may lead to greater euphoria.[188] Pupillary constriction is less pronounced and, if it occurs, is less persistent than that associated with morphine.[54] However, normeperidine, a toxic, renally eliminated hepatic metabolite, accumulates in patients receiving chronic high-dose meperidine therapy, such as those with sickle cell disease or cancer. A similar accumulation occurs in patients with renal insufficiency, in whom the elimination half-life increases from a normal of 14 to 21 hours to 35 hours.[162] Normeperidine causes excitatory neurotoxicity, which manifests as delirium, tremor, myoclonus, or seizures. Based on animal studies, the seizures should not be expected to respond to naloxone.[55] In fact, experimental evidence suggests that naloxone may potentiate normeperidine-induced seizures, presumably by inhibiting an anticonvulsant effect of meperidine.[26] Hemodialysis using a high-efficiency membrane may be of limited clinical benefit but rarely, if ever, is indicated because the toxicity generally is self-limited.

Although primarily an opioid, meperidine is capable of exerting effects at other types of receptors. The most consequential nonopioid-receptor effects occur through the serotonin receptor. Blockade of the presynaptic reuptake of released serotonin may produce the serotonin syndrome, characterized by muscle rigidity, hyperthermia, and altered mental status, particularly in patients using monoamine oxidase inhibitors (MAOIs) (see Chap. 71). However, dextromethorphan (see Dextromethorphan below) also may produce this syndrome. Conversely, the simultaneous use of MAOIs and morphine, fentanyl, or methadone is not expected to produce the serotonin syndrome based on the currently appreciated pharmacology of these drugs. Despite its purported (and likely overstated) beneficial effects on biliary tract physiology, meperidine offers little to support its clinical use and has significant disadvantages. Meperidine use has been dramatically reduced or is closely monitored in many institutions and has been eliminated in other centers because of its adverse risk–benefit profile.

MPTP In 1982, several cases of acute, severe parkinsonian symptoms were identified in IV drug users.[96] The patients were labeled "frozen addicts" because of the severe bradykinesia, and extensive investigations into the etiology of the problem ensued. This ultimately led to the discovery of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), an inadvertent product of presumed errors in the attempted synthesis of the illicit meperidine analog MPPP (1-methyl-4-phenyl-4-propionoxy-piperidine). MPTP is metabolized to the ultimate toxicant MPP$^+$ by monoamine oxidase-B in glial cells. Toxicity is inhibited by pretreatment with deprenyl, a monoamine oxidase-B inhibitor. MPP$^+$ is a paraquatlike xenobiotic capable of selectively destroying the dopamine-containing cells of the substantia nigra by inhibiting mitochondrial oxidative phosphorylation.[139] The index cases initially responded to standard antiparkinsonian therapy, but none improved substantially, and the effects of the medications waned.[5] Although calamitous for exposed patients, MPTP has proved to be invaluable in the development of experimental models for the study of Parkinson's disease. Several of the original "frozen" patients subsequently underwent stereotactic implantation of fetal adrenal tissue grafts into their basal ganglia, with significant clinical improvement.[97]

Dextromethorphan Dextromethorphan is devoid of analgesic properties altogether, even though it is the optical isomer of levorphanol, a potent opioid analgesic. Based on this structural relationship, dextromethorphan is commonly considered an opioid, although its receptor pharmacology is much more complex and diversified. At high doses, dextromethorphan does bind to opioid receptors to produce miosis, respiratory depression, and CNS depression. Reversal of these opioid effects by naloxone is reported. Binding to the PCP site on the NMDA receptor, and subsequent inhibition of calcium influx through this receptor-linked ion channel, causes sedation. This same activity may account for its antiepileptic properties and for its neuroprotective effects in ischemic brain injury. Because NMDA receptor blockade also enhances the analgesic effects of μ-opioid agonists, combination therapy with morphine and dextromethorphan (MorphiDex) has been introduced.

Blockade of presynaptic serotonin reuptake by dextromethorphan may elicit the serotonin syndrome in patients receiving MAOIs.[154] Movement disorders, described as choreoathetoid or dystonialike, occasionally occur and presumably result from alteration of dopaminergic neurotransmission. Dextrorphan, the active *O*-demethylation metabolite of dextromethorphan, is produced by CYP2D6, an enzyme with a well-described genetic polymorphism.[4] Whereas patients with the "extensive metabolizer" polymorphism appear to experience more drug-related psychoactive effects, poor metabolizers experience more adverse effects related to the parent compound.[190]

Dextromethorphan is available without prescription in cold preparations, primarily because of its presumed lack of significant addictive potential. However, abuse of dextromethorphan is increasing, particularly among high school students.[8] This increase in use likely is related to the easy availability of dextromethorphan and its perceived limited toxicity. Common street names include "DXM," "dex," and "robo-shots." Users often have expectations of euphoria and hallucinations, but a dysphoria comparable to that of PCP commonly ensues. Reports of substantial cold medicine consumption raise several concerns, including acetaminophen poisoning, opioid dependency, and bromide toxicity.[75] This last concern relates to the common formulation of dextromethorphan as the hydrobromide salt. At times, the first clue may be an elevated serum chloride concentration when measured on certain autoanalyzers (see Chaps. 6 and 16).

Tramadol Tramadol (Ultram) is a novel synthetic analgesic with both opioid and nonopioid mechanisms responsible for its clinical effects. Although it binds only weakly to μ opioid receptors, tramadol exhibits cross-tolerance with morphine in rats, suggesting an opioid-mediated mechanism of analgesia.[88] The demethylated tramadol metabolite M1 exhibits higher-affinity binding to receptors in vitro and may be important in patients chronically using the drug. However, the role of M1 as an acute analgesic is not well defined. Naloxone only partially reverses tramadol-induced analgesia in mice and in humans, suggesting that an independent, nonopioid mechanism is also involved in mediating the clinical effects of tramadol. This effect appears to be inhibition of reuptake of biogenic amines, specifically serotonin and norepinephrine. This mechanism is supported by the nearly complete reversal of analgesic efficacy by yohimbine, an α_2-adrenergic antagonist that inhibits release of these neurotransmitters. Patients using MAOIs may be at risk for development of the serotonin syndrome.

A large number of spontaneous reports to the Food and Drug Administration suggest that therapeutic use of tramadol may cause seizures, particularly on the first day of therapy. However, epidemiologic studies have not confirmed this association.[50] Tramadol-related seizures are not responsive to naloxone but are suppressed with benzodiazepines. In fact, the package insert cautions against using naloxone in patients with tramadol overdoses because in animals treated with naloxone, the risk of seizure is increased. Correspondingly, one patient in a prospective series had a seizure that was temporally related to naloxone administration.[155] Acute overdose of tramadol is generally considered non–life threatening, and most fatalities were associated with polysubstance overdose.

Tramadol abuse is reported, but its extent is undefined. In a review of physician drug abuse in several states, tramadol was the second most frequent opioid reported.[148] Opioid users recognized tramadol as an opioid only when given in an amount that was six times the therapeutic dose, but at this dose, the users did not develop opioid-like clinical effects such as miosis. Patients may develop typical opioid manifestations after a large overdose. Significant respiratory depression is uncommon and should respond to naloxone.[155] Generally, urine drug screening for drugs of abuse is negative for opioids in tramadol-exposed patients.

Propoxyphene Propoxyphene is a weak analgesic with limited efficacy data and serious safety concerns. Similar to its structural analog methadone, propoxyphene binds μ-opioid receptors and produces the expected opioid clinical findings. However, unanticipated properties of propoxyphene manifest after overdose. Propoxyphene and its hepatic metabolite, norpropoxyphene, produce myocardial sodium channel blockade identical to the type IA antidysrhythmics. This process results in QRS complex widening and negative inotropy. QRS prolongation was identified in 42 (19%) of 222 propoxyphene-poisoned patients.[149] These symptoms can be corrected with parenteral administration of hypertonic sodium bicarbonate or with lidocaine (see A5 Sodium Bicarbonate). As in patients with tricyclic antidepressant overdose, the sodium ion component of the sodium bicarbonate enhances sodium influx through a partially occluded sodium channel by augmenting the extracellular to intracellular sodium concentration gradient. The paradoxical effect of lidocaine, another sodium channel blocker, can be explained by the very different dissociation constants of these two xenobiotics with the sodium channel. Lidocaine may competitively displace propoxyphene and norpropoxyphene, both more highly toxic sodium channel blockers. Naloxone has never been shown to be effective therapy for the cardiotoxic effects of propoxyphene, although hemodynamic improvement in one reported case probably was related to naloxone-induced propoxyphene withdrawal.[62]

Propoxyphene overdose may produce acute CNS toxicity that usually manifests as seizures. In one study of propoxyphene-overdosed patients, 10% of the subjects developed seizures.[149] Although the exact mechanism is unclear, experimental models demonstrate that propoxyphene, and not norpropoxyphene, is capable of inducing seizures. Therapy for seizures should follow standard management strategies, including benzodiazepines or barbiturates. High-dose naloxone (60 mg/kg intraperitoneally) prevents experimental propoxyphene-induced seizures,[55] but its role in seizure termination is undefined.

Propoxyphene use and overdose in the United States is relatively uncommon compared with the other opioids. However, in the United Kingdom, propoxyphene overdose may account for up to 5% of all suicides.[64] Propoxyphene often is formulated with acetaminophen (Darvocet-N, Coproxamol) or salicylates (Darvon compound) to enhance the analgesic effects. Patients who overdose on the combinations may experience toxicity from either of these two nonopioid analgesics. Because patients consequently may be acetaminophen poisoned yet be asymptomatic or manifest only opioid toxicity, empiric quantitative serum analysis for acetaminophen is indicated. Delayed peak serum acetaminophen concentrations after ingestion of combination opioid products may occur. The precise clinical implication of this delay is unclear (see Chap 34). Furthermore, the respiratory depressant effects of propoxyphene may hinder the ability to detect salicylate poisoning by clinical examination, suggesting a situation in which empiric laboratory testing for salicylates may be indicated.

Diphenoxylate and Loperamide Although diphenoxylate is structurally similar to meperidine, its extreme insolubility limits absorption from the GI tract. This factor may enhance its use as an antidiarrheal agent, which presumably occurs via a local opioid effect at the GI μ receptor. However, the standard adult formulation may result in significant systemic absorption and toxicity in children, and all such ingestions should be deemed consequential. Diphenoxylate is formulated with a small dose (0.025 mg) of atropine (as Lomotil), both to enhance its antidiarrheal effect and to discourage illicit use.

Because both components of Lomotil may be absorbed and their pharmacokinetic profiles differ somewhat, a biphasic clinical syndrome is occasionally noted.[111] Patients may manifest atropine poisoning (anticholinergic syndrome), either independently or concomitantly with the opioid effects of diphenoxylate. Delayed, prolonged, or recurrent toxicity is common and is classically related to the delayed gastric emptying effects inherent to both opioids and anticholinergics. However, these effects are more likely explained by the accumulation of the hepatic metabolite difenoxin, which is a significantly more potent opioid than diphenoxylate and possesses a longer serum half-life. Still, the relevance of gastroparesis is highlighted by the retrieval of Lomotil pills by gastric lavage as late as 27 hours postingestion.

A review of 36 pediatric reports of Lomotil overdoses found that although naloxone was effective in reversing the opioid toxicity, recurrence of CNS and respiratory depression was common.[111] This series included a patient with an asymptomatic presentation 8 hours postingestion who was observed for several hours and then discharged. This patient returned to the ED 18 hours postingestion with marked signs of atropinism. In this same series, children with delayed onset of respiratory depression and other opioid effects were reported, and others describe cardiopulmonary arrest 12 hours postingestion. Naloxone infusion may be appropriate for patients with recurrent signs of opioid toxicity. Because of the delayed and possibly severe consequences, all children, and adult patients with potentially significant ingestions, should be admitted for monitored observation in the hospital.

Loperamide (Imodium) is another insoluble meperidine analog that is used to treat diarrhea. This medication is available without a prescription, and the paucity of adverse patient outcomes reported in the medical literature suggests the safety profile of this agent is good.

◼ CLOSTRIDIAL INFECTIONS

Heroin-related clostridial infections, although uncommon, present in a manner similar to those of conventional botulism or tetanus but may be atypical (see Chap. 46).[16] Interestingly, during the 1950s and early 1960s, users of quinine-adulterated heroin in New York City[21] and Chicago[99] were substantially more likely to develop tetanus than were users of nonquinine-adulterated heroin. This likely is a result of the extensive tissue destruction caused by SC quinine administration, which also occurs in patients receiving therapeutic IM quinine. "Black tar heroin," an impure form of heroin, is implicated in multiple epidemics of wound botulism.[18] Whether the minimally processed heroin was contaminated with *Clostridium botulinum* or whether it led to improved anaerobic growing conditions for the spores is not known. Early antitoxin therapy is associated with improved outcome. Other *Clostridia* species (eg, *C. novyi* and *C. sordellii*) are responsible for epidemics of necrotizing fasciitis that are common among users of black tar heroin. Nearly half of the victims of necrotizing fasciitis die of the disease.

SUMMARY

Opioid use is widespread. Overdose and toxicity, both intentional and unintentional, remain major causes of drug-related morbidity and mortality. Lethality related to opioids is primarily caused by respiratory

depression. Thus mechanical ventilation, or administration of a short-acting opioid antagonist such as naloxone, should be adequate initial therapy. An appreciation of the pharmacologic differences between the various opioids allows for the identification and appropriate management of patients poisoned or otherwise adversely affected by these xenobiotics.

Naltrexone
Nalmefene

Naloxone, nalmefene, naltrexone, and methylnaltrexone are pure competitive opioid antagonists at the mu (μ), kappa (κ), and delta (δ) receptors. Opioid antagonists prevent the actions of opioid agonists, reverse the effects of both endogenous and exogenous opioids, and cause opioid withdrawal in opioid-dependent patients. Naloxone is primarily used to reverse respiratory depression in patients manifesting opioid toxicity. The parenteral dose should be titrated to maintain adequate airway reflexes and ventilation. By titrating the dose, beginning with 0.04 mg and increasing as indicated to 0.4 mg, 2 mg, and finally 10 mg, abrupt opioid withdrawal can be prevented. This method of administration limits withdrawal-induced adverse effects, such as vomiting and the potential for aspiration pneumonitis, and a surge in catecholamines with the potential for cardiac dysrhythmias and acute lung injury (ALI). Because of its poor oral bioavailability, oral naloxone may be used to treat patients with opioid-induced constipation. Methylnaltrexone is a parenteral medication and alvimopan an oral capsule that fail to enter the central nervous system (CNS) and are uniquely effective in reversing opioid-induced constipation. Naltrexone is used orally for patients after opioid detoxification to maintain opioid abstinence and as an adjunct to achieve ethanol abstinence. Nalmefene is available for parenteral use with a duration of action between those of naloxone and naltrexone.

HISTORY

The understanding of structure–activity relationships led to the synthesis of many new molecules in the hope of producing potent opioid agonists free of abuse potential. Although this goal has not yet been achieved, opioid antagonists and partial agonists resulted from these investigations. N-Allylnorcodeine was the first opioid antagonist synthesized (in 1915), and N-allylnormorphine (nalorphine) was synthesized in the 1940s.[39,83] Nalorphine was recognized as having both agonist and antagonist effects in 1954. Naloxone was synthesized in 1960, and naltrexone was synthesized in 1963.

CHEMISTRY

Minor alterations can convert an agonist into an antagonist.[38] The substitution of the N-methyl group on morphine by a larger functional group led to nalorphine and converted the agonist levorphanol to the antagonist levallorphan.[35] Naloxone, naltrexone, and nalmefene are derivatives of oxymorphone with antagonist properties resulting from addition of organic or other functional groups.[35,42] Relatedly, nalmefene is a 6-methylene derivative of naltrexone.

PHARMACOLOGY

The μ receptors are responsible for analgesia, sedation, miosis, euphoria, respiratory depression, and decreased gastrointestinal (GI) motility. κ receptors are responsible for spinal analgesia, miosis, dysphoria, anxiety, nightmares, and hallucinations. δ receptors are responsible for analgesia and hunger. The currently available opioid receptor

antagonists are most potent at the μ receptor, with higher doses required to affect the κ and δ receptors. They all bind to the opioid receptor in a competitive fashion, preventing the binding of agonists, partial agonists, or mixed agonist–antagonists without producing any independent action. Naloxone, naltrexone, and nalmefene are similar in their antagonistic mechanism but differ primarily in their pharmacokinetics. Both nalmefene and naltrexone have longer durations of action than naloxone, and both have adequate oral bioavailability to produce systemic effects. Methylnaltrexone can be given orally or parenterally but is excluded from the CNS and only produces peripheral effects. Selective antagonists for μ, κ, and δ are available experimentally and are undergoing investigation.[62]

In the proper doses, pure opioid antagonists reverse all of the effects at the μ, κ, and δ receptors of endogenous and exogenous opioid agonists, except for those of buprenorphine, which has a very high affinity for and slow rate of dissociation from the μ receptor.[62,63] Actions of opioid agonists that are not mediated by interaction with opioid receptors, such as direct mast cell liberation of histamine or the sodium channel-blocking effects of propoxyphene, are not reversed by these antagonists.[3] Chest wall rigidity from rapid fentanyl infusion is usually reversed with naloxone.[23] Opioid-induced seizures in animals, such as from propoxyphene, tend to be antagonized by opioid antagonists, though seizures caused by meperidine (normeperidine) and tramadol are exceptions.[6,30] The benefit in humans is less clear. A report of two newborns who developed seizures associated with fentanyl and morphine infusion demonstrated abrupt clinical and electroencephalographic resolution after administration of naloxone.[13]

Opioids operate bimodally on opioid receptors.[10] At low concentrations, μ opioid receptor agonism is excitatory and actually antianalgesic. This antianalgesic effect is modulated through a G_s protein and usually is less important clinically than the well-known inhibitory actions that result from coupling to a G_o protein at usual analgesic doses. For this reason, extremely low doses of opioid antagonists (ie, 0.25 mcg/kg/h of naloxone) enhance the analgesic potency of opioids, including morphine, methadone, and buprenorphine.[11,29,48] Naloxone also attenuates or prevents the development of tolerance and dependence.[10,29] Coadministration of these very low doses of antagonists or derivatives with the opioid also limits opioid-induced adverse effects such as nausea, vomiting, constipation, and pruritus.[97]

Opioid antagonists may reverse the effects of endogenous opioid peptides, including endorphins, dynorphins, and enkephalins. Endogenous opioids are found in tissues throughout the body and may work in concert with other neurotransmitter systems to modulate many physiologic effects.[22,84,86] For instance, during shock, the release of circulating endorphins produces an inhibition of central sympathetic tone by stimulating κ receptors within the locus coeruleus, resulting in vasodilation. Vagal tone is also enhanced through stimulation of opioid receptors in the nucleus ambiguus.

Research investigating the cardioprotective effects of opioid agonists through their action at the sarcolemmal and mitochondrial K^+ ATP (adenosine triphosphate) channels is ongoing.[64,69,73] Nonselective opioid antagonists may negate these protective effects.

PHARMACOKINETICS AND PHARMACODYNAMICS

The bioavailability of sublingual naloxone is only 10%.[5,38] In contrast, naloxone is well absorbed by all parenteral routes of administration, including the intramuscular (IM), subcutaneous (SC), endotracheal, intranasal, intralingual, and inhalational (nebulized) routes. The onset of action with the various routes of administration are as follows: IV, 1-2 minutes; SC, approximately 5.5 minutes; intralingual, 30 seconds; intranasal, 3.4 minutes; inhalational, 5 minutes; endotracheal, 60 seconds; and IM, 6 minutes.[19,43,52,5878,94] The distribution half-life is rapid (~5 minutes) because of its high lipid solubility. The volume of distribution (Vd) is 0.8 to 2.64 L/kg.[31,33]

A naloxone dose of 13 μg/kg in an adult occupies approximately 50% of the available opioid receptors.[54] The duration of action of naloxone is approximately 20 to 90 minutes and depends on the dose of the agonist, the dose and route of administration of naloxone, and the rates of elimination of the agonist and naloxone.[5,21,85] Naloxone is metabolized by the liver to several compounds, including a glucuronide. The elimination half-life is 60 to 90 minutes in adults and approximately two to three times longer in neonates.[60]

Naltrexone is rapidly absorbed with an oral bioavailability of 5% to 60%, and peak serum concentrations occur at 1 hour.[34,89,93] Distribution is rapid, with a Vd of approximately 15 L/kg and low protein binding.[48] Naltrexone is metabolized in the liver to β-naltrexol (with 2%–8% activity) and 2-hydroxy,3-methoxy-β-naltrexol,[88] and undergoes an enterohepatic cycle.[93] The plasma elimination half-life is 10 hours for β-naltrexone and 13 hours for β-naltrexol,[88,92,93] with a terminal phase of elimination of 96 hours and 18 hours, respectively.[89]

Nalmefene has an oral bioavailability of 40%, with peak serum concentrations usually reached within 1 to 2 hours.[17] However, in the United States, it is currently available only in a parenteral formulation. After SC administration, peak concentrations do not occur for more than 2 hours, though therapeutic concentrations are reached within 5 to 15 minutes.[59] A 1-mg parenteral dose blocked more than 80% of opioid receptors within 5 minutes.[59] The apparent Vd is 3.9 L/kg for the central compartment and 8.6 L/kg at steady state.[59] Protein binding is approximately 45%.[16] Nalmefene has a redistribution half-life of 41 ± 34 minutes and a terminal half-life of 10.8 ± 5 hours after a 1-mg intravenous (IV) dose.[59] It is metabolized in the liver to an inactive glucuronide conjugate that probably undergoes enterohepatic recycling, accounting for approximately 17% of drug elimination in the feces. Less than 5% is excreted unchanged in the urine.

Methylnaltrexone is a quaternary amine methylated derivative of naltrexone that is peripherally restricted because of its poor lipid solubility and inability to cross the blood–brain barrier.[97] After SC administration, peak serum concentrations occur in about 30 minutes. The drug has a Vd of 1.1 L/kg and is minimally protein bound (11%–15%).[59] Although there are several metabolites, 85% of the drug is eliminated unchanged in the urine.[97]

ADVERSE DRUG EFFECTS

Pure opioid antagonists produce no clinical effects in opioid naïve or nondependent patients, even when administered in massive doses.[7]

When exposed to opioid antagonists or agonist–antagonists such as pentazocine, patients dependent upon opioid agonists exhibit opioid withdrawal reactions, including yawning, lacrimation, diaphoresis, rhinorrhea, piloerection, mydriasis, vomiting, diarrhea, myalgias, mild elevations in heart rate and blood pressure, and insomnia. Antagonist-precipitated withdrawal may result in an "overshoot" phenomenon, from a transient increase in circulating catecholamines, resulting in hyperventilation, tachycardia, and hypertension. Under these circumstances, there is a potential for related complications such as myocardial ischemia, heart failure, CNS injury.[45,57] Delirium, although rarely reported with gradual withdrawal, may occur when an opioid antagonist is used to reverse effects in patients dependent upon high doses of opioids or during rapid opioid detoxification.[32] Delirium is unique to these circumstances and is not described in patients withdrawing by opioid abstinence. These

severe manifestations of precipitated opioid withdrawal may occur with ultrarapid opioid detoxification, and are associated with fatalities occurring in the postadministration period.[37] This rapid form of enforced detoxification differs significantly from the opioid withdrawal associated with volitional opioid abstinence (see Chap. 14).

Case reports describe ALI, hypertension, and cardiac dysrhythmias in association with naloxone administration, generally in opioid-dependent patients.[26,56,66,72,77] The clinical complexities of the setting and case reports make it difficult to analyze and attribute these adverse effects solely to naloxone.[8] ALI occurs after heroin overdose in the absence of naloxone,[20] making the exact contribution of naloxone to the problem unclear. Rather, in certain patients, naloxone may unmask ALI previously induced by the opioid but unrecognized because of the patient's concomitant opioid-induced respiratory depression.[20]

If the patient's airway is unprotected during withdrawal and vomiting occurs, aspiration pneumonitis may complicate the recovery. Given the frequency of polysubstance abuse and overdose associated with altered consciousness, the risk of precipitating withdrawal associated vomiting should always be a concern.

Resedation is a function of the relatively short duration of action of the opioid antagonist compared with the opioid agonist. Most opioid agonists have durations of action longer than that of naloxone and shorter than that of naltrexone; the relationship is variable with nalmefene. A long duration of action is advantageous when the antagonist is used to promote abstinence (naltrexone) but is undesired when inappropriately administered to an opioid-dependent patient.

Unmasking underlying cocaine or other stimulant toxicity may explain some of the cardiac dysrhythmias that develop after naloxone-induced opioid reversal in a patient simultaneously using both opioids and stimulants[55] (see Chap. 76).

Antagonists stimulate the release of hormones from the pituitary, resulting in increased concentrations of luteinizing hormone, follicle-stimulating hormone, and adrenocorticotropic hormone and stimulate the release of prolactin in women.[70]

USE OF OPIOID ANTAGONISTS FOR MAINTENANCE OF OPIOID ABSTINENCE

Opioid dependence is managed by substitution of the abused opioid, typically heroin or a prescription opioid, with methadone or buprenorphine or by detoxification and subsequent abstinence. Maintenance of abstinence is often assisted by naltrexone, although any pure opioid antagonist could be used. Typically, naltrexone is chosen because of its oral absorption and long duration of action compared with that of naloxone or nalmefene.[47,53]

When 1 mg of naloxone is administered IV, it prevents the action of 25 mg of IV heroin for 1 hour, whereas 50 mg of oral naltrexone antagonizes this dose of heroin for 24 hours; 100 mg has a blocking effect for 48 hours, and 150 mg is effective for 72 hours. Nalmefene antagonizes the action of 2 μg/kg of IV fentanyl with a duration of action that is similarly dose dependent: 0.5 mg IV last about 4 hours, 2 mg IV lasts about 8 hours, and 50 mg orally lasts about 50 hours.[27,28]

Before naltrexone can be administered for abstinence maintenance, the patient must be weaned from opioid dependence and be a willing participant. Naloxone should be administered IV to confirm that the patient is no longer opioid dependent and safe for naltrexone. With naloxone, opioid withdrawal, if it occurs, will be short lived instead of prolonged after use of naltrexone or nalmefene. Naltrexone does not produce tolerance, although prolonged treatment with naltrexone produces upregulation of opioid receptors.[96]

USE OF OPIOID ANTAGONISTS FOR ETHANOL ABSTINENCE

Naltrexone, particularly the IM depot form, is used as adjunctive therapy in ethanol dependence, based on the theory that the endogenous opioid system modulates ethanol intake.[65,92] Naltrexone reduces ethanol craving, the number of drinking days, and relapse rates.[68] Naltrexone induces moderate to severe nausea in 15% of these patients, possibly as a result of alterations in endogenous opioid tone induced by prolonged ethanol ingestion.[61,92]

OTHER USES

Poorly orally bioavailable opioid antagonists (eg, naloxone) and peripherally restricted opioid antagonists (eg, methylnaltrexone) are used to prevent or treat the constipation occurring as a side effect of opioid pain management.[1,50,97] Methylnaltrexone administered SC results in laxation within 4 hours in nearly half of those who receive the drug for this indication.[81,98]

Take-home naloxone programs are developing around the world. In these programs, opioid abusers are supplied naloxone to be administered to other users after opioid overdose, generally by the SC or intranasal route.[2,76] These bystander programs are credited with saving numerous lives, although concerns exist regarding proper dosing, relative safety, use in mixed overdose, attempts to overcome precipitated withdrawal, and refusal of Emergency Medical Services involvement.

Opioid antagonists are used infrequently in the management of overdoses with nonopioids such as ethanol,[18,75] clonidine,[74] captopril,[87] and valproic acid.[80] In none of these instances is the reported improvement as dramatic or consistent as in the reversal of an opioid. The mechanisms for each of these, though undefined, may relate to reversal of endogenous opioid peptides at opioid receptors.

Naloxone has been used to reverse the effects of endogenous opioid peptides in patients with septic shock, although the results are variable. Treatment is often ineffective and may result in adverse effects, particularly in patients who are opioid tolerant.[15,82] Naloxone may have a temporizing effect via elevation of mean arterial pressure.[36]

Although promising in animal models of spinal cord injury, an investigation of naloxone at doses approximately 100 times greater than those used in the management of overdoses failed to demonstrate improvement in neurologic recovery in humans.[7]

Opioid antagonists are used for treatment of morphine-induced pruritus resulting from systemic or epidural opioids[41,46] and for treatment of pruritus associated with cholestasis.[14,79]

DOSING

The initial dose of antagonist is dependent on the dose of agonist and the relative binding affinity of the agonist and antagonist at the opioid receptors. The presently available antagonists have a greater affinity for the μ receptor than for the κ or δ receptors. Some opioids, such as buprenorphine (see below), require greater than expected doses of antagonist to reverse the effects at the μ receptor.[85,95] The duration of action of the antagonist depends on many drug and patient variables, such as the dose and the clearance of both antagonist and agonist.

A dose of naloxone 0.4 mg IV will reverse the respiratory depressant effects of most opioids and is an appropriate starting dose in nonopioid-dependent patients. However, this dose in an opioid-dependent patient usually produces withdrawal, which should be avoided if

possible. The goal is to produce a spontaneously and adequately ventilating patient without precipitating significant or abrupt opioid withdrawal. Therefore, 0.04 mg is a practical starting dose in most patients, increasing to 0.4 mg, 2 mg, and finally 10 mg. If the patient has no response to 8 to 10 mg, then an opioid is not likely to be responsible for the respiratory depression. The dose in children without opioid dependence is essentially the same as for adults. However, for those with the possibility of withdrawal or recrudescence of severe underlying pain, more gentle reversal with 0.001 mg/kg, with concomitant supportive care, is warranted. Although both the adult and pediatric doses recommended here are lower than those conventionally suggested in other references, the availability of safe and effective interim ventilatory therapy lower the acceptable risk of precipitating withdrawal.

The use of low doses of IV naloxone to reverse opioid overdose may prolong the time to improvement of ventilation, and during this period, assisted ventilation may be required. The same limitation exists with SC naloxone administration, and the absorbed dose is more difficult to titrate than when administered IV.[94] Naloxone can also be administered intranasally, although this route results in the delivery of unpredictable doses. In the prehospital setting, the time to onset of clinical effect of intranasal naloxone is comparable to that of IV or IM naloxone, largely because of the delay in obtaining IV access and slow absorption, respectively.[4,43,] Intranasal naloxone is not currently recommended as first-line treatment by healthcare providers.[44] Nebulized naloxone (2 mg is mixed with 3 mL of 0.9% sodium chloride solution) has similar limitations in dose accuracy and is further limited in patients with severe ventilatory depression, the group most in need of naloxone. These patients are not optimal candidates for inhalation therapy because delivery of a sufficient reversal dose may not occur. Although needleless delivery is a clear prehospital advantage, there is little role for inhospital use of intranasal or nebulized naloxone.

Evaluation for the redevelopment of respiratory depression requires nearly continuous monitoring. Resedation should be treated with either repeated dosing of the antagonist or, in some cases, such as after a long-acting opioid agonist, with another bolus followed by a continuous infusion of naloxone. Two-thirds of the bolus dose of naloxone that resulted in reversal, when given hourly, usually maintains the desired effect.[33] This dose can be prepared for an adult by multiplying the effective bolus dose by 6.6, adding that quantity to 1000 mL, and administering the solution IV at an infusion rate of 100 mL/h. Titration upward or downward is easily accomplished as necessary to both maintain adequate ventilation and avoid withdrawal. A continuous infusion of naloxone is not a substitute for continued vigilance. A period of 12 to 24 hours often is chosen for observation based on the presumed opioid, the route of administration, and the dosage form (eg, sustained release). Body packers are a unique subset of patients who, because the reservoir of drug in the GI tract, require individualized antagonist management strategies (see Special Considerations: SC-4 Internal Concealment of Xenobiotics.

Naloxone is a pregnancy Category C drug.[60] A risk-to-benefit analysis must be considered in pregnant women, particularly those who are opioid tolerant, and their newborns. Inducing opioid withdrawal in the mother probably will induce withdrawal in the fetus and should be avoided. Likewise, administering naloxone to newborns of opioid-tolerant mothers may induce neonatal withdrawal[40] (see Chaps. 30, 31, and 38).

Use of longer-acting opioid antagonists, such as naltrexone and nalmefene, places the patient at substantial risk for protracted withdrawal syndromes. The use of a long-acting opioid antagonist in acute care situations should be reserved for carefully considered special indications, together with extended periods of observation or careful follow-up. An oral dose of 150 mg of naltrexone generally lasts 48 to 72 hours and should be adequate as an antidote for the majority of opioid-intoxicated patients. Discharge of opioid-intoxicated patients after successful administration of a long-acting opioid antagonist, while theoretically attractive, is not well studied. There are concerns about attempts by patients to overcome opioid antagonism by administering high doses of opioid agonist, with subsequent respiratory depression as the effect of the antagonist wanes.

Naltrexone is administered orally in a variety of dosage schedules for treatment of opioid dependence. A common dosing regimen is 50 mg/day Monday through Friday and 100 mg on Saturdays. Alternatively, 100 mg every other day or 150 mg every third day can be administered. The IM extended-release suspension is injected monthly at a recommended dose of 380 mg.[47]

The initial IV dose of nalmefene is 0.1 mg in a 70-kg person in whom opioid dependency is suspected. If withdrawal does not ensue, 0.5 mg can be given, followed by 1 mg in 2 to 5 minutes as necessary. If IV access is unavailable, the IM or SC route can be used, but the onset of action is delayed by 5 to 15 minutes after a 1-mg dose. For reversal of postoperative opioid respiratory depression, a starting dose of 0.25 μg/kg is used followed by incremental doses of 0.25 μg/kg every 2 to 5 minutes to the desired effect or to a total of 1 μg/kg.

Methylnaltrexone SC dosing for opioid-induced constipation is weight based.[98] The dose is 0.15 mg/kg for patients who weigh less than 38 kg and more than 114 kg. For patients who weigh between 38 and less than 62 kg, 8 mg is administered, and for those between 62 and 114 kg, 12 mg is provided. Dosing for patients with renal failure is required at half the recommended dose.

MANAGEMENT OF OVERDOSE

Although the opioid antagonists are all safe in overdose, excessive administration to an opioid-dependent patient will predictably result in opioid withdrawal. When induced by naloxone, all that is generally required is protecting the patient from harm and reassuring the patient that the effects will be short lived. Symptomatic care may be necessary on occasion. After inadvertent administration of nalmefene or naltrexone, the expected duration of the withdrawal syndrome generally mandates the use of pharmacologic intervention.[25,51] Overcoming the opioid receptor antagonism is difficult, but if used in titrated doses, morphine or fentanyl may be successful. Adverse effects from histamine release from morphine and chest wall rigidity from fentanyl should be expected. If more moderate withdrawal is present, the administration of metoclopramide, clonidine, or a benzodiazepine is usually adequate.[45]

What constitutes an appropriate observation period depends on many factors. After IV bolus naloxone, observation for 2 hours should be adequate to determine whether sedation and respiratory depression will return. Although no fatalities were identified in medical examiner records after the rapid prehospital release of patients who had presumably overdosed with heroin and were administered naloxone, the true safety of this practice remains questionable.[9] Although the matched pharmacokinetics of heroin and naloxone suggests potential utility for such a practice, the high frequency of methadone or sustained-release oxycodone use in many communities raises concerns. That is, the pharmacokinetic mismatch of both methadone and sustained-release oxycodone with naloxone results in recurrent opioid toxicity and prevents widespread implementation of this program.[90] Similarly, patients on continuous naloxone infusion must be observed for ≥2 hours after its discontinuation to ensure that respiratory depression does not recur.

The experience with nalmefene is too limited to estimate an adequate observation period, although 24 hours seems prudent to allow sufficient time for underlying opioid toxicity to resurface.

■ BUPRENORPHINE

Naloxone reverses the respiratory depressant effects of buprenorphine in a bell-shaped dose–response curve.[12,71,85,95] Bolus doses of naloxone between 2 to 3 mg followed by a continuous infusion of 4 mg/h in adults were able to fully reverse the respiratory depression associated with IV buprenorphine administered in a total dose of 0.2 and 0.4 mg over 1 hour.[85] Reversal was not apparent until about 45 to 60 minutes after the infusion. A reappearance of respiratory depression occurred when the naloxone infusion was stopped because the distribution of naloxone out of the brain and its subsequent elimination from the body are much faster than those of buprenorphine. Consistent with a bell-shaped response curve, doses of naloxone greater than 4 mg/h actually led to the recurrence of respiratory depression. It is postulated that buprenorphine has differential effects on the μ opioid receptor subtypes (see Chap. 38), with agonist activity at low doses and antagonist action at high doses. Therefore, excess naloxone antagonizes the antagonistic effects of buprenorphine, worsening respiratory depression.

AVAILABILITY

Naloxone (Narcan) for IV, IM, or SC administration is available in concentrations of 0.02, 0.4, and 1.0 mg/mL, with and without parabens in 1- and 2-mL ampules and in 10-mL multidose vials with parabens. Naloxone can be diluted in 0.9% sodium chloride solution or 5% dextrose to facilitate continuous IV infusion. Naloxone is stable in 0.9% sodium chloride solution at a variety of concentrations for up to 24 hours.[24]

Nalmefene (Revex) is available in a 1-mL ampule containing 100 μg/mL and in a 2-mL ampule containing 1 mg/mL.

Naltrexone (Revia, Trexan) is available as a 50-mg capsule-shaped tablet. It is also available as a 380-mg vial for reconstitution with a carboxymethylcellulose and polysorbate diluent to form an injectable suspension intended for monthly IM administration (Vivitrol).

Methylnaltrexone (Relistor) is available as a 12 mg/0.6 mL solution for SC injection.[67]

FOODS, DIETARY AND NUTRITIONAL XENOBIOTICS

CHAPTER 39

DIETING AGENTS AND REGIMENS

Jeanna M. Marraffa
Ephedrine
Dinitrophenol

Obesity is a worldwide epidemic. Nearly 60% of Americans are overweight and 30% are obese (body mass index [BMI] >30 kg/m²).[26,55] Even more alarming, the incidence of obesity in children between the ages of 6 and 19 years has tripled in the past 30 years.[9] Nearly 9 million children and adolescents are now considered overweight.[9] Obesity contributes to 325,000 deaths annually in the United States.[5] Obesity is linked to numerous health risks, including type II diabetes, hypertension, coronary heart disease,[9,19] metabolic syndrome[138] and even low back pain.[119] Because of this, it can be considered a leading preventable health risk, second only to cigarette smoking. In the past several decades, research has been dedicated to the pathophysiology of obesity and to novel therapeutic approaches. Genetic links, including particular gene polymorphisms, have been identified and are being pursued.[3,23,73]

Americans spend $33 billion per year on weight loss therapies and modalities. Dieting and weight loss are attempted by many more people than just those who are overweight and obese by medically defined criteria. Weight loss management is difficult and frequently even the best lifestyle modifications only result in a modest weight loss in a majority of people. Pharmacologic interventions may result in a 5% to 10% weight loss, although a return to baseline upon drug cessation is common.[40] Surgical interventions consistently achieve substantial weight loss, causing up to a 30% reduction in weight, but are not free from complications.[2,16]

Obesity and attempts at weight loss have probably existed since antiquity. One of the earliest accounts of weight loss therapy dates back to 10th-century Spain. King Sancho I, who was obese, underwent successful treatment with a "theriaca," thought to contain plants and possibly opioids, administered with wine and oil. In addition, he was closely supervised and treated by a physician.[60]

Currently, medicinal weight loss therapies (Table 39–1) are available as prescription medications (sibutramine, phentermine); nonprescription dietary supplements (*Citrus aurantium*, chitosan, *Garcinia cambogia,* caffeine); and in late 2007, orlistat, a fat blocker, was approved as a nonprescription diet aid. Acquisition and utilization of natural weight loss remedies have undergone a resurgence since passage of the Dietary Supplement Health and Education Act (DSHEA) of 1994, which created a new category separate from food and drugs. As a result of the DSHEA, numerous botanicals and other substances are offered to consumers as weight loss aids, some with no proven efficacy and some with potentially serious toxicity.

Although dieting aids can be divided into disparate classes, they generally act through one or more of the following mechanisms: (1) appetite suppression, known as *anorectics*; (2) alteration of food absorption or elimination; or (3) increased energy expenditure. The endocannabinoid receptor antagonists such as rimonabant, work in a unique way and have multiple effects, including appetite suppression. Dieting aids that are anorectics are designed to decrease appetite and calorie intake.

The history of dieting agents has a checkered past. A number of weight loss therapies have been withdrawn or banned by the Food and Drug Administration (FDA) because of serious adverse health effects (Table 39–2). For example, phenylpropanolamine (PPA) was withdrawn from the market because of its association with hemorrhagic stroke. Fenfluramine–phentermine (Fen-Phen) was linked to cardiac valvulopathy and primary pulmonary hypertension. γ-Hydroxybutyrate (GHB) and its congeners were initially sold as a dietary supplement (see Chap. 80) and promoted to body builders as a means to "convert fat into muscle" as a result of GHB's effect on growth hormone. Because of overdose toxicity and its association with drug-facilitated sexual assault, GHB is strictly controlled as a Schedule I agent, with limited availability as a Schedule III drug for narcolepsy sodium oxybate (Xyrem). Clenbuterol is a long-acting β_2-adrenergic agonist with β_3-adrenergic agonist effects. Because of its stimulant properties and lipolytic effects, clenbuterol is abused by body builders as an energy source and anoretic agent.[58] Clenbuterol recently has been suggested by celebrities to be an effective diet aid (see Chap. 44).

SYMPATHOMIMETICS

Although controversial, certain sympathomimetic amines still carry official indications for short-term weight reduction (see Table 39-1). Sympathomimetic amines share a β-phenylethylamine parent structure and include phentermine, diethylpropion, and mazindol, which are restricted as Schedule IV agents and carry warnings that advise prescribers to limit use to only a few weeks. Regardless of their source and legal status, sympathomimetics generally share a spectrum of toxicity and produce adverse effects similar to amphetamines (see Chap. 75).

TABLE 39–1. Available Weight Loss Drugs and Dietary Supplements

Drug or Supplement[a]	Mechanism of Action	Regulatory Status	Adverse Effects/Contraindications[b]
Sympathomimetics			
Diethylpropion (Tenuate)	Increased release of norepinephrine and dopamine	Schedule IV prescription drug	Dry mouth, tremor, insomnia, headache, agitation, palpitations, hypertension, stroke, dysrhythmias
Mazindol (Mazanor, Sanorex)	Increased release of norepinephrine and dopamine	Schedule IV prescription drug	Contraindications: MAOI use within 14 days, glaucoma, hyperthyroidism
Phentermine (Fastin, Adipex)	Increased release of norepinephrine and dopamine	Schedule IV prescription drug	
Bitter orange extract (*Citrus aurantium*)	Contains synephrine and octopamine; increases thermogenesis and lipolysis	Dietary supplement	Hypertension, cerebral ischemia, myocardial ischemia, prolonged QT interval
Guarana (*Paullinia cupana*)	Contains caffeine, which may increase thermogenesis	Dietary supplement	Nausea, vomiting, insomnia, diuresis, anxiety, palpitations
Serotonergics			
Sibutramine (Meridia)	Inhibits reuptake of serotonin and norepinephrine	Schedule IV prescription drug	Anxiety, dry mouth, insomnia, headache, hypertension, palpitations, dysmenorrhea
			Contraindications: Same as sympathomimetics
			Serotonin syndrome
GI Agents			
Orlistat (Xenical/Alli)	Inhibits gastric and pancreatic lipases	Prescription and nonprescription drug	Abdominal pain, oily stool, fecal urgency or incontinence; fat-soluble vitamin loss
			Contraindications: Cholestasis, chronic malabsorptive states
Chitosan	Insoluble marine fiber that binds dietary fat	Dietary supplement	Decreased absorption of fat-soluble vitamins
			Contraindications: Shellfish allergy
Fibers/Other Supplements			
Glucomannan	Expands in stomach to increase satiety	Dietary supplement	GI obstruction with tablet form
			Contraindications: Abnormal GI anatomy
Garcinia cambogia	Increases fat oxidation (unproven)	Dietary supplement	None reported
Chromium picolinate	Improves blood glucose and lipids; produces fat loss (unproven)	Dietary supplement	Dermatitis, hepatitis, possibly mutagenic in high doses

[a]Trade names or Latin binomials are given in parentheses.

[b]All xenobiotics are contraindicated during pregnancy and lactation.

■ PHARMACOLOGY

Sympathomimetic amines that act at α- and β-adrenergic receptors are clinically effective in promoting weight loss but have numerous side effects that limit their clinical use. Soon after its introduction as a pharmaceutical for nasal congestion in the 1930s, the prototype sympathomimetic drug amphetamine (Fig. 39-1) was noted to cause weight loss (see Chap. 75). The weight loss effects of amphetamine were also readily apparent in early animal studies, although tolerance to the anorectic effects was also noted.[127] The primary mechanism of action of the weight loss effects of sympathomimetic drugs is central nervous system (CNS) stimulation, resulting from increased release of norepinephrine and dopamine.[125] The effects include direct suppression of the appetite center in the hypothalamus and reduced taste and olfactory acuity, leading to decreased interest in food. Increased energy and the euphoriant effects of the stimulant drugs also contribute to weight loss. However, tachyphylaxis occurs, and the rate of weight loss diminishes within a few weeks of initiating therapy.[44] Significant side effects and abuse potential severely limit the therapeutic use of this class of drugs.

■ ADVERSE EFFECTS

The absence of polar hydroxyl groups from a sympathomimetic amine increases its lipophilicity; therefore, unsubstituted or predominantly alkyl group–substituted compounds (eg, amphetamine, ephedrine, PPA) have greater CNS activity. Mild cardiovascular and CNS stimulant effects include headache, tremor, sweating, palpitations, and insomnia. More severe effects that may occur after overdose of sympathomimetic amines include anxiety, agitation, psychosis, seizures, palpitations, and chest pain.[43,72,79,90,101,111,132]

Hypertension is common after overdose and occasionally after therapeutic use as well. Patients may present with confusion and altered mental status as a result of hypertensive encephalopathy. Reflex bradycardia after exposure to agents with predominantly α-adrenergic agonist effects may accompany the hypertension and provides a clue to the diagnosis. Children with unintentional ingestions may be at especially high risk for hypertensive episodes because of the relatively significant dose per kilogram of body weight. Other manifestations include chest pain, palpitations, tachycardia, syncope, hypertension, mania, psychosis, convulsions, and coronary vasospasm.[14,20,38,98,144]

TABLE 39–2. Unavailable and Withdrawn Weight Loss Drugs and Dietary Supplements

Drug or Supplement[a]	Mechanism of Action	Adverse Effects	Regulation Status, DEA Schedule, or Withdrawal Date
Amphetamine	Increased release of NE and dopamine	Sympathomimetic effects, psychosis, dependence	Schedule II
Benzphetamine (Didrex)	Increased release of NE and dopamine	Sympathomimetic effects, psychosis, dependence	Schedule III
Clenbuterol	β_3-Adrenergic agonist activity	Tachycardia, headache, nausea, vomiting; may be prolonged	Not approved
Dexfenfluramine (Redux)	Promotes central serotonin release and inhibits its reuptake	Valvular heart disease, primary pulmonary hypertension	Withdrawn September 1997
Dieter's teas (senna, cascara, aloe, buckthorn)	Stimulant laxative herbs that promote colonic evacuation	Diarrhea, vomiting, nausea, abdominal cramps, electrolyte disorders, dependence	FDA required label warning, June 1995
Dinitrophenol	Alters metabolism by uncoupling oxidative phosphorylation	Hyperthermia, cataracts, hepatotoxicity	Not approved
Ma-huang (*Ephedra sinica*)	Increased release of NE and dopamine	Sympathomimetic effects, psychosis	Banned by FDA, April 2004
Fenfluramine (Pondimin)	Increased release and decreased reuptake of serotonin	Valvular heart disease, primary pulmonary hypertension	Withdrawn September 1997
Guar gum (Cal-Ban 3000)	Hygroscopic polysaccharide swells in stomach, producing early satiety	Esophageal and small bowel obstruction, fatalities	Banned by FDA, July 1990
Lipokinetix (sodium usniate, norephedrine, 3,5-diiodothyronine, yohimbine, caffeine)	Unknown	Acute hepatitis	FDA warning, November 2001
Phendimetrazine (Adipost, Bontril)	Increased release of NE and dopamine	Sympathomimetic effects, psychosis	Schedule III
Phenylpropanolamine (Dexatrim, Acutrim)	α_1-Adrenergic agonist	Sympathomimetic effects, headache, hypertension, myocardial infarction, intracranial hemorrhage	Withdrawn November 2000
Rimonabant (Acomplia)	Endocannabinoid receptor antagonist	Anxiety, nausea, diarrhea, dizziness	Phase III clinical trials (yet to be approved by FDA)

[a] Trade names or botanical names as appropriate are given in parentheses.

DEA, Drug Enforcement Administration; FDA, Food and Drug Administration; NE, norepinephrine.

Patients with clinically significant hypertension should be treated aggressively with either phentolamine, a rapidly acting α-adrenergic antagonist, or nitroprusside. Analogous to the management of cocaine toxicity, β-adrenergic antagonists should be avoided in the management because the resultant unopposed α-adrenergic agonist effects may lead to greater vasoconstriction and increased hypertension.[4] Patients with agitation, tachycardia, and seizures should be treated with benzodiazepines.

■ SPECIFIC SYMPATHOMIMETIC DIETARY SUPPLEMENTS

Phenylpropanolamine PPA, a sympathomimetic amine (see Fig. 39–1), was available until 2000 as a nonprescription diet aid (eg, Dexatrim, Acutrim). It is both a direct-acting agent, via stimulation of α-adrenergic receptors, and an indirect-acting agent, through release of norepinephrine. Both of these actions cause a net increase in blood pressure when given in high doses. PPA-induced anorexia is mediated via α-adrenergic receptors in the hypothalamus.[140] PPA was voluntarily withdrawn after its use was linked to increased risk of hemorrhagic stroke in women.[66]

Reported toxicity associated with PPA generally results from severe hypertension.[41,43,47,53,61,65,90] A comprehensive review of more than 100 case reports of adverse drug effects involving PPA revealed 24 intracranial hemorrhages, eight seizures, and eight fatalities between 1965 and 1990.[52,75] Some adverse events occurred after ingestion of diet preparations that contained both PPA and caffeine, which have pharmacokinetic and pharmacodynamic interactions.[68,76] Cardiac toxicity, although less common, was reported in two young patients who suffered myocardial injury after therapeutic daily dosing in one
FIGURE 39–1. Sympathomimetic amines formerly and currently used for weight loss.

and acute overdose in the other.[79] Hypertensive emergencies resulting from adverse drug interactions between PPA and drugs such as monoamine oxidase inhibitors (MAOIs) have also been reported.[123]

Ephedrine Ephedra (*Ephedra sinica*), or Ma-huang, is a plant that contains six sympathomimetic amines, known collectively as *ephedra alkaloids.* The two primary alkaloids are ephedrine and pseudoephedrine (see Fig. 39–1). Ephedra was popular as a weight loss dietary supplement until the FDA banned ephedra-containing products in April 2004 because of cases of serious cardiovascular toxicity[14,20,27,38,54,98,132,144] and acute hepatitis.[95] In a review of 140 adverse events reported to MedWatch after use of ephedra, 31% of the cases were considered to be definitely or probably related to the use of ephedra supplements, including four strokes, five cardiac arrests, two myocardial infarctions, and three fatalities.[54] In 2005, there was concern that the FDA ban would be overturned and ephedra would once again be available. But in 2006, the U.S. Court of Appeals upheld the FDA's final rule to ban ephedra. Despite this ban, ephedra still can be obtained from practitioners of complementary medicine as a traditional Chinese herbal medicine for short-term treatment of wheezing and nasal congestion associated with asthma, allergies, and colds. Synthetic ephedrine is still available as the nonprescription medication, such as Primatene for the treatment for asthma.

Since ephedra was banned, herbal weight loss supplements have been reformulated. Many now contain an extract of bitter orange (*C. aurantium*), a natural source of the sympathomimetic amine synephrine, often in combination with caffeine, theophylline, willow bark (containing salicylates), diuretics, and other constituents. The dried fruit peel of bitter orange is a traditional remedy for gastrointestinal (GI) ailments. The predominant constituents, *p*-synephrine (see Fig. 39-1) and octopamine, are structurally similar to epinephrine and norepinephrine. Its isomer *m*-synephrine (phenylephrine or Neo-Synephrine) is used extensively as a vasopressor and nasal decongestant. Although synephrine's physiologic actions are not fully characterized, synephrine appears to interact with amine receptors in the brain and acts at peripheral α_1-adrenergic receptors, resulting in vasoconstriction and increased blood pressure.[48] Some evidence indicates that synephrine may also have β_3-adrenergic agonist activity,[21,48] which could increase lipolysis. β_3-adrenergic agonists were found to have remarkable anti-obesity effects in rodents; however, effects in human are not as profound. Octopamine stimulates lipolysis in rats, hamsters, and dogs, but this effect was not seen in human fat cells.[21,48] A recent review described that nearly 2% of 4140 Californians surveyed had used a *C. aurantium*–containing product several times a week.[70] Adverse effects associated with use of *C. aurantium*–containing weight loss products have been reported, including one case of tachydysrhythmia,[46] one case of cerebral ischemia in a 38-year-old man,[12] one case of exercise-induced syncope and QT interval prolongation in a 22-year-old woman,[96] and one possible case of myocardial infarction in a 55-year-old woman.[97]

SEROTONERGIC AGENTS

Xenobiotics that affect central release and reuptake of serotonin are approved for a number of indications, including depression, anxiety, nicotine addiction, migraine, and premenstrual dysphoric syndrome. Although these drugs all reduce food intake to varying degrees, sibutramine (Meridia) is the only FDA-approved serotonergic agent specifically indicated for treatment of obesity.

Sibutramine acts by blocking the reuptake of both serotonin and norepinephrine, but it does not promote neuronal release of serotonin. Its clinical effects include reduced appetite and increased satiety. This xenobiotic is recommended in doses of 10 to 15 mg/day for obese patients with BMIs above 30 kg/m² without comorbid conditions and for patients with BMIs above 27 kg/m² with comorbid diseases of diabetes mellitus, dyslipidemia, or hypertension. Its effectiveness in producing weight loss was demonstrated in several randomized, double-blind studies.[30,35,78,84] It also decreases binge eating when compared with placebo.[141] Patients receiving intermittent sibutramine therapy have significantly fewer adverse effects than patients who take sibutramine continuously.[142] Clinical use of sibutramine for more than one year is unstudied.

The pharmacologic activity of sibutramine results from hepatic first-pass metabolism by cytochrome P450 (CYP3A4), transforming sibutramine into two active metabolites, mono-desmethylsibutramine and di-desmethylsibutramine, which have half-lives of 14 and 16 hours, respectively. These metabolites are further metabolized and renally excreted. Medications that inhibit CYP3A4, such as cimetidine, erythromycin, and ketoconazole, may slow sibutramine metabolism.[89]

Sibutramine use is associated with psychosis,[10,82,126] hypertension, cardiac ischemia, and death. Since sibutramine was approved in 1998, 397 serious adverse reactions have been reported to the FDA, including 29 deaths. Nineteen of the deaths were attributable to cardiovascular causes, including three deaths in women younger than 30 years.[37] The use of sibutramine as a weight loss agent in the United States and Europe is under scrutiny especially after sibutramine was banned in Italy in March 2002 after two cardiovascular deaths. In a large cohort of patients receiving sibutramine, mania, psychosis, and panic attacks were described, with notable improvement upon drug discontinuation.[103] Cases of dysrhythmias temporally related to sibutramine have also been described.[103]

Because of the concerns with increases in blood pressure and heart rate, a double-blind, placebo-controlled trial in adolescents was performed to evaluate the cardiovascular effects of sibutramine.[30] Although not statically significant, the sibutramine group had a trend toward a slight increase in blood pressure and heart rate compared with those taking placebo. Overall, sibutramine was well tolerated in these patients.[30] However, because sibutramine increases the heart rate and blood pressure, it should not be used in patients with poorly controlled hypertension, coronary artery disease, glaucoma, or previous stroke. Sibutramine taken in combination with MAOIs, selective serotonin reuptake inhibitors, or any xenobiotic that promotes serotonin release or prevents reuptake could induce serotonin syndrome, which is often characterized by agitation, hyperthermia, autonomic instability, and myoclonus. Management should be aimed at treating the specific clinical effects. Benzodiazepines may be useful for tachycardia and hypertension. Rapid identification and management of serotonin syndrome (described in Chap. 72) is essential to prevent associated morbidity and mortality.

Serotonergic drugs used in the past to treat obesity include dexfenfluramine (Redux) and fenfluramine (Pondimin), but these agents were withdrawn because of postmarketing reports of serious cardiac effects associated with their therapeutic use.[13,17,27,37,139] The diet drug combination known as "fen-phen" (fenfluramine with phentermine, an amphetamine derivative) was popular in the 1990s because of the presumed improved side effect profile and efficacy achieved with lower doses of each drug. This drug combination was never approved by the FDA for the treatment of obesity. Because of an unusual and serious cardiac valvulopathy in women taking fen-phen, fenfluramine was withdrawn from the market in 1997.[27] All of the women presented with new heart murmurs and either right- or left-sided valvular abnormalities. Eight of the 24 women also developed newly documented pulmonary hypertension. Several required cardiac surgery and were found to have plaquelike encasement of the leaflets and chordae, with preservation of valvular structure. These pathologic findings are identical to those described in patients with ergotamine-induced valvular disease and in those with carcinoid syndrome. Although subsequent studies confirmed this association, the reported magnitude of risk associated

with these drugs has varied.[64,67,139] Cases of regression of these valvular lesions with cessation of the drugs are reported,[18] and limited evidence indicates that the valvular effects are milder than initially described.[50]

Primary pulmonary hypertension has been described in association with fenfluramine and dexfenfluramine since 1981.[7,17,37,88,109] Primary pulmonary hypertension in association with another anorectic drug, aminorex fumarate, was reported earlier in Europe.[53] In one multicenter case control study of patients with primary pulmonary hypertension, use of anorectic drugs such as dexfenfluramine and fenfluramine for more than 3 months was associated with a 30-fold increased risk of primary pulmonary hypertension in these patients compared with nonusers.[1] Several theories are proposed to explain the mechanism of pulmonary toxicity of these agents,[17] namely, serotonin-mediated constriction of pulmonary arteries[87]; serotonin-mediated platelet aggregation; and vasoconstriction in the lungs leading to microembolization, elevated pulmonary vascular resistance, and pulmonary hypertension.[87]

XENOBIOTICS THAT ALTER FOOD ABSORPTION, METABOLISM, AND ELIMINATION

■ FAT ABSORPTION BLOCKERS

Orlistat (Xenical) was approved by the FDA in 1999 for treatment of obesity. In mid-2007, orlistat (Alli) became available as a nonprescription formulation. The ready availability may pose an abuse potential in patients with eating disorders, and abuse should be considered in patients presenting with adverse events consistent with use of orlistat. Orlistat is the only FDA-approved drug that alters the absorption, distribution, and metabolism of food. Orlistat is a potent inhibitor of gastric and pancreatic lipase, thus reducing lipolysis and increasing fecal fat excretion.[22] The drug is not systemically absorbed but exerts its effects locally in the GI tract. It inhibits hydrolysis of dietary triglycerides and reduces absorption of the products of lipolysis, monoglycerides, and free fatty acids.

Several clinical trials demonstrate that orlistat reduces GI fat absorption by as much as 30%.[145] When taken in association with a slightly calorie-restricted diet, weight loss of approximately 10% body weight can be achieved in 1 year.[121] Moreover, the combination of a very low-energy diet and orlistat is responsible for less weight gain over a 3-year period compared with just a very low-energy diet. The subjects in the orlistat group gained 4.6 kg compared with 7.0 kg in the control group.[108]

Orlistat should be taken only in conjunction with meals that have a high fat content; it should not be consumed in the absence of food intake. Adverse effects correlate with the amount of dietary fat consumption and include abdominal pain, oily stool, fecal incontinence, fecal urgency, flatus, and increased defecation. Systemic effects are rarely reported because of the lack of systemic absorption of orlistat[45,94,130] but include cases of hepatotoxicity secondary to orlistat.[94,130] In a recent cohort of nearly 16,000 patients in England, although there were no cases of serious hepatotoxicity, there were reports of elevations of liver function tests. Two of the cases were deemed as causally related to orlistat, and one had a positive rechallenge result.[103] Because of the increasing use of orlistat, the number of reports of rare adverse events may increase. Concomitant use of natural fibers (6 g of psyllium mucilloid dissolved in water) may reduce the GI side effects of orlistat.[24] Because orlistat reduces absorption of fat-soluble food constituents, daily ingestion of a multivitamin supplement containing vitamins A, D, and K and β-carotene is advised to prevent resultant deficiency. At the time of this writing, there are no reported intentional overdoses of orlistat. In the scenario of overdose and misuse, treatment should be mainly supportive.

Chitosan is a weight loss dietary supplement derived from exoskeletons of marine crustaceans. It is thought to act similarly to orlistat by binding to dietary lipids in the GI tract and reducing breakdown and absorption of fat. Animal models describe an increase fecal fat excretion in rats when they are fed high-fat diets.[34] However, the efficacy of chitosan in humans is disputed.[49,91,92] Some evidence indicates that chitosan may decrease total serum cholesterol concentration in overweight people, but the majority of clinical studies indicate that chitosan is ineffective for weight loss in the absence of dietary and lifestyle modifications.[118] Recently, authors estimated that in the presence of chitosan, it would take more than 7 months to lose 1 lb of body fat.[49] Chitosan is contraindicated in people with shellfish allergy.

■ DIETARY FIBERS

Guar gum is derived from the bean of the *Cyamopsis psorabides* plant and is a hygroscopic polysaccharide that expands 10- to 20-fold in the stomach, forming a gelatinous mass. The purpose of ingesting guar was to cause gastric distension and create the sensation of satiety, thereby decreasing appetite and food intake. Guar gum resulted in numerous cases of esophageal and small bowel obstruction in patients with both preexisting anatomic lesions such as strictures and in individuals with normal GI anatomy, and it was banned in 1992.[51,80,109,117]

Glucomannan is a dietary fiber consisting of glucose and mannose, which is derived from konjac root, a traditional Japanese food. Edible forms of glucomannan include konjac jelly and konjac flour, which is mixed with liquid before ingestion. Purified glucomannan is available in capsule form and is found in various proprietary products marketed for weight loss. On contact with water, glucomannan swells to approximately 200 times its original dry volume, turning into a viscous liquid. It lowers blood cholesterol and glucose concentrations and decreases systolic blood pressure,[6,136] but significant weight loss benefits have not been demonstrated. After several reports of esophageal obstruction, oral glucomannan tablets were banned in Australia in 1985.[56] Serious adverse effects have not been described with encapsulated glucomannan, presumably because slower dissolution allows for GI transit before expansion. Glucomannan capsules are available as a nutritional supplement in the United States, although adequate safety and efficacy studies have not been published.

■ DINITROPHENOL

One of the earliest attempts at a pharmaceutical treatment for obesity was 2,4-dinitrophenol (DNP), which was popularized as a weight loss adjuvant in the 1930s.[129] This chemical, which is used in dyes, wood preservatives, herbicides, and explosives, was never approved as a drug product but was legally available as a diet remedy before enactment of the US Federal Food, Drug, and Cosmetic Act of 1938. By increasing metabolic energy expenditure, it reportedly produced weight loss of 1 to 2 lb per week in doses of 100 mg three times per day.[29] DNP increases metabolic work by uncoupling oxidative phosphorylation in the mitochondria. Through this mechanism, the hydrogen ion gradient that allows ATP synthesis is dissipated, preventing the proton motive force from creating high-energy phosphate bonds and thereby inhibiting ATP production (see Chap. 12). Because the energy loss resulting from inefficient substrate utilization is dissipated as heat, elevated temperature and (occasionally) life-threatening hyperthermia may occur.[128] DNP reportedly was administered to Russian soldiers during World War II to keep them warm during winter battles.[74] Symptoms related to DNP toxicity include malaise, skin rash, headache, diaphoresis, thirst, and dyspnea. Severe toxic effects include hyperpyrexia, hepatotoxicity, agranulocytosis, respiratory failure,

coma, and death.[11,74,128] Delayed-onset cataract was a frequent and serious complication of DNP use.[11]

Epidemic use of DNP occurred in Texas in the 1980s when industrial DNP was synthesized into tablets by a physician and used at his weight loss center. He distributed DNP under the trade name Mitcal. The death of a wrestler following an intentional overdose of Mitcal in 1984 led a Texas court to stop the use of this chemical for weight loss.[74] DNP continues to reappear sporadically as a weight loss treatment, and cases of serious toxicity are still reported.[86,99] Management should be aimed at aggressive cooling. Benzodiazepines should also be used as an adjunct therapy for management of delirium and seizures and to prevent shivering, which occurs during active cooling.

■ HYPOCALORIC DIETS AND CATHARTIC AND EMETIC ABUSE

Medication abuse is common among individuals with eating disorders.[15] Starvation, as well as abuse of laxatives, syrup of ipecac, diuretics, and anorectics has led to many fatalities, often in young patients.[47,62] Fad diets and laxative abuse should be strongly considered in young people with unexplained dehydration, syncope, hypokalemia, and metabolic alkalosis. A variety of extreme calorie-restricted diets resulting in profound weight loss were very popular in the late 1970s, but reports of a possible association between these diets and sudden death followed.[120] Myocardial atrophy was a consistent finding on autopsy. Torsades de pointes and other ventricular dysrhythmias are proposed as causes of death as a result of hypokalemia[120,124] and protein-calorie malnutrition of the heart.[39,120,124]

Because of the negative reports and FDA warnings, the enthusiasm for liquid-protein diets waned. Several current diets (Atkin's plan, South Beach diet) advocate intake of high protein, high fat, and low carbohydrates while allowing unlimited amounts of meat, fish, eggs, and cheese. Lack of carbohydrates induces ketosis, which results in diuresis and dehydration, giving the user the appearance of rapid weight loss. With rehydration and resumption of a normal diet, weight gain generally occurs. In addition, dehydration may cause orthostatic hypotension and ureterolithiasis. Atherosclerosis and hypercholesterolemia may occur as a result of substitution of high-calorie, high-fat foods for carbohydrates. Despite the rapid weight loss early on with these diets, as soon as carbohydrates are reintroduced, weight gain occurs rapidly and significantly.[40]

Dieter's teas that contain combinations of herbal laxatives, including senna and *Cascara sagrada*, may produce profound diarrhea, volume depletion, and hypokalemia. They are associated with cases of sudden death, presumably as a result of cardiac dysrhythmias. Despite FDA warnings of the dangers of these weight loss regimens, dieter's teas remain available in retail stores that sell nutritional supplements and are easily accessible to adolescents.

Chronic laxative use can result in an atonic colon ("cathartic bowel") and the development of tolerance, with the subsequent need to increase dosing to achieve catharsis. Because cathartics do not decrease food absorption, they have limited effects on weight control.[8] Various test methods can be used to detect laxative abuse.[32] Phenolphthalein can be detected as a pink or red coloration to stool or urine after alkalinization. Colonoscopy reveals the benign, pathognomonic "melanosis coli," the dark staining of the colonic mucosa secondary to anthraquinone laxative abuse. The combination of misuse and abuse of laxatives in conjunction with use of orlistat has the potential to cause severe diarrhea and subsequent fluid and electrolyte imbalances. Now that orlistat is readily available, the combination of these two agents being abused needs to be considered.[28]

Chronic use of syrup of ipecac to induce emesis by patients with eating disorders, such as bulimia nervosa, leads to the development of

cardiomyopathy, subsequent dysrhythmias, and death.[47,100] Emetine, a component of syrup of ipecac, is the alkaloid responsible for the severe myopathy. Chronic administration of syrup of ipecac results in tolerance to the emetic effects and increased systemic absorption of emetine.[100] Emetine can be detected in serum by high-pressure liquid chromatography or thin-layer chromatography. It persists for weeks to months after ingestion. In 2003, an FDA advisory committee recommended that the nonprescription drug status of syrup of ipecac be rescinded because of its use by patients with bulimic disorders.

SURGICAL APPROACHES

Although not a specific toxicologic concern, it is imperative to mention surgical interventions for management of obesity. Surgical interventions to manage obesity have increased in frequency over the past years and may provide a long-term solution for obesity. Roux-en-Y gastric bypass (RYGBP), laparoscopic adjustable gastric banding (LAGB), and biliary-pancreatic diversion with duodenal switch (BPD/DS) are the most commonly described techniques.[2,16,36] Patients undergoing these procedures are of particular concern because absorption of vitamins, minerals, and drugs are altered.[69,93,105,116,135] The pharmacokinetics of orally administered medications may be altered as well.[105,116] Consideration of drug properties should be examined closely before initiation in this patient population.[69]

ENDOCANNABINOID RECEPTOR ANTAGONISTS

In recent years, focus on the endocannabinoid system (ECS) and its involvement in weight loss and gain has increased tremendously. The ECS contributes to the regulation of food intake, body weight, and energy balance. The ECS is also being studied for a role in inflammation and neuropathic pain.[63,113,137,143] The research and potential for novel pharmacologic agents to treat conditions, including obesity, neuropathic pain, diarrhea, and abdominal cramps, is promising and exciting.

It has long been known that *Cannabis sativa* stimulates appetite and is an effective antiemetic.[25,102] Despite this, it was not until nearly 1990 when the first tetrahydrocannabinol (THC) receptor was identified[102] (see Chap. 83). Endocannabinoids have a vast effect on metabolic functions, including decreasing satiety, increasing food intake, decreasing glucose uptake, increasing lipogenesis and fibrosis in the liver, and decreasing adiponectin, which negatively correlate with BMI.[59] The ECS peripherally has been shown to be upregulated in the presence of diabetes.[42]

Rimonabant, a CB1 antagonist at therapeutic doses and a CB2 antagonist at supratherapeutic doses, was first described in the early 1990s. Rimonabant (Acomplia) is available as a pharmaceutical in Europe but yet to be FDA approved in the United States. Rimonabant has been investigated in animal models and has shown to induce a reduction of food intake as well as a sustained reduction in body weight in a diet induced obesity model in a rat.[107] Moreover, there was an improvement in insulin resistance with a decline in plasma leptin, insulin, and free fatty acid levels. To confirm that indeed CB1 was involved, the investigators used a group of CB1 receptor knockout mice; in these animals, rimonabant had no effect on dietary intake.[107]

Numerous human studies have evaluated the effects of rimonabant,[33,104,112,115,133] and many are currently ongoing. The RIO (Rimonabant in Obesity and Related Metabolic Disorders) series is the largest series of human research. It is a four part phase III multinational, randomized, double-blind, placebo-controlled studies in

overweight and obese patients with BMIs above 27 kg/m^2. RIO-North America,[104] RIO-Europe,[133] RIO-Lipids,[33] and RIO-Diabetes[115] included nearly 6700 patients. The data from these trials are promising and exciting. In each of the four studies, the rimonabant group had a statistically significant reduction in weight and a more sustainable weight loss compared with the placebo group. Moreover, the individuals in the rimonabant group had a reduction in the incidence of metabolic syndrome; blood pressure, glycosylated hemoglobin, and high-density lipoprotein cholesterol increased.

The most common adverse events include nausea, dizziness, and diarrhea. There is concern that rimonabant increases anxiety and depression. Because of these concerns, the FDA has yet to approve the drug for the U.S. market. In the RIO studies, there was a 30% to 50% dropout rate because of adverse events, including GI distress, anxiety, and depression. The dropout rates were higher in the first year compared with the second and were higher with doses of 20 mg compared with 5 mg.

Little is known regarding the clinical presentation after an overdose of rimonabant. Based on the clinical trials and the pharmacology, however, one might expect anxiety and GI toxicity, including nausea and vomiting. At this point, treatment should be generally considered as supportive. Data from ongoing studies as well as case reports and case series will be insightful as to the expected toxicity.

NOVEL THERAPEUTIC APPROACHES

The desire to identify new biochemical pathways and pharmacologic approaches to weight loss has been around since antiquity. Research continues to evolve in an ongoing effort to determine the underlying etiology of obesity as well as develop new, more advanced pharmacologic interventions.[3,25]

Leptin and the leptin gene have been explored as a basis for obesity and as a therapeutic strategy. Obese patients have depressed plasma leptin concentrations.[57,81,106] Genetically leptin-deficient mice are obese, and leptin replacement produces weight loss. Subcutaneous leptin supplementation appears to induce weight loss in lean and obese adults.[57] In three humans with genetically based obesity caused by a presumed leptin deficiency, leptin replacement therapy resulted in profound weight loss and normalization of endocrine function.[81] Much of the enthusiasm about the potential role for leptin as an anti-obesity therapy has subsided because leptin does not induce the expected response on weight control, suggesting leptin resistance.[106,114]

Ghrelin antagonists have also been suggested as a possible adjunct therapy for weight loss. Ghrelin is a growth hormone–releasing agent produced by the stomach and has been shown to stimulate appetite.[71,73,131] Data suggest that ghrelin and leptin work together.[31,85] Ghrelin antagonists may decrease the increased appetite that often occurs with dietary modifications for weight loss, and such agents are under investigation. Because β_3-adrenergic receptors mediate lipolysis in adipose tissue, β_3-selective agonists are also under investigation as weight loss agents.[110] Neuropeptide Y, a peptide found in the arcuate and paraventricular nucleus of the hypothalamus, is a potent central appetite stimulant. Future drug therapy may target these genes, receptors, and proteins to modify metabolism. As obesity research proceeds and the biologic basis for obesity is defined, new approaches and mechanisms for drug therapy may be identified.

OTHER HERBAL REMEDIES

Several herbal remedies for weight loss have resulted in serious toxicity. In France, germander (*Teucrium chamaedrys*) supplements taken for weight loss resulted in seven cases of hepatotoxicity.[77] A "slimming regimen" first prescribed in a weight loss clinic in Belgium produced an epidemic of progressive renal disease, known as Chinese herb nephropathy, when botanical misidentification led to the substitution of *Stephania tetrandra* with the nephrotoxic plant *Aristolochia fangji*.[134] The toxic constituent, identified as aristolochic acid, has been implicated in numerous cases of renal failure and urothelial carcinoma.[83] A case of profound digitalis toxicity occurred with a laxative regimen contaminated with *Digitalis lanata*.[122] Contamination of herbal products remain a concern today because of the lack of standardization of manufacturing processes. Most recently, a dietary supplement was contaminated with selenium, resulting in nearly 45 serious adverse events (see Chap. 98). Until regulation of herbal products is improved and manufacturing practices worldwide are standardized, sporadic reports of herb-related toxicity likely will continue (see Chaps. 27 and 43).

SUMMARY

Although obesity is a major health concern and a significant cause of preventable diseases and sequelae, unproven weight loss modalities are associated with treatment failure and the potential for significant adverse events. Despite the desire for the "easy" solution, there probably is no appropriate substitute for a balanced weight loss plan that encompasses decreased caloric intake with increased energy expenditure through exercise. Clinicians should be aware of the lack of regulation of most available diet remedies and should report adverse events involving these products to poison centers and to the FDA MedWatch system so that appropriate regulatory actions can be taken to prevent further instances of toxicity. A historical review of compounds used as weight loss agents readily uncovers numerous examples of poorly conceived drug regimens, popular misunderstanding of the benefits and risk of the drugs involved, and relatively poor postmarketing surveillance, leading to unnecessary morbidity and mortality.

CHAPTER 40
IRON

Jeanmarie Perrone

Iron		
MW	=	55.85 daltons
Serum normal concentration	=	80–180 µg/dL
	=	14–32 µmol/L

Iron poisoning, once an all-too-frequent tragedy in children, has become uncommon. This may underscore the success of a poisoning that has been prevented by interventions gleaned from poison center data and poison prevention advocacy. Blister packaging, smaller dosages, and education of parents and healthcare providers have led to a great decline in iron poisoning in the past decade. However, significant poisonings still occur, and when they do, they may not be managed as effectively as in the past because they less commonly occur and clinicians are less familiar with the problem. Clinicians must be vigilant for signs of serious iron poisoning and be ready to intervene if gastrointestinal (GI) symptoms are followed by acid–base disturbances, altered mental status, or hemodynamic compromise.

HISTORY AND EPIDEMIOLOGY

Iron salts such as ferrous sulfate have been used therapeutically for thousands of years and continues to be available, both with and without prescription, for the prevention and treatment of iron-deficiency anemia in patients of all ages. Despite this long history of use, the first reports of iron toxicity only occurred in the mid-20th century. Since then, numerous cases of iron poisoning and fatalities have been reported, mostly in children.[56,57] In 1950, the manufacturer of "fersolate" included a package warning: "Excessive doses of iron can be dangerous. Do not leave these tablets within reach of young children, who may eat them as sweets with harmful results."[85]

The incidence of iron exposures continued to increase in the 1980s, ultimately becoming, in the 1990s, the leading cause of poisoning deaths reported to poison centers among children younger than 6 years. This problem was publicized as a result of a case series of tragic fatalities involving five toddlers in Los Angeles during a 6-month period in 1992, all of whom were exposed to prenatal vitamins containing iron.[92] The association between death and prenatal vitamins highlights the availability of these potentially lethal medications in the homes of families with young children, ironically as a result of more attentive prescribing of prenatal iron. A case control study in Canada identified a fourfold increase in the risk of iron poisoning to the older sibling of a newborn during the first postpartum month.[41] The authors concluded that almost half of all hospital admissions of young children for iron poisoning could be prevented by safer storage of iron supplements in the year before and the year after the birth of a sibling.

In 1997, the Food and Drug Administration (FDA) mandated that all iron salt-containing preparations have warning labels on them regarding the dangers of pediatric iron poisoning.[23] In addition to the warning labels, the FDA launched an educational campaign to alert caregivers and prescribers of the potential toxicity of iron supplements.[24]

Other preventive initiatives instituted by the FDA in 1997 included unit dosing (blister packs) of prescriptions containing more than 30 mg of elemental iron and limitations on the number of pills dispensed (ie, maximum 30-day supply).[24] These efforts to prevent unintentional exposure dramatically decreased the incidence of poisoning and were pivotal in decreasing morbidity and mortality associated with iron poisoning[79] (see Chap. 135 and associated references). Unfortunately, in 2003, the FDA rescinded the blister packaging requirement in response to a lawsuit charging that the FDA did not have jurisdiction over the packaging of dietary supplements.[22] Although isolated fatalities continue to occur,[55] the trend in the National Poison Data System suggests they are becoming less commonly reported (see Chap. 135 and associated references). Iron poisoning may also occur after ingestion of other iron salts, such as ferric chloride, used in industry.[100]

Iron supplements are available in two nonionic forms, carbonyl iron and iron polysaccharide, both of which appear to be less toxic after overdose than are iron salts.[74] Parenteral iron, such as iron dextran, administered intravenously (IV) to patients with renal failure and chronic anemia, may also result in toxicity, as well as anaphylactoid reactions. Newer parenteral formulations, including iron sucrose and sodium ferrous gluconate, appear to be safer.[21]

PHARMACOLOGY, PHARMACOKINETICS, AND TOXICOKINETICS

Iron is an element critical to organ function. As a transition metal, iron can easily accept and donate electrons, thereby shifting from a ferric (Fe^{3+}) to a ferrous (Fe^{2+}) oxidation state (see Chap. 11). This redox interchange allows iron to fulfill its role in multiple protein and enzyme complexes, including cytochromes and myoglobin, although it is principally incorporated into hemoglobin in erythrocytes. Whereas insufficient iron availability results in anemia, excess total body iron results in hemochromatosis.

The body cannot directly excrete iron, so body iron stores are regulated by controlling iron absorption from the GI tract. Iron absorption, which occurs predominantly in the duodenum, is determined by the body's iron requirements. In iron deficiency, iron uptake into intestinal mucosal cells may increase from a normal 10% to 35% to as much as 80% to 95%. After uptake into the intestinal mucosal cells, iron is either stored as ferritin and lost when the cell is sloughed or released to transferrin, a serum iron binding protein. In therapeutic doses, some of these processes become saturated, and absorption into the intestinal cell may be limited. However, in overdose, the oxidative effects of iron on GI mucosal cells lead to dysfunction of this regulatory balance, and passive absorption of iron increases down its concentration gradient[78] (see Pathophysiology below).

Iron supplements are available as the iron salts ferrous gluconate, ferrous sulfate, and ferrous fumarate and as the nonionic preparations carbonyl iron and polysaccharide iron. Additional sources of significant quantities of iron are vitamin preparations, especially prenatal vitamins (Table 40-2). Toxic effects of iron poisoning occur at doses of 10 to 20 mg/kg elemental iron (elemental iron is a measure of the amount of iron present in an iron salt; see Table 40–1). Significant GI symptoms occurred in human adult volunteers who ingested 10 to 20 mg of elemental iron/kg.[9,49] In one volunteer study, six subjects who ingested 20 mg/kg elemental iron developed nausea and voluminous diarrhea within 2 hours, and five of the six subjects had serum iron concentrations above 300 µg/dL.[9]

Chewable vitamins continue to entice children with their sweet taste and recognizable character shapes, increasing the risk of significant

TABLE 40–1. Common Iron Formulations and Their Elemental Iron Contents

Iron Formulation	Elemental Iron (%)
Ionic	
Ferrous chloride	28
Ferrous fumarate	33
Ferrous gluconate	12
Ferrous lactate	19
Ferrous sulfate	20
Nonionic	
Carbonyl iron	98[a]
Iron polysaccharide	46[a]

[a] Although these nonionic iron formulations contain higher elemental iron content than ionic formulations, carbonyl iron and iron polysaccharide have better therapeutic-to-toxic ratios, due to limited GI absorption.

exposure. Children's chewable multivitamins contain less iron per tablet (10–18 mg of elemental iron) than typical prenatal vitamins (65 mg of elemental iron). Toxicity still results when large quantities are ingested, but fatalities have not been reported.[2] One animal study paradoxically demonstrates higher iron concentrations after ingestion of equivalent elemental iron doses of chewable versus solid iron tablets.[59] This finding was attributed, in part, to the limited gastric irritation associated with the chewable iron preparations, resulting in less vomiting and higher iron concentrations.

Iron polysaccharide and carbonyl iron appear to be safer formulations than iron salts despite their high elemental iron content.[45] Carbonyl iron is a form of elemental iron that is highly bioavailable in therapeutic doses compared to other forms of iron because of its high elemental iron content and its very fine, spherical particle size (5 μm). This delayed oxidation is the rate-limiting step that prevents excess absorption.[33] In a rat model of iron toxicity, carbonyl iron had a median lethal dose (LD_{50}) of 50 g/kg compared with an LD_{50} of 1.1 g/kg for ferrous sulfate.[95] No significant toxicity in humans exposed to carbonyl iron has been reported.[74]

Iron polysaccharide contains approximately 46% elemental iron by weight. It is synthesized by neutralization of a ferric chloride carbohydrate solution. This form of iron also appears to have much lower toxicity than iron salts. The estimated LD_{50} in rats is more than 5 g/kg body weight. Retrospective poison center data have shown little toxicity from either of these products.[45]

PATHOPHYSIOLOGY

As a transition metal, iron can assume one of several different oxidation, or valence, states. It is an active participant in reduction oxidation (redox) reactions. In particular, the participation of iron in the Fenton reaction and Haber-Weiss cycle explains its toxicologic effects as a generator of oxidative stress and inhibitor of several key metabolic enzymes (see Chap. 11). Reactive oxygen species oxidize membrane-bound lipids and cause loss of cellular integrity and tissue injury (see Chap. 11).[68,70]

The initial oxidative damage to the GI epithelium produced by iron-induced reactive oxygen species permits iron ions to enter the systemic circulation. Iron ions are rapidly bound to circulating binding proteins,

particularly transferrin. After transferrin is saturated with iron, "free" iron (ie, iron not bound to a transport protein) is widely distributed to the various organ systems, where it promotes damaging oxidative processes. A postmortem series of 11 patients who died from iron ingestion substantiated these findings with measurements of elevated iron concentrations in most major organs examined, including the stomach, liver, brain, heart, lung, small bowel, and kidney.[63] Consistent with gastric and intestinal mucosal oxidative damage, congestion, edema, necrosis, and iron deposition in the gastric and intestinal mucosa as well as hemorrhage and congestion in the lungs, are noted on postmortem examination.[30,31,51]

Iron ions disrupt critical cellular processes such as mitochondrial oxidative phosphorylation. Subsequent buildup of unused hydrogen ions normally incorporated into the synthesis of adenosine triphosphate leads to liberation of H^+ and development of metabolic acidosis (see Chap. 12). In addition, absorption of iron from the GI tract leads to conversion of ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}). Ferric iron ions exceed the binding capacity of plasma, leading to formation of ferric hydroxide and production of three protons ($Fe^{3+} + 3H_2O \rightarrow Fe(OH)_3 + 3H^+$).[68,78]

Decreased cardiac output contributes to hemodynamic shock in animals.[89,98] Although this finding has been attributed to decreased preload and relative bradycardia,[89] a direct negative inotropic effect of iron on the myocardium has also been demonstrated in animal models.[3] Reports of early coagulopathy unrelated to hepatotoxicity[81] led to the identification of free iron as an inhibitor of thrombin formation and the reduction of the effect of thrombin on fibrinogen.[71]

CLINICAL MANIFESTATIONS

Classic teaching posits five clinical stages of iron toxicity based on the pathophysiology of iron poisoning.[6,40,66] Although these stages are conceptually important, they are of limited benefit to clinicians managing poisoned patients. Although the stages are typically described in approximate postingestion time frames, a clinical stage should never be assigned based solely on the number of hours postingestion because patients do not necessarily follow the same temporal course through these stages.

The first stage of iron toxicity is characterized by nausea, vomiting, abdominal pain, and diarrhea. These "local" toxic effects of iron predominate, and subsequent salt and water depletion contribute to the ill appearance of the iron-poisoned patient. Intestinal ulceration, edema, transmural inflammation, and, in some extreme cases, small-bowel infarction and necrosis may occur.[25,69,83] Hematemesis, melena, or hematochezia may cause hemodynamic instability. GI symptoms always occur after significant overdose. Conversely, the absence of symptoms, specifically vomiting, in the first 6 hours after ingestion, essentially excludes serious iron toxicity.

The second, or "latent," stage of iron poisoning commonly refers to the period 6 to 24 hours after resolution of GI symptoms and before development of overt systemic toxicity. Delineation of this stage may have evolved from early case reports of patients whose GI symptoms had resolved before subsequent deterioration.[85] This second stage is not a true quiescent phase because ongoing cellular organ toxicity occurs during this phase.[6] Although clinicians should be wary of patients who no longer have active GI complaints after iron overdose, most such patients have, in fact, recovered and are not in the latent phase. Patients in the latent phase generally have lethargy, tachycardia, or metabolic acidosis. They should be readily identifiable as clinically ill despite resolution of their GI symptoms. In summary, patients who have remained well since ingestion and who have stable vital signs,

a normal mental status, and a normal acid–base balance will have a benign clinical course.

Patients who progress to the third, or "shock," stage of iron poisoning have profound toxicity. This stage may occur in the first few hours after a massive ingestion or 12 to 24 hours after a more moderate ingestion. The etiology of shock may be multifactorial, resulting from hypovolemia, vasodilation, and poor cardiac output,[89,98] with decreased tissue perfusion and an ongoing metabolic acidosis. An iron-induced coagulopathy may worsen bleeding and hypovolemia.[81] Systemic toxicity produces central nervous system effects with lethargy, hyperventilation, seizures, or coma.

The fourth stage of iron poisoning is characterized by hepatic failure, which may occur 2 to 3 days after ingestion.[30] The hepatotoxicity is directly attributed to iron uptake by the reticuloendothelial system in the liver, where it causes oxidative damage.[26,99]

The fifth stage of iron toxicity rarely manifests. Gastric outlet obstruction, secondary to strictures and scarring from the initial GI injury, may develop 2 to 8 weeks after ingestion.[29,35,83]

Patients with chronic iron overload are at increased risk for *Yersinia enterocolitica* infection. Iron is a required growth factor for *Y. enterocolitica*; however, the bacterium lacks the siderophore to solubilize and transport iron intracellularly. Because deferoxamine is a siderophore, it fosters the growth of *Y. enterocolitica*. Patients with chronic iron overload or acute poisoning develop *Yersinia* infection or sepsis as a complication of iron poisoning or deferoxamine therapy.[11,53,55,76] *Yersinia* infection should be suspected in patients who experience abdominal pain, fever, and bloody diarrhea after resolution of iron toxicity. In this setting, cultures should be obtained, fluid and electrolyte repletion accomplished, and fluoroquinolones or third-generation cephalosporin therapy initiated.

DIAGNOSTIC TESTING

■ RADIOGRAPHY

Iron is available in many forms, and the different preparations vary with respect to radiopacity on abdominal radiography.[75] Factors such as the time since ingestion and elemental iron content of the pills also play roles.[58,75] Liquid iron formulations and chewable iron tablets typically are not radiopaque.[19] A retrospective review of iron ingestions in children revealed that abdominal radiographs were positive in only one of 30 patients who ingested chewable vitamins.[19] Because adult preparations have a higher elemental iron content and do not readily disperse, they tend to be more consistently radiopaque.[58] Finding radiopaque pills on an abdominal radiograph is helpful in guiding and evaluating the success of GI decontamination.[36] However, the absence of radiographic evidence of pills is not a reliable indicator to exclude potential toxicity.[58,62]

■ LABORATORY STUDIES

Various laboratory studies are used as surrogate markers to assess the severity of iron poisoning. An anion-gap metabolic acidosis and an elevated lactate concentration may develop in patients with serious iron ingestions. Serial electrolyte measurements may be used to assess progression and response to volume replacement. Anemia may result from GI blood loss but may not be evident initially because of hemoconcentration secondary to plasma volume loss.

Although one small retrospective study of iron-poisoned children found that white blood cells (WBC) above 15,000/mm³ or a blood glucose concentration above 150 mg/dL was 100% predictive of iron concentration above 300 μg/dL,[48] three subsequent similar studies were unable to validate this association.[12,47,62] In practice, an elevated WBC or glucose concentration in the setting of a known or suspected iron

ingestion should raise concern about an elevated serum iron concentration; however, assessment of the signs and symptoms of the patient is more reliable.

Although iron poisoning remains a clinical diagnosis, serum iron concentrations can be used effectively to gauge toxicity and the success of treatment.[6] In the previously mentioned human volunteer study of six adults who ingested 20 mg/kg of elemental iron, all six adults demonstrated significant GI toxicity, and the four who required IV fluid resuscitation had peak serum iron concentrations in the range of 300 μg/dL between 2 and 4 hours after ingestion.[9]

In another study of human volunteers who ingested 5 to 10 mg/kg elemental iron in the form of chewable vitamins, peak serum iron concentrations occurred between 4.2 and 4.5 hours in all subjects.[49] In overdose, peak concentrations of iron are thought to occur 2 to 6 hours after ingestion, depending on the iron preparation.[9,49] Serum iron concentrations between 300 and 500 μg/dL usually correlate with significant GI toxicity and modest systemic toxicity. Concentrations between 500 and 1000 μg/dL are associated with pronounced systemic toxicity and shock.[93] Concentrations above 1000 μg/dL are associated with significant morbidity and mortality.[93] Although elevated serum iron concentrations may be an additional indicator of potentially serious toxicity, lower concentrations cannot be used to exclude the possibility of serious toxicity. A single serum iron concentration may not represent a peak concentration or may be falsely lowered by the presence of deferoxamine unless an atomic absorption technique is used for measurement.[28,34]

Total iron-binding capacity (TIBC) is a measurement of the total amount of iron that can be bound by transferrin in a given volume of serum.[20] Previously, clinical iron toxicity was thought not to occur if the serum iron concentration was less than the TIBC because insufficient circulating "free" iron was present to cause tissue damage. Although this may be true conceptually, further research has clarified the limitations of TIBC values. Most importantly, the in vitro value of TIBC factitiously increases as a result of iron poisoning and thus has a tendency to apparently increase above a concurrently measured serum iron concentration.[9,84] Because of many confounding issues, the TIBC as currently determined has no value in the assessment of iron-poisoned patients.

MANAGEMENT

■ INITIAL APPROACH

As with any serious ingestion, initial stabilization must include supplemental oxygen, airway assessment, and establishment of IV access. Evidence of hematemesis or lethargy after an iron exposure may be a manifestation of significant toxicity. IV volume repletion should begin while orogastric lavage and whole-bowel irrigation (WBI) are considered. In any lethargic patient who likely will deteriorate further, early orotracheal intubation may facilitate safe GI decontamination measures. Abdominal radiography may be used to estimate the iron burden in the GI tract given the caveats discussed earlier. Laboratory values, including chemistries, hemoglobin, iron concentration, coagulation, and hepatic profiles, are necessary in the sickest patients. An arterial or venous blood gas or a lactate concentration rapidly detects a metabolic acidosis. Patients who appear well and had only one or two brief episodes of vomiting can be observed pending discharge. Alternatively, the serum iron concentration can be measured.

■ LIMITING ABSORPTION

GI decontamination procedures should be initiated after stabilization. Adequate gastric emptying is critical after ingestion of xenobiotics,

such as iron, that are not well adsorbed to activated charcoal. Because vomiting is a prominent early symptom in patients with significant toxicity, induced emesis is not recommended. Orogastric lavage is more effective but may be of only limited value because of the large size and poor solubility of most iron tablets, their ability to form adherent masses,[25,88] and their movement into the bowel several hours after ingestion.[42] The presence and location of radiopaque pills on abdominal radiography can help guide orogastric lavage. Orogastric lavage likely will not be successful after iron tablets move past the pylorus, so WBI may be more effective (Figs. 40–1 and 40–2).

Many strategies were used in the past in attempts to improve the efficacy of orogastric lavage. At the present time, no data support the use of oral deferoxamine,[32,39,96,97,102] bicarbonate,[15,16] phosphosoda,[4,27] or magnesium.[13,73,91] Although some of these techniques demonstrate efficacy, avoidance of the associated risks mandates using only 0.9% sodium chloride solution or tap water for orogastric lavage.

The value of WBI in patients with iron poisoning is supported primarily by case reports and one uncontrolled case series.[18,42,80,81] However, the rationale for WBI use is logical, especially considering the limitations of other gastric decontamination modalities. The usual dose of WBI with polyethylene glycol electrolyte lavage solution (PEG-ELS) is 500 mL/h in children and 2 L/h in adults. This rate is best achieved by starting slowly and increasing as tolerated, often using a nasogastric tube and an infusion pump to administer large volumes. Antiemetics such as metoclopramide or serotonin antagonists may be used to treat nausea and vomiting. A large volume (44 L) of WBI was administered safely over a 5-day period to a child who had persistent iron tablets on serial abdominal radiographs[42] (see Antidotes in Depth A3: Whole-Bowel Irrigation) (see Chap. 7).

FIGURE 40–2. The same 17 month old child ten hours after ingestion. Persistent iron pills were removed from the stomach by gastrotomy. No further radiopaque fragments can be visualized; however, acute lung injury is now visible.

FIGURE 40–1. A 17-month-old boy presented to the hospital with lethargy and hematemesis after a large ingestion of iron supplement pills. Despite orogastric lavage and whole-bowel irrigation, iron pills and fragments can be visualized in the stomach 4 hours after ingestion.

For patients with consequential toxicity who demonstrate persistent iron in the GI tract despite orogastric lavage and WBI, upper endoscopy or gastrotomy and surgical removal of iron tablets adherent to the gastric mucosa may be necessary and lifesaving.[25,64,88]

■ DEFEROXAMINE

Deferoxamine has been available since the 1960s as a specific chelator for patients with acute iron overdose or chronic iron overload (eg, multiple transfusions). Deferoxamine, which is derived from culture of *Streptomyces pilosus,* has high affinity and specificity for iron. In the presence of ferric iron (Fe^{3+}), deferoxamine forms the complex ferrioxamine, which is excreted by the kidneys,[43] imparting a reddish-brown color to the urine. (See Fig. 40–3) Deferoxamine chelates free iron and the iron transported between transferrin and ferritin[50,65] but not the iron present in transferrin, hemoglobin, hemosiderin, or ferritin.[5,43] Deferoxamine may work by other mechanisms in addition to binding excess systemic iron. Because 100 mg of deferoxamine mesylate chelates approximately 8.5 mg of ferric iron, recommended or typical therapeutic dosing of deferoxamine does not produce significant excretion of chelated iron in the urine, yet it does often result in dramatic clinical benefits (see Antidotes in Depth A7: Deferoxamine). Sufficient evidence suggests that deferoxamine can reach intracytoplasmic and mitochondrial free iron, thereby limiting intracellular iron toxicity.[50]

IV administration of deferoxamine should be considered in iron-poisoned patients with any of the following findings: metabolic acidosis, repetitive vomiting, toxic appearance, lethargy, hypotension, or signs of shock. Deferoxamine administration also should be considered for any patient with an iron concentration above 500 μg/dL. In patients manifesting serious signs and symptoms of iron poisoning,

FIGURE 40–3. These timed sequential urines were obtained from a small child with a serum iron concentration of 990 μg/dL who was treated with intravenous deferoxamine. A characteristic color change is illustrated. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program)*.

deferoxamine should be initiated as an IV infusion, starting slowly and gradually increasing to a dose of 15 mg/kg/h. Hypotension is the rate-limiting factor as more rapid infusions are used.[37,94,96] Patients who appear toxic or have serum iron concentrations above 500 μg/dL should be treated with IV deferoxamine. Patients who have concentrations below 500 μg/dL or who do not appear toxic should be treated supportively without administration of parenteral deferoxamine (Fig. 40–4).

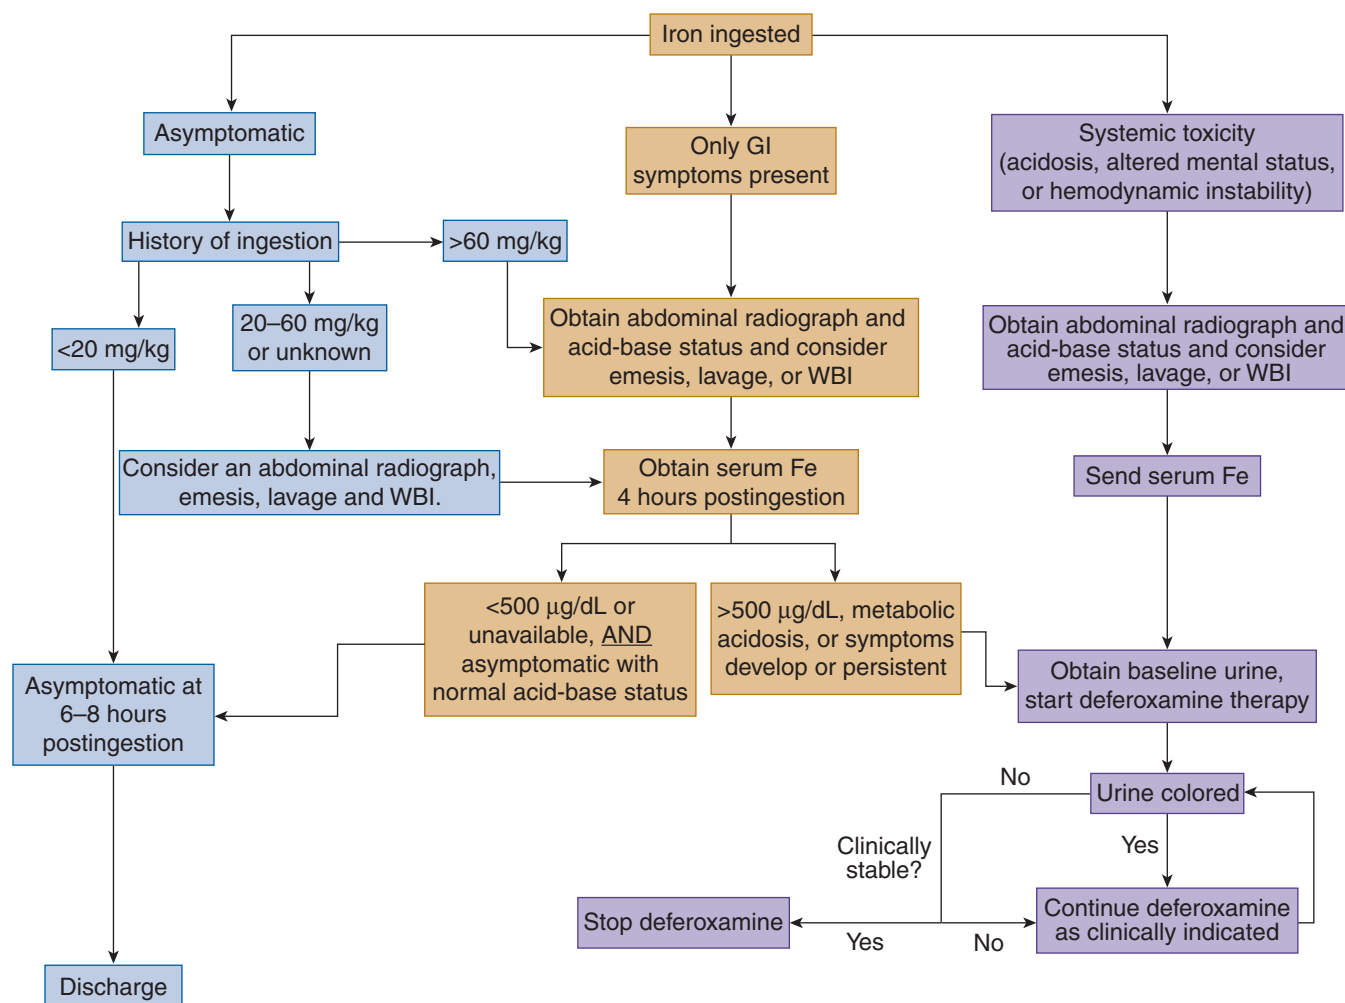
Clinicians have attempted to define the earliest clear end points for deferoxamine therapy because of possible deferoxamine toxicity. In one report, a urine iron-to-creatinine ratio (U_I/Cr) was used to determine if free iron excretion into the urine continued during deferoxamine therapy.[101] This ratio is a more objective measure of the presence of ferrioxamine in the urine than the less reliable and more subjective use of urinary color change.[17,46,90] This method must be further studied clinically before its use can be advocated. Most authors agree that deferoxamine therapy should be discontinued when the patient appears clinically well, the anion-gap acidosis has resolved, and urine color undergoes no further change.[54] In patients with persistent signs and symptoms of serious toxicity after 24 hours of IV deferoxamine, continuing therapy should be undertaken cautiously, if at all, and perhaps at a lower dose (see Antidotes in Depth A7: Deferoxamine).


FIGURE 40–4. Algorithm for decision analysis after iron salt ingestion.

Adverse Effects of Deferoxamine Most adverse effects of deferoxamine are reported in the setting of chronic administration for treatment of hemochromatosis.[38,61,72] The same effects, such as acute lung injury and acute respiratory distress syndrome (ARDS), are also described after treatment for acute iron overdose.[82] Four patients with serum iron concentrations ranging from 430 to 620 μg/dL developed ARDS after IV administration of deferoxamine for 32 to 72 hours.[82] An animal study revealed significantly increased pulmonary toxicity when high-dose deferoxamine therapy was administered in the presence of high concentrations of oxygen (75%–80% FiO_2).[1] The authors suggested that this effect was mediated via an oxygen free radical mechanism (see Antidotes in Depth A7: Deferoxamine).

PATIENT DISPOSITION

Many patients who ingest iron do not develop significant toxic effects. Recommendations for hospital referral of toddlers who ingest iron range from those with potential exposures of 20 mg/kg[6] up to 60 mg/kg.[46] These wide ranges probably result from the interpretation of retrospective studies in possibly "exposed" toddlers for whom the actual doses were estimated. Many authors suggest that doses were overestimated in patients who subsequently did not develop toxicity (see Chap. 135). If a toddler remains asymptomatic or develops minimal or no GI manifestations after a 6-hour observation period in the emergency department (ED), discharge to an appropriate home situation can be considered. Patients who develop GI symptoms and signs of mild poisoning including vomiting and diarrhea can be observed as inpatients outside the ICU. Patients who manifest signs and symptoms of significant iron poisoning, such as metabolic acidosis, hemodynamic instability, or lethargy, should be monitored and treated in an intensive care unit. Except in the case of carbonyl iron, hospital evaluation is recommended for any child with an estimated unintentional ingestion of more than 20 mg/kg of elemental iron. Children who appear well with unintentional ingestions between 10 and 20 mg/kg elemental iron and fewer than two episodes of vomiting should be closely followed at home in consultation with the poison control center.

PREGNANT PATIENTS

The frequent diagnosis of iron-deficiency anemia during pregnancy has led to serious and even fatal iron ingestions in pregnant women.[8,44,60,67,86] In all cases of toxic exposures during pregnancy, maternal resuscitation should always be the primary objective, even if an antidote poses a real or theoretical risk to the fetus. Unproven concerns regarding possible deferoxamine toxicity to fetuses have inappropriately, and at times, disastrously delayed therapy.[60,77] These fears about fetal deferoxamine toxicity are not supported in either human or animal studies,[14,52,87] which have demonstrated that neither iron nor deferoxamine is transferred to fetuses in appreciable quantities. An animal study demonstrated that fetal serum iron concentrations were not elevated and fetal deferoxamine concentrations could not be detected in pregnant near-term ewes poisoned with iron and treated with deferoxamine. Fetal demise under these circumstances presumably results from maternal iron toxicity and not from direct iron toxicity to the fetus. Thus, deferoxamine should be used to treat serious maternal iron poisoning and should never be withheld because of unfounded concern for fetal exposure to deferoxamine.

ADJUNCTIVE THERAPIES

Another modality used experimentally for treatment of iron intoxication is continuous arteriovenous hemofiltration (CAVH). In a study of five iron-poisoned dogs, increased elimination of ferrioxamine in the ultrafiltrate was demonstrated when increasing doses of deferoxamine were infused into the arterial side of the system.[7] This technique is not described in iron-poisoned humans, in whom continuous venovenous hemofiltration (CVVH) is more commonly used. Theoretically, ferrioxamine in the blood could be dialyzable with new high-molecular-weight (large-pore) dialysis filters, but this technique has not been studied.

In toddlers with severe poisoning, exchange transfusion may help to physically remove free iron from the blood while replacing it with normal blood. Exchange transfusion in children is effective for poisonings with theophylline when the volume of drug distribution is small and removal from the blood compartment can be expected. Treatment with exchange transfusion has been suggested in iron poisoning based on early reports and recently reported in the successful treatment of an 18-month-old child with iron poisoning.[10] However, removal of blood volume must be performed cautiously because it may not be well tolerated by iron-poisoned patients with hemodynamic instability.

SUMMARY

Despite FDA-mandated warnings on iron preparations, morbidity and mortality secondary to iron exposures continue. A toddler presenting to the ED after presumed iron exposure who has evidence of GI toxicity and lethargy is at high risk for significant iron toxicity and possibly death. Although iron is available in multiple formulations (eg, prenatal vitamins, ferrous gluconate supplements), toxicity is determined by the amount of elemental iron present; signs and symptoms occur after ingestions of 20 mg/kg of elemental iron. After the patient's condition is stabilized, GI decontamination, including orogastric lavage and WBI using PEG-ELS, should be initiated when indicated because activated charcoal is ineffective in binding iron. Abdominal radiography may be helpful in determining the iron burden in the GI tract with preparations that are radiopaque. After iron is absorbed, GI symptoms of nausea, vomiting, diarrhea, hematemesis, and abdominal pain are prominent. Systemic iron toxicity leads to metabolic acidosis, hypotension, coagulopathy, and multiorgan system failure. Diagnosis and treatment of shock and acidosis, as well as chelation with deferoxamine, may be lifesaving. Education of parents, caregivers, and prescribers may decrease the incidence of serious iron ingestions in the future.

DEFEROXAMINE

Mary Ann Howland
Deferoxamine (DFO) is the parenteral chelator of choice for treatment of acute iron poisoning. Considering that DFO has been used to treat patients with acute iron overdose for a little over 40 years,[30] there is still much that is unknown. No controlled studies have evaluated the efficacy or dosing of DFO. Animal studies and case series from the 1960s and 1970s form the basis for how we use DFO. This information has been supplemented since then by limited case reports and clinical experience. DFO is also used for chelation of aluminum in patients with chronic renal failure. The merits of DFO as a treatment strategy for acute iron overdose is discussed in Chapter 40 and for aluminum toxicity in Chapter 86.

HISTORY AND CHEMISTRY

The development of DFO (or desferrioxamine B) resulted from an analysis of the iron containing metabolites of a species of actinomycetes. DFO is the colorless compound that results when the trivalent iron is chemically removed from ferrioxamine B (Fig. A7–1).[35] Ferrioxamine is a brownish-red compound containing trivalent iron (ferric, Fe^{3+}) and three molecules of trihydroxamic acid isolated from the organism *Streptomyces pilosus.*[35]

DFO is a water-soluble hexadentate chelator with a molecular weight of 561 daltons. The commercial formulation is the mesylate salt with a molecular weight of 657 daltons. One mole of DFO binds 1 mole of Fe^{3+}; therefore, 100 mg DFO as the mesylate salt theoretically can bind 8.5 mg Fe^{3+}.

DFO has a much greater affinity constant for iron (10^{31}) and aluminum (10^{22}) than for zinc, copper, nickel, magnesium, or calcium (10^2–10^{14}).[35] Thus, at physiologic pH, DFO complexes almost exclusively with ferric iron.[26,75]

MECHANISM OF ACTION

DFO binds Fe^{3+} at the 3 N–OH sites, forming an octahedral iron complex (see Fig. A7–1). Once bound, the resultant ferrioxamine is very stable. DFO appears to benefit iron-poisoned patients by chelating free iron (nontransferrin plasma iron) and iron in transit between transferrin and ferritin (labile chelatable iron pool)[29,41,58] while not directly affecting the iron of hemoglobin, hemosiderin, or ferritin.[35] Although in vitro studies suggest that DFO removes iron from ferritin and transferrin with only very little from hemosiderin,[46] in vivo experiments demonstrate that DFO cannot remove iron after the iron is bound to transferrin.[4] DFO does bind "free iron" found in the plasma as nontransferrin plasma iron after transferrin saturation, which only occurs acutely after overdose or chronically in iron overload syndromes.[29] In vitro studies demonstrate that DFO chelates and inactivates cytoplasmic, lysosomal, and probably mitochondrial iron, preventing disruption of mitochondrial function and injury.[25,41] An in vitro study suggests that DFO gains access to cytosol and endosomes through endocytosis rather than passive diffusion.[25] In chronic iron overload, DFO chelates iron deposited in the reticuloendothelial cells found in the spleen, liver, and bone marrow and excretes iron in the urine as ferrioxamine.[29] Whether DFO actually chelates the iron within the reticuloendothelial cells or after liberation into the plasma is unclear. In vitro studies demonstrate that the liver can donate iron to DFO, and thus chelation subsequently may also lead to biliary iron excretion and fecal elimination.[29,45]

PHARMACOKINETICS

The volume of distribution of DFO ranges from 0.6 to 1.33 L/kg.[35,38,53] The initial distribution half-life of DFO is 5 to 10 minutes.[37,63] The terminal elimination half-life of DFO is approximately 6 hours in healthy patients[2] but approximately 3 hours in patients with thalassemia. DFO is metabolized in the plasma to several metabolites (A–F), of which metabolite B is believed to be toxic.[35,38,53,55] Unchanged DFO undergoes glomerular filtration and tubular secretion.[45]

In comparison, ferrioxamine has a smaller volume of distribution than DFO. In nephrectomized dogs, the volume of distribution of ferrioxamine was calculated to be 19% of body weight compared with 50% of body weight for DFO.[35] This finding implies that DFO has a more extensive tissue distribution. The different pharmacokinetic patterns may be related to the potential for facilitated penetrance of the straight-chain molecule DFO compared with that of the octahedral ferrioxamine.[55] Experiments in dogs with normal renal function demonstrate that intravenous (IV) ferrioxamine is entirely eliminated by the kidney within 5 hours[33] via glomerular filtration and partial reabsorption.[45]

The pharmacokinetics of DFO and ferrioxamine differ in healthy versus iron-overloaded patients. Whereas plasma DFO concentrations in healthy patients are approximately twice the concentrations noted in patients with thalassemia major, ferrioxamine concentrations are five times greater in patients with thalassemia major compared with healthy patients.[35,65]

Some investigators suggest that DFO can be administered during hemodialysis to remove ferrioxamine.[76] Hemodialysis,[14,63] particularly high-flux hemodialysis[70] and hemoperfusion,[14] are effective in ferrioxamine removal and are indicated in patients with renal failure.

ANIMAL STUDIES

Guinea pigs given oral lethal doses of ferrous sulfate and oral DFO in a dose calculated to bind most of the iron showed dramatically improved survival rates.[46] Mortality rates in this study and in a swine study[18] directly correlated with the delay to DFO administration.[46]
FIGURE A7–1. Ferrioxamine.

In two canine studies, dogs that received the iron–DFO complex orally had a 40% to 100% mortality.[75,76] When both oral and IV DFO were administered, the mortality rate was 67%.[74] A similar follow-up study demonstrated a 50% mortality rate in dogs given a lethal dose (225 mg/kg) of iron, followed by oral DFO (2.6 g) and IV DFO (0.75–1.5 mg/kg/min for 8–12 hours).[76] These studies discouraged further investigation in the use of oral DFO despite the more favorable results in other animal models.[5,31,46,69]

EARLY HUMAN USE AND HISTORY OF DOSING RECOMMENDATIONS

In one of the earliest case series, 172 hemodynamically stable children who were not severely poisoned were treated with 5 to 10 g oral DFO and either 1 or 2 g intramuscular (IM) DFO every 3 to 12 hours.[74] Patients who were in shock or severely ill received 1 g of DFO IV at a maximum of 15 mg/kg/h every 4 to 12 hours for 2 to 3 days as necessary. Of the 28 patients who developed coma, shock, or both, only three died. One of the three patients who died had received late treatment with DFO.

This case series was expanded to 472 patients, and guidelines for DFO dosing were formulated as a result of this clinical experience.[73] The recommended initial dose of DFO was suggested as 1 g IM followed by 0.5 g at 4 and 8 hours later and then every 4 to 12 hours as necessary, not to exceed 6 g in 24 hours. For patients in shock, DFO was recommended at an initial dose not to exceed 1 g IV and a rate not to exceed 15 mg/kg/h followed 4 and 8 hours later by two 0.5-g doses for a total dosage not to exceed 6 g in 24 hours. These recommendations for total dosages were not scientifically developed and appear to be based on arbitrary assumptions. However, the manufacturer continues to recommend these doses.[19]

URINARY COLOR CHANGE

To further define the role of DFO and the quantitative excretion of urinary iron, investigators studied urinary samples.[46] Several reviews of patients with acute iron poisoning who had received DFO[43,78] investigated the correlation between urinary iron concentrations and systemic toxicity. Most data suggest that the absence of a urine color change, often referred to as a *vin rose* color, after DFO administration indicates very little renal excretion of ferrioxamine.[24] However, unless a baseline

urine color is obtained before DFO administration, post-DFO administration comparisons of urine color are unreliable. No relationship between urinary iron excretion, clinical iron toxicity, and the effectiveness of DFO has been established.

INTRAMUSCULAR VERSUS INTRAVENOUS ADMINISTRATION

Before 1976, IM DFO was the preferred route of administration, and IV DFO was reserved for patients in shock. However, when transfusion-induced iron overload was studied and IM and IV DFO administration were compared, IV DFO significantly enhanced urinary iron elimination.[59] This study provided compelling arguments against IM dosing, as did data showing higher peak and more stable DFO concentrations with IV infusions. A single patient was given 425 mg/kg IV over 24 hours without incident, although the increase in urinary iron excretion seen when the DFO dose increased from 4 to 16 g/d appeared to be of limited consequence.

DURATION OF DOSING

The optimum duration of DFO administration is unknown. In canine models, serum iron concentrations peak within 3 to 5 hours and then decrease quickly as iron is transported out of the blood into the tissues.[71,77] In one human study, initial iron concentrations of approximately 500 μg/dL decreased to approximately 100 μg/dL within 12 hours.[39] Other case reports also suggest that most of the easily accessible iron is distributed out of the blood compartment by 24 hours.[20] Although severely poisoned patients have received DFO for more than 24 hours, pulmonary toxicity is associated with prolonged DFO infusions.[28,51,67] Intuitively, in patients with acute iron overdose, DFO should be administered early and for a shorter duration while the iron is easily accessible in the blood. In patients with chronic iron overload, prolonged infusions of smaller DFO doses are necessary to act as a sink and to slowly remove iron from the limited labile pool and tissue stores.[32]

ADVERSE EFFECTS

DFO administration to patients with acute iron overdose is associated with rate-related hypotension, hypersensitivity reactions and systemic allergic reactions, pulmonary toxicity, and infection. DFO administration to patients with chronic iron overload is associated with auditory, ocular, and pulmonary toxicity and infection.[9,32]

Significant hypotension was first noted in 1965 in two children who were administered approximately 80 to 150 mg/kg DFO IV over 15 minutes.[75] The mechanism for rate-related hypotension is not fully understood, although histamine release is at least partially implicated. Although elevated histamine concentrations were documented in a canine experiment, pretreatment with diphenhydramine was not protective.[76] Intravascular volume depletion caused by iron toxicity also contributes to hypotension. No experiment has determined the maximum safe rate of DFO administration. Adverse effects of DFO, including tachycardia, hypotension, shock, were reported with rapid infusion.[74] These complications resulted in the current recommendations for less rapid IV infusions of DFO not to exceed 15 mg/kg/h.[74-76] Currently suggested IV infusion rates are somewhat empirical because of the lack of robust evidence. Higher rates were administered successfully in critically ill patients when time was of the essence.[11,15,20]

Acute lung injury (ALI) occurs in patients with acute iron overdoses who have received IV administration of DFO (15 mg/kg/h) therapy for more than 24 hours.[3,34,67] Usually, iron concentrations are normal in these patients within 24 hours, and the rationale for continued administration

of DFO was not reported. Examination of the nontoxicologic literature reveals other instances of ALI occurring in patients receiving continuous IV DFO for hemosiderosis and malignancies.[13,23,72] Administration of continuous IV doses of DFO for prolonged (>24 hours) periods was common to all of these patients. The mechanism for development of pulmonary toxicity after DFO is unknown. Pulmonary toxicity may result from excessive DFO chelation of intracellular iron and depletion of catalase, resulting in oxidant damage[27] or generation of free radicals.[1]

DFO therapy may lead to infection with a number of unusual organisms, including *Yersinia enterocolitica*, *Zygomycetes spp*, and *Aeromonas hydrophilia.* The virulence of these organisms is facilitated when the DFO–iron complex acts as a siderophore for their growth.[40,44,47] Most cases of septicemia occurred when DFO was used for treatment of aluminum toxicity in patients receiving chronic hemodialysis.[45] Several cases of *Yersinia* sepsis were reported after acute iron overdose and treatment with DFO.[44,47]

Ocular toxicity characterized by decreased visual acuity, night blindness, color blindness, and retinal pigmentary abnormalities has occurred in patients who received continuous IV DFO for thalassemia and other nonacute iron and aluminum excess conditions.[8,12,17,50,52] Ototoxicity documented by abnormal audiograms indicating partial or total deafness has been reported.[55,56] However, neither ocular toxicity nor ototoxicity has been reported in the setting of acute overdose treatment.

USE IN PREGNANCY

A review of the literature identified 61 cases of intentional iron overdose in pregnant women.[68] Serious iron toxicity with organ involvement was associated with spontaneous abortion, preterm delivery, and maternal death. There is no evidence to indicate that DFO is teratogenic.[68] Neither iron nor DFO appears to cross the ovine placenta.[16] A case report of a pregnant woman with thalassemia and a review of 40 other pregnant patients with thalassemia treated extensively with DFO found no evidence of teratogenicity.[62] Thus, DFO should be administered to pregnant women with acute iron overdose for the same indications as for nonpregnant women and is listed by the Food and Drug Administration (FDA) in pregnancy Category C.

USE IN ALUMINUM TOXICITY

Patients with renal insufficiency are at high risk for aluminum toxicity.[79] Acute aluminum toxicity resulting from bladder irrigations with alum for hemorrhagic cystitis is also reported.[54] Chronic aluminum toxicity is reported from administration of aluminum salts as phosphate binders or from hemodialysis with a water source containing aluminum. DFO binds aluminum to form aluminoxamine, analogous to iron and ferrioxamine. The chelate is a 1:1 octahedral complex with aluminum.[79] Aluminoxamine is excreted renally. In patients with renal insufficiency, hemodialysis (especially with a high-flux membrane) is effective in removing the aluminoxamine and should be used to prevent aluminum redistribution to the CNS and other tissues.[48] The dosing of DFO is unclear but should be tailored to the patient's serum aluminum concentrations, symptomatology, and response.[48] Electroencephalography (EEG) monitoring is recommended. DFO doses of 5 to 15 mg/kg/day, infused over several hours and 6 to 8 hours before a 3- to 4-hour run of high-flux hemodialysis, have been successful and maximize aluminoxamine removal without exacerbating side efects.[48,61] The appropriate duration of this DFO dosing with hemodialysis is unknown and should be based on CNS symptoms, serum aluminum concentrations, and renal function. The correlation of serum aluminum concentrations with toxicity is poorly defined and

may depend on the chronicity of aluminum exposure. Patients are treated for days to weeks, with one holiday per week (see Chap. 86).

INDICATIONS AND DOSING

The indications and dosage schedules for DFO administration are largely empirical.[6,60] Systemic toxicity associated with acute iron poisoning manifested by coma, shock, or metabolic acidosis warrants IV infusion of DFO. The duration of therapy probably should be limited to 24 hours to maximize effectiveness while minimizing the risk of pulmonary toxicity. Some investigators have suggested that more than the recommended dose of 15 mg/kg/h be infused during the first 24 hours for life-threatening iron toxicity, but this recommendation remains to be validated experimentally.[32] We recommend starting with 5 mg/kg/h and increasing over 15 minutes if tolerated to 15 mg/kg/h to minimize the risk of hypotension. In adults, after the first 1000 mg is infused, the subsequent doses can be adjusted to infuse the remainder of the 6 to 8 g over the next 23 hours. In a 70-kg patient, this would be about 3 to 4 mg/kg/h for the next 23 hours. Although patients with mild toxicity can be treated with IM injections of 90 mg/kg of DFO (maximum of 1 g in children or 2 g in adults), this volume of antidote cannot be given IM with ease or painlessly in children. Therefore, few clinicians administer IM DFO, and most prefer the IV route (see Chap. 40). The total daily parenteral dose is limited by the infusion rate in children (if the manufacturer's recommendations are followed). Conservative recommendations in adults limit the dose to 6 to 8 g/day, although doses as high as 16 g/day with diverse dosing regimens have been administered without incident.[15,20,42,5159,66]

AVAILABILITY

DFO mesylate (Desferal) is available in vials containing 500 mg or 2 g of sterile, lyophilized powder. Adding 5 or 20 mL of sterile water for injection to either the 500-mg or the 2-g vial, respectively, results in an approximately 100 mg/mL solution. The drug must be completely dissolved before using. The resulting solution is isotonic, clear, and colorless to slightly yellowish[19] and can be diluted further with 0.9% NaCl solution, glucose in water, or Ringer lactate solution for IV administration. For IM administration, a smaller volume of solution is preferred. Adding 2 or 8 mL of sterile water for injection to the 500-mg or 2-g vial, respectively, results in a stronger yellow-colored solution containing approximately 200 mg/mL.

ADDITIONAL IRON CHELATORS

New iron chelators are being investigated. Pyridoxal isonicotinylhydrase and pyridoxal benzoylhydrazone are potent lipophilic chelators. Lipophilicity increases iron mobilization but may also increase toxicity. Deferiprone is a bidentate oral iron chelator. Three moles of deferiprone are required to bind 1 mole of ferric ion to form a stable complex.[29] Inappropriate ratios of drug to iron may be ineffective or even harmful because of the formation of potentially toxic intermediates.[29] Preliminary animal studies of acute toxicity are contradictory.[10,22,33,36] The effectiveness and long-term safety of deferiprone for chronic iron overload associated with thalassemia major have been questioned.[7,37,49] More recently, deferasirox, an oral iron chelator, has been FDA approved to treat chronic iron overload caused by blood transfusions. Deferasirox, a tridentate ligand, is an iron chelator that binds ferric iron in a 2:1 ratio. The soluble iron complexes are predominantly eliminated in the feces. Preliminary short-term studies demonstrate a comparable efficacy and

side effect profile to DFO in patients with chronic iron overload. There have been no studies evaluating the use of deferasirox in acute iron overdose. Similar to other oral chelators, concerns exist about increasing oral absorption of the deferasirox iron complex and the toxicity of this complex in the setting of an acute iron overdose.[21,57,64]

SUMMARY

DFO is the parenteral chelator of choice for treatment of iron poisoning. Although DFO has been used to treat acute iron overdose for many years,[30] no controlled studies have evaluated its efficacy or dosing. Much of our knowledge derives from animal studies and case series in the 1960s and early 1970s and from limited case reports throughout the ensuing years. DFO is also used for chelation of aluminum in patients with chronic renal failure.

CHAPTER 41
VITAMINS

Beth Y. Ginsburg

Vitamins are essential for normal human growth and development.[43] By definition, a vitamin is a substance that is present in small amounts in natural foods, is necessary for normal metabolism, and whose lack in the diet causes a deficiency disease.[37] According to the American Medical Association, healthy men and nonpregnant women who eat a varied diet do not need supplemental vitamins.[8] In a recent national survey, 73% of adults in the United States reported use of a dietary supplement within the past year.[202] Eighty-five percent of these supplement users reported use of a multivitamin-multimineral. Many of these individuals share the mistaken beliefs that vitamin preparations provide extra energy or promote muscle growth and regularly ingest quantities of vitamins in great excess of the recommended dietary allowances (RDAs) (Table 41–1). Some vitamins are associated with consequential adverse effects when ingested in very large doses.

Vitamins can be divided into two general classes. Most of the vitamins in the *water-soluble* class have minimal toxicity because they are stored to only a limited extent in the body. Thiamine, riboflavin, cyanocobalamin, pantothenic acid, folic acid, and biotin are not reported to cause any toxicity following oral ingestion.[43] Ascorbic acid (vitamin C), nicotinic acid (vitamin B_3), and pyridoxine (vitamin B_6) are associated with toxicity syndromes. The *fat-soluble* vitamins, however, can bioaccumulate to massive degrees. As a result, the potential for toxicity greatly exceeds that of the water-soluble group. Vitamins A, D, and E but not K are associated with toxicity following very large overdose. The adverse effect secondary to vitamin K is limited to severe, and sometimes fatal, anaphylactoid reactions with rapid administration of the intravenous (IV) preparation.[69]

VITAMIN A

MW	= 272.43 daltons
Therapeutic serum concentration	= 65–275 IU/dL
	16.6–83.3 µg/dL
■ HISTORY AND EPIDEMIOLOGY

Vitamin A is present in two forms. Preformed vitamin A as retinol is derived from retinyl esters, its storage form, in animal sources of food. Provitamin A carotenoids are vitamin A precursors and are found in plants. Among the carotenoids, β-carotene is most efficiently made into retinol. The term *vitamin A* was classically only used to refer to the compound retinol. Currently, it is used to describe all retinoids, compounds chemically related to retinol, that exhibit the biological activity of retinol. Retinol can be converted in the body to the retinoids retinal and retinoic acid. Synthetic retinoids have been developed via chemical modification of naturally occurring retinoids, often for a specific therapeutic purpose. Vitamin A activity is expressed in retinol equivalents

(RE). One RE corresponds to 1 µg of retinol or 3.33 international units (IU) of vitamin A activity as retinol. Twelve micrograms of β-carotene is equivalent to 1 RE (3.33 IU).

As a group, retinoids have specific sites of action and varying degrees of biologic potency. Retinoic acid is primarily responsible for maintaining normal growth and differentiation of epithelial cells in mucus-secreting or keratinizing tissue.[137] Vitamin A deficiency results in the disappearance of goblet mucous cells and replacement of the normal epithelium with a stratified, keratinized epithelium. Dermal manifestations are the earliest to develop and include dry skin and hair and broken fingernails. In the cornea, hyperkeratization is called *xerophthalmia* and can lead to permanent blindness. Alterations in the epithelial lining of other organ systems may lead to increased susceptibility to respiratory infections, diarrhea, and urinary calculi. Vitamin A, in the form of 11-*cis*-retinal, plays a critical role in retinal function.[211] Deficiency results in nyctalopia, which is decreased vision in dim lighting, more commonly known as *night blindness*.

Two independent groups discovered vitamin A in 1913.[140,160] They reported that animals fed an artificial diet with lard as the sole source of fat developed a nutritional deficiency characterized by xerophthalmia. They found that this deficiency could be corrected by adding to the diet a factor contained in butter, egg yolks, and cod liver oil. They named this substance "fat soluble vitamin A." The chemical structure of vitamin A was determined in 1930.[111] Vitamin A is also found naturally in liver, fish, cheese, and whole milk. In the United States and other parts of the world, including some developing countries, many cereal, grain, dairy, and other products, as well as infant formulas, are fortified with vitamin A.[6,217] Vitamin A content varies widely among different food types. A 3-oz serving of cooked beef liver contains 30,325 IU (9100 RE) of vitamin A, whereas 1 cup of whole milk contains 305 IU (92 RE) of vitamin A. Fish-liver oils, such as swordfish and black sea bass, have extremely large amounts of vitamin A and may contain more than 180,000 IU (54,050 RE) of vitamin A per gram of oil. Carotenoids are present in yellow and green fruits and vegetables. A raw carrot has a high β-carotene content of approximately 20,250 IU (6080 RE). One half-cup serving of spinach contains approximately 7400 IU (2220 RE) of β-carotene, whereas an apricot or peach contains 500–600 IU (150–180 RE). The average American diet provides about half of its daily vitamin A intake as carotenoids and about half as preformed vitamin A.[41] The RDA of vitamin A is 900 µg RE/d (3000 IU/d) for adult men and 700 µg RE/d (2300 IU/d) for women (Table 41–1).[73] The tolerable upper intake level for adults is 3000 µg RE/d (9900 IU/d).

Vitamin A toxicity can occur in people who ingest large doses of preformed vitamin A in their daily diets. Inuits in the 16th century recognized that ingestion of large amounts of polar bear liver caused a severe illness characterized by headaches and prostration.[70] Arctic explorers in the 1800s knew of the poisonous qualities of polar bear liver and described an acute illness following its ingestion.[77] Explorers also described a condition among the Inuit population known as *pibloktoq*, or "Arctic hysteria," characterized by hysteria, depression, echolalia, insensitivity to extreme cold, and seizures, and believed to be related to ingestion of polar bear liver and other organ meats.[165] Vitamin A toxicity is implicated in the etiology of pibloktoq as some somatic and behavioral effects of vitamin A toxicity closely parallel many of the symptoms reported in Inuit patients diagnosed with pibloktoq.[120] However, the toxic substance in polar bear liver was not identified as vitamin A until 1942.[180] The vitamin A content of polar bear liver is as high as 34,600 IU/g (10,400 RE/g), supporting the view that vitamin A is the toxic factor in liver.[181]

Vitamin A toxicity was reported in an adult who chronically ingested large amounts of beef liver,[103] as well as following ingestion of the liver of the grouper fish *Cephalopholis boenak*, which has a high content of vitamin A.[38] Ingestion of sea whale and seal liver, as well as the livers

TABLE 41–1. Recommended Dietary Daily Allowances/Adequate Daily Intakes*

of large fish, such as shark, tuna, and sea bass, also is associated with development of vitamin A toxicity.

Vitamin A toxicity usually is not expected to occur following ingestion of large doses of provitamin A carotenoids. However, vitamin A–induced hepatotoxicity and neurotoxicity was believed to have developed in an 18-year-old woman who maintained a diet nearly limited to foods rich in β-carotene, including pumpkin, carrots, and liver, for several years.[152]

The majority of cases reported of vitamin A toxicity result from inappropriate use of vitamin supplements.[15,18] In the United States, approximately 1.3% of adults take vitamin A alone as a dietary supplement.[175]

Vitamin A is prescribed for some people for dermatologic and ophthalmic conditions. Vitamin A toxicity often occurs in adults who continue to use the vitamin without medical supervision.[78]

Isotretinoin (Accutane), 13-cis-retinoic acid, is prescribed for treatment of severe cystic acne. Of great concern is the teratogenicity associated with its use. According to the National Disease and Therapeutic Index, 38% of isotretinoin users are females aged 13–19 years. The likelihood of pregnancy in this group underscores the need to inform all users of the contraindication of the use of this drug during pregnancy and the need to demonstrate the absence of pregnancy prior to initiating treatment. This is mandated through the Food and Drug Administration via a risk management program called the System to Manage Accutane-Related Teratogenicity (SMART).[205] The program attempts to ensure that isotretinoin therapy is not initiated in pregnant women and that pregnancy does not occur in women taking isotretinoin. Prescriber education is required as well as patient informed consent, and all prescribers, patients, and dispensing pharmacies are entered in a registry. Women must have two negative urine or serum pregnancy tests before starting treatment and must have a negative pregnancy test before receiving each monthly prescription. Women who are sexually active must use two forms of contraception for at least 1 month before starting isotretinoin, during therapy, and for 1 month after discontinuation of therapy. Pharmacists may fill prescriptions for isotretinoin only if the prescribing physician and patient have complied with the SMART program. In addition, patients must consider the consequences of unintentional pregnancy while they are taking isotretinoin.

All-trans-retinoic acid (ATRA), or tretinoin, is used as a differentiating agent in the treatment of acute promyelocytic leukemia (APL), a disease characterized by the accumulation of promyelocytic blasts

in bone marrow due to obstruction of differentiation of granulocytic cells.[122] ATRA, in combination with anthracycline chemotherapy, improves the complete remission rate, often reported to be greater than 90%, and reduces the incidence of relapse to only 10%–15% when used in a maintenance therapy regimen.[65] Arsenic trioxide is also recognized as an effective differentiating agent for the treatment of APL and works synergistically with ATRA.[223,224] APL differentiation syndrome, previously known as ATRA syndrome or retinoic acid syndrome (RAS), is the main adverse effect and occurs in up 14%–16% of patients who receive ATRA with an associated mortality of about 2%.[167] ATRA has also been used for the treatment of myelodysplastic syndrome and acute myelogenous leukemia.

■ PHARMACOLOGY AND TOXICOKINETICS

Absorption of vitamin A in the small intestine is nearly complete. However, some vitamin A may be eliminated in the feces when large doses are taken. The majority of vitamin A is ingested as retinyl esters, the storage form of retinol.[137] Retinyl esters undergo enzymatic hydrolysis to retinol by digestive enzymes in the intestinal lumen and brush border of the intestinal epithelial wall. A small portion of retinol is absorbed directly into the circulation, where it is bound to retinol-binding protein (RBP) and transported to the liver. Most of the retinol is taken into intestinal epithelial cells by the carrier protein cellular RBP.[157] Subsequently, retinol is re-esterified and incorporated into chylomicrons, which are released into the blood and taken up by the Ito cells of the liver. After large oral doses, significant amounts of retinyl esters coupled to chylomicrons circulate in association with low-density lipoproteins (LDLs) and are delivered to the liver. Approximately 50%–80% of the total vitamin A content of the body is stored in the liver as retinyl esters.[26] The liver releases vitamin A into the bloodstream to maintain a constant plasma retinol concentration and is thus delivered to tissues as needed.

Carotenoid absorption requires bile and absorbable fat in the stomach or intestine. These components combine with carotenoids to form mixed lipid micelles which move into the duodenal mucosal cells via passive diffusion. The majority of β-carotene that is metabolized undergoes central cleavage via oxidation to form retinal which is then reduced to retinol. Retinol is then esterified with fatty acids and incorporated into chylomicrons which are transported to the bloodstream via the lymphatics for delivery to the liver. Massive doses of β-carotene are rarely associated with vitamin A toxicity due to decreased efficiency in absorption secondary to saturation of dissolution in bulk lipid, micellar incorporation, and diffusion due to a reduction in the concentration gradient.[164] Unabsorbed β-carotene is excreted in the feces. In addition, there is a decrease in the rate of conversion of carotenoids to vitamin A.[57] Hypercarotenemia develops when massive doses are ingested. Excess absorbed β-carotene is incorporated with lipoproteins and released into the bloodstream via the lymphatics for delivery to the adipose tissue and adrenals for storage. Hypercarotenemia usually is not associated with morbidity.

The normal plasma retinol concentration is approximately 30–70 μg/dL.[192] Blood concentrations are maintained at the expense of hepatic reserves when insufficient amounts of vitamin A are ingested. A normal adult liver contains enough vitamin A to fulfill the body's requirements for approximately 2 years.[146] Excessive intake of vitamin A is not initially reflected by elevated blood concentrations because vitamin A is soluble in fat but not in water. Instead, hepatic accumulation is increased. This storage system allows for cumulative toxic effects. Although no relationship exists between the magnitude of liver stores and blood concentrations of vitamin A, in chronic vitamin A toxicity serum concentrations are generally >3.49 μmol/L (95 μg/dL).[18] Vitamin A has a half-life of

286 days in the blood.[194,215] Retinoids undergo a variety of metabolic and conjugation pathways and are subsequently eliminated in the feces, urine, or bile.

Clinical toxicity correlates well with total body vitamin A content, which is a function of both dosage and duration of administration. Vitamin A toxicity is rare, with a reported average incidence of <10 cases per year from 1976 to 1987.[18] A randomized double-blind trial, in which 390 women who received 400,000 IU (120,000 RE) of vitamin A as a single dose were compared with 380 women who received placebo, suggested that dosing at this level is well tolerated by postpartum women.[102] Doses of 100,000 IU (30,000 RE) of vitamin A in children aged 6–11 months and 200,000 IU (60,000 RE) of vitamin A every 3 to 6 months for children aged 12–60 months results in few side effects.[17] The minimal dose required to produce toxicity in humans is not established. However, an animal study has shown that the median lethal acute dose in monkeys weighing between 1.0 and 1.8 kg is 560,000 IU (168,000 RE) per kg body weight.[132] In this study, all monkeys receiving >300,000 RE/kg (>999,000 IU/kg) died, whereas none died at a dose of 100,000 RE/kg (333,000 IU/kg). Hepatotoxicity can occur in humans following an acute ingestion of a massive dose of vitamin A (>600,000 IU, 180,000 RE).[117]

Vitamin A toxicity may occur more frequently secondary to chronic ingestions of vitamin A. Hepatotoxicity typically requires vitamin A ingestions of at least 50,000–100,000 IU/d (15,000–30,000 RE/d) for months or years.[6,117] One study found that in patients with vitamin A–induced hepatotoxicity, the average daily vitamin A intake was higher in patients who developed cirrhosis (135,000 IU/d, 40,500 RE/d) compared to patients who developed noncirrhotic liver disease (66,000 IU/d, 20,000 RE/d).[78] However, case reports have documented hepatotoxicity resulting from vitamin A doses as low as 25,000 IU/d (7500 RE/d),[78,117] a dose widely available in nonprescription vitamin A preparations.

■ PATHOPHYSIOLOGY

The mechanism of action for many of the toxic effects of vitamin A may be at the nuclear level. Retinoic acid influences gene expression by combining with nuclear receptors.[137] Retinoids also influence expression of receptors for certain hormones and growth factors. Thus they are able to influence growth, differentiation, and function of target cells.[130]

In epithelial cells and fibroblasts, retinoids affect changes in nuclear transcription, resulting in enhanced production of proteins such as fibronectin and decreased production of other proteins such as collagenase.[134] Excessive concentrations of retinoids lead where goblet cells are present to the production of a thick mucin layer and inhibition of keratinization. In addition, lipoprotein membranes have increased permeability and decreased stability, resulting in extreme thinning of the epithelial tissue.

In vitro studies in bone demonstrate that high doses of vitamin A are capable of directly stimulating bone resorption and inhibiting bone formation. This effect is secondary to increased osteoclast formation and activity and inhibition of osteoblast growth.[154,159,187]

Hepatotoxicity may develop secondary to an acute overdose or ingestion of "low" or "therapeutic" doses if taken over a prolonged time.[78,117] Ninety percent of hepatic vitamin A stores are located in the Ito, or fat-storing, cells of the liver, which are located in the perisinusoidal space of Disse, and are responsible for maintaining normal hepatic architecture.[88,89] Ito cells undergo hypertrophy and hyperplasia as vitamin A storage increases.[117] This results in transdifferentiation of the Ito cell into a myofibroblast-like cell that secretes a variety of extracellular matrix components, leading to narrowing of the perisinusoidal space of Disse, obstruction to sinusoidal blood flow, and
FIGURE 41–1. Schematic demonstration of hepatotoxicity resulting from excessive deposition of vitamin A in the Ito cells of the liver.

noncirrhotic portal hypertension (Fig. 41–1).[48,82,99,112,117,184] Continued ingestion of vitamin A and hepatic storage may lead to obliteration of the space of Disse, sinusoidal barrier damage, perisinusoidal hepatocyte death, fibrosis, and cirrhosis[99,106,117,182] (see Chap. 26). Vitamin A toxicity is associated with idiopathic intracranial hypertension (IIH). Although the role of vitamin A in the development of IIH is not definitively understood, serum concentrations of vitamin A are significantly higher in patients with IIH compared to healthy controls.[104] In addition, cerebrospinal fluid (CSF) concentrations of vitamin A are significantly elevated in patients with IIH compared to patients with normal intracranial pressure (ICP) or patients with other causes of elevated ICP.[214] Unbound, circulating retinol and retinyl esters are proposed to be capable of interacting with cell membranes and producing damage by membranolytic surface-active properties.[104] In the CNS, disruption of cell membrane integrity might lead to disruption of CSF outflow, thereby producing signs and symptoms consistent with IIH.[80,104,115,133]

■ CLINICAL MANIFESTATIONS

Vitamin A toxicity affects the skin, hair, bones, liver, and brain. The most common skin manifestations include xerosis, which is associated with pruritus and erythema, skin hyperfragility, and desquamation.[54,55,220] Retinoid toxicity may cause hair thinning and even diffuse hair loss in 10%–75% of patients.[72,81,114] In addition, the characteristics of the hair may change after regrowth. Hair sometimes becomes permanently curly or kinky.[10] Nail changes include a shiny appearance, brittleness, softening, and loosening.[66] Dryness of mucous membranes develops with chapped lips and xerosis of nasal mucosa, which sometimes is associated with nasal bleeding.[45]

Findings from epidemiologic studies are consistent with bone loss and a resulting increase in fracture risk. In northern Europe, the region with the highest incidence of osteoporotic fractures, dietary intake of vitamin A is high. A study of this population demonstrated that the risk of first hip fracture was increased by 68% for every 1 mg increase in RE intake.[142] This study also showed that compared to intake <0.5 mg/d, intake >1.5 mg/d reduced bone mineral density by 10% at the femoral

neck, 14% at the lumbar spine, and 6% for the total body, and doubled the risk of hip fracture. These findings are supported by other studies demonstrating an increased risk of hip fracture among women with elevated serum vitamin A concentrations and in women ingesting large daily amounts of vitamin A.[67,158] One study found that among women not taking supplemental vitamin A, a diet rich in vitamin A was also associated with an increased fracture risk.[67]

Other musculoskeletal findings include skeletal hyperostoses, most commonly affecting the vertebral bodies of thoracic vertebrae, extraspinal tendon and ligament calcifications, soft tissue ossification, cortical thickening of bone shafts, periosteal thickening, and bone demineralization.[45,146,148] Many of these findings are apparent on radiographs. Patients often complain of bone and joint pain and muscle stiffness or tenderness. Hypercalcemia, with low or normal parathyroid hormone (PTH) concentrations, is thought to be secondary to increased osteoclast activity and bone resorption.[27] Patients with chronic renal failure are at increased risk for developing hypercalcemia at vitamin A doses lower than usual toxic doses secondary to decreased renal metabolism of retinol. This complication occurred in an 8-year-old boy with chronic renal failure following a dose of 12,000 IU/d (3600 RE/d) for at least 2 years.[52] Premature epiphyseal closure in children is reported.[172] Teratogenic effects include interference with skeletal differentiation and growth.[27]

The degree of hepatotoxicity appears to correlate with the dose of vitamin A and chronicity of use. With large doses, cirrhosis develops and may lead to portal hypertension, esophageal varices, jaundice, and ascites.[49,78,117] Hepatotoxicity may be manifested by elevations in bilirubin, aminotransferases, and alkaline phosphatase concentrations.

Idiopathic intracranial hypertension is characterized by elevated ICP in the absence of a structural anomaly. It occurs in patients with altered endocrine function, systemic diseases, impaired cerebral venous drainage, or ingestion of various xenobiotics, including excessive vitamin A (Table 41–2).[5] The syndrome is most common in young obese women, but the etiology remains unknown in the majority of cases. The first case of IIH associated with vitamin A toxicity was described in 1954.[77] However, the symptoms were first described in 1856 by an Arctic explorer who noted vertigo and headache after eating polar bear

liver.[191] Patients typically present with headache and visual disturbances, including sixth nerve palsies, visual field deficits, and blurred vision, and have a normal mental status. Despite severe papilledema, visual loss often is minimal. However, permanent blindness may result from optic atrophy.[131] Other symptoms of neurotoxicity include ataxia, fatigue, depression, irritability, and psychosis.[24]

Isotretinoin is effective in the management of acne. However, its use is associated with teratogenicity. It is thought to interfere with cranial-neural-crest cells, which contribute to the development of both the ear and the conotruncal area of the heart, and may cause malformed or absent external ears or auditory canals and conotruncal heart defects.[119] Although studies have not shown a teratogenic risk with topical preparations, case reports describe fetal malformations associated with topical preparation use during pregnancy.[12,33,107,129,190] In addition, mucocutaneous abnormalities, IIH, corneal opacities, hypercalcemia, hyperuricemia, musculoskeletal symptoms, liver function abnormalities, elevated triglyceride concentrations, and spontaneous abortion are reported.[3,71,76,85,86]

APL differentiation syndrome is the main adverse effect of treatment with ATRA. The syndrome is characterized by dyspnea, pulmonary effusions and infiltrates, fever, weight gain, renal failure, pericardial effusions, and hypotension.[63] Onset of symptoms is typically 2 to 21 days after initiation of ATRA.[167] Elevated leukocyte counts at diagnosis or rapidly increasing counts during ATRA treatment predict the development of APL differentiation syndrome. Its etiology is thought to be related to cytokine release by maturing blast cells. Addition of dexamethasone to the treatment regimen was shown to decrease the incidence of this syndrome to approximately 15% and its mortality to 1%.[64] However, other data demonstrated a 17% occurrence of APL differentiation syndrome despite concurrent use of steroids and not all authors support its use.[167,219]

Symptoms of an acute overdose of vitamin A often develop within hours to 2 days after ingestion.[146] Initial signs and symptoms include headache, papilledema, scotoma, photophobia, seizures, anorexia, drowsiness, irritability, nausea, vomiting, abdominal pain, liver damage, and desquamation.[146] Additional signs and symptoms are associated with chronic toxicity.[146] Nonspecific symptoms include fatigue, fever, weight loss, edema, polydipsia, dysuria, hyperlipidemia, anemia, and menstrual abnormalities.

Hypercarotenemia produces a yellow-orange skin discoloration that can be differentiated from jaundice by the absence of scleral icterus.

■ DIAGNOSTIC TESTING

The diagnosis of vitamin A-associated hepatotoxicity is supported by histologic evidence of Ito cell hyperplasia with fluorescent vacuoles on liver biopsy.[78] Laboratory testing should also include serum electrolytes including calcium, hepatic enzymes, and a complete blood cell count. Because the liver has a large storage capacity for excess vitamin A, hepatotoxicity may occur prior to an elevation in the serum concentration of vitamin A, which may be normal or even low, in the setting of an acute overdose. As the hepatic storage capacity is overwhelmed, the serum concentration may rapidly rise in a nonlinear fashion. Further evaluation should be guided by the clinical presentation and may include bone radiographs, computed tomography of the brain, and lumbar puncture.

■ TREATMENT

Management of a recent acute, large overdose should begin with gastrointestinal decontamination. This can be accomplished with a dose of activated charcoal. In extremely large overdoses that are expected to produce significant toxicity, gastric lavage may be considered. Although most signs and symptoms of vitamin A toxicity resolve within 1 week following vitamin A discontinuation and supportive care, papilledema, desquamation, and skeletal abnormalities may persist for several months. Hypercalcemia should be treated with intravenous fluids, loop diuretics, and prednisone 20 mg/d.[23] Bisphosphonates may be beneficial in refractory cases.

Idiopathic intracranial hypertension may require more aggressive therapy, similar to that of other causes of increased ICP. Depending on the severity of the syndrome, patients may require dexamethasone (0.25–0.5 mg/kg/d in children <40 kg and 12–16 mg/d in adults); an initial adult dose of 250 mg acetazolamide, which can be increased to 500 mg 3 times per day; 40 mg IV furosemide; and 1 g/kg mannitol.[191] Tapering doses of hydrocortisone or prednisone are alternatives to dexamethasone. Acetazolamide decreases CSF formation but may be associated with a transient increase in ICP. Patients with extremely high ICP may benefit from daily lumbar punctures with CSF drainage.

Treatment of APL differentiation syndrome involves prompt administration of corticosteroids, commonly dexamethasone 10 mg IV twice daily for at least 3 days.[167] In severe cases, ATRA should be discontinued or another antineoplastic agent, typically cytarabine, should be added to ATRA in patients with high white blood cell counts.[167] ATRA can be reintroduced upon resolution of the differentiation syndrome.

VITAMIN D

MW = 384.62 daltons
Therapeutic serum concentration = 10–50 ng/mL
■ HISTORY AND EPIDEMIOLOGY

Vitamin D is the name given to both ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3). In humans, both forms of vitamin D have the same biologic potency. Vitamin D is used for the prophylaxis and treatment of rickets, osteomalacia, and osteoporosis, and for the treatment of hypoparathyroidism and skin conditions including psoriasis. Rickets, a disease of urban children living in temperate zones, was thought to result from the lack of a dietary factor or adequate sunshine. In 1919, two independent groups demonstrated that rickets could be prevented or cured by either the addition of cod liver oil to the diet or exposure to sunlight.[101,143] Vitamin D is found in other foods, including butter, cheese, and cream, which contain 12–40 IU/100 g (0.3–1 μg/100 g); eggs, which contain 25 IU/100 g (0.6 μg/100 g); and fatty fish, such as salmon and mackerel, which contain 150–550 IU/100 g (4–14 μg/100 g) and 1100 IU/100 g (28 μg /100 g), respectively. Some foods typically are fortified with vitamin D, including cereals, bread, and milk.[94] Many dietary supplements, such as multivitamins, contain vitamin D. One microgram of vitamin D is equivalent to 40 IU of vitamin D.

Vitamin D deficiency should not occur in individuals who are exposed to adequate sunlight and eat a well-balanced diet. Casual exposure of cutaneous tissues to ultraviolet light during the summer months should produce adequate vitamin D storage for winter months.[83] Total body sun exposure provides the vitamin D equivalent of 10,000 IU/d (250 μg/d);[207] the body requires only a total vitamin D supply of 4000 IU/d (100 μg/d).[207] Breast-fed infants may require supplemental vitamin D if they have limited exposure to sunlight because the vitamin D content of human milk is extremely low.[43] Other groups susceptible to vitamin D deficiency include the elderly, vegans, and persons without adequate sunlight exposure. The daily adequate intake of vitamin D for nonelderly adults is 200 IU/d (5 μg/d).[73] This dose approximates the vitamin D content of a half-teaspoon of cod liver oil.[163] These doses appear to prevent rickets and osteomalacia. However, larger doses of vitamin D may be required for treatment of osteoporosis or hypoparathyroidism.

Rickets has been eliminated as a major public health concern in children in Europe and North America since the fortification of milk with vitamin D. Outbreaks of vitamin D poisoning subsequently occurred in Europe in the 1950s because of excessive fortification of milk and cereals to compensate for wartime nutritional deprivation of children.[50] This vitamin D poisoning led to a period of prohibition of vitamin D fortification of foods.[94] More recently, a study showed that milk and infant formulas rarely contain the amount of vitamin D stated on the label and may be either significantly underfortified or overfortified, leading to vitamin D deficiency or toxicity.[94] One case series demonstrated vitamin D toxicity in eight patients who drank local dairy milk that was excessively fortified with vitamin D_3.[105] Many cases of vitamin D toxicity result from continued supplementation of vitamin D and calcium initially prescribed for treatment of hypoparathyroidism, osteoporosis, or osteomalacia, due to inadequate patient followup.[47,124,168] Two reports describe vitamin D toxicity in families secondary to use of a highly concentrated vitamin D preparation in nut oil that was not intended for human consumption.[53,169] Another case report describes vitamin D poisoning secondary to contamination of table sugar with crystalline vitamin D_3.[209] Vitamin D toxicity can occur secondary to vitamin D_3 exposure in the form of rodenticides (Chap. 108).

■ PHARMACOLOGY AND TOXICOKINETICS

Vitamin D itself is not biologically active but must go through extensive metabolism to an active form, whether it is ingested from a food source or synthesized in the body. Vitamin D_3 is synthesized in the skin from 7-dehydrocholesterol (provitamin D_3) in a reaction catalyzed by ultraviolet B irradiation (Fig. 41–2).[124] Vitamin D_3 then is bound to vitamin D-binding protein, a protein that also binds vitamin D from the diet, and afterward enters the circulation. In the endoplasmic reticulum of the liver, vitamin D_3 is metabolized to 25-hydroxyvitamin D [25(OH)D] by vitamin D-25-hydroxylase.[74] Once formed, 25(OH)D is again bound to vitamin D-binding protein and transported to the proximal convoluted tubule in the kidney for hydroxylation to 1,25-dihydroxyvitamin D [1,25(OH)₂D], or calcitriol, by 25(OH)D-1α-hydroxylase.[74] Once formed, 1,25(OH)₂D is secreted back into circulation, bound to vitamin D-binding protein, and delivered to target cells where it binds to receptors.

Vitamin D might be more appropriately called a hormone rather than a vitamin because it is synthesized in the body, circulates in the blood, and then binds to receptors in order to evoke its biologic action. The primary role of vitamin D is regulation of calcium homeostasis via interactions with the intestines and bones. Protein-bound calcitriol is taken up by cells and then binds to a specific nuclear vitamin D receptor protein that, in turn, binds to regulatory sequences on chromosomal DNA.[124] The result is induction of gene transcription and translation of proteins that carry out the cellular functions of vitamin D. In the intestines, calcitriol increases the production of calcium-binding proteins and plasma membrane calcium pump proteins, thereby increasing
FIGURE 41–2. Schematic representation of the synthesis and physiologic response to Vitamin D.

calcium absorption through the duodenum.[108] In the bone, calcitriol stimulates osteoclastic precursors to differentiate into mature osteo-clasts.[95] Mature osteoclasts, together with PTH, lead to mobilization of calcium stores from bone, thereby raising serum concentrations of calcium. Given sufficient serum concentrations of calcium, calcitriol promotes bone mineralization by osteoblasts, resulting in increased deposition of calcium hydroxyapatite into the bone matrix.[95] Calcitriol also binds to a vitamin D receptor in the parathyroid glands, which leads to decreased synthesis and secretion of PTH.[153] The vitamin D receptor is present in most cells of the body including lymphocytes, epidermal skin cells, and tumor cells.[183] The binding of calcitriol can inhibit proliferation and induce terminal differentiation.[171] Although the role of vitamin D has not been elucidated in all cells, abnormalities present during vitamin D deficiency may help identify the function of vitamin D in various tissues.

Vitamin D deficiency results in hypocalcemia, leading to increased secretion of PTH, which acts to restore plasma calcium concentrations at the expense of bone. In children, this situation leads to rickets in which newly formed bone is not adequately mineralized and results in bone deformities and growth defects. Adults develop osteomalacia, a disease characterized by undermineralized bone matrix. Patients typically present with bone pain and tenderness and proximal muscle weakness. Bone deformities are limited to the advanced stages of disease.

The literature varies regarding the toxic dose of vitamin D, with little scientific data available for corroboration. The current "no observed adverse effect level" or tolerable upper intake dose was conservatively set at 2000 IU/d (50 µg/d)[73,207] but this determination occurred without the consideration of studies showing that doses as high as 4400 IU/d (110 µg/d) and 100,000 IU (2500 µg) for 4 days did not result in adverse effects.[196,203,207] Case reports describe toxicity in the setting of vitamin D intake of 50,000–150,000 IU or, simply, doses in the milligram range, daily for prolonged periods.[47,168]

■ PATHOPHYSIOLOGY

The hallmark of vitamin D toxicity is hypercalcemia. Vitamin D in the form of $1,25(OH)_2D$ promotes calcium absorption from the gut and mobilization of calcium from bone. Vitamin D toxicity may be associated with a plasma concentration of $25(OH)D$ 20 times higher than normal, whereas the concentration of $1,25(OH)_2D$ remains exceedingly variable.[74,169] 25-Hydroxyvitamin D can mimic the action of $1,25(OH)_2D$ when it is present in excess and can bind to receptors usually specific for $1,25(OH)_2D$.[74,124] Alternatively, $25(OH)D$, which has a higher affinity for vitamin D-binding protein compared to $1,25(OH)_2D$, may preferentially bind to vitamin D-binding protein when it is present in elevated concentrations, displacing $1,25(OH)_2D$ and allowing it to circulate in an unbound form, or loosely bound to albumin.[208] A study of patients with vitamin D toxicity who had normal or near-normal total $1,25(OH)_2D$ levels had elevated free $1,25(OH)_2D$ levels.[169] The availability of $1,25(OH)_2D$ to its receptors likely is increased, resulting in vitamin D toxicity.

■ CLINICAL MANIFESTATIONS

Patients with vitamin D toxicity present with signs and symptoms characteristic of hypercalcemia.[124] Early manifestations include weakness, fatigue, somnolence, irritability, headache, dizziness, muscle and bone pain, nausea, vomiting, abdominal cramps, and diarrhea or constipation. As the calcium concentration increases, hypercalcemia may induce polyuria and polydipsia. Diuresis results in salt and water depletion, further impairing calcium excretion.

Severe hypercalcemia may present with ataxia, confusion, psychosis, seizures, coma, and renal failure. In addition, cardiac dysrhythmias result from a shortened refractory period and slowed conduction. ECG findings include increased PR intervals, widening of QRS complexes, QT shortening, and flattened T waves.[155] Patients can develop metastatic calcification of the kidneys, blood vessels, myocardium, lung, and skin. Several patients with vitamin D toxicity have presented with anemia.[173,185] Proposed mechanisms for anemia include a direct effect of vitamin D on hematopoietic cells and inhibition of erythropoietin production.[173]

■ DIAGNOSTIC TESTING

Vitamin D toxicity should be considered in patients presenting with signs and symptoms of hypercalcemia. In addition to an elevated serum calcium, laboratory results may reveal hyperphosphatemia given that vitamin D facilitates phosphate absorption in the small intestine, enhances its mobilization from bone, and decreases its excretion by the kidney.[135] The diagnosis should be suspected in children with nephrocalcinosis and hypercalcuria even if serum calcium and phosphorus concentrations are normal.[149]

■ MANAGEMENT

Treatment of hypercalcemia in patients with vitamin D toxicity should include discontinuation of both vitamin D and calcium supplementation, maintenance of a low-calcium diet, and administration of adequate volumes of oral or IV fluid to increase renal calcium clearance.[124] Many cases of hypercalcemia will respond to such supportive care. Following rehydration, a loop diuretic, such as furosemide at a standard dose, can be added to promote calcium excretion.[124] Corticosteroids, in doses of hydrocortisone, 100 mg/d, or prednisone, 20 mg/d, improve hypercalcemia and hypercalcuria in vitamin D poisoning. Studies have attempted to explain this effect as being a result of either decreased intestinal calcium absorption or inhibition of bone resorption.[113,198] Bisphosphonates, such as pamidronate, 90 mg IV, and coldronate, 600 mg IV, were used successfully in cases of severe hypercalcemia.[123,178] These drugs inhibit bone resorption via actions on osteoclasts. Their use may preclude the need for hemodialysis in refractory cases of hypercalcemia. Calcitonin, a hypocalcemic hormone secreted by the thyroid gland that directly inhibits osteoclast activity, can be used to decrease bone resorption. Salmon calcitonin was successfully used to treat refractory hypercalcemia in a child with vitamin D poisoning at a dose of 4 U/kg IM twice daily until hypercalcemia resolved at 15 days.[144]

ANTIOXIDANTS (VITAMINS E AND C)

The antioxidants include vitamins E and C, and β-carotene. During the 1990s, the concept that antioxidants had a protective effect against atherosclerosis and carcinogenesis was widely promoted. This notion was based on the "oxidative-modification hypothesis" of atherosclerosis, which proposes that atherogenesis is initiated by lipid peroxidation of LDLs.[51] Unregulated or prolonged production of cellular oxidants leading to oxidant-induced DNA damage is thought to be responsible for carcinogenesis.[116] Epidemiologic evidence seems to support the use of antioxidants for these indications.[118,176,195] However, several prospective, randomized, placebo-controlled clinical trials, designed to test for the effect of antioxidant vitamins on cardiovascular disease and cancer, have consistently shown that commonly used antioxidant regimens do not significantly reduce or prevent overall cardiovascular events or cancer.[31,87,91,156,200,221]

VITAMIN E

MW	= 430.69 daltons
Therapeutic serum concentration	= 0.5–2.0 mg/dL
■ HISTORY AND EPIDEMIOLOGY

Vitamin E includes eight naturally occurring compounds in two classes—tocopherols and tocotrienols—which have differing biologic activities. The most biologically active form is RRR-α-tocopherol, previously known as d-α-tocopherol, which is the most widely available form of vitamin E in food. A synthetic form of α-tocopherol, often used in vitamin supplements, contains a mixture of d and l isomers and is designated all-rac-α-tocopherol (previously d,l-α-tocopherol).

The existence of vitamin E was first demonstrated in 1922 by researchers noting that female rats deficient in a dietary principal were unable to sustain a pregnancy.[60] Testicular lesions in male rats were described in deficiency states, and vitamin E was referred to as the "antisterility vitamin."[137] Vitamin E was first isolated from wheat-germ oil in 1936.[59] The richest sources of vitamin E include nuts, wheat germ, whole grains, vegetable and seed oils, including soybean, corn, cottonseed, and safflower, and the products made from these oils. In general, animal products are poor sources of vitamin E. Human milk, in contrast to cow's milk, has sufficient α-tocopherol to meet the needs of breast-fed infants.[137] In the United States, approximately 12.7% of adults take vitamin E alone as a dietary supplement.[175] Supplementation should not be necessary in persons who consume a well-balanced diet. One IU is equivalent to 1 mg α-tocopherol acetate.

Vitamin E deficiency occurs in patients with malabsorption syndromes, which may occur in the presence of pancreatic insufficiency or hepatobiliary disease, such as biliary atresia.[25] Patients with abetalipoproteinemia are at risk for vitamin E deficiency.[13] In this rare disease, absorption and transport of vitamin E are impaired secondary to a lack of chylomicron and β-lipoprotein formation. Manifestations of deficiency are variable but seem to have the most effect in organ systems that rely on vitamin E for normal functioning.[137] The clinical syndrome is primarily manifested by a peripheral neuropathy and spinocerebellar syndrome that improves with supplemental vitamin E.[145] Symptoms include ophthalmoplegia, hyporeflexia, gait disturbances, and decreased sensitivity to vibration and proprioception.[25]

Vitamin E is an essential nutrient. It is believed to be necessary for normal functioning of the nervous, reproductive, muscular, cardiovascular, and hematopoietic systems. Use of vitamin E has been proposed for a wide range of conditions. In most cases, scientific rationale for its use is lacking or is based on in vitro or animal data that have not been validated in humans or have demonstrated equivocal results.[25] As examples, vitamin E has been used for treatment of recurrent abortion, hemolytic anemias, claudication, wound healing, tardive dyskinesia, epilepsy, and adult respiratory distress syndrome. In addition, much research over the past decade has focused on the use of vitamin E for the prevention and treatment of cardiovascular disease and cancer, with disappointing results.[201]

■ PHARMACOLOGY AND TOXICOKINETICS

Vitamin E absorption is dependent on the ingestion and absorption of fat. The presence of bile also is essential. Vitamin E is passively absorbed in the intestinal tract into the lymphatic circulation by a nonsaturable process. Approximately 45% of a dose is absorbed in this manner and subsequently enters the bloodstream in chylomicrons, which are taken up by the liver. Vitamin E then is secreted back into the circulation, where it is primarily associated with LDLs. Vitamin E is distributed to all tissues, with the greatest accumulation in adipose tissue, liver, and muscle.

The primary biologic function of vitamin E is as an antioxidant. It prevents damage to biologic membranes by protecting polyunsaturated fats within membrane phospholipids from oxidation.[32] It accomplishes this task by preferentially binding to peroxyl radicals and forming the corresponding organic hydroperoxide and tocopheroxyl radical, which, in turn, interacts with other antioxidant compounds, such as ascorbic acid, thereby regenerating tocopherol. Vitamin E may be responsible for cell growth and proliferation by combating the inhibitory effects of lipid peroxidation.[145] Vitamin E may have a negative role in the regulation of cellular proliferation through its nonoxidant properties, such as inhibition of protein kinase C activity.[145]

Large amounts of vitamin E, ranging from 400–800 IU/d (400–800 mg/d) for months to years, were previously thought to be without apparent harm.[43] Vitamin E supplementation results in few obvious adverse effects, even at doses as high as 3200 mg/d (3200 IU/d).[19] In several species, the oral median lethal dose was 2000 mg/kg (2000 IU/kg) or more, and significant adverse effects were observed only when daily doses were >1000 mg/kg (>1000 IU/kg), equivalent to 200–500 mg/kg (200–500 IU/kg) in humans.[146] However, a meta-analysis reveals that all cause mortality may increase at doses ≥400 IU/d (≥400 mg/d).[147]

■ PATHOPHYSIOLOGY

In vitro studies demonstrate that vitamin E in high doses may have a paradoxical pro-oxidant effect.[2,30,147] The pro-oxidant effect of vitamin E on LDLs is related to the production of α-tocopheroxyl radicals, which normally are inhibited by other antioxidants such as vitamin C. High doses of vitamin E may displace other antioxidants, thereby disrupting the natural balance of the antioxidant system and increasing vulnerability to oxidative damage.[100] High doses of vitamin E may inhibit human cytosolic glutathione S-transferases, enzymes that are active in the detoxification of drugs and endogenous toxins.[206]

■ CLINICAL MANIFESTATIONS

Gastrointestinal symptoms, including nausea and gastric distress, were reported in patients who had received vitamin E 2,000–2,500 IU/d (2000–2500 mg/d).[92,216] Diarrhea and abdominal cramps were reported in patients who received a dose of 3200 IU/d (3200 mg/d).[9] Reports of other adverse effects, including fatigue, weakness, emotional changes, thrombophlebitis, increased serum creatinine concentration, and decreased thyroid hormone concentrations, have not been reproduced in other case series or clinical trials.[146]

The most significant toxic effect of vitamin E, at doses exceeding 1000 IU/d (1000 mg/d), is its ability to antagonize the effects of vitamin K.[43] Vitamin E appears to increase the epoxidation of vitamin K to its inactive form, thereby increasing the vitamin K requirement severalfold.[19,210] Although high oral doses of vitamin E typically do not produce a coagulopathy in normal humans with adequate vitamin K stores, coagulopathy may develop in vitamin K–deficient patients or those taking warfarin.[19,42,62,210] Animal studies demonstrate that absorption of both vitamins A and K is impaired by large doses of vitamin E.[25,179]

Use of an IV vitamin E preparation (E-Ferol) was associated with a severe epidemic of unexplained thrombocytopenia, renal dysfunction, hepatomegaly, cholestasis, ascites, hypotension, and metabolic

acidosis in low-birth-weight infants in several neonatal intensive care units in the early 1980s.[29] Use of polysorbate 20 and polysorbate 80 for emulsification of lipids and fat-soluble vitamins in this IV vitamin E product was implicated as the cause of this syndrome, rather than vitamin E.

VITAMIN C

MW	= 176.12 daltons
Therapeutic serum concentration	= 0.4–2.0 mg/dL
■ HISTORY AND EPIDEMIOLOGY

Vitamin C alone, also known as *ascorbic acid*, is ingested by approximately 12.4% of the United States adult population.[175] In the United States approximately 80.3% of men and 86.4% of women who take multiple dietary supplements also take vitamin C, making it one of the most widely consumed xenobiotics, in addition to a B-complex preparation, within this group.[28] Vitamin C has long been used as a preventative for the common cold. Interestingly, an extensive review of 14 studies of the role of vitamin C in the treatment of the common cold suggested that only eight were valid investigations, and none of the studies demonstrated any therapeutic benefit.[36] Its function as an antioxidant has led to its use for the prevention and treatment of cardiovascular disease and cancer. Human data from clinical trials have failed to demonstrate that vitamin C significantly reduces or prevents overall cardiovascular events or cancer. Vitamin C may have a role as a reducing agent in the treatment of idiopathic methemoglobinemia. However, it is less effective than standard treatment with methylene blue and therefore not employed.[136] Vitamin C is popularly used to promote wound healing, treat cataracts, combat chronic degenerative diseases, counteract the effects of aging, and increase mental attentiveness and decrease stress.[43,146] However, little, if any, objective data demonstrate a benefit of treatment for any of these indications.[43]

Vitamin C has long been associated with prevention of scurvy.[136] In 1747, James Lind, a physician in the British Royal Navy, analyzed the relationship between diet and scurvy and confirmed the protective and curative effects of citrus fruits. Vitamin C was isolated from cabbage in 1928 and subsequently shown in 1932 to be the active antiscorbutic factor in lemon juice. It was given the name *ascorbic acid* to indicate its role in preventing scurvy. Other dietary sources of vitamin C include tomatoes, strawberries, and potatoes. Today, those at risk for developing scurvy include the elderly, alcoholics, chronic drug users, and others with inadequate diets, including infants fed formula diets with insufficient concentrations of vitamin C.[136] Symptoms include gingivitis, poor wound healing, bleeding, and petechiae and ecchymoses. Musculoskeletal symptoms consisting of arthralgias, myalgias, hemarthrosis, and muscular hematomas develop in 80% of cases.[61] Children experience severe pain in their lower limbs secondary to subperiosteal bleeding.[61]

■ PHARMACOLOGY AND TOXICOKINETICS

Following ingestion, intestinal absorption of vitamin C occurs via an active transport system that is saturable.[177] The absorptive capacity is reached with ingestions of approximately 3 g/d, and vitamin C dietary supplements are commonly taken in doses of 500 mg/d. When given as a single oral dose, absorption decreases from 75% at 1 g to 20% at 5 g. Vitamin C is distributed from the plasma to all cells in the body. Tissue uptake is also a saturable process.[146] Metabolic degradation of vitamin C to oxalate accounts for 30%–40% of oxalate excreted daily.[84] Because absorption and metabolic conversion are saturable, large ingestions of vitamin C should not significantly increase oxalate production.[189] Only a small amount of vitamin C is filtered through the glomeruli, and tubular resorption, a saturable process that may compete with uric acid, usually is almost complete.[22] Plasma concentrations of vitamin C typically are maintained at approximately 1 mg/dL. The kidney efficiently eliminates excess vitamin C as unchanged ascorbic acid.

Vitamin C is a cofactor in several hydroxylation and amidation reactions by functioning as a reducing agent.[126,127] As a result, vitamin C plays an important role in the synthesis of collagen, carnitine, folinic acid, and norepinephrine. It also influences the processing of hormones such as oxytocin, antidiuretic hormone, and cholecystokinin. Vitamin C reduces iron from the ferric to the ferrous state in the stomach, thereby increasing intestinal absorption of iron. Vitamin C may be involved in steroidogenesis in the adrenals. Vitamin C also has a pro-oxidant effect in vivo.[170] This effect is not believed to occur at doses <500 mg/d but may occur in the setting of overdose.

■ CLINICAL MANIFESTATIONS

The possibility of oxalate nephrolithiasis is not a significant clinical concern.[76] Nevertheless, conflicting studies and reports regarding the association between vitamin C overdose and the development of oxalosis exist. Some reports of high urine oxalate concentrations likely were erroneous because of conversion of ascorbate to oxalate in alkaline urine samples left standing after collection.[11,213] Individual case reports documenting the presence of oxalate stones in the setting of vitamin C overdose often have involved either IV administration or patients with chronic renal failure.[14,75,121,139,146,199] A prospective study on the risk of kidney stones in men did not support an association between high daily vitamin C intake and stone formation.[44] This was also demonstrated in a study involving daily ingestion of 4 g of ascorbic acid for 5 days in healthy men in which there was no increase in urinary oxalate excretion.[11] Another study did show increased rates of oxalate absorption and endogenous synthesis contributing to hyperoxaluria, but this effect was found in individuals with a prior history of renal calcium oxalate stones and not in individuals without a prior history of calcium oxalate stones.[35] In contrast, other reports show an increase in urinary oxalate and calcium oxalate crystallization following ingestion of high doses of calcium in both stone-formers and non-stone-formers.[16,138] Gastrointestinal tract effects of high doses of vitamin C may include localized esophagitis, given prolonged mucosal contact with ascorbic acid, and an osmotic diarrhea.[98,212]

VITAMIN B₆

MW	= 169 daltons
Therapeutic serum concentration	= 3.6–18 ng/mL
■ HISTORY

Pyridoxine, pyridoxal, and pyridoxamine are related compounds that have the same physiologic properties. Although all three compounds are included in the term *vitamin B₆*, the vitamin has been assigned the name *pyridoxine*. This vitamin was discovered in 1936 as the water-soluble factor whose deficiency was responsible for the development of dermatitis in rats.[136] In humans, deficiency is characterized by a seborrheic dermatitis around the eyes, nose, and mouth, cheilosis, stomatitis, glossitis, and blepharitis.[193] More importantly, pyridoxine deficiency is associated with seizures.

Pyridoxine is found in several foods, including meat, liver, whole-grain breads and cereals, soybeans, and vegetables.[136] Deficiency should not occur in humans who eat a well-balanced diet.[193]

Pyridoxine is popularly used as a component of bodybuilding regimens and for treatment of premenstrual syndrome and carpal tunnel syndrome.[1,56] High doses have been used for treatment of schizophrenia and autism with variable results.[68,125]

■ PHARMACOLOGY

All forms of vitamin B₆ are well absorbed from the intestinal tract. Pyridoxine is rapidly metabolized to pyridoxal, pyridoxal phosphate (PLP), and 4-pyridoxic acid.[222] PLP accounts for approximately 60% of circulating vitamin B₆ and is the primary form that crosses cell membranes.[136] Most vitamin B₆ is renally excreted as 4-pyridoxic acid, with only 7% excreted unchanged in the urine.[136,222] Experiments in anephric rats demonstrate an up to 10-fold increase in susceptibility to pyridoxine-induced neurotoxicity, suggesting a need for caution when prescribing pyridoxine to patients with renal failure.[128]

PLP is the active form of vitamin B₆. It is a coenzyme required for the synthesis of γ-aminobutyric acid (GABA), an inhibitory neurotransmitter. Decreased GABA formation in the setting of pyridoxine deficiency may contribute to seizures.[136] Isoniazid and other hydrazines inhibit the enzyme responsible for conversion of pyridoxine to PLP[96] (see Chap. 57). Therefore, pyridoxine should be administered concomitantly with isoniazid. Seizures resulting from isoniazid overdose often are successfully treated with pyridoxine (see A15: Pyridoxine).

■ PATHOPHYSIOLOGY

Interestingly, like pyridoxine deficiency, pyridoxine toxicity is characterized by neurologic effects. The pathophysiology of pyridoxine neurotoxicity is not well defined. However, studies indicate that the mammalian peripheral sensory nervous system is vulnerable to large doses of pyridoxine.[186] Histopathology in dogs reveals sensory distal axonopathy with relative sparing of the cell body.[97] Peripheral sensory nerves may be particularly vulnerable to circulating xenobiotics because of the permeability of their associated blood vessels.[186] Compared to the CNS, these nerves lack the blood–brain barrier. In addition, the nerves of the CNS may be relatively shielded from pyridoxine toxicity because pyridoxine is transported into the CNS by a saturable mechanism.[186]

■ CLINICAL MANIFESTATIONS

Chronic overdoses are associated with progressive sensory ataxia and severe distal impairment of proprioception and vibratory sensation. Touch, pain, and temperature sensation may be minimally impaired, and reflexes may be diminished or absent. These findings were first described in 1983 in a case series of seven patients who were taking pyridoxine 2–6 g/d for 2–40 months for premenstrual syndrome.[186] Nerve conduction and somatosensory studies in these patients showed

dysfunction in the distal sensory peripheral nerves. Nerve biopsy showed widespread, nonspecific axonal degeneration. This syndrome has since been reported with pyridoxine doses as low as 200 mg/d.[166] Among 26 patients with elevated serum pyridoxine concentrations, the most common symptoms reported were numbness (96%), burning pain (49.9%), tingling (57.7%), balance difficulties (30.7%), and weakness (7.8%).[188] In most cases, symptoms gradually improved over several months with abstinence from pyridoxine. However, symptoms may still progress for 2–3 weeks after pyridoxine discontinuation.[21]

Acute neurotoxicity may occur when a massive amount of pyridoxine is administered as a single dose or given over a few days.[4] Large overdoses of pyridoxine are associated with incoordination, ataxia, seizures, and death.[204] Administration of IV pyridoxine 2 g/kg in two patients for the treatment of mushroom poisoning resulted in permanent dorsal root and sensory ganglia deficits.[4]

NICOTINIC ACID

MW   = 123 daltons
Therapeutic = not determined
concentration
■ HISTORY

Nicotinic acid, or niacin, was discovered to be an essential dietary component in the early 1900s.[79] A deficiency of this vitamin, also known as vitamin B₃, causes pellagra, which is characterized by dermatitis, diarrhea, and dementia. This disease had been prevalent for centuries in countries that heavily relied on maize as a dietary staple until it was determined that pellagra could be prevented by increasing dietary intake of fresh eggs, milk, and fresh meat, including liver.[136] Other food sources of nicotinic acid include fish, poultry, nuts, legumes, and whole-grain and enriched breads and cereals. Supplementation of flour with nicotinic acid in 1939 probably is responsible for the near eradication of this disease in the United States. Chronic alcohol users still develop pellagra, likely secondary to malnutrition.

Niacin was introduced as a treatment for hyperlipidemia in 1955.[7] Nicotinic acid reduces triglyceride synthesis, with a resultant drop in very-low-density lipoprotein cholesterol and LDL cholesterol and a rise in high-density-lipoprotein cholesterol.[79] Therapy usually is started with single doses of 100–250 mg. Frequency of dose and total daily dose are gradually increased until a dose of 1.5–2.0 g/d is reached. If the LDL cholesterol concentration is not sufficiently decreased with this dosing regimen, the dose is further increased to 3.0 g/d. These doses of niacin are 100-fold higher than the amount necessary to meet adult nutritional needs.[174]

More recently, the nonmedicinal use of niacin for the purpose of altering or masking the results of urine testing for illicit drugs was noted.[34,150] However, there is no evidence that ingestion of niacin is capable of this effect.

■ PHARMACOLOGY AND TOXICOKINETICS

Nicotinic acid is well absorbed from the intestinal tract and is distributed to all tissues. With therapeutic dosing, little unchanged vitamin is excreted in the urine. When extremely high doses are ingested, the unchanged vitamin is the major urinary component. Nicotinic acid ultimately is converted to nicotinamide adenine dinucleotide (NAD⁺) and nicotinamide adenine dinucleotide phosphate (NADP⁺), which are the physiologically active forms of this

vitamin. NADH and NADPH act as coenzymes for proteins that catalyze oxidation–reduction reactions that are essential for tissue respiration.[136]

CLINICAL MANIFESTATIONS

The most common adverse effects associated with niacin use are vasodilatory such as cutaneous flushing and pruritus. These effects may occur at doses of 0.5–1.0 g/d.[141] Symptoms are caused by the production of prostaglandin D2 and E2 via the G protein–coupled receptor, GPR109A.[20] Flushing occurs because of the predilection for the skin as a source of prostaglandin production after niacin ingestion.[197] Prostaglandins D2 and E2 act on receptors DP1 and EP2/4 in dermal capillaries causing vasodilation.[110] Vasodilatory side effects occur in up to 100% of patients, particularly when given an immediate-release form of niacin.[141] Although tolerance to flushing usually develops over several weeks, 25%–40% of patients discontinue niacin use because of vasodilatory symptoms.[46,141,174] A dose of 325 mg of aspirin taken 30 minutes before ingestion of niacin diminishes flushing.[218] This is because aspirin inhibits cyclooxygenase thereby decreasing production of prostaglandins.

Recent in vitro studies demonstrate that methylnicotinate induces serotonin release from human platelets in addition to prostaglandin D2 release from human mast cells.[161] Also, animal studies demonstrate the ability of various serotonin antagonists including cyproheptadine to inhibit the niacin-induced temperature increase, associated with flush, by 90%.[161] Flavanoids are being studied as a potential treatment for niacin flush due to their ability to inhibit both niacin-induced plasma prostaglandin D2 and serotonin increase in a rat model.[162] In a small human study, a dietary supplement containing 150 mg of the flavanoid quercetin decreased the severity and longevity of erythema and burning sensation scores on a visual scale.[109]

Other strategies for reduced flushing include dosing with meals, and avoidance of alcohol, hot beverages, spicy foods, and hot baths or showers close to or after dosing.[46] Flushing may also be decreased by starting at a low dose and gradually increasing to the full dose. Tolerance to flushing may develop after several weeks, but flushing will recur if doses are missed.

Because rapid absorption of niacin seems to be related to development of flushing, modified time-release preparations of niacin were developed. Unfortunately, these preparations are more likely to produce gastrointestinal side effects, such as epigastric distress, nausea, and diarrhea.[141] In addition, niacin-induced hepatotoxicity occurs more frequently and is more severe in patients treated with modified-release niacin rather than immediate-release niacin.[39,174] Elevated liver enzyme concentrations may occur with doses as low as 1 g/d, whereas symptoms of hepatic dysfunction occur at doses of 2–3 g/d.[141] These patients may have elevated serum bilirubin and ammonia concentrations and a prolonged prothrombin time. They may present with fatigue, anorexia, nausea, vomiting, and jaundice. In most cases, liver function improves following niacin withdrawal.[58,141] Severe cases have progressed to fulminant hepatic failure and hepatic encephalopathy.[40,93,151] Niacin also causes amblyopia, hyperglycemia, hyperuricemia, coagulopathy, myopathy, and hyperpigmentation.[90]

SUMMARY

Healthy adults consuming a well-balanced diet do not require vitamin supplementation. However, vitamins are popularly believed to be a panacea and are commonly taken in supraphysiologic doses. Because the therapeutic index is large, toxicity generally does not develop unless very large doses are taken for sustained periods. Physicians should consider hypervitaminosis in the differential diagnosis when patients present with symptomatology consistent with a vitamin toxicity syndrome. A thorough history, with emphasis on diet and prescribed and supplemental vitamin use, is important.

CHAPTER 42
ESSENTIAL OILS

Sarah Eliza Halcomb

Essential oils are a class of polyaromatic hydrocarbons extracted through steam distillation or cold pressed from the leaves, flowers, bark, wood, fruit, or peel of a single parent plant. The term "essential" refers to the essence of a plant, rather than an indispensible component of the oil or a vital biologic function. These organic compounds are a complex mixture of chemicals with structures that give the oil its aroma, therapeutic properties, and occasionally cause toxicity. More than 500 essential oils exist and can be categorized into five chemical groups: terpenes, quinines, substituted benzenes, aromatic/aliphatic esters, and phenols and aromatic/aliphatic alcohols.

HISTORY AND EPIDEMIOLOGY

Use of plant-derived essential oils in the practice of herbal medicine has a long and colorful history, dating back thousands of years. The virtues of these extracts have been mentioned in ancient Egyptian and Greek medical literature and throughout the Bible.

Essential oils were used to treat everything from asthma to snakebites until the early 20th century. In America "Indian doctors" frequently sold these products, claiming they learned medicinal secrets from local Native American tribes. These remedies were advertised at medicine shows and demonstrated by troupes such as the famous Kickapoo Indian Medicine Company. The purpose of these traveling caravans was to sell patent medicines, which typically contained substantial quantities of ethanol, in addition to other xenobiotics of uncertain therapeutic value. A bottle of Kickapoo Oil sold at the beginning of the 20th century purportedly contained "camphor, ether, capsicum, oil of cloves, oil of sassafras and myrrh." Needless to say, the risk-to-benefit ratio for this did not favor the patient, and the "doctors" who sold them quite rightly earned a reputation for quackery.[86]

With the ascent of scientific research, many essential oil remedies fell from use. More recently, however, trends in globalization and natural healing have led to a popular resurgence in the use of essential oils in developed countries. Essential oils currently are marketed for use in aromatherapy and certain complementary medicines. The reintroduction of these xenobiotics into mainstream society has highlighted the need for research and toxicity studies to ensure that appropriate decision making and care can be provided to exposed patients.

■ ABSINTHE; OIL OF WORMWOOD
Thujone

History Absinthe is an emerald green liqueur made from the extract of the wormwood plant *Artemisia absinthium*. The earliest references to wormwood date to 1500 B.C., when its antihelminthic properties were

described. It is thought that Napoleon's soldiers popularized the drink upon their return from Algeria, where they had added wormwood extract to their wine to avoid helminthic infections during the war.[43]

Absinthe achieved exceptional popularity in the late 19th century in Europe. Famous artists and authors including Lautrec, Van Gogh, Baudelaire, and Wilde sat for hours in the cafes of Paris, drinking the green liqueur and romanticizing its aphrodisiac effects. However, recognition of the devastating side effects led the French, Swiss, and American governments to ban its sale by the early 1900s.[43] It remained off the market in the United States until December of 2007 when a small company, St. George Spirits of Alameda, became the first company to sell absinthe in the United States since 1912. Absinthe is also sold without its toxic ingredient, thujone, as Pernod.

Many people have speculated on the cause of Vincent Van Gogh's bizarre behavior. Some have concluded that his fondness for absinthe may have contributed to his seizures and psychotic episodes. However, it is more likely that his consumption of large amounts of ethanol contributed to his erratic behavior.

Pharmacology The toxic component in oil of wormwood is thujone, a monoterpene ketone, which exists in α- and β-diastereoisomeric forms.[42] After oral absorption, both isomers undergo species-specific hydroxylation reactions by the cytochrome P450 system, followed by glucuronidation in the hepatocyte, leading to production of several renally eliminated nontoxic metabolites.[42]

Pathophysiology The α-stereoisomer is generally accepted to be the more toxic of the two isomers and the parent compound antagonizes the γ-aminobutyric acid (GABA)$_A$ receptor by binding at the picrotoxin site on the chloride channel, leading to neuroexcitation that may manifest as hallucinations or seizures, presumably in a dose-dependent fashion.[42] Interestingly, ethanol enhances GABA activity and may have a protective effect by reducing seizures in mice.[43]

Thujones are implicated in the development of porphyria-like syndromes by inducing the synthesis of 5-aminolevulinic acid synthetase, leading to increased porphyrin production. This finding suggests that individuals with defects in heme synthesis may unmask a porphyria-like syndrome upon ingestion of thujones.[11]

Clinical Features Case reports of toxicity reflect a recent resurgence in the popularity of the absinthe liquor, which has reappeared on the market in Europe and America.[90] Clinical features of acute toxicity are similar to those of ethanol intoxication, including euphoria and confusion, which may progress to restlessness, visual hallucinations, and delirium. Chronic abusers may suffer from seizures, hallucinations, and erratic behavior.[4] Although thujone is the purported agent in the development of these symptoms, the concentrations of thujone make it more likely that ethanol is responsible for the reported toxicity.

Rhabdomyolysis and acute renal failure have occurred following ingestion of oil of wormwood intended for preparation as absinthe.[90] The etiology of the rhabdomyolysis has not been elucidated.[90]

■ CAMPHOR
History One of the first western references to camphor is found in Marco Polo's description of his travels.[28] Camphor was traded widely throughout Asia. Historically it was used as a rubefacient, antiseptic, decongestant, and moth repellent. It gained immense popularity as a liniment during the American Civil War, and the US government

signed a contract with China to buy the entire camphor output of Formosa (Taiwan).

The French introduced camphor to Europe in 1879.[28] Camphor oil is extracted from an evergreen tree from the Laurel family *Cinnamomum camphora,*[19] which is native to eastern China, Japan, and Taiwan. It is primarily used today in nasal decongestant ointments such as Vicks Vapo-Rub, although in the recent past it was widely used in moth repellents (Chap. 103).

Pharmacology Camphor belongs to the terpene family and is capable of causing CNS toxicity.[19] Camphor is a monoterpene ketone that is rapidly absorbed from the gastrointestinal (GI) tract and then undergoes extensive first-pass metabolism. After hydroxylation and glucuronidation in the liver, its inactive metabolites undergo urinary excretion.[69,82]

Pathophysiology Camphor toxicity is reported after its ingestion, inhalation, and nasal administration. It is rapidly absorbed from the GI tract or through mucous membranes. Camphor is highly lipid soluble and readily crosses the blood–brain barrier and placenta. Seizures are common postingestion, although the specific mechanism of action is not elucidated. Cellular respiration is inhibited by camphor and similar compounds, resulting in increased excitability of neuronal tissue. Children seem particularly prone to hepatotoxicity because of the relative immaturity of their hepatic enzyme systems. They may develop hepatotoxicity resembling Reye syndrome.[47] The fetus is thought to be susceptible to toxicity through the same mechanism. Several cases of camphor use as an abortifacient and a single case of fetal demise after ingestion are reported.[68,91]

Clinical Features Camphor ingestion results in rapid onset of nausea and vomiting, followed by headache, agitation, and seizures.[21] Symptom onset usually occurs within minutes of ingestion. Seizures can occur in isolation without antecedent gastrointestinal effects.[5] Inhalational and dermal exposures typically result in local irritation.

■ OIL OF CLOVES
Eugenol

History In Medieval and Renaissance Europe, cloves were considered one of the most important commodities in the world second only to nutmeg. Clove oil is extracted from the plant *Syzygium aromaticum*, also known as *Eugenia aromatica*. This evergreen plant is native to the islands of the Malaccan Straits. Its unopened buds, when dried, are known as cloves. Eugenol has been used for centuries as a remedy for toothache and in multiple dental products.[8]

Pharmacology Eugenol, a phenol, is the principal component of clove oil. Very little available data on the metabolism of eugenol is available. An in vitro study found that incubation of isolated rat hepatocytes with eugenol resulted in a glucuronic acid conjugate, although other conjugates with sulfate and glutathione were found.[80]

Pathophysiology Little is known about the pathophysiology of eugenol toxicity. Intravenous infusion and intratracheal instillation of eugenol in rats led to the development of hemorrhagic pulmonary edema, which is thought to result from oxidative damage.[53,93]

In vitro studies of hepatic cell cultures incubated with eugenol demonstrated marked glutathione depletion, covalent bonding of conjugates to cell proteins, and cell death. These findings indicate that a reactive intermediate might be formed, leading to toxicity.[80] Nerve conduction studies performed with frog sciatic nerves demonstrate that eugenol irreversibly blocks impulse conduction. Eugenol has been demonstrated to inhibit peripheral sensory nerve conduction at low doses, but is associated with CNS depression at higher doses.[51]

Clinical Features A case report on the neurotoxicity of eugenol described a 24-year-old woman who spilled a small amount of clove oil on her face in an attempt to relieve a toothache. Permanent infraorbital anesthesia and anhidrosis resulted.[45] Likewise, inhibition of the pharyngeal reflex by inhalation of clove cigarettes is reported to cause aspiration pneumonitis.[30,35]

Inadvertent oral administration of 1–2 teaspoons of clove oil resulted in marked CNS depression, metabolic acidosis, and elevation of aminotransferases in two children.[39,52]

■ OIL OF EUCALYPTUS
Eucalyptol

History The eucalyptus tree is native to Australia. Its extracts were historically used as an aboriginal fever remedy. In 1778, the Surgeon General of the First Fleet arrived in Australia and noted that these unusual trees produced a gumlike resin, which he distilled into a quart of oil and sent back to England for further examination. The introduction of eucalyptus oil to the West led to an increased demand for the product to relieve the symptoms of the common cold and influenza. Eucalyptol is found in many nonprescription cough preparations and is widely used for treatment of upper respiratory infections because of its purported antiinflammatory effects.[48] Although oral administration of eucalyptol-containing products rarely causes toxicity, ingestion of eucalyptus oil has resulted in morbidity and mortality.

Pharmacology Eucalyptus oil contains up to 70% eucalyptol, a monocyclic terpene compound. Eucalyptol, also known as 1,8-cineole, is rapidly absorbed from the gastrointestinal tract. It undergoes oxidation in the liver to form hydroxycineole, and subsequently undergoes further glucuronidation and excretion.[89] In rats, the main urinary metabolites have been characterized as 2-hydroxycineole, 3-hydroxycineole, and 1,8-dihydroxycineol-9-oic acids.[56,74] Rabbits given oral eucalyptus excrete 2-exo-hydroxycineole and 2-endo-hydroxycineole, as well as 3-exo-hydroxycineole and 3-endo-hydroxycineole in the urine.[62]

Ingestion of less than 1 teaspoon (5 mL) of eucalyptus oil has resulted in severe toxicity.[1,6,27] The lowest lethal doses reported are 4–5 mL[57] in adults and 1.9 g in a 10-year-old boy.[63] However, ingestion of higher doses in another case series caused less severe effects.[88]

Pathophysiology The mechanism of toxicity is unclear because little toxicity seems to be associated with eucalyptol.[24]

Clinical Features Symptoms develop rapidly and include headache and light-headedness progressing to CNS depression. Serious poisoning is marked by respiratory depression and vomiting, which heighten the risk of aspiration.[73,81]

OIL OF LAVENDER

History Lavender has been used as a fragrance and tonic for centuries. The Gospel of Luke mentions its use, referring to it by its ancient name, spikenard, when Mary anointed Jesus' feet with lavender oil and dried them with her hair. Lavender enjoys the distinction of being the most commonly used ingredient in perfume production worldwide.

Pharmacology There are four major species of lavender: *Lavandula latifolia* and *L. augustifolia*, otherwise known as English lavender; *L. stoechus* or French lavender; and *L. intermedis*, a hybrid cross between English and French lavenders. Oil of lavender is derived from the steam distillation of the flowers and leaves of the plant.[17] It is predominately used as a topical agent, and undergoes rapid absorption from the skin, achieving peak serum concentration approximately 20 minutes after application.[46] Linalool, linalyl acetate, and β-caryophyllene are the primary active constituents of the oil. The former two are rapidly oxidized when exposed to air forming hydroperoxides. These highly reactive molecules rapidly cross the epidermis and form protein adducts, initiating a cascade of immunomodulatory events.[36] In an elegant experiment, both lavender and tea tree oil were shown to elicit a dose-dependent increase in estrogen responsivity and antiandrogenic activity in in vitro breast cancer cell cultures similar to the effects of estradiol.[41]

Pathophysiology The constituents of lavender oil undergo auto-oxidation when exposed to air leading to skin sensitization and the development of contact dermatitis.

A case series reported the development of gynecomastia in three prepubertal boys using lavender oil. All three children had extensive endocrine evaluations, with no abnormalities detected, and in each case the gynecomastia resolved when lavender oil was discontinued. One of the children was also using a tea tree oil preparation topically.[41]

Clinical Features The predominant clinical feature of exposure is contact dermatitis. Unexplained or "idiopathic" gynecomastia in prepubertal boys with negative endocrine evaluations should prompt questions regarding the use of essential oils.

OIL OF NUTMEG
Myristicin

History During the Middle Ages, spices were prized for their medicinal and preservative qualities. Chief among these spices was nutmeg, which, after silver and gold, was the most valued commodity in the western world. In addition to its soporific and emetic properties, nutmeg was purported to be a prophylactic against the plague. Nutmeg has been used unsuccessfully as an abortifacient and used as a hallucinogen.

In 1510, a European explorer named Ludovico de Varthema described seeing the nutmeg tree flourishing in the Indonesian archipelago on the Bandas Islands, which was the only place on Earth that the spice could be found. This discovery led to an intense competition among the great navies of Europe to dominate the spice trade.[71]

Pharmacology Nutmeg oil is extracted from the fruit of the evergreen tree *Myristica fragrans*. Its main active ingredient is thought to be myristicin, although other putative toxins derived from the extraction process include mace, eugenol, and other terpenes.[67] Case reports of

toxicity suggest that patients become symptomatic 3–6 hours after ingestion of one to three whole nuts or 1–2 tablespoons of ground nutmeg. Myristicin is oxidized in the hepatic P450 system to 5-allyl-1-methoxy-2,3-dihydroxybenzene,[94] which then undergoes glucuronidation and urinary excretion.

Pathophysiology Animal studies have suggested that myristicin-induced CNS toxicity may result from increased serotonin concentrations in the brain.[83] Myristicin has been known to inhibit monoamine oxidase,[83,84] which theoretically could lead to an adverse reaction if combined with another monoamine oxidase inhibitor. Another in vitro experiment showed that myristicin was converted to the amphetamine derivative 3-methoxy-4,5-methylene dioxyamphetamine,[13] which may explain its euphoric effects. Other animal studies have demonstrated fatty degeneration of the liver.[87]

Clinical Features CNS effects tend to be the predominant clinical features of nutmeg poisoning. Nutmeg toxicity may mimic anticholinergic toxicity, with flushing, dryness, tachycardia, hypertension, agitation, and altered mental status.[66] One feature that may help differentiate anticholinergic toxicity from nutmeg ingestion is that the pupils often are small.

Escalating doses result in increasing drowsiness that may progress to coma. Abdominal pain is frequently reported, but nausea and vomiting are uncommon. The toxic syndrome typically resolves within 24 hours, although resolution may be delayed.[32] A single fatality is reported in the literature.[23]

OIL OF PENNYROYAL
Pulegone

History References to pennyroyal oil date back to antiquity when Pliny the Elder wrote about its insect repellent effects in Book 20 of his masterpiece, *The Natural History*. Its scientific name *Mentha pulegium* is derived from the Latin pulex, which means flea. Both the fresh plant and smoke from the burning leaves were used as early insect repellents. Over the centuries this essential oil also developed a reputation for being an abortifacient and an emmenagogue.[12] The 16th-century English herbalist Gerard noted, "Pennie Royall boiled in wine and drunken, provoketh the monthly terms, bringeth forth the secondine, the deade childe and unnatural birth."[22] An early American 19th-century pamphlet recommended a recipe that included drinking a pint of pennyroyal water to induce abortion.[78] The toxic effects of pennyroyal were first described in a case report to The Lancet in 1897.[2] Today, Internet searches for pennyroyal oil lead to multiple web sites where women relate their experiences with the substance for inducing abortion.

Pharmacology The active ingredient in pennyroyal oil is R(+)-pulegone, a monoterpene commonly found in mint oils. Toxicity predominately results from ingestion of pennyroyal for the purposes of inducing abortion, although cases of oil administration to children with gastrointestinal complaints are reported.[7] Toxicity is noted in mice when 300–500 mg/kg is administered, and a human fatality was reported at an approximate dose of 500 mg/kg.

After ingestion, pulegone is metabolized by the P450 system in the liver to methofuran and other reactive metabolites, which in turn are excreted in the urine.

Pathophysiology The reactive metabolites of pulegone bind to cell proteins, disrupting normal cellular function and resulting in cellular damage.[3] Methofuran also appears to be associated with pennyroyal-induced pulmonary toxicity, which is manifested as bronchiolar necrosis.[31] Electrophilic reactive metabolites of pulegone deplete hepatic glutathione concentrations by reacting with the nucleophilic cysteinyl sulfhydryl group on glutathione, further worsening hepatotoxicity.[79] This hepatotoxicity is manifested as centrilobular necrosis, which occurs in both mouse and human specimens.[31]

Clinical Features Case reports describe a variety of symptoms after ingestion of pennyroyal oil. The most common symptoms of significant toxicity seem to include abdominal discomfort, nausea, vomiting, dizziness, syncope, and coma. Ingestion of 5–10 mL has been associated with coma and seizures, and ingestion of 15 mL may cause death.[3,7,76] Early symptoms are manifested by gastrointestinal and CNS toxicity,[7] followed by the development of hepatic and renal dysfunction.[76,85] In fatal ingestions, patients have developed disseminated intravascular coagulation and hepatic failure manifested as purpuric rash, epistaxis, vaginal bleeding, and oozing at venipuncture sites.[3,76,65]

■ OIL OF PEPPERMINT

Menthol
History Plants in the mint family have been used as medicinal herbs for centuries. One of the first known references to the medicinal qualities of mint comes from the Ebers Papyrus, an ancient Egyptian pharmacopoeia dating back to 1552 B.C. In this document, mint is mentioned as one of the recommended remedies for indigestion and nausea. According to ancient Greek mythology, Hades, the god of the underworld, fell in love with the beautiful nymph Minthe. The affair was short-lived, however, as Hades' jealous wife Persephone turned Minthe into a plant. Hades tempered the curse on the nymph by making the plant fragrant. Peppermint oil is extracted from the plant *Mentha piperita* and is widely used in flavorings and aromatherapy.

Pharmacology Menthol, the active ingredient in peppermint oil, is a cyclic terpene alcohol that is rapidly absorbed from the GI tract when ingested. In the liver, menthol undergoes hydroxylation to form p-menthane-3,8-diol and 3,8-dihydroxy-p-menthane-7-carboxylic acid by the P450 microsomal enzyme system. These metabolites subsequently are glucuronidated by uridine diphosphate (UDP)-glucuronyl transferase and excreted in the urine.[25]

Pathophysiology The unique cooling property of menthol adds to its commercial value and is one of the most studied features of the oil. Electrophysiologic investigations have shown that menthol has a dose-dependent effect on calcium concentrations across cell membranes. Inhibition of calcium efflux results in depolarization and, in turn, increases electrical discharges from cold receptors.[25] The increased electrical activity in the trigeminal nerve is thought to be responsible for the subjective impression that menthol has a decongestant effect

on the nasal passages.[25] Research has shown that menthol actually increases nasal congestion and causes an inhibition of upper airway muscle reflexes.[61]

Clinical Features Rare case reports of menthol toxicity appear in the literature. The reported symptoms include CNS effects such as ataxia, confusion, and coma,[64] nausea, and vomiting.[60,70]

■ OIL OF PINE AND TURPENTINE
α-Pinene

History Pine oil and turpentine are distilled from the wood of conifer trees particularly of the genus *Pinus*. Turpentine has been historically used as a solvent and paint thinner, whereas pine oil is derived from turpentine and is used as a disinfectant. Turpentine has also been used medicinally in the past as a diuretic and expectorant.

Toxicokinetics The main active ingredient in pine oil is α-pinene, a monoterpene hydrocarbon that is absorbed via the GI tract or through inhalation. The lipophilicity of this compound results in its accumulation in adipose tissue and slow metabolism. The primary modes of metabolism include hydration, hydroxylation, and acetylation reactions, after which inactive metabolites undergo renal excretion.[50] Turpentine also contains α-pinene as its main constituent; however, β-pinene, camphene, and limonene are also found in this product.[34] Like pine oil, these constituents are rapidly absorbed through the GI tract or inhalation and are renally excreted.[72]

Pathophysiology Pine oil and turpentine are volatile hydrocarbon compounds with low viscosity. Aspiration and inhalational injury is common when low-viscosity hydrocarbons are ingested or inhaled, because of inhibited surfactant production in the alveoli[14] (see Chap. 106). Household cleaning products which contain pine oil as an additive to increase the solution's viscosity appear to result in limited inhalational injury when aspiration occurs. However, significant risk of pulmonary injury is associated with turpentine ingestion and aspiration or inhalation.[29] Animal studies suggest that the LD50 for inhalational injury is 5204.8 ppm.[9]

Clinical Features Pine oil ingestion results in a characteristic pine odor on the breath,[92] whereas turpentine ingestion reportedly causes the urine to smell of violets.[65] Significant ingestions may result in CNS depression that progresses from headache, dizziness, and blurry vision to lethargy and coma.[15] Aspiration resulting in pneumonitis, acute lung injury, and acute respiratory distress syndrome reportedly causes subsequent development of pneumatocoeles.[14,92] Inhalational exposure to turpentine fumes causes increased airway resistance and irritation of the oral mucosa in study subjects.[26] Delayed hemorrhagic cystitis has been reported up to 72 hours after a turpentine ingestion.[49] Further details on the management of hydrocarbon aspiration are given in Chap. 106.

■ OIL OF TEA TREE

History Tea tree oil has been used by Australian aborigines as a topical antimicrobial agent for centuries.[16] Recently, researchers have conducted in vitro studies on the antimicrobial properties of this essential oil and have confirmed that tea tree oil has some microbicidal efficacy.[37,44] Tea tree oil is widely available in over-the-counter topical preparations that claim to have antimicrobial properties.

Pharmacology   Tea tree oil is obtained by the steam distillation of the *Melaluca alternifolia* tree which is indigenous to New South Wales, Australia. Very little data exist on the pharmacokinetics of tea tree oil, although the antibacterial properties are thought to be due in part to a disturbance in cellular potassium fluxes.[20] The main active ingredient, terpinen-4-ol, is thought to be the principal antimicrobial component in tea tree oil.[16]

Clinical Features   Like lavender oil, tea tree oil has been reported to cause prepubertal gynecomastia in boys, likely secondary to estrogenic effects.[41]

■ OIL OF WINTERGREEN
Methyl salicylate

History   European botanists became fascinated by medicinal plants upon the discovery of the New World. John Bartram established the first botanical garden in the United States in 1728 and was named the "Botanizer Royal for America" in 1765. His collection included the *Gaultheria procumbens*, or the Eastern Teaberry, which is a fragrant ground cover plant whose leaves were steamed. The distilled product, oil of wintergreen, was used topically to relieve the symptoms of rheumatism.[10] Oil of wintergreen is also obtained from the twigs of Sweet Birch, or Betula lenta. It is found in topical preparations worldwide, such as Tiger Balm and Ben-Gay, which are used to treat myalgias. The active ingredient in oil of wintergreen is methyl salicylate, which has a pleasant smell and taste, posing a significant hazard to children. Interestingly enough, there are many other names for this essential oil, including checkerberry oil, sweet birch oil, mountain tea, teaberry, groundberry oil, gaultheria oil, and spicewood oil.

Five milliliters of oil of wintergreen is equivalent in salicylate content to 7 g aspirin, and numerous case reports of fatalities after even small ingestions are reported.[33,58,75]

Pharmacology   Methyl salicylate is absorbed both from the GI tract and transdermally,[59] and can cause significant toxicity:[18,40] Once absorbed, methyl salicylate enters the circulation and is transported to the liver, where it undergoes hydrolysis to form salicylic acid. The salicylic acid undergoes conjugation with glycine and glucuronic acid, forming salicyluric acid, salicyl acyl, and phenolic glucuronide.[54] Salicylates are predominantly excreted by the kidney as salicyluric acid (75%), free salicylic acid (10%), salicylic phenol (10%) acyl (5%) glucuronides, and gentisic acid (<1%).[55]

Pathophysiology   An extensive discussion of salicylate pathophysiology is given in Chap. 35.

Clinical Features   Oil of wintergreen overdose can result in a toxic syndrome of salicylate poisoning, characterized by nausea, vomiting, tinnitus, hyperpnea, and tachypnea. Patients often present with diaphoresis and mental status changes. Severe toxicity is associated with seizures, cerebral edema, acute lung injury, coma, and death. Further details on the laboratory tests and treatment of salicylate toxicity are given in Chap. 35.

DIAGNOSTIC TESTING

Laboratory studies are of limited value in essential oil toxicity. Generally, blood or urine concentrations of the active ingredients are not available in a meaningful time frame. However, the patient's clinical status should determine which laboratory studies are to be ordered.

Patients who present with altered mental status or seizures warrant a complete evaluation that may include basic metabolic studies, a head CT and lumbar puncture for serious potential structural or metabolic etiologies, such as hypoglycemia or hyponatremia. In patients who present with respiratory distress, chest radiographs and continuous pulse oximetry are warranted.

A few of the essential oils require specific studies:

Absinthe: Laboratory studies should include a complete blood count (CBC), chemistry panel, creatine phosphokinase concentration, and glucose monitoring in patients who present with seizures. Urinalysis should be performed to evaluate for myoglobinuria.

Camphor, Nutmeg: Useful laboratory studies include a chemistry panel to evaluate hydration status and liver enzyme concentrations.

Pennyroyal: CBC and liver function studies, including the aminotransferases, bilirubin, prothrombin time, and partial thromboplastin time, and a β-HCG in women are indicated.

Wintergreen: Salicylate concentrations and acid–base status should be determined.

TREATMENT

Treatment of symptomatic essential oil toxicity is generally supportive, including administration of intravenous fluids and supplemental oxygen. A dose of activated charcoal may be helpful in alert patients with an intact airway. Benzodiazepines are the mainstay of treatment in patients who present with agitation and seizures.

A few of the essential oils require specific treatment:

Absinthe: If rhabdomyolysis is present, hydration and urinary alkalinization may be appropriate, depending on the clinical severity.

Clove: In patients who exhibit signs of hepatotoxicity, *N*-acetylcysteine (NAC) should be administered. Although no definitive studies on NAC use in this patient population are available, the suggestion that NAC is protective in the rat model,[80] combined with the safety profile of NAC, warrant its use in the setting of eugenol-induced hepatotoxicity.

Pennyroyal: Patients who present with a recent history of pennyroyal ingestion should undergo gastric decontamination with gastric lavage and administration of activated charcoal. NAC therapy is warranted following significant pennyroyal oil ingestions, given the depletion of hepatic glutathione stores.[3,38] Administration of NAC should continue until the patient's clinical status improves or hepatotoxicity resolves. NAC should be administered in the same doses used for acetaminophen toxicity because no trials have demonstrated the optimal dose in the setting of pennyroyal poisoning. If no signs of hepatic or renal toxicity develop, the traditional 21-hour course of intravenous NAC should suffice. If oral NAC is administered, a 24- to 36-hour period of administration should prevent hepatotoxicity, given the 1- to 2-hour half-life of pennyroyal oil and its metabolites.[3] In asymptomatic patients with minimal ingestions, a brief observation period of 3–6 hours is sufficient. An animal study demonstrated that treatment of mice with a combination of disulfiram and cimetidine prior to pennyroyal administration diminished the hepatotoxic effects, but whether these treatments would be beneficial in human toxicity is uncertain.[77]

SUMMARY

Essential oils are increasingly being used as an alternative form of medical therapy. In general, the topical use of these products is associated with minimal toxicity. However, ingestion, prolonged inhalation or massive

cutaneous application or application to abraded skin of essential oils may result in significant morbidity and mortality. Suspected cases of essential oil toxicity should be reported to the regional poison center to enhance our epidemiologic data with regard to essential oil toxicity.

CHAPTER 43
HERBAL PREPARATIONS

Oliver L. Hung

Although, there is increased awareness of the widespread use of herbal preparations in the United States, frequently physicians seek information about the use of these products only after the patient demonstrates toxicity perhaps not completely attributable to a pharmaceutical product or a disease process. Some historical examples of toxicity from herbal usage include the death a professional baseball pitcher from ephedra in 2003, and its subsequent banning by the FDA in 2004;[183] six cases of anticholinergic poisoning from contaminated Paraguay tea in New York City in 1994;[33,95] three cases of life-threatening bradycardia following consumption of *Jin Bu Huan* tablets in Colorado in 1993;[38] and four cases of agranulocytosis with one death following consumption of *Chui Fong Tou Ku Wan* in San Francisco in 1975.[168] Although few studies have examined this issue, most herbal preparations used in developed countries appear to be safe. From 1983 to 1989, the National Poisons Unit, London, received 1070 inquiries regarding exposures to herbal extracts, of which 270 (25.2%) patients were symptomatic. The investigators were able to demonstrate a probable association between exposure and effect in only 32 of the 270 cases (12%).[159] In Hong Kong, Chinese herbal medicines and proprietary medicines accounted for only 0.2% of all acute medical admissions despite their use by 40%–60% of the population whereas Western medications were responsible for 4.4% of acute medical admissions.[48,49] In the United States, a multicenter poison center study reported in 2003 collected 2253 calls involving dietary supplements including herbals; 493 patient exposures were determined to be caused by dietary supplement and were associated with 5 deaths, 13 seizures, 8 cases of coma, and 9 cases of hepatotoxicity.[154] The overall severity outcome among dietary supplement cases was greater compared to outcomes of other poison center–reported exposures.[154] In developing countries where herbal usage is much greater, reported poisoning from herbal preparation usage appears to be higher. In Southern Africa and in Oman, traditional medicines account for 6%–15% of hospital admissions for acute poisonings.[92,107,127,187]

DEFINITION

The botanical definition of the term *herb* is specific for certain leafy plants without woody stems. However, the term *herbal preparations* often includes nonherb plant materials, even animal and mineral products. Thus, in a broad sense, the term herbals includes any "natural" or "traditional" remedy, but these terms also are poorly defined. Although these products often are also called *medications*, this terminology may be inaccurate and misleading. Many herbal preparations purportedly are used for their nonspecific "adaptogenic" properties by permitting the body return to a normal state by resisting stress, but they lack any specific medicinal effects. Because many herbal users and herbalists do not consider herbal preparations medications, use of the term *herbal medicine* by the clinician may convey a different, and perhaps unintended, meaning. For these reasons, it may be inappropriate and without benefit to refer to these products as medication, but they are xenobiotics.

Herbal preparations are considered to be a subset of "alternative medical therapies." These therapies are defined as interventions that

are neither widely taught in medical schools nor generally available in US hospitals.[71] When these alternative medical therapies are used in conjunction with conventional medical therapies, they are also known as *complementary and alternative medicine* (CAM).[143] The National Center for Complementary and Alternative Medicine (NCCAM) groups CAM into five domains: whole medical systems (eg, Ayurveda, homeopathy), mind–body medicine (eg, prayer, hypnosis), biologically based practices (eg, herbal preparations, dietary supplements), manipulative and body-based practices (eg, acupressure, chiropractic, massage), and energy medicine (eg, therapeutic touch).[143]

For regulatory purposes the US government classifies herbal preparations as a type of dietary supplement, which means that the Food and Drug Administration (FDA) classifies them as nutrients with nondrug status.[59] However, many nonherbals, such as vitamins, minerals, nutritional supplements, and food additives, are also dietary supplements (Chaps. 39, 41, and 42).

The study of herbal preparations is complicated by the lack of standardized nomenclature, while the diversity of common, proprietary, and botanical names may increase the confusion. A single plant preparation may have many common names, in addition to its botanical name. For example, *Datura stramonium* is also known as jimson weed, Angel's trumpet, apple of Peru, Jamestown weed, thornapple, and tolguacha. Likewise, a common name for a plant, such as gordolobo, may refer to several botanical plants, such as *Verbascum thapsus* and *Gnaphalium macounii*.[100] The mandrake refers not only to the belladonna-alkaloid–containing *Mandragora officinarum* but also the podophyllum-containing *Podophyllum peltatum*. Thus, accurate classification of herbal preparations is very difficult, which limits effective study and increases the risk of adverse effects.

HISTORICAL BACKGROUND

Since ancient times and perhaps since prehistoric times, people of all cultures have used herbal preparations to treat disease and promote health.[53] A 60,000-year-old Iraqi burial site contained eight different medicinal plants, suggesting very early historical usage.[179] The earliest surviving written account of medicinal plants is the Egyptian Ebers papyrus, circa 1500 B.C., which lists dozens of medicinal plants and their intended uses. In India, the *Vedas*, epic poems written in approximately 1500 B.C., contain references to herbal preparations of the time. In China, the *Divine Husbandman's Classic*, written in the 1st century A.D., lists 252 herbal preparations. In ancient Europe, herbal medicines were the mainstay of healing. In the 1st century, the Greek physician Dioscorides wrote one of the first European herbal books, *De Materia Medica*, which listed 600 herbals and was translated into many languages. Shamans and folk healers from the Americas, Africa, Australia, and Asia continue to include herbals for spiritual and medicinal purposes, based on oral traditions passed from generation to generation.

During the Scientific Revolution, European scientists began to isolate purified extracts of plant products for use as medicinal agents. In 1804 and 1832, morphine and codeine were isolated from the sap of the poppy plant *Papaver somniferum*.[89] In the mid-18th century, Edward Stone described in a letter to the president of the Royal Society of Medicine the successful use of the bark of the willow tree in curing "agues" (fever).[28] In 1829, salicin, the active ingredient of the willow bark, was identified. Its derivative sodium salicylate was marketed in 1875 as a treatment for rheumatic fever and as an antipyretic. The enormous success of this drug led to the synthesis of acetylsalicylic acid in 1899. The original name, aspirin (*acetyl-spiric* acid), is said to have been derived from *Spiraea*, the plant genus from which salicylic acid once was prepared. Even today, plant preparations still are being investigated for

the development of modern drugs. Sweet wormwood (*Artemisia annua*, qing hao) was first described as a treatment for malaria in China in 168 B.C.[113] In 1971, the active parent compound artemisinin was first isolated by Chinese investigators. Artemisinin, when used in combination with other antimalarials, is considered the best treatment for drug-resistant malaria.[106,133,170] Prescriptions from plant-derived medicines currently represent approximately 25% of prescriptions dispensed in the United States[4,202] and at least 60% of nonprescription medications still contain one or more natural products as ingredients.[62]

Today, herbal preparations continue to be the dominant form of healing in the developing world because of the high cost of "western" medical treatment and the scarcity of "western"-trained medical personnel.[61,118,121,134] The World Health Organization estimates that 4 billion people, up to 80% of the world population, use herbal preparations for some aspect of primary healthcare.[4,207] In the developed world in recent years there has been a resurgence in herbal preparation usage.[70] In 1991, a US survey determined that 2.5% of respondents had used herbal preparations in the prior year.[70] When the same survey was repeated in 1997 reported herbal usage in the previous year increased to 12.1%.[71] Two studies published in 2002 and 2004 revealed that 14% and 19% of the population used at least one herbal supplement during the preceding week and past 12 months, respectively.[12,110] Factors attributed to this resurgence in use include lower cost and ease of purchase compared to prescription medications; consumer empowerment; dissatisfaction with conventional therapies; and a perception by many users that herbals are better and safer.[44,178]

Herbal preparations and other dietary supplements are no longer sold exclusively in health food stores but are readily available for sale in mainstream retail outlets such as grocery stores, drug stores, complementary medicine practitioners, offices, mail order companies, the Internet, and gasoline stations. In 1999, sales of herbal preparations in the United States were estimated to be approximately $4 billion, with an annual growth rate of 18% per year.[25] In 1998, several US pharmaceutical companies launched a line of herbal products.[6] However, the explosive increase in demand in the 1990s was followed by marked decreases in the early 2000s. Market growth (food, drug, and mass market retailers [FDM]) dropped by 1% in 2000, 21% in 2001, and 14% in 2002.[19-21] The drop in sales was attributed to negative publicity concerning the dangers associated with ephedra and kava kava and the lack of efficacy of some popular herbal preparations, such as ginkgo and St. John's wort.[20,21] By 2005, the US herbal market appeared to have stabilized, and more recently in 2007 total estimated US herbal sales and recorded FDM US herbal sales increased 4.4% and 7.6%, respectively from the previous year.[32] Total US herbal dietary supplement sales were estimated at $4.79 billion in 2007, representing direct sales of $2.501 billion, natural and health food sales of $1.537 billion, and sales of $752 million from mass market retailers.[32]

Although they often are used by consumers in the hope of preventing or treating medical illness, herbals are not classified as medications and therefore, despite reports of toxicity associated with their usage, no systematic evaluation of herbal efficacy or safety is required. Additionally problematic is that patients often do not consider herbal preparations as medications and may not provide a history of usage unless questioned specifically about herbal usage. In an urban emergency department (ED) survey, 21.7% of respondents reported using herbal preparations. For 15.6% of these users, the herbal preparation was being used specifically to treat aspects of the patient's presenting chief complaint. Thirty-seven percent of herbal users reported that their physicians were unaware of their herbal preparation usage.[97] A survey of outpatients in a veteran's administration hospital revealed that 43% of respondents were taking at least one dietary supplement with prescription medications. Of those taking dietary supplements,

45% had a potential for xenobiotic dietary supplement interactions when considered with the respondent's prescription medications.[157] A recent telephone survey by the AARP determined that 63% of respondents 50 years or older admitted to current or prior usage of CAM but that only 22% said they had discussed their CAM use with their physician. Herbal product and dietary supplement usage was reported by 42% of respondents.[2] The most common reasons given for not discussing their use of CAM with their physician were: physician never asked (42%); respondent did not know they should (30%); there was not enough time in the office visit (19%); respondent assumed physician would not know about the topic (17%); and respondent thought doctor would be dismissive (12%).[2]

Herbal preparation use also appears to vary greatly by the community surveyed. Rural areas of Mississippi and southwestern West Virginia reported that 71% and 73% of respondents, respectively, used herbal preparations in the past year.[44,45,58] Among Chinese Americans in New York City and Hispanic Americans in west Texas, herbal preparation use was reported to be 43% and 50%, respectively.[130,158] Use of herbal preparations appears to be higher among people with chronic illness such as AIDS, rheumatoid arthritis, and cancer.[109,111,200] In the United States, increased likelihood of herbal preparation usage is associated with multiple factors, including concurrent illness and diverse socioeconomic and cultural influences.

Unfortunately, the medical profession's response to the widespread usage of herbal preparations appears to be inconsistent with one study suggesting that the medical practitioner's knowledge of current herbal preparation regulations is grossly inadequate.[9] Several studies have attempted to determine how US hospitals regulate herbal preparation use in their facilities.[7,13,55,79] Depending on the study, only 31% to 79% of respondents reported having formal policies governing the usage of herbal preparations in their facilities. Herbal preparation use was completely banned in 11%–22% of facilities. However, the majority of facilities did allow the use of herbal preparations if they were ordered by an authorized prescriber. Identified concerns addressed in these studies included difficulties in identifying products (particularly "home supply" products), and concerns for appropriate dosing, efficacy, safety, and consistency. The conflicting approaches have been attributed to healthcare facilities attempting to balance patient-centered care with their legal and ethical concerns about these products.[24,79]

In 1998, Congress established the National Center for Complementary and Alternative Medicine at the National Institutes of Health to stimulate, develop, and support research in complementary and alternative medicines.[131] The following is a summary of NCCAM-funded studies and their evaluation of the effectiveness of specific herbal preparations. In 2002, St. John's wort was found to be no more effective in treating depression than was placebo.[101] In 2004, hawthorne extract was described as ineffective in treating congestive heart failure.[1] In 2005, echinacea was determined to be ineffective in preventing symptoms of the common cold.[192] In 2006, glucosamine and chondroitin sulfate were considered unable to reduce pain in patients with osteoarthritis of the knee.[54] In 2006, saw palmetto was found not to improve symptoms or objective measures of benign prostatic hypertrophy over a 1-year followup.[15] In 2008, a pilot study failed to demonstrate any benefit of using ginkgo biloba in delaying the onset of dementia in the elderly.[67]

REGULATION OF HERBAL PREPARATIONS

In the US, herbal preparations are not subjected to the same standards and regulations as drugs. The FDA has gradually assumed an increased role in its vigilance over the manufacturing, marketing, and

sales of herbal preparations. In 1994, Congress passed the Dietary Supplement Health and Education Act (DSHEA), which reduced the FDA's oversight of products categorized as dietary supplements.[74] Dietary supplements include vitamins, minerals, herbals, amino acids, and any product that had been sold as a "supplement" before October 15, 1994.[59] After October 15, 1994, any new ingredient intended for use in dietary supplements requires notification and approval by the FDA at least 75 days in advance of marketing. The FDA must review and determine whether the proposed ingredient is expected to be safe under the intended conditions for use. However, because most ingredients contained in dietary supplements were in use prior to 1994, the vast majority of dietary supplements are not subject to even this weakened premarket safety evaluation. After marketing, if the FDA determines that a manufactured dietary supplement is unsafe, the agency can warn the public, suggest changes to make the supplement safer, urge the manufacturer to recall the product, recall the product, or ban the product.

On several occasions the FDA has urged manufacturers to stop producing dietary supplements containing unsafe products. In July 2001, the FDA warned dietary supplement manufacturers to stop marketing products containing aristolochic acid because of nephrotoxicity and to remove comfrey products from the market because of hepatotoxicity. In November 2001, the FDA warned the manufacturer of LipoKinetix (containing phenylpropanolamine, caffeine, yohimbine, diiodothyronine, usnic acid) to remove the supplement from the marketplace because of reports of associated hepatotoxicity. In 2002, the FDA warned consumers and healthcare providers of the risk of hepatotoxicity associated with the use of kava-containing products.[197] However, the FDA did not ban the development of kava-containing products or ban their sale in the United States. In March 2004, the FDA warned dietary supplement manufacturers to stop manufacturing androstenedione or face enforcement actions.[196] To ban a dietary supplement from the marketplace, the FDA must prove that the product is unsafe. In April 2004, the FDA banned all sales of dietary supplements containing ephedra. This was the first FDA prohibition of a supplement since 1994.[195]

Because the law requires the FDA to consider dietary supplements as food products, quality control issues and production methods are governed by the Current Good Manufacturing Practices regulations for foods.[194] However, these regulations only ensure that foods, and thus dietary supplements, are produced under sanitary conditions; they do not guarantee the safety or efficacy of the product, as is required for pharmaceuticals. Before the FDA's release of the final rule Current Good Manufacturing Practices in 2007, there had been no attempt to ensure the purity and composition of herbal products.[75] In fact, two studies suggest that many herbal preparations do not even contain appreciable quantities of the listed herb. In one study of 54 ginseng products, 60% of those analyzed contained pharmacologically insignificant amounts of ginseng and 25% contained no ginsenosides at all.[123] A study of echinacea preparations determined that 10% of preparations contained no measurable echinacea, the assayed species was consistent with labeled content in 52% of the sample, and only 43% met the quality standard described by the label.[81] From 2004 to 2008, the FDA investigated online sales of dietary supplements purported to treat erectile dysfunction or enhance sexual performance by purchasing and analyzing the ingredients of these products.[193] One-third of the purchased dietary supplements (6 out of 17) contained undisclosed prescription drug ingredients: sildanafil or substances similar to sildanafil or vardenafil.[193]

Herbal products can be initially marketed without any proof of testing for efficacy or safety. Although packaging that claims to cure or prevent a specific disease is not permitted unless approved by the FDA, claims detailing how a product affects the "body's structure or function"

are permissible. Substantiation of these claims is required if challenged by regulators,[194] but their methodology and requirements are not well defined. These findings were corroborated by a study evaluating herbal advertising on the Internet. The study determined that 81% of Web sites marketing dietary supplements made one or more health claims without approval from the FDA, and of these sites, 55% made specific claims to treat, prevent, or cure specific diseases.[139]

In March 1999, the FDA implemented new dietary supplement labeling rules. All dietary supplement labels must provide a statement of identity (eg, ginseng); net quantity of contents (eg, 60 capsules); structure–function claims with disclaimers that the product has not been evaluated by the FDA; directions for use; supplements fact panel (list of serving size, amount, and active ingredients); other ingredients list; and name and place of business of manufacturer, packer, or distributor. In February 2000, the FDA advised dietary supplement manufacturers not to make pregnancy-related claims on their products. In October 2004, the FDA sent warning letters to eight companies for making unsubstantiated claims over the Internet regarding the use of dietary supplement products for weight loss. In addition, it sent letters to major retailers of dietary supplements suggesting that it may take enforcement action against misbranded products and is "intent on starting a program of inspection of retail establishments to identify products bearing unsubstantiated claims in their labeling." The Dietary Supplement and Nonprescription Drug Consumer Protection Act was signed into law in December 2006.[66] Under this law, manufacturers, packers, or distributors of nutritional supplements are required to notify the FDA about serious adverse events related to their products. In 2007, the FDA issued its current good manufacturing practices final rule, effective in June 2008. The final rule is more stringent than previous regulations and it contains sections similar to current good manufacturing practices for drugs. Manufacturers are now required to evaluate the identity, purity, strength, and composition of their dietary supplements. Yet, unlike the FDA regulations for drugs; the final rule still does not require any proof of efficacy or safety. In essence, the FDA, through its regulations, has gradually shifted dietary supplements from a poorly regulated food product into a unique category between a conventional food product and a drug. This has served to increase the philosophical debate on both sides: from proponents who view dietary supplements as more similar to food groups (eg, chamomile tea) and want less government regulation, to proponents who argue that herbs are pharmacologically active drugs (eg, ephedra) that that require greater regulation.[132,140]

PHARMACOLOGIC PRINCIPLES

The pharmacologic activity of herbal preparations (plant containing or derived) can be classified by five active constituent classes: volatile oils, resins, alkaloids, glycosides, and fixed oils.[181]

- **Volatile oils** are aromatic plant ingredients. They are also called ethereal or essential oils, because they evaporate at room temperatures. Many are mucous membrane irritants and have CNS activity. Examples of herbs containing volatile oils include pennyroyal oil (*Mentha pulegium*), catnip (*Nepeta cataria*), chamomile (*Chamomilla recutita*), and garlic (*Allium sativum*) (Chap. 42).
- **Resins** are complex chemical mixtures of acrid resins, resin alcohols, resinol, tannols, esters, and resenes. These substances are often strong gastrointestinal irritants. Examples of resin-containing herbs include dandelion (*Taraxacum officinale*), elder (*Sambucus* spp), and black cohosh root (*Cimicifuga racemosa*).

- **Alkaloids** are a heterogeneous group of alkaline, organic, and nitrogenous compounds. The alkaloid compound usually is found throughout the plant. This class consists of many pharmacologically active and toxic compounds. Examples of alkaloid-containing herbs include aconitum (*Aconitum napellus*), goldenseal (*Hydrastis canadensis*), and jimson weed (*Datura stramonium*).

- **Glycosides** are esters that contain a sugar component (glycol) and a nonsugar (aglycone), which yields one or more sugars during hydrolysis. They include the anthroquinones, saponins, cyanogenic glycosides, and lactone glycosides. The anthroquinones (senna [*Cassia acutifolia*] and aloe [*Aloe vera*]) are irritating cathartics. Saponins (licorice [*Glycyrrhiza lepidota*] and ginseng [*Panax ginseng* and *P. quinquefolius*]) are mucous membrane irritants, cause hemolysis, and have steroid activity. Cyanogenic glycosides found in apricot, cherry, and peach pits release cyanide. Lactone glycosides (tonka beans [*Dipteryx odorata*]) have anticoagulant activities. Cardiac glycosides defined as cardioactive steroids (Chap. 64) are found in foxglove (*Digitalis* spp) and oleander (*Nerium oleander*).

- **Fixed oils** are esters of long-chain fatty acids and alcohols. Herbs containing fixed oils are generally used as emollients, demulcents, and bases for other agents. Generally, they are the least active and least dangerous of all herbal preparations. Examples include olive (*Olea europaea*) and peanut (*Arachis hypogaea*) oils.

■ FACTORS CONTRIBUTING TO HERBAL TOXICITY

The toxicity of a plant may vary widely and depends on conditions such as the time of year and developmental stage at which the plant is collected.[100] The pyrrolizidine alkaloid content of *Senecio* leaves varies widely from month to month and year to year.[100] In some cases, only selective parts of a plant used to prepare an herbal preparation are responsible for its toxicity. For example, the pyrrolizidine content of comfrey–pepsin capsules varies from 270 to 2900 mg/kg, depending on whether the leaves or roots were used in the preparation.[99] The geographical area in which the plant is collected may affect its toxicity. *Senecio longilobus* from Gardner Canyon, Arizona, may contain up to 18% pyrrolizidine alkaloids by dry weight, the highest level recorded for any *Senecio* plant species (normal concentration is 0.5%). Finally, conditions and duration of storage may affect its toxicity. The toxicity of *Crotalaria* decreases with storage because of the breakdown of pyrrolizidines.

Few poisonings result from the inherent toxicity of the herbal, because of the low concentration of active ingredient and the known safety of the chosen herb (Table 43-1). Instead, poisonings tend to result from the misuse, overuse (including increased concentration in some commercial derivative products), misidentification, misrepresentation, or contamination of the product. Heavy-metal poisonings from lead, cadmium, mercury, copper, zinc, and arsenic are associated with herbal preparation usage.[40,49,60,64,68,155,159,165] High concentrations of these elements sometimes result from contamination during the manufacturing process of some herbal or patent medications (ready-made preparations used by traditional Chinese herbalists). In some cases, as with cinnabar (mercuric sulfide) and calomel (mercurous chloride), these ingredients are intentionally included for purported medicinal benefit.[108] Patent medications may also contain pharmaceutical medications, such as acetaminophen, aspirin, antihistamines, or corticosteroids.[50,64] Many of these medicines are not listed on the packaging and may not even be approved for use in the United States. For example, four cases of agranulocytosis followed consumption of *Chui Fong Tou Ku Wan*, a preparation that contains both aminopyrine (which is not approved for nonprescription sales

in the United States) and phenylbutazone (which was withdrawn from the US market), neither of which are listed on the packaging.[168] Both aminopyrine and phenylbutazone are associated with agranulocytosis.

CLASSIFICATION OF TOXICITY

Herbal preparations are associated with a wide variety of toxicologic manifestations (Table 43-2). In addition, many individual herbal preparations are associated with multiple toxicologic effects. To better understand these effects, it is useful to organize herbal toxicity into several general categories.[63]

■ DIRECT HEALTH RISKS

Direct health risks include pharmacologically predictable and dose-dependent toxic reactions, idiosyncratic toxic reactions, long-term toxic effects, and delayed toxic effects. For example, ingestion of aconite tea, in the suggested dose, causes tachydysrhythmias and hypotension. Idiosyncratic toxic reactions cannot be predicted on the basis of principal pharmacologic properties. For example, ingestion of chamomile tea results in anaphylaxis in a small subset of patients with probable allergies to the Compositae family. Long-term toxic effects occur only after chronic usage. For example, chronic use of herbal anthranoid laxatives results in muscular weakness from hypokalemia. Delayed toxic effects include carcinogenicity and teratogenicity. Another example is urothelial cancers in humans as a result of prolonged consumption of *Aristolochia*.[147]

■ INDIRECT HEALTH RISKS

Herbal use may adversely impact health by altering previous conventional prescription medication therapy. A patient may discontinue or become less compliant with previous therapy, with untoward consequences. Alternatively, the addition of an herbal preparation may affect the pharmacologic effect, principally by altering the bioavailability or clearance of concurrently used medications. Coadministration of St. John's wort, an inducer of CYP3A4, with the protease inhibitor indinavir, which is metabolized by this enzyme, may result in decreased plasma indinavir concentrations and potentially decreased antiretroviral activity.[162]

MOST WIDELY USED HERBAL SUPPLEMENTS

The most popular herbal supplements (food, drug, and mass-market retail outlets [excluding warehouse buying clubs and convenience store sales]) in the United States in 2007 are listed below in order of sales.[32] The top five represent more than 100 million dollars of sales.[32]
