Goldfrank's Toxicologic Emergencies

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

NINTH EDITION

Goldfrank's Toxicologic Emergencies

Lewis S. Nelson, MD, FAACT, FACEP, FACMT

Associate Professor of Emergency Medicine
New York University School of Medicine
Attending Physician, Emergency Medicine
Bellevue Hospital Center and New York University Langone
Medical Center
Director, Fellowship in Medical Toxicology
New York City Poison Center and New York University
School of Medicine
New York, New York

Robert S. Hoffman, MD, FAACT, FACMT

Associate Professor of Emergency Medicine and Medicine
(Clinical Pharmacology)
New York University School of Medicine
Attending Physician, Emergency Medicine and Internal Medicine
Bellevue Hospital Center and New York University Langone
Medical Center
Director, New York City Poison Center
New York, New York

Neal A. Lewin, MD, FACEP, FACMT, FACP

The Stanley and Fiona Druckenmiller Clinical Professor of
Emergency Medicine and Medicine (Pharmacology)
New York University School of Medicine
Director, Didactic Education
Emergency Medicine Residency
Attending Physician, Emergency Medicine and Internal Medicine
Bellevue Hospital Center and New York University Langone
Medical Center
Consultant, New York City Poison Center
New York, New York

Lewis R. Goldfrank, MD, FAAEM, FAACT, FACEP, FACMT, FACP

Herbert W. Adams Professor and Chair
Department of Emergency Medicine
New York University School of Medicine
Director, Emergency Medicine
Bellevue Hospital Center and New York University Langone
Medical Center
Medical Director, New York City Poison Center
New York, New York

Mary Ann Howland, PharmD, DABAT, FAACT

Clinical Professor of Pharmacy
St. John's University College of Pharmacy
Adjunct Professor of Emergency Medicine
New York University School of Medicine
Bellevue Hospital Center and New York University Langone
Medical Center
Senior Consultant in Residence
New York City Poison Center
New York, New York

Neal E. Flomenbaum, MD, FACEP, FACP

Professor of Clinical Medicine
Weill Cornell Medical College of Cornell University
Emergency Physician-in-Chief
New York-Presbyterian Hospital
Weill Cornell Medical Center
Consultant, New York City Poison Center
New York, New York

McGraw Hill **Medical**

New York   Chicago   San Francisco   Lisbon   London   Madrid   Mexico City
Milan   New Delhi   San Juan   Seoul   Singapore   Sydney   Toronto

Digitalis purpurea, the purple foxglove, is a legendary plant that contains the cardiac glycoside digitoxin, closely related to the therapeutically useful but potentially toxic cardiac glycoside digoxin. The electrocardiogram demonstrates high degree atrioventrical nodal blockade in a patient with atrial fibrillation/flutter, an abnormality closely linked to cardioactive steroid poisoning. The vial contains the widely available digoxin-specific Fab antibody fragment that is used to treat poisoning by digoxin and other cardioactive steroids. The 3-dimensional ribbon structure of digoxin specific Fab illustrates its ability engulf and render harmless the active non-glycoside form of the digoxin molecule.

DEDICATION

*To the staffs of our hospital emergency departments
who have worked with remarkable courage, concern, compassion,
and understanding in treating the patients discussed in this text and
many thousands more like them*

*To the staff of the New York City Poison Center
who have quietly and conscientiously integrated their skills with ours
to serve these patients and to the many others who never needed a hospital visit
because of their efforts*

*To all the faculty, fellows, residents, and students who have studied toxicology with us
whose inquisitiveness has helped us continually strive to understand complex and evolving problems and
develop methods to teach them to others*

*To my wife Laura for her unwavering support; to my children
Daniel, Adina, and Benjamin for their inquisitiveness and insight;
to my parents Dr. Irwin and Myrna Nelson for the foundation they provided;
and to my family, friends, and colleagues
who keep me focused on what is important in life. (L.N.)*

*To my wife Gail; to my children Justin and Jesse
for their support and patience; and
to my parents, who made it possible (N.L.)*

*To my husband Bob; to my children Robert and Marcy;
to my mother and to the loving memory of my father; and to family,
friends, colleagues, and students for all their help
and continuing inspiration (M.A.H.)*

*To my wife Ali; my children Casey and Jesse; my parents; and my friends,
family, and colleagues for their never-ending patience and forgiveness for the
time I have spent away from them (R.H.)*

*To my children Rebecca, Jennifer, Andrew and Joan, Michelle and James;
to my grandchildren Benjamin, Adam, Sarah, Kay, Samantha, and Herbert
who have kept me acutely aware of the ready availability
of possible poisons; and to my wife, partner, and best friend Susan
whose support was and is essential
and whose contributions will be found throughout the text (L.G.)*

*To the memories of my parents Mollie and Lieutenant H. Stanley Flomenbaum
whose constant encouragement to help others nonjudgmentally led me to
consider toxicologic emergencies many years ago. To my wife Meredith Altman
Flomenbaum, RNP, and to my children Adam, David, and Sari who have
competed with this text for my attention but who have underscored
the importance of these efforts (N.F.)*

*To the memory of Donald A. Feinfeld, MD. Don was a wonderful collaborator, thoughtful
intellectual, nephrologist, and poet who was an active participant at our monthly
meetings as well as a critical author for the previous five editions of our text.
His warmth, compassion and intellect will be missed.*

TABLE OF ANTIDOTES IN DEPTH

Readers of previous editions of Goldfrank's Toxicologic Emergencies *are undoubtedly aware that the editors have always felt that an emphasis on general management of poisoning or overdoses coupled with sound medical management is more important or as important as the selection and use of a specific antidote in the vast majority of cases. Nevertheless, there are some instances where nothing other than the timely use of a specific antidote or therapy will be essential for a patient. For this reason, and also because the use of such strategies may be problematic, controversial, or unfamiliar to the practitioner (as new antidotes continue to emerge), we have included a section (or sections) at the end of each chapter where an in-depth discussion of such antidotes and therapies are relevant. The following Antidotes in Depth are included in this edition.*

TABLE OF CONTENTS

PART A

THE GENERAL APPROACH TO MEDICAL TOXICOLOGY 31

PART B

THE FUNDAMENTAL PRINCIPLES OF MEDICAL TOXICOLOGY 155

SECTION 1

Biochemical and Molecular Basis 157

SECTION 2

Pathophysiologic Basis: Organ Systems 228

CONTRIBUTORS

Judith C. Ahronheim, MD

Professor of Medicine
SUNY Downstate
Brooklyn, New York
Adjunct Professor of Medicine and Member
Bioethics Institute, New York Medical College
Valhalla, New York
Chapter 32, "Geriatric Principles"

Kavita M. Babu, MD

Assistant Professor of Emergency Medicine
Brown University Alpert Medical School
Program in Medical Toxicology
Department of Emergency Medicine
Rhode Island Hospital
Providence, Rhode Island
Chapter 25, "Gastrointestinal Principles"
Chapter 82, "Hallucinogens"

Theodore C. Bania, MD, MS

Assistant Professor of Medicine
Columbia University College of Physicians
and Surgeons
Director of Research and Toxicology
St. Luke's Roosevelt Hospital Center
New York, New York
Antidote in Depth A21, "Intravenous Fat Emulsions"

Fermin Barrueto, Jr., MD

Clinical Assistant Professor of Emergency Medicine
University of Maryland
Chair, Department of Emergency Medicine
Upper Chesapeake Health Systems
Baltimore, Maryland
Chapter 110, "Sodium Monofluoroacetate
and Fluoroacetamide"

James Dave Barry, MD

Program Director, Naval Medical Center
Portsmouth Emergency Medicine Residency
Assistant Adjunct Professor
Uniformed Services University of the Health Sciences
Portsmouth, Virginia
Chapter 58, "Antimalarials"

Joseph M. Betz, PhD

Director, Dietary Supplement Methods and Reference
Materials Program
Office of Dietary Supplements
U.S. National Institutes of Health
Bethesda, Maryland
Chapter 118, "Plants"

Michael C. Beuhler, MD, FACMT

Adjunct Assistant Professor of Emergency Medicine
University of North Carolina at Chapel Hill
Medical Director, Carolinas Poison Center
Charlotte, North Carolina
Chapter 111, "Phosphorus"

Steven B. Bird, MD

Assistant Professor of Emergency Medicine
University of Massachusetts Medical School
Worcester, Massachusetts
Chapter 91, "Chromium"

George M. Bosse, MD

Associate Professor of Emergency Medicine
University of Louisville
Medical Director
Kentucky Regional Poison Center
Louisville, Kentucky
Chapter 48, "Antidiabetics and Hypoglycemics"

Nicole C. Bouchard, MD, FRCPC

Assistant Clinical Professor
Columbia University Medical Center
Director of Medical Toxicology
Assistant Site Director
New York-Presbyterian Hospital
New York, New York
Chapter 49, "Thyroid and Antithyroid Medications"

Edward W. Boyer, MD, PhD

Associate Professor of Emergency Medicine
University of Massachusetts Medical School
Chief, Division of Medical Toxicology
UMass-Memorial Medical Center
Worcester, Massachusetts
Chapter 57, "Antituberculous Medications"

Jeffrey R. Brubacher, MD

Assistant Professor
University of British Columbia
Emergency Physician
Vancouver General Hospital
Vancouver, British Columbia, Canada
Chapter 61, "β-Adrenergic Antagonists"

D. Eric Brush, MD

Assistant Professor of Emergency Medicine
Division of Toxicology
University of Massachusetts Medical Center
Worcester, Massachusetts
Chapter 120, "Marine Envenomations"

Keith K. Burkhart, MD

Professor of Clinical Emergency Medicine
Pennsylvania State University College of Medicine
Medical Officer
Center for Drug Evaluation and Research
Food and Drug Administration
Silver Spring, Maryland
Chapter 116, "Methyl Bromide and Other Fumigants"

Michelle Burns Ewald, MD

Assistant Professor of Pediatrics
Harvard Medical School
Fellowship Director, Harvard Medical Toxicology Fellowship
Medical Director, Regional Center for Poison Control and Prevention
Attending Physician, Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts
Chapter 99, "Silver"

Diane P. Calello, MD

Assistant Professor of Pediatrics and Emergency Medicine
Chief, Section of Toxicology
Robert Wood Johnson Medical School
UMDNJ
Staff Toxicologist, New Jersey Poison Information and Education
Systems (NJPIES)
New Brunswick, New Jersey
Chapter 98, "Selenium"

Louis R. Cantilena, MD, PhD

Professor of Medicine and Pharmacology
Department of Medicine
Uniformed Services University
Bethesda, Maryland
Chapter 138, "Adverse Drug Events and Postmarketing Surveillance"

Gar Ming Chan, MD

Assistant Clinical Professor of Emergency Medicine
New York University School of Medicine
Attending Physician, North Shore University Hospital
Manhasset, New York
Chapter 92, "Cobalt"

Yiu-cheung Chan, MD, MBBS, FHKAM, FHKCEM, FRCS(Ed)

Associate Consultant, Director of Toxicology Training
Hong Kong Poison Information Centre
Hong Kong SAR, China
Chapter 112, "Strychnine"

Nathan Phillip Charlton, MD

Assistant Professor of Emergency Medicine
University of Virginia
Charlottesville, Virginia
Chapter 128, "Smoke Inhalation"

Alan N. Charney, MD

Clinical Professor of Medicine
New York University School of Medicine
New York, New York
Chapter 16, "Fluid, Electrolyte, and Acid–Base Principles"

William K. Chiang, MD

Associate Professor of Emergency Medicine
New York University School of Medicine
Chief of Emergency Services, Bellevue Hospital Center
Attending Physician
Bellevue Hospital Center and New York University
Langone Medical Center
New York, New York
Chapter 20, "Otolaryngologic Principles"
Chapter 75, "Amphetamines"

Jason Chu, MD

Assistant Professor of Clinical Medicine
Columbia University College of Physicians and Surgeons
Medical Toxicologist
St. Luke's-Roosevelt Hospital Center
New York, New York
Chapter 28, "Genitourinary Principles"
Chapter 51, "Antimigraine Medications"

Richard Church, MD

Fellow in Medical Toxicology
University of Massachusetts Medical Center
Worcester, Massachusetts
Chapter 25, "Gastrointestinal Principles"

Cathleen Clancy, MD

Associate Medical Director
National Capital Poison Center
Associate Professor
Department of Emergency Medicine
George Washington University Medical Center
Attending Physician
Bethesda Naval Emergency Department
Washington, District of Columbia
Chapter 22, "Electrophysiologic and Electrocardiographic Principles"

Richard Franklin Clark, MD

Professor of Medicine
University of California at San Diego
Director, Division of Medical Toxicology
University of California San Diego Medical Center
San Diego, California
Chapter 113, "Insecticides: Organic Phosphorus Compounds and Carbamates"
Antidote in Depth A35, "Antivenom (Scorpion and Spider)"

Steven C. Curry, MD

Director, Department of Medical Toxicology
Banner Good Samaritan Medical Center
Professor of Clinical Medicine
University of Arizona College of Medicine
Phoenix, Arizona
Chapter 13, "Neurotransmitters and Neuromodulators"

John A. Curtis, MD

Assistant Professor of Emergency Medicine
Associate Director, Fellowship in Medical Toxicology
Drexel University College of Medicine
Attending Physician
Hahnemann University Hospital
Philadelphia, Pennsylvania
Chapter 97, "Nickel"

Andrew Dawson, MBBS

Professor, Peradeniya University
Program Director
South Asian Clinical Toxicology Research Collaboration
Peradeniya, Sri Lanka
Chapter 109, "Barium"

Kathleen A. Delaney, MD

Clinical Professor, Division of Emergency Medicine
University of Texas Southwestern Medical School
Dallas, Texas
Chapter 12, "Biochemical and Metabolic Principles"
Chapter 15, "Thermoregulatory Principles"
Chapter 26, "Hepatic Principles"
Antidote in Depth A10, "Dextrose"

Francis Jerome DeRoos, MD

Associate Professor of Emergency Medicine
University of Pennsylvania School of Medicine
Residency Director
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 60, "Calcium Channel Blockers"
Chapter 62, "Other Antihypertensives"

Suzanne Doyon, MD, FACMT

Medical Director,
Maryland Poison Center
University of Maryland School of Pharmacy
Baltimore, Maryland
Chapter 47, "Anticonvulsants"

Dainius A. Drukteinis, MD, JD

Attending Physician
MetroWest Medical Center
Framingham, Massachusetts
Chapter 140, "Risk Management and Legal Principles"

Michael Eddleston, MD, PhD, MRCP

Clinical Pharmacology Unit
University of Edinburgh
Scottish Poisons Information Bureau
Royal Infirmary of Edinburgh
Edinburgh, United Kingdom
Chapter 113, "Insecticides: Organic Phosphorus Compounds and Carbamates"
Chapter 136, "International Perspectives on Medical Toxicology"

Brenna M. Farmer, MD

Assistant Professor of Medicine
Weill-Cornell Medical College
Attending Physician
New York Presbyterian-Weill-Cornell Medical Center
New York, New York
Chapter 80, "γ-Hydroxybutyric Acid"
Chapter 86, "Aluminum"
Chapter 139, "Medication Safety and Adverse Drug Events"

Donald A. Feinfeld, MD (Deceased)

Nephrology Fellowship Director
Beth Israel Medical Center
Professor of Medicine
Albert Einstein College of Medicine
Consultant in Nephrology
New York City Poison Center
New York, New York
Chapter 27, "Renal Principles"

Kathy Lynn Ferguson, DO

Attending Physician
Emergency Medicine and Medical Toxicology
New York Hospital Queens
Flushing, New York
Chapter 74, "Sedative–Hypnotics"

Jeffrey S. Fine, MD

Assistant Professor of Emergency Medicine and Pediatrics
New York University School of Medicine
Attending Physician
Bellevue Hospital Center and New York University Langone Medical Center New York, New York
Chapter 30, "Reproductive and Perinatal Principles"
Chapter 31, "Pediatric Principles"

Mark A. Flomenbaum, MD, PhD

Associate Professor of Pathology and Laboratory Medicine
Boston University School of Medicine
Director, Autopsy Services
Boston Medical Center
Boston, Massachusetts
Chapter 33, "Postmortem Toxicology"

Neal E. Flomenbaum, MD, FACEP, FACP

Professor of Clinical Medicine
Weill Cornell Medical College of Cornell University
Emergency Physician-in-Chief
New York-Presbyterian Hospital
Weill Cornell Medical Center
Consultant, New York City Poison Center
New York, New York
Chapter 3, "Initial Evaluation of the Patient: Vital Signs and Toxic Syndromes"
Chapter 4, "Principles of Managing the Acutely Poisoned or Overdosed Patient"
Chapter 35, "Salicylates"
Chapter 108, "Pesticides: An Overview of Rodenticides and a Focus on Principles"

Marsha D. Ford, MD

Adjunct Professor of Emergency Medicine
University of North Carolina, Chapel Hill
Director, Carolinas Poison Center
Carolinas Medical Center
Charlotte, North Carolina
Chapter 88, "Arsenic"

Jessica A. Fulton, DO

Attending Physician
Grandview Hospital
Grandview, New Jersey
Chapter 104, "Caustics"

Howard L. Geyer, MD, PhD

Assistant Professor of Neurology
Albert Einstein College of Medicine
Director, Division of Movement Disorders
Montefiore Medical Center
Bronx, New York
Chapter 46, "Botulism"
Antidote in Depth A8, "Botulinum Antitoxin"

Beth Y. Ginsburg, MD

Assistant Professor of Emergency Medicine
Mount Sinai School of Medicine
Attending Physician
Elmhurst Hospital Center
Elmhurst, New York
Chapter 41, "Vitamins"

Jeffrey A. Gold, MD

Associate Professor of Medicine
Oregon Health and Sciences University
Portland, Oregon
Chapter 78, "Ethanol Withdrawal"

David S. Goldfarb, MD

Professor of Medicine and Physiology
New York University School of Medicine
Chief, Nephrology Section
New York Harbor VA Medical Center
New York, New York
Chapter 9, "Principles and Techniques Applied to Enhance Elimination"

**Lewis R. Goldfrank, MD,
FAACT, FAAEM, FACEP, FACMT, FACP**

Herbert W. Adams Professor and Chair
Department of Emergency Medicine
New York University School of Medicine
Director, Emergency Medicine
Bellevue Hospital Center and New York University
Langone Medical Center
Medical Director, New York City Poison Center
New York, New York
Chapter 3, "Initial Evaluation of the Patient: Vital Signs and Toxic Syndromes"
Chapter 4, "Principles of Managing the Acutely Poisoned or Overdosed Patient"
Chapter 117, "Mushrooms"
Antidote in Depth A8, "Botulinum Antitoxin"

Howard A. Greller, MD, FACEP, FACMT

Assistant Professor of Emergency Medicine
New York University School of Medicine
Attending Physician
North Shore University Hospital
Manhasset, New York
Chapter 70, "Lithium"
Workbook Cases and Questions

Martin Griffel, MD

Associate Professor of Anesthesiology
New York University School of Medicine
Director, Cardiovascular ICU
New York University Langone Medical Center
New York, New York
Chapter 67, "Inhalational Anesthetics"

Anne-Bolette Gude, MD

Clinical Pharmacologist
Novo Nordisk
Virum, Denmark
Chapter 7, "Techniques Used to Prevent Gastrointestinal Absorption"

David D. Gummin, MD, FAACT, FACEP, FACMT

Clinical Assistant Professor
Medical College of Wisconsin
Medical Director
Wisconsin Poison Center
Milwaukee, Wisconsin
Chapter 106, "Hydrocarbons"

Jason B. Hack, MD

Associate Professor of Emergency Medicine
Program Director, Medical Toxicology
Brown University, Warren Alpert Medical School
Rhode Island Hospital
Providence, Rhode Island
Chapter 64, "Cardioactive Steroids"

David A. Haggerty, MD

Fellow in Medical Toxicology
Division of Medical Toxicology
Department of Emergency Medicine
Drexel University College of medicine
Philadelphia, Pennsylvania
Chapter 97, "Nickel"

In-Hei Hahn, MD

Assistant Professor of Clinical Medicine
Columbia University College of Physicians and Surgeons
Associate Attending, Emergency Medicine
Assistant Director of Research
St. Luke's-Roosevelt Hospital Center, Danbury Hospital
New York, New York
Chapter 119, "Arthropods"

Sarah Eliza Halcomb, MD

Assistant Professor of Emergency Medicine
Washington University School of Medicine
Section Chief - Medical Toxicology
Washington University-Barnes-Jewish Hospital
St. Louis, Missouri
Chapter 42, "Essential Oils"

Richard J. Hamilton, MD

Professor and Chairman of Emergency Medicine
Drexel University College of Medicine
Philadelphia, Pennsylvania

Chapter 14, *"Withdrawal Principles"*

Nikolas B. Harbord, MD

Assistant Professor of Medicine
Albert Einstein College of Medicine
Attending Nephrologist
Beth Israel Medical Center
Brooklyn, New York

Chapter 27, *"Renal Principles"*

Robert G. Hendrickson, MD

Associate Professor of Emergency Medicine
Oregon Health and Science University
Associate Medical Director
Oregon Poison Center
Emergency Physician and Medical Toxicologist
Oregon Health and Science University
Portland, Oregon

Chapter 34, *"Acetaminophen"*
Antidote in Depth A4, *"N-Acetylcysteine"*

Fred M. Henretig, MD

Professor of Pediatrics and Emergency Medicine
University of Pennsylvania School of Medicine
Director, Section of Clinical Toxicology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Chapter 94, *"Lead"*

Christina H. Hernon, MD

Assistant Professor of Emergency Medicine
University of Massachusetts Medical School
Division of Medical Toxicology
University of Massachusetts Memorial Medical Center
Worcester, Massachusetts

Chapter 57, *"Antituberculous Medications"*

Robert A. Hessler, MD, PhD

Associate Professor of Emergency Medicine
New York University School of Medicine
Attending Physician
Bellevue Hospital Center, New York University Langone
Medical Center and Veterans Administration Medical
Center, Manhattan
New York, New York

Chapter 23, *" Hemodynamic Principles"*

Lotte C. G. Hoegberg, MS (Pharm), PhD

Pharmacist, Danish Poison Information Centre
Copenhagen, Denmark

Chapter 7, *"Techniques Used to Prevent Gastrointestinal Absorption"*

Robert J. Hoffman, MD, MS

Assistant Professor
Albert Einstein College of Medicine
Research Director
Beth Israel Medical Center
New York, New York

Chapter 65, *"Methylxanthines and Selective β_2 Adrenergic Agonists"*

Robert S. Hoffman, MD, FAACT, FACMT

Associate Professor of Emergency Medicine and Medicine
(Pharmacology)
New York University School of Medicine
Attending Physician, Emergency Medicine and Internal Medicine
Bellevue Hospital Center and New York University
Langone Medical Center
Director, New York City Poison Center
New York, New York

Chapter 3, *"Initial Evaluation of the Patient: Vital Signs and Toxic Syndromes"*
Chapter 4, *"Principles of Managing the Acutely Poisoned or Overdosed Patient"*
Chapter 16, *"Fluid, Electrolyte, and Acid-Base Principles"*
Chapter 21, *"Respiratory Principles"*
Chapter 76, *"Cocaine"*
Chapter 90, *"Cadmium"*
Chapter 100, *"Thallium"*
Chapter 135, *"Poison Centers and Poison Epidemiology"*
Antidote in Depth A24, *"Benzodiazepines"*
Antidote in Depth A25, *"Thiamine Hydrochloride"*
Antidote in Depth A29, *"Prussian Blue"*

Michael G. Holland, MD, FAACT, FACEP, FACMT, FACOEM

Clinical Assistant Professor
SUNY Upstate Medical University
Consultant Medical Toxicologist
Upstate New York Poison Center
Syracuse, New York
Attending Physician
Center for Occupational Health at Glens Falls Hospital
Glens Falls, New York

Chapter 114, *"Insecticides: Organic Chlorines, Pyrethrins/Pyrethroids, and Insect Repellents"*

Christopher P. Holstege, MD

Associate Professor of Emergency Medicine and Pediatrics
University of Virginia School of Medicine
Director, Division of Medical Toxicology
University of Virginia Health System
Charlottesville, Virginia

Chapter 126, *"Cyanide and Hydrogen Sulfide"*

William J. Holubek, MD

Attending Physician
Department of Emergency Medicine
New York Methodist Hospital
Brooklyn, New York

Chapter 36, *"Nonsteroidal Antiinflammatory Drugs"*

Mary Ann Howland, PharmD, DABAT, FAACT

Clinical Professor of Pharmacy
St. John's University
College of Pharmacy
Adjunct Professor of Emergency Medicine
New York University School of Medicine
Bellevue Hospital Center and New York University
Langone Medical Center
Senior Consultant in Residence
New York City Poison Center
New York, New York

Chapter 3, "Initial Evaluation of the Patient: Vital Signs and Toxic Syndromes"
Chapter 4, "Principles of Managing the Acutely Poisoned or Overdosed Patient"
Chapter 8, "Pharmacokinetic and Toxicokinetic Principles"
Chapter 32, "Geriatric Principles"
Antidote in Depth A1, "Syrup of Ipecac"
Antidote in Depth A2, "Activated Charcoal"
Antidote in Depth A3, "Whole-Bowel Irrigation and Other Intestinal Evacuants"
Antidote in Depth A4, "N-Acetylcysteine"
Antidote in Depth A6, "Opioid Antagonists"
Antidote in Depth A7, "Deferoxamine"
Antidote in Depth A9, "L-Carnitine"
Antidote in Depth A11, "Octreotide"
Antidote in Depth A12, "Physostigmine Salicylate"
Antidote in Depth A13, "Leucovorin (Folinic Acid) and Folic Acid"
Antidote in Depth A15, "Pyridoxine"
Antidote in Depth A16, "Vitamin K_1"
Antidote in Depth A17, "Protamine"
Antidote in Depth A19, "Glucagon"
Antidote in Depth A20, "Digoxin-Specific Antibody Fragments (Fab)"
Antidote in Depth A23, "Flumazenil"
Antidote in Depth A24, "Benzodiazepines"
Antidote in Depth A26, "Dimercaprol (British Anti-Lewisite or BAL)"
Antidote in Depth A27, "Succimer (2,3-Dimercaptosuccinic Acid)"
Antidote in Depth A28, "Edetate Calcium Disodium (CaNa$_2$EDTA)"
Antidote in Depth A30, "Calcium"
Antidote in Depth A31, "Fomepizole"
Antidote in Depth A32, "Ethanol"
Antidote in Depth A33, "Pralidoxime"
Antidote in Depth A34, "Atropine"
Antidote in Depth A38, "Sodium and Amyl Nitrite"
Antidote in Depth A39, "Sodium Thiosulfate"
Antidote in Depth A40, "Hydroxocobalamin"
Antidote in Depth A41, "Methylene Blue"

Oliver L. Hung, MD

Attending Physician
Department of Emergency Medicine
Morristown Memorial Hospital
Morristown, New Jersey

Chapter 43, "Herbal Preparations"

Gary E. Isom, PhD

Professor of Toxicology
Purdue University
Clinical Assistant Professor of Pharmacology
Indiana University School of Medicine
West Lafayette, Indiana

Chapter 126, "Cyanide and Hydrogen Sulfide"

David N. Juurlink, BPhm, MD, PhD, FAACT, FACMT, FRCPC

Associate Professor, Faculty of Medicine
University of Toronto
Division Head, Clinical Pharmacology and Toxicology
Sunnybrook Health Sciences Centre
Toronto, Ontario, Canada

Chapter 69, "Antipsychotics"

Bradley J. Kaufman, MD, MPH

Assistant Professor, Department of Emergency Medicine
Albert Einstein College of Medicine
Bronx, New York
Attending Physician
Department of Emergency Medicine
Long Island Jewish Medical Center
New Hyde Park, New York
Division Medical Director
Fire Department of the City of New York
New York, New York

Chapter 130, "Hazmat Incident Response"

Brian Kaufman, MD

Associate Professor of Medicine, Anesthesiology and Neurosurgery
New York University School of Medicine
Co-Director Critical Care
New York University Langone Medical Center
New York, New York

Chapter 66, "Local Anesthetics"
Chapter 67, "Inhalational Anesthetics"

William Kerns, II, MD, FACEP, FACMT

Medical Toxicology Fellowship Director
Division of Medical Toxicology
Department of Emergency Medicine and
Carolinas Poison Center
Attending Toxicologist
Carolinas Medical Center and Carolinas Poison Center
Charlotte, North Carolina
Antidote in Depth A18, "Insulin-Euglycemia Therapy"

Mark A. Kirk, MD

Associate Professor of Emergency Medicine and Pediatrics
University of Virginia
Charlottesville, Virginia
Special Advisor for Chemical Defense and Medical Toxicology
Office of Health Affairs
Department of Homeland Security
Washington, DC

Chapter 10, "Use of the Intensive Care Unit"
Chapter 126, "Cyanide and Hydrogen Sulfide"
Chapter 128, "Smoke Inhalation"

Barbara M. Kirrane, MD

Assistant Professor of Emergency Medicine
Yale University
Attending Physician
New Haven, Connecticut

Chapter 140, "Risk Management and Legal Principles"

Kurt C. Kleinschmidt, MD

Professor of Surgery, Division of Emergency Medicine
University of Texas Southwestern Medical Center
Medical Director, Toxicology
Parkland Memorial Hospital
Dallas, Texas

Chapter 12, "Biochemical and Metabolic Principles"

Edwin K. Kuffner, MD

Senior Director for Medical Affairs
McNeil Pharmaceuticals
Fort Washington, Pennsylvania

Chapter 79, "Disulfiram and Disulfiramlike Reactions"
Chapter 103, "Camphor and Moth Repellents"

Melisa W. Lai Becker, MD

Instructor, Harvard Medical School
Director, Division of Medical Toxicology
Emergency Physician
Department of Emergency Medicine
Cambridge Health Alliance
Cambridge, Massachusetts

Chapter 99, "Silver"

David C. Lee, MD

Clinical Associate Professor of Emergency Medicine
New York University School of Medicine
Director of Research
North Shore University Hospital–Manhasset
Manhasset, New York

Chapter 74, "Sedative–Hypnotics"

Neal A. Lewin, MD, FACEP, FACMT, FACP

The Stanley and Fiona Druckenmiller Clinical Professor of
Emergency Medicine and Medicine (Pharmacology)
New York University School of Medicine
Director, Didactic Education
Emergency Medicine Residency
Attending Physician, Emergency Medicine and Internal Medicine
Bellevue Hospital Center and New York University
Langone Medical Center
Consultant, New York City Poison Center
New York, New York

Chapter 3, "Initial Evaluation of the Patient: Vital Signs and Toxic Syndromes"
Chapter 4, "Principles of Managing the Acutely Poisoned or Overdosed Patient"
Chapter 29, "Dermatologic Principles"
Chapter 63, "Antidysrhythmics"

Erica L. Liebelt, MD

Professor of Pediatrics and Emergency Medicine
University of Alabama at Birmingham School of Medicine
Director Medical Toxicology Services
Birmingham, Alaska

Chapter 73, "Cyclic Antidepressants"

Heather Long, MD

Assistant Professor of Emergency Medicine
Albany Medical Center
Albany, New York

Chapter 81, "Inhalants"

Nima Majlesi, DO

Research Director
Attending Physician
Staten Island University Hospital
Staten Island, New York

Chapter 101, "Zinc"

Kishor Malavade, MD

Clinical Assistant Professor of Psychiatry
New York University School of Medicine
Director, Comprehensive Psychiatric Emergency Program
Bellevue Hospital Center
New York, New York

Chapter 17, "Psychiatric Principles"

Alex F. Manini, MD, MS

Assistant Professor of Emergency Medicine
Mount Sinai School of Medicine

PREFACE

Goldfrank's Toxicologic Emergencies is a multi-authored text of close to 2000 pages prepared by using the education and management principles we apply at the New York City Poison Center and at our clinical sites. In this ninth edition of *Goldfrank's Toxicologic Emergencies*, we proudly offer readers an approach to medical toxicology using evidence-based principles viewed through a lens of bedside clinical practice. The case history is no longer incorporated in the chapter, but these cases and the critical questions appropriate for discussion are available on the website initially established in the eighth edition. We believe that this supplementary use of the cases recreates a learning environment much like the original text published in 1976 and permits us to use additional text space without creating a heavier, less portable text. In this edition, all the chapters have been revised, and several new chapters have been added. The greatest additions are found in the form of both Antidotes in Depth and Special Considerations, which allow us to address major advances in thought in a highly focused fashion.

Our goal is to assist in understanding new intellectual approaches with an emphasis on the ever-expanding role of medical and clinical toxicologists at the beginning of the twenty-first century. We have continued to increase the number of nationally and internationally known authors who have expertise in their respective areas by reassigning many of the chapters to these experts.

The ninth edition expands on our progress in the eighth edition to use the electronic format. The book has been dramatically improved with the use of full-color graphics and a single art style that will expand and enhance the educational value of the imagery of each chapter and of the image section on the website.

The complete "text" now consists of a hard copy component that offers readers the option of holding while consulting, as they have done previously, as well as an electronic workbook component available on our website (goldfrankstoxicology.com).

The workbook, which includes both case studies and annotated multiple-choice questions, is now available on this website and is dramatically enhanced. Many of the cases are relevant classic examples of toxicologic emergencies, and the remainder are new, extensively discussed cases from our regional monthly meetings at the New York City Poison Center. The collective wisdom of many of the current and former text authors continues to guide these sessions as it has for 30 years. Drs. Lewis S. Nelson and Robert S. Hoffman have analyzed these problems, distilled the discussions, and recreated the spirit of these meetings in the printed versions of the cases. Revised annotated multiple-choice questions based on each chapter were developed by the respective chapter authors and edited by Drs. Howard A. Greller and Dean G. Olsen to enhance self-learning and meet the intellectual needs of our readers. Each question has been meticulously meta-tagged by these editors. This allows the learner to sort by a variety of test strategies that are focused on a particular xenobiotic, clinical finding, or therapeutic strategy, to name a few, with the goal of improved individualized learning.

The rewriting and reorganization of this edition of the text has again required an enormous personal effort by each author and the editors as it has in the past, which we hope will facilitate reading, learning, and better patient care. Work on the next edition of this text literally begins the day that the current edition is published because this is such a rapidly evolving field. Although "tearing down" and reconstructing the text between each edition is an extreme exercise, it prevents the editors from accepting and promulgating unfounded treatments and outdated concepts. We hope that you agree that this exercise is worthwhile and that each "new text" continues to serve you well. As always, we encourage your thoughtful comments, and we will do our best, as always, to incorporate your suggestions into future editions.

If this text helps to provide better patient care and stimulates interest in medical toxicology for students of medicine, nursing, and pharmacy and by residents, fellows, and faculty in diverse specialties, our efforts will have indeed been worthwhile.

Lewis S. Nelson
Neal A. Lewin
Mary Ann Howland
Robert S. Hoffman
Lewis R. Goldfrank
Neal E. Flomenbaum

ACKNOWLEDGMENTS

CHAPTER 1

HISTORICAL PRINCIPLES AND PERSPECTIVES

Paul M. Wax

The term *poison* first appeared in the English literature around the year 1230 A.D. to describe a potion or draught that was prepared with deadly ingredients.[41,140] The history of poisons and poisoning, however, dates back thousands of years. Throughout the millennia, poisons have played an important role in human history—from political assassination in Roman times, to weapons of war, to contemporary environmental concerns, and to weapons of terrorism.

This chapter offers a perspective on the impact of poisons and poisoning on history. It also provides a historic overview of human understanding of poisons and the development of toxicology from antiquity to the present. The development of the modern poison control center, the genesis of the field of medical toxicology, and the recent increasing focus on medication errors and biologic and chemical weapons are examined. Chapter 2 describes poison plagues and unintentional disasters throughout history and examines the societal consequences of these unfortunate events. An appreciation of past failures and mistakes in dealing with poisons and poisoning promotes a keener insight and a more critical evaluation of present-day toxicologic issues and helps in the assessment and management of future toxicologic problems.

POISONS, POISONERS, AND ANTIDOTES OF ANTIQUITY

The earliest poisons consisted of plant extracts, animal venoms, and minerals. They were used for hunting, waging war, and sanctioned and unsanctioned executions. The *Ebers Papyrus*, an ancient Egyptian text written about 1500 B.C. that is considered to be among the earliest medical texts, describes many ancient poisons, including aconite, antimony, arsenic, cyanogenic glycosides, hemlock, lead, mandrake, opium, and wormwood.[91,140] These poisons were thought to have mystical properties, and their use was surrounded by superstition and intrigue. Some agents, such as the Calabar bean (*Physostigma venenosum*) containing physostigmine, were referred to as "ordeal poisons." Ingestion of these substances was believed to be lethal to the guilty and harmless to the innocent.[91] The "penalty of the peach" involved the administration of peach pits, which we now know contain the cyanide precursor amygdalin, as an ordeal poison. Magicians, sorcerers, and religious figures were the toxicologists of antiquity. The Sumerians, in about 4500 B.C., were said to worship the deity Gula, who was known as the "mistress of charms and spells" and the "controller of noxious poisons" (Table 1–1).[140]

■ ARROW AND DART POISONS

The prehistoric Masai hunters of Kenya, who lived 18,000 years ago, used arrow and dart poisons to increase the lethality of their weapons.[19] One of these poisons appears to have consisted of extracts of *Strophanthus* species, an indigenous plant that contains strophanthin, a digitalis-like substance.[91] Cave paintings of arrowheads and spearheads reveal that these weapons were crafted with small depressions at the end to hold the poison.[141] In fact, the term *toxicology* is derived

from the Greek terms *toxikos* ("bow") and *toxikon* ("poison into which arrowheads are dipped").[2,141]

References to arrow poisons are cited in a number of other important literary works. The ancient Indian text *Rig Veda*, written in the 12th century B.C., refers to the use of *Aconitum* species for arrow poisons.[19] In the *Odyssey*, Homer (ca. 850 B.C.) wrote that Ulysses anointed his arrows with a variety of poisons, including extracts of *Helleborus orientalis* (thought to act as a heart poison) and snake venoms.[108] Aristotle (384–322 B.C.) described how the Scythians prepared and used arrow poisons.[143] Finally, reference to weapons poisoned with the blood of serpents can be found in the writings of Ovid (43 B.C.–18 A.D.).[148]

■ CLASSIFICATION OF POISONS

The first attempts at poison identification and classification and the introduction of the first antidotes took place during Greek and Roman times. An early categorization of poisons divided them into fast poisons, such as strychnine, and slow poisons, such as arsenic. In his treatise, *Materia Medica*, the Greek physician Dioscorides (40–80 A.D.) categorized poisons by their origin—animal, vegetable, or mineral.[141] This categorization remained the standard classification for the next 1500 years.[141]

Animal Poisons Animal poisons usually referred to the venom from poisonous animals. Although the venom from poisonous snakes has always been among the most commonly feared poisons, poisons from toads, salamanders, jellyfish, stingrays, and sea hares are often as lethal. Nicander of Colophon (204–135 B.C.), a Greek poet and physician who is considered to be one of the earliest toxicologists, experimented with animal poisons on condemned criminals.[127] Nicander's poems *Theriaca* and *Alexipharmaca* are considered to be the earliest extant Greek toxicologic texts, describing the presentations and treatment of poisonings from animal toxins.[140] A notable fatality from the effects of an animal toxin was Cleopatra (69–30 B.C.), who reportedly committed suicide by deliberately falling on an asp.[71]

Vegetable Poisons Theophrastus (ca. 370–286 B.C.) described vegetable poisons in his treatise *De Historia Plantarum*.[72] Notorious poisonous plants included *Aconitum* species (aconite, monks-hood), *Conium maculatum* (poison hemlock), *Hyoscyamus niger* (henbane), *Mandragora officinarum* (mandrake), *Papaver somniferum* (opium poppy), and *Veratrum album* (hellebore). Aconite was among the most frequently encountered poisonous plants and was described as the "queen mother of poisons."[140] Hemlock was the official poison used by the Greeks and was used in the execution of Socrates (ca. 470–399 B.C.) and many others.[129] Poisonous plants used in India at this time included *Cannabis indica* (marijuana), *Croton tiglium* (croton oil), and *Strychnos nux vomica* (poison nut, strychnine).[72]

Mineral Poisons The mineral poisons of antiquity consisted of the metals antimony, arsenic, lead, and mercury. Undoubtedly, the most famous of these was lead. Lead was discovered as early as 3500 B.C. Although controversy continues about whether an epidemic of lead poisoning among the Roman aristocracy contributed to the fall of the Roman Empire, lead was certainly used extensively during this period.[53,106] In addition to its considerable use in plumbing, lead was also used in the production of food and drink containers.[60] It was common practice to add lead directly to wine or to intentionally prepare the wine in a lead kettle to improve its taste. Not surprisingly, chronic lead poisoning became widespread. Nicander described the first case of lead poisoning in the 2nd century B.C.[145] Dioscorides, writing in the 1st century A.D., noted that fortified wine was "most hurtful to the nerves."[145] Lead-induced gout ("saturnine gout") may have also been widespread among the Roman elite.[106]

TABLE 1–1. Important Early Figures in the History of Toxicology

Person	Date	Importance
Gula	ca. 4500 B.C.	First deity associated with poisons
Shen Nung	ca. 2000 B.C.	Chinese emperor who experimented with poisons and antidotes and wrote treatise on herbal medicine
Homer	ca. 850 B.C.	Wrote how Ulysses anointed arrows with the venom of serpents
Aristotle	384–322 B.C.	Described the preparation and use of arrow poisons
Theophrastus	ca. 370–286 B.C.	Referred to poisonous plants in *De Historia Plantarum*
Socrates	ca. 470–399 B.C.	Executed by poison hemlock
Nicander	204–135 B.C.	Wrote two poems that are among the earliest works on poisons: *Theriaca* and *Alexipharmaca*
King Mithridates VI	ca. 132–63 B.C.	Fanatical fear of poisons; developed mithradatum, one of the first universal antidotes
Sulla	81 B.C.	Issued *Lex Cornelia*, the first anti-poisoning law
Cleopatra	69–30 B.C.	Committed suicide with deliberate cobra envenomation
Andromachus	37–68 A.D.	Refined mithradatum; known as the Theriac of Andromachus
Dioscorides	40–80 A.D.	Wrote *Materia Medica*, which classified poisons by animal, vegetable, and mineral
Galen	ca. 129–200 A.D.	Prepared "nut theriac" for Roman emperors, a remedy against bites, stings, and poisons; wrote *De Antidotis I* and *II*, which provided recipes for different antidotes, including mithradatum and panacea
Ibn Wahshiya	9th century	Famed Arab toxicologist; wrote toxicology treatise *Book on Poisons*, combining contemporary science, magic, and astrology
Moses Maimonides	1135–1204	Wrote *Treatise on Poisons and Their Antidotes*
Petrus Abbonus	1250–1315	Wrote *De Venenis*, major work on poisoning

Gases Although not animal, vegetable, or mineral in origin, the toxic effects of gases were also appreciated during antiquity. In the 3rd century B.C., Aristotle commented that "coal fumes (carbon monoxide) lead to a heavy head and death"[69] and Cicero (106–43 B.C.) referred to the use of coal fumes in suicides and executions.

■ POISONERS OF ANTIQUITY

Given the increasing awareness of the toxic properties of some naturally occurring substances and the lack of analytical detection techniques, homicidal poisoning was common during Roman times. In an attempt to curtail this practice, in 81 B.C. the Roman dictator Sulla issued the first law against poisoning, the *Lex Cornelia*. According to its provisions, a perpetrator convicted of poisoning, would be sentenced to either loss of property and exile (if the guilty party was of high social rank) or exposure to wild beasts (if of low social rank). During this period, members of the aristocracy commonly used "tasters" to shield themselves from potential poisoners, a practice also in vogue during the reign of Louis XIV in 16th century France.[148]

One of the most infamous poisoners of ancient Rome was Locusta, who was known to experiment on slaves with poisons that included aconite, arsenic, belladonna, henbane, and poisonous fungi. In 54 A.D., Nero's mother, Agrippina, hired Locusta to poison Emperor Claudius (Agrippina's husband and Nero's stepfather) as part of a scheme to make Nero emperor. As a result of these activities, Claudius, who was a great lover of mushrooms, died from *Amanita phalloides* poisoning,[17] and in the next year, Britannicus (Nero's stepbrother) also became one of Locusta's victims. In his case, Locusta managed to fool the taster by preparing unusually hot soup that required additional cooling after the soup had been officially tasted. At the time of cooling, the poison was surreptitiously slipped into the soup. Almost immediately after drinking the soup, Britannicus collapsed and died. The exact poison remains in doubt, although some authorities suggest that it was a cyanogenic glycoside.[133]

■ EARLY QUESTS FOR THE UNIVERSAL ANTIDOTE

The recognition, classification, and use of poisons in ancient Greece and Rome were accompanied by an intensive search for a universal antidote. In fact, many of the physicians of this period devoted significant parts of their careers to this endeavor.[140] Mystery and superstition surrounded the origins and sources of these proposed antidotes. One of the earliest specific references to a protective agent can be found in Homer's *Odyssey*, when Ulysses is advised to protect himself by taking the antidote "moli." Recent speculation suggests that moli referred to *Galanthus nivalis*, which contains a cholinesterase inhibitor. This agent could have been used as an antidote against poisonous plants such as *Datura stramonium* (jimsonweed) that contain the anticholinergic alkaloids scopolamine, atropine, and hyoscyamine.[114]

Theriacs and the Mithradatum The Greeks referred to the universal antidote as the *alexipharmaca* or *theriac*.[140] The term alexipharmaca was derived from the words alexipharmakos ("which keeps off poison") and *antipharmakon* ("antidote"). Over the years, alexipharmaca was increasingly used to refer to a method of treatment, such as the induction of emesis by using a feather. Theriac, which originally had referred to poisonous reptiles or wild beasts, was later used to refer to the antidotes. Consumption of the early theriacs (ca. 200 B.C.) was reputed to make people "poison-proof" against bites of all venomous animals except the asp. Their ingredients included aniseed, anmi, apoponax, fennel, meru, parsley, and wild thyme.[140]

The quest for the universal antidote was epitomized by the work of King Mithradates VI of Pontus (132–63 B.C.).[70] After repeatedly being subjected to poisoning attempts by his enemies during his youth, Mithradates sought protection by the development of universal antidotes. To find the best antidote, he performed acute toxicity experiments on criminals and slaves. The theriac he concocted, known as the "mithradatum," contained a minimum of 36 ingredients and was thought to be protective against aconite, scorpions, sea slugs, spiders, vipers, and all other poisonous substances.[69] Mithradates took his concoction every day.

Ironically, when an old man, Mithradates attempted suicide by poison but supposedly was unsuccessful because he had become poison-proof. Having failed at self-poisoning, Mithradates was compelled to have a soldier kill him with a sword. Galen described Mithradates' experiences in a series of three books: *De Antidotis I*, *De Antidotis II*, and *De Theriaca ad Pisonem*.[70,146]

The Theriac of Andromachus, also known as the "Venice treacle" or "galene," is probably the most famous theriac. According to Galen, this preparation, formulated during the 1st century A.D., was considered an improvement over the mithradatum.[146] It was prepared by Andromachus (37–68 A.D.), physician to Emperor Nero. Andromachus added to the mithradatum ingredients such as the flesh of vipers, squills, and generous amounts of opium.[152] Other ingredients were removed. Altogether, 73 ingredients were required. It was advocated to "counteract all poisons and bites of venomous animals," as well as a host of other medical problems, such as colic, dropsy, and jaundice, and it was used both therapeutically and prophylactically.[140,146] As evidence of its efficacy, Galen demonstrated that fowl receiving poison followed by theriac had a higher survival rate than fowl receiving poison alone.[140] It is likely, however, that the scientific rigor and methodology used differed from current scientific practice.

By the Middle Ages, the Theriac of Andromachus contained more than 100 ingredients. Its synthesis was quite elaborate; the initial phase of production lasted months, followed by an aging process that lasted years, somewhat similar to that of vintage wine.[87] The final product was often more solid than liquid in consistency.

Other theriac preparations were named after famous physicians (Damocrates, Nicolaus, Amando, Arnauld, and Abano) who contributed additional ingredients to the original formulation. Over the centuries, certain localities were celebrated for their own peculiar brand of theriac. Notable centers of theriac production included Bologna, Cairo, Florence, Genoa, Istanbul, and Venice. At times, theriac production was accompanied by great fanfare. For example, in Bologna, the mixing of the theriac could take place only under the direction of the medical professors at the university.[140]

Whether these preparations were of actual benefit is uncertain. Some suggest that the theriac may have had an antiseptic effect on the gastrointestinal tract, but others state that the sole benefit of the theriac derived from its formulation with opium.[87] Theriacs remained in vogue throughout the Middle Ages and Renaissance, and it was not until 1745 that their efficacy was finally questioned by William Heberden in *Antitheriaka: An Essay on Mithradatum and Theriaca*.[70] Nonetheless, pharmacopeias in France, Spain, and Germany continued to list these agents until the last quarter of the 19th century, and theriac was still available in Italy and Turkey in the early 20th century.[18,87]

Sacred Earth Beginning in the 5th century B.C., an adsorbent agent called *terra sigillata* was promoted as a universal antidote. This agent, also known as the "sacred sealed earth," consisted of red clay that could be found on only one particular hill on the Greek island of Lemnos. Perhaps somewhat akin to the 20th-century "universal antidote," it was advocated as effective in counteracting all poisons.[140] With great ceremony, once per year, the terra sigillata was retrieved from this hill and prepared for subsequent use. According to Dioscorides, this clay was formulated with goat's blood to make it into a paste. At one time, it was included as part of the Theriac of Andromachus. Demand for terra sigillata continued into the 15th century. Similar antidotal clays were found in Italy, Malta, Silesia, and England.[140]

Charms Charms, such as toadstones, snakestones, unicorn horns, and bezoar stones, were also promoted as universal antidotes. Toadstones, found in the heads of old toads, were reputed to have the capability to extract poison from the site of a venomous bite or sting. In addition, the toadstone was supposedly able to detect the mere presence of poison

by producing a sensation of heat upon contact with a poisonous substance.[140]

Similarly, snakestones extracted from the heads of cobras (known as *piedras della cobra de Capelos*) were also reported to have magical qualities.[14] The 17th-century Italian philosopher Athanasius Kircher (1602–1680) became an enthusiastic supporter of snakestone therapy for the treatment of snakebite after conducting experiments, demonstrating the antidotal attributes of these charms "in front of amazed spectators." Kircher attributed the efficacy of the snakestone to the theory of "attraction of like substances." Francesco Redi (1626–1698), a court physician and contemporary of Kircher, debunked this quixotic approach. A harbinger of future experimental toxicologists, Redi was unwilling to accept isolated case reports and field demonstrations as proof of the utility of the snakestone. Using a considerably more rigorous approach, *provando et riprovando* (by testing and retesting), Redi assessed the antidotal efficacy of snakestone on different animal species and different toxins and failed to confirm any benefit.[14]

Much lore has surrounded the antidotal effects of the mythical unicorn horn. Ctesias, writing in 390 B.C., was the first to chronicle the wonders of the unicorn horn, claiming that drinking water or wine from the "horn of the unicorn" would protect against poison.[140] The horns were usually narwhal tusks or rhinoceros horns, and during the Middle Ages, the unicorn horn may have been worth as much as 10 times the price of gold. Similar to the toadstone, the unicorn horn was used both to detect poisons and to neutralize them. Supposedly, a cup made of unicorn horn would sweat if a poisonous substance was placed in it.[85] To give further credence to its use, a 1593 study on arsenic-poisoned dogs reportedly showed that the horn was protective.[85]

Bezoar stones, also touted as universal antidotes, consisted of stomach or intestinal calculi formed by the deposition of calcium phosphate around a hair, fruit pit, or gallstone. They were removed from wild goats, cows, and apes and administered orally to humans. The Persian name for the bezoar stone was *pad zahr* ("expeller of poisons"); the ancient Hebrews referred to the bezoar stone as *bel Zaard* ("every cure for poisons"). Over the years, regional variations of bezoar stones were popularized, including an Asian variety from wild goat of Persia, an Occidental variety from llamas of Peru, and a European variety from chamois of the Swiss mountains.[48,140]

OPIUM, COCA, CANNABIS, AND HALLUCINOGENS IN ANTIQUITY

Although it was not until the mid-19th century that the true perils of opiate addiction were first recognized, juice from the *Papaver somniferum* was known for its medicinal value in Egypt at least as early as the writing of the *Ebers Papyrus* in 1500 B.C. Egyptian pharmacologists of that time reportedly recommended opium poppy extract as a pacifier for children who exhibited incessant crying.[126] In Ancient Greece, Dioscorides and Galen were early advocates of opium as a therapeutic agent. During this time, it was also used as a means of suicide. Mithradates' lack of success in his own attempted suicide by poisoning may have been the result of an opium tolerance that had developed from previous repetitive use.[126] One of the earliest descriptions of the abuse potential of opium is attributed to Epistratos (304–257 B.C.), who criticized the use of opium for earache because it "dulled the sight and is a narcotic."[126]

Cocaine use dates back to at least 300 B.C., when South American Indians reportedly chewed coca leaves during religious ceremonies.[100] Chewing coca to increase work efficacy and to elevate mood has remained commonplace in some South American societies for thousands of years. An Egyptian mummy from about 950 B.C. revealed

significant amounts of cocaine in the stomach and liver, suggesting oral use of cocaine during this time period.[104] Large amounts of tetrahydrocannabinol (THC) were also found in the lung and muscle of the same mummy. Another investigation of 11 Egyptian (1079 B.C.–395 A.D.) and 72 Peruvian (200–1500 A.D.) mummies found cocaine, thought to be indigenous only to South America, and hashish, thought to be indigenous only to Asia, in both groups.[113]

Cannabis use in China dates back even further, to around 2700 B.C., when it was known as the "liberator of sin."[100] In India and Iran, cannabis was used as early as 1000 B.C. as an intoxicant known as *bhang*.[103] Other currently abused agents that were known to the ancients include cannabis, hallucinogenic mushrooms, nutmeg, and peyote. As early as 1300 B.C., Peruvian Indian tribal ceremonies included the use of mescaline-containing San Pedro cacti.[100] The hallucinogenic mushroom, *Amanita muscaria*, known as "fly agaric," was used as a ritual drug and may have been known in India as "soma" around 2000 B.C.

■ EARLY ATTEMPTS AT GASTROINTESTINAL DECONTAMINATION

Nicander's *Alexipharmaca* (*Antidotes for Poisons*) recommended induction of emesis by one of several methods: (a) ingesting warm linseed oil; (b) tickling the hypopharynx with a feather; or (c) "emptying the gullet with a small twisted and curved paper."[87] Nicander also advocated the use of suction to limit envenomation.[141] The Romans referred to the feather as the "vomiting feather" or "pinna." Most commonly, the feather was used after a hearty feast to avoid the gastrointestinal discomfort associated with overeating. At times, the pinna was dipped into a nauseating mixture to increase its efficacy.[90]

TOXICOLOGY DURING THE MEDIEVAL AND RENAISSANCE PERIODS

After Galen (ca. A.D. 129–200), there is relatively little documented attention to the subject of poisons until the works of Ibn Wahshiya in the 9th century. Citing Greek, Persian, and Indian texts, Wahshiya's work, titled *Book of Poisons*, combines contemporary science, magic, and astrology during his discussion of poison mechanisms (as they were understood at that time), symptomatology, antidotes (including his own recommendation for a universal antidote), and prophylaxis. He categorized poisons as lethal by sight, smell, touch, and sound, as well as by drinking and eating. For victims of an aconite-containing dart arrow, Ibn Wahshiya recommended excision, followed by cauterization and topical treatment with onion and salt.[82]

Another significant medieval contribution to toxicology can be found in Moses Maimonides' (1135–1204) *Treatise on Poisons and Their Antidotes* (1198). In part one of this treatise, Maimonides discussed the bites of snakes and mad dogs and the stings of bees, wasps, spiders, and scorpions.[124] He also discussed the use of cupping glasses for bites (a progenitor of the modern suctioning device) and was one of the first to differentiate the hematotoxic (hot) from the neurotoxic (cold) effects of poison. In part two, he discussed mineral and vegetable poisons and their antidotes. He described belladonna poisoning as causing a "redness and a sort of excitation."[124] He suggested that emesis should be induced by hot water, *Anethum graveolens* (dill), and oil, followed by fresh milk, butter, and honey. Although he rejected some of the popular treatments of the day, he advocated the use of the great theriac and the mithradatum as first- and second-line agents in the management of snakebite.[124]

On the subject of oleander poisoning, Petrus Abbonus (1250–1315) wrote that those who drink the juice, spines, or bark of oleander will develop anxiety, palpitations, and syncope.[21] He described the clinical presentation of opium overdose as someone who "will be dull, lazy, and sleepy, without feeling, and he will neither understand nor feel anything, and if he does not receive succor, he will die." Although this "succor" is not defined, he recommended that treatment of opium intoxication include drinking the strongest wine, rubbing the extremities with alkali and soap, and olfactory stimulation with pepper. To treat snakebite, Abbonus suggested the immediate application of a tourniquet, as well as oral suctioning of the bite wound, preferably performed by a servant. Interestingly, from a 21st-century perspective, Abbonus also suggested that St. John's wort had the magical power to free anything from poisons and attributed this virtue to the influence of the stars.[21]

■ THE SCIENTISTS

Paracelsus' (1493–1541) study on the dose–response relationship is usually considered the beginning of the scientific approach to toxicology (Table 1–2). He was the first to emphasize the chemical nature of toxic agents.[111] Paracelsus stressed the need for proper observation and experimentation regarding the true response to chemicals. He underscored the need to differentiate between the therapeutic and toxic properties of chemicals when he stated in his *Third Defense*, "What is there that is not poison? All things are poison and nothing [is] without poison. Solely, the dose determines that a thing is not a poison."[40]

Although Paracelsus is the best known Renaissance toxicologist, Ambroise Pare (1510–1590) and William Piso (1611–1678) also contributed to the field. Pare argued against the use of the unicorn horn and bezoar stone.[89] He also wrote an early treatise on carbon monoxide poisoning. Piso is credited as one of the first to recognize the emetic properties of ipecacuanha.[121]

■ MEDIEVAL AND RENAISSANCE POISONERS

Along with these advances in toxicologic knowledge, the Renaissance is mainly remembered as the age of the poisoner, a time when the art of poisoning reached new heights (Table 1–3). In fact, poisoning was so rampant during this time that in 1531, King Henry VIII decreed that convicted poisoners should be boiled alive.[50] From the 15th to 17th centuries, schools of poisoning existed in Venice and Rome. In Venice, poisoning services were provided by a group called the Council of Ten, whose members were hired to perform murder by poison.[148]

Members of the infamous Borgia family were considered to be responsible for many poisonings during this period. They preferred to use a poison called "La Cantarella," a mixture of arsenic and phosphorus.[143] Rodrigo Borgia (1431–1503), who became Pope Alexander VI, and his son, Cesare Borgia, were reportedly responsible for the poisoning of cardinals and kings.

In the late 16th century, Catherine de Medici, wife of Henry II of France, introduced Italian poisoning techniques to France. She experimented on the poor, the sick, and the criminal. By analyzing the subsequent complaints of her victims, she is said to have learned the site of action and time of onset, the clinical signs and symptoms, and the efficacy of poisons.[54]

Murder by poison remained quite popular during the latter half of the 17th and the early part of the 18th centuries in Italy and France. The Marchioness de Brinvilliers (1630–1676) tested her poison concoctions on hospitalized patients and on her servants and allegedly murdered her husband, father, and two siblings.[52,133] Among the favorite poisons of the Marchioness were arsenic, copper sulfate, corrosive sublimate (mercury bichloride), lead, and tartar emetic (antimony potassium tartrate).[143] Catherine Deshayes (1640–1680), a fortuneteller and sorceress, was one of the last "poisoners for hire" and

TABLE 1–2. Important Figures in Toxicology from Paracelsus to the 1900s

Person	Date	Importance
Paracelsus	1493–1541	Introduced the dose–response concept to toxicology
Ambroise Pare	1510–1590	Spoke out against unicorn horns and bezoars as antidotes
William Piso	1611–1678	First to study emetic qualities of ipecacuanha
Bernardino Ramazzini	1633–1714	Father of occupational medicine; wrote *De Morbis Artificum Diatriba*
Richard Mead	1673–1754	Wrote English-language book about poisoning
Percivall Pott	1714–1788	Wrote the first description of occupational cancer, relating the chimney sweep occupation to scrotal cancer
Felice Fontana	1730–1805	First scientific study of venomous snakes
Philip Physick	1767–1837	Early advocate of orogastric lavage to remove poisons
Baron Guillaume Dupuytren	1777–1835	Early advocate of orogastric lavage to remove poisons
Francois Magendie	1783–1855	Discovered emetine and studied the mechanisms of cyanide and strychnine
Bonaventure Orfila	1787–1853	Father of modern toxicology; wrote *Traite des Poisons*; first to isolate arsenic from humans organs
James Marsh	1794–1846	Developed reduction test for arsenic
Robert Christison	1797–1882	Wrote *Treatise on Poisons*, one of the most influential texts of the early 19th century
Grand Marshall Bertrand	1813	Demonstrated the efficacy of charcoal in arsenic ingestion
Claude Bernard	1813–1878	Studied the mechanisms of toxicity of carbon monoxide and curare
Edward Jukes	1820	Self-experimented with orogastric lavage apparatus known as Jukes' syringe
Theodore Wormley	1826–1897	Wrote *Micro-Chemistry of Poisons*, the first American book devoted exclusively to toxicology
Pierre Touery	1831	Demonstrated the efficacy of charcoal in strychnine ingestion
Hugo Reinsch	1842–1884	Developed qualitative tests for arsenic and mercury
Alfred Garrod	1846	Conducted the first systematic study of charcoal in an animal model
Max Gutzeit	1847–1915	Developed method to quantitate small amounts of arsenic
Benjamin Howard Rand	1848	Conducted the first study of the efficacy of charcoal in humans
O.H. Costill	1848	Wrote the first book on symptoms and treatment of poisoning
Louis Lewin	1850–1929	Studied many toxins, including methanol, chloroform, snake venom, carbon monoxide, lead, opioids, and hallucinogenic plants
Rudolf Kobert	1854–1918	Studied digitalis and ergot alkaloids
Albert Niemann	1860	Isolated cocaine alkaloid
Alice Hamilton	1869–1970	Conducted landmark investigations associating worksite chemical hazards with disease; led reform movement to improve worker safety

was implicated in countless poisonings, including the killing of more than 2000 infants.[54] Better known as "La Voisine," she reportedly sold poisons to women wishing to rid themselves of their husbands. Her particular brand of poison was a concoction of aconite, arsenic, belladonna, and opium known as "la poudre de succession."[143] Ultimately, de Brinvilliers was beheaded, and Deshayes was burned alive for their crimes. In an attempt to curtail these rampant poisonings, Louis XIV issued a decree in 1662 banning the sale of arsenic, mercury, and other poisons to customers not known to apothecaries and requiring poison buyers to sign a register declaring the purpose for their purchase.[133]

A major center for poison practitioners was Naples, the home of the notorious Madame Giulia Toffana. She reportedly poisoned more than 600 people, preferring a particular solution of white arsenic (arsenic trioxide), better known as "aqua toffana," and dispensed under the guise of a cosmetic. Eventually convicted of poisoning, Madame Toffana was executed in 1719.[20]

EIGHTEENTH- AND NINETEENTH-CENTURY DEVELOPMENTS IN TOXICOLOGY

The development of toxicology as a distinct specialty began during the 18th and 19th centuries (see Table 1–2).[112] The mythological and magical mystique of poisoners began to be gradually replaced by an increasingly rational, scientific, and experimental approach to these agents. Much of the poison lore that had survived for almost 2000 years was finally debunked and discarded. The 18th-century Italian Felice Fontana was one of the first to usher in the modern age. He was an early experimental toxicologist who studied the venom of the European viper and wrote the classic text *Traite sur le Venin de la Vipere* in 1781.[75] Through his exacting experimental study on the effects of venom, Fontana brought a scientific insight to toxicology previously lacking and demonstrated that clinical symptoms resulted

TABLE 1–3. Notable Poisoners from Antiquity to the Present

Poisoner	Date	Victim(s)	Poison(s)
Locusta	54–55 A.D.	Claudius and Britannicus	*Amanita phalloides*, cyanide
Cesare Borgia	1400s	Cardinals and kings	La Cantarella (arsenic and phosphorus)
Catherine de Medici	1519–1589	Poor, sick, criminals	Unknown agents
Hieronyma Spara	Died 1659	Taught women how to poison their husbands	Mana of St. Nicholas of Bari (arsenic trioxide)
Marchioness de Brinvilliers	Died 1676	Hospitalized patients, husband, father	Antimony, arsenic, copper, lead, mercury
Catherine Deshayes	Died 1680	>2000 infants, many husbands	La poudre de succession (arsenic mixed with aconite, belladonna, and opium)
Madame Giulia Toffana	Died 1719	>600 people	Aqua toffana (arsenic trioxide)
Mary Blandy	1752	Father	Arsenic
Anna Maria Zwanizer	1807	Random people	Antimony, arsenic
Marie Lefarge	1839	Husband	Arsenic (first use of Marsh test)
John Tawell	1845	Mistress	Cyanide
William Palmer, MD	1855	Fellow gambler	Strychnine
Madeline Smith (acquitted)	1857	Lover	Arsenic
Edmond de la Pommerais, MD	1863	Patient and mistress	Digitalis
Edward William Pritchard, MD	1865	Wife and mother-in-law	Antimony
George Henry Lamson, MD	1881	Brother-in-law	Aconite
Adelaide Bartlett (acquitted)	1886	Husband	Chloroform
Florence Maybrick	1889	Husband	Arsenic
Thomas Neville Cream, MD	1891	Prostitutes	Strychnine
Johann Hoch	1892–1905	Serial wives	Arsenic
Cordelia Botkin	1898	Feminine rival	Arsenic (in chocolate candy)
Roland Molineux	1898	Acquaintance	Cyanide of mercury
Hawley Harvey Crippen, MD	1910	Wife	Hyoscine
Frederick Henry Seddon	1911	Boarder	Arsenic (fly paper)
Henri Girard Landru	1912	Acquaintances	*Amanita phalloides*
Robert Armstrong	1921	Wife	Arsenic (weed killer)
Landru	1922	Many women	Cyanide
Suzanne Fazekas	1929	Supplied poison to 100 wives to kill husbands	Arsenic
Sadamichi Hirasawa	1948	Bank employees	Potassium cyanide
Christa Ambros Lehmann	1954	Friend, husband, father-in-law	E-605 (parathion)
Nannie Doss	1954	11 relatives, including five husbands	Arsenic
Carl Coppolino, MD	1965	Wife	Succinylcholine
Graham Frederick Young	1971	Stepmother, coworkers	Antimony, thallium
Judias V. Buenoano	1971	Husband, son	Arsenic
Ronald Clark O'Bryan	1974	Son and neighborhood children	Cyanide (in Halloween candy)
Unknown	1978	Georgi Markov, Bulgarian dissident	Ricin
Jim Jones	1978	>900 people in mass suicide	Cyanide
Harold Shipman, MD	1974–1998	Patients (100s)	Heroin
Unidentified	1982	Seven people	Extra Strength Tylenol mixed with cyanide
Donald Harvey	1983–1987	Patients	Arsenic
George Trepal	1988	Neighbors	Thallium
Michael Swango, MD	1980s–1990s	Hospitalized patients	Arsenic, potassium chloride, succinylcholine
Charles Cullen, RN	1990s–2003	Hospitalized patients	Digoxin
Unknown	2004	Viktor Yushchenko, Ukrainian presidential candidate	Dioxin
Unknown	2006	Alexander Litvinenko	Polonium-210

from the poison (venom) acting on specific target organs. During the 18th and 19th centuries, attention focused on the detection of poisons and the study of toxic effects of drugs and chemicals in animals.[105] Issues relating to adverse effects of industrialization and unintentional poisoning in the workplace and home environment were raised. Also during this time, early experience and experimentation with methods of gastrointestinal decontamination took place.

■ DEVELOPMENT OF ANALYTICAL TOXICOLOGY AND THE STUDY OF POISONS

The French physician Bonaventure Orfila (1787–1853) is often called the father of modern toxicology.[105] He emphasized toxicology as a distinct, scientific discipline, separate from clinical medicine and pharmacology.[11] He was also an early medical-legal expert who championed the use of chemical analysis and autopsy material as evidence to prove that a poisoning had occurred. His treatise *Traite des Poisons* (1814)[110] evolved over five editions and was regarded as the foundation of experimental and forensic toxicology.[149] This text classified poisons into six groups: acrids, astringents, corrosives, narcoticoacrids, septics and putrefiants, and stupefacients and narcotics.

A number of other landmark works on poisoning also appeared during this period. In 1829, Robert Christison (1797–1882), a professor of medical jurisprudence and Orfila's student, wrote *A Treatise on Poisons*.[29] This work simplified Orfila's poison classification schema by categorizing poisons into three groups: irritants, narcotics, and narcoticoacrids. Less concerned with jurisprudence than with clinical toxicology, O.H. Costill's *A Practical Treatise on Poisons*, published in 1848, was the first modern clinically oriented text to emphasize the symptoms and treatment of poisoning.[33] In 1867, Theodore Wormley (1826–1897) published the first American book written exclusively on poisons titled the *Micro-Chemistry of Poisons*.[46,151]

During this time, important breakthroughs in the chemical analysis of poisons resulted from the search for a more reliable assay for arsenic. Arsenic was widely available and was the suspected cause of a large number of deaths. In one study, arsenic was used in 31% of 679 homicidal poisonings.[143] A reliable means of detecting arsenic was much needed by the courts.

Until the 19th century, poisoning was mainly diagnosed by its resultant symptoms rather than by analytic tests. The first use of a chemical test as evidence in a poisoning trial occurred in the 1752 trial of Mary Blandy, who was accused of poisoning her father with arsenic.[93] Although Blandy was convicted and hanged publicly, the test used in this case was not very sensitive and depended in part on eliciting a garlic odor upon heating the gruel that the accused had fed to her father.

During the 19th century, James Marsh (1794–1846), Hugo Reinsch, and Max Gutzeit (1847–1915) each worked on this problem. Assays bearing their names are important contributions to the early history of analytic toxicology.[94,105] The "Marsh test" to detect arsenic was first used in a criminal case in 1839 during the trial of Marie Lefarge, who was accused of using arsenic to murder her husband.[133] Orfila's trial testimony that the victim's viscera contained minute amounts of arsenic helped to convict the defendant, although subsequent debate suggested that contamination of the forensic specimen may have also played a role.

In a further attempt to curtail criminal poisoning by arsenic, the British Parliament passed the Arsenic Act in 1851. This bill, which was one of the first modern laws to regulate the sale of poisons, required that the retail sale of arsenic be restricted to chemists, druggists, and apothecaries and that a poison book be maintained to record all arsenic sales.[15]

Homicidal poisonings remained common during the 19th century and early 20th century. Infamous poisoners of that time included William Palmer, Edward Pritchard, Harvey Crippen, and Frederick Seddon.[143] Many of these poisoners were physicians who used their knowledge of medicine and toxicology in an attempt to solve their domestic and financial difficulties by committing the "perfect" murder. Some of the poisons used were aconitine (by Lamson, who was a classmate of Christison), *Amanita phalloides* (Girard), arsenic (by Maybrick, Seddon, and others), antimony (by Pritchard), cyanide (by Molineux and Tawell), digitalis (by Pommerais), hyoscine (by Crippen), and strychnine (by Palmer and Cream) (see Table 1–3).[23,140,143]

In the early 20th century, forensic investigation into suspicious deaths, including poisonings, was significantly advanced with the development of the medical examiner system replacing the much-flawed coroner system that was subject to widespread corruption. In 1918, the first centrally controlled medical examiner system was established in New York City. Alexander Gettler, considered the father of forensic toxicology in the United States, established a toxicology laboratory within the newly created New York City Medical Examiner's Office. Gettler pioneered new techniques for the detection of a variety of substances in biologic fluids, including carbon monoxide, chloroform, cyanide, and heavy metals.[47,105]

Systematic investigation into the underlying mechanisms of toxic substances also commenced during the 19th century. To cite just a few important accomplishments, Francois Magendie (1783–1855) studied the mechanisms of toxicity and sites of action of cyanide, emetine, and strychnine.[45] Claude Bernard (1813–1878), a pioneering physiologist and a student of Magendie, made important contributions to the understanding the toxicity of carbon monoxide and curare.[81] Rudolf Kobert (1854–1918) studied digitalis and ergot alkaloids and authored a textbook on toxicology for physicians and students.[79,108] Louis Lewin (1850–1929) was the first person to intensively study the differences between the pharmacologic and toxicologic actions of drugs. Lewin studied chronic opium intoxication, as well as the toxicity of carbon monoxide, chloroform, lead, methanol, and snake venom. He also developed a classification system for psychoactive drugs, dividing them into euphorics, phantastics, inebriants, hypnotics, and excitants.[88]

■ THE ORIGIN OF OCCUPATIONAL TOXICOLOGY

The origins of occupational toxicology can be traced to the early 18th century and to the contributions of Bernardino Ramazzini (1633–1714). Considered the father of occupational medicine, Ramazzini wrote *De Morbis Artificum Diatriba* (*Diseases of Workers*) in 1700, which was the first comprehensive text discussing the relationship between disease and workplace hazards.[51] Ramazzini's essential contribution to the care of the patient is epitomized by the addition of a standard question to a patient's medical history: "What occupation does the patient follow?"[49] Altogether Ramazzini described diseases associated with 54 occupations, including hydrocarbon poisoning in painters, mercury poisoning in mirror makers, and pulmonary diseases in miners.

In 1775, Sir Percivall Pott proposed the first association between workplace exposure and cancer when he noticed a high incidence of scrotal cancer in English chimney sweeps. Pott's belief that the scrotal cancer was caused by prolonged exposure to tar and soot was confirmed by further investigation in the 1920s, indicating the carcinogenic nature of the polycyclic aromatic hydrocarbons contained in coal tar (including benzo[*a*]pyrene).[67]

Dr. Alice Hamilton (1869–1970) was another pioneer in occupational toxicology, whose rigorous scientific inquiry had a profound impact on linking chemical toxins with human disease. A physician, scientist, humanitarian, and social reformer, Hamilton became the first

female professor at Harvard University and conducted groundbreaking studies of many different occupational exposures and problems, including carbon monoxide poisoning in steelworkers, mercury poisoning in hatters, and wrist drop in lead workers. Hamilton's overriding concerns about these "dangerous trades" and her commitment to improving the health of workers led to extensive voluntary and regulatory reforms in the workplace.[8,58]

■ ADVANCES IN GASTROINTESTINAL DECONTAMINATION

Using gastric lavage and charcoal to treat poisoned patients was introduced in the late 18th and early 19th century. A stomach pump was first designed by Munro Secundus in 1769 to administer neutralizing substances to sheep and cattle for the treatment of bloat.[24] The American surgeon Philip Physick (1768–1837) and the French surgeon Baron Guillaume Dupuytren (1777–1835) were two of the first physicians to advocate gastric lavage for the removal of poisons.[24] As early as 1805, Physick demonstrated the use of a "stomach tube" for this purpose. Using brandy and water as the irrigation fluid, he performed stomach washings in twins to wash out excessive doses of tincture of opium.[24] Dupuytren performed gastric emptying by first introducing warm water into the stomach via a large syringe attached to a long flexible sound and then withdrawing the "same water charged with poison."[24] Edward Jukes, a British surgeon, was another early advocate of poison removal by gastric lavage. Jukes first experimented on animals, performing gastric lavage after the oral administration of tincture of opium. Attempting to gain human experience, he experimented on himself, by first ingesting 10 drams (600 g) of tincture of opium and then performing gastric lavage using a 25-inch-long, 0.5-inch-diameter tube, which became known as Jukes' syringe.[99] Other than some nausea and a 3-hour sleep, he suffered no ill effects, and the experiment was deemed a success.

The principle of using charcoal to adsorb poisons was first described by Scheele (1773) and Lowitz (1785), but the medicinal use of charcoal dates to ancient times.[32] The earliest reference to the medicinal uses of charcoal is found in Egyptian papyrus from about 1500 B.C.[32] The charcoal used during Greek and Roman times, referred to as "wood charcoal," was used to treat those with anthrax, chlorosis, epilepsy, and vertigo. By the late 18th century, topical application of charcoal was recommended for gangrenous skin ulcers, and internal use of a charcoal-water suspension was recommended for use as a mouthwash and in the treatment of bilious conditions.[32]

The first hint that charcoal might have a role in the treatment of poisoning came from a series of courageous self-experiments in France during the early 19th century. In 1813, the French chemist Bertrand publicly demonstrated the antidotal properties of charcoal by surviving a 5-g ingestion of arsenic trioxide that had been mixed with charcoal.[64] Eighteen years later, before the French Academy of Medicine, the pharmacist Touery survived an ingestion consisting of 10 times the lethal dose of strychnine mixed with 15 g of charcoal.[64] One of the first reports of charcoal used in a poisoned patient was in 1834 by the American Hort, who successfully treated a mercury bichloride–poisoned patient with large amounts of powdered charcoal.[4]

In the 1840s, Garrod performed the first controlled study of charcoal when he examined its utility on a variety of poisons in animal models.[64] Garrod used dogs, cats, guinea pigs, and rabbits to demonstrate the potential benefits of charcoal in the management of strychnine poisoning. He also emphasized the importance of early use of charcoal and the proper ratio of charcoal to poison. Other toxic substances, such as aconite, hemlock, mercury bichloride, and morphine were also studied during this period. The first charcoal efficacy studies in humans were performed by the American physician B. Rand in 1848.[64]

But, it was not until the early 20th century that an activation process was added to the manufacture of charcoal to increase its effectiveness. In 1900, the Russian Ostrejko demonstrated that treating charcoal with superheated steam significantly enhanced its adsorbing power.[32] Despite this improvement and the favorable reports mentioned, charcoal was only occasionally used in gastrointestinal decontamination until the early 1960s, when Holt and Holz repopularized its use.[61]

■ THE INCREASING RECOGNITION OF THE PERILS OF DRUG ABUSE

Opioids Although the medical use of opium was promoted by Paracelsus in the 16th century, the popularity of this agent was given a significant boost when the distinguished British physician Thomas Sydenham (1624–1689) formulated laudanum, which was a tincture of opium containing cinnamon, cloves, saffron, and sherry. Sydenham also formulated a different opium concoction known as "syrup of poppies."[78] A third opium preparation called Dover's powder was designed by Sydenham's protégé, Thomas Dover; this preparation contained ipecac, licorice, opium, salt-peter, and tartaric acid.

John Jones, the author of the 18th century text *The Mysteries of Opium Reveal'd*, was another enthusiastic advocate of its "medicinal" uses.[78] A well-known opium user himself, Jones provided one of the earliest descriptions of opiate addiction. He insisted that opium offered many benefits if the dose was moderate but that discontinuation or a decrease in dose, particularly after "leaving off after long and lavish use," would result in such symptoms as sweating, itching, diarrhea, and melancholy. His recommendation for the treatment of these withdrawal symptoms included decreasing the dose of opium by 1% each day until the drug was totally withdrawn. During this period, the number of English writers who became well-known opium addicts, included Elizabeth Barrett Browning, Samuel Taylor Coleridge, and Thomas De Quincey. De Quincey, author of *Confessions of an English Opium Eater*, was an early advocate of the recreational use of opiates. The famed Coleridge poem *Kubla Khan* referred to opium as the "milk of paradise," and De Quincey's *Confessions* suggested that opium held the "key to paradise." In many of these cases, the initiation of opium use for medical reasons led to recreational use, tolerance, and dependence.[78]

Although opium was first introduced to Asian societies by Arab physicians some time after the fall of the Roman Empire, the use of opium in Asian countries grew considerably during the 18th and 19th centuries. In one of the more deplorable chapters in world history, China's growing dependence on opium was spurred on by the English desire to establish and profit from a flourishing drug trade.[126] Opium was grown in India and exported east. Despite Chinese protests and edicts against this practice, the importation of opium persisted throughout the 19th century, with the British going to war twice in order to maintain their right to sell opium. Not surprisingly, by the beginning of the 20th century, opium abuse in China was endemic.

In England, opium use continued to increase during the first half of the 19th century. During this period, opium was legal and freely available from the neighborhood grocer. To many, its use was considered no more problematic than alcohol use.[56] The Chinese usually self-administered opium by smoking, a custom that was brought to the United States by Chinese immigrants in the mid-19th century; the English use of opium was more often by ingestion, that is, "opium eating."

The liberal use of opiates as infant-soothing agents was one of the most unfortunate aspects of this period of unregulated opiate use.[79] Godfrey's Cordial, Mother's Friend, Mrs. Winslow's Soothing Syrup, and Quietness were among the most popular opiates for children.[83] They were advertised as producing a natural sleep and recommended for teething and bowel regulation, as well as for crying. Because of the

wide availability of opiates during this period, the number of acute opiate overdoses in children was consequential and would remain problematic until these unsavory remedies were condemned and removed from the market.

With the discovery of morphine in 1805 and Alexander Wood's invention of the hypodermic syringe in 1853, parenteral administration of morphine became the preferred route of opiate administration for therapeutic use and abuse.[66] A legacy of the generous use of opium and morphine during the United States Civil War was "soldiers' disease," referring to a rather large veteran population that returned from the war with a lingering opiate habit.[118] One hundred years later, opiate abuse and addiction would again become common among US military serving during the Vietnam War. Surveys indicated that as many as 20% of American soldiers in Vietnam were addicted to opiates during the war—in part because of its widespread availability and high purity there.[123]

Growing concerns about opiate abuse in England led to the passing of the Pharmacy Act of 1868, which restricted the sale of opium to registered chemists. But in 1898, the Bayer Pharmaceutical Company of Germany synthesized heroin from opium (Bayer also introduced aspirin that same year).[134] Although initially touted as a nonaddictive morphine substitute, problems with heroin use quickly became evident in the United States.

Cocaine Ironically, during the later part of the 19th century, Sigmund Freud and Robert Christison, among others, promoted cocaine as a treatment for opiate addiction. After Albert Niemann's isolation of cocaine alkaloid from coca leaf in 1860, growing enthusiasm for cocaine as a panacea ensued.[74] Some of the most important medical figures of the time, including William Halsted, the famed Johns Hopkins surgeon, also extolled the virtues of cocaine use. Halsted championed the anesthetic properties of this drug, although his own use of cocaine and subsequent morphine use in an attempt to overcome his cocaine dependency would later take a considerable toll.[109] In 1884, Freud wrote *Uber Cocaine*,[142] advocating cocaine as a cure for opium and morphine addiction and as a treatment for fatigue and hysteria.

During the last third of the 19th century, cocaine was added to many popular over-the-counter tonics. In 1863, Angelo Mariani, a Frenchman, introduced a new wine, "Vin Mariani," that consisted of a mixture of cocaine and wine (6 mg of cocaine alkaloid per ounce) and was sold as a digestive aid and restorative.[100] In direct competition with the French tonic was the American-made Coca-Cola, developed by J.S. Pemberton. It was originally formulated with coca and caffeine and marketed as a headache remedy and invigorator. With the public demand for cocaine increasing, patent medication manufacturers were adding cocaine to thousands of products. One such asthma remedy was "Dr. Tucker's Asthma Specific," which contained 420 mg of cocaine per ounce and was applied directly to the nasal mucosa.[74] By the end of the 19th century, the first American cocaine epidemic was underway.[102]

Similar to the medical and societal adversities associated with opiate use, the increasing use of cocaine led to a growing concern about comparable adverse effects. In 1886, the first reports of cocaine-related cardiac arrest and stroke were published.[119] Reports of cocaine habituation occurring in patients using cocaine to treat their underlying opiate addiction also began to appear. In 1902, a popular book, *Eight Years in Cocaine Hell*, described some of these problems. *Century Magazine* called cocaine "the most harmful of all habit-forming drugs," and a report in *The New York Times* stated that cocaine was destroying "its victims more swiftly and surely than opium."[39] In 1910, President William Taft proclaimed cocaine to be "public enemy number 1."

In an attempt to curb the increasing problems associated with drug abuse and addiction, the 1914 Harrison Narcotics Act mandated stringent control over the sale and distribution of narcotics (defined as opium, opium derivatives, and cocaine).[39] It was the first federal law in the United States to criminalize the nonmedical use of drugs. The bill required doctors, pharmacists, and others who prescribed narcotics to register and to pay a tax. A similar law, the Dangerous Drugs Act, was passed in the United Kingdom in 1920.[56] To help enforce these drug laws in the United States, the Narcotics Division of the Prohibition Unit of the Internal Revenue Service (a progenitor of the Drug Enforcement Agency) was established in 1920. In 1924, the Harrison Act was further strengthened with the passage of new legislation that banned the importation of opium for the purpose of manufacturing heroin, essentially outlawing the medicinal uses of heroin. With the legal venues to purchase these drugs now eliminated, users were forced to buy from illegal street dealers, creating a burgeoning black market that still exists today.

Sedative-Hypnotics The introduction to medical practice of the anesthetic agents nitrous oxide, ether, and chloroform during the 19th century was accompanied by the recreational use of these agents and the first reports of volatile substance abuse. Chloroform "jags," ether "frolics," and nitrous parties became a new type of entertainment. Humphrey Davies was an early self-experimenter with the exhilarating effects associated with nitrous oxide inhalation. In certain Irish towns, especially where the temperance movement was strong, ether drinking became quite popular.[97] Horace Wells, the American dentist who introduced chloroform as an anesthetic, became dependent on this volatile solvent and later committed suicide.

Until the last half of the 19th century aconite, alcohol, hemlock, opium, and prussic acid (cyanide) were the primary agents used for sedation.[30] During the 1860s, new, more specific sedative-hypnotics, such as chloral hydrate and potassium bromide, were introduced into medical practice. In particular, chloral hydrate was hailed as a wonder drug that was relatively safe compared with opium, and was recommended for insomnia, anxiety, and delirium tremens, as well as for scarlet fever, asthma, and cancer. But within a few years, problems with acute toxicity of chloral hydrate, as well as its potential to produce tolerance and physical dependence, became apparent.[30] Mixing chloral hydrate with ethanol was noted to produce a rather powerful "knockout" combination that would become known as a "Mickey Finn." Abuse of chloral hydrate, as well as other new sedatives such as potassium bromide, would prove to be a harbinger of 20th-century sedative-hypnotic abuse.

Hallucinogens American Indians used peyote in religious ceremonies since at least the 17th century. Hallucinogenic mushrooms, particularly *Psilocybe* mushrooms, were also used in the religious life of Native Americans. These were called "teonanacatl," which means "God's sacred mushrooms" or "God's flesh."[115] Interest in the recreational use of cannabis also accelerated during the 19th century after Napoleon's troops brought the drug back from Egypt, where its use among the lower classes was widespread. In 1843, several French Romantics, including Balzac, Baudelaire, Gautier, and Hugo, formed a hashish club called "Le Club des Hachichins" in the Parisian apartment of a young French painter. Fitz Hugh Ludlow's *The Hasheesh Eater*, published in 1857, was an early American text espousing the virtues of marijuana.[86]

Absinthe, an ethanol-containing beverage that was manufactured with an extract from wormwood (*Artemisia absinthium*), was very popular during the last half of the 19th century.[80] This emerald-colored, very bitter drink was memorialized in the paintings of Degas, Toulouse-Lautrec, and Van Gogh and was a staple of French society during this period.[12] α-Thujone, a psychoactive component of wormwood and a noncompetitive γ-aminobutyric acid type A GABA$_A$ blocker, is thought to be responsible for the pleasant feelings, as well as for the hallucinogenic effects, hyperexcitability, and significant neurotoxicity associated with this drink.[63] Van Gogh's debilitating episodes

of psychosis were likely exacerbated by absinthe drinking.[137] Because of the medical problems associated with its use, absinthe was banned throughout most of Europe by the early 20th century.

A more recent event that had significant impact on modern-day hallucinogen use was the synthesis of lysergic acid diethylamide (LSD) by Albert Hofmann in 1938.[62] Working for Sandoz Pharmaceutical Company, Hofmann synthesized LSD while investigating the pharmacologic properties of ergot alkaloids. Subsequent self-experimentation by Hofmann led to the first description of its hallucinogenic effects and stimulated research into the use of LSD as a therapeutic agent. Hofmann is also credited with isolating psilocybin as the active ingredient in *Psilocybe mexicana* mushrooms in 1958.[100]

TWENTIETH-CENTURY EVENTS

■ EARLY REGULATORY INITIATIVES

The development of medical toxicology as a medical subspecialty and the important role of poison control centers began shortly after World War II. Before then, serious attention to the problem of household poisonings in the United States had been limited to a few federal legislative antipoisoning initiatives (Table 1–4). The 1906 Pure Food and Drug Act was the first federal legislation that sought to protect the public from problematic and potentially unsafe drugs and food. The driving force behind this reform was Harvey Wiley, the chief chemist at the Department of Agriculture. Beginning in the 1880s, Wiley investigated the problems of contaminated food. In 1902, he organized the "poison squad," which consisted of a group of volunteers who did self-experiments with food preservatives.[5] Revelations from the "poison squad," as well as the publication of Upton Sinclair's muckraking novel *The Jungle*[132] in 1906, exposed unhygienic practices of the meatpacking industry and led to growing support for legislative intervention. Samuel Hopkins Adams' reports about the patent medicine industry revealed that some drug manufacturers added opiates to soothing syrups for infants and led to the call for reform.[120] Although the 1906 regulations were mostly concerned with protecting the public from adulterated food, regulations protecting against misbranded patent medications were also included.

The Federal Caustic Poison Act of 1927 was the first federal legislation to specifically address household poisoning. As early as 1859, bottles clearly demarcated "poison" were manufactured in response to a rash of unfortunate dispensing errors that occurred when oxalic acid was unintentionally substituted for a similarly appearing Epsom salts solution.[26] Before 1927, however, "poison" warning labels were not required on chemical containers, regardless of toxicity or availability. The 1927 Caustic Act was spearheaded by the efforts of Chevalier Jackson, an otolaryngologist, who showed that unintentional exposures to household caustic agents were an increasingly frequent cause of severe oropharyngeal and gastrointestinal burns. Under this statute, for the first time, alkali- and acid-containing products had to clearly display a "poison" warning label.[139]

The most pivotal regulatory initiative in the United States before World War II—and perhaps the most significant American toxicologic regulation of the 20th century—was the Federal Food, Drug, and Cosmetic Act of 1938. Although the Food and Drug Administration (FDA) had been established in 1930 and legislation to strengthen the 1906 Pure Food and Drug Act was considered by Congress in 1933, the proposed revisions still had not been passed by 1938. Then the elixir of sulfanilamide tragedy in 1938 (see Chap. 2) claimed the lives of 105 people who had ingested a prescribed liquid preparation of the antibiotic sulfanilamide inappropriately dissolved in diethylene glycol. This event finally provided the catalyst for legislative intervention.[98,147]

Before the elixir disaster, proposed legislation called only for the banning of false and misleading drug labeling and for the outlawing of dangerous drugs without mandatory drug safety testing. After the tragedy, the proposal was strengthened to require assessment of drug safety before marketing, and the legislation was ultimately passed.

■ THE DEVELOPMENT OF POISON CONTROL CENTERS

World War II led to the rapid proliferation of new drugs and chemicals in the marketplace and in the household.[36] At the same time, suicide was recognized as a leading cause of death from these agents.[9] Both of these factors led the medical community to develop a response to the serious problems of unintentional and intentional poisonings. In Europe during the late 1940s, special toxicology wards were organized in Copenhagen and Budapest,[57] and a poison information service was begun in the Netherlands (Table 1–5).[144] A 1952 American Academy of Pediatrics study revealed that more than 50% of childhood "accidents" in the United States were the result of unintentional poisonings.[60] This study led Edward Press to open the first US poison control center in Chicago in 1953.[116] Press believed that it had become extremely difficult for individual physicians to keep abreast of product information, toxicity, and treatment for the rapidly increasing number of potentially poisonous household products. His initial center was organized as a cooperative effort among the departments of pediatrics at several Chicago medical schools, with the goal of collecting and disseminating product information to inquiring physicians, mainly pediatricians.[117]

By 1957, 17 poison control centers were operating in the United States.[36] With the Chicago center serving as a model, these early centers responded to physician callers by providing ingredient and toxicity information about drug and household products and making treatment recommendations. Records were kept of the calls, and preventive strategies were introduced into the community. As more poison control centers opened, a second important function, providing information to calls from the general public, became increasingly common. The physician pioneers in poison prevention and poison treatment were predominantly pediatricians who focused on unintentional childhood ingestions.[122]

During these early years in the development of poison control centers, each center had to collect its own product information, which was a laborious and often redundant task.[35] In an effort to coordinate poison control center operations and to avoid unnecessary duplication, Surgeon General James Goddard responded to the recommendation of the American Public Health Service and established the National Clearinghouse for Poison Control Centers in 1957.[96] This organization, placed under the Bureau of Product Safety of the Food and Drug Administration, disseminated 5-inch by 8-inch index cards containing poison information to each center to help standardize poison center information resources. The Clearinghouse also collected and tabulated poison data from each of the centers.

Between 1953 and 1972, a rapid, uncoordinated proliferation of poison control centers occurred in the United States.[92] In 1962, there were 462 poison control centers.[1] By 1970, this number had risen to 590,[84] and by 1978, there were 661 poison control centers in the United States, including 100 centers in the state of Illinois alone.[128] The nature of calls to centers changed as lay public–generated calls began to outnumber physician-generated calls. Recognizing the public relations value and strong popular support associated with poison centers, some hospitals started poison control centers without adequately recognizing or providing for the associated responsibilities. Unfortunately, many of these centers offered no more than a part-time telephone service located in the back of the emergency department or pharmacy, staffed by poorly trained personnel.[128]

TABLE 1–4. Protecting Our Health: Important US Regulatory Initiatives Pertaining to Xenobiotics Since 1900

Date	Federal Legislation	Intent
1906	Pure Food and Drug Act	Early regulatory initiative. Prohibits interstate commerce of misbranded and adulterated foods and drugs.
1914	Harrison Narcotics Act	First federal law to criminalize the nonmedical use of drugs. Taxed and regulated distribution and sale of narcotics (opium, opium derivatives, and cocaine).
1927	Federal Caustic Poison Act	Mandated labeling of concentrated caustics.
1930	Food and Drug Administration (FDA)	Established successor to the Bureau of Chemistry; promulgation of food and drug regulations.
1937	Marijuana Tax Act	Applied controls to marijuana similar to those applied to narcotics.
1938	Federal Food, Drug, and Cosmetic Act	Required toxicity testing of pharmaceuticals before marketing.
1948	Federal Insecticide, Fungicide, and Rodenticide Act	Provided federal control for pesticide sale, distribution, and use.
1951	Durham-Humphrey Amendment	Restricted many therapeutic drugs to sale by prescription only
1960	Federal Hazardous Substances Labeling Act	Mandated prominent labeling warnings on hazardous household chemical products.
1962	Kefauver-Harris Drug Amendments	Required drug manufacturer to demonstrate efficacy before marketing
1963	Clean Air Act	Regulated air emissions by setting maximum pollutant standards.
1966	Child Protection Act	Banned hazardous toys when adequate label warnings could not be written.
1970	Comprehensive Drug Abuse and Control Act	Replaced and updated all previous laws concerning narcotics and other dangerous drugs.
1970	Environmental Protection Agency (EPA)	Established and enforced environmental protection standards.
1970	Occupational Safety and Health Act (OSHA)	Enacted to improve worker and workplace safety. Created National Institute for Occupational Safety and Health (NIOSH) as research institution for OSHA.
1970	Poison Prevention Packaging Act	Mandated child-resistant safety caps on certain pharmaceutical preparations to decrease unintentional childhood poisoning.
1972	Clean Water Act	Regulated discharge of pollutants into US waters.
1972	Consumer Product Safety Act	Established Consumer Product Safety Commission to reduce injuries and deaths from consumer products.
1972	Hazardous Material Transportation Act	Authorized the Department of Transportation to develop, promulgate, and enforce regulations for the safe transportation of hazardous materials.
1973	Drug Enforcement Administration (DEA)	Successor to the Bureau of Narcotics and Dangerous Drugs; charged with enforcing federal drug laws.
1973	Lead-based Paint Poison Prevention Act	Regulated the use of lead in residential paint. Lead in some paints was banned by Congress in 1978.
1974	Safe Drinking Water Act	Set safe standards for water purity.
1976	Resource Conservation and Recovery Act (RCRA)	Authorized EPA to control hazardous waste from the "cradle-to-grave," including the generation, transportation, treatment, storage, and disposal of hazardous waste.
1976	Toxic Substance Control Act	Emphasis on law enforcement. Authorized EPA to track 75,000 industrial chemicals produced or imported into the United States. Required testing of chemicals that pose environmental or human health risk.
1980	Comprehensive Environmental Response Compensation and Liability act (CERCLA)	Set controls for hazardous waste sites. Established trust fund (Superfund) to provide cleanup for these sites. Agency for Toxic Substances and Disease Registry (ATSDR) created.
1983	Federal Anti-Tampering Act	Response to cyanide laced Tylenol deaths. Outlawed tampering with packaged consumer products.
1986	Controlled Substance Analogue Enforcement Act	Instituted legal controls on analog (designer) drugs with chemical structures similar to controlled substances.
1986	Drug-Free Federal Workplace Program	Executive order mandating drug testing of federal employees in sensitive positions.
1986	Superfund Amendments and Reauthorization Act (SARA)	Amendment to CERCLA. Increased funding for the research and cleanup of hazardous waste (SARA) sites.
1988	Labeling of Hazardous Art Materials Act	Required review of all art materials to determine hazard potential and mandated warning labels for hazardous materials.
1994	Dietary Supplement Health and Education Act	Permitted dietary supplements including many herbal preparations to bypass FDA scrutiny.
1997	FDA Modernization Act	Accelerated FDA reviews, regulated advertising of unapproved uses of approved drugs
2002	The Public Health Security and Bioterrorism Preparedness and Response Act	Tightened control on biologic agents and toxins; increased safety of the US food and drug supply, and drinking water; and strengthened the Strategic National Stockpile.
2005	Combat Methamphetamine Epidemic Act	Part of the Patriot Act, this legislation restricted nonprescription sale of the methamphetamine precursor drugs ephedrine and pseudoephedrine used in the home production of methamphetamine
2009	Family Smoking Prevention and Tobacco Control Act	Empowered FDA to set standards for tobacco products

TABLE 1-5. Twentieth Century Milestones in the Development of Medical Toxicology

Year	Milestone
1949	First toxicology wards open in Budapest and Copenhagen
1949	First poison information service begins in the Netherlands
1952	American Academy of Pediatrics study shows that 51% of children's "accidents" are the result of the ingestion of potential poisons
1953	First US poison control center opens in Chicago
1957	National Clearinghouse for Poison Control Centers established
1958	American Association of Poison Control Centers (AAPCC) founded
1961	First Poison Prevention Week
1963	Initial call for development of regional Poison Control Centers (PCCs)
1964	Creation of European Association for PCCs
1968	American Academy of Clinical Toxicology (AACT) established
1972	Introduction of microfiche technology to poison information
1974	American Board of Medical Toxicology (ABMT) established
1978	AAPCC introduces standards of regional designation
1983	First examination given for Specialist in Poison Information (SPI)
1985	American Board of Applied Toxicology (ABAT) established
1992	Medical Toxicology recognized by American Board of Medical Specialties (ABMS)
1994	First ABMS examination in Medical Toxicology
2000	Accreditation Council for Graduate Medical Education (ACGME) approval of residency training programs in Medical Toxicology
2000	Poison Control Center Enhancement and Awareness Act
2004	Institute of Medicine (IOM) Report on the future of poison centers is released, calling for a greater integration between public health sector and poison control services

Despite the "growing pains" of these poison control services during this period, there were many significant achievements were made. A dedicated group of physicians and other healthcare professionals began devoting an increasing proportion of their time to poison related matters. In 1958, the American Association of Poison Control Centers (AAPCC) was founded to promote closer cooperation between poison centers, to establish uniform standards, and to develop educational programs for the general public and healthcare professionals.[59] Annual research meetings were held, and important legislative initiatives were stimulated by the organization's efforts.[96] Examples of such legislation include the Federal Hazardous Substances Labeling Act of 1960, which improved product labeling; the Child Protection Act of 1966, which extended labeling statutes to pesticides and other hazardous substances; and the Poison Prevention Packaging Act of 1970, which mandated safety packaging. In 1961, in an attempt to heighten public awareness of the dangers of unintentional poisoning, the third week of March was designated as the Annual National Poison Prevention Week.

Another organization that would become important, the American Academy of Clinical Toxicology (AACT), was founded in 1968 by a diverse group of toxicologists.[31] This group was "interested in applying principles of rational toxicology to patient treatment" and in improving the standards of care on a national basis.[125] The first modern

textbooks of clinical toxicology began to appear in the mid-1950s with the publication of Dreisbach's *Handbook of Poisoning* (1955)[43]; Gleason, Gosselin, and Hodge's *Clinical Toxicology of Commercial Products* (1957)[55]; and Arena's *Poisoning* (1963).[10] Major advancements in the storage and retrieval of poison information were also instituted during these years. Information as noted above on consumer products initially appeared on index cards distributed regularly to poison centers by the National Clearinghouse, and by 1978, more than 16,000 individual product cards had been issued.[129] The introduction of microfiche technology in 1972 enabled the storage of much larger amounts of data in much smaller spaces at the individual poison centers. Toxifile and POISINDEX, two large drug and poison databases using microfiche technology, were introduced and gradually replaced the much more limited index card system.[128] During the 1980s, POISINDEX, which had become the standard database, was made more accessible by using CD-ROM technology. Sophisticated information about the most obscure toxins was now instantaneously available by computer at every poison center.

In 1978, the poison control center movement entered an important new stage in its development when the AAPCC introduced standards for regional poison center designation.[92] By defining strict criteria, the AAPCC sought to upgrade poison center operations significantly and to offer a national standard of service. These criteria included using poison specialists dedicated exclusively to operating the poison control center 24 hours per day and serving a catchment area of between 1 and 10 million people. Not surprisingly, this professionalization of the poison center movement led to a rapid consolidation of services. An AAPCC credentialing examination for poison information specialists was inaugurated in 1983 to help ensure the quality and standards of poison center staff.[7]

In 2000, the Poison Control Center Enhancement and Awareness Act was passed by Congress and signed into law by President Clinton. For the first time, federal funding became available to provide assistance for poison prevention and to stabilize the funding of regional poison control centers. This federal assistance permitted the establishment of a single nationwide toll-free phone number (800-222-1222) to access poison centers. At present, 59 centers contribute data to a National Poison Database System (NPDS) which from 1983 to 2006 was known as Toxic Exposure Surveillance System (TESS). Recently, the Centers for Disease Control and Prevention (CDC) has been collaborating with the AAPCC to conduct real-time surveillance of this data to help facilitate the early detection of chemical exposures of public health importance.[150]

A poison control center movement has also grown and evolved in Europe over the past 35 years, but unlike the movement in the United States, it focused from the beginning on establishing strong centralized toxicology treatment centers. In the late 1950s, Gaultier in Paris developed an inpatient unit dedicated to the care of poisoned patients.[57] In the United Kingdom, the National Poison Information Service developed at Guys Hospital in 1963 under Roy Goulding[57] and Henry Matthew initiated a regional poisoning treatment center in Edinburgh about the same time.[117] In 1964, the European Association for Poison Control Centers was formed at Tours, France.[57]

■ THE RISE OF ENVIRONMENTAL TOXICOLOGY AND FURTHER REGULATORY PROTECTION FROM TOXIC SUBSTANCES

The rise of the environmental movement during the 1960s can be traced, in part, to the publication of Rachel Carson's *Silent Spring* in 1962, which revealed the perils of an increasingly toxic environment.[27] The movement also benefited from the new awareness by those

involved with the poison control movement of the growing menace of toxins in the home environment.[25] Battery casing fume poisoning, resulting from the burning of discarded lead battery cases, and acrodynia, resulting from exposure to a variety of mercury-containing products,[38] both demonstrated that young children are particularly vulnerable to low-dose exposures from certain toxins. Worries about the persistence of pesticides in the ecosystem and the increasing number of chemicals introduced into the environment added to concerns of the environment as a potential source of illness, heralding a drive for additional regulatory protection.

Starting with the Clean Air Act in 1963, laws were passed to help reduce the toxic burden on our environment (see Table 1–4). The establishment of the Environmental Protection Agency in 1970 spearheaded this attempt at protecting our environment, and during the next 10 years, numerous protective regulations were introduced. Among the most important initiatives was the Occupational Safety and Health Act of 1970, which established the Occupational Safety and Health Administration (OSHA). This act mandates that employers provide safe work conditions for their employees. Specific exposure limits to toxic chemicals in the workplace were promulgated. The Consumer Product Safety Commission was created in 1972 to protect the public from consumer products that posed an unreasonable risk of illness or injury. Cancer-producing substances, such as asbestos, benzene, and vinyl chloride, were banned from consumer products as a result of these new regulations. Toxic waste disasters such as those at Love Canal, New York, and Times Beach, Missouri, led to the passing of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, also known as the Superfund) in 1980. This fund is designed to help pay for cleanup of hazardous substance releases posing a potential threat to public health. The Superfund legislation also led to the creation of the Agency for Toxic Substances and Disease Registry (ATSDR), a federal public health agency charged with determining the nature and extent of health problems at Superfund sites and advising the US Environmental Protection Agency and state health and environmental agencies on the need for cleanup and other actions to protect the public's health. In 2003, the ATSDR became part of the National Center for Environmental Health of the CDC.

MEDICAL TOXICOLOGY COMES OF AGE

Over the past 25 years, the primary specialties of medical toxicologists have changed. The development of emergency medicine and preventive medicine as medical specialties led to the training of more physicians with a dedicated interest in toxicology. By the early 1990s, emergency physicians accounted for more than half the number of practicing medical toxicologists.[43] The increased diversity of medical toxicologists with primary training in emergency medicine, pediatrics, preventive medicine, or internal medicine has helped broaden the goals of poison control centers and medical toxicologists beyond the treatment of acute unintentional childhood ingestions. The scope of medical toxicology now includes a much wider array of toxic exposures, including acute and chronic, adult and pediatric, unintentional and intentional, and occupational and environmental exposures.

The development of medical toxicology as a medical subspecialty began in 1974, when the AACT created the American Board of Medical Toxicology (ABMT) to recognize physician practitioners of medical toxicology.[6] From 1974 to 1992, 209 physicians obtained board certification, and formal subspecialty recognition of medical toxicology by the American Board of Medical Specialties (ABMS) was granted in 1992. In that year, a conjoint subboard with representatives from the American Board of Emergency Medicine, American Board of Pediatrics, and American Board of Preventive Medicine was established, and the first ABMS-sanctioned examination in medical toxicology

was offered in 1994. By 2009, a total of more than 400 physicians were board certified in medical toxicology. The American College of Medical Toxicology (ACMT) was founded in 1994 as a physician-based organization designed to advance clinical, educational, and research goals in medical toxicology. In 1999, the Accreditation Council of Graduate Medical Education (ACGME) in the United States formally recognized postgraduate education in medical toxicology, and by 2009, 25 fellowship training programs had been approved.

During the 1990s in the United States, some medical toxicologists began to work on establishing regional toxicology treatment centers. Adapting the European model, such toxicology treatment centers could serve as referral centers for patients requiring advanced toxicologic evaluation and treatment. Goals of such inpatient regional centers included enhancing care of poisoned patients, strengthening toxicology training, and facilitating research. The evaluation of the clinical efficacy and fiscal viability of such programs is ongoing.

The professional maturation of advanced practice pharmacists and nurses with primary interests in clinical toxicology has also taken place over the past two decades. In 1985, the AACT established the American Board of Applied Toxicology (ABAT) to administer certifying examinations for nonphysician practitioners of medical toxicology who meet their rigorous standards.[5] By 2009, more than 85 toxicologists, who mostly held either a PharmD or a PhD in pharmacology or toxicology, were certified by this board.

RECENT POISONINGS AND POISONERS

Although accounting for just a tiny fraction of all homicidal deaths (0.16% in the United States), notorious lethal poisonings continued throughout the 20th century (Table 1–3).[1]

In England, Graham Frederick Young developed a macabre fascination with poisons.[73] In 1971, at age 14 years, he killed his stepmother and other family members with arsenic and antimony. Sent away to a psychiatric hospital, he was released at age 24 years, when he was no longer considered to be a threat to society. Within months of his release, he again engaged in lethal poisonings, killing several of his coworkers with thallium. Ultimately, he died in prison in 1990.

In 1978, Georgi Markov, a Bulgarian defector living in London, developed multisystem failure and died 4 days after having been stabbed by an umbrella carried by an unknown assailant. The postmortem examination revealed a pinhead-sized metal sphere embedded in his thigh where he had been stabbed. Investigators hypothesized that this sphere had most likely carried a lethal dose of ricin into the victim.[34] This theory was greatly supported when ricin was isolated from the pellet of a second victim who was stabbed under similar circumstances.

In 1982, deliberate tampering with nonprescription tylenol preparations with potassium cyanide caused 7 deaths in Chicago.[44] Because of this tragedy, packaging of nonprescription medications was changed to decrease the possibility of future product tampering.[101] The perpetrator(s) were never apprehended, and other deaths from nonprescription product tampering were reported in 1991.[28]

In 1998, Judias Buenoano, known as the "black widow," was executed for murdering her husband with arsenic in 1971 to collect insurance money. She was the first female executed in Florida in 150 years. The fatal poisoning had remained undetected until 1983, when Buenoano was accused of trying to murder her fiancé with arsenic and by car bombing. Exhumation of the husband's body, 12 years after he died, revealed substantial amounts of arsenic in the remains.[3]

Healthcare providers have been implicated in several poisoning homicides as well. An epidemic of mysterious cardiopulmonary arrests at the Ann Arbor Veterans Administration Hospital in Michigan in July and August 1975 was attributed to the homicidal use of pancuronium by two nurses.[138] Intentional digoxin poisoning by hospital

personnel may have explained some of the increased number of deaths on a cardiology ward of a Toronto pediatric hospital in 1981, but the cause of the high mortality rate remained unclear.[22] In 2000, an English general practitioner Harold Shipman was convicted of murdering 15 female patients with heroin and may have murdered as many as 297 patients during his 24-year career. These recent revelations prompted calls for strengthening the death certification process, improving preservation of case records, and developing better procedures to monitor controlled drugs.[65]

Also in 2000, Michael Swango, an American physician, pleaded guilty to the charge of poisoning a number of patients under his care during his residency training. Succinylcholine, potassium chloride, and arsenic were some of the agents he used to kill his patients.[136] Attention to more careful physician credentialing and to maintenance of a national physician database arose from this case because the poisonings occurred at several different hospitals across the country. Continuing concerns about healthcare providers acting as serial killers is highlighted by a recent case in New Jersey in which a nurse, Charles Cullen, was found responsible for killing patients with digoxin.[16]

By the end of the 20th century, 24 centuries after Socrates was executed by poison hemlock, the means of implementing capital punishment had come full circle. Government-sanctioned execution in the United States again favored the use of a "state" poison—this time, the combination of sodium thiopental, pancuronium, and potassium chloride.

The use of a poison to achieve political ends has again resurfaced in several incidents from the former Soviet Union. In December 2004, it was announced that the Ukrainian presidential candidate Viktor Yushchenko was poisoned with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), a potent dioxin.[130] The dramatic development of chloracne over the face of this public person during the previous several months suggested dioxin as a possibly culprit. Given the paucity of reports of acute dioxin poisoning, however, it wasn't until laboratory tests confirmed that Yushenko's dioxin levels were more than 6000 times normal that this diagnosis was confirmed. In another case, a former KGB agent and Russian dissident Alexander Litvinenko was murdered with polonium-210. Initially thought to be a possible case of heavy metal poisoning, Litvinenko developed acute radiation syndrome manifested by acute gastrointestinal symptoms followed by alopecia and pancytopenia before he died.[95]

■ RECENT DEVELOPMENTS

Medical Errors Beginning in the 1980s, several highly publicized medication errors received considerable public attention and provided a stimulus for the initiation of change in policies and systems. Ironically, all of the cases occurred at nationally preeminent university teaching hospitals. In 1984, 18-year-old Libby Zion died from severe hyperthermia soon after hospital admission. Although the cause of her death was likely multifactorial, drug–drug interactions and the failure to recognize and appropriately treat her agitated delirium also contributed to her death.[13] State and national guidelines for closer house staff supervision, improved working conditions, and a heightened awareness of consequential drug–drug interactions resulted from the medical, legislative, and legal issues of this case. In 1994, a prominent health journalist for the *Boston Globe*, Betsy Lehman, was the unfortunate victim of another preventable dosing error when she inadvertently received four times the dose of the chemotherapeutic agent cyclophosphamide as part of an experimental protocol.[76] Despite treatment at a world-renowned cancer center, multiple physicians, nurses, and pharmacists failed to notice this erroneous medication order. An overhaul of the medication-ordering system was implemented at that institution after this tragic event.

Another highly publicized death occurred in 1999, when 18-year-old Jesse Gelsinger died after enrolling in an experimental gene-therapy study. Gelsinger, who had ornithine transcarbamylase deficiency, died from multiorgan failure 4 days after receiving, by hepatic infusion, the first dose of an engineered adenovirus containing the normal gene. Although this unexpected death was not the direct result of a dosing or drug–drug interaction error, the FDA review concluded that major research violations had occurred, including failure to report adverse effects with this therapy in animals and earlier clinical trials and to properly obtain informed consent.[131] In 2001, Ellen Roche, a 24-year-old healthy volunteer in an asthma study at John Hopkins University, developed a progressive pulmonary illness and died 1 month after receiving 1 g of hexamethonium by inhalation as part of the study protocol.[135] Hexamethonium, a ganglionic blocker, was once used to treat hypertension but was removed from the market in 1972. The investigators were cited for failing to indicate on the consent form that hexamethonium was experimental and not FDA approved. Calls for additional safeguards to protect patients in research studies resulted from these cases.

In late 1999, the problems of medical errors finally received the high visibility and attention that it deserved in the United States with the publication and subsequent reaction to an Institute of Medicine (IOM) report suggesting that 44,000 to 98,000 fatalities each year were the result of medical errors.[77] Many of these errors were attributed to preventable medication errors. The IOM report focused on its findings that errors usually resulted from system faults and not solely from the carelessness of individuals.

Chemical Terrorism and Preparedness The terrorist attacks on the World Trade Center and the Pentagon on September 11, 2001, with the subsequent release of a multitude of toxic substances followed within days by the mailing of letters containing lethal amounts of anthrax in October 2001, resulted in profound changes in preparedness strategies against future terrorist strikes. Defending against biologic and chemical terrorism suddenly took on a much heightened sense of urgency. The asymmetric nature of the terrorism menace has led to increasing concerns that traditional industrial chemicals—so-called "chemical agents of opportunity"—may pose a more likely threat than a military chemical warfare agent attack. Responding to these events, poison centers and medical toxicologists from both emergency response and public health backgrounds are playing an increasingly visible role in terrorism preparedness training and leadership.

These events have led to a new realization that poison control centers serve an essential public health function that extends significantly beyond the traditional prevention of childhood poisonings. Responding to these new challenges, an IOM report released in 2004 calls for a more formal integration of poison center services into local, state, and federal public health preparedness and response.[68]

TOXICOLOGY IN THE TWENTY-FIRST CENTURY

As new challenges and opportunities arise in the 21st century, two new toxicologic disciplines have emerged: toxicogenomics and nanotoxicology.[37,42,107] These nascent fields constitute the toxicologic responses to rapid advances in genetics and material sciences. Toxicogenomics combines toxicology with genomics dealing with how genes and proteins respond to toxic substances. The study of toxicogenomics attempts to better decipher the molecular events underlying toxicologic mechanisms, develop predictors of toxicity through the establishment of better molecular biomarkers, and better understand genetic susceptibilities that pertain to toxic substances such as unanticipated idiosyncratic drug reactions.

Nanotoxicology refers to the toxicology of engineered tiny particles, usually smaller than 100 nm. Given the extremely small size of nanoparticles, typical barriers at portals of entry may not prevent absorption or may themselves be adversely affected by the nanoparticles. Ongoing studies focus on the translocation of these particles to sensitive target sites such as the central nervous system or bone marrow.[107]

SUMMARY

Since the dawn of recorded history, toxicology has impacted greatly on human events, and although over the millennia the important poisons of the day have changed to some degree, toxic substances continue to challenge our safety. The era of poisoners for hire may have long ago reached its pinnacle, but problems with drug abuse, intentional self-poisoning, exposure to environmental chemicals, and the potential for biologic and chemical terrorism continues to challenge us. Unfortunately, knowledge acquired by one generation is often forgotten or discarded inappropriately by the next generation, leading to a cyclical historic course. This historic review is meant to describe the past and to better prepare toxicologists and society for the future.

CHAPTER 2
TOXICOLOGIC PLAGUES AND DISASTERS IN HISTORY

Paul M. Wax

Throughout history, mass poisonings have caused suffering and misfortune. From the ergot epidemics of the Middle Ages to contemporary industrial disasters, these plagues have had great political, economic, social, and environmental ramifications. Particularly within the past 100 years, as the number of toxins and potential toxins has risen dramatically, toxic disasters have become an increasingly common event. The sites of some of these events—Bhopal (India), Chernobyl (Ukraine), Jonestown (Guyana), Love Canal (New York), Minamata Bay (Japan), Seveso (Italy), West Bengal (India)—have come to symbolize our increasingly toxic habitat. Globalization has led to the proliferation of toxic chemicals throughout the world and their rapid distribution. Many chemical factories that store large amounts of potentially lethal chemicals are not secure. Given the increasing attention to terrorism preparedness, an appreciation of chemicals as agents of opportunity for terrorists has suddenly assumed great importance. This chapter provides an overview of some of the most consequential and historically important toxin-associated disasters.

GAS DISASTERS

Inhalation of toxic gases and oral ingestions resulting in food poisoning tend to subject the greatest number of people to adverse consequences of a toxic exposure. Toxic gas exposures may be the result of a natural disaster (volcanic eruption), industrial mishap (fire, chemical release), chemical warfare, or an intentional homicidal or genocidal endeavor (concentration camp gas chamber). Depending on the toxin, the clinical presentation may be acute, with a rapid onset of toxicity (cyanide), or subacute or chronic, with a gradual onset of toxicity (air pollution).

One of the earliest recorded toxic gas disasters resulted from the eruption of Mount Vesuvius near Pompeii, Italy, in 79 A.D. (Table 2–1). Poisonous gases generated from the volcanic activity reportedly killed thousands.[37] A much more recent natural disaster occurred in 1986 in Cameroon, when excessive amounts of carbon dioxide spontaneously erupted from Lake Nyos, a volcanic crater lake.[20] Approximately 1700 human and countless animal fatalities resulted from exposure to this asphyxiant.

A toxic gas leak at the Union Carbide pesticide plant in Bhopal, India in 1984 resulted in one of the greatest civilian toxic disasters in modern history.[136] An unintended exothermic reaction at this carbaryl-producing plant caused the release of more than 24,000 kg of methyl isocyanate. This gas was quickly dispersed through the air over the densely populated area surrounding the factory where many of the workers lived, resulting in at least 2500 deaths and 200,000 injuries.[87] The initial response to this disaster was greatly limited by a lack of pertinent information about the toxicity of this chemical as well as the poverty of the residents. A follow-up study 10 years later showed persistence of small-airway obstruction among survivors.[32] Chronic

eye problems were also reported.[2] Calls for improvement in disaster preparedness and strengthened right-to-know laws regarding potential toxic exposures resulted from this tragedy.[53,136]

The release into the atmosphere of 26 tons of hydrofluoric acid at a petrochemical plant in Texas in October 1987 resulted in 939 people seeking medical attention at nearby hospitals. Ninety-four people were hospitalized, but there were no deaths.[144]

More than any other single toxin, carbon monoxide has been involved with the largest number of toxic disasters. Catastrophic fires, such as the Cocoanut Grove Nightclub fire in 1943, have caused hundreds of deaths at a time, many of them from carbon monoxide poisoning.[39] A 1990 fire deliberately started at the Happy Land Social Club in the Bronx, New York, claimed 87 victims, including a large number of nonburn deaths,[80] and the 2003 fire at the Station nightclub in West Warwick, Rhode Island, killed 98 people.[122] Carbon monoxide poisoning was a major determinant in many of these deaths, although hydrogen cyanide gas and simple asphyxiation may have also contributed to the overall mortality.

Another notable toxic gas disaster involving a fire occurred at the Cleveland Clinic in Cleveland, Ohio in 1929, where a fire in the radiology department resulted in 125 deaths.[36] The burning of nitrocellulose radiographs produced nitrogen dioxide, cyanide, and carbon monoxide gases held responsible for many of the fatalities. In 2003, at least 243 people died and 10,000 people became ill after a drilling well exploded in Gaogiao, China, releasing hydrogen sulfide and natural gas into the air.[149] A toxic gas cloud covered 25 square kilometers. Ninety percent of the villagers who lived in the village adjoining the gas well died.

The release of a dioxin-containing chemical cloud into the atmosphere from an explosion at a hexachlorophene production factory in Seveso, Italy in 1976, resulted in one of the most serious exposures to dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin).[52] The lethality of this agent in animals has caused considerable concern for acute and latent injury from human exposure. Despite this apprehension, chloracne was the only significant clinical finding related to the dioxin exposure at 5-year follow-up.[10]

Air pollution is another source of toxic gases that causes significant disease and death. Complaints about smoky air date back to at least 1272, when King Edward I banned the burning of sea-coal.[134] By the 19th century—the era of rapid industrialization in England—winter "fogs" became increasingly problematic. An 1873 London fog was responsible for 268 deaths from bronchitis. Excessive smog in the Meuse Valley of Belgium in 1930, and in Donora, Pennsylvania, in 1948, was also blamed for excess morbidity and mortality. In 1952, another dense sulfur dioxide–laden smog in London was responsible for 4000 deaths.[78] Both the initiation of long-overdue air-pollution reform in England and Parliament's passing of the 1956 Clean Air Act resulted from this latter "fog."

WARFARE AND TERRORISM

Exposure to xenobiotics with the deliberate intent to inflict harm claimed an extraordinary number of victims during the 20th century (Table 2–2). During World War I, chlorine and phosgene gases and the liquid vesicant mustard were used as battlefield weapons, with mustard causing approximately 80% of the chemical casualties.[112] Reportedly, 100,000 deaths and 1.2 million casualties were attributable to these chemical attacks.[37] The toxic exposures resulted in severe airway irritation, acute lung injury, hemorrhagic pneumonitis, skin blistering, and ocular damage. Chemical weapons were used again in the 1980s during the Iran—Iraq war.

TABLE 2–1. Gas Disasters

Xenobiotic	Location	Date	Significance
Poisonous gas	Pompeii, Italy	79 A.D.	>2000 deaths from eruption of Mt. Vesuvius
Smog (SO_2)	London	1873	268 deaths from bronchitis
NO_2, CO, CN	Cleveland Clinic, Cleveland, OH	1929	Fire in radiology department; 125 deaths
Smog (SO_2)	Meuse Valley, Belgium	1930	64 deaths
CO, CN	Cocoanut Grove Night Club, Boston	1942	498 deaths from fire
CO	Salerno, Italy	1944	>500 deaths on a train stalled in a tunnel
Smog (SO_2)	Donora, PA	1948	20 deaths; thousands ill
Smog (SO_2)	London	1952	4000 deaths attributed to the fog/smog
Dioxin	Seveso, Italy	1976	Unintentional industrial release of dioxin into environment; chloracne
Methyl isocyanate	Bhopal, India	1984	>2000 deaths; 200,000 injuries
Carbon dioxide	Cameroon	1986	>1700 deaths from release of gas from Lake Nyos
Hydrofluoric acid	Texas City, TX	1987	Atmospheric release; 94 hospitalized
CO, ?CN	Happy Land Social Club, Bronx, NY	1990	87 deaths in fire from toxic smoke
Hydrogen sulfide	Xiaoying, China	2003	243 deaths and 10,000 became ill from gas poisoning after a gas well exploded
CO, ?CN	West Warwick, RI	2003	98 deaths in fire

The Nazis used poisonous gases during World War II to commit mass murder and genocide. Initially, the Nazis used carbon monoxide to kill. To expedite the killing process, Nazi scientists developed Zyklon-B gas (hydrogen cyanide gas). As many as 10,000 people per day were killed by the rapidly acting cyanide, and millions of deaths were attributable to the use of these gases.

Agent Orange was widely used as a defoliant during the Vietnam War. This herbicide consisted of a mixture of 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and 2,4-dichlorophenoxyacetic acid (2,4-D), as well as small amounts of a contaminant, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), better known as dioxin. Over the years, a large number of adverse health effects have been attributed to Agent Orange exposure. A 2002 Institute of Medicine study concluded that among Vietnam veterans, there is sufficient evidence to demonstrate an association between this herbicide exposure and chronic lymphocytic leukemia, soft tissue sarcomas, non-Hodgkin lymphomas, Hodgkin disease, and chloracne.[59]

Mass exposure to the very potent organic phosphorus compound sarin occurred in March 1995, when terrorists released this chemical warfare agent in three separate Tokyo subway lines.[102] Eleven people were killed, and 5510 people sought emergency medical evaluation at more than 200 hospitals and clinics in the area.[124] This mass disaster introduced the spectra of terrorism to the modern emergency medical services system, resulting in a greater emphasis on hospital preparedness, including planning for the psychological consequences of such events. Sarin exposure also resulted in several deaths and hundreds of casualties in Matsumoto, Japan in June 1994.[92,99]

During recent wars and terrorism events, a variety of physical and neuropsychologic ailments have been attributed to possible exposure to toxic agents.[27,57] Gulf War syndrome is a constellation of chronic

TABLE 2–2. Warfare and Terrorism Disasters

Toxin	Location	Date	Significance
Chlorine	Iraq	2007	Used against US troops and Iraqi civilians
Chlorine, mustard gas, phosgene	Ypres, Belgium	1915–1918	100,000 dead and 1.2 million casualties from chemicals during World War I
CN, CO	Europe	1939–1945	Millions murdered by Zyklon-B (HCN) gas
Agent Orange	Vietnam	1960s	Contains dioxin; excess skin cancer
Mustard gas	Iraq–Iran	1982	New cycle of war gas casualties
Possible toxin	Persian Gulf	1991	Gulf War syndrome
Sarin	Matsumoto, Japan	1994	First terrorist attack in Japan using sarin
Sarin	Tokyo	1995	Subway exposure; 5510 people sought medical attention
Dust and other particulates	New York City	2001	World Trade Center collapse from terrorist air strike
Fentanyl derivative	Moscow	2002	Used by the Russian military to subdue terrorists in Moscow theatre
Ricin	Washington, DC	2004	Detected in Dirksen Senate Office Building; no illness reported

symptoms, including fatigue, headache, muscle and joint pains, ataxia, paresthesias, diarrhea, skin rashes, sleep disturbances, impaired concentration, memory loss, and irritability, noted in thousands of Persian Gulf War veterans without a clearly identifiable cause. A number of etiologies have been advanced to explain these varied symptoms, including exposure to the smoke from burning oil wells; chemical and biologic warfare agents, including nerve agents; and medical prophylaxis, such as the use of pyridostigmine bromide or anthrax and botulinum toxin vaccines, although the actual etiology remains unclear. An agreed upon toxicologic mechanism remains elusive.[41,57,60,61,62,71,113,133]

After the terrorist attacks on New York City in September 11, 2001, that resulted in the collapse of World Trade Center, persistent cough and increased bronchial responsiveness was noted among 8% of New York City Fire Department workers who were exposed to large amounts of dust and other particulates during the clean-up.[108,109] This condition, known as World Trade Center cough syndrome, is characterized by upper airway (chronic rhinosinusitis) and lower airway findings (bronchitis, asthma, or both) as well as, at times, gastroesophageal reflux dysfunction (GERD).[108] The risk of development of hyperreactivity and reactive airways dysfunction was clearly associated with the intensity of exposure.[17]

The Russian military used a mysterious "gas" to incapacitate Chechen rebels at a Moscow theatre in 2002, resulting in the deaths of more than 120 hostages. Although never publically indentified, the gas may have consisted of a highly potent aerosolized fentanyl derivative such as carfentanil and an inhalational anesthetic such as halothane. Better preparation of the rescuers with suitable amounts of naloxone may have help prevent many of these seemingly unanticipated casualties.[140]

Ricin was found in several government buildings, including a mail processing plant in Greenville, South Carolina in 2003 and the Dirksen Senate Office Building in Washington, DC in 2004. Although no cases of ricin-associated illness ensued, increased concern was generated because the method of delivery was thought to be the mail, and irradiation procedures designed to kill microbials such as anthrax would not inactivate chemical toxins such as ricin.[15,118]

FOOD DISASTERS

Unintentional contamination of food and drink has led to numerous toxic disasters (Table 2–3). Ergot, produced by the fungus *Claviceps purpurea*, caused epidemic ergotism as the result of eating breads and cereals made from rye contaminated by *C. purpurea.* In some epidemics, convulsive manifestations predominated, and in others, gangrenous manifestations predominated.[89] Ergot-induced severe vasospasm was thought to be responsible for both presentations.[88] In 994 A.D.,

TABLE 2–3. Food Disasters

Xenobiotic	Location	Date	Significance
Ergot	Aquitania, France	994 A.D.	40,000 died in the epidemic
Ergot	Salem, Massachusetts	1692	Neuropsychiatric symptoms may be attributable to ergot
Lead	Devonshire, England	1700s	Colic from cider contaminated during production
Arsenious acid	France	1828	40,000 cases of polyneuropathy from contaminated wine and bread
Lead	Canada	1846	134 men died during the Franklin expedition, possibly because of contamination of food stored in lead cans
Arsenic	Staffordshire, England	1900	Arsenic-contaminated sugar used in beer production
Cadmium	Japan	1939–1954	Itai-Itai ("ouch-ouch") disease
Hexachlorobenzene	Turkey	1956	4000 cases of porphyria cutanea tarda
Methyl mercury	Minamata Bay, Japan	1950s	Consumption of organic mercury poisoned fish
Triorthocresyl phosphate	Meknes, Morocco	1959	Cooking oil adulterated with turbojet lubricant
Cobalt	Quebec City, Canada and others	1960s	Cobalt beer cardiomyopathy
Methylenedianiline	Epping, England	1965	Jaundice
Polychlorinated biphenyls	Japan	1968	Yusho ("rice oil disease")
Methyl mercury	Iraq	1971	>400 deaths from contaminated grain
Polybrominated biphenyls	Michigan	1973	97% of state contaminated through food chain
Polychlorinated biphenyls	Taiwan	1979	Yu-Cheng ("oil disease")
Rapeseed oil (denatured)	Spain	1981	Toxic oil syndrome affected 19,000 people
Arsenic	Buenos Aires	1987	Malicious contamination of meat; 61 people underwent chelation
Arsenic	Bangladesh and West Bengal, India	1990s–present	Ground water contaminated with arsenic; millions exposed; 100,000s with symptoms; greatest mass poisoning in history
Tetramine	China	2002	Snacks deliberated contaminated, resulting in 42 deaths and 300 people with symptoms
Arsenic	Maine	2003	Intentional contamination of coffee; one death and 16 cases of illness
Nicotine	Michigan	2003	Deliberate contamination of ground beef; 92 people became ill
Melamine	China	2008	50,000 hospitalized from tainted infant formula

40,000 people died in Aquitania, France, in one such epidemic.[76] Convulsive ergotism was initially described as a "fire which twisted the people," and the term "St. Anthony's fire" (*ignis sacer*) was used to refer to the excruciating burning pain experienced in the extremities that is an early manifestation of gangrenous ergotism. The events surrounding the Salem, Massachusetts witchcraft trials have also been attributed to the ingestion of contaminated rye. The bizarre neuropsychiatric manifestations exhibited by some of the individuals associated with this event may have been caused by the hallucinogenic properties of ergotamine, a lysergic acid diethylamide (LSD) precursor.[23,85]

During the last half of the 20th century, unintentional mass poisoning from food and drink contaminated with toxic chemicals became all too common. One of the more unusual poisonings occurred in Turkey in 1956, when wheat seed intended for planting was treated with the fungicide hexachlorobenzene and then inadvertently used for human consumption. Approximately 4000 cases of porphyria cutanea tarda were attributed to the ingestion of this toxic wheat seed.[119]

Another example of chemical food poisoning took place in Epping, England in 1965. In this incident, a sack of flour became contaminated with methylenedianiline when the chemical unintentionally spilled onto the flour during transport to a bakery. Subsequent ingestion of bread baked with the contaminated flour produced hepatitis in 84 people. This outbreak of toxic hepatitis became known as Epping jaundice.[67]

The manufacture of polybromated biphenyls (PBBs) in a factory that also produced food supplements for livestock resulted in the unintentional contamination of a large amount of livestock feed in Michigan in 1973.[24] Significant morbidity and mortality among the livestock population resulted, and increased human tissue concentrations of PBBs were reported,[145] although human toxicity seemed limited to vague constitutional symptoms and abnormal liver function tests.[22]

The chemical contamination of rice oil in Japan in 1968 caused a syndrome called Yusho ("rice oil disease"). This occurred when heat-exchange fluid containing polychlorinated biphenyls (PCBs) and polychlorinated dibenzofurans (PCDFs) leaked from a heating pipe into the rice oil. More than 1600 people developed chloracne, hyperpigmentation, an increased incidence of liver cancer, or adverse reproductive effects. In 1979 in Taiwan, 2000 people developed similar clinical manifestations after ingesting another batch of PCB-contaminated rice oil. This latter epidemic was referred to as Yu-Cheng ("oil disease").[63]

In another oil contamination epidemic, consumption of illegally marketed cooking oil in Spain in 1981 was responsible for a mysterious poisoning epidemic that affected more than 19,000 people and resulted in at least 340 deaths. Exposed patients developed a multisystem disorder referred to as toxic oil syndrome (or toxic epidemic syndrome), characterized by pneumonitis, eosinophilia, pulmonary hypertension, scleroderma-like features, and neuromuscular changes. Although this syndrome was associated with the consumption of rapeseed oil denatured with 2% aniline, the exact etiologic agent was not definitively identified at the time. Subsequent investigations suggest that the fatty acid oleyl anilide may have been the putative agent.[35,64,65]

In 1999, an outbreak of health complaints related to consuming Coca Cola occurred in Belgium, when 943 people, mostly children, complained of gastrointestinal symptoms, malaise, headaches, and palpitations after drinking Coca Cola.[100] Many of those affected complained of an "off taste" or bad odor to the soft drink. Millions of cans and bottles were removed from the market at a cost of $103 million.[100] In some of the bottles, the carbon dioxide was contaminated with small amounts of carbonyl sulfide, which hydrolyzes to hydrogen sulfide, and may have been responsible for odor-triggered reactions. Mass psychogenic illness may have contributed to the large number of medical complaints because the concentrations of the carbonyl sulfide (5–14 g/L) and hydrogen sulfide (8–17 g/L) were very low and unlikely to cause systemic toxicity.[42]

Epidemics of heavy metal poisoning from contaminated food and drink have also occurred throughout history. Epidemic lead poisoning is associated with many different vehicles of transmission, including leaden bowls, kettles, and pipes. A famous 18th-century epidemic was known as the Devonshire colic. Although the exact etiology of this disorder was unknown for many years, later evidence suggested that the ingestion of lead-contaminated cider was responsible.[137]

Intentional chemical contamination of food may also occur. Multiple cases of metal poisoning occurred in Buenos Aires in 1987, when vandals broke into a butcher's shop and poured an unknown amount of acaricide (45% sodium arsenite solution) over 200 kg of partly minced meat.[115] The contaminated meat was purchased by 718 people. Of 307 meat purchasers who submitted to urine sampling, 49 had urine arsenic concentrations of 76 to 500 μg/dL, and 12 had urine arsenic concentrations above 500 μg/dL (normal urine arsenic is <50–100 g/dL).

Recent cases of deliberate mass poisoning have heightened concerns about food safety and security. In China in 2002, a jealous food vendor adulterated fried dough sticks, sesame cakes, and rice prepared in a rival's snack bar by surreptitiously putting a large amount of tetramine (tetramethylene disulfotetramine) into the raw pastry material. More than 300 people who consumed these adulterated snacks became ill, and 42 died.[31] In Maine in 2003, a disillusioned parishioner contaminated the communal coffee pot at a church bake sale with arsenic. One victim died within 12 hours, and five others developed hypotension.[146] Also in 2003 in Michigan, 92 people became ill after ingesting contaminated ground beef deliberately contaminated with a nicotine pesticide by a supermarket employee.[6]

At the end of the 20th century and beginning the 21st century, what may be the greatest mass poisoning in history is occurring in Bangladesh and India's West Bengal State.[34,94,110,127] In Bangladesh alone, 60 million people are routinely drinking arsenic-contaminated ground water and at least 220,000 inhabitants of India's West Bengal have been diagnosed with arsenic poisoning.[93] Symptoms reported include melanosis, depigmentation, hyperkeratosis, hepatomegaly, splenomegaly, squamous cell carcinoma, intraepidermal carcinoma, and gangrene.[34] In a country long plagued by dysentery, attempts to purify the water supply led to the drilling of millions of wells into the superficial water table. Unknown to the engineers, this water was naturally contaminated with arsenic, creating several thousand tube wells with extremely high concentrations of arsenic—up to 40 times the acceptable concentration. Although toxicity from arsenic-contaminated groundwater was previously reported from other areas of the world, including Argentina, China, Mexico, Taiwan (black foot disease), and Thailand, the number of people at risk in Bangladesh and West Bengal is by far the largest.

Methyl mercury is responsible for several poisoning epidemics in the past half century. During the 1950s, a Japanese chemical factory that manufactured vinyl chloride and acetaldehyde routinely discharged mercury into Minamata Bay, resulting in contamination of the aquatic food chain. An epidemic of methyl mercury poisoning ensued as the local people ate the poisoned fish.[107,132] Chronic brain damage, tunnel vision, deafness, and severe congenital defects were associated with this outbreak.[107]

Another mass epidemic of methyl mercury poisoning occurred in Iraq in 1971, when the local population consumed homemade bread prepared from wheat seed treated with a methyl mercury fungicide.[16] Six thousand hospital admissions and more than 400 deaths were associated with this disaster. As was the case of the hexachlorobenzene exposure in Turkey 15 years previously, the treated grain, intended for use as seed, was instead used as food.

From 1939 to 1954, contamination of the local water supply with the wastewater runoff from a zinc–lead–cadmium mine in Japan was believed responsible for causing Itai-Itai ("ouch-ouch") disease,

an unusual chronic syndrome manifested by extreme bone pain and osteomalacia. The local water was used for drinking and irrigation of the rice fields. Approximately 200 people who lived along the banks of the Jintsu River developed these peculiar symptoms, which were thought most likely to be caused by the cadmium.[3]

More than 50,000 infants were hospitalized in China in 2008 from the ill effects of melamine-contaminated powdered infant formulae.[58] Melamine (1,3,5-triazine–2,4,6-triamine) is a component in many adhesives, glues, plastics, and laminated products (e.g., plywood, cleaners, cement, cleansers, fire-retardant paint). More than 20 Chinese companies produced the tainted formula. Analysis of these formulas found melamine concentrations as high as 2500 ppm. Clinically, exposure to high doses of melamine has been associated with the development of nephrolithiasis, obstructive uropathy, and in some cases acute renal failure. Melamine contamination of pet food resulting in deaths in dogs and cats had previously been reported.[22] The melamine disaster also demonstrates that globalization and international agribusiness may facilitate worldwide distribution of contaminated foodstuffs. After the initial reports of melamine contamination in China, investigation in the United States revealed that certain brands of cookies, biscuits, candies, and milk sold in this country were also tainted with melamine, some of which was traced to an origin in China.[58]

MEDICINAL DRUG DISASTERS

Illness and death as a consequence of therapeutic drug use occur as sporadic events, usually affecting individual patients, or as mass disasters, affecting multiple (sometimes hundreds or thousands) patients. Sporadic single-patient medication-induced tragedies usually result from errors (Chap. 1) or unforeseen idiosyncratic reactions. Mass therapeutic drug disasters have generally occurred secondary to poor safety testing, a lack of understanding of diluents and excipients, drug contamination, or problems with unanticipated drug–drug interactions or drug toxicity (Table 2–4).

In September and October 1937, more than 105 deaths were associated with the use of one of the early sulfa preparations—elixir of sulfanilamide-Massengill—that contained 72% diethylene glycol as the vehicle for drug delivery. Little was known about diethylene glycol toxicity at the time, and many cases of renal failure and death occurred.[44] To avoid similar tragedies in the future, animal drug testing was mandated by the Food, Drug, and Cosmetic Act of 1938.[138] Unfortunately, diethylene glycol continues to be sporadically used in other countries as a medicinal diluent, resulting in deaths in South Africa (1969), India (1986), Nigeria (1990), Bangladesh (1990–1992), and Haiti (1995–1996).[139] In 1996 in Haiti, at least 88 Haitian children died (case fatality rate of 98% for those who remained in Haiti) after ingesting an acetaminophen elixir formulated with diethylene glycol–contaminated glycerin.[101,117] More recently, in Panama in 2006, glycerin contaminated with diethylene glycol found in prescription liquid cough syrup resulted in at least 121 cases of poisoning and 78 deaths (case fatality rate, 65.5%).[19,112] Investigators of this last outbreak discovered that the contaminated glycerin was imported to Panama from China via a European broker, demonstrating that improprieties in pharmaceutical manufacturing may have worldwide implications. In Nigeria in 2009, a tainted teething formula was responsible for 84 deaths in children.[7] The pharmaceutical manufacturers intended to purchase propylene glycol, a component of the teething formula but had bought the diluent in a jerrycan instead of the original container, and the chemical contained diethylene glycol.

A lesser-known drug manufacturing event, also involving an early sulfa antimicrobial, occurred in 1940 to 1941, when at least 82 people died from the therapeutic use of sulfathiazole that was contaminated with phenobarbital (Luminal).[129] The responsible pharmaceutical company, Winthrop Chemical, produced both sulfathiazole and phenobarbital, and the contamination likely occurred during the tableting process because the tableting machines for the two medications were adjacent to each other and were used interchangeably. Each contaminated sulfathiazole tablet contained about 350 mg of phenobarbital (and no

TABLE 2–4. Medicinal Disasters

Xenobiotic	Location	Date	Significance
Thallium	US	1920s–1930s	Treatment of ringworm; 31 deaths
Diethylene glycol	US	1937	Elixir of sulfanilamide; renal failure
Thorotrast	US	1930s–1950s	Hepatic angiosarcoma
Phenobarbital	US	1940–1941	Sulfathiazole contaminated with phenobarbital; 82 deaths
Diethylstilbestrol (DES)	US, Europe	1940s–1970s	Vaginal adenocarcinoma in daughters
Stalinon	France	1954	Severe neurotoxicity from triethyltin
Clioquinol	Japan	1955–1970	Subacute myelooptic neuropathy (SMON); 10,000 symptomatic
Thalidomide	Europe	1960s	5000 cases of phocomelia
Isoproterenol 30%	Great Britain	1961–1967	3000 excess asthma deaths
Pentachlorophenol	US	1967	Used in hospital laundry; nine neonates ill, two deaths
Benzyl alcohol	US	1981	Neonatal gasping syndrome
Tylenol-cyanide	Chicago	1982	Tampering incident resulted in seven homicides
L-Tryptophan	US	1989	Eosinophilia myalgia syndrome
Diethylene glycol	Haiti	1996	Acetaminophen elixir contaminated; renal failure; >88 pediatric deaths
Diethylene glycol	Panama	2006	Cough preparation contaminated with DEG, causing 78 deaths
Diethylene glycol	Nigeria	2009	Teething formula contaminated with DEG, causing 84 deaths

sulfathiazole), and the typical sulfathiazole dosing regimen was several tablets within the first few hours of therapy. Twenty-nine percent of the production lot was contaminated. Food and Drug Administration (FDA) intervention was required to assist with the recovery of the tablets, although 22,000 contaminated tablets were never found.[129]

In the early 1960s, one of the worst drug related modern-day events occurred with the release of thalidomide as an antiemetic and sedative–hypnotic.[33] Its use as a sedative–hypnotic by pregnant women caused about 5000 babies to be born with severe congenital limb anomalies.[89] This tragedy was largely confined to Europe, Australia, and Canada, where the drug was initially marketed. The United States was spared because of the length of time required for review and the rigorous scrutiny of new drug applications by the FDA.[86]

A major therapeutic drug event that did occur in the United States involved the recommended and subsequent widespread use of diethylstilbestrol (DES) for the treatment of threatened and habitual abortions. Despite the lack of convincing efficacy data, as many as 10 million Americans received DES during pregnancy or in utero during a 30-year period, until the drug was prohibited for use during pregnancy in 1971. Adverse health effects associated with DES use include increased risk for breast cancer in "DES mothers" and increased risk of a rare form of vaginal cancer, reproductive tract anomalies, and premature births in "DES daughters."[47,51]

Thorotrast (thorium dioxide 25%) is an intravenous radiologic contrast medium that was widely used between 1928 and 1955. Its use was associated with the delayed development of hepatic angiosarcomas, as well as skeletal sarcomas, leukemia, and "thorotrastomas" (malignancies at the site of extravasated thorotrast).[126,141]

The use of thallium to treat ringworm infections in the 1920s and 1930s also led to needless morbidity and mortality.[48] Understanding that thallium caused alopecia, dermatologists and other physicians prescribed thallium acetate, both as pills and as a topical ointment (Koremlu), to remove the infected hair. A 1934 study found 692 cases of thallium toxicity after oral and topical application and 31 deaths after oral use.[96] "Medicinal" thallium was subsequently removed from the market.

The "Stalinon affair" in France in 1954 involved the unintentional contamination of a proprietary oral medication that was marketed for the treatment of staphylococcal skin infections, osteomyelitis, and anthrax. Although it was supposed to contain diethyltin diiodide and linoleic acid, triethyltin, a potent neurotoxin and the most toxic of organotin compounds, and trimethyltin were present as impurities. Of the approximately 1000 people who received this medication, 217 patients developed symptoms, and 102 patients died.[11,18]

An unusual syndrome, featuring a constellation of abdominal symptoms (pain and diarrhea) followed by neurologic symptoms (peripheral neuropathy and visual disturbances, including blindness) was experienced by approximately 10,000 Japanese people between 1955 and 1970, resulting in several hundred deaths.[70] This presentation, subsequently labeled subacute myelooptic neuropathy (SMON), was associated with the use of the gastrointestinal disinfectant clioquinol, known in the West as Entero-Vioform and most often used for the prevention of travelers' diarrhea.[98] In Japan, this drug was referred to as "sei-cho-zai" ("active in normalizing intestinal function"). It was incorporated into more than 100 nonprescription proprietary medications and was used by millions of people, often for weeks or months. The exact mechanism of toxicity has not been determined, but recent investigators theorize that clioquinol may enhance the cellular uptake of certain metals, particularly zinc, and that the clioquinol–zinc chelate may act as a mitochondrial toxin, causing this syndrome.[14] New cases declined rapidly when clioquinol was banned in Japan.

In 1981, a number of premature neonates died with a "gasping syndrome," manifested by severe metabolic acidosis, respiratory depression with gasping, and encephalopathy.[46] Before the development of these findings, the infants had all received multiple injections of heparinized bacteriostatic sodium chloride solution (to flush their indwelling catheters) and bacteriostatic water (to mix medications), both of which contained 0.9% benzyl alcohol. Accumulation of large amounts of benzyl alcohol and its metabolite benzoic acid in the blood was thought to be responsible for this syndrome.[46]

A nursery mass poisoning occurred in 1967, when nine neonates developed extreme diaphoresis, fever, and tachypnea without rash or cyanosis. Two fatalities resulted, although the other infants responded dramatically to exchange transfusions. The illness was traced to sodium pentachlorophenate used as an antimildew agent in the hospital laundry.[8]

In 1989 and 1990, eosinophilia-myalgia syndrome, a debilitating syndrome somewhat similar to toxic oil syndrome, developed in more than 1500 people who had used the dietary supplement L-tryptophan.[64,135] These patients presented with disabling myalgias and eosinophilia, often accompanied by extremity edema, dyspnea, and arthralgias. Skin changes, neuropathy, and weight loss sometimes developed. Intensive investigation revealed that all affected patients had ingested L-tryptophan produced by a single manufacturer that had recently introduced a new process involving genetically altered bacteria to improve L-tryptophan production. A contaminant produced by this process probably was responsible for this syndrome.[21] The banning of L-tryptophan by the FDA set in motion the passage of the Dietary Supplement Health and Education Act of 1994. This legislation, which attempted to regulate an uncontrolled industry, inadvertently facilitated industry marketing of dietary supplements bypassing FDA scrutiny.

In recent years, a number of therapeutic drugs previously approved by the FDA have been withdrawn from the market because of concerns about health risks.[148] Many more drugs have been given "black box warnings" by the FDA because of their propensity to cause serious or life-threatening adverse effects. In 2009, more than 400 drugs had such black box warnings.[45] Some of the withdrawn drugs had been responsible for causing serious drug–drug interactions (astemizole, cisapride, mibefradil, terfenadine).[95] Other drugs were withdrawn because of a propensity to cause hepatotoxicity (troglitazone), anaphylaxis (bromfenac sodium), valvular heart disease (fenfluramine, dexfenfluramine), rhabdomyolysis (cerivastatin), hemorrhagic stroke (phenylpropanolamine), and other adverse cardiac and neurologic effects (ephedra, rofecoxib). One of the more disconcerting drug problems to arise was the development of cardiac valvulopathy and pulmonary hypertension in patients taking the weight-loss drug combination fenfluramine and phentermine (fen-phen) or dexfenfluramine.[29,123] The histopathologic features observed with this condition were similar to the valvular lesions associated with ergotamine and carcinoid. Interestingly, appetite suppressant medications, as well as ergotamine and carcinoid, all increase available serotonin.

ALCOHOL AND ILLICIT DRUG DISASTERS

Unintended toxic disasters have also involved the use of alcohol and other drugs of abuse (Table 2-5). Arsenical neuropathy developed in an estimated 40,000 people in France in 1828, when wine and bread were unintentionally contaminated by arsenious acid.[84] The use of arsenic-contaminated sugar in the production of beer in England in 1900 resulted in at least 6000 cases of peripheral neuropathy and 70 deaths (Staffordshire beer epidemic).[105]

During the early 20th century, particularly during Prohibition, the ethanolic extract of Jamaican ginger (sold as "the Jake") was a popular ethanol substitute in the southern and midwestern United States.[90] It was sold legally because it was considered a medical supplement to

TABLE 2–5. Alcohol and Illicit Drug Disasters

Xenobiotic	Location	Date	Significance
Triorthocresyl phosphate	US	1930–1931	Ginger Jake paralysis
Methanol	Atlanta, GA	1951	Epidemic from ingesting bootleg whiskey
Methanol	Jackson, MI	1979	Occurred in a prison
MPTP	San Jose, CA	1982	Illicit meperidine manufacturing resulting in drug-induced parkinsonism
Heroin heated on aluminum foil	Netherlands	1982	Spongiform leukoencephalopathy
3-Methyl fentanyl	Pittsburgh, PA	1988	"China-white" epidemic
Methanol	Baroda, India	1989	Moonshine contamination; 100 deaths
Fentanyl	New York City	1990	"Tango and Cash" epidemic
Methanol	New Delhi, India	1991	Antidiarrheal medication contaminated with methanol; >200 deaths
Methanol	Cuttack, India	1992	Methanol-tainted liquor; 162 deaths
Scopolamine	US East Coast	1995–1996	325 cases of anticholinergic poisoning in heroin users
Methanol	Cambodia	1998	>60 deaths
Methanol	Nicaragua	2006	800 became ill, 15 blind, 45 deaths

MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

treat headaches and aid digestion and was not subject to Prohibition. For years, the Jake was sold adulterated with castor oil, but in 1930, as the price of castor oil rose, the Jake was reformulated with an alternative adulterant, triorthocresyl phosphate (TOCP). Little was previously known about the toxicity of this compound, and TOCP proved to be a potent neurotoxin. From 1930 to 1931, at least 50,000 people who drank the Jake developed TOCP poisoning, manifested by upper and lower extremity weakness ("ginger Jake paralysis") and gait impairment ("Jake walk" or "Jake leg").[90] A quarter century later, in Morocco, the dilution of cooking oil with a turbojet lubricant containing TOCP caused an additional 10,000 cases of TOCP-induced paralysis.[125]

In the 1960s, cobalt was added to several brands of beer as a foam stabilizer. Certain local breweries in Quebec City, Canada; Minneapolis, Minnesota; Omaha, Nebraska; and Louvain, Belgium added 0.5–5.5 ppm cobalt to their beer. This resulted in epidemics of fulminant heart failure among heavy beer drinkers (cobalt-beer cardiomyopathy).[1,91]

Epidemic methanol poisoning among those seeking ethanol and other inebriants is well described. In one such incident in Atlanta, Georgia in 1951, the ingestion of methanol-contaminated bootleg whiskey caused 323 cases of methanol poisoning, including 41 deaths. In another epidemic in 1979, 46 prisoners became ill after ingesting a methanol-containing diluent used in copy machines.[130]

In recent years, major mass methanol poisonings have continued to occur in developing countries, where store-bought alcohol is often prohibitively expensive. In Baroda, India in 1989, at least 100 people died and another 200 became ill after drinking a homemade liquor that was contaminated with methanol.[5] In New Delhi, India in 1991, an inexpensive antidiarrheal medicine, advertised to contain large amounts of ethanol, was instead contaminated with methanol, causing more than 200 deaths.[28] The following year, in Cuttack, India, 162 people died and an additional 448 were hospitalized after drinking methanol-tainted liquor.[12] A major epidemic of methanol poisoning occurred in 1998 in Cambodia, when rice wine was contaminated with methanol.[4] At least 60 deaths and 400 cases of illness were attributed to the methanol. Most recently, in Nicaragua in 2006, more than 800 people became ill and 45 died after drinking "aguardiente," an alcoholic beverage made with methanol instead of the more expensive ethanol. Fifteen people became blind.[128]

So-called "designer drugs" are responsible for several toxicologic disasters. In 1982, several injection drug users living in San Jose, California who were attempting to use a meperidine analog MPPP (1-methyl-4-phenyl-4-propionoxy-piperidine) developed a peculiar, irreversible neurologic disease closely resembling parkinsonism.[73] Investigation revealed that these patients had unknowingly injected trace amounts of MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), which was present as an inadvertent product of the clandestine MPPP synthesis. The subsequent metabolism of MPTP to MPP$^+$ resulted in a toxic compound that selectively destroyed cells in the substantia nigra, causing severe and irreversible parkinsonism. The vigorous pursuit of the cause of this disaster led to a better understanding of the pathophysiology of parkinsonism and the development of possible future treatments.

Another example of a "designer drug" mass poisoning occurred in the New York City metropolitan area in 1991, when a sudden epidemic of opioid overdoses occurred among heroin users who bought envelopes labeled "Tango and Cash."[40] Expecting to receive a new brand of heroin, the drug users instead purchased the much more potent fentanyl. Increased and unpredictable toxicity resulted from the inability of the dealer to adjust ("cut") the fentanyl dose properly. Some purchasers presumably received little or no fentanyl, while others received potentially lethal doses. A similar epidemic involving 3-methylfentanyl occurred in 1988 in Pittsburgh, Pennsylvania.[82]

At least 325 cases of anticholinergic poisoning occurred among heroin users in New York City; Newark, New Jersey; Philadelphia, Pennsylvania; and Baltimore, Maryland from 1995 to 1996.[9] The "street drug" used in these cases was adulterated with scopolamine. Whereas naloxone treatment was associated with increased agitation and hallucinations, physostigmine administration resulted in resolution of symptoms. Why the heroin was adulterated was unknown, although the use of an opiate–scopolamine mixture was reminiscent of the morphine–scopolamine combination therapy known as "twilight sleep" that was extensively used in obstetric anesthesia during the early 20th century.[104]

Another unexpected complication of heroin use was observed in the Netherlands in the 1980s, when 47 heroin users developed mutism and spastic quadriparesis that was pathologically documented to be spongiform leukoencephalopathy.[147] In these and subsequent cases in Europe

and the United States, the users inhaled heroin vapors after the heroin powder had been heated on aluminum foil, a drug administration technique known as "chasing the dragon."[68,147] The exact toxic mechanism has not been elucidated.

OCCUPATION-RELATED CHEMICAL DISASTERS

Unfortunately, occupation-related toxic epidemics have become increasingly common (Table 2-6). Such poisoning syndromes tend to have an insidious onset and may not be recognized clinically until years after the exposure. A specific toxin may cause myriad problems, among the most worrisome being the carcinogenic and mutagenic potentials.

Although the 18th-century observations of Ramazzini and Pott introduced the concept of certain diseases as a direct result of toxic exposures in the workplace, it was not until the height of the 19th-century industrial revolution that the problems associated with the increasingly hazardous workplace became apparent.[56] During the 1860s, a peculiar disorder, attributed to the effects of inhaling mercury vapor, was described among manufacturers of felt hats in New Jersey.[142] Mercury nitrate was used as an essential part of the felting process at the time. "Hatter's shakes" refers to the tremor that developed in an estimated 10% to 60% of hatters surveyed.[142] Extreme shyness, another manifestation of mercurialism, also developed in many hatters in later studies. Five percent of hatters during this period died from renal failure.

Other notable 19th-century and early 20th-century occupational tragedies included an increased incidence of mandibular necrosis (phossy jaw) among workers in the matchmaking industry who were exposed to white phosphorus,[54] an increased incidence of bladder tumors among synthetic dye makers who used β–Naphthylamine,[49] and an increased incidence of aplastic anemia among artificial leather manufacturers who used benzene.[121] The epidemic of phossy jaw among matchmakers had a latency period of 5 years and a mortality rate of 20% and has been called the "greatest tragedy in the whole story of occupational disease."[25] The problem continued in the United States until Congress passed the White Phosphorus Match Act in 1912, which established a prohibitive tax on white phosphorus matches.[85]

Since antiquity, occupational lead poisoning has been a constant threat. Workplace exposure to lead was particularly problematic during the 19th century and early 20th century because of the large number of industries that relied heavily on lead. One of the most notorious of the "lead trades" was the actual production of white lead and lead oxides. Palsies, encephalopathy, and death from severe poisoning were reported.[50] Other occupations that resulted in dangerous lead exposures included pottery glazing, rubber manufacturing, pigment manufacturing, painting, printing, and plumbing.[81] Given the increasing awareness of harm suffered in the workplace, the British Factory and Workshop Act of 1895 required governmental notification of occupational diseases caused by lead, mercury, and phosphorus poisoning, as well as of occupational diseases caused by anthrax.[75]

Exposures to asbestos during the 20th century have resulted in continuing extremely consequential occupational and environmental disasters.[30,97] Despite the fact that the first case of asbestosis was reported in 1907, asbestos was heavily used in the shipbuilding industries in the 1940s as an insulating and fireproofing material. Since the early 1940s, 8 to 11 million individuals were occupationally exposed to asbestos,[77] including 4.5 million individuals who worked in the shipyards. Asbestos-related diseases include mesothelioma, lung cancer, and pulmonary fibrosis (asbestosis). A threefold excess of cancer deaths, primarily of excess lung cancer deaths, has been observed in asbestos-exposed insulation workers.[120]

The manufacture and use of a variety of newly synthesized chemicals has also resulted in mass occupational poisonings. In Louisville, Kentucky in 1974, an increased incidence of angiosarcoma of the liver was first noticed among polyvinyl chloride polymerization workers who were exposed to vinyl chloride monomer.[38] In 1975, chemical factory workers exposed to the organochlorine insecticide chlordecone (Kepone) experienced a high incidence of neurologic abnormalities, including tremor and chaotic eye movements.[131] An increased incidence of infertility among male Californian pesticide workers exposed to 1,2-dibromochloropropane (DBCP) was noted in 1977.[143]

RADIATION DISASTERS

A discussion of mass poisonings is incomplete without mention of the large number of radiation disasters that have characterized the 20th century (Table 2-7). The first significant mass exposure to radiation occurred among several thousand teenage girls and young women employed in the dial-painting industry.[26] These workers painted luminous numbers on watch and instrument dials with paint that contained radium. Exposure occurred by licking the paint brushes and inhaling radium-laden dust. Studies showed an increase in bone-related cancers, as well as aplastic anemia and leukemia, in exposed workers.[83,106]

TABLE 2–6. Occupational Disasters

Xenobiotic	Location	Date	Significance
Polycyclic aromatic hydrocarbons	England	1700s	Scrotal cancer among chimney sweeps; first description of occupational cancer
Mercury	New Jersey	Mid to late 1800s	Outbreak of mercurialism in hatters
White phosphorus	Europe	Mid to late 1800s	Phossy jaw in matchmakers
β-Naphthylamine	Worldwide	Early 1900s	Bladder cancer in dye makers
Benzene	Newark, NJ	1916–1928	Aplastic anemia among artificial leather manufacturers
Asbestos	Worldwide	20th century	Millions at risk for asbestos-related disease
Vinyl chloride	Louisville, KY	1960s–1970s	Hepatic angiosarcoma among polyvinyl chloride polymerization workers
Chlordecone	James River, VA	1973–1975	Neurologic abnormalities among insecticide workers
1, 2-Dibromochloropropane	California	1974	Infertility among pesticide makers

TABLE 2–7. Radiation Disasters

Xenobiotic	Location	Date	Significance
Radium	Orange, NJ	1910s–1920s	Increase in bone cancer in dial-painting workers
Radium	US	1920s	"Radithor" (radioactive water) sold as radium-containing patent medication
Radiation	Hiroshima and Nagasaki, Japan	1945	First atomic bombs dropped at end of World War II; clinical effects still evident today
Radiation	Chernobyl, Ukraine	1986	Unintentional radioactive release; acute radiation sickness
Cesium	Goiania, Brazil	1987	Acute radiation sickness and radiation burns

At the time of the "watch" disaster, radium was also being sold as a nostrum touted to cure all sorts of ailments, including rheumatism, syphilis, multiple sclerosis, and sexual dysfunction. Referred to as "mild radium therapy" to differentiate it from the higher-dose radium that was used in the treatment of cancer at that time, such particle-emitting isotopes were hailed as powerful natural elixirs that acted as metabolic catalysts to deliver direct energy transfusions.[79]

During the 1920s, dozens of patent medications containing small doses of radium were sold as radioactive tablets, liniments, or liquids. One of the most infamous preparations was Radithor. Each half-ounce bottle contained slightly more than 1 Ci of radium-228 and radium-226. This radioactive water was sold all over the world "as harmless in every respect" and was heavily promoted as a sexual stimulant and aphrodisiac, taking on the glamour of a recreational drug for the wealthy.[79] More than 400,000 bottles were sold. The 1932 death of Eben Byers a Radithor connoisseur from chronic radiation poisoning drew increased public and governmental scrutiny to this unregulated radium industry and helped end the era of radioactive patent medications.[79]

Concerns about the health effects of radiation have continued to escalate since the dawn of the nuclear age in 1945. Long-term follow-up studies 50 years after the atomic bombings at Hiroshima and Nagasaki demonstrate an increased incidence of leukemia, other cancers, radiation cataracts, hyperparathyroidism, delayed growth and development, and chromosomal anomalies in exposed individuals.[66]

The unintentional nuclear disaster at Chernobyl, Ukraine in April 1986 again forced the world to confront the medical consequences of 20th-century scientific advances that created the atomic age.[43] The release of radioactive material resulted in 31 deaths and the hospitalization of more than 200 people for acute radiation sickness. By 2003, the predominant long-term effects of the event appeared to be childhood thyroid cancer and psychological consequences.[111] In some areas of heavy contamination, the increase in childhood thyroid cancer has increased 100-fold.[116]

Another serious radiation event occurred in Goiania, Brazil in 1987 when an abandoned radiotherapy unit was opened in a junkyard and 244 people were exposed to cesium-137. Of those exposed, 104 showed evidence of internal contamination, 28 had local radiation injuries, and eight developed acute radiation syndrome. There were at least four deaths.[103,114]

In September 1999, a nuclear event at a uranium-processing plant in Japan set off an uncontrolled chain reaction, exposing 49 people to radiation.[69] Radiation measured outside the facility reached 4000 times the normal ambient level. Two workers died from the effects of the radiation.

MASS SUICIDE BY POISON

Toxic disasters have also manifested themselves as events of mass suicide. In 1978 in Jonestown, Guyana, 911 members of the Peoples Temple died after drinking a beverage containing cyanide.[13] Although the majority of those deaths may have been by suicide, some appear to have been involuntary.[74]

In 1997, phenobarbital and ethanol (sometimes assisted by physical asphyxiation) was the suicidal method favored by 39 members of the Heavens Gate cult in Rancho Santa Fe, California, a means of suicide recommended in the book *Final Exit*.[55] Apparently, the cult members committed suicide to shed their bodies in hopes of hopping aboard an alien spaceship they believed was in the wake of the Hale-Bopp comet.[72]

SUMMARY

Unfortunately, toxicologic plagues and disasters have had all-too-prominent roles in history. An understanding of the pathogenesis of these toxic plagues pertaining to drug, food, and occupational safety is critically important to prevent future disasters. Such events make us aware that many of the toxic agents involved are potential agents of opportunity for terrorists and nonterrorists who seek to harm others. Given the practical and ethical limitations in studying the effects of many specific toxins in humans, lessons from these unfortunate tragedies must be fully mastered and retained for future generations.

THE GENERAL APPROACH TO MEDICAL TOXICOLOGY

This page intentionally left blank

CHAPTER 3

INITIAL EVALUATION OF THE PATIENT: VITAL SIGNS AND TOXIC SYNDROMES

Lewis S. Nelson, Neal A. Lewin, Mary Ann Howland, Robert S. Hoffman, Lewis R. Goldfrank, and Neal E. Flomenbaum

For more than 200 years, American physicians and nurses have attempted to standardize their approach to the assessment of patients. At the New York Hospital in 1865, pulse rate, respiratory rate, and temperature were incorporated into the bedside chart and called "vital signs."[6] It was not until the early part of the 20th century, however, that blood pressure determination also became routine. Additional components of the standard emergency assessment, such as oxygen saturation by pulse oximetry, capillary blood glucose, and pain severity, are now also beginning to be considered vital signs. Although assessment of oxygen saturation, capillary glucose, and pain severity are essential components of the clinical assessment and are important considerations throughout this text, they are not discussed in this chapter.

In the practice of medical toxicology, vital signs play an important role beyond assessing and monitoring the overall status of a patient, as they frequently provide valuable physiologic clues to the toxicologic etiology and severity of an illness. The vital signs also are a valuable parameter, which are used to assess and monitor a patient's response to supportive treatment and antidotal therapy.

Table 3–1 presents the normal vital signs for various age groups. However, this broad range of values considered normal should serve merely as a guide. Only a complete assessment of a patient can determine whether or not a particular vital sign is truly clinically normal. This table of normal vital signs is useful in assessing children because normal values for children vary considerably with age, and knowing the range of normal variation is essential. Normal temperature is defined as 95° to 100.4°F (35° to 38°C).

The difficulty in defining what constitutes "normal" vital signs in an emergency setting has been inadequately addressed and may prove to be an impossible undertaking. Published normal values may have little relevance to an acutely ill or anxious patient in the emergency setting, yet that is precisely the environment in which we must define abnormal vital signs and address them accordingly. Even in nonemergent situations, "normalcy" of vital signs depends on the clinical condition of the patient. A sleeping or comatose patient may have physiologic bradycardia; a slow heart rate appropriate for his or her low energy requiring state. For these reasons, descriptions of vital signs as "normal" or "stable" are too nonspecific to be meaningful and therefore should never be accepted as defining normalcy in an individual patient. Conversely, no patient should be considered too agitated, too young, or too gravely ill for the practitioner to obtain a complete set of vital signs; indeed, these patients urgently need a thorough evaluation that includes all of the vital signs. Also, the vital signs must be recorded as accurately as possible first in the prehospital setting, again with precision and accuracy

as soon as a patient arrives in the emergency department, and serially thereafter as clinically indicated.

Many xenobiotics affect the autonomic nervous system, which, in turn, affects the vital signs via the sympathetic pathway, the parasympathetic pathway, or both. Meticulous attention to both the initial and repeated determinations of vital signs is of extreme importance in identifying a pattern of changes suggesting a particular xenobiotic or group of xenobiotics. The value of serial monitoring of the vital signs is demonstrated by the patient who presents with an anticholinergic overdose who is then given the antidote, physostigmine. In this situation, it is important to recognize when tachycardia becomes bradycardia (i.e., anticholinergic syndrome followed by physostigmine excess). Meticulous attention to these changes ensures that the therapeutic interventions can be modified or adjusted accordingly.

Similarly, consider the course of a patient who has opioid-induced bradypnea (a decreased rate of breathing) and then develops tachypnea (an increased rate of breathing) after the administration of the opioid antagonist naloxone. The analysis becomes exceedingly complicated when that patient may have been exposed to two or more substances, such as an opioid combined with cocaine. In this situation, the effects of cocaine may be "unmasked" by the naloxone used to counteract the opioid, and the clinician must then be forced to differentiate naloxone-induced opioid withdrawal from cocaine toxicity. The assessment starts by analyzing diverse information, including vital signs, history, and physical examination.

Table 3–2 describes the most typical toxic syndromes. This table includes only vital signs that are thought to be characteristically abnormal or pathognomonic and directly related to the toxicologic effect of the xenobiotic. The primary purpose of the table, however, is to include many findings, in addition to the vital signs, that together constitute a toxic syndrome. Mofenson and Greensher[5] coined the term *toxidromes* from the words *toxic syndromes* to describe the groups of signs and symptoms that consistently result from particular toxins. These syndromes are usually best described by a combination of the vital signs and clinically apparent end-organ manifestations. The signs that prove most clinically useful are those involving the central nervous system (CNS; mental status), ophthalmic system (pupil size), gastrointestinal system (peristalsis), dermatologic system (skin dryness versus diaphoresis), mucous membranes (moistness versus dryness), and genitourinary system (urinary retention versus incontinence). Table 3–2 includes some of the most important signs and symptoms and the xenobiotics most commonly responsible for these manifestations. A detailed analysis of each sign, symptom, and toxic syndrome can be found in the pertinent chapters throughout the text. In this chapter, the most typical toxic syndromes (see Table 3–2) are considered to enable the appropriate assessment and differential diagnosis of a poisoned patient.

In considering a toxic syndrome, the reader should always remember that the actual clinical manifestations of a poisoning are far more variable than the syndromes described in Table 3–2. The concept of the toxic syndrome is most useful when thinking about a clinical presentation and formulating a framework for assessment. Although some patients may present as "classic" cases, others manifest partial toxic syndromes or formes frustes. These incomplete syndromes may still provide at least a clue to the correct diagnosis. It is important to understand that partial presentations (particularly in the presence of multiple xenobiotics) do not necessarily imply less severe disease and, therefore, are comparably important to appreciate.

In some instances, an unexpected combination of findings may be particularly helpful in identifying a xenobiotic or a combination of xenobiotics. For example, a dissociation between such typically paired changes as an increase in pulse with a decrease in blood pressure (cyclic antidepressants or phenothiazines), or the presentation of a decrease

TABLE 3–1. Normal Vital Signs by Age[a]

Age	Systolic BP (mm Hg)	Diastolic BP (mm Hg)	Pulse (beats/min)	Respirations (breaths/min)[b]
Adult	≤120	<80	60–100	16–24
16 years	≤120	<80	80	16–30
12 years	119	76	85	16–30
10 years	115	74	90	16–30
6 years	107	69	100	20–30
4 years	104	65	110	20–30
4 months	90	50	145	30–35
2 months	85	50	145	30–35
Newborn	65	50	145	35–40

[a] The normal rectal temperature is defined as 95°F to 100.4°F (35°C–38°C) for all ages. For children 1 year of age or younger, these values are the mean values for the 50th percentile. For older children, these values represent the 90th percentile at a specific age for the 50th percentile of weight in that age group.

[b] These values were determined in the emergency department and may be environment and situation dependent.

in pulse with an increase in blood pressure (ergot alkaloids) may be extremely helpful in diagnosing a toxic etiology. The use of these unexpected or atypical clinical findings is demonstrated in Chap. 23 .

BLOOD PRESSURE

Xenobiotics cause hypotension by four major mechanisms: decreased peripheral vascular resistance, decreased myocardial contractility, dysrhythmias, and depletion of intravascular volume. Many xenobiotics can initially cause orthostatic hypotension without marked supine hypotension, and any xenobiotic that affects autonomic control of the heart or peripheral capacitance vessels may lead to orthostatic hypotension (Table 3–3). Hypertension from xenobiotics may be caused by CNS sympathetic overactivity, increased myocardial contractility or increased peripheral vascular resistance, or a combination of these.

Blood pressure and pulse rate may vary significantly as a result of changes in receptor responsiveness, degree of physical fitness, and degree of atherosclerosis. Changing patterns of blood pressure often assist in the diagnostic evaluation: overdose with a monoamine oxidase inhibitor (MAOI) characteristically causes an initial normal blood pressure, to be followed by hypertension, which, in turn, may be followed abruptly by severe hypotension (Chap. 71).

PULSE RATE

Extremely useful clinical information can be obtained by evaluating the pulse rate (Table 3–4 and Chap. 23). Although the carotid artery is usually easily palpable, for reasons of both safety and reliability, the brachial artery is preferred in infants and in adults older than 60 years. The normal heart rate for adults was defined by consensus more than 50 years ago as a regular rate greater than 60 beats/min and less than 100 beats/min. More recent studies[7,8] suggest that 95% of the population have bradycardia and tachycardia thresholds of 50 beats/min and 90 beats/min, respectively. In our text, we have chosen to retain the consensus values.

Because pulse rate is the net result of a balance between sympathetic (adrenergic) and parasympathetic (muscarinic and nicotinic) tone, many xenobiotics that exert therapeutic or toxic effects or cause pain syndromes, hyperthermia, or volume depletion also affect the pulse rate. With respect to temperature, there is a direct correlation between pulse rate and temperature in that pulse rate increases approximately 8 beats/min for each 1.8°F (1°C) elevation in temperature.[4]

The inability to differentiate easily between sympathomimetic and anticholinergic xenobiotic effects by vital signs alone illustrates the

TABLE 3–2. Toxic Syndromes

Group	Vital Signs				Mental Status	Pupil Size	Peristalsis	Diaphoresis	Other
	BP	P	R	T					
Anticholinergics	–/↑	↑	±	↑	Delirium	↑	↓	↓	Dry mucous membranes, flush, urinary retention
Cholinergics	±	±	–/↑	–	Normal to depressed	±	↑	↑	Salivation, lacrimation, urination, diarrhea, bronchorrhea, fasciculations, paralysis
Ethanol or sedative–hypnotics	↓	↓	↓	–/↓	Depressed, agitated	±	↓	–	Hyporeflexia, ataxia
Opioids	↓	↓	↓	↓	Depressed	↓	↓	–	Hyporeflexia
Sympathomimetics	↑	↑	↑	↑	Agitated	↑	–/↑	↑	Tremor, seizures
Withdrawal from ethanol or sedative–hypnotics	↑	↑	↑	↑	Agitated, disoriented hallucinations	↑	↑	↑	Tremor, seizures
Withdrawal from opioids	↑	↑	–	–	Normal, anxious	↑	↑	↑	Vomiting, rhinorrhea, piloerection, diarrhea, yawning

↑ = increases; ↓ = decreases; ± = variable; – = change unlikely; BP, blood pressure; P, pulse; R, respirations; T, temperature.

principle that no single vital sign abnormality can definitively establish a toxicologic diagnosis. In trying to differentiate between a sympathomimetic and anticholinergic toxic syndrome, it should be understood that although tachycardia commonly results from both sympathomimetic and anticholinergic xenobiotics, when tachycardia is accompanied by diaphoresis or increased bowel sounds, adrenergic toxicity is suggested, but when tachycardia is accompanied by decreased sweating, absent bowel sounds, and urinary retention, anticholinergic toxicity is likely.

TABLE 3–4. Common Xenobiotics That Affect the Pulse[a]

Bradycardia	Tachycardia

γ-Hydroxybutyric acid	Phencyclidine
Opioids	Sympathomimetics
Organic phosphorus compounds	Thyroid hormone
	Yohimbine

[a]Chap. 23 lists additional xenobiotics that affect the heart rate.

RESPIRATIONS

Establishment of an airway and evaluation of respiratory status are the initial priorities in patient stabilization. Although respirations are typically assessed initially for rate alone, careful observation of the depth and pattern is essential (Table 3–5) for establishing the etiology of a systemic illness or toxicity.[1] Unfortunately, very few investigators have actually measured the respiratory rate in large populations of normal people, let alone in emergency department patients. Two papers[2,3] investigating respiratory rates in emergency department patients differ substantially in their determinations of normal ranges from the remainder of the literature. The combined results of these investigations suggest "normal" respiratory rates are 16 to 24 breaths/min in adults with more rapid rates that are inversely related to age in children.

The term *hyperventilation* may mean tachypnea (an increase in ventilatory rate), hyperpnea (an increase in tidal volume), or both. When hyperventilation results solely or predominantly from hyperpnea, the clinicians may miss this important finding entirely, instead erroneously describing such a hyperventilating patient as normally ventilating or even *hypoventilating* if bradypnea is also present. The ventilatory status of the patient must be viewed in the context of the patient's physiologic condition.

Hyperventilation may result from the direct effect of a CNS stimulant, such as the direct effect of salicylates, on the brainstem. However, salicylate poisoning characteristically produces hyperventilation by tachypnea, but it also produces hyperpnea, with or without tachypnea. Pulmonary injury from any source, including aspiration of gastric contents, may lead to hypoxemia with a resultant tachypnea. Later, tachypnea may change to bradypnea, hypopnea (shallow breathing), or both. Bradypnea may occur when a CNS depressant acts on the brainstem. A progression from fast to slow breathing may also occur in a patient exposed to increasing concentrations of cyanide or carbon monoxide.

TEMPERATURE

Temperature evaluation and control are critical. However, temperature assessment can be done only if safe and reliable equipment is used. The

TABLE 3–5. Common Xenobiotics That Affect Respiration[a]

Bradypnea	Tachypnea
α_2-Adrenergic agonists	Cyanide
Botulinum toxin	Dinitrophenol and congeners
Elapidae venom	Epinephrine
Ethanol and other alcohols	Ethylene glycol

Sedative-hypnotics	Nicotine (early)
	Pulmonary irritants
	Salicylates
	Sympathomimetics

[a]Chap. 21 lists additional xenobiotics affecting respiratory rate.

risks of inaccuracy are substantial when an oral temperature is taken in a tachypneic patient, an axillary temperature or a temporal artery temperature is taken in any patient (especially those found outdoors), or a tympanic temperature is taken in a patient with cerumen impaction. Obtaining rectal temperatures using a nonglass probe is essential for safe and accurate temperature determinations in agitated individuals and is considered the standard method of temperature determination in this text.

The core temperature or deep internal temperature (T) is relatively stable (98.6° ± 1.08°F; 37° ± 0.6°C) under normal physiologic circumstances. Hypothermia (T <95°F; <35°C) and hyperthermia (T >100.4°F; >38°C) are common manifestations of toxicity. Severe or significant hypothermia and hyperthermia, unless immediately recognized and managed appropriately, may result in grave complications and inappropriate or inadequate resuscitative efforts. Life-threatening hyperthermia (T >106°F; >41.1°C) from any cause may lead to extensive rhabdomyolysis, myoglobinuric renal failure, and direct liver and brain injury and must therefore be identified and corrected immediately.

Hyperthermia may result from a distinct neurologic response to a signal demanding thermal "upregulation." This signal can be from internal generation of heat beyond the capacity of the body to cool, such as occurs in association with agitation or mitochondrial uncoupling, or from an externally imposed physical or environmental factor, such as the environmental conditions causing heat stroke or the excessive swaddling in clothing causing hyperthermia in infants. Fever, or pyrexia, is hyperthermia due to an elevation in the hypothalamic thermoregulatory set-point.

Regardless of etiology, core temperatures higher than 106°F (41.1°C) are extremely rare unless normal feedback mechanisms are overwhelmed. Hyperthermia of this extreme nature is usually attributed to environmental heat stroke; extreme psychomotor agitation; or xenobiotic-related

temperature disturbances such as malignant hyperthermia, the serotonin syndrome, or the neuroleptic malignant syndrome.

A common xenobiotic-related hyperthermia pattern that frequently occurs in the emergency department is defervescence after an acute temperature elevation resulting from agitation or a grand mal seizure. Table 3–6 is a representative list of xenobiotics that affect body temperature. (Chap. 15 provides greater detail.)

Hypothermia is probably less of an immediate threat to life than hyperthermia, but it requires rapid appreciation, accurate diagnosis, and skilled management. Hypothermia impairs the metabolism of many xenobiotics, leading to unpredictable delayed toxicologic effects when the patient is warmed. Many xenobiotics that lead to an alteration of metal status place patients at great risk for becoming hypothermic from exposure to cold climates. Most importantly, a hypothermic patient should never be declared dead without both an extensive assessment and a full resuscitative effort of adequate duration, taking into consideration the difficulties in resuscitating cold but living patients. This is true whenever the body temperature remains less than 95°F (35°C) (Chap. 15).

SUMMARY

Early, accurate determinations followed by serial monitoring of the vital signs are as essential in medical toxicology as in any other type of emergency or critical care medicine. For this reason, the vital signs are an essential part of the initial evaluation of every case, and serial vital signs are always necessary throughout the patient's clinical evaluation. Careful observation of the vital signs helps to determine appropriate therapeutic interventions and guide the clinician in making necessary adjustments to initial and subsequent therapeutic interventions. When pathognomonic clinical and laboratory findings are combined with accurate initial and sometimes changing vital signs, a toxic syndrome may become evident, which will aid in both general supportive and specific antidotal treatment. Toxic syndromes will also guide further diagnostic testing.

CHAPTER 4

PRINCIPLES OF MANAGING THE ACUTELY POISONED OR OVERDOSED PATIENT

Lewis S. Nelson, Neal A. Lewin, Mary Ann Howland, Robert S. Hoffman, Lewis R. Goldfrank, and Neal E. Flomenbaum

OVERVIEW

For almost 5 decades, medical toxicologists and information specialists have used a clinical approach to poisoned or overdosed patients that emphasizes treating the patient rather than treating the poison. Too often in the past, patients were initially all but neglected while attention was focused on the ingredients listed on the containers of the product(s) to which they presumably were exposed. Although the astute clinician must always be prepared to administer a specific antidote immediately in instances when nothing else will save a patient, all poisoned or overdosed patients will benefit from an organized, rapid clinical management plan (Fig. 4-1).

Over the past 2 decades, some basic tenets and long-held beliefs regarding the initial therapeutic interventions in toxicologic management have been questioned and subjected to an "evidence-based" analysis. For example, in the mid-1970s, most medical toxicologists began to advocate a standardized approach to a comatose and possibly overdosed adult patient, typically calling for the intravenous (IV) administration of 50 mL of $D_{50}W$, 100 mg of thiamine and 2 mg of naloxone along with 100% oxygen at high flow rates. The rationale for this approach was to compensate for the previously idiosyncratic style of overdose management encountered in different healthcare settings and for the unfortunate likelihood that omitting any one of these measures at the time that care was initiated in the emergency department (ED) would result in omitting it altogether. It was not unusual then to discover from a laboratory chemistry report more than 1 hour after a supposedly overdosed comatose patient had arrived in the ED that the initial blood glucose was 30 or 40 mg/dL—a critical delay in the management of unsuspected and consequently untreated hypoglycemic coma. Today, however, with the widespread availability of accurate rapid bedside testing for capillary glucose and pulse oximetry for oxygen saturation, coupled with a much greater appreciation by all physicians of what needs to be done for each suspected overdose patient, clinicians can safely provide a more rational, individualized approach to determine the need for, and in some instances more precise amounts of, dextrose, thiamine, naloxone, and oxygen.

A second major approach to providing more rational individualized early treatment for toxicologic emergencies involves a closer examination of the actual risks and benefits of various gastrointestinal (GI) emptying interventions. Appreciation of the potential for significant adverse effects associated with all types of GI emptying interventions and recognition of the absence of clear evidence-based support of efficacy have led to a significant reduction in the routine use of activated charcoal (AC) and almost complete elimination of syrup of ipecac–induced emesis or orogastric lavage and cathartic-induced intestinal evacuation. In 2004, the American Academy of Pediatricians (AAP)

all but entirely abandoned its recommendations for the use of syrup of ipecac in the home. The efficacy of orogastric lavage, even when indicated by the nature or type of ingestion, is limited by the amount of time elapsed since the ingestion. The value of whole-bowel irrigation (WBI) with polyethylene glycol electrolyte solution (PEG-ELS) appears to be much more specific and limited than originally thought, and some of the limitations and (uncommon) adverse effects of AC are now more widely recognized.

Similarly, interventions to eliminate absorbed xenobiotics from the body are now much more narrowly defined or, in some cases, abandoned. Multiple-dose activated charcoal (MDAC) is useful for select but not all xenobiotics. Ion trapping in the urine is only beneficial, achievable, and relatively safe when the urine can be maximally alkalinized after a significant salicylate, phenobarbital, or chlorpropamide poisoning. Finally, the roles of hemodialysis, hemoperfusion, and other extracorporeal techniques are now much more specifically defined. With the foregoing in mind, this chapter represents our current efforts to formulate a logical and effective approach to managing a patient with probable or actual toxic exposure.

Table 4-1 provides a recommended stock list of antidotes and therapeutics for the treatment of poisoned or overdosed patients.

MANAGING ACUTELY POISONED OR OVERDOSED PATIENTS

Rarely, if ever, are all of the circumstances involving a poisoned patient known. The history may be incomplete, unreliable, or unobtainable; multiple xenobiotics may be involved; and even when a xenobiotic etiology is identified, it may not be easy to determine whether the problem is an overdose, an allergic or idiosyncratic reaction, or a drug–drug interaction. Similarly, it is sometimes difficult or impossible to differentiate between adverse effects of a correct dose of medication and the consequences of a deliberate or unintentional overdose. The patient's presenting signs and symptoms may force an intervention at a time when there is almost no information available about the etiology of the patient's condition (Table 4-2), and as a result, therapeutics must be thoughtfully chosen empirically to treat or diagnose a condition without exacerbating the situation.

INITIAL MANAGEMENT OF PATIENTS WITH A SUSPECTED EXPOSURE

Similar to the management of any seriously compromised patient, the clinical approach to the patient potentially exposed to a xenobiotic begins with the recognition and treatment of life-threatening conditions, including airway compromise, breathing difficulties, and circulatory problems such as hemodynamic instability and serious dysrhythmias. After the "ABCs" (airway, breathing, and circulation) have been addressed, the patient's level of consciousness should be assessed because this helps determine the techniques to be used for further management of the exposure.

MANAGEMENT OF PATIENTS WITH ALTERED MENTAL STATUS

Altered mental status (AMS) is defined as the deviation of a patient's sensorium from normal. Although it is commonly construed as a depression in the patient's level of consciousness, a patient with agitation, delirium, psychosis, and other deviations from normal is also

Is the patient having difficulty breathing?

Yes → Obtain control of the airway, ventilation, and oxygenation

No → Obtain oxygen saturation by pulse oximetry

Obtain vital signs. Are life-threatening abnormalities present?

Yes →
1. Attach the patient to a cardiac monitor; obtain a 12-lead ECG
2. Obtain oxygen saturation by pulse oximetry and an ABG (or VBG) and give supplemental oxygen if not already done
3. Start an intravenous line
4. Obtain rapid bedside glucose concentration and send blood for glucose and electrolytes; save blood for other studies

No

Consider empiric administration of
1. Hypertonic dextrose
2. Thiamine
3. Naloxone

Consider the use of emergent therapies for seizures, significant psychomotor agitation, cardiac dysrhythmias, or severe metabolic abnormalities → Obtain a rapid history; perform a rapid physical examination

Can a specific toxic syndrome be identified?

Yes → Treat the toxic syndrome

No

Obtain a thorough history
Reassess and complete the physical examination
Send bloods: electrolytes, glucose, CBC, ABG,(or VBG), acetaminophen, as indicated

Consider gastric emptying with orogastric lavage → Consider prevention of xenobiotic absorption with
1. Activated charcoal
2. Whole-bowel irrigation → Evaluate for enhanced elimination
1. Multiple-dose activated charcoal
2. Urinary alkalinization
3. Extracorporeal drug removal

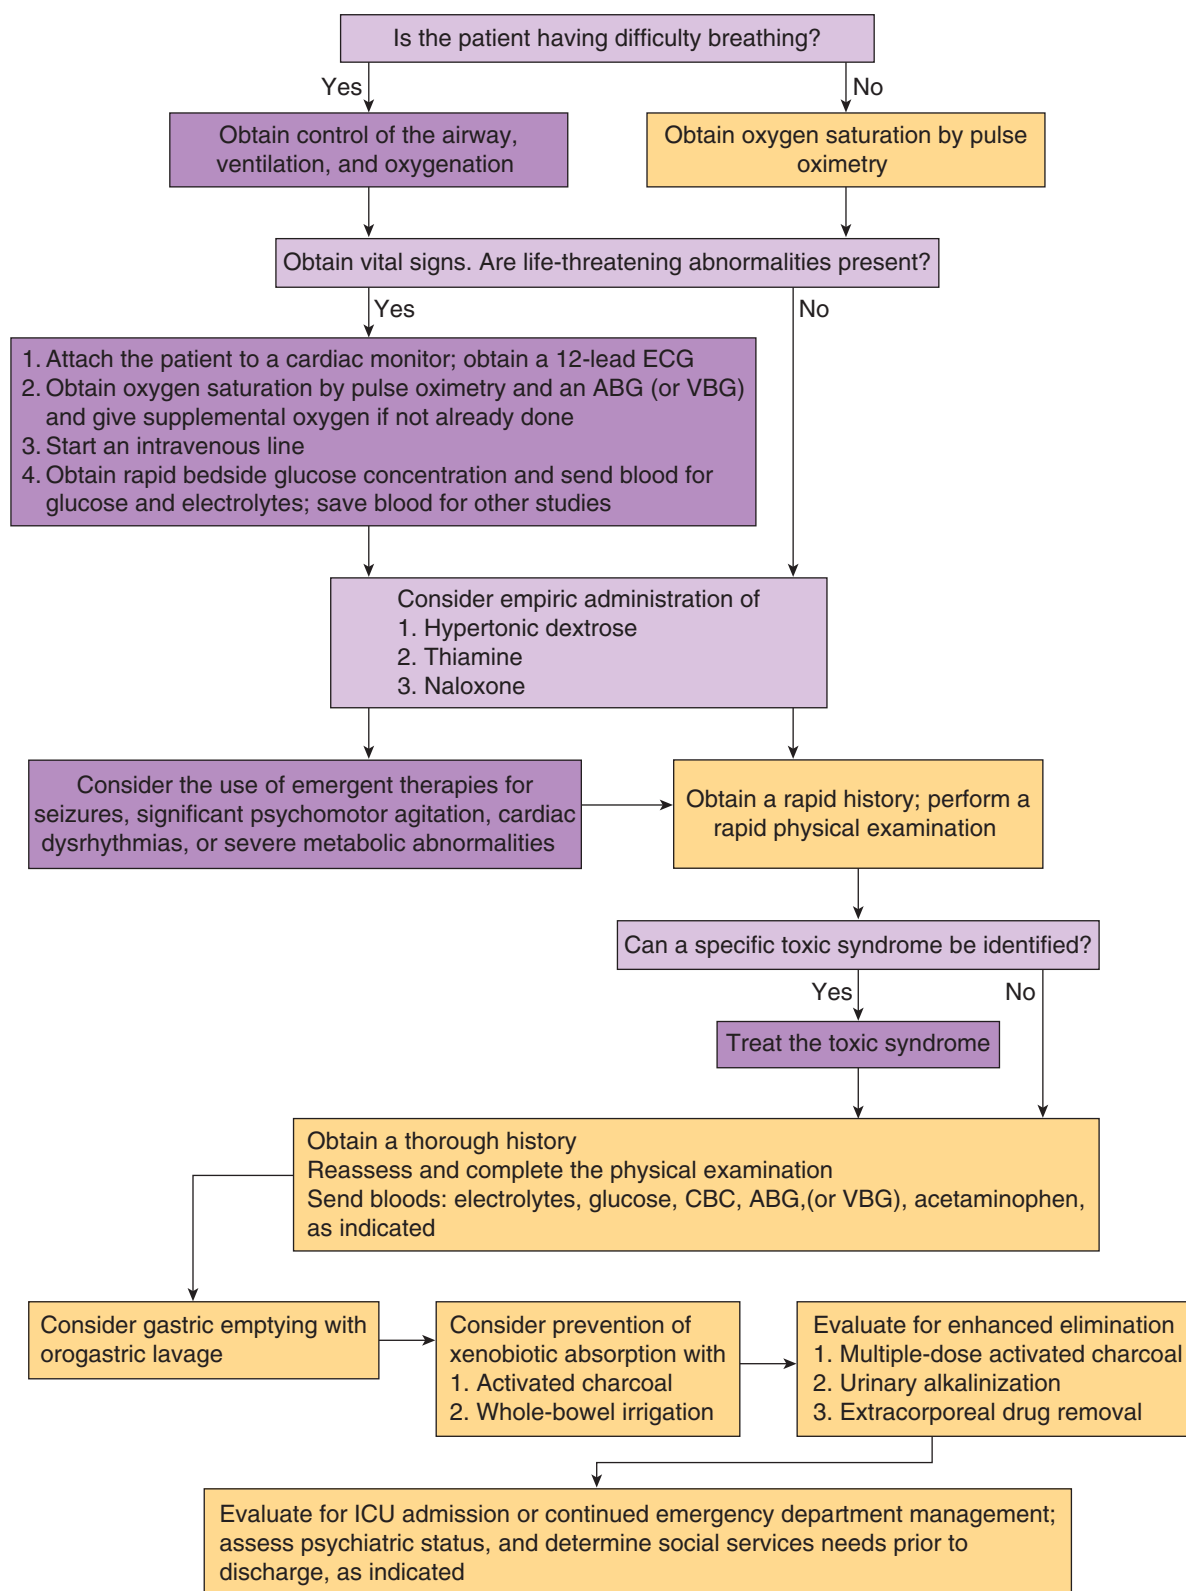
Evaluate for ICU admission or continued emergency department management; assess psychiatric status, and determine social services needs prior to discharge, as indicated


FIGURE 4-1 This algorithm is a basic guide to the management of poisoned patients. A more detailed description of the steps in management may be found in the accompanying text. This algorithm is only a guide to actual management, which must, of course, consider the patient's clinical status.

TABLE 4–1. Antidotes and Therapeutics for the Treatment of Poisonings and Overdoses[a]

Therapeutics[b]	Uses	Therapeutics[b]	Uses
Activated charcoal (p. 108)	Adsorbs xenobiotics in the GI tract	Ipecac, syrup of (p. 104)	Induces emesis
Antivenom (*Crotalinae*) (p. 1608)	Crotaline snake envenomations	Magnesium sulfate or magnesium citrate (p. 114)	Induces catharsis
Antivenom (*Elapidae*) (p. 1308)	Coral snake envenomations	Magnesium sulfate injection	Cardioactive steroids, hydrofluoric acid, hypomagnesemia, ethanol withdrawal, torsades de pointes
Antivenom (*Latrodectus mactans*) (p. 1582)	Black widow spider envenomations		
Atropine (p. 1473)	Bradydysrhythmias, cholinesterase inhibitors (organic phosphorus compounds, physostigmine) muscarinic mushrooms (*Clitocybe, Inocybe*) ingestions	Methylene blue (1% solution) (p. 1708)	Methemoglobinemia
		N-acetylcysteine (Acetadote) (p. 500)	Acetaminophen and other causes of hepatotoxicity
Benzodiazepines (p1109)	Seizures, agitation, stimulants, ethanol and sedative–hypnotic withdrawal, cocaine, chloroquine, organic phosphorus compounds	Naloxone hydrochloride (Narcan) (p. 579)	Opioids, clonidine
		Norepinephrine (Levophed)	Hypotension (preferred for cyclic antidepressants)
Botulinum antitoxin (ABE-trivalent) (p. 695)	Botulism	Octreotide (Sandostatin) (p. 734)	Oral hypoglycemic induced hypoglycemia
Calcium chloride, calcium gluconate (p. 1381)	Fluoride, hydrofluoric acid, ethylene glycol, CCBs, hypomagnesemia, β-adrenergic antagonists	Oxygen (Hyperbaric) (p. 1671)	Carbon monoxide, cyanide, hydrogen sulfide
		D-Penicillamine (Cuprimine) (p. 1261)	Copper
L-Carnitine (p. 711)	Valproic acid	Phenobarbital	Seizures, agitation, stimulants, ethanol and sedative–hypnotic withdrawal
Cyanide kit (nitrites, p. 1689; sodium thiosulfate, p. 1692)	Cyanide		
Dantrolene (p. 1001)	Malignant hyperthermia	Phentolamine (p. 1096)	Cocaine, MAOI interactions, epinephrine, and ergot alkaloids
Deferoxamine mesylate (Desferal) (p. 604)	Iron	Physostigmine salicylate (Antilirium) (p. 759)	Anticholinergics
Dextrose in water (50% adults; 20% pediatrics; 10% neonates) (p. 728)	Hypoglycemia	Polyethylene glycol electrolyte solution (p. 114)	Decontaminates GI tract
Digoxin-specific antibody fragments (Digibind and Digifab) (p. 946)	Cardioactive steroids	Pralidoxime chloride, (2-PAM-chloride; Protopam) (p. 1467)	Acetylcholinesterase inhibitors (organic phosphorus agents and carbamates)
Dimercaprol (BAL, British anti-Lewisite) (p. 1229)	Arsenic, mercury, gold, lead	Protamine sulfate (p. 880)	Heparin anticoagulation
Diphenhydramine	Dystonic reactions, allergic reactions	Prussian blue (Radiogardase) (p. 1334)	Thallium, cesium
DTPA (p. 1779)	Radioactive isotopes	Pyridoxine hydrochloride (Vitamin B$_6$) (p. 845)	Isoniazid, ethylene glycol, gyromitrin-containing mushrooms
Edetate calcium disodium (calcium disodium versenate, CaNa$_2$ EDTA) (p. 1290)	Lead, other selected metals		
Ethanol (oral and parenteral dosage forms) (p. 1419)	Methanol, ethylene glycol	Sodium bicarbonate (p. 520)	Ethylene glycol, methanol, salicylates, cyclic antidepressants, methotrexate, phenobarbital, quinidine, chlorpropamide, type 1 antidysrhythmics, chlorphenoxy herbicides
Fat emulsion (Intralipid 20% (p. 976)	Cardiac arrest, local anesthetics		
Flumazenil (Romazicon) (p. 1072)	Benzodiazepines		
Folinic acid (Leucovorin) (p. 783)	Methotrexate, methanol	Sorbitol (p. 114)	Induces catharsis
Fomepizole (Antizole) (p. 1414)	Ethylene glycol, methanol	Starch (p. 1349)	Iodine
Glucagon (p. 910)	β-Adrenergic antagonists, CCBs	Succimer (Chemet) (p. 1284)	Lead, mercury, arsenic
Glucarpidase (p. 787)	Methotrexate	Thiamine hydrochloride (Vitamin B$_1$) (p. 1129)	Thiamine deficiency, ethylene glycol, chronic ethanol consumption ("alcoholism")
Hydroxocobalamin (Cyanokit) (p. 1695)	Cyanide		
Insulin (p. 893)	β-Adrenergic antagonists, CCBs, hyperglycemia		
Iodide, potassium (SSKI) (p. 1775)	Radioactive iodine (I[131])	Vitamin K$_1$ (Aquamephyton) (p. 876)	Warfarin or rodenticide anticoagulants

[a] Each emergency department should have the vast majority of these antidotes immediately available, some of these antidotes may be stored in the pharmacy, and others may be available from the Centers for Disease Control and Prevention, but the precise mechanism for locating each one must be known by each staff member.

[b] A detailed analysis of each of these agents is found in the text in the Antidotes in Depth section on the page cited to the right of each antidote or therapeutic listed.

CCB, calcium channel blocker; DTPA, diethylenetriaminepentaacetic acid; EDTA, ethylenediamine tetraacetic acid; GI, gastrointestinal; MAOI, monoamine oxidase inhibitor; SSKI, saturated solution of potassium iodide.

TABLE 4–2. Clinical and Laboratory Findings in Poisoning and Overdose

Agitation	Anticholinergics,[a] hypoglycemia, phencyclidine, sympathomimetics,[b] withdrawal from ethanol and sedative–hypnotics
Alopecia	Alkylating agents, radiation, selenium, thallium
Ataxia	Benzodiazepines, carbamazepine, carbon monoxide, ethanol, hypoglycemia, lithium, mercury, nitrous oxide, phenytoin
Blindness or decreased visual acuity	Caustics (direct), cocaine, cisplatin, mercury, methanol, quinine, thallium
Blue skin	Amiodarone, FD&C #1 dye, methemoglobinemia, silver
Constipation	Anticholinergics,[a] botulism, lead, opioids, thallium (severe)
Deafness, tinnitus	Aminoglycosides, cisplatin, metals, loop diuretics, quinine, salicylates
Diaphoresis	Amphetamines, cholinergics,[c] hypoglycemia, opioid withdrawal, salicylates, serotonin syndrome, sympathomimetics,[b] withdrawal from ethanol and sedative–hypnotics
Diarrhea	Arsenic and other metals, boric acid (blue-green), botanical irritants, cathartics, cholinergics,[c] colchicine, iron, lithium, opioid withdrawal, radiation
Dysesthesias, paresthesias	Acrylamide, arsenic, ciguatera, cocaine, colchicine, thallium
Gum discoloration	Arsenic, bismuth, hypervitaminosis A, lead, mercury
Hallucinations	Anticholinergics,[a] dopamine agonists, ergot alkaloids, ethanol, ethanol and sedative–hypnotic withdrawal, LSD, phencyclidine, sympathomimetics,[b] tryptamines
Headache	Carbon monoxide, hypoglycemia, monoamine oxidase inhibitor–food interaction (hypertensive crisis), serotonin syndrome
Metabolic acidosis (elevated anion gap)	Methanol, uremia, ketoacidosis (diabetic, starvation, alcoholic), paraldehyde, phenformin, metformin, iron, isoniazid, lactic acidosis, cyanide, protease inhibitors, ethylene glycol, salicylates, toluene
Miosis	Cholinergics,[c] clonidine, opioids, phencyclidine, phenothiazines
Mydriasis	Anticholinergics,[a] botulism, opioid withdrawal, sympathomimetics[b]
Nystagmus	Barbiturates, carbamazepine, carbon monoxide, ethanol, lithium, monoamine oxidase inhibitors, phencyclidine, phenytoin, quinine
Purpura	Anticoagulant rodenticides, clopidogrel, corticosteroids, heparin, pit viper venom, quinine, salicylates, warfarin
Radiopaque ingestions	Arsenic, enteric-coated tablets, halogenated hydrocarbons, metals (e.g., iron, lead)
Red skin	Anticholinergics,[a] boric acid, disulfiram, hydroxocobalamin, scombroid, vancomycin
Rhabdomyolysis	Carbon monoxide, doxylamine, HMG-CoA reductase inhibitors, sympathomimetics,[b] *Tricholoma equestre*
Salivation	Arsenic, caustics, cholinergics,[c] ketamine, mercury, phencyclidine, strychnine
Seizures	Bupropion, camphor, carbon monoxide, cyclic antidepressants, *Gyromitra* mushrooms, hypoglycemia, isoniazid, methylxanthines, ethanol and sedative–hypnotic withdrawal
Tremor	Antipsychotics, arsenic, carbon monoxide, cholinergics,[c] ethanol, lithium, mercury, methyl bromide, sympathomimetics,[b] thyroid replacement
Weakness	Botulism, diuretics, magnesium, paralytic shellfish, steroids, toluene
Yellow skin	Acetaminophen (late), pyrrolizidine alkaloids, β carotene, amatoxin mushrooms, dinitrophenol

[a] Anticholinergics, including antihistamines, atropine, cyclic antidepressants, and scopolamine.

[b] Sympathomimetics, including adrenergic agonists, amphetamines, cocaine, and ephedrine.

[c] Cholinergics, including muscarinic mushrooms; organic phosphorus compounds and carbamates, including select Alzheimer's disease drugs and physostigmine; and pilocarpine and other direct-acting xenobiotics.

HMG-CoA, 3-hydroxy-3-methyl-glutaryl-CoA); LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor.

considered to have an AMS. After airway patency is established or secured, an initial bedside assessment should be made regarding the adequacy of breathing. If it is not possible to assess the depth and rate of ventilation, then at least the presence or absence of regular breathing should be determined. In this setting, any irregular or slow breathing pattern should be considered a possible sign of the incipient apnea, requiring ventilation with 100% oxygen by bag–valve–mask followed as soon as possible by endotracheal intubation and mechanical ventilation. Endotracheal intubation may be indicated for some cases of coma resulting from a toxic exposure to ensure and maintain control of the airway and to enable safe performance of procedures to prevent GI absorption or eliminate previously absorbed xenobiotics.

Although in many instances, the widespread availability of pulse oximetry to determine O_2 saturation has made arterial blood gas (ABG) analysis less of an immediate priority, pulse oximetry has not eliminated the importance of blood gas analysis entirely. An ABG determination will more accurately define the adequacy not only of oxygenation (PO_2, O_2 saturation) and ventilation (PCO_2) but may also alert the physician to possible toxic-metabolic etiologies of coma characterized by acid–base disturbances (pH, PCO_2) (Chap. 16).

In addition, carboxyhemoglobin determinations are now available by point of care testing and both carboxyhemoglobin and methemoglobin may be determined on venous or arterial blood specimens (Chaps. 125 and 127). In every patient with an AMS, a bedside rapid capillary glucose concentration should be obtained as soon as possible.

After the patient's respiratory status has been assessed and managed appropriately, the strength, rate, and regularity of the pulse should be evaluated, the blood pressure determined, and a rectal temperature obtained. Both a 12-lead electrocardiogram (ECG) and continuous rhythm monitoring are essential. Monitoring will alert the clinician to dysrhythmias that are related to toxic exposures either directly or indirectly via hypoxemia or electrolyte imbalance. For example, a 12-lead ECG demonstrating QRS widening and a right axis deviation might indicate a life-threatening exposure to a cyclic antidepressant or another xenobiotic with sodium channel–blocking properties. In these cases, the physician can anticipate such serious sequelae as ventricular tachydysrhythmias, seizures, and cardiac arrest and consider both the early use of specific treatment (antidotes), such as IV sodium bicarbonate, and avoidance of medications, such as procainamide and other class IA and IC antidysrhythmics, which could exacerbate the situation.

Extremes of core body temperature must be addressed early in the evaluation and treatment of a comatose patient. Life-threatening hyperthermia (temperature >105°F; >40.5°C) is usually appreciated when the patient is touched (although the widespread use of gloves as part of universal precautions has made this less apparent than previously). Most individuals with severe hyperthermia, regardless of the etiology, should have their temperatures immediately reduced to about 101.5°F (38.7°C) by sedation if they are agitated or displaying muscle rigidity and by ice water immersion (Chap. 15). Hypothermia is probably easier to miss than hyperthermia, especially in northern regions during the winter months, when most arriving patients feel cold to the touch. Early recognition of hypothermia, however, helps to avoid administering a variety of medications that may be ineffective until the patient becomes relatively euthermic, which may cause iatrogenic toxicity as a result of a sudden response to xenobiotics previously administered.

For a hypotensive patient with clear lungs and an unknown overdose, a fluid challenge with IV 0.9% sodium chloride or lactated Ringer's solution may be started. If the patient remains hypotensive or cannot tolerate fluids, a vasopressor or an inotropic agent may be indicated, as may more invasive monitoring.

At the time that the IV catheter is inserted, blood samples for glucose, electrolytes, blood urea nitrogen (BUN), a complete blood count (CBC), and any indicated toxicologic analysis can be obtained. A pregnancy test should be obtained in any woman with childbearing potential. If the patient has an AMS, there may be a temptation to send blood and urine specimens to identify any central nervous system (CNS) depressants or so-called drugs of abuse along with other medications. But the indiscriminate ordering of these tests rarely provides clinically useful information. For the potentially suicidal patient, an acetaminophen concentration should be routinely requested, along with tests affecting the management of any specific xenobiotic, such as carbon monoxide, lithium, theophylline, iron, salicylates, and digoxin (or other cardioactive steroids), as suggested by the patient's history, physical examination, or bedside diagnostic tests. In the vast majority of cases, the blood tests that are most useful in diagnosing toxicologic emergencies are not the toxicologic assays but rather the "nontoxicologic" routine metabolic profile tests such as BUN, glucose, electrolytes, and blood gas analysis.

Xenobiotic-related seizures may broadly be divided into three categories: (1) those that respond to standard anticonvulsant treatment (typically using a benzodiazepine); (2) those that either require specific antidotes to control seizure activity or that do not respond consistently to standard anticonvulsant treatment, such as isoniazid-induced seizures requiring pyridoxine administration; and (3) those that may *appear* to respond to initial treatment with cessation of tonic–clonic activity but that leave the patient exposed to the underlying, unidentified toxin or to continued electrical seizure activity in the brain, as is the case with carbon monoxide poisoning and hypoglycemia.

Within the first 5 minutes of managing a patient with an AMS, four therapeutic interventions should be *considered*, and if indicated, administered:

1. High-flow oxygen (8–10 L/min) to treat a variety of xenobiotic-induced hypoxic conditions

2. Hypertonic dextrose: 0.5–1.0 g/kg of $D_{50}W$ for an adult or a more dilute dextrose solution ($D_{10}W$ or $D_{25}W$) for a child; the dextrose is administered as an IV bolus to diagnose and treat or exclude hypoglycemia

3. Thiamine (100 mg IV for an adult; usually unnecessary for a child) to prevent or treat Wernicke encephalopathy

4. Naloxone (0.05 mg IV with upward titration) for an adult or child with opioid-induced respiratory compromise

The clinician must consider that hypoglycemia may be the sole or contributing cause of coma even when the patient manifests focal neurologic findings; therefore, dextrose administration should only be omitted when hypoglycemia can be definitely excluded by accurate rapid bedside testing. Also, while examining a patient for clues to the etiology of a presumably toxic-metabolic form of AMS, it is important to search for any indication that trauma may have caused, contributed to, or resulted from the patient's condition. Conversely, the possibility of a concomitant drug ingestion or toxic metabolic disorder in a patient with obvious head trauma should also be considered.

The remainder of the physical examination should be performed rapidly but thoroughly. In addition to evaluating the patient's level of consciousness, the physician should note abnormal posturing (decorticate or decerebrate), abnormal or unilateral withdrawal responses, and pupil size and reactivity. Pinpoint pupils suggest exposure to opioids or organic phosphorus insecticides, and widely dilated pupils suggest anticholinergic or sympathomimetic poisoning. The presence or absence of nystagmus, abnormal reflexes, and any other focal neurologic findings may provide important clues to a structural cause of AMS. For clinicians accustomed to applying the Glasgow Coma Score (GCS) to all patients with AMS, assigning a score to the overdosed or poisoned patient may provide a useful measure for assessing changes in neurologic status. However, in this situation, the GCS should never be used for prognostic purposes because despite a low GCS, complete recovery from properly managed toxic-metabolic coma is the rule rather than the exception (Chap. 18).

Characteristic breath or skin odors may identify the etiology of coma. The fruity odor of ketones on the breath suggests diabetic or alcoholic ketoacidosis but also the possible ingestion of acetone or isopropyl alcohol, which is metabolized to acetone. The pungent, minty odor of oil of wintergreen on the breath or skin suggests methyl salicylate poisoning. The odors of other substances such as cyanide ("bitter almonds"), hydrogen sulfide ("rotten eggs"), and organic phosphorus compounds ("garlic") are described in detail in Chap. 20 and summarized in Table 20-1.

FURTHER EVALUATION OF ALL PATIENTS WITH SUSPECTED XENOBIOTIC EXPOSURES

Auscultation of breath sounds, particularly after a fluid challenge, helps to diagnose pulmonary edema, acute lung injury, or aspiration

pneumonitis when present. Coupled with an abnormal breath odor of hydrocarbons or organic phosphorus compounds, for example, crackles and rhonchi may point to a toxic pulmonary etiology instead of a cardiac etiology; this is important because the administration of certain cardioactive medications may be inappropriate or dangerous in the former circumstances.

Heart murmurs in an injection drug user, especially when accompanied by fever, may indicate bacterial endocarditis. Dysrhythmias may suggest overdoses or inappropriate use of cardioactive xenobiotics, such as digoxin and other cardioactive steroids, β-adrenergic antagonists, calcium channel blockers, and cyclic antidepressants.

The abdominal examination may reveal signs of trauma or alcohol-related hepatic disease. The presence or absence of bowel sounds helps to exclude or to diagnose anticholinergic toxicity and is important in considering whether to manipulate the GI tract in an attempt to remove the toxin.

Examination of the extremities might reveal clues to current or former drug use (track marks, skin-popping scars); metal poisoning (Mees lines, arsenical dermatitis); and the presence of cyanosis or edema suggesting preexisting cardiac, pulmonary, or renal disease (Chap. 29).

Repeated evaluation of the patient suspected of an overdose is essential for identifying new or developing findings or toxic syndromes and for early identification and treatment of a deteriorating condition. Until the patient is completely recovered or considered no longer at risk for the consequences of a xenobiotic exposure, frequent reassessment must be provided, even as the procedures described below are carried out. Toxicologic etiologies of abnormal vital signs and physical findings are summarized in Tables 3–1 to 3–6. Toxic syndromes, sometimes called "toxidromes," are summarized in Table 3-1.

Typically in the management of patients with toxicologic emergencies, there is both a necessity and an opportunity to obtain various diagnostic studies and ancillary tests interspersed with stabilizing the patient's condition, obtaining the history, and performing the physical examination. Chapters 5, 6, and 22 discuss the timing and indications for diagnostic imaging procedures, qualitative and quantitative diagnostic laboratory studies, and the use and interpretation of the ECG in evaluating and managing poisoned or overdosed patients.

THE ROLE OF GASTROINTESTINAL EVACUATION

A series of highly individualized treatment decisions must now be made. As noted previously and as discussed in detail in Chapter 7, the decision to evacuate the GI tract or administer AC can no longer be considered standard or routine toxicologic care for most patients. Instead, the decision should be based on the type of ingestion, estimated quantity and size of pill or tablet, time since ingestion, concurrent ingestions, ancillary medical conditions, and age and size of the patient. The indications, contraindications, and procedures for performing orogastric lavage and for administering WBI, AC, MDAC, and cathartics are listed in Tables 7–1 through 7–4 and are discussed both in Chapter 7 and in the specific Antidotes in Depth sections immediately following Chapter 7.

■ ELIMINATING ABSORBED XENOBIOTICS FROM THE BODY

After deciding whether or not an intervention to try to *prevent* absorption of a xenobiotic is indicated, the clinician must next consider the applicability of techniques available to eliminate xenobiotics already absorbed. Detailed discussions of the indications for and techniques of manipulating urinary pH (ion trapping), diuresis, hemodialysis, hemoperfusion, hemofiltration, and exchange transfusion are found in

Chapter 9. Briefly, patients who may benefit from these procedures are those who have systemically absorbed xenobiotics amenable to one of these techniques and whose clinical condition is both serious (or potentially serious) and unresponsive to supportive care or whose physiologic route of elimination (liver–feces, kidney–urine) is impaired.

Alkalinization of the urinary pH for acidic xenobiotics has only limited applicability. Commonly, sodium bicarbonate can be used to alkalinize the urine (as well as the blood) and enhance salicylate elimination (phenobarbital and chlorpropamide are less common indications), and sodium bicarbonate also prevents toxicity from methotrexate (see Antidotes in Depth: Sodium Bicarbonate). Acidifying the urine to hasten the elimination of alkaline substances is difficult to accomplish, probably useless, and possibly dangerous and therefore has no role in poison management. Forced diuresis also has no indication and may endanger the patient by causing pulmonary or cerebral edema.

If extracorporeal elimination is contemplated, hemodialysis should be considered for overdoses of salicylates, methanol, ethylene glycol, lithium, and xenobiotics that are both dialyzable and cause fluid and electrolyte problems. If available, hemoperfusion or high-flux hemodialysis should be considered for overdoses of theophylline, phenobarbital, and carbamazepine (although rarely, if ever, for the last two). When hemoperfusion is the method of choice (as for a theophylline overdose) but not available, hemodialysis is a logical, effective alternative and certainly preferable to delaying treatment until HP becomes available. Peritoneal dialysis is too ineffective to be of practical utility, and hemodiafiltration is not as efficacious as hemodialysis or hemoperfusion, although it may play a role between multiple runs of dialysis or in hemodynamically compromised patients who cannot tolerate hemodialysis. In theory, both hemodialysis and hemoperfusion *in series* may be useful for a very few life-threatening overdoses such as salicylates. Plasmapheresis and exchange transfusion are used to eliminate xenobiotics with large molecular weights that are not dialyzable (Chap. 9).

AVOIDING PITFALLS

The history alone may not be a reliable indicator of which patients require naloxone, hypertonic dextrose, thiamine, and oxygen. Instead, these therapies should be *considered* (unless specifically contraindicated) only after a clinical assessment for all patients with AMS. The physical examination should be used to guide the use of naloxone. If dextrose or naloxone is indicated, sufficient amounts should be administered to exclude or treat hypoglycemia or opioid toxicity, respectively.

In a patient with a suspected but unknown overdose, the use of vasopressors should be avoided in the initial management of hypotension before administering fluids or assessing filling pressures.

Attributing an AMS to alcohol because of its odor on a patient's breath is potentially dangerous and misleading. Small amounts of alcohol and its congeners generally produce the same breath odor as do intoxicating amounts. Conversely, even when an extremely high blood ethanol concentration is *confirmed* by the laboratory, it is dangerous to ignore other possible causes of an AMS. Because chronic alcoholics may be awake and seemingly alert with ethanol concentrations in excess of 500 mg/dL, a concentration that would result in coma and possibly apnea and death in a nontolerant person, finding a high ethanol concentration does not eliminate the need for further search into the cause of a depressed level of consciousness.

The metabolism of ethanol is fairly constant at 15 to 30 mg/dL/h. Therefore, as a general rule, regardless of the initial blood alcohol concentration, a presumably "inebriated" comatose patient who is still unarousable 3 to 4 hours after initial assessment should be considered to have head trauma, a cerebrovascular accident, CNS infection, or other toxic-metabolic etiology for the alteration in consciousness, until

proven otherwise. Careful neurologic evaluation of the completely undressed patient supplemented by a head computed tomography scan or a lumbar puncture is frequently indicated in such cases. This is especially important in dealing with a seemingly "intoxicated" patient who appears to have only a minor bruise because the early treatment of a subdural or epidural hematoma or subarachnoid hemorrhage is critical to a successful outcome.

ADDITIONAL CONSIDERATIONS IN MANAGING PATIENTS WITH A NORMAL MENTAL STATUS

As in the case of the patient with AMS, vital signs must be obtained and recorded. Initially, an assumption may have been made that the patient was breathing adequately, and if the patient is alert, talking, and in no respiratory distress, all that remains to document is the respiratory rate and rhythm. Because the patient is alert, additional history should be obtained, keeping in mind that information regarding the number and types of xenobiotics ingested, time elapsed, prior vomiting, and other critical information may be unreliable, depending in part on whether the ingestion was intentional or unintentional.

When indicated for the potential benefit of the patient, another history should be privately and independently obtained from a friend or relative after the patient has been initially stabilized. Recent emphasis on compliance with the federal Health Insurance Portability and Accountability Act (HIPAA) may inappropriately discourage clinicians from attempting to obtain information necessary to evaluate and treat patients. Obtaining such information from a friend or relative without unnecessarily giving that person information about the patient may be the key to successfully helping such a patient without violating confidentiality.

Speaking to a friend or relative of the patient may provide an opportunity to learn useful and reliable information regarding the ingestion, the patient's frame of mind, a history of previous ingestions, and the type of support that is available if the patient is discharged from the ED. At times, it may be essential to initially separate the patient from any relatives or friends to obtain greater cooperation from the patient and avoid violating confidentiality and because their anxiety may interfere with therapy. Even if the history obtained from a patient with an overdose proves to be unreliable, it may nevertheless provide clues to an overlooked possibility of a second ingestant or reveal the patient's mental and emotional condition. As is often true of the history, physical examination, or laboratory assessment in other clinical situations, the information obtained may confirm but never exclude possible causes.

At this point in the management of a conscious patient, a focused physical examination should be performed, concentrating on the pulmonary, cardiac, and abdominal examinations. A neurologic survey should emphasize reflexes and any focal findings.

APPROACHING PATIENTS WITH INTENTIONAL EXPOSURES

Initial efforts at establishing rapport with the patient by indicating to the patient concern about the problems that led to the ingestion and the availability of help after the xenobiotic is removed (if such procedures are planned) may help make management easier. If GI decontamination is deemed necessary, the reason for and nature of the procedure should be clearly explained to the patient together with reassurance that after the procedure is completed, there will be ample time to discuss related problems and provide additional care. These considerations are especially important in managing the patient with an intentional overdose who may be seeking psychiatric help or emotional support. In deciding on the necessity of GI decontamination, it is important to consider that a resistant patient may transform a procedure of only potential value into one with predictable adverse consequences.

SPECIAL CONSIDERATIONS FOR MANAGING PREGNANT PATIENTS

In general, a successful outcome for both the mother and fetus depends on optimum management of the mother, and proven effective treatment for a potentially serious toxic exposure to the mother should never be withheld based on theoretical concerns regarding the fetus.

■ PHYSIOLOGIC FACTORS

A pregnant woman's total blood volume and cardiac output are elevated through the second trimester and into the later stages of the third trimester. This means that signs of hypoperfusion and hypotension manifest later than they would in a woman who is not pregnant, and when they do, uterine blood flow may already be compromised. For these reasons, the possibility of hypotension in a pregnant woman must be more aggressively sought and, if found, more rapidly treated. Maintaining the patient in the left-lateral decubitus position helps prevent supine hypotension resulting from impairment of systemic venous return by compression of the inferior vena cava. The left lateral decubitus position is also the preferred position for orogastric lavage, if this procedure is deemed necessary.

Because the tidal volume is increased in pregnancy, the baseline PCO_2 will normally be lower by approximately 10 mm Hg. Appropriate adjustment for this effect should be made when interpreting ABG results.

■ USE OF ANTIDOTES

Limited data is available on the use of antidotes in pregnancy. In general, antidotes should not be used if the indications for use are equivocal. On the other hand, antidotes should not be withheld if their use may reduce potential morbidity and mortality. Risks and benefits of either decision must be considered. For example, reversal of opioid-induced respiratory depression calls for the use of naloxone, but in an opioid-dependent woman, the naloxone can precipitate acute opioid withdrawal, including uterine contractions and possible induction of labor. Very slow, careful, IV titration starting with 0.05 mg naloxone may be indicated unless apnea is present, cessation of breathing appears imminent, or the PO_2 or O_2 saturation is already compromised. In these instances, naloxone may have to be administered in higher doses (i.e., 0.4–2.0 mg) or assisted ventilation provided or a combination of assisted ventilation and small doses of naloxone used.

An acetaminophen overdose is a serious maternal problem when it occurs throughout pregnancy, but the fetus is at greatest risk in the third trimester. Although acetaminophen crosses the placenta easily, *N*-acetylcysteine has somewhat diminished transplacental passage. During the third trimester, when both the mother and the fetus may be at substantial risk from a significant acetaminophen overdose with manifest hepatoxicity, immediate delivery of a mature or viable fetus may need to be considered.

In contrast to the situation with acetaminophen, the fetal risk from iron poisoning is less than the maternal risk. Because deferoxamine is a large charged molecule with little transplacental transport, deferoxamine should never be withheld out of unwarranted concern for fetal toxicity when indicated to treat the mother.

Carbon monoxide (CO) poisoning is particularly threatening to fetal survival. The normal PO_2 of the fetal blood is approximately 15 to

20 mm Hg. Oxygen delivery to fetal tissues is impaired by the presence of carboxyhemoglobin, which shifts the oxyhemoglobin dissociation curve to the left, potentially compromising an already tenuous balance. For this reason, hyperbaric oxygen is recommended for much lower carboxyhemoglobin concentrations in the pregnant compared with the nonpregnant woman (Chap. 125 and Antidotes in Depth: Hyperbaric Oxygen). Early notification of the obstetrician and close cooperation among involved physicians are essential for best results in all of these instances.

MANAGEMENT OF PATIENTS WITH CUTANEOUS EXPOSURE

The xenobiotics that people are commonly exposed to externally include household cleaning materials; organic phosphorus or carbamate insecticides from crop dusting, gardening, or pest extermination; acids from leaking or exploding batteries; alkalis, such as lye; and lacrimating agents that are used in crowd control. In all of these cases, the principles of management are as follows:

1. Avoid secondary exposures by wearing protective (rubber or plastic) gowns, gloves, and shoe covers. Cases of serious secondary poisoning have occurred in emergency personnel after contact with xenobiotics such as organic phosphorus compounds on the victim's skin or clothing.
2. Remove the patient's clothing, place it in plastic bags, and then seal the bags.
3. Wash the patient with soap and copious amounts of water *twice* regardless of how much time has elapsed since the exposure.
4. Make no attempt to neutralize an acid with a base or a base with an acid. Further tissue damage may result from the heat generated by this reaction.
5. Avoid using any greases or creams because they will only keep the xenobiotic in close contact with the skin and ultimately make removal more difficult.

Chapter 29 discusses the principles of managing cutaneous exposures.

MANAGEMENT OF PATIENTS WITH OPHTHALMIC EXPOSURES

Although the vast majority of toxicologic emergencies result from ingestion, injection, or inhalation, the eyes are occasionally the routes of systemic absorption or are the organs at risk. The eyes should be irrigated with the eyelids fully retracted for no less than 20 minutes. To facilitate irrigation, a drop of an anesthetic (e.g., proparacaine) in each eye should be used, and the eyelids should be kept open with an eyelid retractor. An adequate irrigation stream may be obtained by running 1 L of normal saline through regular IV tubing held a few inches from the eye or by using an irrigating lens. Checking the eyelid fornices with pH paper strips is important to ensure adequate irrigation; the pH should normally be 6.5 to 7.6 if accurately tested, although when using paper test strips, the measurement will often be near 8.0. Chapter 19 describes the management of toxic ophthalmic exposures in more detail.

IDENTIFYING PATIENTS WITH NONTOXIC EXPOSURES

There is a risk of needlessly subjecting a patient to potential harm when a patient with a nontoxic exposure is treated aggressively with GI evacuation techniques and other forms of management indicated for serious exposures. More than 40% of exposures reported to poison centers annually are judged to be nontoxic or minimally toxic. The following general guidelines[1,2] for considering an exposure nontoxic or minimally toxic will assist clinical decision making:

1. Identification of the product and its ingredients is possible.
2. None of the US Consumer Product Safety Commission "signal words" (CAUTION, WARNING, or DANGER) appear on the product label.
3. The history permits the route(s) of exposure to be determined.
4. The history permits a reliable approximation of the maximum quantity involved with the exposure.
5. Based on the available medical literature and clinical experience, the potential effects related to the exposure are expected to be at most benign and self-limited and do not require referral to a clinician.[1,2]
6. The patient is asymptomatic or has developed the expected benign self-limited toxicity.

ENSURING OPTIMAL OUTCOME

The best way to ensure an optimal outcome for the patient with a suspected toxic exposure is to apply the principles of basic and advanced life support in conjunction with a planned and staged approach, always bearing in mind that a toxicologic etiology or coetiology for any abnormal conditions necessitates modifying whatever standard approach is brought to the bedside of a severely ill patient. For example, it is extremely important to recognize that xenobiotic-induced dysrhythmias or cardiac instability require alterations in standard protocols that assume a primary cardiac or nontoxicologic etiology (Chaps. 22 and 23).

Typically, only some of the xenobiotics to which a patient is exposed will ever be confirmed by laboratory analysis. The thoughtful combination of stabilization, general management principles, and specific treatment when indicated will result in successful outcomes in the vast majority of patients with actual or suspected exposures.

SUMMARY

Patients with a suspected overdose or poisoning and an AMS present some of the most serious initial challenges. Conscious patients, asymptomatic patients, and pregnant patients with possible xenobiotic exposures raise additional management issues, as do the victims of toxic cutaneous or ophthalmic exposures. One of the most frequent toxicologic emergencies that clinicians must deal with is a patient with a suspected toxic exposure to an unidentified xenobiotic (medication or substance), sometimes referred to as an *unknown overdose*. Considering not only those patients who have an AMS but also those who are suicidal, those who use illicit drugs, or those who are exposed to xenobiotics of which they are unaware, many toxicologic emergencies at least partly involve an unknown component.

CHAPTER 5
DIAGNOSTIC IMAGING

David T. Schwartz

Diagnostic imaging can play a significant role in the management of many toxicologic emergencies. Radiographic studies can directly visualize the xenobiotic in some cases, but in others, they reveal the effects of the xenobiotic on various organ systems (Table 5–1). Radiography can confirm a diagnosis (e.g., by visualizing the xenobiotic), assist in therapeutic interventions such as monitoring gastrointestinal (GI) decontamination, and detect complications of the xenobiotic exposure.[180]

Conventional radiography is readily available in the emergency department (ED) and is the imaging modality most frequently used in acute patient management. However, other imaging modalities can be used in toxicologic emergencies, including computed tomography (CT); enteric and intravascular contrast studies; ultrasonography; transesophageal echocardiography (TEE); magnetic resonance imaging (MRI/MRA); and nuclear scintigraphy, including positron emission tomography (PET) and single-photon emission tomography (SPECT).

VISUALIZING THE XENOBIOTIC

A number of xenobiotics are radiopaque and can potentially be detected by conventional radiography. Radiography is most useful when a substance that is known to be radiopaque has been ingested or injected. When the identity of the xenobiotic is unknown, the usefulness of radiography is very limited. When ingested, a radiopaque xenobiotic may be seen on an abdominal radiograph. Injected radiopaque xenobiotics are also amenable to radiographic detection. If the toxic material itself is available for examination, it can be radiographed outside of the body to detect any radiopaque contents (Fig. 103-1).[76]

■ RADIOPACITY

The radiopacity of a xenobiotic is determined by several factors. First, the intrinsic radiopacity of a substance depends on its physical density (g/cm^3) and the atomic numbers of its constituent atoms. Biologic tissues are composed mostly of carbon, hydrogen, and oxygen and have an average atomic number of approximately 6. Substances that are more radiopaque than soft tissues include bone, which contains calcium (atomic number 20); radiocontrast agents containing iodine (atomic number 53) and barium (atomic number 56); iron (atomic number 26); and lead (atomic number 82). Some xenobiotics have constituent atoms of high atomic number, such as chlorine (atomic number 17), potassium (atomic number 19), and sulfur (atomic number 16), that contribute to their radiopacity.

The thickness of an object also affects its radiopacity. Small particles of a moderately radiopaque xenobiotic are often not visible on a radiograph. Finally, the radiographic appearance of the surrounding area also affects the detectability of an object. A moderately radiopaque tablet is easily seen against a uniform background, but in a patient, overlying bone or bowel gas often obscures the tablet.

■ ULTRASONOGRAPHY

Compared with conventional radiography, ultrasonography theoretically is a useful tool for detecting ingested xenobiotics because it depends on echogenicity rather than radiopacity for visualization. Solid pills within the fluid-filled stomach may have an appearance similar to gallstones within the gallbladder. In one in vitro study using a water-bath model, virtually all intact pills could be visualized.[7] The authors were also successful at detecting pills within the stomachs of human volunteers who ingested pills. Nonetheless, reliably finding pills scattered throughout the GI tract, which often contains air and feces that block the ultrasound beam, is a formidable task. Ultrasonography, therefore, has limited clinical practicality.

INGESTION OF AN UNKNOWN XENOBIOTIC

Although a clinical policy issued by the American College of Emergency Physicians in 1995 suggested that an abdominal radiograph should be obtained in unresponsive overdosed patients in an attempt to identify the involved xenobiotic, the role of abdominal radiography in screening a patient who has ingested an unknown xenobiotic is questionable.[6] The number of potentially ingested xenobiotics that are radiopaque is limited. In addition, the radiographic appearance of an ingested xenobiotic is not sufficiently distinctive to determine its identity (Fig. 5–1).[202] However, when ingestion of a radiopaque xenobiotic such as ferrous sulfate tablets or another metal with a high atomic number is suspected, abdominal radiographs are helpful.[5] In addition, knowledge of potentially radiopaque xenobiotics is useful in suggesting diagnostic possibilities when a radiopaque xenobiotic is discovered on an abdominal radiograph that was obtained for reasons other than suspected xenobiotic ingestion, such as in a patient with abdominal pain (Fig. 5–2).[179,186]

Several investigators have studied the radiopacity of various medications.[52,59,81,87,97,147,176,189,197] These investigators used an in vitro water-bath model to simulate the radiopacity of abdominal soft tissues.[176] The studies found that only a small number of medications exhibit some degree of radiopacity. A short list of the more consistently radiopaque xenobiotics is summarized in the mnemonic CHIPES—chloral hydrate, "heavy metals," iron, phenothiazines, and enteric-coated and sustained-release preparations.

The CHIPES mnemonic has several limitations.[176] It does not include all of the pills that are radiopaque in vitro such as acetazolamide and busulfan. Most radiopaque medications are only moderately radiopaque, and when ingested, they dissolve rapidly, becoming difficult or impossible to detect. "Psychotropic medications" include a wide variety of compounds of varying radiopacity.[147,176] For example, whereas trifluoperazine (containing fluorine; atomic number 9) is radiopaque in vitro, chlorpromazine (containing chlorine; atomic number 17) is not.[176]

Finally, sustained-release preparations and those with enteric coatings have variable composition and radiopacity. Pill formulations of fillers, binders, and coatings vary between manufacturers, and even a specific product can change depending on the date of manufacture. Furthermore, the insoluble matrix of some sustained-release preparations is radiopaque, and when seen on a radiograph, these tablets may no longer contain active medication. Some sustained-release cardiac medications such as verapamil and nifedipine have inconsistent radiopacity.[119,188,199]

EXPOSURE TO A KNOWN XENOBIOTIC

When a xenobiotic that is known to be radiopaque is involved in an exposure, radiography plays an important role in patient care.[5] Radiography can confirm the diagnosis of a radiopaque xenobiotic exposure, quantify the approximate amount of xenobiotic involved,

TABLE 5–1. Xenobiotics with Diagnostic Imaging Findings

Xenobiotic	Imaging Study[a]	Finding
Amiodarone	Chest	Phospholipidosis (interstitial and alveolar filling), pulmonary fibrosis
Asbestos	Chest	Interstitial fibrosis (asbestosis), calcified pleural plaques, mesothelioma
Beryllium	Chest	Acute: Airspace filling; chronic: hilar adenopathy
Body packer	Upper GI series or abdominal CT	Ingested packets, ileus, bowel obstruction
Carbon monoxide	Head CT, MRI SPECT, PET	Bilateral basal ganglia lucencies, white matter demyelinization, cerebral dysfunction
Caustic ingestion	Enteric contrast	Esophageal perforation or stricture
Chemotherapeutics (busulfan, bleomycin)	Chest	Interstitial pneumonitis
Cholinergics	Chest	Diffuse airspace filling (bronchorrhea)
Cocaine	Chest, abdominal Noncontrast Head CT, MRI, TEE, SPECT, PET	Diffuse airspace filling, pneumomediastinum, pneumothorax, aortic dissection, perforation SAH, intracerebral hemorrhage, infarction, cerebral dysfunction, dopamine receptor downregulation
Corticosteroids	Skeletal	Avascular necrosis (femoral head)
Ethanol	Chest Head CT, MRI, SPECT, PET	Dilated cardiomyopathy, aspiration pneumonitis, rib fractures, cortical Cortical atrophy, cerebellar atrophy, SDH (head trauma), cerebellar and cortical dysfunction
Fluorosis	Skeletal	Osteosclerosis, osteophytosis, ligament calcification
Hydrocarbons (low viscosity)	Chest	Aspiration pneumonitis
Inhaled allergens	Chest	Hypersensitivity pneumonitis
Iron	Abdominal	Radiopaque tablets
Irritant gases	Chest	Diffuse airspace filling thorax
Lead	Skeletal, abdominal	Metaphyseal bands in children (proximal tibia, distal radius), bullets (dissolution near joints) Ingested leaded paint chips or other leaded compounds
Manganese	Brain MRI	Basal ganglia and midbrain hyperintensity
Mercury (elemental)	Abdominal, skeletal, or chest	Ingested, injected, or embolic deposits
Metals (Pb, Hg, TI, As)	Abdominal	Ingested xenobiotic
Nitrofurantoin	Chest	Hypersensitivity pneumonitis
Opioids	Chest	Acute lung injury
	Abdominal	Ileus
Phenytoin	Chest	Hilar lymphadenopathy
Procainamide, INH, hydralazine	Chest	Pleural and pericardial effusions (xenobiotic-induced lupus syndrome)
Salicylates	Chest	Acute lung injury
Silica, coal dust	Chest	Interstitial fibrosis, hilar adenopathy (egg-shell calcification)

and monitor its removal from the body. Examples include ferrous sulfate, sustained-release potassium chloride,[193] and heavy metals.

■ IRON TABLET INGESTION

Adult-strength ferrous sulfate tablets are readily detected radiographically because they are highly radiopaque and disintegrate slowly when ingested. Aside from confirming an iron tablet ingestion and quantifying the amount ingested, radiographs repeated after whole-bowel irrigation help to determine whether further GI decontamination is needed (Fig. 5–3).[51,61,101,146,151,153,205] Nonetheless, caution must be exercised in using radiography to exclude an iron ingestion. Some iron preparations are not radiographically detectable. Liquid, chewable, or encapsulated ("Spansule") iron preparations rapidly fragment and disperse after ingestion. Even when intact, these preparations are less radiopaque than ferrous sulfate tablets.[52]

■ HEAVY METALS

Heavy metals, such as arsenic, cesium, lead, manganese, mercury, potassium, and thallium, can be detected radiographically. Examples of metal exposure include leaded ceramic glaze (Fig. 5–4),[168] paint chips
FIGURE 5–1. Ingestion of an unknown substance. A 46-year-old man presented to the emergency department with a depressed level of consciousness. Because he also complained of abdominal pain and mild diffuse abdominal tenderness, a computed tomography (CT) scan of the abdomen was obtained. The CT revealed innumerable tablet-shaped densities within the stomach (*arrows*). The CT finding was suspicious for an overdose of an unknown xenobiotic. Orogastric lavage was attempted, and the patient vomited a large amount of whole navy beans. CT is able to detect small, nearly isodense structures such as these that cannot be seen using conventional radiography. (*Image contributed by Dr. Earl J. Reisdorff, MD, Michigan State University, Lansing, Michigan.*)
FIGURE 5–2. Detection of a radiopaque substance on an abdominal radiograph. An abdominal radiograph obtained on a patient with upper abdominal pain revealed radiopaque material throughout the intestinal tract (*arrows*). Further questioning of the patient revealed that he had been consuming bismuth subsalicylate (Pepto-Bismol) tablets to treat his peptic ulcer (bismuth, atomic number 83). The identification of radiopaque material does not allow determination of the nature of the substance.

A

B

FIGURE 5–3. Iron tablet overdose. (**A**) The identification of the large amount of radiopaque tablets confirms the diagnosis in a patient with a suspected iron overdose and permits rough quantification of the amount ingested. (**B**) After emesis and whole-bowel irrigation, a second radiograph revealed some remaining tablets and indicated the need for further intestinal decontamination. A third radiograph after additional bowel irrigation demonstrated clearing of the intestinal tract. (*Images contributed by the Toxicology Fellowship of the New York City Poison Center.*)

FIGURE 5–4. An abdominal radiograph of a patient who intentionally ingested ceramic glaze containing 40% lead. (*Image contributed by the Toxicology Fellowship of the New York City Poison Center.*)

FIGURE 5–5. An abdominal radiograph in an elderly woman incidentally revealed radiopaque material in the pelvic region. This was residual from gluteal injection of antisyphilis therapy she had received 35 to 40 years earlier. The injections may have contained an arsenical. (*Image contributed by Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.*)

containing lead (Fig. 94–5),[112,133]mercuric oxide (Fig. 96–1),[122] thallium salts (atomic number 81),[44,134] and zinc (atomic number 30).[23] Arsenic (atomic number 33; Fig. 5–5)[77,116,203] with lower atomic numbers is also radiopaque.

Mercury Unintentional ingestion of elemental mercury can occur when a glass thermometer or a long intestinal tube with a mercury-containing balloon breaks. Liquid elemental mercury can be injected subcutaneously or intravenously. Radiographic studies assist débridement by detecting mercury that remains after the initial excision. Elemental mercury that is injected intravenously produces a dramatic radiographic picture of pulmonary embolization (Fig. 5–6).[23,26,112,126,130,143]

Lead Ingested lead can be detected only by abdominal radiography, such as in a child with lead poisoning who has ingested paint chips (see Fig. 91-5). Metallic lead (e.g., a bullet) that is embedded in soft tissues is not usually systemically absorbed. However, when the bullet is in contact with an acidic environment such as synovial fluid or cerebrospinal fluid (CSF), there may be significant absorption. Over many years, mechanical and chemical action within the joint causes the bullet to fragment and gradually dissolve.[43,45,53,192,196] Radiography can confirm the source of lead poisoning by revealing metallic material in the joint or CSF (Fig. 5–7).

■ XENOBIOTICS IN CONTAINERS

In some circumstances, ingested xenobiotics can be seen even though they are of similar radiopacity to surrounding soft tissues. If a xenobiotic is ingested in a container, the container itself may be visible.

Body Packers "Body packers" are individuals who smuggle large quantities of illicit drugs across international borders in securely sealed

packets.[3,15,16,25,36,56,95,109,125,132,156,181,183,201] The uniformly shaped, oblong packets can be seen on abdominal radiographs either because there is a thin layer of air or metallic foil within the container wall or because the packets are outlined by bowel gas (Fig. 5–8). In some cases, a "rosette" representing the knot at the end of the packet is seen.[183] Intraabdominal calcifications (pancreatic calcifications and bladder stones) have occasionally been misinterpreted as drug-containing packets.[201,217]

The sensitivity of abdominal radiography for such packets is high, in the range of 85% to 90%. The major role of radiography is as a rapid screening test to confirm the diagnosis in individuals suspected of smuggling drugs, such as persons being held by airport customs agents. However, because packets are occasionally not visualized and the rupture of even a single packet can be fatal, abdominal radiography should not be relied on to exclude the diagnosis of body packing. Ultrasonography has also been used to rapidly detect packets, although it also should not be relied on to exclude such a life-threatening ingestion.[33,78,136] After intestinal decontamination, an upper GI series with oral contrast or CT with enteric contrast can reveal any remaining packets.[80,91,148]

Body stuffers A "body stuffer" is an individual who, in an attempt to avoid imminent arrest, hurriedly ingests contraband in insecure packaging.[170] The risk of leakage from such haphazardly constructed
FIGURE 5–6. Elemental mercury exposures. (**A**) Unintentional rupture of a Cantor intestinal tube distributed mercury throughout the bowel. (**B**) The chest radiograph in a patient after intravenous injection of elemental mercury showing metallic pulmonary embolism. The patient developed respiratory failure, pleural effusions, and uremia and expired despite aggressive therapeutic interventions. (**C**) Subcutaneous injection of liquid elemental mercury is readily detected radiographically. Because mercury is systemically absorbed from subcutaneous tissues, it must be removed by surgical excision. (**D**) A radiograph after surgical débridement reveals nearly complete removal of the mercury deposit. Surgical staples and a radiopaque drain are visible. *(Image A contributed by Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital Center; image B contributed by Dr. N. John Stewart, Department of Emergency Medicine, Palmetto Health, University of South Carolina School of Medicine and images C and D contributed by the Toxicology Fellowship of the New York City Poison Center.)*
FIGURE 5–7. A "lead arthrogram" discovered many years after a bullet wound to the shoulder. At the time of the initial injury, the bullet was embedded in the articular surface of the humeral head (*arrow*). The portion of the bullet that protruded into the joint space was surgically removed, leaving a portion of the bullet exposed to the synovial space. A second bullet was embedded in the muscles of the scapula. Eight years after the injury, the patient presented with weakness and anemia. Extensive lead deposition throughout the synovium is seen. The blood lead concentration was 91 μg/dL. *(Image contributed by the Toxicology Fellowship of the New York City Poison Center.)*

containers is high. Unfortunately, radiographic studies cannot reliably confirm or exclude such ingestions.[187]

Occasionally, a radiograph will demonstrate the ingested container (Fig. 5–9). If the drug is in a glass or in a hard-plastic crack vial, the container may be seen.[90] If the body stuffer swallows soft plastic bags containing the drug, the containers are not usually visible. However, in three reported cases, "baggies" were visualized by abdominal CT.[37,48,83,105,85,157,180]

■ HALOGENATED HYDROCARBONS

Some halogenated hydrocarbons can be visualized radiographically.[31,38] Radiopacity is proportionate to the number of chlorine atoms. Both carbon tetrachloride (CCl_4) and chloroform ($CHCl_3$) are radiopaque. Because these liquids are immiscible in water, a triple layer may be seen within the stomach on an upright abdominal radiograph—an uppermost air bubble, a middle radiopaque chlorinated hydrocarbon layer, and a lower gastric fluid layer. However, these ingestions are rare, and the quantity ingested is usually too small to show this effect. Other halogenated hydrocarbons such as methylene iodide are highly radiopaque.[216]

■ MOTHBALLS

Some types of mothballs can be visualized by radiography. Whereas relatively nontoxic paradichlorobenzene mothballs (containing chlorine; atomic number 17) are moderately radiopaque, more toxic naphthalene mothballs are radiolucent.[194] If the patient is known to have swallowed mothballs, the difference in radiopacity may help determine the type. However, if a mothball ingestion is not already suspected, the more toxic naphthalene type may not be detected. Radiographs of mothballs outside of the patient can help distinguish these two types (see Fig. 103–1).

■ RADIOLUCENT XENOBIOTICS

A radiolucent xenobiotic may be visible because it is less radiopaque than surrounding soft tissues. Hydrocarbons such as gasoline are relatively radiolucent when embedded in soft tissues. The radiographic appearance resembles subcutaneous gas as seen in a necrotizing soft tissue infection (Fig. 5–10).

■ SUMMARY

Obtaining an abdominal radiograph in an attempt to identify pills or other xenobiotics in a patient with an unknown ingestion is unlikely to be helpful and is, in general, not warranted. Radiography is most useful when the suspected xenobiotic is known to be radiopaque, as is the case with iron tablets and heavy metals. If the material is available, the xenobiotic can be radiographed within the patient's abdomen, elsewhere in the patient's body, or outside of the patient.

EXTRAVASATION OF INTRAVENOUS CONTRAST MATERIAL

Extravasation of intravenous (IV) radiographic contrast material is a common occurrence. In most cases, the volume extravasated is small, and there are no clinical sequelae.[17,35,54,169] Rarely, a patient has an extravasation large enough to cause cutaneous necrosis and ulceration.

Recently, the incidence of sizable extravasations has increased because of the use of rapid-bolus automated power injectors for CT studies.[208] Fortunately, nonionic low-osmolality contrast solutions are currently nearly always used for these studies. These solutions are far less toxic to soft tissues than older ionic high-osmolality contrast materials.

The treatment of contrast extravasation has not been studied in a large series of human subjects and is therefore controversial. Various strategies have been proposed. The affected extremity should be elevated to promote drainage. Although topical application of heat causes vasodilation and could theoretically promote absorption of extravasated contrast material, the intermittent application of ice packs has been shown to lower the incidence of ulceration.[35] Rarely, an extremely large volume of liquid is injected into the soft tissues, which requires surgical decompression when there are signs of a compartment syndrome. A radiograph of the extremity will demonstrate the extent of extravasation.[35]

Precautions should be taken to prevent extravasation. A recently placed, well-running IV catheter should be used. The distal portions of the extremities (hands, wrist, and feet) should not be used as IV sites for injecting contrast. Patients who are more vulnerable to complications and those whose veins may be more fragile, such as infants, debilitated patients, and those with an impaired ability to communicate, must be closely monitored to prevent or determine if extravasation occurs.

VISUALIZING THE EFFECTS OF A XENOBIOTIC ON THE BODY

The lungs, central nervous system (CNS), GI tract, and skeleton are the organ systems that are most amenable to diagnostic imaging. Disorders of the lungs and skeletal system are seen by plain radiography. For abdominal pathology, contrast studies and CT are more useful, although plain radiographs can diagnose intestinal obstruction, perforation, and radiopaque foreign bodies. Imaging of the CNS uses CT, MRI, and nuclear scintigraphy (PET and SPECT).

FIGURE 5–8. Radiographs of three "body packers" showing the various appearances of drug packets. Drug smuggling is accomplished by packing the gastrointestinal tract with large numbers of manufactured, well-sealed containers. (**A**) Multiple oblong packages of uniform size and shape are seen throughout the bowel. (**B**) The packets are visible in this patient because they are surrounded by a thin layer of air within the wall of the packet. (**C**) Metallic foil is part of the packet's container wall in this patient. *(Images contributed by Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)*

FIGURE 5–9. Two "body stuffers." Radiography infrequently helps with the diagnosis. (**A**) An ingested glass crack vial is seen in the distal bowel (*arrow*). The patient had ingested his contraband several hours earlier at the time of a police raid. Only the tubular-shaped container, and not the xenobiotic, is visible radiographically. The patient did not develop signs of cocaine intoxication during 24 hours of observation. (**B**) Another patient in police custody was brought to the emergency department for allegedly ingesting his drugs. The patient repeatedly denied this. The radiographs revealed "nonsurgical" staples in his abdomen (*arrows*). When questioned again, the patient admitted that he had swallowed several plastic bags that were stapled closed. *(Images contributed by the Toxicology Fellowship of the New York City Poison Center.)*

■ SKELETAL CHANGES CAUSED BY XENOBIOTICS

A number of xenobiotics affect bone mineralization. Toxicologic effects on bone result in either increased or decreased density (Table 5–2). Some xenobiotics produce characteristic radiographic pictures, although exact

FIGURE 5–10. Subcutaneous injection of gasoline into the antecubital fossa. The radiolucent hydrocarbon mimics gas in the soft tissues that is seen with a necrotizing soft tissue infection such as necrotizing fasciitis or gas gangrene (*arrows*). *(Image contributed by the Toxicology Fellowship of the New York City Poison Center.)*

diagnoses usually depend on correlation with the clinical scenario.[10,145] Furthermore, alterations in skeletal structure develop gradually and are usually not visible unless the exposure continues for at least 2 weeks.

Lead Poisoning Skeletal radiography may suggest the diagnosis of chronic lead poisoning even before the blood lead concentration is obtained. With lead poisoning, the metaphyseal regions of rapidly growing long bones develop transverse bands of increased density along the growth plate (Fig. 5–11).[21,160,163,174] Characteristic locations are the distal femur and proximal tibia. Flaring of the distal metaphysis also occurs. Such lead lines are also seen in the vertebral bodies and iliac crest. Detected in approximately 80% of children with a mean lead concentration of 49 ± 17 μg/dL, lead lines usually occur in children between the ages of 2 and 9 years.[21] In most children, it takes several weeks for lead lines to appear, although in very young infants (2–4 months old), lead lines may develop within days of exposure.[221] After exposure ceases, lead lines diminish and may eventually disappear.

Lead lines are caused by the toxic effect of lead on bone growth and do not represent deposition of lead in bone. Lead impedes resorption of calcified cartilage in the zone of provisional calcification adjacent to the growth plate. This is termed *chondrosclerosis*.[21,47] Other xenobiotics that cause metaphyseal bands are yellow phosphorus, bismuth, and vitamin D (Chap. 41).

Fluorosis Fluoride poisoning causes a diffuse increase in bone mineralization. Endemic fluorosis occurs where drinking water contains very high levels of fluoride (≥2 or more parts per million), or as an occupational exposure among aluminum workers handling cryolite (sodium–aluminum fluoride). The skeletal changes associated with fluorosis are osteosclerosis (hyperostosis

TABLE 5–2. Xenobiotic Causes of Skeletal Abnormalities

Increased Bone Density	Diminished Bone Density (Either Diffuse Osteoporosis or Focal Lesions)

Metaphyseal bands (children)
    Lead, bismuth, phosphorus:
        Chondrosclerosis caused by
           toxic effect on bone growth
 	
Diffuse increased bone density
    Fluorosis:
        Osteosclerosis (hyperostosis
           deformans), osteophytosis,
           ligament calcification; usually
           involves the axial skeleton
           (vertebrae and pelvis) and
           may cause compression of
           the spinal cord and nerve
           roots
    Hypervitaminosis A (pediatric):
        Cortical hyperostosis and
           subperiosteal new bone
           formation; diaphyses
           of long bones have
           an undulating appearance
    Hypervitaminosis D (pediatric):
        Generalized osteosclerosis,
           cortical thickening, and
           metaphyseal bands
	Corticosteroids:
	    Osteoporosis: Diffuse
	    Osteonecrosis: Focal lesions, e.g.
	        avascular necrosis of the femoral
	        head; loss of volume with both
	        increased and decreased bone
	        density; osteonecrosis also occurs
	        in alcoholism, bismuth arthropathy,
	        Caisson disease (dysbarism), trauma
	Hypervitaminosis D (adult):
	    Focal or generalized osteoporosis.
	Injection drug use:
	    Osteomyelitis (focal lytic lesions)
	        caused by septic emboli; usually
	        affects vertebral bodies and
	        sternomanubrial joint.
	Vinyl chloride monomer:
	    Acroosteolysis (distal phalanges)

A

B

FIGURE 5–11. (A) A radiograph of the knees of a child with lead poisoning. The metaphyseal regions of the distal femur and proximal tibia have developed transverse bands representing bone growth abnormalities caused by lead toxicity. The multiplicity of lines implies repeated exposures to lead. (B) The abdominal radiograph of the child shows many radiopaque flakes of ingested leaded paint chips. Lead poisoning also caused abnormally increased cortical mineralization of the vertebral bodies, which gives them a boxlike appearance. *(Images contributed by Dr. Nancy Genieser, Department of Radiology, Bellevue Hospital Center.)*

deformans), osteophytosis, and ligament calcification. Fluorosis primarily affects the axial skeleton, especially the vertebral column and pelvis. Thickening of the vertebral column may cause compression of the spinal cord and nerve roots. Without a history of fluoride exposure, the clinical and radiographic findings can be mistaken for osteoblastic skeletal metastases. The diagnosis of fluorosis is confirmed by histologic examination of the bone and measurement of fluoride levels in the bone and urine.[22,210]

Focal Loss of Bone Density   Skeletal disorders associated with focal diminished bone density (or mixed rarefaction and sclerosis) include osteonecrosis, osteomyelitis, and osteolysis. Osteonecrosis, also known as avascular necrosis, most often affects the femoral head, humeral head, and proximal tibia.[127] There are many causes of osteonecrosis. Xenobiotic causes include long-term corticosteroid use and alcoholism. Radiographically, focal skeletal lucencies and sclerosis are seen, ultimately with loss of bone volume and collapse (Fig. 5–12A).

Acroosteolysis is bone resorption of the distal phalanges and is associated with occupational exposure to vinyl chloride monomer. Protective measures have reduced its incidence since it was first described in the early 1960s.[164]

Osteomyelitis is a serious complication of injection drug use. It usually affects the axial skeleton, especially the vertebral bodies, as well as the sternomanubrial and sternoclavicular joints (Fig. 5–12B).[74,79] Back pain or neck pain in IV drug users warrants careful consideration. A spinal epidural abscess causing spinal cord compression may accompany vertebral osteomyelitis.[92,125] Radiographs are negative early in the disease course before skeletal changes are visible and the diagnosis is confirmed by MRI or CT (Fig. 5–12C).
FIGURE 5–12. (A) Avascular necrosis causing collapse of the femoral head in a patient with long-standing steroid-dependent asthma (*arrow*). (B) A patient with vertebral body osteomyelitis complicating injection drug use. Destruction of the intervertebral disk and endplates of C3 and C4 are seen (*arrow*). Operative culture of the bone grew *Staphylococcus aureus.* (C) An injection drug user with thoracic back pain, leg weakness, and low-grade fever. Radiographs of the spine were negative. Magnetic resonance image showing an epidural abscess (*arrow*) compressing the spinal cord. The cerebral spinal fluid in the compressed thecal sac is bright white on this T2-weighted image. *(From Levitan R: Thoracolumbar spine. In: Schwartz DT, Reisdorff EJ, eds:* Emergency Radiology. *New York, McGraw-Hill; 2000:343, with permission.)*

■ SOFT TISSUE CHANGES

Certain abnormalities in soft tissues, predominantly as a consequence of infectious complications of injection drug use, are amenable to radiographic diagnosis.[74,75,79,99,198] In an injection drug user who presents with signs of local soft tissue infections, radiography is indicated to detect a retained metallic foreign body, such as a needle fragment, or subcutaneous gas, as may be seen in a necrotizing soft tissue infection such as necrotizing fasciitis. CT is more sensitive at detecting soft tissue gas than is conventional radiography. CT and ultrasonography can also detect subcutaneous or deeper abscesses that require surgical or percutaneous drainage.

■ PULMONARY AND OTHER THORACIC PROBLEMS

Many xenobiotics that affect intrathoracic organs produce pathologic changes that can be detected on chest radiographs.[9,12,24,49,63,75,140,172,219] The lungs are most often affected, resulting in dyspnea or cough, but the pleura, hilum, heart, and great vessels may also be involved.[6] Patients with chest pain may have a pneumothorax, pneumomediastinum, or aortic dissection. Patients with fever, with or without respiratory symptoms, may have a focal infiltrate, pleural effusion, or hilar lymphadenopathy.

Chest radiographic findings may suggest certain diseases, although the diagnosis ultimately depends on a thorough clinical history. When a specific xenobiotic exposure is known or suspected, the chest radiograph can confirm the diagnosis and help in assessment. If a history of xenobiotic exposure is not obtained, a patient with an abnormal chest radiograph may initially be misdiagnosed as having pneumonia or another disorder that is more common than xenobiotic-mediated lung disease.[166] Therefore, all patients with chest radiographic abnormalities must be carefully questioned regarding possible xenobiotic exposures at work or at home, as well as the use of medications or other drugs.

Many pulmonary disorders are radiographically detectable because they result in fluid accumulation within the normally air-filled lung. Fluid may accumulate within the alveolar spaces or interstitial tissues of the lung, producing the two major radiographic patterns of pulmonary disease: airspace filling and interstitial lung disease (Table 5–3). Most xenobiotics are widely distributed throughout the lungs and produce a diffuse rather than a focal radiographic abnormality.

Diffuse Airspace Filling.   Overdose with various xenobiotics, including salicylates, opioids, and paraquat, may cause acute lung injury (formerly known as noncardiogenic pulmonary edema) with or without

TABLE 5–3. Chest Radiographic Findings in Toxicologic Emergencies

| Radiographic Finding	Responsible Xenobiotic	Disease Processes
Diffuse airspace filling	Salicylates	Acute lung injury
	Opioids	
	Paraquat	
	Irritant gases: NO_2 (silo filler's disease), phosgene ($COCl_2$), Cl_2, H_2S	
	Organic phosphorus compounds, carbamates	Cholinergic stimulation (bronchorrhea)
	Alcoholic cardiomyopathy, cocaine, doxorubicin, cobalt	Congestive heart failure
Focal airspace filling	Low-viscosity hydrocarbons	Aspiration pneumonitis
	Gastric contents aspiration: CNS depressants, alcohol, seizures	
Multifocal airspace filling	Injection drug user	Septic emboli
Interstitial patterns	Inhaled organic allergens: Farmer's lung, pigeon breeder's lung	Hypersensitivity pneumonitis
Fine or coarse reticular or reticulonodular pattern	Nitrofurantoin, penicillamine	
Patchy airspace filling is seen in some cases	Antineoplastics: Busulfan, bleomycin, carmustine, cyclophosphamide, methotrexate	Cytotoxic lung damage
	Amiodarone	Phospholipidosis
	Talcosis (illicit drug contaminant)	Injected particulates
	Pneumoconiosis: Asbestosis, silicosis, coal dust, berylliosis (chronic)	Inhaled inorganic particulates
Pleural effusion	Procainamide, hydralazine, INH, methyldopa	Drug-induced systemic lupus erythematosus
Pneumomediastinum Pneumothorax	"Crack" cocaine and marijuana (forceful inhalation), ipecac and alcoholism (forceful vomiting), subclavian vein injection puncture	Barotrauma
Pleural plaques (calcified)	Asbestos exposure	Fibrosis or asbestosis
Lymphadenopathy	Phenytoin, methotrexate (rare)	Pseudolymphoma
	Silicosis (eggshell calcification), berylliosis	Pneumoconiosis
Cardiomegaly (chronic exposure)	Ethanol, doxorubicin, cocaine, cobalt amphetamine, ipecac syrup	Dilated cardiomyopathy
	Drug-induced systemic lupus erythematosus (procainamide, hydralazine, INH)	Pericardial effusion
Aortic enlargement	Cocaine	Aortic dissection.
FIGURE 5–13. Diffuse airspace filling. The chest radiograph of a patient who had recently injected heroin intravenously presented with respiratory distress and acute lung injury. The heart size is normal.

FIGURE 5–14. Focal airspace filling as a result of hydrocarbon aspiration. A 34-year-old man aspirated gasoline. The chest radiograph shows bilateral lower lobe infiltrates.

diffuse alveolar damage and characterized by leaky capillaries (Fig. 5–13).[75,85,89,123,184,191,218] There are, of course, many other causes of acute lung injury, including sepsis, anaphylaxis, and major trauma.[213] Other xenobiotic exposures that may result in diffuse airspace filling include inhalation of irritant gases that are of low water solubility such as phosgene ($COC1_2$), nitrogen dioxide (silo filler's disease), chlorine, hydrogen sulfide, and sulfur dioxide (Chaps. 124, 128).[79,102] Organic phosphorus insecticide poisoning causes cholinergic hyperstimulation, resulting in bronchorrhea (Chap. 113). Smoking "crack" cocaine is associated with diffuse alveolar hemorrhage.[60,75,79,165,219]

Focal Airspace Filling.   Focal infiltrates are usually caused by bacterial pneumonia, although aspiration of gastric contents also causes localized airspace disease.[75,195] Aspiration may occur during sedative–hypnotic or alcohol intoxication or during a seizure. During ingestion, low-viscosity hydrocarbons often enter the lungs while they are being swallowed (Figs. 5–14 and 105–2). There may be a delay in the development of radiographic abnormalities, and the chest radiograph may not appear to be abnormal until 6 hours after the ingestion.[8] During aspiration, the most dependent portions of the lung are affected. When the patient is upright at the time of aspiration, the lower lung segments are involved. When the patient is supine, the posterior segments of the upper and lower lobes are affected.[62]

Multifocal Airspace Filling.   Multifocal airspace filling occurs with septic pulmonary emboli, which is a complication of injection drug use and right-sided bacterial endocarditis. The foci of pulmonary infection often undergo necrosis and cavitation (Fig. 5–15).[75,79]

Interstitial Lung Diseases.   Toxicologic causes of interstitial lung disease include hypersensitivity pneumonitis, use of medications with direct pulmonary toxicity, and inhalation or injection of inorganic particulates.[75] Interstitial lung diseases may have an acute, subacute, or chronic course. On the chest radiograph, acute and subacute disorders cause a fine reticular or reticulonodular pattern (Fig. 5–16). Chronic interstitial disorders cause a coarse reticular "honeycomb" pattern.

Hypersensitivity pneumonitis.   Hypersensitivity pneumonitis is a delayed-type hypersensitivity reaction to an inhaled or ingested allergen.[40,96,166]

Inhaled organic allergens such as those in moldy hay (farmer's lung) and bird droppings (pigeon breeder's lung) cause hypersensitivity pneumonitis in sensitized individuals. There are two clinical syndromes: an acute, recurrent illness and a chronic, progressive disease. The acute illness presents with fever and dyspnea. In these cases, the

FIGURE 5–15. Multifocal airspace filling. The chest radiograph in an injection drug user who presented with high fever but without pulmonary symptoms. Multiple ill-defined pulmonary opacities are seen throughout both lungs, which are characteristic of septic pulmonary emboli. His blood cultures grew *Staphylococcus aureus*.

FIGURE 5–16. Reticular interstitial pattern. The chest radiograph of a patient with cardiac disease who presented to the emergency department with progressive dyspnea. The initial diagnostic impression was interstitial pulmonary edema. The patient was taking amiodarone for malignant ventricular dysrhythmias (note the implanted automatic defibrillator). The lack of response to diuretics and the high-resolution CT pattern suggested that this was toxicity to amiodarone. The medication was stopped, and there was partial clearing over several weeks. *(Image contributed by Dr. Georgeann McGuinness, Department of Radiology, New York University.)*

chest radiograph is normal or may show fine interstitial or alveolar infiltrates. Chronic hypersensitivity pneumonitis causes progressive dyspnea, and the radiograph shows interstitial fibrosis.

The most common medication causing hypersensitivity pneumonitis is nitrofurantoin. Respiratory symptoms occur after taking the medication for 1 to 2 weeks. Other medications that may cause hypersensitivity pneumonitis include sulfonamides and penicillins.

Antineoplastics. Various chemotherapeutic agents, such as busulfan, bleomycin, cyclophosphamide, and methotrexate, cause pulmonary injury by their direct cytotoxic effect on alveolar cells.[39,65] The radiographic pattern is usually interstitial (reticular or nodular) but may include airspace filling or mixed patterns. The patient presents with dyspnea, fever, and pulmonary infiltrates that begin after several weeks of therapy. Other causes of these clinical and radiographic findings must be considered, including opportunistic infection, pulmonary carcinomatosis, pulmonary edema, and intraparenchymal hemorrhage. Symptoms usually resolve with discontinuation of the offending medication.

Amiodarone. Amiodarone toxicity causes phospholipid accumulation within alveolar cells and may result in pulmonary fibrosis. An interstitial radiographic pattern is seen, although airspace filling may also occur (see Fig. 5–16) (Chap. 63).

Particulates. Inhaled inorganic particulates, such as asbestos, silica, and coal dust, cause pneumoconiosis. This is a chronic interstitial lung disease characterized by interstitial fibrosis and loss of lung volume.[32,138,167,215] IV injection of illicit xenobiotics that have particulate contaminants, such as talc, causes a chronic interstitial lung disease known as talcosis.[1,55,212]

Pleural Disorders Asbestos-related calcified pleural plaques develop many years after asbestos exposure (Fig. 5–17). These lesions do not cause clinical symptoms and have only a minor association with malignancy and interstitial lung disease. Asbestos-related pleural plaques should not be called *asbestosis* because that term refers specifically to the interstitial lung disease caused by asbestos. Pleural plaques must be distinguished from mesotheliomas, which are not calcified, enlarge at a rapid rate, and erode into nearby structures such as the ribs.

A
B

FIGURE 5–17. (**A**) Calcified plaques typical of asbestos exposure are seen on the pleural surfaces of the lungs, diaphragm, and heart. The patient was asymptomatic; this was an incidental radiographic finding. (**B**) The computed tomography (CT) scan demonstrates that the opacities seen on the chest radiograph do not involve the lung itself. A lower thoracic image shows calcified pleural plaques (the diaphragmatic plaque is seen on the *right*). The CT confirms that there is no interstitial lung disease ("asbestosis").
FIGURE 5–18. Two patients with chest pain after cocaine use. (**A**) Pneumomediastinum after forceful inhalation while smoking "crack" cocaine. A fine white line representing the pleura elevated from the mediastinal structures is seen (*arrows*). The patient's chest pain resolved during a 24-hour period of observation. (**B**) Thoracic aortic dissection and rupture after cocaine use. The patient presented with chest pain radiating to the back. Chest radiography reveals a wide and indistinct aortic contour (*arrow*). *(Images contributed by the Toxicology Fellowship of the New York City Poison Center.)*

Pleural effusions occur with drug-induced systemic lupus erythematosus.[140] The medications most frequently implicated are procainamide, hydralazine, isoniazid, and methyldopa. The patient presents with fever as well as other symptoms of systemic lupus erythematosus.

Pneumothorax and pneumomediastinum are associated with illicit drug use. These complications are related to the route of administration rather than to the particular drug. Barotrauma associated with Valsalva maneuver or intense inhalation with breath holding during the smoking of "crack" cocaine or marijuana results in pneumomediastinum (Fig. 5–18A).[20,50,75,150] Pneumomediastinum is one cause of cocaine-related chest pain that can be diagnosed by chest radiography. Forceful vomiting after ingestion of syrup of ipecac or alcohol may produce a Mallory-Weiss syndrome, pneumomediastinum, and mediastinitis (Boerhaave syndrome).[220] Intravenous drug users who attempt to inject into the subclavian and internal jugular veins may cause a pneumothorax.[46]

Lymphadenopathy Phenytoin may cause drug-induced lymphoid hyperplasia with hilar lymphadenopathy.[140] Chronic beryllium exposure results in hilar lymphadenopathy that mimics sarcoidosis, with granulomatous changes in the lung parenchyma. Silicosis is associated with "eggshell" calcification of hilar lymph nodes.

Cardiovascular Abnormalities Dilated cardiomyopathy occurs in chronic alcoholism and exposure to cardiotoxic medications such as doxorubicin (Adriamycin). Enlargement of the cardiac silhouette may also be caused by a pericardial effusion, which may accompany drug-induced systemic lupus erythematosus. Aortic dissection is associated with use of cocaine and amphetamines.[66,75,114,152,162] The chest radiograph may show an enlarged or indistinct aortic knob and an ascending or descending aorta (Fig. 5–18B).

■ ABDOMINAL PROBLEMS

Abdominal imaging modalities include conventional radiography, CT, GI contrast studies, and angiography.[68] Conventional radiography is limited in its ability to detect most intraabdominal pathology because most pathologic processes involve soft tissue structures that are not well seen. Plain radiography readily visualizes gas in the abdomen and is therefore usable to diagnose pneumoperitoneum (free intraperitoneal air) and bowel distension caused by mechanical obstruction or diminished gut motility (adynamic ileus). Other abnormal gas collections, such as intramural gas associated with intestinal infarction, are seen infrequently (Table 5–4).[73,120,128,137,186]

Pneumoperitoneum GI perforation is diagnosed by seeing free intraperitoneal air under the diaphragm on an upright chest radiograph. Peptic ulcer perforation is associated with crack cocaine use.[2,29,107] Esophageal or gastric perforation (or tear) can be a complication of forceful emesis induced by syrup of ipecac or alcohol intoxication or attempted placement of a large-bore orogastric tube (Fig. 5–19).[220] Esophageal and gastric perforation may also occur after the ingestion of caustics such as iron, alkali, or acid.[103] Esophageal perforation causes pneumomediastinum and mediastinitis.

Obstruction and Ileus Both mechanical bowel obstruction and adynamic ileus (diminished gut motility) cause bowel distension. With mechanical obstruction, there is a greater amount of intestinal distension proximal to the obstruction and a relative paucity of gas and intestinal collapse distal to the obstruction. In adynamic ileus, the bowel distension is relatively uniform throughout the entire intestinal tract. On the upright abdominal radiograph, both mechanical obstruction and adynamic ileus show air-fluid levels. In mechanical obstruction, air-fluid levels are seen at different heights and produce a "stepladder" appearance.

Mechanical bowel obstruction may be caused by large intraluminal foreign bodies such as a body packer's packets or a medication bezoar.[64,197] Adynamic ileus may result from the use of opioids, anticholinergics, and tricyclic antidepressants (Fig. 5–20).[15,68] Because adynamic ileus is seen in many diseases, the radiographic finding of an ileus is not helpful diagnostically. When the distinction between obstruction and adynamic ileus cannot be made based on the abdominal radiographs, abdominal CT can clarify the diagnosis.[135]

TABLE 5–4. Plain Abdominal Radiography in Toxicologic Emergencies

Radiographic Finding	Xenobiotic
Pneumoperitoneum (hollow viscus perforation)	Caustics: Iron, alkali, acids Cocaine GI decontamination (ipecac, lavage tube)
Mechanical obstruction (intraluminal foreign body) Intestinal gastric outlet ⎫ Upper GI esophageal ⎭ series	Foreign-body ingestion: Body packer, enteric-coated pills (bezoar)
Ileus (diminished gut motility)	Opioids Anticholinergics Cyclic antidepressants Mesenteric ischemia caused by cocaine, oral contraceptives, cardioactive steroids, hypokalemia, hypomagnesemia
Intramural gas (intestinal infarction) Bowel wall thickening Hepatic portal venous gas (CT is more sensitive)	Cocaine Ergot alkaloids Oral contraceptives Calcium channel blockers Hypotension
Foreign-body ingestion	Iron pills Metals (As, Cs, Hg, K, Pb, Tl) Body packers and stuffers Bismuth subsalicylate Calcium carbonate Enteric-coated and sustained-release tablets Pica (calcareous clay).
FIGURE 5–20. Methadone maintenance therapy causing marked abdominal distension. The radiograph reveals striking large bowel dilatation, termed *colonic ileus*, caused by chronic opioid use. A similar radiographic picture is seen with anticholinergic poisoning. A contrast enema can clarify the diagnosis. *(Image contributed by Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)*
FIGURE 5–19. Gastrointestinal perforation after gastric lavage with a large-bore orogastric tube. The upright chest radiograph shows air under the right hemidiaphragm and pneumomediastinum (*arrows*). An esophagram with water-soluble contrast did not demonstrate the perforation. Laparotomy revealed perforation of the anterior wall of the stomach.

Mesenteric Ischemia In most patients with intestinal ischemia, plain abdominal radiographs show only a nonspecific or adynamic ileus pattern. In a small proportion of patients with ischemic bowel (5%), intramural gas is seen.[15] Rarely, gas is also seen in the hepatic portal venous system. CT is better able to detect signs of mesenteric ischemia, particularly bowel wall thickening.[14]

Intestinal ischemia and infarction may be caused by use of cocaine, other sympathomimetics, and the ergot alkaloids, which induce mesenteric vasoconstriction.[79,110,130] Calcium channel blocker overdoses cause splanchnic vasodilation and hypotension that may result in intestinal ischemia. Superior mesenteric vein thrombosis may be caused by hypercoagulability associated with chronic oral contraceptive use.

Gastrointestinal Hemorrhage and Hepatotoxicity Radiography is not usually helpful in the diagnosis of such common abdominal complications as GI bleeding and hepatotoxicity.

The now obsolete radiocontrast agent thorium dioxide (Thorotrast; thorium, atomic number 90) provides a unique example of pharmaceutical-induced hepatotoxicity. It was used as an angiographic contrast agent until 1947, when it was found to cause hepatic malignancies. The radioactive isotope of thorium has a half-life of 400 years. It accumulates within the reticuloendothelial system and remains there for the life of the patient. It had a characteristic radiographic appearance, with multiple punctate opacities in the liver,
FIGURE 5–21. An abdominal radiograph of a patient who had received thorium dioxide (Thorotrast) for a radiocontrast study many years previously. The spleen (*vertical white arrow*), liver (*horizontal black arrow*), and lymph nodes (*horizontal white arrow*) are demarcated by thorium retained in the reticuloendothelial system. (*Image contributed by Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.*)

spleen, and lymph nodes (Fig. 5–21). Patients who received thorium before its removal from the market may still present with hepatic malignancies.[18,204]

Contrast Esophagram and Upper Gastrointestinal Series Ingestion of a caustic may cause severe damage to the mucosal lining of the esophagus. This can be demonstrated by a contrast esophagram. However, in the acute setting, upper endoscopy should be performed rather than an esophagram because it provides more information about the extent of injury and prognosis.[111] In addition, administration of barium will coat the mucosa, making endoscopy difficult. For later evaluation, a contrast esophagram identifies mucosal defects, scarring, and stricture formation (Figs. 5–22 and 104–3).[129]

The choice of radiographic contrast agent (barium or water-soluble material) depends on the clinical situation. If the esophagus is severely strictured and there is risk of aspiration, barium should be used because water-soluble contrast material is damaging to the pulmonary parenchyma. If, on the other hand, esophageal or gastric perforation is suspected, water-soluble contrast is safer because extravasated barium is highly irritating to mediastinal and peritoneal tissues, but extravasated water-soluble contrast is gradually absorbed into the circulation.

Ingested foreign bodies may cause esophageal and gastric outlet obstruction. Esophageal obstruction because of a drug packet can be demonstrated by a contrast esophagram. Concretions of ingested material in the stomach may cause gastric outlet obstruction. This has been reported with potassium chloride tablets and enteric-coated aspirin.[11,185]

Abdominal Computed Tomography CT provides great anatomic definition of intraabdominal organs and plays an important role in the diagnosis of a wide variety of abdominal disorders. In most cases, both oral and IV contrast are administered. Oral contrast delineates the intestinal lumen. IV contrast is needed to reliably detect lesions in hepatic and splenic parenchyma, the kidneys, and the bowel wall.

Certain abdominal complications of poisonings are amenable to CT diagnosis. Intestinal ischemia causes bowel wall thickening; intramural hemorrhage; and at a later stage, intramural gas and hepatic portal venous gas.[14] Splenic infarction and splenic and psoas abscesses

A

B

FIGURE 5–22. (**A**) A barium swallow performed several days after ingestion of liquid lye shows intramural dissection and extravasation of barium with early stricture formation. (**B**) At 3 weeks postingestion, there is an absence of peristalsis, diffuse narrowing of the esophagus, and reduction in size of the fundus and antrum of the stomach as a result of scarring. (*Images contributed by Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.*)
A **B**

FIGURE 5–23. (**A**) Chest radiograph of a young drug abuser who used the supraclavicular approach for heroin injection. The large mass in the left chest was suspicious for a pseudoaneurysm. (**B**) An arch aortogram performed on the patient revealed a large pseudoaneurysm and hematoma subsequent to an arterial tear during attempted injection. Surgical repair was performed. (*Images contributed by Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital.*)

are complications of IV drug use that may be diagnosed on CT.[15] Radiopaque foreign substances such as intravenously injected elemental mercury may be detected and accurately localized by CT.[126] Radiolucent foreign bodies, such as a body packer's packets, may be detected by using enteric contrast.[83,85]

Vascular Lesions Angiography may detect such complications of injection drug use as venous thrombosis and arterial laceration causing pseudoaneurysm formation (Figs. 5–23 and 5–24). IV injection of amphetamine, cocaine, or ergotamine causes necrotizing angiitis that is associated with microaneurysms, segmental stenosis, and arterial thrombosis. These lesions are seen in the kidneys, small bowel, liver, pancreas, and cerebral circulation (Fig. 5–25).[34,161] Complications include aneurysm rupture and visceral infarction. Renal lesions cause severe hypertension and renal failure.[175]

■ NEUROLOGIC PROBLEMS

Diagnostic imaging studies have revolutionized the management of CNS disorders.[57,71] Both acute brain lesions and chronic degenerative changes can be detected (Table 5–5).[118] Some xenobiotics have a direct toxic effect on the CNS; others indirectly cause neurologic injury by causing hypoxia, hypotension, hypertension, cerebral vasoconstriction, head trauma, or infection.

Imaging Modalities CT can directly visualize brain tissue and many intracranial lesions.[70] CT is the imaging study of choice in the emergency setting because it readily detects acute intracranial hemorrhage as well as parenchymal lesions that are causing mass effect. CT is fast, widely available on an emergency basis, and can accommodate critical support and monitoring devices. Infusion of IV contrast further delineates intracerebral mass lesions such as tumors and abscesses.

MRI has largely supplanted CT in nonemergency neurodiagnosis. It offers better anatomic discrimination of brain tissues and areas of cerebral edema and demyelination. However, MRI is no better than CT
FIGURE 5–24. Venogram of a 50-year-old patient who routinely injected heroin into his groin. Occlusion of the femoral vein (*black arrow*) with diffuse aneurysmal dilation (*small arrow*) and extensive collaterals are shown. Incidental radiopaque materials are noted in the right buttock (*double arrow*). By history, this represents either bismuth or arsenicals he received as antisyphilitic therapy. (*Image contributed by Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital.*)
FIGURE 5–25. A selective renal angiogram in an injection methamphetamine user demonstrating multiple small and large aneurysms (*arrows*). *(Image contributed by Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital Center.)*

FIGURE 5–26. Subarachnoid hemorrhage after intravenous cocaine use. The patient had sudden severe headache followed by a generalized seizure. Extensive hemorrhage is seen surrounding the midbrain (*white arrows*) and in the right Sylvian fissure (*black arrow*). Angiography revealed an aneurysm at the origin of the right middle cerebral artery.

in detecting acute blood collections or mass lesions. In the emergency setting, the disadvantages of MRI outweigh its strengths. MRI is usually not readily available on an emergency basis, image acquisition time is long, and critical care supportive and monitoring devices are often incompatible with MR scanning machines.[121]

Nuclear scintigraphy that uses CT technology (SPECT and PET) is being used as a tool to elucidate functional characteristics of the CNS. Examples include both immediate and long-term effects of various xenobiotics on regional brain metabolism, blood flow, and neurotransmitter function.[115,154,207]

Emergency Head CT Scanning An emergency noncontrast head CT scan is obtained to detect acute intracranial hemorrhage and focal brain lesions causing cerebral edema and mass effect. Patients with these lesions present with focal neurologic deficits, seizures, headache, or altered mental status. Toxicologic causes of intraparenchymal and subarachnoid hemorrhage include cocaine and other sympathomimetics (Fig. 5–26).[113,117] Cocaine-induced vasospasm may cause ischemic infarction, although this is not well seen by CT until 6 to 24 or more hours after onset of the neurologic deficit (Fig. 5–27). Drug-induced CNS depression, most commonly ethanol intoxication, predisposes the patient to head

TABLE 5–5. Head CT (Noncontrast) in Toxicologic Emergencies

CT Finding	Brain Lesion	Xenobiotic Etiology
Hemorrhage	Intraparenchymal hemorrhage Subarachnoid hemorrhage	Sympathomimetics: cocaine ("crack"), amphetamine, phenylpropanolamine, phencyclidine, ephedrine, pseudoephedrine
		Mycotic aneurysm rupture (IDU)
	Subdural hematoma	Trauma secondary to ethanol, sedative-hypnotics, seizures
		Anticoagulants
Brain lucencies	Basal ganglia focal necrosis (also subcortical white matter lucencies)	Carbon monoxide, cyanide, hydrogen sulfide, methanol, manganese
	Stroke: Vasoconstriction	Sympathomimetics: cocaine ("crack"), amphetamine, phenylpropanolamine, phencyclidine, ephedrine, pseudoephedrine, ergotamine
	Mass lesion: tumor, abscess	Septic emboli, AIDS-related CNS toxoplasmosis or lymphoma
Loss of brain tissue	Atrophy: Cerebral, cerebellar	Alcoholism, toluene

CNS, central nervous system; IDU, injection drug use.

FIGURE 5–27. Acute stroke confirmed by diffusion-weighted magnetic resonance image (MRI). A 39-year-old man presented with left facial weakness that began 3 hours earlier after smoking crack cocaine. He also complained of left arm "tingling" but had a normal examination. A stat noncontrast computed tomography (CT) scan was obtained that was interpreted as normal (**A**), although in retrospect there was subtle loss of the normal gray/white differentiation (*arrow*). MRI was obtained to confirm that the facial palsy was a stroke and not a peripheral seventh cranial nerve palsy. Standard MRI sequence (T1-weighted, T2 weighted, and FLAIR) were normal in this early ischemic lesion (**B** and **C**). Diffusion-weighed imaging (DWI) is able to show such early ischemic change—cytotoxic (intracellular) edema (**D**). The patient's facial paresis improved but did not entirely resolve. A repeat CT scan 2 days later showed an evolving (subacute) infarction with vasogenic edema (**E**). Infarction was presumably due to vasospasm because no carotid artery lesion or cardiac source of embolism was found. (*From Schwartz DT:* Emergency Radiology: Case Studies*, New York, McGraw-Hill; 2008:517, with permission.*)

trauma, which may result in a subdural hematoma or cerebral contusion (Fig. 5-28). Toxicologic causes of intracerebral mass lesions include septic emboli complicating injection drug use and HIV-associated CNS toxoplasmosis and lymphoma (Fig. 5-29).[19,74,79,149] On a contrast CT, such tumors and focal infections exhibit a pattern of "ring enhancement."

Xenobiotic-Mediated Neurodegenerative Disorders A number of xenobiotics directly damage brain tissue, producing morphologic changes that may be detectable using CT and MRI. Such changes include generalized atrophy, focal areas of neuronal loss, demyelinization, and cerebral edema. Imaging abnormalities may help

establish a diagnosis or predict prognosis in a patient with neurologic dysfunction after a xenobiotic exposure. In some cases, the imaging abnormality will suggest a toxicologic diagnosis in a patient with a neurologic disorder in whom a xenobiotic exposure was not suspected clinically.[4,13,57,100,104,155,165,214]

Atrophy Ethanol is the most widely used neurotoxin. With long-term ethanol use, there is a widespread loss of neurons and resultant atrophy. In some alcoholics, the loss of brain tissue is especially prominent in the cerebellum. However, the amount of cerebral or cerebellar atrophy does not always correlate with the extent of cognitive impairment or gait disturbance.[42,67,84,86,106,209,211] Chronic solvent exposure, such as
FIGURE 5–28. An acute subdural hematoma in an alcoholic patient after an alcohol binge. A crescent-shaped blood collection is seen between the right cerebral convexity and the inner table of the skull (*arrow*).

FIGURE 5–29. An injection drug user with ring-enhancing intracerebral lesions. The patient presented with fever and altered mental status. In this patient, the lesions represent multiple septic emboli complicating acute *Staphylococcus aureus* bacterial endocarditis. A similar ring-enhancing appearance is seen with lesions caused by toxoplasmosis or primary central nervous system lymphoma in patients with AIDS. This patient was HIV negative.
FIGURE 5–30. A head computed tomography scan of a patient with mental status changes after carbon monoxide poisoning. The scan shows characteristic bilateral symmetrical lucencies of the globus pallidus (*arrows*). *(Image contributed by Dr. Paul Blackburn, Maricopa Medical Center, Arizona.)*

to toluene (occupational and illicit use), also causes diffuse cerebral atrophy.[93,171]

Focal Degenerative Lesions Carbon monoxide poisoning produces focal degenerative lesions in the brain. In about half of patients with severe neurologic dysfunction after carbon monoxide poisoning, CT scans show bilateral symmetric lucencies in the basal ganglia, particularly the globus pallidus (Figs. 5-30 and 125–1).[27,94,100,141,155,158,159,177,178,182,200,206] The basal ganglia are especially sensitive to hypoxic damage because of their limited blood supply and high metabolic requirements. Subcortical white matter lesions also occur after carbon monoxide poisoning. Although less frequent than lesions of the basal ganglia, white matter lesions are more clearly associated with a poor neurologic outcome. MRI is more sensitive than CT at detecting these white matter abnormalities.[27,57,104,159,200]

Basal ganglion lucencies, white matter lesions, and atrophy are caused by other xenobiotics such as methanol,[12,41,69,82,142,173] ethylene glycol, cyanide,[58,139] hydrogen sulfide, inorganic and organic mercury,[131] manganese,[13,190] heroin,[104,108] barbiturates, chemotherapeutic agents, solvents such as toluene,[57,93,17150,83,156] and podophyllin.[28,144] Nontoxicologic disorders may cause similar imaging abnormalities, including hypoxia, hypoglycemia, and infectious encephalitis.[82,88]

Nuclear Scintigraphy Whereas both CT and MRI display cerebral anatomy, nuclear medicine studies provide functional information about the brain. Nuclear scintigraphy uses radioactive isotopes that are bound to carrier molecules (ligands). The choice of ligand depends

on the biologic function being studied. Brain cells take up the radiolabeled ligand in proportion to their physiologic activity or the regional blood flow. The radioactive emission from the isotope is detected by a scintigraphic camera, which produces an image showing the quantity and distribution of tracer. Better anatomic detail is provided by using CT techniques to generate cross-sectional images. There are two such technologies: SPECT and PET. These imaging modalities have been used in the research and clinical settings to study the neurologic effects of particular xenobiotics and the mechanisms of xenobiotic-induced neurologic dysfunction.

SPECT uses conventional isotopes such as technetium-99m and iodine-123.[115] These isotopes are bound to ligands that are taken up in the brain in proportion to regional blood flow, reflecting the local metabolic rate.

PET uses radioactive isotopes of biologic elements such as carbon-11, oxygen-15, nitrogen-13, and fluoride-18 (a substitute for hydrogen).[154] These radioisotopes have very short half-lives so that PET scanning requires an onsite cyclotron to produce the isotope. The isotopes are incorporated into molecules such as glucose, oxygen, water, various neurotransmitters, and drugs. Labeled glucose is taken up in proportion to the local metabolic rate for glucose. Uptake of labeled oxygen demonstrates the local metabolic rate for oxygen. Labeled neurotransmitters generate images reflecting their concentration and distribution within the brain.

Both PET and SPECT have been used to study the effects of various xenobiotics on cerebral function. For example, although both CT and MRI can detect cerebellar atrophy in chronic alcoholics, there is a poor correlation between the magnitude of cerebellar atrophy and the clinical signs of cerebellar dysfunction. PET scans may demonstrate diminished cerebellar metabolic rate for glucose, which correlates more accurately with the patient's clinical status.[72,209]

In patients with severe neurologic dysfunction after carbon monoxide poisoning, SPECT regional blood flow measurements show diffuse hypometabolism in the frontal cortex.[30] In one patient, severe perfusion abnormalities improved slightly over several months in proportion to the patient's gradual clinical improvement.[98] In another patient treated with hyperbaric oxygen, a SPECT scan revealed increased blood flow in the frontal lobes, although the blood flow still remained significantly less than normal.[124]

In patients who chronically use cocaine, SPECT blood flow scintigraphy demonstrates focal cortical perfusion defects. The extent of these perfusion defects correlates with the frequency of drug use. Focal perfusion defects probably represent local vasculitis or small areas of infarction.[92,202] PET scanning has been used to demonstrate the effects of cocaine on cerebral blood flow and regional glucose metabolism. PET neurotransmitter studies show promise in elucidating potential mechanisms of action of cocaine. Using radiolabeled dopamine analogs, downregulation of dopamine (D_2) receptors has been noted after a cocaine binge. This finding may be responsible for cocaine craving that occurs during cocaine withdrawal. Using ^{11}C-labeled cocaine, uptake of cocaine can be demonstrated in the basal ganglia, a region rich in dopamine receptors.[207]

Much has been learned about these imaging modalities, and initial applications can be applied to patient care. These imaging modalities are capable of demonstrating abnormalities in many patients with xenobiotic exposures, although other patients with significant cerebral dysfunction have normal studies.

SUMMARY

This chapter has highlighted a variety of situations in which diagnostic imaging studies are useful in toxicologic emergencies. Imaging can be an important tool in establishing a diagnosis, assisting in the treatment of patients, and detecting complications of a toxicologic emergency. The imaging modalities include plain radiography, CT, enteric and intravascular contrast studies, nuclear scintigraphy, and ultrasonography. However, effective use of a diagnostic test requires a firm understanding of the clinical situations in which each test can be useful, knowledge of the capabilities and limitations of the tests, and how the results should be applied to the care of an individual patient.

CHAPTER 6
LABORATORY PRINCIPLES

Petrie M. Rainey

Medical toxicology addresses harm caused by acute and chronic exposures to excessive amounts of a xenobiotic. The management of toxicologic emergencies is a major component of medical toxicology. Detecting the presence or measuring the concentration of xenobiotics and other acutely toxic xenobiotics is the primary activity of the analytical toxicology laboratory. Such testing is closely intertwined with therapeutic drug monitoring, in which drug concentrations are measured as an aid to optimizing drug dosing regimens. In addition to drugs, measurements may be made of a variety of xenobiotics such as pesticides, herbicides, and poisons found in plants, animals, or the environment. The toxicology laboratory is frequently viewed in much the same way as other clinical laboratories often are—as a "black box" that converts orders into test results. Because toxicology testing volumes are relatively low and menus are extensive, testing is not as highly automated as in other clinical laboratories. Many results may be "hand-made the old-fashioned way." The downside of this may be somewhat longer turnaround times. But the upside is that toxicology laboratory personnel have the incentive and flexibility to develop substantial expertise. Medical toxicologists who understand how toxicology testing is done will be able to apply the results more effectively.

RECOMMENDATIONS FOR ROUTINELY AVAILABLE TOXICOLOGY TESTS

Despite a common focus, there is remarkable variability in the range of tests offered by analytical toxicology laboratories. Test menus may range from once-daily testing for routinely monitored drugs and common drugs of abuse to around-the-clock availability of a broad array of assays with the theoretical potential to identify several thousand compounds. Recently, consensus documents have been developed that recommend tests that should be available to support management of poisoned patients presenting to emergency departments.[22,37] Although they make specific recommendations, these guidelines recognize that no set of recommendations will be universally appropriate and note that it is impossible for a clinical laboratory to offer a full spectrum of toxicology testing in real time.

Decisions on the menu of tests to be offered by any specific laboratory should be decided by the laboratory director in consultation with the medical toxicologists and other clinicians who will use the service and should take into account regional patterns of use of licit and illicit drugs and environmental toxins, as well as resources available and competing priorities.

The recommendations in Table 6–1 were developed by the National Academy of Clinical Biochemists (NACB) from a consensus process that involved clinical biochemists, medical toxicologists, forensic toxicologists, and emergency physicians.[37] Although these tests should be readily available in the clinical laboratory, they should not be considered as a test panel for possibly poisoned patients. As with all laboratory tests, they should be selectively ordered based on the patient's clinical presentation or other relevant factors. Suggested turnaround time for reporting serum concentrations of the drugs listed in Table 6-1 was 1 hour or less. Quantitative tests for serum methanol and ethylene glycol were also

recommended, with the reservations that these tests are not needed in all settings and that a realistic turnaround time is 2 to 4 hours. Serum cholinesterase testing with a turnaround time of less than 4 hours was proposed by some participants but did not achieve a general consensus. In the United Kingdom, the National Poisons Information Service and the Association of Clinical Biochemists have recommended a nearly identical list of tests, omitting the anticonvulsants.[22]

Although the consensus for the menu of serum assays was generally excellent, there was less agreement as to the need for qualitative urine assays. This was largely a result of issues of poor sensitivity and specificity, poor correlation with clinical effects, and infrequent alteration of patient management. Although these were potential issues for all of the urine drug tests, they led to explicit omission of tests for tetrahydrocannabinol (THC) and benzodiazepines from the recommended list despite their widespread use. THC results were thought to have little value in managing patients with acute problems, and tests for benzodiazepines were believed to have an inadequate spectrum of detection. Testing for amphetamines, propoxyphene, and phencyclidine were only recommended in areas where use was prevalent. It was also suggested that diagnosis of tricyclic antidepressant (TCA) toxicity not be based solely on the results of a urine screening immunoassay because a number of other drugs may cross-react. The significance of TCA results should always be correlated with electrocardiographic and clinical findings. The only urine test included in the United Kingdom guidelines was a spot test for paraquat.[22] Paraquat testing was omitted in the NACB guidelines because of a very low incidence of paraquat exposure in North America.[37]

The NACB guidelines also recommend the availability of broad-spectrum toxicology testing with the tests in Table 6–1 to be used for selected patients with presentations compatible with poisoning but who remain undiagnosed and who are not improving. In general, such testing should not be ordered until the patient is stabilized and input has been obtained from a medical toxicologist or poison center. This second level of testing may be provided directly by the local laboratory or by referral to a reference laboratory or a regional toxicology center.

Many physicians order a broad-spectrum toxicology screen on a poisoned patient if one is readily available, but only approximately 2% of clinical laboratories provide relatively comprehensive toxicology services (as estimated from proficiency testing data[3]). Although broad-spectrum toxicology screens can identify most drugs present in overdosed patients,[12] the results of broad-spectrum screens infrequently alter management or outcomes.[11,12,15,21,24,25]

The extent to which the NACB recommendations are being followed may be estimated from the numbers of laboratories participating in various types of proficiency testing. Result summaries from the 2007 series of proficiency surveys administered by the College of American Pathologists suggest that quantitative assays for acetaminophen, carbamazepine, carboxyhemoglobin, digoxin, ethanol, iron, lithium, methemoglobin, phenobarbital, salicylate, theophylline, and valproic acid are available in 50% to 60% of laboratories that offer routine clinical testing, as are screening tests for drugs of abuse in urine. About one in four laboratories offers measurement of transferrin or iron-binding capacity.[3]

About 2% of laboratories participated in proficiency testing for a full range of toxicology services. These full-service laboratories typically offer quantitative assays for additional therapeutic drugs, particularly TCAs, as well as assays that are designated as broad-spectrum or comprehensive toxicology screens. About two-thirds of these full-service toxicology laboratories offer testing for volatile alcohols other than ethanol.[3]

Although relatively few laboratories offer a wide range of in-house testing, most laboratories send out specimens to reference laboratories that offer large toxicology menus. The turnaround time for such

TABLE 6–1. Toxicology Assays Recommended by the National Academy of Clinical Biochemists

Quantitative Serum Assays	Qualitative Urine Assays
Acetaminophen	Amphetamines
Carbamazepine	Barbiturates
Cooximetry (carboxyhemoglobin, methemoglobin, oxygen saturation)	Cocaine
	Opiates
Digoxin	Propoxyphene
Ethanol	Phencyclidine
Iron (plus transferrin or iron-binding capacity)	Tricyclic antidepressants
Lithium	
Phenobarbital	
Salicylate	
Theophylline	
Valproic acid	

"send-out" tests ranges from a few hours to several days, depending on the proximity of the reference laboratory and the type of test requested.

Even in full-service toxicology laboratories, the test menu may vary substantially from institution to institution. Larger laboratories typically offer one or more broad-spectrum testing choices, often referred to as "tox screens." There is as much variety in the range of xenobiotics detected by various toxicologic screens as there is in the total menu of toxicologic tests. Routinely available tests are usually listed in a printed or online laboratory manual. Laboratories with comprehensive services may be able to offer ad hoc chromatographic assays for additional xenobiotics that are not listed. Testing that is sent to a reference laboratory is often not listed in the laboratory manual. The best way to determine if a particular xenobiotic can be detected or quantitated is to ask the director or supervisor of the toxicology or clinical chemistry section because laboratory clerical staff may only be aware of tests listed in the manual.

USING THE TOXICOLOGY LABORATORY

There are many reasons for toxicologic testing. The most common function is to confirm or exclude toxic exposures suspected from a patient's history and physical examination results. A laboratory result provides a level of confidence not readily obtained otherwise and may avert other unproductive diagnostic investigations driven by the desire for completeness and medical certainty. Testing increased diagnostic certainty in more than half of cases,[2,11,15] and in some instances, a diagnosis may be based primarily on the results of testing. This can be particularly important in poisonings with xenobiotics having delayed onset of clinical toxicity, such as acetaminophen, or in patients with ingestion of multiple xenobiotics. In these instances, characteristic clinical findings may not have developed at the time of presentation or may be obscured or altered by the effects of coingestants.

Testing can provide two key parameters that will have a major impact on the clinical course, namely, the xenobiotic involved and the intensity of the exposure. This information can assist in triage decisions, such as whether to admit a patient or to observe the individual

for expectant discharge. Serum concentrations can facilitate decisions to use specific antidotes or specific interventions to hasten elimination. Well-defined exposure information can also facilitate provision of optimum advice by poison centers, whose personnel do not have the ability to make decisions based on direct observation of the patient. Serum concentrations can be used to determine when to institute and when to terminate interventions such as hemodialysis or antidote administration and can support the decision to transfer the patient from intensive care or discharge him or her from the hospital. Finally, positive findings for ethanol or drugs of abuse in trauma patients may serve as an indication for substance use intervention as well as a risk marker for the likelihood of future trauma.[11]

The confirmation of a clinical diagnosis of poisoning provides an important feedback function, whereby the physician may evaluate the diagnosis against a "gold standard." Another important benefit is reassurance (e.g., reassurance that an unintentional ingestion did not result in absorption of a toxic amount of xenobiotic). Such reassurance may allow a physician to avoid spending excessive time with patients who are relatively stable. It may also allow admissions to be made and interventions undertaken more confidently and efficiently than would be likely based solely on a clinical diagnosis. Testing may also be indicated for medicolegal reasons. Diagnoses with legal implications should be established "beyond a reasonable doubt." Although testing for illicit drugs is often done for medical purposes, it is almost impossible to dissociate such testing from legal considerations. Documentation is also important in malevolent poisonings, intentional or unintentional child abuse or neglect involving therapeutic or illicit drugs, and pharmacologic elder abuse. When test results may be used to document criminal activity, consideration should be given to having testing done in a forensic laboratory maintaining a full chain of custody. This is usually done in conjunction with a law enforcement request or protocol (e.g., drug-facilitated sexual assault) and not usually for medical purposes.

The documentation function is also important outside the medicolegal arena. Results of testing in a central laboratory are almost invariably entered into the patient's medical record and may often provide definitive confirmation of a problem. Documentation also has an additional importance that goes beyond the individual cases. Medical toxicology does not lend itself readily to experimental human investigation. Much of toxicologic knowledge has been derived from experiments of nature recorded in case reports and case series. Hard data, such as xenobiotic concentrations, may serve as key quantitative variables in summarizing and correlating data. That laboratory results can be reliably and generally easily found in the medical record makes them particularly valuable in retrospective reviews. A related service that the toxicology laboratory may provide is testing in support of experimental investigations.

The key to optimum use of the toxicology laboratory is communication. This begins with learning the laboratory's capabilities, including what xenobiotics are on its menus, which ones can be measured and which merely detected, and what are anticipated turnaround times. For screening assays, one should know which xenobiotics are routinely detected; which ones can be detected if specifically requested; and which ones cannot be detected, even when present at concentrations that result in toxicity.

A key item is learning which specimens are appropriate for the test requested. A general rule is that quantitative tests require serum (red stopper) or heparinized plasma (green stopper) but not ethylenediamine tetraacetic acid (EDTA) plasma (lavender stopper) or citrate plasma (light-blue stopper). EDTA and citrate bind divalent cations that may serve as cofactors for enzymes used as reagents or labels in various assays. Additionally, liquid EDTA and citrate anticoagulants dilute the specimen. Serum or plasma separator tubes (identifiable by the separator gel in the tube) are also acceptable, provided that

prolonged gel contact before testing is avoided. Some hydrophobic drugs may diffuse slowly into the gel, leading to falsely low results after several hours. A random, clean urine specimen is generally preferred for toxicology screens because the higher drug concentrations usually found in urine can compensate for the lower sensitivity of the broadly focused screening techniques. A urine specimen of 20 mL is usually optimal. Requirements for all specimens may vary from laboratory to laboratory.

When making a request for a screening test, an important—and often overlooked—item of communication is specifying any xenobiotics that are particularly suspected. This knowledge allows the laboratory to set up the tests for those drugs first and possibly adjust the protocols to increase sensitivity or specificity. This may save an hour or more in the time needed to receive the critical information.

Consultation with the laboratory regarding puzzling cases or unusual needs may allow consensus on an effective and feasible testing strategy. The full capabilities of a toxicology laboratory are often not apparent from published lists of tests available. Most full-service laboratories devote substantial efforts to meeting reasonable requests and often provide consultations at no charge.

The laboratory should also be contacted whenever results appear inconsistent or discrepant with the clinical presentation. The most common causes for this are interferences and preanalytical errors. Analytical interference is caused by materials in the specimen that interfere with the measurement process, leading to falsely high or low results. For example, hemoglobin may interfere with a variety of spectrophotometric tests by absorbing the light used to make the measurement. Preanalytical errors are events that occur before laboratory analysis and produce incorrect or misleading results, such as mislabeling, specimen contamination by intravenous solutions, and incorrect collection time or technique. The laboratory will be familiar with the common sources of discrepant results. If a discrepancy is the result of laboratory error, it is critical that the laboratory be informed so that steps can be taken to understand the source of the error and avoid a recurrence.

METHODS USED IN THE TOXICOLOGY LABORATORY

Most tests in the toxicology laboratory are directed toward the identification or quantitation of xenobiotics. The primary techniques used include spot tests, spectrochemical tests, immunoassays, and chromatographic techniques. Mass spectrometry may also be used, usually in conjunction with gas chromatography (GS) or liquid chromatography. Table 6–2 compares the basic features of these methodologies. Other methodologies include ion-selective electrode measurements of lithium, atomic absorption spectroscopy or inductively coupled plasma mass spectroscopy for lithium and heavy metals, and anodic stripping methods for heavy metals. Many adjunctive tests, including glucose, creatinine, electrolytes, osmolality, metabolic products, and enzyme activities, may also be useful in the management of poisoned patients. The focus here is on the major methods used for directly measuring xenobiotics.

■ SPOT TESTS

The simplest tests are spot tests. These rely on the rapid reaction of a xenobiotic with a chemical reagent to produce a colored product (e.g., the formation of a colored complex between salicylate and ferric ions). Because the reagents may cause precipitation of serum proteins, spot tests are more commonly performed on urine specimens or gastric aspirates. Such tests were once a mainstay of toxicologic testing. Because of the poor selectivity of chemical reagents, as well as substantial variability in visual interpretation, these assays suffer from fairly frequent false-positive results and occasional false-negative results. As more sensitive and more specific methods have become available, spot tests have waned in popularity. Only a few are still in use, largely to fill gaps in testing menus or to rapidly exclude some common poisonings. The introduction of point-of-care testing devices that have better sensitivity and specificity and are designed to facilitate compliance with regulations is likely to further reduce the use of spot tests.

■ SPECTROCHEMICAL TESTS

Spectrochemical tests are sophisticated versions of spot tests. They also rely on a chemical reaction to form a light-absorbing substance. They differ in that the reaction conditions and reagent concentrations are carefully controlled and the amount of light absorbed is quantitatively measured at one or more specific wavelengths. The use of specific wavelengths enhances the sensitivity and, particularly, the specificity of the detection, and the measurement of the amount of light absorbed under controlled conditions allows quantitation of the substance.

When an analyte is intrinsically light absorbing, no reaction may be necessary. Cooximetry (also known as hemoximetry) represents

TABLE 6–2. Relative Comparison of Toxicology Methods

Method	Sensitivity	Specificity	Quantitation	Analyte Range	Speed	Cost
Spot test	+	±	No	Few	Fast	$

$ = very low
$$$$ = very high cost

a sophisticated application of spectrophotometry to the measurement of various forms of hemoglobin in a hemolyzed blood sample. Measurement of light absorbance at multiple wavelengths allows several hemoglobin species to be simultaneously quantitated. For mathematical reasons, the number of wavelengths used must be greater than the number of different types of hemoglobin present. This is why classic pulse oximetry, which uses only two wavelengths, yields spurious results in the presence of significant amounts of methemoglobin or carboxyhemoglobin (Chaps. 21, 125, and 127).

Most analytes are neither as deeply colored nor as highly concentrated as hemoglobin species. Their detection requires the generation of an intensely light-absorbing product, as is done in spot tests. The difference between a spot test and a spectrochemical one lies in whether the colored product is visually observed or quantitatively measured in a spectrophotometer. Because spectrophotometers can also measure ultraviolet and infrared light, it is not necessary for the product to have a visible color. Early spectrochemical assays typically measured the absorbance after conversion of all of the analyte to the light-absorbing product. Modern assays usually use rate spectrophotometry, taking multiple absorbance measurements over time to determine the rate of change in light absorbance as the reaction proceeds. During the initial phase of the reaction, this rate is constant and proportional to the initial concentration of the analyte. This significantly reduces the time needed to obtain a result because it is not necessary for the reaction to go to completion first, and it allows the averaging of multiple measurements, improving precision. Furthermore, it is unaffected by nonreacting substances that absorb light at the test wavelength because the absorbance of the nonreacting substances is constant and does not contribute to the rate of change in the absorbance.

Rate spectrophotometry remains subject to interference by substances that react to produce a light-absorbing product, thereby falsely increasing the apparent concentration. Substances that inhibit the assay reaction or that consume reagents without producing a light-absorbing product give falsely low results. For example, ascorbic acid produces negative interference in many spectrophotometric assays that use oxidation reactions to generate colored products.

Cooximetry is relatively free of interferences because the concentrations of the hemoglobins are so much higher than other substances in the blood. However, the presence of intensely colored substances (e.g., methylene blue) may cause spurious increases or decreases in the apparent percentages of the hemoglobins. Modern instruments are often able to recognize a significantly atypical pattern of absorbance and generate an error message in addition to or instead of a result.

One way to improve the selectivity of a spectrochemical assay is to increase the selectivity of the reaction that generates the light-absorbing product. Enzymes, which can catalyze highly selective reactions, are often used for this purpose. For example, many assays for ethanol use alcohol dehydrogenase to catalyze the oxidation of ethanol to acetaldehyde, with concomitant reduction of the cofactor NAD^+ (oxidized form of nicotinamide adenine dinucleotide) to NADH (reduced form of nicotinamide adenine dinucleotide). The initial rate of increase in light absorption produced by the conversion of NAD^+ to NADH is proportional to the concentration of ethanol. Although other alcohols, such as isopropanol and methanol, can also be oxidized by alcohol dehydrogenase, they are much poorer substrates with low rates of reaction and correspondingly low levels of interference.

Many other enzymatic assays also rely on measuring the change in light absorption at 340 nm when NAD^+ is converted to NADH or vice versa. These include enzymatic assays for ethylene glycol, as well as some enzyme-linked immunoassays, such as EMIT (enzyme-multiplied immunoassay technique) assays. All such assays are potentially subject to interference by specimens with high concentrations of lactate. Lactate dehydrogenase, which is naturally present in serum, will oxidize this lactate to pyruvate if NAD^+ becomes available for simultaneous reduction to NADH. When a serum specimen with high lactate is mixed with assay reagents that contain NAD^+, oxidation of the lactate contributes to the total rate of NADH production. The increased rate of NADH production results in a false increase in the measured concentration of the target analyte.

■ IMMUNOASSAYS

The need to measure very low concentrations of an analyte with a high degree of specificity led to the development of immunoassays. The combination of high affinity and high selectivity makes antibodies excellent assay reagents. There are two common types of immunoassays: noncompetitive and competitive. In noncompetitive immunoassays, the analyte is sandwiched between two antibodies, each of which recognizes a different epitope on the analyte. In competitive immunoassays, analyte from the patient's specimen competes for a limited number of antibody binding sites with a labeled version of the analyte provided in the reaction mixture. Because most drugs are too small to have two distinct antibody binding sites, drug immunoassays are usually competitive.

In competitive immunoassays, increasing the concentration of xenobiotic in the specimen results in increased displacement of labeled xenobiotic from the antibodies. The amount of xenobiotic in the specimen can be determined by measuring either the amount of label remaining bound to the assay antibodies or the amount of label free in solution. In the earliest immunoassays, the label was a radioisotope, typically iodine-125, tritium, or carbon-14. The bound and free radioactivity were physically separated, for example, by using a second antibody to cross-link and precipitate the assay antibody, along with its bound radioactivity (Fig. 6–1) or by adsorbing the free label with activated charcoal. Today, radioimmunoassays are relatively uncommon because of problems associated with handling and disposal of radioactivity. They are primarily used for xenobiotics with insufficient demand to justify the development costs of more sophisticated nonisotopic assays.

Nonisotopic immunoassays are currently the most widely used methodologies for the measurement of drugs. They offer high selectivity and good precision and are readily adapted to automated analyzers, thereby decreasing both the cost and the turnaround time of the assays. The effort involved in developing these assays is substantial. Accordingly, the xenobiotics for which immunoassays are available are limited to those for which there is a high demand, such as widely monitored therapeutic drugs and the drugs of abuse included in workplace drug screening. However, after assay development is completed, production costs are relatively low, allowing the tests to be widely distributed at reasonable prices.

The most widely used nonisotopic drug immunoassays are in the category of homogenous immunoassays. Homogenous immunoassays measure differences in the properties of bound and free labels, rather than directly measuring one or the other after their physical separation. Avoiding a separation step allows homogenous immunoassays to be readily adapted to automated analysis. Homogenous techniques that are in wide use include EMIT (Fig. 6–2), kinetic inhibition of microparticles in solution (KIMS), cloned enzyme donor immunoassay (CEDIA), and fluorescence polarization immunoassay (FPIA).

Many of the newest automated immunoassays are again using physical separation techniques. In these assays, the detection antibody is physically attached to a solid support, and separation occurs by a simple wash step. This wash step removes the patient's serum along with many potentially interfering substances. Newer solid supports
FIGURE 6–1. Competitive radioimmunoassay. (**A**) No drug from the specimen is present to displace the I[125]-labeled drug. Adding the cross-linking antibody precipitates the assay antibody, along with high amounts of bound radioactivity. (**B**) Unlabeled drug in the specimen displaces some of the labeled drug. The displaced label is left in solution when the cross-linking antibody is added, resulting in less radioactivity in the precipitate.

FIGURE 6–2. Enzyme-multiplied immunoassay technique (EMIT) immunoassay. The drug to be measured is labeled by being attached to the enzyme glucose-6-phosphate dehydrogenase (G6PD) near the active site. (**A**) Binding of the enzyme-labeled drug to the assay antibody blocks the active site, inhibiting conversion of NAD+ (oxidized form of nicotinamide adenine dinucleotide) to NADH (reduced form of nicotinamide adenine dinucleotide). (**B**) Unlabeled drug from the specimen can displace the drug-enzyme conjugate from the antibody, thereby unblocking the active site and increasing the rate of reaction.

consist of fine glass fibers or latex microparticles. These have very high total surface areas that allow for rapid equilibration and short assay times. Older assays of this type used antibodies bound to large plastic beads or wells of microtiter plates and required long incubation steps because of substantial times required for diffusion of the reactants to the antibodies.

Fig. 6–3 shows a schematic magnetic microparticle enzyme-labeled chemiluminescent competitive immunoassay. A single enzyme label can generate many photons, allowing high signal amplification. Coupled with a background luminescence that is essentially zero, such assays can measure concentrations below the nanomolar level. Many variations of this approach are in use. Enzyme substrates may be used that result in fluorescent or colored products. Enzymes other than alkaline phosphatase may be used as labels, or non-enzymatic fluorescent, chemiluminescent, or electroluminescent labels may be used. Non-magnetic microparticles may be captured in glass fiber filters

during the washing and signal generation steps. These new techniques are readily automated and have higher sensitivities than homogenous immunoassays.

Microparticle capture assays are a type of competitive immunoassays that have become very popular, especially for urine drug-screening tests. The use of either latex or colloidal gold colored microparticles because the label enables the result to be read visually as the presence or absence of a colored band, with no special instrumentation required. Competitive binding occurs as the assay mixture is drawn by capillary action through a porous membrane. This design feature is responsible for alternate names for the technique: lateral flow immunoassay or immunochromatography.

The simplest design uses an antidrug antibody bound to colored microparticles and a capture zone consisting of immobilized drug

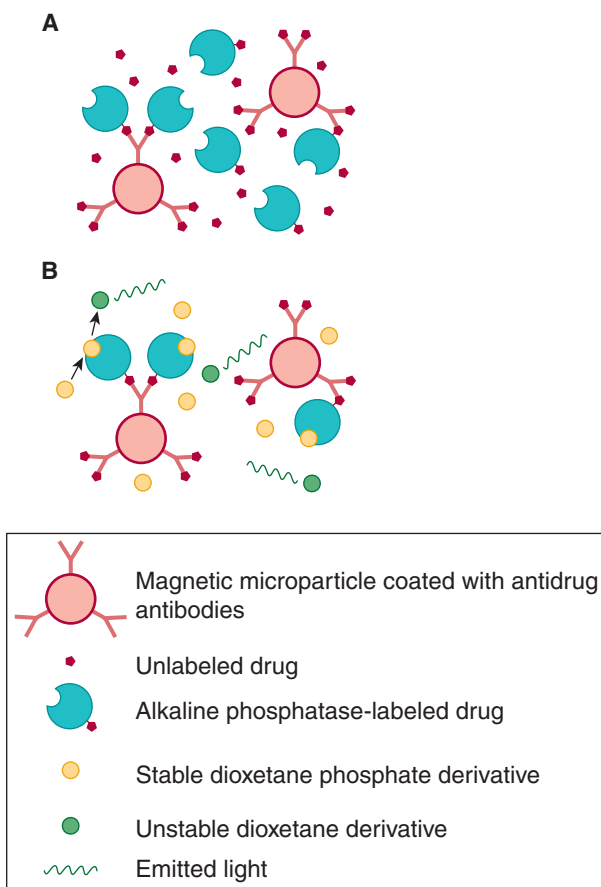

FIGURE 6–3. Magnetic microparticle chemiluminescent competitive immunoassay. (**A**) Unlabeled drug from the specimen competes with alkaline phosphatase-labeled drug for binding to antibody-coated magnetic microparticles. The microparticles are then held by a magnetic field while unbound material is washed away. (**B**) A diox-etane phosphate derivative is added and is dephosphorylated by microparticle-bound alkaline phosphatase to give an unstable dioxetane product that spontaneously decom-poses with emission of light. The rate of light production is directly proportional to the amount of alkaline phosphatase bound to the microparticles and inversely proportional to the concentration of competing unlabeled drug from the specimen.

A

B   **C**

FIGURE 6–4. Microparticle capture immunoassay. (**A**) Diagram of a device before specimen addition. Colored microbeads (about the size of red blood cells) coated with antidrug antibodies (Y) are in the specimen well. At the far end of a porous strip are capture zones with immobilized drug molecules (•) and a control zone with antibodies recognizing the antibodies that coat the microbeads. (**B**) Adding the urine specimen suspends the microbeads, which are drawn by capillary action through the porous strip and into an absorbent reservoir (*hatched area*) at the far end of the strip. In the absence of drug in the urine, the antibodies will bind the beads to the capture zone containing the immobilized drug and form a colored band. Excess beads will be bound by antibody–antibody interactions in the control zone, forming a second colored band that verifies the integrity of the antibodies in the device. (**C**) If the urine contains the drug (•) in concentrations exceeding the detection limit, all of the antibodies on the microbeads will be occupied by drug from the specimen, and the microbeads will not be retained by the immobilized drug in the capture zone. No colored band will form. However, the beads will be bound and form a band in the control zone.

(Fig. 6–4). If the specimen is xenobiotic free, the beads will bind to the immobilized analyte, forming a colored band. When the amount of drug in the patient specimen exceeds the detection limit, all of the anti-body sites will be occupied by drug from the specimen, and no labeled antibody will be retained in the capture zone. The use of multiple anti-bodies and discrete capture zones with different immobilized analytes can allow several xenobiotics to be detected with a single device.

A disadvantage of this design is the potential for causing confusion because a positive test result is indicated by the absence of a band. More complex (and more expensive) variations have been developed in which a colored band denotes a positive test result.

Although immunoassays have a high degree of sensitivity and selec-tivity, they are also subject to interferences and problems with cross-reactivity. Cross-reactivity refers to the ability of the assay antibody to bind to xenobiotics other than the target analyte. Xenobiotics with similar chemical structures may be efficiently bound, which can lead to falsely elevated results. In some situations, cross-reactivity can be beneficially exploited. For example, some immunoassays effectively detect classes of drugs rather than one specific drug. Immunoassays

for opiates use antibodies that recognize various xenobiotics that are structurally related to morphine, including codeine, hydrocodone, and hydromorphone. Oxycodone typically has less cross-reactivity, and higher concentrations are required to give a positive result. However, structurally unrelated synthetic opioids, such as meperidine and methadone, have little or no cross-reactivity and are not detected by opiate immunoassays. Immunoassays for the benzodiazepine class react with a wide variety of benzodiazepines but with varying degrees of sensitivity.[10,17]

Class specificity can be a two-edged sword. Assays for the TCA fam-ily have similar reactivity with amitriptyline, nortriptyline, imipramine, and desipramine and can be used to provide a semiquantitative estimate of the total concentration of any combination of these drugs. However, a large number of other drugs with tricyclic structures, including car-bamazepine, many phenothiazines, and diphenhydramine, also cross-react and generate a signal, particularly at concentrations found in patients who overdose. Qualitative tests, such as microparticle capture assays, may then yield false-positive results if the signal generated by the cross-reacting drug (e.g., carbamazepine) exceeds the detection limit of the immunoassay. With quantitative or semiquantitative assays, how-ever, the apparent concentration produced by a cross-reacting drug is generally well below TCA concentrations associated with toxicity.

Even when an antibody is selected to be specific to a single drug, it is common that metabolites of the target drug show some cross-reactivity. This, too, may be beneficial. When the metabolite is an active one (e.g., carbamazepine epoxide), the contribution of its cross-reactivity may yield results that correlate better with the drug effect than the true concentration of the parent drug alone.

Immunoassays are also subject to interference by substances that impair detection of the label. Elevated lactate concentrations may lead

to spuriously increased drug concentrations in specimens tested by EMIT, as described above. Immunoassays that rely on enzyme labels are particularly sensitive to nonspecific interference because enzyme activity is highly dependent on reaction conditions. A number of substances that can inhibit the enzyme reaction in EMIT assays are used to adulterate urine submitted for drug abuse testing with the intent of producing false-negative results (see the discussion of drug-abuse screening tests under "Special Considerations for Drug Abuse Screening Tests" below). Such adulteration may be detected when the rate of reaction is lower than the rate observed with a drug-free control.

■ CHROMATOGRAPHY

Chromatography encompasses several related techniques in which analyte specificity is achieved by physical separation. The unifying mechanism for separation is the partition of the analytes between a stationary phase and a moving phase (mobile phase). In most instances, the stationary phase consists of very fine particles arranged in a thin layer or enclosed within a column. The mobile phase flows through the spaces between the particles. Analytes are in a rapid equilibrium between solution in the mobile phase and adsorption to the surfaces of the particles. They move when in the mobile phase and stop when adsorbed to the stationary phase. The average velocity of the analyte xenobiotics depends on the relative time spent in the moving versus stationary phase. Xenobiotics that partition primarily into the mobile phase have average velocities slightly lower than the mobile phase velocity. Average velocity decreases as the proportion of time adsorbed to the stationary phase increases. Under controlled conditions, these average velocities are highly reproducible. Xenobiotics may be provisionally identified based on their characteristic velocity. This is measured as the distance traveled relative to the solvent migration distance in thin-layer chromatography, or the amount of time required to traverse the length of a chromatography column. These characteristic parameters are referred to as the R_F value and *retention time*, respectively.

Chromatography is a separation method and must be combined with a detection method to allow identification and measurement of the separated substances. Chromatographic behavior is sufficiently reproducible that the failure to detect a signal at an R_F value or retention time characteristic of a compound effectively excludes the presence of that compound in amounts greater than the detection limit. On the other hand, a number of different substances may have migration velocities that are identical or nearly so. A positive finding is therefore not completely specific. Definitive identification depends on having additional information, which may be obtained through selective detection techniques or by confirmatory testing using a second method. The sensitivity of chromatographic methods depends on both the amount of specimen available and the sensitivity of the detection method. The detection limit may range from less than 10 pg with mass spectrometric detection to more than 10 μg when detection is achieved by forming a colored product using a postchromatographic chemical reaction.

A major advantage of chromatographic techniques is that multiple xenobiotics may be detected and measured in a single procedure. It is not always necessary to know in advance the specific xenobiotic to be looked for. For this reason, chromatographic techniques have a major role in screening for multiple xenobiotics.

Most chromatographic procedures require extraction and concentration of the xenobiotics to be analyzed before the chromatography is done. Extraction results in removal of salts, proteins, and other materials that may exhibit unfavorable interactions with either of the chromatographic phases. Concentration allows the substances to be introduced in a narrow "band," so that compounds with slightly different relative mobilities become completely resolved, or separated from one another,

rather than overlapping. This also results in a more intense signal as a band passes through the detector and increases sensitivity.

Extraction of drugs is most commonly done with organic solvents, but "solid-phase extraction" is also very popular.[9] Solid-phase extraction is a modified chromatographic procedure in which a urine or serum specimen is passed through a short chromatography column with a hydrophobic stationary phase. Most drugs are sufficiently hydrophobic so that they partition almost completely into the stationary phase and are retained on the column. Subsequently, the retained xenobiotics are eluted with an organic solvent. The organic solvents from either extraction technique are evaporated to concentrate the extracted xenobiotics. The extraction process allows the analyte from a large volume of specimen to be concentrated. Detection sensitivity can thereby be increased, provided large volume specimens can be readily obtained, as is true with urine.

Often a preextraction treatment is used to increase the hydrophobicity of the substances to be extracted. The most common manipulation is pH adjustment, either upward or downward, to convert charged forms of drugs into uncharged, extractable ones. In other instances, enzymatic or chemical hydrolysis may be used to convert water-soluble glucuronide metabolites back to their more readily extracted parent compounds; for example, conversion of morphine glucuronide to morphine.

In thin-layer chromatography (TLC), the concentrated extracts are redissolved in a small amount of solvent and spotted onto a thin layer of silica gel that is supported on a glass or plastic plate or embedded in a fiber matrix. A typical TLC plate has room for several different spots of extracts from samples and controls. The plates are placed vertically in closed tanks containing a shallow layer of an organic solvent mixture. As the solvent is drawn upward through the silica gel by capillary action, various xenobiotics are carried along at characteristic velocities determined by their partition between the moving organic solvent and the stationary silica gel (Fig. 6–5). Silica gel is
FIGURE 6–5. Thin-layer chromatography. (**A**) Concentrated extracts from patient (*P*) and control (*C*) specimens are dried in small spots on a plate coated with a thin layer of silica gel particles. The plate is placed vertically into an organic solvent mixture, which is being drawn up the plate by capillary action. The leading edge (or solvent front, shown by the *dotted line*) reaches the extracts and begins to dissolve them. (**B**) Various substances are moving at different rates, depending on the relative proportion of time spent in the moving solvent (mobile phase) and adsorbed to the silica gel (stationary phase). (**C**) The development of the chromatogram is stopped when the solvent front nears the top. Various substances are seen at characteristic positions relative to the solvent front. The patient specimen contains a substance that can be tentatively identified as compound *b* in the control mixture based on its relative mobility. Although shown as *shaded spots* here for clarity, most drugs are colorless and are visualized at the end of the chromatography by being dipped or sprayed with reagents that form colored products. The tentative identification of the unknown drug as compound *b* requires that it show the predicted behavior with the visualizing reagents.

polar, so hydrophobic xenobiotics migrate rapidly and hydrophilic ones more slowly. Adjusting the composition of the solvent mixture allows optimization of the migration rates. After sufficient solvent migration, the plates are removed from the tanks, dried, and sprayed with a series of reagents that convert the xenobiotics to be detected into various colored derivatives. The xenobiotics are thereby visualized as colored spots and identified by their migration distance (R_F value), as well as by the various colors produced after each spray. Those that are metabolized can be further confirmed by the finding of additional spots corresponding to characteristic metabolites. Identifications can be most confidently made when an authentic sample of the xenobiotic has been included as a control on the plate.

TLC has the ability to identify the presence of a large number of xenobiotics and is widely used in "drug screens." Visualization as colored spots generally requires fairly large amounts of material. For this reason, TLC is usually used with urine and gastric aspirate specimens because they typically have higher concentrations of many drugs than do corresponding serum specimens and because they are readily available in large volumes.

Drawbacks to TLC include the need for multiple steps—extraction, concentration, chromatography, and a series of detection reactions. This makes TLC a relatively slow and labor-intensive procedure. Interpretation of the spots requires a skilled technologist who knows the TLC behavior of commonly encountered xenobiotics. Quantitation is difficult and rarely attempted. Therefore, TLC is primarily used to demonstrate the presence of a drug. It is of limited value in identifying a drug not previously seen by the chromatographer unless a possible candidate is suggested to the laboratory and an authentic sample (i.e., a standard) can be obtained to verify its behavior in the TLC system. Also, drugs that have limited excretion in the urine might not be readily detected.

In the past, full-service toxicology laboratories used classical TLC procedures to screen urine for a variety of drugs. The development of a commercial kit for TLC of drugs in urine (Toxilab, Varian, Inc., Palo Alto, CA) has reduced the time, labor, and expertise required and has extended its practicability to a broader range of laboratories.[13] The use of a standardized procedure also allows tentative identification of a drug not previously encountered by comparing its characteristics with those of a broad range of drugs provided in a compendium by the manufacturer. Identifications made solely on the basis of agreement with characteristics described in the compendium should be considered provisional until confirmed by additional testing.

In the related technique of high-performance liquid chromatography (HPLC), the stationary phase is packed into a column and the mobile phase is pumped through under high pressure (Fig. 6–6). This allows good flow rates to be achieved, even when solid phases with very small particle sizes are used. Smaller particle size increases surface area, decreases diffusion distances, and improves resolution, but the spaces between the particles are also smaller, increasing the resistance to flow. The use of high pressure and small particles allows better separations in a fraction of the time required for TLC.

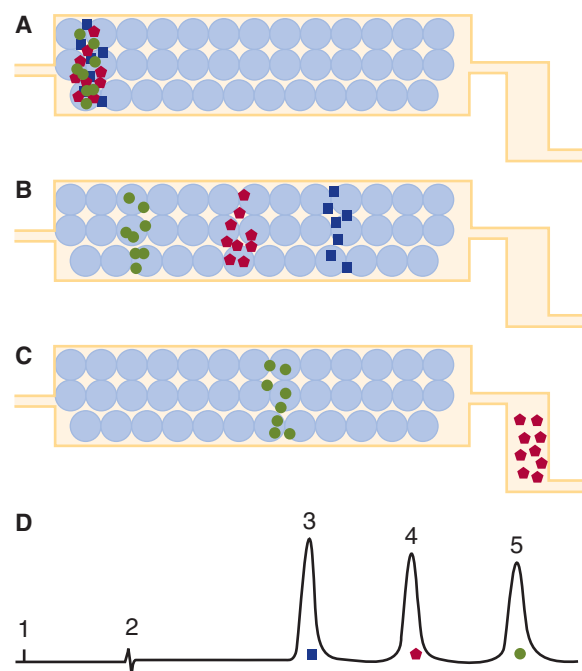
Another way that HPLC often differs from TLC is that HPLC typically uses "reverse-phase" chromatography. Reverse-phase chromatography uses stationary phases in which the silica gel particles have had hydrocarbon molecules covalently linked to the outer surface. This reduces the surface charge on the silica, thereby reducing its hydrophilicity, and simultaneously coats the particles with a permanently bonded oil-like layer. At the same time, solvent polarity is increased by using a primarily aqueous mobile phase with varying amounts of organic solvent. Because of these modifications, whereas hydrophobic xenobiotics are more strongly adsorbed by the stationary phase, hydrophilic ones tend to remain in the mobile phase. This results in


FIGURE 6–6. High-performance liquid chromatography (HPLC). HPLC is schematically shown. (**A**) A mixture of three compounds (■) (●) (⬟) is injected into a column filled with a spherical reversed-phase packing. (**B**) The compounds move through the column at characteristic speeds. The most hydrophilic compound (■) moves most quickly, and the most hydrophobic compound (●) moves most slowly. (**C**) The compound of intermediate polarity (⬟) has reached the detection cell, where it absorbs light directed through the cell and generates a signal proportional to its concentration. (**D**) Illustration of the HPLC tracing that might result: *1* indicates the time of injection. The artifact at *2* results when the injection solvent reaches the detector and indicates the retention time of a completely unretained compound. The peaks at *3*, *4*, and *5* correspond to the separated compounds. For example, peak *4* might be amitriptyline, peak *3* might be the more polar metabolite, nortriptyline, and peak *5* could be the more hydrophobic internal standard *N*-ethylnortriptyline. Later-emerging peaks are typically wider and shorter because of more time for diffusive forces to spread out the molecules.

an order of elution from the column that is approximately the reverse of that seen with organic solvents and unmodified silica gel. Thus, the term *reverse-phase chromatography* is used. Both TLC and HPLC can be done using either "normal-phase" or "reverse-phase" conditions. However, TLC is more commonly done in normal phase and HPLC more commonly in reverse phase. A variety of hydrocarbons can be used to derivatize the silica gel. By far, the most common reverse phase columns use an octadecyl hydrocarbon as the outer coating and are often referred to as C-18 columns.

In HPLC, the xenobiotics are detected after they exit the chromatographic column. In this case, they are identified by their retention time (the characteristic time required to traverse the column). Because most xenobiotics absorb ultraviolet light, detection is commonly by ultraviolet spectroscopy using specially designed flow-through cuvettes. Measuring light absorbance at a selected wavelength allows the amount of the xenobiotic to be determined. Accuracy is often enhanced by comparing the absorbance of the target analyte with absorbance of an internal standard (i.e., a compound with a different retention time that is added in a fixed amount to all specimens). The ratio of the drug absorbance to the internal standard absorbance is proportional to the drug concentration in the specimen.

Although most HPLC detectors allow a selection of the detection wavelength, only one wavelength is commonly used during a given run. Some detectors, however, allow absorbance at multiple wavelengths to be determined, either by rapidly and repeatedly scanning through a range of wavelengths or by breaking white light into its component wavelengths only after it has passed through the detection cuvette and then using an array of photodiode detectors to make measurements at multiple wavelengths simultaneously. These techniques can allow the absorbance spectrum of a compound to be determined as it elutes from the column. This information can supplement the retention time and allow more specific identifications to be made.

TLC generally requires one or more hours to complete and provides qualitative identification of xenobiotics present at concentrations of 1 mg/L or higher. In contrast, HPLC can routinely provide quantitation of xenobiotics at 10-fold lower concentrations in less than 1 hour (provided the calibration was done in advance). Thus, HPLC is often the method of choice for measuring serum concentrations of xenobiotics for which no immunoassay is available. Relative disadvantages of HPLC in comparison with TLC are the much higher costs of the equipment, the inability to analyze multiple samples simultaneously, and a relative inability to analyze drugs with a wide range of polarities with a single assay. The latter limitation inhibits the use of HPLC as a broad drug-screening technique.

GC is similar in principle to HPLC, except that the moving phase is a gas, usually the inert gas helium but occasionally nitrogen. The schematic illustration of HPLC in Figure 6–6 is also applicable to GC. The low flow resistance of gas allows high flow rates that make possible substantially longer columns than are used in HPLC. This offers the dual advantages of high resolution and fast analysis. As was true in HPLC, most GC assays incorporate an internal standard to increase precision.

Because the inert carrier gas does not engage in intermolecular interactions, partition of the analytes into the moving gas phase depends primarily on their natural volatility. Elevated column temperatures are required to achieve sufficient volatility for analysis of most xenobiotics. The use of a temperature gradient (the column temperature is programmed to increase throughout the course of the analysis) can allow xenobiotics with a wide range of volatility to be analyzed in a single run. This feature makes GC suitable for screening assays encompassing a broad range of drugs.

GC is limited to xenobiotics that are reasonably volatile at temperatures below 572°F (300°C), above which the stationary phase may begin to break down. Two principal attributes of a xenobiotic limit its volatility: its size and its ability to form hydrogen bonds. Xenobiotics that form hydrogen bonds via amino, hydroxyl, and carboxylate moieties can be made more volatile by replacing hydrogens on oxygen and nitrogen atoms with a non-bonding, preferably large, substituent. (Large substituents sterically hinder access to the acceptor electron pairs on the nitrogen and oxygen atoms.) A number of derivatizing agents can be used to add appropriate substituents. The most common derivatives involve the trimethylsilyl (TMS) group. Although derivatization with TMS substantially increases the molecular weight, the resulting derivative is much more volatile as a consequence of the loss of hydrogen bonding.

In traditional packed-column GC, the packing may consist of inert support particles with a thin coating of nonvolatile, high-molecular-weight oil that comprises the stationary phase. It is increasingly common for the stationary phase to be covalently bonded to the support particles. A highly useful variant of GC is capillary chromatography. A long, thin capillary tube of fused silica is coated on the inside with a covalently bonded stationary phase. The mobile gas phase flows through the tiny channel in the middle. These capillaries are flexible, allowing very long columns (≥10 m) to be coiled into a small space.

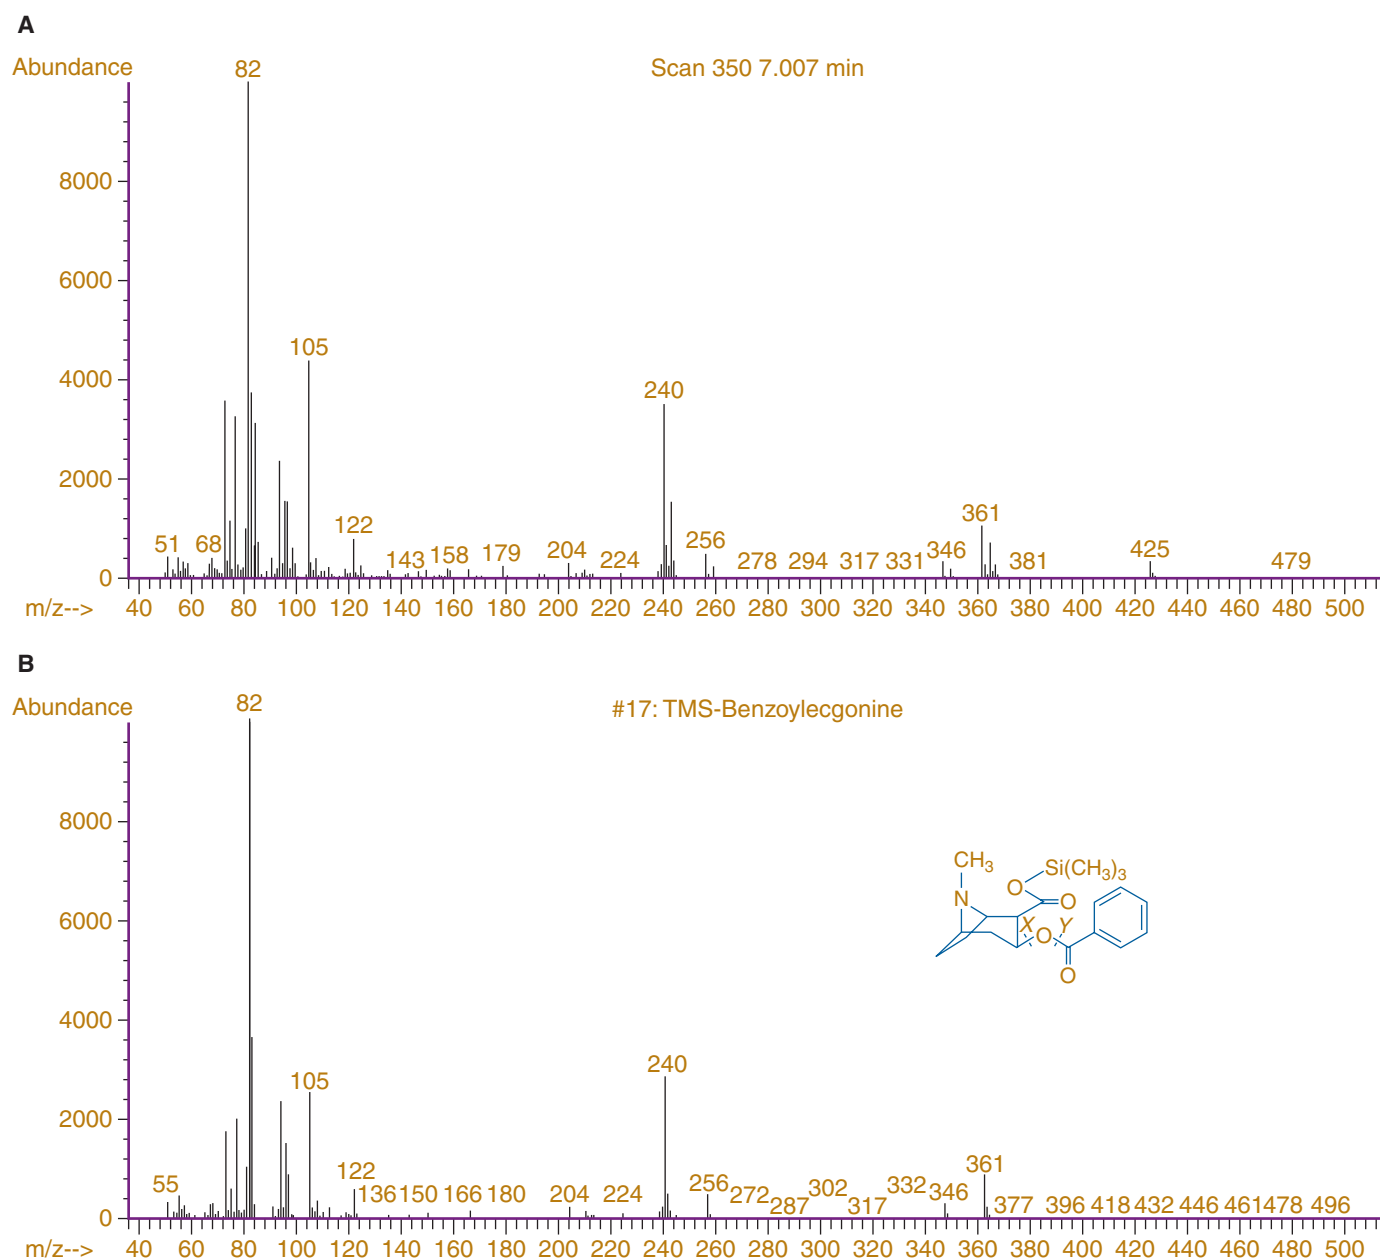
The long column length, coupled with highly uniform conditions throughout the column, results in extremely high resolution. The small diameter of the column allows rapid thermal equilibration and the use of steep temperature gradients that can speed analysis. The major drawback to capillary chromatography is a very limited column capacity. Special techniques are needed to restrict the amount of material introduced into the column and thereby to avoid overloading it. High-sensitivity detectors are required to measure the small quantities that can be chromatographed.

A number of detectors are available for GC. The most common detector, particularly for packed columns, is the flame ionization detector. This involves directing the outflow of the column into a hydrogen flame. Organic molecules emerging from the column are burned, creating charged combustion intermediates that can be measured as a current. The amount of current flow is largely determined by the mass of carbon that is being burned. Nitrogen–phosphorus detectors are also widely used in drug analysis. In this modification of a flame ionization detector, a heated bead coated with an alkali metal salt is used to selectively generate ions from xenobiotics containing nitrogen or phosphorus. These devices detect broad ranges of substances but do not identify them. The identity of the compounds detected must be inferred from the retention time.

The mass spectrometer can serve as a highly sensitive GC detector and also possesses the ability to generate highly characteristic mass spectra from the compounds it is detecting. A special requirement of the mass spectrometer is that it requires a high vacuum to prevent the ionic particles that it creates from interacting with other molecules or ions. This requires removal of the inert carrier gas and is easiest when there is a low total gas flow, such as occurs with capillary GC. The mass spectrometer, in turn, provides good sensitivity for the small amounts of analyte that can be accommodated in capillary GC.

This detection process also begins by generating ions from the analyte. This is usually done using electron impact ionization. The gas phase analyte is separated from the bulk of the carrier gas and introduced into an ionization chamber, where it is bombarded by a stream of electrons. Electron impact can dislodge an electron from the analyte, creating a positively charged ion and frequently imparting sufficient energy to the ion to break it into pieces. If fragmentation occurs, conservation of charge requires that one of the resulting fragments be a positively charged ion. The fragments into which a molecular ion can break are characteristic of the xenobiotics because is the relative probability that a given fragment will carry the positive charge.

The mass spectrometer then uses electromagnetic filtering to direct only ions of a specified mass-to-charge (*m/z*) ratio to a detector. Because most of the ions produced have a single positive charge, the observed peaks generally correspond to the mass of the ions. The detector has sufficient electronic amplification that a single ion could theoretically be detected, accounting for the high sensitivity of mass spectrometric detection. By rapidly scanning through a range of masses that are sequentially allowed to reach the detector, a mass spectrum may be generated. The mass spectrum records the masses of the pieces produced by fragmentation of the parent ion, as well as the relative frequency with which these fragments are produced and detected. The highest mass observed in the spectrum usually corresponds to the mass of intact parent ions generated from collisions that were not energetic enough to cause fragmentation.

Figure 6–7 shows the mass spectrum obtained from a gas chromatograph at a time when the TMS derivative of the cocaine metabolite benzoylecgonine was emerging from the capillary column. The mass spectrum of any compound is highly distinctive and usually unique. The primary exception involves optical enantiomers, both of which have the same mass spectrum. Toxicologically significant examples of


A

B

FIGURE 6–7. Mass spectrum of the trimethylsilyl derivative of benzoylecgonine (TMS-BE). (**A**) Mass spectrum of effluent from a gas chromatography (GC) column at the retention time of TMS-BE. The unfragmented parent ion of TMS-BE is at a mass-to-charge (*m/z*) ratio of 361. The two fragment peaks at *m/z* 243 and 259 result from fracture of the bonds at *X* and *Y*, respectively, in structure of TMS-BE (inset in **B**). Additional peaks at *m/z* 243, 259, and 364 are derived from trideuterated TMS-BZE (*d*$_3$-TMS-BE) added as an internal standard. The mass spectrometer can identify and quantify TMS-BE and *d*$_3$-TMS-BE independently of one another by measuring the heights of the peaks unique for each compound. The peak at *m/z* 425 is from a coeluting contaminant. (**B**) Mass spectrum of pure TMS-BE.

enantiomers include *d*-methamphetamine, a drug of abuse; *l*-metham-phetamine, which is found in decongestant inhalers; and dextrorphan, the major metabolite of the cough suppressant dextromethorphan, and levorphan (levorphanol), a controlled substance.

To avoid the need to scan the full range of masses in a typical mass spectrum, selected ion monitoring is often used. Here, the mass spectrometer is typically programmed to filter and detect only three of the larger and more characteristic peaks in the spectrum. In the case of TMS benzoylecgonine (TMS-BE), the peaks at *m/z* 240, 256, and 361 are used. The concentration of TMS-BE in the specimen is determined

from the ratio of the peak height at *m/z* 240 to a peak height at *m/z* 243 that results from a corresponding fragment of a triply deuterium-labeled internal standard, *d*$_3$-TMS-BE (see Fig. 6-7). The specificity of the identification is verified by finding peaks at *m/z* 256 and *m/z* 361, with peak height ratios to the peak at *m/z* 240 comparable to the ratios seen with authentic TMS-BE. The detection at the correct retention time of a xenobiotic producing all three peaks in the correct ratios produces an extremely specific identification.

The high sensitivity and specificity afforded by GS/mass spectrometry is being further extended by the related hybrid technique of liquid

chromatography/tandem mass spectrometry, often abbreviated as LC/MS/MS. Initially restricted to research settings, the technique is now becoming available in a few toxicology laboratories.[19] In LC/MS/MS, a tandem mass spectrometer is used as the detector for liquid chromatography system. The initial ionization is done under conditions that do not promote fragmentation and is commonly achieved by adding or removing a proton rather than forcefully dislodging an electron. The resulting ions have a mass that differs from that of the parent molecule by 1 mass unit ($[M+H]^+$ or $[M–H]^-$) The first mass spectrometer is used to selectively filter only unfragmented ions with the expected molecular mass. As the selected ions exit the first mass spectrometer at high speed, they are allowed to collide with molecules of an inert gas. These collisions cause the ions to break apart to create the fragment mass spectrum that is detected by the second mass spectrometer. The additional selection step provided by the first mass spectrometer greatly enhances specificity and reduces background signal, enhancing sensitivity.

QUANTITATIVE DRUG MEASUREMENTS

When properly used to guide dosing adjustments, drug concentration measurements improve medical outcomes.[6] However, many therapeutic drug measurements are drawn at inappropriate times or are made without an appropriate therapeutic question in mind. An essential requirement for interpretation of xenobiotic concentrations is that the relationship between concentrations and effects must be known. Such knowledge is available for routinely monitored xenobiotics and is often encapsulated in published ranges of therapeutic concentrations and toxic concentrations. Concentrations designated as "toxic" are usually higher than the upper end of the therapeutic range and typically represent concentrations at which toxicity is acute and potentially serious (see back cover).

For most xenobiotics, the relationships between toxic concentrations and effects cannot be systematically studied in humans and consequently are often incompletely defined. These relationships are largely inferred from data provided in overdose case reports and case series. The measurement of xenobiotic concentrations in overdose cases in which concentration–effect relationships are not well defined may contribute more to the management of future overdosed patients than to the management of the patient in whom the measurements were made.

For toxicologists, xenobiotic concentrations are especially useful in two ways. For xenobiotics whose toxicity is delayed or is clinically inapparent during the early phases of an overdose, concentrations may have substantial prognostic value and facilitate anticipatory management. These concentrations may also be used to make decisions regarding the use of antidotes or of interventions to hasten drug elimination, such as hemodialysis.

Quantitative xenobiotic measurements are subject to various interferences, but these are less problematic than in qualitative assays. Signals generated by cross-reacting substances are weaker than those from the target analyte and are relatively unlikely to lead to a false diagnosis of toxicity, particularly if the target analyte is absent. Such cross-reactivity can be exploited in some instances to provide confirmatory evidence of a poison for which no specific assay is immediately available. For example, the immunoassay finding of apparent subtoxic levels of TCAs can help confirm a diphenhydramine overdose, and the finding of a measurable digoxin concentration in an unexposed patient may suggest poisoning with other cardioactive steroids of plant or animal origin. Negative interferences are much less frequent. Table 6–3 summarizes some of the more common interferences in quantitative assays for drugs and poisons. Extensive information on interferences with laboratory tests, including toxicology tests, may be found online.

Interferences in chromatographic methods usually result from the presence of other compounds with migration rates similar to the target analyte. Because the migration rates are rarely exactly the same, the laboratory can often recognize the presence of the interference as an overlapping peak when both compounds are present. In such instances, the interference may impair accurate measurement of the drug concentration. When no target xenobiotic is present, misidentification of the interfering peak as the target becomes much more likely because a single peak is seen at approximately the expected position. Because

TABLE 6–3. Interferences in Quantitative Assays for Xenobiotics

Analyte	Technique	Potential Interferences
Acetaminophen	Spectrochemical	Bilirubin, phenacetin, renal failure, salicylates
	Immunoassay	Phenacetin (clinically a true-positive test result)
Carboxyhemoglobin	Spectrochemical	Fetal hemoglobin, hydroxocobalamin
Digoxin	Immunoassay	Other cardioactive steroids (found in oleander, red squill, Chan Su), endogenous digoxin-like substances (found in hepatic and renal failure, neonates, pregnancy), digoxin metabolites in renal failure, spironolactone, canrenone (spironolactone metabolite), human anti-mouse antibodies, digoxin immune Fab
Iron	Spectrochemical	Citrate, deferoxamine, EDTA, gadolinium contrast agents, hemolysis, oxalate
Lithium	Electrochemical	Hemolysis, lithium heparin (clinically a true positive result) abnormal serum sodium
Methemoglobin	Spectrochemical	Lipemia, methylene blue, sulfhemoglobin
Salicylate	Spectrochemical	Bilirubin, diflunisal, ketosis, salicylamide, salicylsalicylate
	Immunoassay	Diflunisal
Theophylline	Immunoassay	Caffeine, lipemia

EDTA, ethylenediamine tetraacetic acid.

interferences in chromatographic methods are generally unique to a specific method, information about these interferences should be obtained by asking the laboratory.

Xenobiotic measurements are unlike most other laboratory measurements in that the concentrations are highly dependent on the timing of the measurement. Knowledge of the pharmacokinetics of a xenobiotic can substantially enhance the ability to draw meaningful conclusions from a measured concentration. Some xenobiotics alter their pharmacokinetic behavior at very high concentrations. These changes in pharmacokinetics may be predictable from the mechanisms of drug clearance and the extent of binding to plasma proteins and to tissues (Chap. 8).

Knowledge of the relationship between xenobiotic concentrations and effects, or pharmacodynamics, is also important. Effects depend on local concentrations at the site of action, typically at cell membrane receptors or intracellular locations. Serum or plasma concentrations can be correlated with effects only when these concentrations are in equilibrium with concentrations at the site of action. Table 6–4 lists several circumstances that may alter the normal ratio of xenobiotic concentrations measured in serum or plasma to concentrations found at the site of action, thereby altering the usual concentration–effect relationships. During the absorption and distribution phases, the concentration ratio will be higher than its equilibrium value, yet often the only xenobiotic concentration measured after an acute overdose is one obtained while absorption and distribution are still ongoing. This effect may explain some observations of apparent poor correlation between measured concentrations and toxic effects.

For xenobiotics that bind significantly to plasma proteins, it is the concentration of xenobiotic that is not bound to proteins (the free-xenobiotic concentration) that is in equilibrium with concentrations at the site of action. For most drugs at therapeutic concentrations, the free-drug concentration is an approximately constant percentage of the total drug concentration. The total concentration is what is usually measured in the laboratory. Under these conditions, the ratio of total concentration to active site concentration is approximately constant, and a reasonable correlation between total concentration and effects can be expected.

A major change in the free fraction occurs after treatment of digoxin toxicity with digoxin immune Fab, when the free digoxin concentration falls from approximately 75% of the total concentration to less than 1% as a consequence of digoxin binding by the antidigoxin antibody fragments. At the same time, there is extensive redistribution of digoxin from tissues to plasma, leading to substantial increases in total digoxin concentration. This situation may be further complicated by complex digoxin immune Fab interference in many digoxin immunoassays.

Measurement of free-drug concentrations can clarify such situations.[16] Assays for free phenytoin are available in many laboratories. Assays for other free-drug concentrations may require special arrangements. The availability and expected turnaround time can be provided by the laboratory. For example, for patients treated with digoxin immune Fab, newer immunoassays that use antibodies attached to microparticles or glass fibers give results that can be used to set an upper bound on free-digoxin concentrations and thereby verify adequacy of treatment.[26]

■ TOXICOLOGY SCREENING

A test unique to the toxicology laboratory is the toxicology screen, or "tox screen." Depending on the laboratory, this term may refer to a single testing methodology with the ability to detect multiple xenobiotics, such as a thin-layer or GS, it may refer to a panel of individual tests, such as a drug-abuse screen; or it may be a combination of broad-spectrum and individual tests. The widespread use of the term "tox screen" is unfortunate because this inappropriately implies for many physicians the availability of a test that can confirm or exclude poisoning as a diagnosis. There are many more toxic xenobiotics in the world than there are named diseases. However, a relatively limited number of xenobiotics account for most serious poisonings. As a result, in one study, a comprehensive toxicology screening protocol using multiple detection methods applied to both serum and urine specimens was able to identify more than 98% of implicated xenobiotics.[12] This suggests that a comprehensive "tox screen" can exclude poisoning with a substantial degree of reliability. However, this study was done some time ago, when the rate of introduction of new drugs was much slower than is currently the case. Many newer therapeutic drugs may not be identified even by "comprehensive" screens currently in use.[36] Moreover, comprehensive toxicology screens typically do not detect elemental ions, including bromide, lithium, iron, lead, and other heavy metals, nor do they necessarily detect drugs that are toxic at extremely low concentrations, such as digoxin or fentanyl. Table 6–5 lists a number of xenobiotics encountered in emergency toxicology that may not be detected by routine toxicology screening.

It should therefore be apparent that a negative toxicology screen result cannot exclude poisoning. It is equally true that a positive finding does not necessarily confirm a diagnosis of poisoning. For assays that detect only the presence of a xenobiotic, it is not possible to distinguish

TABLE 6–4. Factors that May Alter Concentration–Effect Relationships		
Factor	Effect	Examples
Measurement during absorption phase	Underestimation of eventual effects	Sustained-release preparations; large ingestions of poorly soluble xenobiotics (e.g., salicylates); xenobiotics that slow gastric emptying (e.g., TCAs)
Measurement during distribution phase	Overestimation of effects	Lithium, digoxin, TCAs
Decreased binding to proteins	Underestimation of effects	Phenytoin
Saturation of binding proteins	Underestimation of effects	Salicylate, valproic acid
Binding by antidote	Variable	Digoxin/digoxin immune Fab

TCA, tricyclic antidepressant.

TABLE 6–5. Xenobiotics of Concern that are Often not Detected by Toxicology Screens

Antidysrhythmics	γ-Hydroxybutyrate
Anticholinergics	Herbal preparations
Anticoagulants	Hypoglycemics
Anticonvulsants	Iron
Antipsychotics	Isopropanol
β-Adrenergic agonists and antagonists	Ketamine
	Lithium
Calcium channel blockers	Lysergic acid diethylamide
Carbon monoxide	Methylene dioxyamphetamine
Clonidine	Methylene dioxymethamphetamine
Cyanide	Metals
"Designer drugs"	Methanol
Digoxin	Methemoglobin
Diphenhydramine	Solvents
Ethylene glycol	Serotonin reuptake inhibitors
Fentanyl	Strychnine

TABLE 6–6. Positive and Negative Predictive Values of Toxicology Screens

Sensitivity/ Specificity (%/%)	Prior Probability		
	10%	50%	95%
98/98 (excellent)	84%/99.8%	98%/98%	99.9%/72%
80/95 (mediocre)	64%/98%	94%/83%	99.7%/20%

benign or therapeutic levels from toxic ones. Quantitative tests may falsely suggest toxicity when drug concentrations are measured during the drug's distribution phase, which may extend for several hours with drugs such as digoxin and lithium. Moreover, the phenomenon of tolerance may allow chronic drug users to be relatively unaffected by concentrations that would be quite toxic to a non-using individual. Because comprehensive drug screens may differ widely between institutions and patterns of exposure also show substantial regional variation, there is limited ability to draw meaningful conclusions from any study of the sensitivity and specificity of such screens for detecting or excluding poisoning.

The predictive power of the result of a toxicology screen depends on a number of factors, including the likelihood of poisoning before receiving the test results (the prior probability or the prevalence), the range of xenobiotics effectively detected, and the frequency of false-positive results. It should be noted that false-positive and false-negative results may be either analytical or clinical in origin. A clinical false-positive result occurs when a xenobiotic is detected that is not contributing to the medical problem (e.g., a therapeutic amount of acetaminophen). A clinical false-negative result may occur when the wrong test is ordered (e.g., a screen for drugs of abuse for a patient with acetaminophen poisoning).

Table 6–6 explores the positive and negative predictive values of two hypothetical toxicology screens. The sensitivity of 98% and specificity of 98% in one scenario reflect the sensitivity of a broadly comprehensive toxicology screen[12] and an achievable false-positive rate of 2%. The second scenario has a sensitivity of only 80% and a specificity of 95% and represents plausible but mediocre performance. Three sets of prior probabilities are considered: 10%, 50%, and 95%. A prior probability of 10% might be seen if screening were indiscriminately applied to all patients in an emergency department or in a scenario in which xenobiotics were being excluded as a secondary cause of lethargy in an older patient who fell and struck his head. Both screens do well at excluding xenobiotics when their presence is already unlikely. However, a positive finding from either does not yield a fully convincing diagnosis of

the presence of a xenobiotic. A prior probability of 50% falls into the range of prevalence actually observed in patients for whom toxicology screens were ordered (see below). In this scenario of maximum uncertainty, both screens do a good job of diagnosing poisoning, but xenobiotic exclusion by the mediocre screen will be incorrect in one of six instances.

A prior probability of 95% represents testing in which the clinical presentation strongly suggests poisoning, as in the investigation of lethargy in a known regular drug user. Although positive findings in either screen raise the probability to almost complete certainty, negative findings from the excellent screen are incorrect one time out of four, whereas negative results from the mediocre screen are wrong four times out of five. Overall, toxicology screens have better positive predictive value than negative predictive value. This observation should give pause to those who primarily order toxicology screens "to rule out poisoning."

Although only approximately 2% of laboratories offer comprehensive toxicology screening,[3] most laboratories offer some sort of testing in response to a request for a toxicology screen. This may consist of a panel of immunoassays for drugs of abuse or a urine TLC screen, or it may result in a comprehensive screening test performed at a reference laboratory. Other laboratories may offer a focused, rather than a comprehensive, screening panel. Larger laboratories may have several types of "tox screens" available for use in different situations. Among laboratories that do not limit their tests exclusively to commercially available methods, it is likely that no two will have exactly the same menu of drugs that can be reliably detected. Some laboratories address the issue of providing useful information in a timely fashion through the use of focused, rather than comprehensive, screening protocols.[34] These screens include xenobiotics locally prevalent in overdose cases or drugs for which there are specific interventions. Table 6–7 suggests the possible composition of a focused screen.

Given the trends toward increasing automation and decreasing personnel in clinical laboratories, it is relevant to ask what benefits may be derived from such testing. Studies show that comprehensive toxicologic screening has the potential to provide significant information, with utility varying with the indication for testing. The prevalence of positive results has ranged from 34% to 86% of specimens submitted for testing. When drug exposure, as predicted from the patient's history and physical examination, was compared with screening results, clinically unsuspected substances were found in 7% to 48% of the cases, and clinically suspected xenobiotics were not found in 9% to 25%.[11,12,15,24,25] However, limited utility is suggested by studies showing that the results of comprehensive screening affect management in fewer than 15% of cases,[24] and in many instances, in fewer than 5% of cases.[11,15,21,25,32] A survey of emergency physicians found that more than 75% were not fully aware of the range of drugs detected and not detected by their laboratory's toxicology screen. The majority believed that the screen was more comprehensive than it actually was.[7]

TABLE 6–7. Components of a Focused Toxicology Screen

Serum Tests	Urine Tests
Acetaminophen	Cocaine metabolite
Ethanol	Opiates
Salicylates	TCAs[a]
Tricyclic antidepressants (semiquantitative immunoassay)	
Consider including:	
Barbiturates	Amphetamines
Cooximetry[b]	Barbiturates[a]
Iron	Benzodiazepines
Lithium	Methadone
Theophylline	Phencyclidine
Valproic acid	Propoxyphene
Volatile alcohols[c]	
Other locally prevalent drugs	

[a] If not included in serum tests.

[b] Requires whole-blood specimen.

[c] Methanol, isopropanol (+ acetone).

TCA, tricyclic antidepressant.

One reason for a limited effect on management is the substantial time delay before results of comprehensive screening are available. Generally, more than 3 hours is required for the report of a negative result, and an even longer time is required for confirmation of a positive finding. By this time, most consequential management decisions have been implemented. Another possible explanation for the limited utility of screening is that comprehensive screening is largely available only in major medical centers, where consultation from a medical or clinical toxicologist is more likely to be available. Such experts may be more able to make correct diagnoses and initiate appropriate management relying on clinical findings alone.

Several recently introduced point-of-care devices are capable of rapidly screening urine for the presence of drugs of abuse, as well as TCAs. Results are typically available in 20 to 30 minutes. In a small study of one such device, diagnosis was believed to have been aided in 82% of cases, and clinical management was changed in 25%.[2] Additional studies are needed to ascertain the utility of point-of-care drug screening in emergency toxicology.[35]

A useful alternative to the toxicology screen is the toxicology hold. This is a set of serum and urine specimens drawn at the time of presentation, when xenobiotic concentrations are likely to be near maximum concentrations, and initially held refrigerated or frozen without testing. This allows a specimen to remain available for subsequent testing if needed. Most laboratories hold such specimens for several days.

BEDSIDE TOXICOLOGY TESTS

Testing at the bedside is attractive for emergency toxicology. When a specific diagnosis is being considered, a bedside test can provide confirmation or exclusion quickly and often inexpensively,[18] enabling appropriate management to be initiated. This benefit must be balanced against the generally poorer sensitivity and specificity of bedside tests in comparison with testing in the clinical laboratory, the lack of quantitative information for most tests, the lack of laboratory support, the need to perform testing in accord with regulatory requirements (see below), record-keeping issues, and the erosion of the time advantage when multiple bedside tests are done on the same patient.

Table 6–8 lists some tests that can be conveniently performed at the bedside. Spot tests can also be done at the bedside, although many spot tests use hazardous reagents that may not be suitable for use in many bedside settings. A major problem with bedside tests that are not done with commercial devices is that these are considered "highly complex" tests under federal regulations, although they may be very simple to perform. This classification results from the fact that they are not subject

TABLE 6–8. Bedside Toxicology Tests

Test	Substrate	Drug or Poison	Comments
Alcohol dehydrogenase	Saliva	Ethanol	Other alcohols may interfere. Some tests only give concentration ranges.
Breath analysis	Breath	Carbon monoxide	Ethanol may interfere.
Breath analysis	Breath	Ethanol	Good cooperation is required. Ethanol in the oral cavity interferes. Calibrated to give whole-blood rather than serum concentration.
Ferric chloride	Urine	Salicylate	Acetaminophen and phenothiazines interfere (limited utilization).
Meixner	Mushroom	Amatoxins	Paper must contain lignin (filter paper, which is lignin-free, must be used as a negative control). Requires strong acid. Some false-positives and false-negative test results have been seen
Microparticle agglutination	Urine	Drugs of abuse	KIMS variant with visual endpoint. Separate test for each drug.
Microparticle capture	Urine	Drugs of abuse	Single device detects one or more of the drugs listed in Table 6-10 in a variety of menus available from multiple manufacturers. Some multitest devices include TCAs. Higher false-positive and false-negative rates than for clinical laboratory testing.
Oxalate crystals	Urine	Ethylene glycol	Metabolic end product. Not detected during early stages. Nonspecific.

KIMS, kinetic interaction of microparticles in solution; TCA, tricyclic antidepressant.

to the validation processes required for Food and Drug Administration (FDA)–approved commercial devices. Meeting the regulations requires significant initial and ongoing investment of time. The Meixner test[1] (for amatoxins in mushrooms) and breath analysis (for ethanol or carbon monoxide from human breath) are exempted from these regulations because they are not considered to involve human specimens (see Regulatory Issues Affecting Toxicology Testing below).

In testing in overdose situations, most specimens will have either zero or very high concentrations of target analytes, and correct identification of the presence or absence of a substance is likely even with imprecise methods. Unfortunately, when point-of-care drug-screening devices have been compared with laboratory testing at concentrations near cutoff limits, performance has been variable.[33,35] An extensive study using a more representative range of urine drug concentrations observed higher rates of correct results, but performance remained inferior to that of immunoassays conducted with laboratory instrumentation.[8]

A clinical and methodologic issue with bedside drug-screening assays is whether positive results will subsequently be subjected to confirmatory testing. The extra investment of labor needed to submit a specimen tends to discourage laboratory confirmation. The argument in favor of routine confirmation is that this is an accepted standard of practice, even for screening assays that have lower false-positive rates than the point-of-care devices (see Special Considerations for Drug Abuse Screening Tests below). The counterargument is that if testing is limited to populations with a high prior probability of drug exposure, the predictive value of a positive test result is high. The NACB guidelines actually recommend against routine confirmation of positive results of drug-screening immunoassays done solely for medical reasons but suggest that all such unconfirmed positive results be reported as being "presumptive."[37]

REGULATORY ISSUES AFFECTING TOXICOLOGY TESTING

Since 1992, medical laboratory testing has been governed by federal regulations (42 CFR part 405 et seq) issued under the authority of the Clinical Laboratory Improvement Amendments of 1988 (often referred to as CLIA-88 or simply CLIA). These regulations apply to all laboratory testing of human specimens for medical purposes, regardless of site. They include the universal requirement for possession of an appropriate certificate to perform even the simplest of tests. The remaining requirements depend on the complexity of the test. These regulations become important to the clinician whenever testing is done at the bedside, whether using spot tests or commercial point-of-care devices such as dipsticks, glucose meters, or urine drug-screening devices.

The regulations divide testing into three categories: waived, moderate complexity, and high complexity. Waived tests include a number of specifically designated simple tests, including urine dipsticks, urine pregnancy tests, urine drug-screening immunoassay devices, and blood glucose measurements with a hand-held monitor. The only legal requirement for performing waived testing are the possession of an appropriate CLIA certificate (certificate of waiver or higher) and performance of the test in accordance with the manufacturer's instructions.

There are substantial additional requirements for both moderate and highly complex testing, most of which simply represent good laboratory practice. Table 6–9 lists the most significant of these requirements. Most assays performed with commercial kits or devices are classified as belonging to the moderately complex category. All tests not specifically classified as waived or moderately complex are considered highly complex. This includes essentially all noncommercial tests, including

---

TABLE 6–9. Major Clinical Laboratory Improvement Amendments (CLIA) Requirements for Laboratory Testing

Waived Tests
Certificate of waiver
Follow manufacturer's instructions exactly

Moderate-Complexity Tests
CLIA certificate
Record keeping
Test method verification
Written procedures
Qualified laboratory director
Personnel educational requirements
Documented training of all testing personnel
Annual competency testing of all personnel
Two levels of controls daily
Participate in proficiency testing every 4 months
Verify calibration and reportable range at least every 6 months
Quality assessment program
Biennial inspection and certification

High-Complexity Tests
All moderate-complexity requirements *plus*
Qualified onsite supervisor *or*
Daily review of all results by qualified supervisor

---

spot tests, because the testing materials have not been subject to review and approval by the FDA.

These regulations have had a substantial impact in all areas of laboratory testing. Some of the most significant effects have been on bedside testing, including spot tests and point-of-care devices. Although clinical laboratories had been following most required practices before the implementation of the regulations, this was usually not the case for testing done at other sites. Most institutions have now established point-of-care testing programs to facilitate compliance with the regulations, as well as with additional requirements of accrediting agencies, such as the Joint Commission. Any toxicologic or other testing done at the point of care should be set up in consultation with the institutional program. Often, all point-of-care testing is done under a CLIA certificate held by the program. There is frequently a point-of-care testing coordinator who may make recommendations or personally assist in efficiently addressing the assorted requirements.

This table lists only the most significant requirements of the regulations implementing CLIA. These regulations continue to evolve. Accrediting agencies such as the Joint Commission may have additional requirements. Consultation with the clinical laboratory or with an institutional point-of-care coordinator is recommended before implementing any testing.

However, such testing may be covered by state laws or by institutional or accrediting agency policies. The NACB guidelines recommend that breath testing be overseen by the clinical laboratory and meet the same standards as other point-of-care testing.[37]

Personnel unaccustomed to quality control and assessment practices may find the CLIA requirements initially burdensome. Nonetheless, compliance is important. Following these practices may lead to a threefold reduction in incorrect results,[31] thereby greatly improving the

quality of care provided to the patient. Moreover, noncompliant testing is illegal under federal law and may also be illegal under state law. Any untoward outcome associated with illegal testing creates a major risk management liability for both the institution and the individual. Additionally, billing for any testing that is not CLIA compliant may be considered fraudulent.

Another area in which the CLIA regulations have impacted toxicology testing is in the provision of infrequently requested tests. Meeting regulatory requirements involves a substantial labor investment even when few patient specimens are being tested. Mounting pressures to reduce laboratory costs make it less likely that laboratories will continue to maintain such assays.

Another important regulation, although not part of CLIA regulations, requires that the medical reason for ordering a test be provided with the order. Federal regulations require that the ordering physician provide the diagnosis that establishes the medical necessity for the test, either by name or by diagnostic code (CPT code). Laboratories may not use a "best guess" to assign codes to undocumented test requests.

SPECIAL CONSIDERATIONS FOR DRUG ABUSE SCREENING TESTS

Testing for drugs of abuse is a significant component of medical toxicology testing. These tests are widely used in the evaluation of potential poisonings and are assuming an increasing role is assuring the appropriate use of pain medications.[28] Initial testing is usually done with a screening immunoassay. Although drug-screening immunoassays were initially developed for use in workplace drug-screening programs and are not always optimal for medical purposes, their wide availability low cost and ease of use formats led to their nearly universal adoption in clinical laboratories. Growth of the market for medical drug screening has led to the development of point-of-care tests specifically for medical use, but these devices largely retain the deficiencies of their predecessors. Drug abuse testing for nonmedical reasons is generally considered to be forensic testing, and confirmation of immunoassay results is considered mandatory in such circumstances. Confirmatory testing can compensate for some immunoassay shortcomings but is frequently not performed when screening tests are done for medical purposes. Despite the widespread use of drug-screening immunoassays in medical practice, studies suggest that many physicians do not fully understand the capabilities and limitations of these tests.[28]

The most commonly tested-for drugs are amphetamines, cannabinoids, cocaine, opiates, and phencyclidine. These are often referred to as the NIDA 5, because they are the five drugs that were recommended in 1988 by the National Institute on Drug Abuse (NIDA) for drug screening of federal employees. (Responsibility for recommendations for federal drug testing now lies with the Substance Abuse and Mental Health Services Administration [SAMHSA].) Drug-screening immunoassays are also frequently done for barbiturates and benzodiazepines and less frequently for meperidine, methadone, and propoxyphene. Drug-screening devices intended primarily for medical use may also include tests for acetaminophen or TCAs. Table 6–10 lists some of the general characteristics of these tests. Commercial urine immunoassays are also available for buprenorphine, lysergic acid diethylamide, methaqualone, methylenedioxymethamphetamine (MDMA), and oxycodone. Drug-screening immunoassays are available in a number of formats, which may differ in performance. Almost all of them are designed to be used with urine specimens because these can be obtained noninvasively and generally have higher concentrations than serum, enhancing the sensitivity of the test.

The drug-screening tests for cannabinoids and cocaine are directed toward inactive drug metabolites rather than the active parent compound. The parent drugs, cocaine and tetrahydrocannabinol, are both short lived and persist for no more than a few hours after use. The metabolites remain present substantially longer. Detection of the metabolites increases the ability to detect any recent drug use. However, this limits the utility of the assays for determining whether a patient is currently under the influence of the drug. Because the metabolites are rapidly formed, a negative test result generally excludes toxicity, but a positive test result indicates only use in the recent past, not current toxicity.

To increase sensitivity for detection of less-recent drug use, substrates other than urine can be used for drug screening, including hair and meconium. The latter is used to document intrauterine drug exposure (Chap. 30). SAMHSA is planning to develop regulations governing the use of hair, saliva, and sweat specimens for federal workplace testing after their performance characteristics have been adequately studies. This can be expected to increase the availability of clinical testing using these substrates. However, testing performed on hair and sweat are unlikely to offer advantages over testing of serum and urine for the management of toxicologic emergencies.

The stigma attached to a positive test result for an abused drug requires that special care be exercised in performing and reporting the test results. To protect citizens' rights, many states have legislated specific requirements for workplace drug screening. In some states, the requirements apply only to screening in the workplace, exempting testing for medical purposes. Laws in other states might apply to all drug screening. Although they are not always legally required, some workplace drug-screening practices have been widely applied to all drug screening.

The use of specific cutoff concentrations is nearly universal. Test results are considered positive only when the concentration of drugs in the specimen exceeds a predetermined threshold. This threshold should be set sufficiently high that false-positive results as a consequence of analytic variability or cross-reactivity are extremely infrequent. They should also be low enough to consistently give a positive result in persons who are using drugs. Cutoff concentrations used vary with the drug or drug class under investigation. In some drug-screening immunoassays, the laboratory has the option of selecting from several cutoff values.

The use of cutoff values sometimes creates confusion when a patient who is known to have recently used a drug has a negative result reported on a drug screen. In such instances, the drug is usually present but at a concentration below the cutoff value. Another potential problem occurs when a patient's drug-screening test result is positive after previously having become negative. This is usually interpreted as indicating renewed drug use, but it may actually be an artifact. Urine drug concentrations are directly proportional to the serum drug concentrations but inversely proportional to the rate of urine production. The rate of the urine flow may vary up to 100-fold, with a resulting possible 100-fold change in the urine drug concentration. This effect is often exploited by individuals who drink large quantities of water before taking a urine drug test to increase urine flow and decrease urine drug concentrations. In contrast, a decrease in the rate of urine production may result in a positive test result following a negative one despite no new drug exposure. A similar effect may be produced by changes in urine pH. Drugs containing a basic nitrogen may demonstrate ionic trapping, with increasing concentrations as urine pH decreases. Similarly, excretion of the phenobarbital anion may increase with increasing urine pH. This phenomenon is medically exploited by alkalinizing the urine to increase phenobarbital excretion.

TABLE 6–10. Performance Characteristics of Common Drug Abuse Screening Immunoassays[a]

Drug/Class	Detection Limits[b]	Confirmation Limits[b]	Detection Interval[c]	Comments
Amphetamines	1000 ng/mL	500 ng/mL amphetamine or MDMA	1–2 d (2–4 d)	Decongestants, ephedrine, *l*-methamphetamine, selegilene and bupropion metabolites may give false-positives test results; MDA and MDMA are variably detected. Confirmation of methamphetamine requires detection of >500 ng/mL with >200 ng/mL of metabolite, amphetamine.
Barbiturates	200 ng/mL Secobarbital		2–4 d	Phenobarbital may be detected for up to 4 weeks.
Benzodiazepines	100–300 ng/mL		1–30 d	Benzodiazepines vary in reactivity and potency. Hydrolysis of glucuronides increases sensitivity. False-positive test results maybe be seen with oxaprozin.
Cannabinoids	50 ng/mL; 20ng/mL; 25 ng/mL; 100ng/mL THCA	15 ng/mL THCA	1–3 d (>1 mo)	Screening assays detect inactive and active cannabinoids; confirmatory assay detects inactive metabolite THCA. Duration of positivity is highly dependent on screening assay detection limits.
Cocaine	300 ng/mL BE	150 ng/mL BE	2 d (1 wk)	Screening and confirmatory assays detect inactive metabolite BE. False-positive test results are unlikely.
Opiates	2000 ng/mL; 300 ng/mL	2000 ng/mL; morphine or codeine	1–2 d; 2–4 d (<1 wk)	>10 ng/mL of heroin metabolite 6-monoacetyl morphine is also confirmatory. Semisynthetic opiates derived from morphine show variable cross-reactivity. Fully synthetic opioids (e.g., fentanyl, meperidine, methadone, propoxyphene, tramadol) have minimal cross-reactivity. Quinolones may cross-react.
Methadone	300 ng/mL		1–4 d	Doxylamine may cross-react.
Phencyclidine	25 ng/mL	25 ng/mL	4–7 d (>1 mo)	Dextromethorphan, diphenhydramine, ketamine, and venlafaxine may cross-react.
Propoxyphene	300 ng/mL		3–10 d	Duration of positivity depends on cross-reactivity of metabolite norpropoxyphene.

[a] Performance characteristics vary with manufacturer and may change over time. for the most accurate information, consult the package insert of the current lot or contact the manufacturer.

[b] Substance Abuse and Mental Health Services Administration recommendations[5] are shown as the first value for amphetamines, cannabinoids, cocaine, opiates, and phencyclidine immunoassays and as only values for confirmatory assays. Other commercial immunoassay cutoffs are also listed. Other gas spectrometry cutoffs are set by the laboratory.

[c] Values are after typical use; values in parentheses are after heavy or prolonged use.

BE, benzoylecgonine; MDA, methylenedioxyamphetamine; MDMA, methylenedioxymethamphetamine; THCA, tetrahydrocannabinoic acid.

Another widely used practice is the confirmation of positive screening results using an analytical methodology different from that used in the screen, such as an immunoassay screen followed by chromatographic confirmation. The possibility of simultaneous false-positive results by two distinct methods is quite low. Clinical laboratories may differ in their policies with regard to confirmatory testing. Some may confirm all positive results from screening immunoassays, but others may not provide any confirmatory testing unless it is explicitly requested.

The most common confirmatory method is gas chromatography/mass spectrometry (GS/MS). The high specificity afforded by the combination of the retention time and the mass spectrum makes false-positive results extremely unlikely. GC/MS also has greater sensitivity than the screening immunoassays, minimizing failed confirmations because of drug concentrations below the sensitivity of the confirmatory assay. Some states require GC/MS confirmation for workplace drug screening, and it may be legally required for all drug screening.

Immunoassay results can generally be obtained within 1 hour. Confirmatory testing usually requires at least several hours. This can create a problem when confirmation of initial immunoassay results is considered mandatory. Most laboratories provide a verbal report of a presumptive positive result to facilitate medical management but may not enter the result into a permanent record, such as the laboratory computer, until after confirmation has been completed.

The importance of confirmatory testing in workplace drug screening follows from the relatively low prevalence of positive results. A screening test with both sensitivity and specificity of 98% will produce two false-positive results per 100 subjects tested. A workforce with a 2% prevalence of illicit drug use will yield two true-positive results per 100 subjects. The predictive value of a positive test will only be 50% (two of four). This is an unacceptable level of certainty for results that might be used to terminate employment. Although the prevalence of recent drug use in the workforce is low, rates of positivity of 34% to 86% have been reported for selective drug screening of emergency department populations. Given a 50% prevalence of recent drug use, the positive predictive value of same screening test increases to 98% (see Table 6–6).

A high prior probability of drug positivity for patients tested in medical settings results in a very high posterior probability after a

positive test result. Confirmatory testing is much less critical in such a setting, particularly because a positive finding infrequently has consequences that extend beyond the medical management of the patient. An exception may occur when results of testing performed on motor vehicle crash victims can be subsequently subpoenaed as evidence in legal proceedings. Confirmatory testing also becomes more important in drug abuse testing associated with chronic pain management programs, in which unexpected findings may result in termination of care. Chromatographic tests that identify individual opiates can distinguish between prescribed and nonprescribed drugs.

One workplace drug-screening practice that is not widely followed in medical toxicology is maintenance of a chain of custody. Employers generally insist on chain of custody for workplace testing because actions taken in response to a positive result may be contested in court. A chain of custody provides results that are readily defended in court. Laboratories providing testing for medical purposes rarely keep a chain of custody because it is quite expensive and does not benefit the patient. Additionally, the medical personnel responsible for obtaining the specimens are rarely trained in collection requirements for a chain of custody.

The lack of chain of custody may create problems when persons with no medical complaints present at an emergency department or other medical facility requesting the performance of a drug-screening test. Unless the facility is prepared to initiate the chain of custody at the time of specimen collection and the laboratory is prepared to maintain it, such persons should be redirected to a site maintained by a commercial laboratory that routinely performs workplace drug testing and has appropriate procedures in place. Many laboratories have had the experience of unwittingly performing drug abuse testing for nonmedical purposes because the reason for the testing is not always included on the test requisition. To avoid liability issues, the laboratory may choose to include a disclaimer with every drug-screening report indicating that the results are for purposes of medical management only.

Another practice common in workplace testing but rare in medical laboratories is testing for specimen validity. It is common for individuals to try to "beat" a workplace drug test through a variety of means, including diluting the specimen (either physiologically by water ingestion or by direct addition of water to the specimen), substituting "clean" urine obtained from another individual, or adding various substances that will either destroy drugs in the specimen or inactivate the enzymes or antibodies used in the screening immunoassays. Such substances include acids, bases, oxidizing agents (bleach, nitrite, peroxide, peroxidase, iodine, chromate), glutaraldehyde, pyridine, niacin detergents, and soap. SAMHSA requires validity testing for all specimens in federal workplace testing, including measurement of urinary pH, specific gravity, and creatinine concentration, as well as tests for the presence of adulterants.[5] Dipsticks are available that detect the most common adulterants. However, manipulation or adulteration is rarely a problem in medical specimens, and clinical laboratories infrequently provide validity testing.

PERFORMANCE CHARACTERISTICS OF COMMON DRUG-SCREENING ASSAYS

Medical toxicologists, toxicology laboratory directors, and practicing physicians may frequently get questions about the significance of drug-screening assays, particularly about the causes of false-positive results. Often these questions come from an individual who recently had a positive test result. Table 6–10 summarizes drug-screening test performance characteristics, which are discussed in more detail below.

Immunoassays for opiates are directed toward morphine but have good cross-reactivity with many (but not all) structurally similar natural and semisynthetic opiates. The extent of cross-reactivity may vary between manufacturers. For example, oxycodone exhibits approximately 30% cross-reactivity relative to morphine in a fluorescence polarization immunoassay but less than 5% cross-reactivity in a number of other screening assays.[17,28] A failure to appreciate the poor detection of oxycodone can create problems when opiate-screening immunoassays are used to confirm that patients receiving prescription oxycodone for chronic pain are indeed taking it rather than diverting it for illicit sale. If a low cross-reactivity assay is used, a patient taking oxycodone as prescribed might have a negative result, but another patient who is selling the oxycodone and using the proceeds to buy heroin would have a positive result. To address this problem, assays specific for oxycodone have been introduced. These assays are sensitive to therapeutic amounts of oxycodone but relatively insensitive to other opiates.

Synthetic opioids, such as dextromethorphan, fentanyl, meperidine, methadone, propoxyphene, and tramadol, show little or no cross-reactivity in opiate immunoassays. Urine immunoassays specific for meperidine, methadone, and propoxyphene are available. Given the increasing importance of buprenorphine as maintenance therapy for opiate dependency, it is worth noting that the combination of high potency and low cross-reactivity means that buprenorphine will generally not be detected by opiate immunoassays. Immunoassays for detection of buprenorphine have therefore been developed.

A positive immunoassay result may reflect multiple contributions from various opiates and opiate metabolites. Concentrations of morphine glucuronide in the urine may be up to 10-fold higher than the concentrations of unchanged morphine and can contribute substantially to positive results. A positive opiate result after the use of heroin (diacetylmorphine) is primarily a result of the morphine and morphine glucuronide that result from heroin metabolism. Distinguishing heroin from other opiates requires detection of 6-monoacetylmorphine, the heroin-specific metabolite. Small amounts of the metabolite may be detected by GC/MS for up to 24 hours after use. A half-life of 5 minutes means that unchanged heroin can only be found in the urine if sampling is done immediately after use.

The duration of positivity of an opiate immunoassay after last use depends on the identity and amount of the opiate used, the specific immunoassay, the cutoff value, and the pharmacokinetics of the individual. Currently, SAMHSA recommends a cutoff equivalent to 2000 ng/mL of morphine for workplace screening because poppy seeds can rarely produce transient positive results with the previously recommended cutoff of 300 ng/mL. However, most toxicology laboratories continue to use a 300 ng/mL cutoff.

Drug-screening assays for "cocaine" are actually assays for the inactive cocaine metabolite benzoylecgonine, which is eliminated more slowly than cocaine. This extends the duration of positivity after last use from a few hours to 2 days and sometimes to a week or longer after prolonged heavy use. Because the assay is directed toward an inactive metabolite, positive results do not equate with toxicity but merely indicate recent exposure. The assay is highly specific for benzoylecgonine, and false-positive results are extremely uncommon (Chap. 76).

Immunoassays for cannabinoids are also directed toward an inactive metabolite, in this case tetrahydrocannabinoic acid. These immunoassays exhibit cross-reactivity with other cannabinoids but little else. Because cannabinoids are structurally unique and occur only in plants of the genus *Cannabis*, false–positive results are quite uncommon (Chap. 83) It is unusual, although possible, to become exposed to sufficient "second-hand" or sidestream marijuana smoke to develop a positive urine test result.[4] Legal hemp products include fiber, oil, and seedcake derived from *Cannabis* varieties with low concentrations of cannabinoids. Hemp food products contain insufficient amounts of tetrahydrocannabinol to produce psychoactive effects and usually will

not increase urinary cannabinoid concentrations above a 50 ng/mL screening threshold.[10,28]

Interpretation of a positive result for cannabinoids can be problematic. Urine may be positive for up to 3 days after occasional recreational use. However, with heavy or prolonged use, there may be significant accumulation of cannabinoids in adipose tissue. These stored cannabinoids are slowly released into the bloodstream and can produce positive findings for 1 month or more. Consequently, little can be concluded from a positive finding in terms of current toxicity. Because positive results in the absence of toxicity are very common and because tetrahydrocannabinol is rarely responsible for serious acute toxicity, NACB guidelines recommend against its routine inclusion in drug screening for patients with acute symptoms.[37]

Amphetamine-screening tests have the greatest problems with false-positive results. A number of structurally related compounds may have significant cross-reactivity, including bupropion metabolites and nonprescription decongestants such as pseudoephedrine, as well as *l*-ephedrine, which is found in a variety of herbal preparations. Some over-the counter nasal inhalers contain *l*-methamphetamine, the less potent levorotary isomer of *d*-methamphetamine. It is particularly problematic because it not only cross-reacts in immunoassays but also cannot be distinguished from the *d*-isomer by mass spectrometry.[10] This cross-reactivity is beneficial from the point of view of the medical toxicologist because all of these compounds may produce serious stimulant toxicity. But it is problematic in drug abuse screening because of the widespread legitimate use of cold medications. Assays with greater selectivity for amphetamine or methamphetamine have been developed. Although these assays produce fewer false-positive results caused by decongestant cross-reactivity, they are also less sensitive for the detection of other abused amphetamine-like compounds, including methylenedioxyamphetamine (MDA), MDMA, and phentermine. Cross-reactivity patterns vary from assay to assay.[17] The manufacturer's literature should be consulted for specific details.

Testing for benzodiazepines is complicated by the wide array of benzodiazepines that differ substantially in their potency, cross-reactivity, and half-lives. There are also substantial differences in the detection patterns of the various immunoassays.[10,17] This heterogeneity complicates the interpretation of benzodiazepine-screening assays. Screening results may be positive in persons using low therapeutic doses of diazepam but negative after an overdose of a highly potent benzodiazepine such as clonazepam. To improve the scope of detection, some assays use antibodies to oxazepam, which is a metabolite of a number of different benzodiazepines. These assays may have poor sensitivity to benzodiazepines that are not metabolized to oxazepam. False-negative results may occur for benzodiazepines that are excreted in the urine almost entirely as glucuronides that have poor cross-reactivity with antibodies directed toward an unmodified benzodiazepine. This is one reason for the poor detectability of lorazepam in some screening assays. The latter situation has led to the recommendation that specimens be treated with β-glucuronidase before analysis.[20] Some assays now include β-glucuronidase in the reagent mixture or use antibodies directed toward glucuronidated metabolites. The frequency of false-negative results, as well as the fact that benzodiazepines are relatively benign in overdose, have led the NACB guidelines to withhold recommendation for routine screening of urine for benzodiazepines until these problems with the immunoassays are addressed.[37]

Barbiturates are comparable to benzodiazepines in their heterogeneity of potency, cross-reactivity, and half-lives, although the differences are less substantial. Specific assays for serum phenobarbital can often help to clarify the significance of a positive barbiturate screen.

Some phencyclidine screening assays may give positive results with dextromethorphan, ketamine, or diphenhydramine but only when these are used in amounts above usual therapeutic quantities. A positive result may serve as a clue to a possible overdose with any of these substances. Furthermore, much of the illicit phencyclidine (PCP) actually consists of a mixture of various congers and byproducts of synthesis. The cross-reactivity of these xenobiotics with the assay varies significantly and may result in false-negative assay results in patients who use PCP.

MEASUREMENT OF ETHANOL CONCENTRATIONS

Measuring ethanol may have ramifications beyond guiding medical management, particularly when performed on crash victims. Although testing for ethanol in urine is common in workplace drug screening, most testing in clinical laboratories is done using serum or plasma. Concentrations are most commonly measured enzymatically using alcohol dehydrogenase. In larger toxicology laboratories, ethanol measurements are often done using a GC assay that can also distinguish and measure isopropanol and methanol, as well as the isopropanol metabolite acetone. Alcohols with lower volatility, including ethylene and propylene glycol, are usually not detected by this assay. Because both enzymatic and chromatographic assays have substantial specificity for ethanol, confirmatory testing with a second method is uncommon.

Breath alcohol analyzers may also be used in assessing ethanol intoxication, as may point-of-care devices that measure salivary ethanol. These measurements are less precise than laboratory assays[14,30] and are more subject to interference by other alcohols and other organic solvents. Breath-alcohol analyzers require good cooperation from the patient to obtain an appropriate breath sample and are typically calibrated to give results approximating whole-blood alcohol concentrations. For the above reasons, confirmation of positive findings with a laboratory measurement may sometimes be desirable.

Blood alcohol concentrations used legally to define driving under the influence have no particular clinical significance but may have risk management implications for patient discharge. Whereas legal standards are written in terms of whole-blood alcohol concentrations, clinical laboratories usually measure alcohol in serum or plasma. Serum and plasma alcohol concentrations are essentially identical, but both will be higher than the alcohol concentration measured in a whole-blood specimen obtained at the same time. This is a result of the lower concentration of alcohol in the red blood cells. The ratio of serum alcohol to whole-blood alcohol varies from individual to individual, with a median value of 1.15.[27] It is more likely than not that an individual with a serum alcohol concentration of less than 92 mg/dL will have a whole-blood alcohol concentration of less than 80 mg/dL (<0.10%, w/v) (Chap. 77).

CHAPTER 7

TECHNIQUES USED TO PREVENT GASTROINTESTINAL ABSORPTION

Anne-Bolette Gude and Lotte C. G. Hoegberg

Gastrointestinal (GI) decontamination is a controversial issue in medical toxicology. It plays a central role in the initial management of orally poisoned patients and frequently is the only treatment available other than routine supportive care. Unfortunately, as is true in most areas of medical toxicology, valid studies that demonstrate the effects of GI decontamination on clinically meaningful endpoints are difficult to find. The heterogeneity of poisoned patients demands that very large randomized studies be performed because most patients who present to an emergency department (ED) have an unreliable history and a low-risk exposure. These factors, as well as other significant sources of bias, are often hidden in inclusion and exclusion criteria of the available studies. The numerous consequential determinants contribute to the difficulties in designing and completing studies that provide sound evidence for or against a particular therapeutic option. Incontrovertible endpoints, such as complication-specific mortality, also demand exceptionally large studies because the overall morbidity and mortality of poisoned patients is quite low. Whereas other endpoints, such as the length of stay in the hospital or intensive care unit (ICU), change in xenobiotic concentration, the rate of secondary complications, and the need for specific treatments such as expensive antidotes, must be considered, these surrogate markers are not adequately rigorous and are inadequately precise measures of morbidity. In the science of GI decontamination, we are also faced with the dilemma that randomizing half of a group of potentially ill patients to no decontamination is a significant ethical concern—we rarely omit decontamination unless a minimally toxic exposure has occurred or an effective, safe, readily available, and inexpensive antidote exists. Because acetaminophen meets many of these parameters, it has been used both as the xenobiotic of choice in volunteer overdose studies[28,59,67,159] and in a recent Australian evaluation of actually poisoned patients.[37] However, despite its widespread use as a model, the applicability of the management approach for acetaminophen poisoning to other ingestions is limited.

As might be suspected, no available study provides adequate guidance for the management of a patient who has definitely ingested an unknown xenobiotic at an unknown time. Fortunately, in most cases, there is some component of the history or clinical presentation, such as vital signs, physical examination, and focused diagnostic studies such as an ECG and anion gap, that might offer insight into the nature of the ingested xenobiotic (Chap. 3).

For many, the ongoing controversy or debate on GI decontamination culminated in 1997 with the publication of the position statements on activated charcoal, orogastric lavage, syrup of ipecac induced emesis, and whole-bowel irrigation (WBI) from the American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT).[29,86,124,125,142,151-153] Contrary to initial expectations, these excellent reviews failed to end the debate; they simply highlighted many shortcomings and ambiguities within this field. A 2000 study concluded that despite having the evidence reviewed and consensus recommendations made, poison specialists at North American poison centers still offered a wide variety of recommendations for GI decontamination.[79] The study evaluated decontamination options for a theoretical patient with a difficult scenario of an overdose of enteric-coated aspirin. The recommendations made were often inconsistent with the published position statements, and in some cases, were frankly dangerous. Even toxicologists who made substantial contributions to the development of these consensus statements disagreed on certain aspects of the treatment, although to a lesser extent. In a similar study, when an interactive questionnaire was sent to 14 European Poison Centers, significant differences in the protocols for the recommended method of GI decontamination, timing, and intervention doses were found.[58] These differences suggest that there is inadequate evidence available to produce a proper evidence-based answer for many of the decisions in question. In most of the clinical studies that provide evidence to form the basis for the consensus statements, either there are very few patients with consequential ingestions included, or these specific patients were excluded from the study. Similarly, there are no studies for most drugs with modified release kinetics or for newly marketed drugs. Thus, the clinician must often make decisions based on a philosophical approach and an understanding of specific principles rather than evidence.

More recent studies investigating the trends in GI decontamination in both the advice given by poison centers and the clinical setting show a considerable decline in the use of all methods of decontamination.[29,88,95] One study specifically evaluating orogastric lavage found that during the years 1993 to 1997, an average of 18.7% of all poisoned patients received orogastric lavage compared with an average of 10.3% of poisoned patients during the years 1998 to 2003. The decline in the use of GI decontamination after the publication of the position statements is also probably a result of the epidemiologic shift in the developed world away from overdoses of more lethal substances, such as barbiturates and tricyclic antidepressants, to benzodiazepines and serotonergic reuptake inhibitors, with a natural resultant decrease in morbidity and mortality. Although true, for the Western world, studies in developing countries indicate a different pattern of poisonings with patients ingesting xenobiotics such as organic phosphorus compounds and other pesticides and herbicides with a more lethal toxicologic profile.[45]

This chapter does not discuss details with regard to the evaluation of the amount and type of xenobiotic ingested or other strategies for managing a patient with an unknown overdose; these issues are discussed in Chapter 4. Rather, the focus is on determining which decontamination technique or combination of techniques is preferred after an indication for GI decontamination has been established. The literature published since the previously mentioned position statements is emphasized, existing evidence is summarized, and areas necessitating further investigation are identified. Detailed discussions of emesis, catharsis, and activated charcoal can be found in the corresponding Antidotes in Depth sections, Syrup of Ipecac, Whole-Bowel Irrigation and Other Intestinal Evacuants, and Activated Charcoal. In addition, when the ingested xenobiotic is known, readers should refer to the decontamination sections found in Chapters 34 through 127, which will offer insight into xenobiotic-specific issues that may alter decontamination strategies.

GASTRIC EMPTYING

The principle theory governing gastric emptying is very simple: If a portion of xenobiotic can be removed before absorption, its potentially toxic effect should either be prevented or minimized. From 1982 to 1995, several important clinical trials attempted to define the role of

gastric emptying in poisoned patients.[3,19,32,73,86,104,123,150] Although all of these studies were flawed because of the inclusion of a large number of low-risk patients, numerous restrictive exclusion criteria, and a variety of other biases, they clearly demonstrated that many patients can be successfully managed without aggressive gastric emptying. The clinical parameters listed in Table 7–1 help to identify individuals for whom gastric emptying is usually not indicated based on a risk-to-benefit analysis. In contrast, for a small subset of patients (see Table 7–1), gastric emptying may be indicated. A thorough understanding of this risk analysis is essential when deciding whether gastric emptying is appropriate for a patient who has ingested a xenobiotic.

Time is an important consideration, in that for gastric emptying to be beneficial, a consequential amount of xenobiotic must still be present in the stomach. Demographic studies have found that very few poisoned patients arrive at the ED within 1 to 2 hours after ingestion. In most studies, the average time from ingestion to presentation was approximately 3 to 4 hours, with significant variations.[80,87,124,144] This delay diminishes the likelihood of recovering a large percentage of the xenobiotic from the stomach unless the patient has ingested a xenobiotic that slows gastric emptying rates.

As is discussed in more depth in the Orogastric Lavage section later in this chapter, many authors advise against interventions beyond 1 hour after ingestion. Recent data highlight the arbitrary nature of this limitation. One human volunteer study evaluated the pharmacokinetic effects of diphenhydramine and oxycodone in a simulated acetaminophen overdose.[63] This model is relevant because of the rapid absorption of acetaminophen and the presence of many such combination products in the marketplace. Whereas diphenhydramine did not delay gastric emptying significantly, oxycodone delayed the time to peak acetaminophen concentration by approximately 1 hour. Although GI decontamination was not part of the study protocol, it can be inferred that acetaminophen was available for GI decontamination for a longer time than the 1-hour guideline suggests. Case reports have also reported poisoned patients with the xenobiotic still in the stomach (as confirmed by computed tomography or gastroscopy) as residuals or pharmacobezoars, from 5 hours up to several days after ingestion.[43,84]

In fact, markedly prolonged gastric emptying half-lives and gastric hypomotility were demonstrated using gastric scintigraphy in a prospective study on 85 poisoned patients.[1] Remarkably, these findings occurred with ingestions such as acetaminophen, which are not typically expected to prolong gastric emptying. Patients who underwent orogastric lavage did not have significantly different gastric emptying half-lives, suggesting that the procedure itself was not the cause of the gastroparesis. There was also no evidence that activated charcoal affected gastric emptying rates. The authors speculated that stress in an overdosed patient might be part of the etiology of the hypomotility observed and that the management of patients should not be based on the assumption that GI motility is normal.

Assessment of whether or not gastric emptying is appropriate for a patient continues with an evaluation for potential contraindications (Table 7–2). Regardless of the severity of the ingestion and other contributing factors, such as time, there must be no contraindication to gastric emptying procedures. Because the demonstrable benefit of emptying after ingestion of an unidentified xenobiotic is marginal at best, even relative contraindications usually dictate that the procedure should not be attempted.

After the decision to perform gastric emptying has been made, the clinician must choose between the two available methods. Either emesis can be induced with the administration of syrup of ipecac or orogastric lavage can be performed by cautious aspiration of gastric contents using a large-bore tube and small amounts of water. Although the numerical benefit of either method of gastric emptying has, in several studies, rarely averaged more than a 50% reduction in the absorption of a xenobiotic when performed under optimal research conditions,[86,151] this clinical benefit could be sizable if the ingested dose places the patient on the steep portion of the dose–response curve (Chap. 8). Under these circumstances a small reduction in dose might translate into a significant reduction in toxicity.

TABLE 7–1. Risk Assessment: When to Consider Gastric Emptying

Gastric Emptying Is Usually Not Indicated If[a]	Gastric Emptying May Be Indicated If[b]
The xenobiotic has limited toxicity at almost any dose	There is reason to believe that, given the time of ingestion, a significant amount of the ingested xenobiotic is still present in the stomach.
Although the xenobiotic ingested is potentially toxic, the dose likely ingested is less than that expected to produce significant illness.	The ingested xenobiotic is known to produce serious toxicity *or* the patient has obvious signs or symptoms of life-threatening toxicity.
The ingested xenobiotic is well adsorbed by activated charcoal, and the amount ingested is not expected to exceed the adsorptive capacity of activated charcoal.	The ingested xenobiotic is not adsorbed by activated charcoal or activated charcoal is unavailable.
Significant spontaneous emesis has occurred.	Although the ingested xenobiotic is adsorbed by activated charcoal, the amount ingested exceeds the activated charcoal-to-xenobiotic ratio of 10:1 even when using a dose of activated charcoal that is twice the standard dose recommended.
The patient presents many hours postingestion and has minimal signs or symptoms of poisoning.	The patient has not had spontaneous emesis.
The ingested xenobiotic has a highly efficient antidote (e.g., acetaminophen and NAC).	No highly effective specific antidote exists or alternative therapies (e.g., hemodialysis) pose a significant risk to the patient.

[a] Patients who fulfill these criteria can be decontaminated safely with activated charcoal alone or may require no decontamination at all.

[b] Patients who fulfill these criteria should be considered candidates for gastric emptying *if* there are no contraindications. For individuals who meet some of these criteria but who are judged not to be candidates for gastric emptying, single- or multiple-dose activated charcoal and/or whole-bowel irrigation should be considered.

NAC, *N*-acetylcysteine.

TABLE 7–2. Indications and Contraindications to Orogastric Lavage

Indications	Contraindications
The patient meets criteria for gastric emptying (see Table 7-1). The benefits of gastric emptying outweigh the risks.	The patient does not meet criteria for gastric emptying (see Table 7-1). The patient has lost or will likely lose his or her airway protective reflexes and has not been intubated. (After the patient has been intubated, orogastric lavage can be performed if otherwise indicated.). Ingestion of an alkaline caustic Ingestion of a foreign body (e.g., a drug packet) Ingestion of a xenobiotic with a high aspiration potential (e.g., a hydrocarbon) in the absence of endotracheal intubation The patient is at risk of hemorrhage or gastro-intestinal perforation because of underlying pathology, recent surgery, or other medical condition that could be further compromised by the use of orogastric lavage. Ingestion of a xenobiotic in a form known to be too large to fit into the lumen of the lavage tube (e.g., many modified-release preparations)

OROGASTRIC LAVAGE

Many authors have adopted the consensus approach that orogastric lavage should not be considered unless a patient has ingested a potentially life-threatening amount of a xenobiotic and the procedure can be undertaken within 60 minutes of ingestion.[86,151] Since the publication of the clinical studies cited above,[3,19,32,73,86,104,123,150] studies of orogastric lavage have been scarce. One crossover study used 4 g of an acetaminophen solution as a marker and randomized the subjects to either control or orogastric lavage performed at 30 minutes postingestion. Although the study found a mean 20% reduction in the AUC (area under the plasma drug concentration versus time curve) of acetaminophen with orogastric lavage compared with controls, the confidence interval of ±28% suggests a rather modest and very unreliable effect.[60]

Two other prospective, randomized, crossover studies in volunteers measured the effect of activated charcoal versus orogastric lavage, with interventions at either 5 or 30 minutes postingestion.[90,91] Both studies used therapeutic doses of moclobemide, temazepam, and verapamil. Interestingly, when orogastric lavage was performed 5 minutes after ingestion, there was no significant pharmacokinetic effect on any of the drugs ingested. However, when orogastric lavage was performed 30 minutes after ingestion of moclobemide, the AUC was reduced by 44% compared with controls; there were no effects on the pharmacokinetic profiles of the other two drugs. These results most likely illustrate the very varied and unreliable effect of orogastric lavage even when performed by the same experienced professionals under controlled experimental conditions.

Another study evaluated the effect of activated charcoal compared with activated charcoal followed by orogastric lavage at 30 minutes postingestion.[90] Therapeutic doses of temazepam, ibuprofen, and citalopram were studied. In this model, the combination of activated charcoal and orogastric lavage was not superior to activated charcoal alone. A retrospective case study of 17 patients ingesting *Datura stramonium* seeds found that seeds were recovered in only 57% (eight of 14) of patients subjected to orogastric lavage. There was no significant effect of the removal of the seeds on clinical endpoints such as length of stay in hospital, use of the ICU, or use of the antidote physostigmine.[133]

It is important to highlight the differences between volunteer studies using therapeutic doses of drugs and actual patients with clinically significant overdoses. The most important aspect of this comparison is a bias against gastric emptying and toward a benefit of activated charcoal. The drugs used in these volunteer studies are all well-adsorbed by activated charcoal and the doses of activated charcoal are significantly in excess of its binding capacity for the drug. Larger doses, as might occur in clinically important ingestions are likely to saturate activated charcoal. An additional bias is introduced against gastric emptying because the small amounts of drugs used are unlikely to alter gastric motility and thus the drugs may pass through the pylorus before orogastric lavage can occur. A synthesis of available data can be used to develop indications for orogastric lavage (see Table 7–2). When deciding whether or not to actually perform orogastric lavage on a poisoned patient, these indications, contraindications, and potential adverse effects must be considered. Table 7–3 summarizes the technique of orogastric lavage.

Reported adverse effects of orogastric lavage include injury to the airway, esophagus,[22] and stomach,[40] as well as severe hypernatremia.[105]

TABLE 7–3. The Technique of Performing Orogastric Lavage

Select the correct tube size

Adults and adolescents: 36–40 French

Children: 22–28 French

Procedure

1. If there is potential airway compromise, endotracheal or nasotracheal intubation should precede orogastric lavage.
2. The patient should be kept in the left lateral decubitus position. Because the pylorus points upward in this orientation, this positioning theoretically helps prevent the xenobiotic from passing through the pylorus during the procedure.
3. Before insertion, the proper length of tubing to be passed should be measured and marked on the tube. The length should allow the most proximal tube opening to be passed beyond the lower esophageal sphincter.
4. After the tube is inserted, it is essential to confirm that the distal end of the tube is in the stomach.
5. Any material present in the stomach should be withdrawn and immediate instillation of activated charcoal should be considered for large ingestions of xenobiotics known to be adsorbed by activated charcoal.
6. In adults, 250 mL aliquots of a room-temperature saline lavage solution is instilled via a funnel or lavage syringe. In children, aliquots should be 10 to 15 mL/kg to a maximum of 250 mL.
7. Orogastric lavage should continue for at least several liters in an adult and for at least 0.5 to 1.0 L in a child or until no particulate matter returns and the effluent lavage solution is clear.
8. After orogastric lavage, the same tube should be used to instill activated charcoal if indicated.

A case of hypernatremia resulted from a lavage that was performed using 12 L of hypertonic saline.[105] An observational case series studying 14 consecutive gastric lavages performed in a resource-poor location found three deaths directly related to the procedure, all of which seemed to have resulted from inadequate airway protection.[46] These cases, as well as other well-known complications such as aspiration pneumonitis,[151,153] demonstrate that orogastric lavage is not risk free and should only be considered based on the rigorous indications for gastric emptying listed in Table 7–1.

■ SYRUP OF IPECAC

A comprehensive summary of the pharmacology and the evidence for induced emesis is available in the Antidotes in Depth: Syrup of Ipecac. Since 1997, very little original work has been published other than reviews and the position statement recommendations.[86] Additionally, a revision of the position paper found no new evidence to support any modification in recommendations.[124] At the time of this writing, no additionally useful materials were found.

Although many animal and human studies show a reduction in drug concentrations with induced emesis, no clinical benefit for this technique has been proven. Furthermore, as the benefits of activated charcoal are recognized and the time to its administration evaluated, it has become evident that the administration of syrup of ipecac delays the administration of activated charcoal, as well as any other oral treatment (symptomatic or specific antidotes).

Syrup of ipecac is absolutely contraindicated when the patient has ingested a caustic or a xenobiotic with a high aspiration potential, such as a hydrocarbon. Because vomiting in the setting of altered consciousness increases the likelihood of pulmonary aspiration, syrup of ipecac can only be used when the patient has a normal mental status *and* can be predicted to have a normal mental status at 1 hour after administration, when emesis may still occur. In the clinical setting, it is rare to identify patients with consequential ingestions who present early enough to require gastric emptying and who are expected to retain their airway protective reflexes for a minimum of 1 hour. Therefore, most consensus statements correctly conclude that, given the lack of evidence demonstrating a clinically meaningful benefit of induced emesis *and* the significant contraindications, the routine administration of syrup of ipecac in the ED should be abandoned.[85,124] Although other emetics and methods to induce emesis exist, data are insufficient to support their routine use.

Gastric decontamination of children in the home has always been an attractive concept because both the xenobiotic and time of ingestion are known and there is a high likelihood that the xenobiotic is still in the stomach. A prospective observational study evaluated 75 cases of probably poisoned children (of 14,603 human exposures) in which home administration of syrup of ipecac had been recommended by a poison specialist.[57] Cases in which syrup of ipecac was indicated but not available in the home were included in this group if the parents stated that syrup of ipecac could be obtained within 15 minutes. The administration of syrup of ipecac occurred in less than 30 minutes in only 20% of cases, and the reported overall mean time to emesis was 58 minutes from ingestion. Initial emesis occurred in less than 60 minutes in only 36% of cases. Numerous studies illustrate that the time to performing GI decontamination is critical. Clearly, the problem with syrup of ipecac is the time delay from administration to onset of emesis. Additionally, the uncertainty of the effect of the administered dose serves as a further delaying factor. A study in 12 adult volunteers showed that with a 20-mL dose, two of six volunteers had not vomited within 4 hours, but all volunteers (six of six) had vomited within 60 minutes after receiving a 30-mL dose.[157]

| TABLE 7–4. Indications and Contraindications for Syrup of Ipecac ||
Indications	Contraindications
The patient meets criteria for gastric emptying (see Table 7-1). Orogastric lavage cannot be performed or is contraindicated because of the size of the xenobiotic formulation. The history and/or physical examination suggest that there is likely to be a clinically significant amount of xenobiotic remaining in the stomach. The benefits of gastric emptying outweigh the risks from the contraindications.	The patient does not meet criteria for gastric emptying (see Table 7–1). Either activated charcoal or another oral therapy is expected to be necessary in the next several hours. Airway protective reflexes might be lost within the next hour Ingestion of a caustic Ingestion of a foreign body such as a drug packet or sharp item Ingestion of a xenobiotic with a high aspiration potential such as a hydrocarbon. The patient is younger than 6 months of age, elderly, or debilitated. The patient has a premorbid condition that would be compromised by vomiting.

A four-limb randomized study using 10 healthy volunteers studied the effect of 30 mL of syrup of ipecac administered at 5, 30, and 60 minutes after the ingestion of 3.9 g of acetaminophen. The fourth limb served as a control. Only the 5-minute intervention was significantly different from control and showed a decrease in bioavailability of approximately 67%.[132] This study also noted that sedation was a significant adverse effect of syrup of ipecac, which makes this therapy difficult to recommend in patients who have ingested any potentially sedating xenobiotic.

A study using the 2003 Toxic Exposure Surveillance System (TESS) database (Chap. 135) evaluated the effect of home use of syrup of ipecac on the rate of referral to EDs across the United States. The study found that there was no reduction in ED use nor any improvement in patient outcome from home administration of syrup of ipecac.[18] Based on these findings and other data, the American Academy of Pediatrics published its policy statement on poison treatment in the home, concluding that syrup of ipecac should no longer be used as a standard home treatment in cases of poisoning.[6] Despite this, some authors still believe that there is a limited role for ipecac-induced emesis.[94] Table 7–4 summarizes the indications and contraindications for administration of syrup of ipecac. The only reasonable conclusion is that induction of emesis has an extremely limited role in the contemporary management of poisoned patients.

PREVENTION OF XENOBIOTIC ABSORPTION

■ ACTIVATED CHARCOAL

Activated charcoal has long been recognized as an effective method for reducing the systemic absorption of many xenobiotics. For certain xenobiotics, it also enhances elimination through interruption of either the enterohepatic or enteroenteric cycle.[17,33,81] Its superb adsorptive properties theoretically make it the single most useful management strategy for diverse patients with acute oral overdoses.[7-9,18,28,34,72,120,121]

But overall, as is true for the other methods of GI decontamination, there is a lack of sound evidence of its benefits as defined by clinically meaningful endpoints. This opinion is reflected both in the consensus statements and in the overall trend toward no decontamination as shown in AAPCC data (Chap. 135).[29,103,104] The consensus opinion concluded that a single dose of activated charcoal should not be administered routinely in the management of poisoned patients and, based on volunteer studies, the effectiveness of activated charcoal decreased with time, providing the greatest benefit within 1 hour of ingestion. There was no evidence that the administration of a single dose of activated charcoal improved clinical outcome. Additionally, it is generally accepted that unless either airway protective reflexes are intact (and expected to remain so) or the patient's airway has been protected, the administration of activated charcoal is contraindicated.[29]

Only a few studies have used valid clinical endpoints in an attempt to demonstrate a benefit of GI decontamination. A 2-year study concluded that activated charcoal was associated with a higher incidence of vomiting, a more prolonged ED stay, and a failure to improve clinical outcome compared with supportive care.[103] However, despite randomizing 1479 patients to either activated charcoal on even days and of no decontamination on odd days, only 399 patients were placed in the activated charcoal group, and 1080 patients were placed in the control group. This very uneven patient distribution suggest a selection bias that is inadequately described in the study. The authors concluded that there appeared to be no benefit to decontamination procedures, although they admitted that length of stay (one of their endpoints) was more dependent on the wait for psychiatric evaluation and the availability of a mental health bed for patient transfer than the resolution of clinical poisoning. The inclusion of a significant number of low-risk patients in this study introduced a clear bias against determining any benefit of decontamination. Furthermore, the validity of the study is questionable because patients with significant acetaminophen overdoses were excluded given that there are sound data to support improved clinical outcomes or laboratory parameters of diminished hepatotoxicity in acetaminophen-poisoned patients treated with activated charcoal.[21,140]

Theoretically, the early administration of activated charcoal to patients presenting with a significant oral overdose of a potentially toxic xenobiotic would lower systemic exposure to that xenobiotic and thus be of benefit to the patient. Surprisingly, this intuitive result has been difficult to demonstrate using clinically relevant endpoints in large unselected populations of poisoned patients.

A randomized, controlled clinical trial of all oral overdose patients ($n = 327$) presenting to the ED of a large hospital in an urban setting during 16 consecutive months found no difference in clinical endpoints such as length of stay or other outcomes between patients treated with a single dose of activated charcoal compared with no decontamination. The study excluded seven severely poisoned patients who all arrived within 1 hour of ingestion; the majority of the patients in the trial (nearly 60%) arrived within 2 hours postingestion. The most common xenobiotics ingested were acetaminophen, benzodiazepines, and newer antidepressants with low case-fatality rates.[38]

A large trial ($n = 4629$) from a rural and resource-poor location (Sri Lanka) studying patients self-poisoned primarily with pesticides and yellow oleander (*Thevetia*) seeds found no difference in mortality rates between no activated charcoal, single-dose activated charcoal, or a regimen of multiple-dose activated charcoal (MDAC). It is important to note that the first 1904 patients in the control group actually received orogastric lavage, as was the case for all patients presenting within 2 hours of ingestion of substantial amounts of pesticides or potentially toxic xenobiotics because of pressure from the national doctors' union. Although the authors claim that logistic regression analysis found

no influence of lavage on their results, the data are not presented.[47] Furthermore, in an article on compliance related to activated charcoal, nested within this randomized, controlled trial, it is stated that a large number of patients included in the trial had undergone gastric emptying in some form before being transferred from peripheral hospitals.[106] The results of this trial are probably valid for their particular setting and patient profiles but cannot be generalized to developed nations. In contrast with the lack of effect on clinical endpoints such as death, a pharmacokinetic analysis from another subset of patients ($n = 104$) from this large trial found a significant increase in plasma clearance of the *Thevetia* cardenolides in patients administered both single-dose activated charcoal and MDAC. There was no difference between groups in mortality, but given the absolute numbers of two to three deaths per group, this could be related to a lack of power in the study design.[127]

Time Factors Many authors state that administration of a single dose of activated charcoal should be considered if a patient has ingested a potentially toxic amount of a xenobiotic (that is known to be adsorbed to activated charcoal) within the previous hour. This position was chosen because there are insufficient data to support or exclude the use of single-dose activated charcoal therapy more than 1 hour beyond xenobiotic ingestion.[29] The efficacy of activated charcoal administered more than 1 hour after xenobiotic ingestion is continuously debated and has been evaluated in several studies. Recent studies support the use of activated charcoal even late after the drug overdose.[55,74,78,140]

In volunteers, the effect of activated charcoal administered 2 and 4 hours after ingestion of acetaminophen demonstrated no significant difference in plasma acetaminophen concentration compared with controls. In contrast, when administered 1 hour after a simulated acetaminophen ingestion, activated charcoal reduced plasma acetaminophen concentrations significantly.[159] Likewise, when the effectiveness of activated charcoal administered 1, 2, and 3 hours after xenobiotic ingestion was determined, only the 1-hour group had a different pharmacokinetic profile from the control group.[59] Although these data do not support the administration of activated charcoal as a GI decontamination strategy more than 1 hour after an overdose, the applicability of these results to actual overdosed patients has not been adequately evaluated. The method in this volunteer study was an 8-hour fast followed by a small meal 1 hour before the administration of 3 to 4 g of acetaminophen.[59,159] Considering the rapid absorption of acetaminophen and the small 3- to 4-g doses used, it is highly probable that little or no acetaminophen would be left in the GI tract to be adsorbed by activated charcoal, limiting the potential time to benefit from activated charcoal to approximately 1 hour.

In contrast, activated charcoal given 3 hours after a xenobiotic overdose was investigated in vivo, again using acetaminophen and a larger-than-standard dose (i.e., 75 g) of activated charcoal. The results demonstrated some benefit in administering activated charcoal 3 hours after an overdose because there were significantly lower serum acetaminophen concentrations in the activated charcoal group than in the control group.[135] In a similar study, activated charcoal was effective in reducing the systemic absorption of a xenobiotic (acetaminophen) when administered 1 and 2 hours after ingestion, although the effect of the 2-hour intervention was substantially less than at 1 hour, reemphasizing the importance of early intervention.[28]

Activated charcoal administered between 0.5 and 4 hours to 17 patients who had ingested potentially toxic doses of citalopram demonstrated a pronounced effect on clearance and bioavailability. The result was a 72% increase in clearance and a 22% decrease in bioavailability when activated charcoal was administered. The data set included concentration–time data from 53 patients studied after 63 citalopram overdose events.[55]

Despite a delay to activated charcoal of 0.5 to 6.0 hours after a quetiapine overdose, a significant benefit for a single dose of activated

charcoal was demonstrated. Activated charcoal decreased the fraction absorbed of quetiapine by 35%. No apparent effect on clearance was demonstrated.[75]

A meta-analysis was performed to evaluate the effect of activated charcoal on xenobiotic absorption during the first 6 hours after ingestion. Data were obtained from 64 controlled studies in which activated charcoal was compared with placebo up to 6 hours after drug ingestion in volunteers. Additional considerations were given to the influence of physical and pharmacologic properties, and the activated charcoal-to-drug ratio was evaluated. The authors concluded that activated charcoal was most effective when administered immediately after xenobiotic ingestion. Even with a delay of 4 hours after ingestion, 25% of the participants achieved at least a 32% reduction in absorption, especially when activated charcoal was given with large charcoal-to-drug ratios. Activated charcoal was most effective for xenobiotics with large molecular weights and volumes of distribution (Vd) where other treatment options, including dialysis, are limited.[78] Activated charcoal should therefore be considered in poisoned patients even when they present late to medical care.

Similarly, when aminotransferase elevations were measured in patients with acetaminophen overdose who presented more than 4 hours after ingestion, patients who received activated charcoal along with *N*-acetylcysteine (NAC) had better outcomes than those who received NAC alone. This study had certain limitations, though, because its observations methodology was neither randomized nor blinded.[140]

Thus, it should be clear that the use of a 1-hour time frame is meant more as a guideline than an absolute cutoff. It is only logical that if an intervention is effective at 59 minutes, it will also be beneficial at 61 minutes. Although it is logical that efficacy decreases as time from ingestion increases, in certain cases, some benefit may be derived many hours postingestion. As discussed above, good data from patients with actual ingestions demonstrate that a significant amount of xenobiotic can be found in the stomach beyond this arbitrary 1-hour time frame. Additional benefits on enhanced elimination are discussed below.

The recommendation that activated charcoal should be administered within 1 hour of ingestion limits the potential to treat most poisoned patients. A study over a 6-month period identifying 63 patients who had taken potentially serious overdoses demonstrated a median time of arrival to healthcare of 136 minutes after the overdose. Only 15 patients presented within 1 hour, and only four of 10 patients who qualified received activated charcoal within 1 hour. The results demonstrate not only the difficulty in clinically assessing patients before 1 hour but also the difficulty in adhering to the principle of treating patients with activated charcoal when they arrive within 1 hour unless activated charcoal could be safely administered to appropriate patients before hospitalization.[80]

Prehospital use of activated charcoal has not gained wide acceptance because of the concern that it would not be administered properly by the untrained lay public and that many children would refuse to drink the charcoal slurry. An 18-month consecutive case series demonstrated that activated charcoal can be administered successfully in the home by the lay public. Home use of activated charcoal significantly reduced the time to activated charcoal administration after xenobiotic ingestion from a mean of 73 ± 18.1 minutes for ED treatment to a mean of 38 ± 18.3 minutes for home treatment.[139] However, many still consider this evidence insufficient to recommend that activated charcoal be stored in the home.

A prospective follow-up study from Finland evaluated the adherence to a new protocol of administering activated charcoal in the prehospital setting. The protocol was implemented by either the first-response unit or paramedics. Activated charcoal was indicated in 722 of 2047 patients. Of these patients, 555 actually received activated charcoal at a mean of 88 minutes after ingestion. There were no adverse effects noted, although 72 patients refused to drink the charcoal. This study shows that it is feasible to administer activated charcoal in the prehospital setting, but its clinical implications are unknown.[2]

In reality, many factors, such as the presence of food in the stomach, sustained-release formulations, and co-ingestions with anticholinergic or opioid properties, which delay gastric emptying can slow the rate of absorption of a xenobiotic. These factors increase the time frame for possible adsorption to activated charcoal. An increased effect of activated charcoal was shown in a randomized, crossover study in which volunteers were administered acetaminophen in either the presence or absence of the anticholinergic drug atropine and subsequently given a single dose of activated charcoal 1 hour later. Activated charcoal was more effective in reducing acetaminophen bioavailability in the presence of an anticholinergic agent.[60]

Dosing The optimal dose of oral activated charcoal has never been fully established. Since the beginning of its clinical use as a GI decontaminant, various factors have been recommended for determining the optimal dose of activated charcoal. Two factors commonly discussed are the patient's weight and the quantity of the xenobiotic ingested. The problem in using the quantity of the xenobiotic as a basis for activated charcoal dosing is that the amount is usually unknown, and there is an implication that nothing else in the GI tract will occupy binding sites on activated charcoal. Additionally, the xenobiotic is often unknown, and xenobiotics vary enormously in their toxicities, rate of absorption, and the clinical effects they produce (e.g., respiratory depression, convulsions, and effect on gastric emptying rate). Some xenobiotics are well adsorbed to activated charcoal, but others are not.[33] Because of variables such as the physical properties of the formulation ingested (liquid, solid, or sustained-release pill), the volume and pH of gastric and intestinal fluids, and the presence of other xenobiotics adsorbed by activated charcoal,[9,13,65,66,94,112,114] the optimal dose cannot be known with certainty in any given patient.

Information concerning the maximum adsorptive capacity of activated charcoal for the particular xenobiotic ingested permits a theoretical calculation of an adequate dose,[4,7,12,14,26,34,109,110,112,113,128,129,131,137,146,149] assuming that the amount of xenobiotic ingested is known. However, clinicians must remain cognizant of the risk of approaching or exceeding the adsorptive capacity of the standard dose of approximately 1 g/kg of body-weight of activated charcoal. This possibility has been investigated in only a few studies.[4,14,24,131]

Thus, the idea that a fixed activated charcoal-to-xenobiotic ratio is appropriate for all xenobiotics is clearly imperfect. It is possible, however, to develop a logical approach to dosing based on available data. The optimal activated charcoal dose is theoretically the minimum dose that completely adsorbs the ingested xenobiotic and, if relevant, that maximizes enhanced elimination. The results of in vitro studies show that the ideal activated charcoal-to-xenobiotic ratio varies widely, but a common recommendation is to deliver an activated charcoal-to-xenobiotic ratio of 10:1 or 50 to 100 g of activated charcoal to adult patients, whichever is greater. From a theoretical perspective, this amount will adsorb 5 to 10 g of a xenobiotic, which should be adequate for most poisonings.[7,8,29,33,96,113] Based on available data from in vivo and in vitro studies, the actual recommended dosing regimen for activated charcoal is 25 to 100 g in adults (1 g/kg of body weight) and 0.5 to 2.0 g/kg of body weight in children.[29,33] These recommendations are generally based more on activated charcoal tolerance than on efficacy. When calculation of a 10:1 ratio exceeds these recommendations, either gastric emptying or MDAC therapy should be considered.

For example, consider a patient who intentionally overdosed by ingesting thirty 0.25-mg digoxin pills (total dose, 7.5 mg). Achieving a 10:1 ratio is quite easy, and a standard dose of 1 g/kg might exceed

a 10,000:1 ratio. In comparison, consider a patient who intentionally ingests thirty 325-mg aspirin pills (total dose, 9.75 g). In this case, obtaining a 10:1 activated charcoal-to-xenobiotic ratio is quite difficult and is even less likely if a patient ingests 60 or 100 of the aspirin pills. Poisoning with a combination of xenobiotics may also approach or exceed the maximum adsorption capacity for the standard dose of activated charcoal.

Methods to Increase the Palatability of Activated Charcoal Activated charcoal has a pronounced gritty texture, and it immediately sticks in the throat because it adheres to the mucosal surfaces and begins to cake.[33] In addition, the black appearance and insipid taste of activated charcoal make it less attractive.

There have been numerous attempts at making activated charcoal more appealing by providing flavors, including jam,[41] chocolate syrup,[76,108] cherry extract or syrup,[117,158] juice,[117] sorbitol,[35,39,102] saccharin,[36] strawberry flavor,[116] orange or peppermint oil,[33] melted milk chocolate,[48,49] chocolate milk,[26,117] soda,[26,117,126] yogurt,[67] and ice cream.[26,97,143] Because activated charcoal adsorbs the flavoring agents, the palatable taste often disappears within minutes after mixing.[33,35,36,41] But in cases in which the activated charcoal does not completely adsorb the flavoring agents, they provided a pleasant taste without significantly reducing the adsorptive properties of the activated charcoal.[33,35,36] The general recommendation, however, remains that activated charcoal should be mixed with water.[6,77]

Contraindications and Complications Vomiting frequently complicates the administration of activated charcoal. A prospective cohort study estimating the incidence of vomiting subsequent to the therapeutic administration of activated charcoal to poisoned children younger than 18 years of age showed that one of five of these children vomited. Children with previous vomiting or nasogastric tube administration were at highest risk.[118] This incidence of vomiting appears to be greater when activated charcoal is administered with sorbitol.[152] Also, although rare, inadvertent direct instillation of activated charcoal into the lungs has resulted from a misplaced nasogastric tube, leading to severe pulmonary complications and death. Administration of activated charcoal to already intubated patients is associated with a low incidence of aspiration pneumonia.[107] Another study found that pulmonary complications associated with activated charcoal aspiration might be primarily related to the aspiration of acidic gastric content and not directly related to aspiration of activated charcoal.[130] A retrospective study found that only 1.6% of unselected overdose patients aspirated and that administration of activated charcoal was not found to be an associated risk factor.[74] Pulmonary aspiration in overdose patients who have received activated charcoal is more easily documented because activated charcoal is a very identifiable marker.

Although relatively few reports of clinically significant emesis and pulmonary aspiration resulting from the administration of activated charcoal exist, the severity of these complications is clear. Consequently, it is important to evaluate, particularly in patients determined to be at limited risk from their exposures, whether single-dose activated charcoal therapy is likely to be beneficial based on the indications and contraindications listed in Table 7–5. This is especially true in small children, in whom the risks of a nasogastric tube might outweigh the benefits of activated charcoal.

■ MULTIPLE-DOSE ACTIVATED CHARCOAL

MDAC is typically defined as more than two sequential doses of activated charcoal.[152] In many cases, the actual number of doses administered is substantially greater. This technique serves two purposes: (1) to prevent ongoing absorption of a xenobiotic that persists in the GI tract (usually in the form of a modified-release preparation) and

TABLE 7–5. Indications and Contraindications for Single-Dose Activated Charcoal Therapy without Gastric Emptying

Indications	Contraindications
The patient does not meet criteria for gastric emptying (see Table 7–1) or gastric emptying is likely to be harmful.	Activated charcoal is known not to adsorb a clinically meaningful amount of the ingested xenobiotic.
The patient has ingested a potentially toxic amount of a xenobiotic that is known to be adsorbed by activated charcoal.	Airway protective reflexes are absent or expected to be lost, and the patient is not intubated.
The ingestion has occurred within a time frame amenable to adsorption by activated charcoal or clinical factors are present that suggest that not all of the xenobiotic has already been systemically absorbed.	Gastrointestinal perforation is likely as in cases of caustic ingestions. Therapy may increase the risk and severity of aspiration, such as in the presence of hydrocarbons with a high aspiration potential. Endoscopy will be an essential diagnostic modality (caustics)

(2) to enhance elimination by either disrupting enterohepatic recirculation or by "gut dialysis" (enteroenteric recirculation).

The 1999 position statement of the AACT and the EAPCCT concluded that based on clinical studies, MDAC should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. Data have confirmed enhanced elimination of these drugs, although no controlled studies have demonstrated clinical benefit. Volunteer studies have demonstrated that MDAC increases the elimination of amitriptyline, dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenylbutazone, phenytoin, piroxicam, and sotalol, but there are insufficient clinical data to support or exclude the use of this therapy.[152]

Although technically correct, the preceding statements suffer from a lack of evidence. Because the clinical studies used to formulate this opinion all lack sufficient numbers of significantly poisoned patients, they induce a bias against any benefit of MDAC. Additionally, none of the studies included a detailed analysis of sustained- or extended-release formulations, which are widely used today. Three recent studies with clinical endpoints are discussed below. Unfortunately, their results are discordant, which highlights the difficulties within this field of study.

A single-blind, randomized, placebo-controlled trial was designed to assess the efficacy of MDAC in the treatment of patients with yellow oleander (cardioactive steroid) poisoning. This clinical study demonstrated that MDAC (defined as 50 g of activated charcoal every 6 hours for 3 days) effectively reduced life-threatening cardiac dysrhythmias, deaths, and the need for ICU admission.[42] In this dataset, to save one life, only 18 patients needed to receive MDAC. This study demonstrates that consequential benefits of GI decontamination may become evident when investigations are performed in significantly poisoned patients. It further highlights that general recommendations only apply to patients in general and that severely ill patients deserve individualized care.

In contrast with the above-mentioned study are the results from a large (*n* = 4629) randomized, controlled trial from Sri Lanka in which patients self-poisoned with primarily pesticides and yellow oleander

seeds were randomized to no decontamination, single-dose activated charcoal, and MDAC. There was no difference between groups regarding the ultimate clinical endpoint, mortality. As mentioned previously, the "no decontamination group" was not ideal because a large and relatively unaccounted for number of patients had received some form of gastric emptying either before entering the trial (at primary hospital setting) or later on in the trial after pressure from the national doctors' union.[47] In a small study (*n* = 12) of patients poisoned by carbamazepine, individuals were randomized to either single-dose activated charcoal or MDAC. The duration of coma, mechanical ventilation, and length of stay were significantly decreased in the group receiving multiple doses of activated charcoal, corresponding with a measured significantly shorter half-life of carbamazepine.[20]

Similar to single-dose activated charcoal, MDAC can produce emesis, with subsequent pulmonary aspiration of gastric contents containing activated charcoal. It is intuitive that these risks are greater with multiple- than with single-dose therapy. One retrospective study attempted to determine the frequency of complications associated with the use of MDAC.[44] The authors identified nearly 900 patients who had received MDAC and found that only 0.6% of patients had clinically significant pulmonary aspiration. Although no patients developed GI obstruction, 9% had hypernatremia or hypermagnesemia without any clinical consequences noted. The authors did not specify whether the multiple-dose regimens administered included the use of cathartics, but the profile of the adverse reactions listed above suggests that this is probably the case. Despite the obvious limitations, this study demonstrates a reasonably low rate of complications associated with MDAC.

Table 7–6 summarizes the indications and contraindications for MDAC therapy. Because the optimal doses and intervals for repeated doses of activated charcoal have not been established, recommendations are based more on amounts that can be tolerated than on amounts that might be considered pharmacologically appropriate. Table 7–7 lists typical dosing regimens. Larger doses and shorter intervals should be used for patients with more severe toxicity. It is reasonable to base endpoints either on the patient's clinical condition or on xenobiotic concentrations when they are easily measured.

In rats with bile duct externalization, intestinal perfusion with activated charcoal increased the elimination of intravenous acetaminophen and carbamazepine by 7% and 3% within 3.5 hours, respectively. The lack of effect of activated charcoal on the elimination of acetaminophen, carbamazepine, and their metabolites was suggested to be because of the small amounts of the xenobiotics diffusing into the intestine or by inadequate luminal stirring.[51,52]

TABLE 7–6. Indications and Contraindications for Multiple-Dose Activated Charcoal Therapy

Indications	Contraindications
Ingestion of a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline	Any contraindication to single-dose activated charcoal
Ingestion of a life-threatening amount of another xenobiotic that undergoes enterohepatic or enteroenteric recirculation and that is adsorbed to activated charcoal	The presence of an ileus or other causes of diminished peristalsis
Ingestion of a significant amount of any slowly released xenobiotic or of a xenobiotic known to form concretions or bezoars	

TABLE 7–7. Technique of Administering Multiple-Dose Activated Charcoal Therapy

Initial dose orally or via orogastric or nasogastric tube

Adults and children: 1 g/kg of body weight or a 10:1 ratio of activated charcoal to xenobiotic, whichever is greater. After massive ingestions, 2 g/kg of body weight might be indicated if such a large dose can be easily administered and tolerated.

Repeat doses orally or via orogastric or nasogastric tube

Adults and children: 0.5 g/kg of body weight every 4–6 hours for 12–24 hours in accordance with the dose and dosage form of xenobiotic ingested (larger doses or shorter dosing intervals may occasionally be indicated).

Procedure

1. Add 8 parts of water to the selected amount of powdered form. All formulations, including prepacked slurries, should be shaken well for at least 1 minute to form a transiently stable suspension before the patient drinks it or it is instilled via orogastric or nasogastric tube.
2. Activated charcoal can be administered with a cathartic *for the first dose only* when indicated, but cathartics should never be administered routinely and never be repeated with subsequent doses of activated charcoal.
3. If the patient vomits the dose of activated charcoal, it should be repeated. Smaller, more frequent doses or continuous nasogastric administration may be better tolerated. An antiemetic may be needed.
4. If a nasogastric or orogastric tube is used for MDAC administration, time should be allowed for the last dose to pass through the stomach before the tube is removed. Suctioning the tube itself before removal may prevent subsequent activated charcoal aspiration.

MDAC, multiple-dose activated charcoal.

Further clinical and toxicokinetic studies concerning MDAC are needed to establish an optimal dosing regimen and to confirm an effect on relevant endpoints. Readers are referred to Antidotes in Depth: Activated Charcoal for a more detailed discussion of single-dose activated charcoal and MDAC therapy.

WHOLE-BOWEL IRRIGATION

WBI represents a method of purging the GI tract in an attempt to prevent further absorption of xenobiotics. This is achieved through the oral or nasogastric administration of large amounts of an osmotically balanced polyethylene glycol electrolyte lavage solution (PEG-ELS). This decontamination technique was subjected to a thorough literature review, which was published as a position statement in 1997 and revised in 2004.[125,142] The position statement was unable to establish a clear set of evidence-based indications for the use of WBI because no clinical outcome studies have been performed. When experimental, theoretical, and anecdotal human experience is considered, the use of WBI with PEG-ELS can be supported for patients with potentially toxic ingestions of sustained-release pharmaceuticals. Other theoretical indications include the ingestion of large amounts of a xenobiotic with a slow absorptive phase in which morbidity is expected to be high, the ingested xenobiotic is not adsorbed by activated charcoal, and when other methods of GI decontamination are unlikely to be either safe or beneficial. The removal of packets of xenobiotics from body packers can be considered a unique indication for WBI. Similarly, patients who have ingested large amounts of plant or mushroom material might be highly amenable to treatment with WBI.

WBI cannot be applied safely if the GI tract is not intact, there are signs of ileus or obstruction, or there is significant GI hemorrhage or in patients with inadequate airway protection, uncontrolled vomiting, or consequential hemodynamic instability that compromises GI function or integrity. Additionally, the combination of WBI and activated charcoal results in an in vitro decrease in the adsorption of xenobiotics by activated charcoal, especially when the WBI solution is premixed with activated charcoal. Activated charcoal seems to be most efficacious if administered before initiating WBI.[11,70,85,93] Since the publication of the position statement, only three studies of varying degrees of evidence and some case reports have been published, as discussed below.

The effect of WBI on the pharmacokinetics of a modified-release formulation of acetaminophen and the progression of radiopaque markers through the GI tract was studied using a prospective randomized, crossover design.[101] Ten volunteers ingested the acetaminophen in supratherapeutic doses of 75 mg/kg together with a capsule containing 24 small markers. One study day served as control during which no interventions were undertaken. On the intervention day, the volunteers were subjected to WBI beginning 30 minutes after ingestion and continued until rectal effluent was determined to be clear. The average duration of WBI was 6 hours. No tablets or markers were recovered in the effluent. Only two of 10 patients had adverse effects such as nausea and abdominal cramping, and one volunteer vomited. The authors found a nonsignificant 11.5% reduction in the AUC of acetaminophen. The study had an 80% power to detect a 25% difference in AUC, which was arbitrarily set because there is no clinically established minimal relevant difference for a reduction in the AUC of a xenobiotic. The significance of this reduction would also vary in relation to the toxic properties of a xenobiotic (e.g., small versus large therapeutic index, availability of an effective antidote). In theory, for some xenobiotics, an 11% reduction in absorption might mean the difference between serious and life-threatening toxicity. The authors also found that in eight of 10 subjects, whereas the radiopaque markers were all located in the cecum after WBI, the markers were scattered throughout the small intestine in the control group. This observation indicates that WBI has the capability to move objects in the GI tract, at least to some degree. Although the authors stated that they would discontinue WBI when the rectal effluent was clear, this did not occur, and they chose an endpoint in which the final effluent was straw-colored to yellowish-brown, which might have been too short a time. Nevertheless, during the 6-hour mean duration of therapy, they managed to move the markers out of the small intestine more rapidly with WBI, which might limit absorption. Of note, the entire model has limited applicability because WBI would never be considered for a patient with an acetaminophen overdose.

A randomized, three-phase, crossover study using nine volunteers studied the use of activated charcoal alone compared with activated charcoal followed by WBI in preventing the absorption of three different sustained-release drugs (carbamazepine, theophylline, and verapamil), all of which were administered in therapeutic doses. This study also found that WBI seemed to decrease the efficacy of activated charcoal, but that the pharmacokinetic profile was still better than no intervention, although these results were probably largely an effect of activated charcoal.[90] As mentioned above, study designs using activated charcoal and small doses of xenobiotics tend to bias the study toward a benefit of activated charcoal. In an overdose scenario, when activated charcoal adsorptive capacity may be exceeded, it is intuitive that the benefits of other modalities would be more evident.

The third study evaluating the combined use of activated charcoal and WBI found that there were significant decreases in the adsorption of fluoxetine to activated charcoal and an increase in the desorption of the xenobiotic from activated charcoal.[12] Although these data support

the findings of the studies previously cited in the position statement, they may have limited applicability as WBI would rarely, if ever, be indicated for fluoxetine overdose. However, they do highlight the potential risk of WBI causing desorption of xenobiotics that have been already adsorbed to activated charcoal.

A small, retrospective, descriptive case series of 16 body packers treated with WBI supports the safety of WBI for body packers. Although the complication rate was reported as 12.5% (two of 16), these complications were not serious. One case of mild cocaine toxicity resulted from leakage, and one heroin body packer had to undergo surgery because of retained packages. There was no correlation between the dose of PEG-ELS, drug type, or packet quantity and length of hospital stay. Because there was no control group, it is not possible to evaluate whether WBI influenced any clinical outcome.[53]

WBI has also been used to treat xenobiotic overdoses in pregnant women and children. One such case involved an iron overdose in a woman during the third trimester of pregnancy; she was treated successfully and without complications.[154] A pediatric case report describes combined WBI with succimer therapy and eventually colonoscopic removal of ingested lead pellets. Abdominal radiographs showed two small lead pellets, which WBI failed to remove, therefore requiring endoscopic removal.[31] Several reports support the use of WBI in children, including an intentional ingestion of mercury,[134] two pediatric body packers,[148] and a 16-month-old boy who had ingested a significant amount of iron.[155] In the latter case, despite WBI, the iron bezoar was not removed, treatment was eventually stopped, and the bezoar was expelled after a normal diet was resumed.[155]

Thus, there is no new convincing evidence of the clinical efficacy of WBI. Additional case reports and series demonstrate the overall safety of this procedure as well as some beneficial effect on secondary endpoints, but the benefits remain generally theoretical. There is some evidence against the simultaneous administration of activated charcoal with WBI, and there is little doubt that PEG-ELS reduces the adsorptive capacity of activated charcoal in vitro.

The indications for WBI must, at the present time, remain theoretical because the only support for the efficacy of this procedure comes from surrogate markers and anecdotal experience. Table 7–8 summarizes the indications and contraindications for WBI.

TABLE 7–8. Indications and Contraindications for Whole-Bowel Irrigation

Indications	Contraindications
Potentially toxic ingestions of sustained-release drugs	Airway protective reflexes are absent or expected to become so in a patient who has not been intubated
Ingestion of a toxic amount of a xenobiotic that is not adsorbed to activated charcoal when other methods of GI decontamination are not possible or not efficacious	GI tract is not intact. Signs of ileus, obstruction, significant GI hemorrhage, or hemodynamic instability that might compromise GI motility
Removal of illicit drug packets from body packers	Persistent vomiting
	Signs of leakage from cocaine packets (indication for surgical removal)

GI, gastrointestinal.

CATHARTICS

At present, there is no indication for the routine use of cathartics as a method of either limiting absorption or enhancing elimination. A single dose can be given as an adjunct to activated charcoal therapy when there are no contraindications and constipation or an increased GI transit time is expected. Multiple-dose cathartics should never be used, and magnesium-containing cathartics should be avoided in patients with renal insufficiency. (See Antidotes in Depth A3: Whole-Bowel Irrigation and Other Intestinal Evacuants for more information on cathartics and WBI.)

SURGERY AND ENDOSCOPY

Surgery and endoscopy are occasionally indicated for decontamination of poisoned patients. As might be expected, no controlled studies have been conducted, and potential indications are based largely on case reports and case series. A prospective, uncontrolled series of 50 patients with cocaine packet ingestion was published more than 20 years ago.[23] The patients were conservatively managed and only underwent surgery if there were signs of leakage or mechanical bowel obstruction. Bowel obstruction occurred in three patients, who promptly underwent successful emergency laparotomy; another six patients chose elective surgery. The authors concluded that body packers should be treated conservatively and only operated on for xenobiotic leakage or bowel obstruction.[23]

Similarly, another study performed a 16-year retrospective analysis of all body packers treated in a single center.[136] Of the 2880 body packers who were identified, 2.2% developed symptoms of severe cocaine toxicity after rupture of a package; 43 (68%) of the symptomatic patients died before surgery could be initiated, and 20 (32%) underwent emergency laparotomy to remove the drug packets and survived.

A recent report described two cases of body packers who successfully underwent surgery to remove drug packets. In one case, the indications were rupture and signs of cocaine toxicity. In the other cases, the indication for surgery was bowel obstruction.[115] Because most packages do not spontaneously rupture, mechanical obstruction is probably the most common reason for surgery on a body packer.[147] Leakage from heroin-containing packages can usually be managed by naloxone infusion, but the lack of antidote when cocaine packages rupture necessitates surgery (Chaps. 38, 76 and SC-4: Internal Concealment of Xenobiotic).[147]

Over the years, a few case reports have presented mixed results for the endoscopic removal of drug packets or pharmacobezoars from the stomach.[27,43,138,141,147] At present, this method is not generally recommended because of concerns about packet rupture. However, under exceptional circumstances, there is certainly a precedent for attempting this procedure in a highly controlled setting such as an ICU or operating room.

In rare cases of massive iron overdoses when emesis, orogastric lavage, and gastroscopy failed, gastrotomy was performed. The significant clinical improvement and postoperative recovery indicated that surgery in these particular cases was the correct approach.[54,76]

OTHER ADJUNCTIVE METHODS USED FOR GASTROINTESTINAL DECONTAMINATION

Other agents, such as cholecystokinin, have been considered as adjuncts to standard measures for GI decontamination.[50,68] Pharmaceuticals that either speed up GI passage or slow down gastric emptying have been administered in an attempt to minimize the absorption of a xenobiotic. In all cases, the results have been negligible, and the potential risks of administering additional pharmacologically active agents to an already poisoned patient seem to outweigh any benefit.[5,156] Agents other than activated charcoal that reduce the absorption of xenobiotics from the GI tract have also been studied, including sodium polystyrene for lithium[16,98-100,145] or thallium overdose.[71] There have also been case reports of the use of the lipid-lowering resins cholestyramine and colestipol to interrupt the enterohepatic circulation of digoxin, digitoxin, and chlordane to increase elimination.[15,56,83,122] With the increased use of activated charcoal and availability of digoxin specific Fab fragments, indications for lipid-lowering resins for cardioactive steroid ingestions seem obsolete.

■ COMBINATION TREATMENTS

The combination of several different methods of GI decontamination has been studied and, more importantly, is extensively practiced clinically. The combination of gastric emptying (mainly orogastric lavage) followed by activated charcoal is the subject of many investigations, both in volunteers[28] and in two often-discussed clinical studies.[86,123] Only the small subset of significantly ill patients seemed to benefit from combined therapy. On closer examination, this group was comprised of only three patients compared with 17 patients who received activated charcoal alone.[86] This comparison of small, uneven, and unpaired numbers, together with a retrospective stratification, poses consequential statistical problems and limits the potential for generalization of the authors' results.

A volunteer study, although also small in numbers ($n = 12$), used a controlled, randomized, paired design.[28] The subjects received approximately 4 g of acetaminophen (as 30 to 40 tablets of 125-mg strength) 1 hour after a standardized breakfast meal. The interventions (orogastric lavage plus activated charcoal versus activated charcoal alone) were carried out 1 hour after ingestion. There were no significant differences in the AUC of acetaminophen between the two arms (power of 80% to detect a minimum relevant difference of 15%), but there was a 50% reduction for both arms compared with controls. It must be emphasized, however, this was not a clinical endpoint.

Similarly, a clinical study of 981 consecutive acetaminophen poisonings over a 10-year period found that patients who had ingested more than 10 g of acetaminophen by history and had received activated charcoal were significantly less likely to have a concentration of acetaminophen requiring antidotal therapy compared with patients who received no decontamination. Patients who received both orogastric lavage and activated charcoal did not have a further benefit.[21] Thus, the combination of orogastric lavage followed by activated charcoal only seems appropriate in cases in which orogastric lavage is indicated and the xenobiotic is adsorbed to activated charcoal. In cases in which activated charcoal alone is usually beneficial, there is little rationale to expose the patient to the additional risks of orogastric lavage. Although acetaminophen is a reasonable drug to study, the universal availability of a benign and inexpensive antidote contraindicates aggressive gastric emptying in acetaminophen overdose even if some benefit could be demonstrated.

The combination of activated charcoal and WBI would seem to make sense in that it might hasten GI passage and at the same time have the protective adsorptive effect of activated charcoal. However, based on the studies cited previously, it seems that if activated charcoal is administered with WBI, the adsorptive capacity of activated charcoal is reduced. Thus, we recommend administering activated charcoal before PEG-ELS if both are indicated and using WBI with great caution in patients who have already received MDAC. There is concern about the practice of treating asymptomatic cocaine body packers with WBI combined with activated charcoal because severe peritonitis may result if activated charcoal spills into the peritoneum after surgical intervention. The administration of activated charcoal is not expected to prevent routine surgery, and because the use of activated charcoal may increase the risk of surgical complications, activated charcoal should not be used under these circumstances.

■ GENERAL ASPECTS

Only a few GI decontamination studies provide guidance based on meaningful clinical endpoints. One of the few studies addressing meaningful clinical parameters was a retrospective analysis reviewing the management of all patients presenting to an ED with a diagnosis of deliberate self-poisoning.[64] The study evaluated 561 patients who were treated in 1999, comparing them with patients treated in 1989, 1992, and 1996.[64] The authors found that despite dramatically changing trends of GI decontamination, there were no significant changes in the proportion of patients admitted to the hospital, although there was a reduction in the rate of admission to the ICU. The patient populations did not change significantly over the years with regard to the female-to-male ratio, the age distribution, and the types of xenobiotics ingested. The authors mention that there might be unmeasured differences between the populations and unrecognized differences in practice that might have been influential. However, in 1989, most of the patients were treated with orogastric lavage, almost no patients received activated charcoal, and approximately 33% did not receive any gastric decontamination at all. In comparison, in 1996, more than 50% of patients received activated charcoal alone and fewer than 25% had no GI decontamination at all. In 1999, only 13% of patients received activated charcoal, 0.7% received a combination of orogastric lavage followed by activated charcoal, 0.5% were given WBI, and nearly 86% received no decontamination at all. There were no changes in overall mortality from poisonings over the years, although the number of fatalities was very low. Thus, although the trends in GI decontamination dramatically shifted toward less intervention over the years studied, there was no measurable worsening in outcome when large groups of patients were studied. It must be emphasized that this was a retrospective analysis with fairly nonspecific outcome measures, and possible improvements in other aspects of clinical treatment of poisoned patients were not considered.

The trends in practice noted in the above study reflect the overall combined philosophy of the position statements, which are applicable to the vast majority of poisoned patients. They highlight the benign nature of many exposures and the benefits of good supportive care. In contrast, the previously mentioned survey of recommendations for a theoretical patient with a serious enteric-coated aspirin overdose reveal less consensus in that 36 different courses of action were proposed for the same patient. Most of the poison centers and toxicologists did, however, recommend at least one dose of activated charcoal.[79] This distinction serves as a reminder that the existing studies and consensus statements cannot be applied to all cases and that a lack of data produce significant uncertainty in choices for GI decontamination in either atypical or severely poisoned patients.[69]

It is essential to note that only one study has ever demonstrated a survival advantage for any form of GI decontamination of poisoned patients.[42] Its unique design, involving a cohort of patients with life-threatening toxicity, forces a reassessment of all previous literature and confirms that the principles of decontamination are sound. It also suggests that the failure of most studies to demonstrate a benefit result not from a failure of the techniques used but from applying decontamination techniques to subsets of patients who were likely to have good outcomes regardless of intervention.

■ SUMMARY

The approach to GI decontamination needs to be more individualized than previously thought. No decontamination method is completely free of risks. The indications and contraindications for GI decontamination must be well defined for each patient, and the method of choice must depend largely on what was ingested, how much was ingested, and when it was ingested. It is important to be aware of the differences in the patterns of ingested xenobiotics when it comes to rural and urban settings as well as industrialized and developing worlds. In some areas, there is a shift towards less toxic pharmaceutical ingestions but also a possible increase in potentially more toxic recreational drug overdoses. Decontamination thus probably must be even more individualized than previously thought. Evidence now points away from the routine GI decontamination of most patients presenting to an ED with an oral drug overdose. A single dose of activated charcoal alone will be sufficient in moderate-risk patients, and only in a small subset of exceptionally high-risk patients will the benefit of orogastric lavage outweigh the risks. This approach is of course dependent on adequate medical assessment of patient history being undertaken promptly at admission without significant delays.

The absolute time frame for when decontamination is indicated depends on many factors, such as the rate of gastric emptying, the rate of xenobiotic absorption, and the possibility of enterohepatic recirculation. The commonly stated short time frame of up to 1 hour postingestion for intervention is most likely an underestimation of the time frame during which a benefit is likely to be realized, although this has not yet been fully investigated.

Judging from the evidence available today, activated charcoal must be the first choice, only accompanied by orogastric lavage when the desirable ratio of activated charcoal to xenobiotic cannot be achieved and the xenobiotic is still thought to be accessible in the stomach. Orogastric lavage as a single intervention is reserved for cases in which the ingested xenobiotic is not adsorbed by activated charcoal and there is reason to believe that the ingested xenobiotic is both life threatening *and* still in the stomach. Syrup of ipecac–induced emesis has a very limited therapeutic role but might be reserved for situations with an absolute need for GI decontamination; when activated charcoal is not expected to be effective; and when orogastric lavage and WBI are, for practical purposes, impossible. Multiple-dose activated charcoal and WBI have narrowly defined indications, which may broaden in the future as more studies focus on subsets of significantly poisoned patients.

The advancement of medical toxicology depends on well-designed clinical studies that concentrate on measuring the effect of GI decontamination using precise, reproducible, and relevant clinical endpoints. For each approach, it must be determined if the benefits of decontamination outweigh the potential risks. If proven beneficial, firm criteria need to be set for the future selection of patients for whom these treatments are beneficial and therefore indicated. One goal must be to reduce complications by identifying patients who can be safely managed without decontamination. At the same time, we must be ever vigilant for patients with ingestions of unstudied highly lethal xenobiotics and massive amounts of studied xenobiotics, as well as those who present early in their clinical course with life-threatening signs and symptoms. This uncommon subset is most likely to benefit from more aggressive GI decontamination. Thus, it is recommended that some form of GI decontamination be considered in *every* patient with potentially life-threatening toxicity regardless of the time since ingestion as long as no absolute contraindications exist.

ANTIDOTES IN DEPTH (A1)

SYRUP OF IPECAC

Mary Ann Howland
Emetine

The role of syrup of ipecac has changed dramatically over the past decade. Once the mainstay of poison management, a critical evaluation of animal, volunteer, and a limited number of clinical studies suggests that ipecac administration should be reserved for a very few rare circumstances, if any, rather than administered on a routine basis.[3,5,32] The rationale for this change is based on the facts that (1) most poisonings in children are benign; (2) many adults overdose with xenobiotics that rapidly cause an altered mental status, which constitutes a contraindication to the administration of ipecac; (3) ipecac-induced vomiting may be delayed or persistent, thereby resulting in a delay in the administration of activated charcoal; and (4) the abuse of ipecac by bulimics is substantial.[54]

Syrup of ipecac is an emetic that has been used for the management of poisonings since the 1950s and has been available without prescription since the late 1960s. Pediatricians were encouraged to advise parents to keep syrup of ipecac in their homes. Many physicians currently believe that there is no role for syrup of ipecac in the prehospital or hospital setting and that the abuse of syrup of ipecac by patients with bulimia outweighs any benefit originating from keeping syrup of ipecac as a nonprescription drug. The Food and Drug Administration (FDA) is still reviewing whether to make syrup of ipecac available only by prescription. Advocates for maintaining the nonprescription status of syrup of ipecac support home stocking of ipecac for use in remote areas and limiting use in healthcare facilities to those rare instances when activated charcoal, orogastric lavage, or whole-bowel irrigation with polyethylene glycol electrolyte lavage solution may be inappropriate or inadequate. Changing the availability of syrup of ipecac to prescription status only could result in the complete disappearance of syrup of ipecac from the pharmaceutical market if the FDA requires a new drug application.[51] Under these circumstances, it might not be profitable for any drug company to invest in a new drug application.

COMPOSITION

Ipecac is derived from the dried rhizome and roots of plants found in Brazil belonging to the family Rubiaceae, such as *Cephaelis acuminata* and *Cephaelis ipecacuanha*.[59,60] Cephaeline and emetine are the two alkaloids largely responsible for the production of nausea and vomiting, with cephaeline being the more potent.[31] Each 15-mL dose of syrup of ipecac contains 16 to 21 mg of cephaeline and 6.4 to 21 mg of emetine, resulting in variable cephaeline-to-emetine ratios. Syrup of ipecac also contains a small amount of psychotrine, which does not contribute to emesis but is currently under investigation for its potential anti-HIV effects.

PHARMACOKINETICS OF IPECAC ALKALOIDS

After 20 or 30 mL of syrup of ipecac was administered to human volunteers plasma, vomitus, and urine concentrations of emetine and cephaeline were determined by the use of high-performance liquid chromatography (HPLC).[50,65] Peak plasma concentrations of the alkaloids were reached by 20 minutes to 1 hour and were undetectable at 2 to 6 hours. Only 2% of the total amount of alkaloids in the ipecac were excreted in the urine within 48 hours but remained detectable in the urine for 2 weeks in all 12 volunteers and for 12 weeks in one of two subjects who were tested subsequently.

MECHANISM OF ACTION

Syrup of ipecac induces vomiting by local activation of peripheral emetic sensory receptors in the proximal small intestine and by central stimulation of the chemoreceptor trigger zone that serves as a sensory area, resulting in subsequent activation of the central vomiting center.[55] $5HT_3$ receptors mediate the nausea and vomiting produced by syrup of ipecac by both mechanisms. This was demonstrated in 40 volunteers by administering a specific $5HT_3$ antagonist 30 minutes before administration of syrup of ipecac; the $5HT_3$ antagonist prevented or attenuated the nausea and vomiting in a dose-dependent fashion.[21] In fact, syrup of ipecac is used to assess the efficacy of $5HT_3$ antagonists such as ondansetron and other antiemetics.[8,16,52]

TIME TO ONSET OF VOMITING AND NUMBER OF VOMITING EPISODES

In one of the earliest studies evaluating the delay in onset to vomiting after syrup of ipecac administration, 88% of 214 children who were given 20 mL of syrup of ipecac and copious amounts of water vomited within 30 minutes (mean, 18.7 minutes).[45] Adverse events secondary to syrup of ipecac were not noted. Subsequent studies demonstrated similar findings.[7,14,17,19,23,30,33,57,58]

The onset of emesis after syrup of ipecac administration does not appear to be affected by fluid administration before or after administration of syrup of ipecac, by the temperature of the fluids, or by gentle patient motion or walking.[19,20,23,53] Consequently, it is inadvisable to force fluids and safer to maintain the patient in an appropriate stationary setting (e.g., chair or stretcher). Milk should not be given with the syrup of ipecac because the onset of emesis may be delayed, although the success of inducing vomiting does not appear to be affected.[20] This delay is consistent with the ability of milk to delay gastric emptying and thereby retard contact between ipecac and the peripheral emetic sensory receptors.[61]

The average number of episodes of vomiting after syrup of ipecac administration is three, with a range of one to eight episodes.[30] The duration of syrup of ipecac–induced vomiting averages 23 to 60 minutes.[30,44] Although some investigators have suggested durations lasting up to 3 to 4 hours,[36,39] it is probably reasonable to assume that vomiting that persists for more than 2 hours is unrelated to syrup of ipecac administration, and another cause should be sought. This warning is of particular importance when syrup of ipecac is used at home.

VOLUNTEER STUDIES

Many studies have assessed the effectiveness of syrup of ipecac–induced emesis in decreasing absorption of a xenobiotic and then compared the results with other methods of gastric decontamination, such as gastric lavage or activated charcoal.[39,40,48] These same studies support the concept that the sooner syrup of ipecac is administered after ingestion, the greater the amount of the ingested xenobiotic that will be recovered. The decrease in the amount of xenobiotic absorbed varies from study to study as a result of differences in study design, including time to initiation of the various techniques and the particular xenobiotic used to assess efficacy. Volunteer studies using small lavage tubes were further limited because of both the quantity of the xenobiotic that was administered and the limited potential of the tube to recover the xenobiotic. In a small, well-quantified study, when six adult volunteers were given 20 mL of syrup of ipecac at 5 or 30 minutes after acetaminophen ingestion, absorption was inhibited by 65% and 0%, respectively.[40] In this same volunteer model, absorption was inhibited by 80% and 40% when 50 g of activated charcoal was given at 5 and 30 minutes postingestion.[41]

A subsequent investigation demonstrated that the reduction in the area under the plasma drug concentration versus time curve was equivalent for patients treated with syrup of ipecac–induced emesis and patients treated with activated charcoal plus a cathartic.[58] Comparison of orogastric lavage, syrup of ipecac–induced emesis, and activated charcoal, all given at 60 minutes to adult volunteers, after ingestion of ampicillin showed reductions of 32%, 38%, and 57%, respectively.[58] Adult volunteers given syrup of ipecac 5 minutes after administration of 30 capsules containing a radionucleotide marker demonstrated a mean 54% removal (range, 21%–89%) compared with a mean removal of 35.5% (range, 1%–71%) with orogastric lavage.[66] Other researchers demonstrated recoveries from 0% to 85%.[7,17,18,57] Children given a magnesium hydroxide marker before administration of syrup of ipecac demonstrated a mean recovery of 28%, although the range was 0% to 78%.[17]

OVERDOSED PATIENTS

In one study of self-poisoned adults, they were randomized to receive either syrup of ipecac or orogastric lavage with a 33-French lavage tube. All patients had subsequent gastric endoscopy.[47] Thirteen patients were given syrup of ipecac and vomited within 23 minutes (range, 11–25 minutes). Two of these patients had tablets in the vomitus and on endoscopy, only those two had residual tablets in the stomach. Ten of 17 patients who were lavaged had tablets in the lavage fluid, all of whom had tablets in the stomach at the time of endoscopy. Two additional patients also had residual tablets in the stomach,[47] suggesting a potential additional benefit of activated charcoal after emesis and lavage.

This same group of investigators used barium-marked 3-mm³ pellets to evaluate the effectiveness of gastric emptying.[48] Forty self-poisoned patients were given 20 pellets on admission and randomized immediately to therapy with either orogastric lavage or syrup of ipecac–induced emesis. Approximately 45% of the pellets were removed in both the orogastric lavage and the syrup of ipecac groups. Two patients in the lavage group and one in the syrup of ipecac group had 100% removal of pellets, and two patients in the lavage group had no removal.[48]

OUTCOME STUDIES

A large emergency department (ED) study addressed whether gastric emptying with either syrup of ipecac followed by activated charcoal or orogastric lavage followed by activated charcoal was more effective than activated charcoal alone in overdosed patients.[28] Syrup of ipecac did not affect the outcome in treated patients.

A study using the Toxic Exposure Surveillance System (TESS) database determined that home use of syrup of ipecac did not reduce the rate of ED referrals.[13] It could have been predicted that this study would not identify an improvement in patient outcome because most children have no clinical sequelae from exposure. Group statistics cannot identify a potentially beneficial effect that occurs rarely.

CONTRAINDICATIONS

Syrup of ipecac should not be administered to patients who have ingested acids or alkalis, are younger than 6 months of age, are expected to deteriorate rapidly, have a depressed mental status, have a compromised gag reflex, have ingested objects such as batteries or sharps, or have a need for rapid gastrointestinal evacuation to prevent absorption. Syrup of ipecac should not be administered to those for whom the hazards of vomiting and aspiration of the ingested substance outweigh the risks associated with systemic absorption (e.g., hydrocarbons), those who have significant prior vomiting, those for whom vomiting will delay administration of an oral antidote, and those with a hemorrhagic diathesis or a nontoxic ingestion, or when toxin is no longer expected to be in the stomach.

ADVERSE EFFECTS

Considering the number of times it has been administered without incident in this country, syrup of ipecac should be considered a relatively safe drug when given in therapeutic doses to patients for whom there are no contraindications. Sedation, especially in children, pulmonary aspiration (most likely from vomiting), and diarrhea are often reported.[32] When ipecac contacts the lower gastrointestinal tract, irritation leads to diarrhea, as was demonstrated in a recent volunteer study.[8] Uncommon problems that have occurred after therapeutic doses of syrup of ipecac include a Mallory-Weiss esophageal tear in an adult given 30 mL of syrup of ipecac for a multidrug overdose,[56] herniation of the stomach into the left chest in a child who had a previously unrecognized underlying congenital defect of the diaphragm,[46] intracerebral

hemorrhage,[25] and pneumomediastinum.[63] Additional problems associated with syrup of ipecac administration include pulmonary aspiration of stomach contents, volatile hydrocarbons or foreign bodies, and the associated time delay before it is possible to perform a necessary therapeutic intervention such as administration of activated charcoal or an oral antidote. Another reported problem is the emesis-induced vagal response of bradycardia.[37]

The surreptitious self-administration of frequent doses of syrup of ipecac by patients with bulimia and other related eating disorders results in substantial morbidity, such as extreme muscle weakness, congestive cardiomyopathy, and mortality.[1,10,31,34,42,49,64] Myofibril analysis of ipecac-abusing patients reveals degeneration and a "moth-eaten" appearance, and electron microscopy reveals Z-band streaming and disorganization.[29] When emetine was routinely used for the treatment of amebiasis in the early 1900s, cardiovascular and neuromuscular toxicity occurred. Similarly, inadvertent administration of the fluid extract of ipecac, which is 14 times more potent than syrup of ipecac, produces violent and protracted vomiting, diarrhea, seizures, cardiac toxicity, including PR interval prolongation, T-wave abnormalities, QRS complex abnormalities, atrial dysrhythmias, premature ventricular beats, and ventricular fibrillation, neuromuscular toxicity, including weakness and neuropathy, shock, and death.[31] Surreptitious chronic intentional ipecac poisoning of children, a form of Munchausen Syndrome by Proxy, has also been reported.[11,15,35,62] Self-administration by a child for the purpose of seeking attention and family distraction has also been reported.[43] The findings in these children included vomiting, diarrhea, lethargy, irritability, hypothermia, and hypotonia. The children described had been brought to healthcare providers by their parents for atypical patterns of vomiting and had multiple unsuccessful clinical evaluations.

LABORATORY DETECTION OF SYRUP OF IPECAC

When surreptitious use of syrup of ipecac is suspected as the cause of chronic vomiting, screening the urine, plasma, and vomitus for emetine (thin-layer chromatography screen—Toxi-Lab or HPLC) may be useful.[6,35,65]

CURRENT ROLE OF SYRUP OF IPECAC IN POISON MANAGEMENT

Most authorities agree with the American Academy of Pediatrics' statement that syrup of ipecac should no longer be used routinely.[3,4,32] Instead of promoting the concept of the maintenance of syrup of ipecac in the home, the Academy of Pediatrics currently states that "the first action for a caregiver of a child who may have ingested a toxic substance is to consult with the local poison center."[4] Logically, the sooner that syrup of ipecac is administered after ingestion, the more effective it may be in reducing absorption of the xenobiotic. For this reason, rather than completely abandoning syrup of ipecac, perhaps a targeted approach should be developed. This would mean continuing to promote the stocking of syrup of ipecac in the home setting in remote areas.

Only a few groups of patients are considered appropriate candidates for the use of syrup of ipecac. Patients who are candidates for syrup of ipecac are those who (1) ingest a xenobiotic with considerable risk of toxicity that does not cause a rapid change in mental status, such as acetaminophen or salicylates; (2) consume massive amounts of a toxin that may exceed the binding capacity of activated charcoal, such as salicylates; or (3) ingest a toxin not bound to activated charcoal, such as lithium. Under these circumstances, if the presence of unabsorbed

xenobiotic in the stomach remains a potential problem, then the use of syrup of ipecac may be appropriate in rare instances when weighed against the utility of activated charcoal or whole-bowel irrigation with polyethylene glycol electrolyte lavage solution. The time frame for this decision is usually within 1 to 2 hours after ingestion.

ADMINISTRATION

The dose of syrup of ipecac is 15 mL in children 1 to 12 years old and 30 mL in older children and adults. If vomiting does not ensue after the first dose, the same dose may be repeated once 20 to 30 minutes after administration of the first dose. For children 6 to 12 months of age, the dose of syrup of ipecac is 5 to 10 mL, and its use should be limited to a maximum single 10-mL dose.[12,27] Water can be offered but is not essential for success. Vomiting will occur in most patients. Home users should be warned that persistent vomiting for more than 2 hours may indicate toxicity from the primary xenobiotics ingested not the antidote, necessitating medical evaluation.

CONCLUSION

There are very few cases in which syrup of ipecac is indicated in the home setting because typically most ingestions are either nontoxic or, conversely, of such consequence that an imminent deterioration in mental status may occur making syrup of ipecac administration dangerous. Parents in areas with poor access to a healthcare facility should still be encouraged to keep syrup of ipecac and activated charcoal at home as potential first aid measures, but caregivers should be cautioned to use them only on the advice of a regional poison center or physician.

In the ED, the role of syrup of ipecac is extremely limited. One of the only possible candidates for syrup of ipecac in the overdose setting is a child or adult who arrives in the ED shortly after the ingestion of a large number of poorly soluble tablets of a size unlikely to be removed by lavage and also unlikely to cause a rapid change in mental status. One other candidate is a child or adult who has taken such a large amount of a highly toxic substance that a favorable activated charcoal-to-drug ratio cannot be attained with certainty, and an antidote is not available. Whole-bowel irrigation should be considered as a suitable alternative when the xenobiotic has a prolonged absorptive phase.

ANTIDOTES IN DEPTH (A2)

ACTIVATED CHARCOAL

Mary Ann Howland

Activated charcoal (AC) is an excellent nonspecific adsorbent. The current debate regarding the role of AC in poison management relies on reconciling evidence-based studies in volunteers and heterogeneous poisoned and overdosed patients with clinical experience.[4] AC should be considered for administration to a poisoned or overdosed patient after a risk-to-benefit assessment for the substance presumably ingested and ideally also for the circumstances of the exposure for a particular patient.[13] The benefits include inactivating a potentially toxic xenobiotic; the risks include vomiting and subsequent aspiration pneumonia. The merits of AC as a decontamination strategy are discussed in detail in Chap. 7.

HISTORY

Activated charcoal, a fine, black, odorless powder, has been recognized for almost two centuries as an effective adsorbent of many substances. In 1930, the French pharmacist Touery demonstrated the powerful adsorbent qualities of AC by ingesting several lethal doses of strychnine mixed with AC in front of colleagues; he suffered no ill effects.[6] An American physician, Holt, first used AC to save a patient from mercury bichloride poisoning in 1934.[6] However, it was not until the 1940s that Anderson began to systematically investigate the adsorbency of AC and unquestionably demonstrated that AC is an excellent broad-spectrum gastrointestinal (GI) adsorbent.[6-8]

ADSORPTION: MECHANISMS AND CONSIDERATIONS

AC is produced in a two-step process, beginning with the pyrolysis of various carbonaceous materials such as wood, coconut, petroleum, or peat. This processing is followed by treatment at high temperatures with a variety of oxidizing (activating) agents such as steam or carbon dioxide to increase adsorptive capacity through formation of an internal maze of pores with a huge surface area.[31,58,109,134] The rate of adsorption depends on external surface area, and the adsorptive capacity depends on the far larger internal surface area.[31,102,108] The adsorptive capacity may be modified by altering the size of the pores. Current AC products have pore sizes that range from 10 to 1000 angstroms (Å), with most of the internal surface area created by 10- to 20-Å-sized pores.[27,29,31] Most xenobiotics are of moderate molecular weight (100–800 daltons) and adsorb well to pores in the range of 10 to 20 Å. Mesoporous charcoals with a pore size of 20 to 200 Å have a greater capacity to adsorb larger xenobiotics as well as those in their larger hydrated forms.[82]

The relationship between AC surface area and adsorptive capacity was studied in vitro and in vivo in animals and in humans. When the surface area is large, the adsorptive capacity is increased, but affinity is decreased because van der Waals forces and hydrophobic forces are diminished.[136] The actual adsorption of a xenobiotic by AC is believed to rely on hydrogen bonding, ion–ion, dipole, and van der Waals forces, suggesting that most xenobiotics are best adsorbed by AC in their dissolved, nonionized form.[31] A superactivated charcoal with a surface area approximately double the current AC formulations demonstrated in both in vitro and in vivo studies a greater maximum adsorptive capacity.[32,121]

Thus, according to the Henderson-Hasselbalch equation, weak bases are best adsorbed at basic pHs, and weak acids are best adsorbed at acidic pHs. For example, cocaine, a weak base, binds to AC with a maximum adsorptive capacity of 273 mg of cocaine per gram of AC at a pH of 7.0; this capacity is reduced to 212 mg of cocaine per gram of AC at a pH of 1.2.[81] Desorption (drug dissociation from AC) may occur, especially for weak acids, as the AC-drug complex passes from the stomach through the intestine and as the pH changes from acidic to basic.[12,46,103,108,133] Whereas strongly ionized and dissociated salts, such as sodium chloride and potassium chloride, are poorly adsorbed, nonionized or weakly dissociated salts, such as iodine and mercuric chloride, respectively, are adsorbed. The adsorption to AC of a weakly dissociated metallic salt such as mercuric chloride ($HgCl_2$) decreases with decreasing pH because the number of complex ions of the type $HgCl_3$ and $HgCl_4$ increases and the number of electroneutral molecules ($HgCl_2$) is reduced.[7] Nonpolar, poorly water-soluble organic substances are more likely to be adsorbed from an aqueous solution than polar, water-soluble substances.[31] Among the organic molecules, aromatics are better adsorbed than aliphatics; molecules with branched chains are better adsorbed than those with straight chains; and molecules containing nitro groups are better adsorbed than those containing hydroxyl, amino, or sulfonic groups.[31]

Desorption may lead to systemic absorption of larger total amounts of xenobiotic over several days; in this case, the elimination half-life of the xenobiotic appears to increase, but peak concentrations remain unaffected.[103] The clinical effects of desorption can be minimized by giving a sufficiently large dose of AC to overcome the decreased affinity of the xenobiotic secondary to pH change such as by using multiple-dose AC.[67,90,101,112,126] Although ethanol and other solvents such as polyethylene glycol are minimally adsorbed by AC, they nonetheless may decrease the adsorptive capacity of AC for a coingested xenobiotic by competing for AC binding with that xenobiotic.[14,103,106]

In vitro studies demonstrate that adsorption begins within about 1 minute of administration of AC but may not reach equilibrium for 10 to 25 minutes.[32,97] AC decreases the systemic absorption of most xenobiotics, including acetaminophen, aspirin, barbiturates, cyclic antidepressants, glutethimide, phenytoin, theophylline, and most inorganic and organic materials.[45,97,111] Notable xenobiotics *not* amenable to AC are the alcohols, acids and alkalis, iron,[49] lithium, magnesium, potassium, and sodium salts. Although the binding of AC to cyanide is less than 4%, the toxic dose is small and 50 g of AC would theoretically be able to bind more than 10 lethal doses of potassium cyanide.

Efficacy of AC is directly related to the quantity administered. The effect of the AC-to-drug ratio on adsorption was demonstrated both

in vitro and in vivo with *para*-aminosalicylate (PAS). In vitro, the fraction of unadsorbed PAS decreased from 55% to 3% as the AC-to-PAS ratio increased from 1:1 to 10:1 at a pH of 1.2.[107] This study provides the best scientific basis for the 10:1 AC-to-drug ratio dose typically recommended. In human volunteers, as the AC-to-PAS ratio increased from 2.5:1 to 50:1, the total 48-hour urinary excretion decreased from 37% to 4%.[108] Presumably this occurred because more of the PAS was adsorbed by AC in the lumen of the GI tract rather than being absorbed systemically. These same studies demonstrate AC saturation at low ratios of AC to drug and argue for a 10:1 ratio of AC to xenobiotic.

The clinical efficacy of administered AC is inversely related to the time elapsed after ingestion and depends largely on the rate of absorption of the xenobiotic. For example, early administration of AC is much more important with rapidly absorbed xenobiotics. In this situation, AC functions to prevent the absorption of xenobiotic into the body by achieving rapid adsorption in the GI tract. After a xenobiotic is systemically absorbed or parenterally administered, AC may still enhance elimination through a mechanism referred to as *gastrointestinal dialysis*. This is accomplished with multiple doses of AC.

PALATABILITY

The black and gritty nature of AC has led to the development of many formulations to increase palatability and patient acceptance. Bentonite, carboxymethyl cellulose, and starch[53,96,124] are used as thickening agents, and cherry syrup, chocolate syrup, sorbitol, sucrose, saccharin, ice cream, and sherbet[32,76,83,140] are used as flavoring agents. Most of these additives do not decrease the adsorptive capacity; however, improvement in palatability and acceptance is minimal or nonexistent with all of these formulations.[30] Although a milk chocolate formulation of AC evaluated by children was rated superior in palatability to standard AC preparations,[41] it was never marketed in the United States. A marketed AC product with cherry flavoring was rated by adult volunteers as preferable over plain AC, and a statistically significant larger quantity of the flavored AC was ingested.[26] However, in adult overdosed patients, this was not the case because most patients consumed the entire bottle of AC with or without cherry flavoring. Many of the subjects did not like the taste and actually preferred the plain AC.[63] Two studies in adult overdosed patients compared different brands of AC without additives or flavoring to determine the quantity of AC typically ingested.[18,47] In one study, approximately half of the 50 g of AC offered was ingested, and 7% of the patients vomited.[18] In the other study, 60 g of AC as Liqui-Char or CharcoAid G was offered, and approximately 95% of each formulation was consumed in 20 minutes. There was no difference in the amount consumed even though the palatability of the granular form of AC (CharcoAid G) was rated higher.[47]

Cold cola was used to enhance palatability in volunteer children and adults. Children preferred regular cola over diet cola. The adults rated the cola charcoal combination preferable to the plain charcoal.[118,123]

ADVERSE EFFECTS

The use of AC is relatively safe, although emesis, which especially occurs after rapid administration; constipation; and diarrhea frequently occur after AC administration.[102] Constipation and diarrhea are more likely to result from the ingestion itself than from the AC. However, black stools that are negative for occult blood, black tongues, and mucous membranes are frequently observed. Serious adverse effects of AC include pulmonary aspiration of AC with or without gastric contents[9,43,51,54,55,56,64,91,97,113,125]; peritonitis from spillage of enteric

contents, including AC, into the peritoneum after GI perforation caused by orogastric lavage;[84] and intestinal obstruction and pseudo-obstruction, especially after repeated doses of AC in the presence of either dehydration[20,78,93,119,137] or prior bowel adhesions.[52]

Although a significant number of patients aspirate gastric contents before endotracheal intubation and administration of AC,[95,122] the incidence of AC aspiration after endotracheal intubation was reported to vary from 4% to 25%, depending on the nature of the study. A retrospective investigation demonstrated a 1.6% incidence of aspiration pneumonitis in unselected overdosed patients. Altered mental status, spontaneous emesis, and tricyclic antidepressant overdose were associated risk factors; AC was not in itself a risk factor.[62]

HOME AND PREHOSPITAL ADMINISTRATION

Prehospital administration of AC by emergency medical technicians and paramedics may expedite the administration of AC after overdose.[2,138] However, the cost of implementation of such a program would have to be weighed against the small number of patients who would actually benefit.[61]

In a study intended to simulate home administration, the acceptance of a dose of AC given as a water slurry in a paper cup was studied in 50 young children.[22] The children were told to drink the substance, which did not taste bad, and that it would make them feel better and not ill. Eighty-six percent of the children readily drank the AC slurry, and 76% of them consumed 95% to 100% of the total dose. Of seven children in a simulated home environment administered AC in regular cola, three drank 1 g/kg, two drank about half this therapeutic dose, and the other two drank very little.[123] A prospective poison center case series demonstrated successful administration of AC in the home. In this series, the median age of the patients was 3 years, and the median dose of AC ingested was 12 g.[129] However, other attempts at getting children to ingest AC were not as successful; in one study, difficulty was noted in 70% of attempts to administer a standard dose of AC to children in the home setting.[37] A recent review of AC in the home suggested variable success depending on the parent and child.[42]

ADMINISTRATION AND DOSING

AC should not be routinely administered to all poisoned or overdosed patients. Single-dose AC should be administered when a xenobiotic is still expected to be available for adsorption in the GI tract and the benefit of preventing absorption outweighs the risk. The optimal dose of AC is unknown.[4] However, most authorities recommend a minimum dose of AC of 1 g/kg of body weight or a 10:1 ratio of AC to xenobiotic, up to an amount that can be tolerated by the patient and safely administered if the dose is known, which usually represents 50 to 100 g in adults. AC that is not premixed is best administered as a slurry in a 1:8 ratio of AC to suitable liquid, such as water or cola.

Administration may be facilitated by offering children an opaque, decorated, covered cup and a straw.[139] Contraindications to AC include presumed GI perforation and the need for endoscopic visualization, as may occur after caustic ingestion. To prevent aspiration pneumonitis from oral AC administration, it is imperative that the patient's airway be assessed. When the potential for airway compromise is substantial, oral AC should be withheld until airway assessment is accomplished. Subsequently, a risk-to-benefit assessment with regard to the need for airway protection and the need for AC should be made.

Other considerations that must be made before the administration of AC are the determination of normal GI motility, normal bowel sounds, and a normal abdominal examination without distension or signs of an

acute abdomen. If bowel function is compromised, AC should be with-held or delayed until the stomach can be decompressed to decrease the risk of subsequent vomiting and aspiration.

THE USE OF ACTIVATED CHARCOAL WITH CATHARTICS OR WHOLE-BOWEL IRRIGATION WITH POLYETHYLENE GLYCOL ELECTROLYTE LAVAGE SOLUTION

Cathartics are often used with AC; however, evidence suggests that AC alone is comparably effective to AC plus a single dose of cathartic (sorbitol or magnesium citrate).[3,67,85,86,90,96,102,110] If a cathartic is used, it should be used only once because repeated doses of magnesium-containing cathartics are associated with hypermagnesemia,[94,128] and repeated doses of any cathartic can be associated with severe and even fatal fluid and electrolyte problems.[44]

Whole-bowel irrigation with polyethylene glycol electrolyte lavage solution may significantly decrease the in vitro and in vivo adsorp-tive capacity of AC,[57] depending on the individual xenobiotic and its formulation.[10,73] The most likely explanation is competition for the surface of the AC for solute adsorption.

MULTIPLE-DOSE ACTIVATED CHARCOAL

Multiple-dose AC (MDAC) functions to prevent the absorption of xen-obiotics that are slowly absorbed from the GI tract and to enhance the elimination of suitable xenobiotics that have already been absorbed.

MDAC decreases xenobiotic absorption when large amounts of xen-obiotics are ingested and dissolution is delayed (e.g., masses, bezoars), when xenobiotic formulations exhibit a delayed or prolonged release phase (e.g., enteric coated, extended release), or when reabsorption can be prevented (e.g., enterohepatic circulation of active xenobiotic, active metabolites, or conjugated xenobiotic hydrolyzed by gut bacteria to active xenobiotic).

The ability of MDAC to enhance elimination after absorption had already occurred was first reported in 1982.[15] This report concluded that orally administered MDAC enhanced the total body clearance (nonrenal clearance) of six healthy volunteers given 2.85 mg/kg of body weight of intravenous (IV) phenobarbital.[15] The serum half-life of phe-nobarbital decreased from 110 ± 8 to 45 ± 6 hours. An accompanying editorial suggested that MDAC enhanced the diffusion of phenobarbi-tal from the blood into the GI tract and trapped it there, to be excreted later in the stool. In this manner, AC was said to perform as an "infinite sink," allowing for "gastrointestinal dialysis" to occur.[75]

These findings were subsequently confirmed by studies in dogs and rats using IV aminophylline.[36,88] Using an isolated perfused rat small intestine, the concept of gastrointestinal dialysis[88] was elegantly demonstrated because AC dramatically affected the pharmacokinetics of theophylline and produced a constant intestinal clearance that was approximately equivalent to intestinal blood flow.[88] The toxicokinetic considerations underlying the ability of MDAC to enhance elimina-tion are similar to those involved in deciding whether hemodialysis would be appropriate for a given xenobiotic and requires the xeno-biotic to be in the blood compartment (low volume of distribution), have limited protein binding, and have prolonged endogenous clear-ance. Although MDAC increases the elimination of digitoxin,[114] phenobarbital,[116] carbamazepine,[17,19] phenylbutazone,[98] dapsone,[99] nadolol,[39] theophylline,[16,80,132] salicylate,[117] quinine,[5] cyclosporine,[59] propoxyphene,[65] nortriptyline, and amitriptyline, its clinical utility remains to be defined.[5,24,66,130]

EXPERIMENTAL STUDIES

An analysis of 28 volunteer studies involving 17 xenobiotics was unable to correlate the physiochemical properties of a particular xenobiotic with the ability of MDAC to decrease the plasma half-life of that xenobiotic.[23] Although the half-life was not thought to be the best marker of enhanced elimination, it was the only parameter consis-tently evaluated in these exceptionally diverse studies. The xenobiotics with the longest intrinsic plasma half-lives seemed to demonstrate the largest percent reduction in plasma half-life when MDAC was used. A subsequent animal model with therapeutic doses of four simultane-ously administered IV xenobiotics (acetaminophen, digoxin, theophyl-line, and valproic acid) clarified the role of pharmacokinetics on the effectiveness of AC.[25] Theophylline, acetaminophen, and valproic acid all have small volumes of distribution. However, of the three, only valproic acid is highly protein bound at the doses used, which probably accounted for the inability of AC to increase its clearance. An increased clearance with MDAC was demonstrated for the three other xenobiotics. The most rapid and dramatic effect of MDAC was demonstrated on the clearance of theophylline. Large volumes of distribution alone may not exclude benefit from MDAC. Although digoxin has a large volume of distribution, it requires several hours to distribute from the blood to the tissues. MDAC is beneficial as long as the digoxin remains in the blood compartment and distribution is incomplete.

The benefits of MDAC undoubtedly depend on a number of patient variables and xenobiotic exposure characteristics. Most important to remember, however, is that volunteer studies do not accurately reflect the overdose situation[89] in which saturation of plasma protein binding, saturation of first-pass metabolism, and acid–base disturbances may make more free xenobiotic available for an enteroenteric effect and therefore more amenable to MDAC use.

OVERDOSE STUDIES

In a randomized clinical study, patients who overdosed with pheno-barbital were given a single dose of AC, and others were given mul-tiple doses.[116] Although the half-life of phenobarbital was significantly decreased in the MDAC group (36 vs. 93 hours), the length of intuba-tion time required by each group did not differ from one another. This study has been criticized as being too small, having unevenly matched groups, and focusing on a single end point (extubation) that may be dependent on factors other than patient condition (e.g., the time of day) to determine the potential clinical benefit.

The most compelling demonstration of the benefits of MDAC in the overdose setting to date comes from a study done in Sri Lanka of patients with severe cardiac toxicity caused by intentional overdose with yellow oleander seeds.[35] An initial dose of 50 g of AC was admin-istered to all patients, who were then randomized to 50 g of AC every 6 hours for 3 days or placebo. There were statistically fewer deaths and fewer life-threatening dysrhythmias in the MDAC group. A more recent randomized, controlled trial compared MDAC, single-dose AC, and no AC in self-poisoned patients.[40] About one-third of the patients ingested yellow oleander seeds, and a little less than one-third ingested organic phosphorous or carbamate pesticides. In contrast to the former study, this trial found no difference in mortality between the groups. It is unclear how these trials done in Sri Lanka apply to management in developed countries such as the United States, where the use of antidotes such as digoxin-specific antibody fragments for cardioactive steroid poisoning and atropine and pralidoxime for organic phosphorous pesticide poisoning routinely complement GI decontamination.

ADMINISTRATION OF MDAC

An initial loading dose of AC should be administered to adults and children in an AC-to-xenobiotic ratio of 10:1 or 1 g/kg of body weight (if xenobiotic exposure amount is unknown). The correct dose and interval of AC for multiple dosing, when it is indicated, is best tailored to the amount and dosage form of the xenobiotic ingested, the severity of the overdose, the potential lethality of the xenobiotic, and the patient's ability to tolerate AC. Benefit should always be weighed against risk. Doses of AC for multiple dosing have varied considerably in the past, ranging from 0.25 to 0.5 g/kg of body weight every 1 to 6 hours to 20 to 60 g for adults every 1, 2, 4, or 6 hours. Some evidence suggests that the total dose administered may be more important than the frequency of administration.[60,135] In some cases, continuous nasogastric administration of AC can be used, especially when vomiting is a problem.[46,105,135] The editors of this text consider a dose of 0.5 g/kg of body weight (~25–50 g in adults) every 4 to 6 hours for up to 12 to 24 hours to be an appropriate regimen in most circumstances.

ADVERSE EFFECTS OF MDAC

The adverse effects of MDAC include diarrhea only when sorbitol-containing charcoal preparations are used, constipation, vomiting with a subsequent risk of aspiration, intestinal obstruction, and reduction of serum concentrations of therapeutically used xenobiotics.[38,93,97,113] Any complication observed with single-dose AC is a possibility with MDAC.

SUMMARY

When benefit exceeds risk and administration is timely, AC is a very effective nonspecific adsorbent. AC should be of benefit to a patient with a potentially life-threatening ingestion involving a xenobiotic expected to be present in the GI tract and that is adsorbable by AC and for whom there are no contraindications. MDAC is useful to prevent systemic absorption of a xenobiotic with a prolonged absorptive phase such as an extended-release formulation. In the postabsorptive phase of managing an exposure, MDAC may decrease the elimination half-lives of a variety of xenobiotics through diverse mechanisms, including GI dialysis, thereby providing potential treatment to some xenobiotic overdoses occurring by any routes. For this postabsorptive effect to be of clinical importance, the xenobiotic or an active metabolite must first be characterized by a lengthy elimination phase because MDAC is given every 4 to 6 hours. In addition, xenobiotics with a small volume of distribution, or that fit a two-compartment model with a prolonged initial distribution phase and low or saturable plasma protein binding, are theoretically most accessible to MDAC. In both the use of AC and MDAC, care must be taken to avoid pulmonary aspiration and intestinal obstruction.

With respect to the use of AC before the patient's arrival at the hospital, home availability of AC should be encouraged in remote locations where healthcare is not immediately available. As more palatable forms of AC are developed, children may accept this therapy more readily, but even without such forms, the benefits are substantial and the risks lower than often suggested.[72,74]

ANTIDOTES IN DEPTH (A3)

WHOLE-BOWEL IRRIGATION AND OTHER INTESTINAL EVACUANTS

Mary Ann Howland

Xenobiotics that promote intestinal evacuation are referred to as *laxatives, cathartics, purgatives, promotility agents*, and *evacuants*. Using different doses, the same xenobiotic may often accomplish any or all of these tasks, but with different side effect profiles. Laxatives promote a soft-formed or semifluid stool within 6 hours to 3 days, depending on the xenobiotic and the dose used. Cathartics promote a rapid, watery evacuation within 1 to 3 hours.[37] The term *purgatives* is used to relate the force associated with bowel evacuation. Promotility agents stimulate gastrointestinal (GI) motor function via the enteric nervous system by affecting acetylcholine, serotonin, motilin, or intestinal chloride channels. Evacuants are commonly used to cleanse the bowel before a procedure, with an onset of action of as little as 30 to 60 minutes, but typically requiring 4 hours for a more complete effect. Although it is far from perfect, the most effective process of evacuating the intestinal tract in poisoned patients is referred to as whole-bowel irrigation (WBI). WBI is typically accomplished using polyethylene glycol 3350 (PEG), which is added to a balanced electrolyte lavage solution (PEG-ELS).

The traditional classification of laxatives into the categories of bulk-forming, softener or emollient, lubricant, stimulant or irritant, saline, hyperosmotic, and evacuant is largely empirical. Bulk-forming agents include high-fiber products such as methylcellulose, polycarbophil, and psyllium; softeners or emollients include docusate calcium. Mineral oil is the sole lubricant. None of these three classes of cathartics is used therapeutically in medical toxicology because their onsets of action are often delayed for several days. In addition, softeners cause an increase in intestinal permeability for a few hours and may therefore increase the absorption of some xenobiotics.[78] Mineral oil may enhance the absorption of lipid-soluble xenobiotics and aspiration could result in a lipoid pneumonia.[102]

Stimulant or irritant laxatives include anthraquinones (sennosides, aloe, and casanthranol), diphenylmethane (bisacodyl), and castor oil. Abdominal discomfort, cramping, and tenesmus are common early manifestations. Long-term use produces bowel habituation and damage to intestinal tissue. Thus, stimulant and irritant laxatives are rarely used today in medical toxicology because of their significant GI side effects.

Saline (meaning salt) cathartics, which include magnesium citrate, magnesium hydroxide, magnesium sulfate, sodium phosphate, and sodium sulfate, are used infrequently and cautiously in medical toxicology. Hyperosmotic agents, including sorbitol and lactulose, are also occasionally considered in poisoned patients.

When different cathartics were compared with respect to time to first stool and number of stools,[38,46,68,69,90] sorbitol produced 10 to 15 watery stools and the most abdominal cramping before catharsis. Sorbitol produced stools in the shortest amount of time but with the highest incidence of nausea, vomiting. generated gas, abdominal cramping, and increased flatus.[42,43,71] The nauseating sweetness of sorbitol resulted in patient preference of magnesium citrate. In comparison, the first bowel movement typically occurs about 1 hour after the start of WBI with PEG-ELS.

Potential adverse effects associated with cathartics and promotility agents include dehydration, absorption of magnesium or other absorbable electrolytes, hypokalemia and metabolic alkalosis from dehydration, activation of the renin–angiotensin–aldosterone system, phosphate-induced renal nephropathy[16,84] and colonic fermentation of digestible sugars. Cathartic-induced rectal prolapse occurred in 2 geriatric patients.[45] The use of repetitive doses of cathartics, either by design or unintentionally, has led to increased risk of hypermagnesemia and death.[40,70,86]

Following the use of hypertonic phosphate enemas and oral sodium phosphate, hypocalcemia, hyperphosphatemia, and hypokalemia were reported.[22,28,31,52,58,79,88] In many of these cases, the recommended dose was used.[22] Frail elderly patients, children, and those with decreased renal function may be most susceptible to adverse effects.[9,11]

Multiple-dose activated charcoal (MDAC) regimens containing 70% sorbitol used to enhance elimination resulted in severe cathartic-related adverse effects in at least four case reports.[1,27,51,62] The potential for sorbitol-related adverse events from the unintentional use of repetitive activated charcoal (AC) dosing was emphasized by a survey revealing that 16% of hospitals surveyed only stocked AC premixed with sorbitol.[103] The retention of sorbitol after repetitive doses in an aperistaltic gut may lead to significant morbidity from gas formation and abdominal distention as a result of the digestive action of gut bacteria.[51]

MECHANISM OF ACTION

The effects of saline cathartics are largely attributed to their relatively nonabsorbable ions that establish an osmotic gradient and draw water into the gut. The increased water leads to increased intestinal pressure and a subsequent increase in intestinal motility.[20] Magnesium ion also leads to the release of cholecystokinin from the duodenal mucosa, which stimulates intestinal motor activity and alters fluid movement, contributing to the cathartic effect.[12,89] The hyperosmotic laxatives, including sorbitol, lactulose, and glycerin, also draw water into the gut, thereby producing diarrhea.

PEG is a nonabsorbable, isoosmotic indigestible molecule that remains in the colon and together with the water diluent is evacuated, resulting in WBI without producing flatus and cramps. A balanced electrolyte solution is added which practically eliminates electrolyte abnormalities and helps prevent fluid shifts across the GI mucosa. Many studies of WBI using PEG-ELS demonstrate patient acceptance, effectiveness, and safety when used for bowel preparation.[3,10,21,23,25,77,94,97]

Promotility agents such as metoclopramide and erythromycin stimulate gut motor function. Metoclopramide mediates GI $5HT_4$ receptor agonist and D_2 receptor antagonist activity which both result in increased acetylcholine release and GI motility. Erythromycin also stimulates gut motor function but via direct stimulation of GI motilin receptors.[75] Lubiprostone is a novel promotility drug that stimulates

chloride secretion and enhances the contraction of gastric and colonic musculature.[41] Although lubiprostone has been used with WBI for the treatment of constipation, their combined use has not yet been reported in poisoned patients.

GASTROINTESTINAL EVACUATION AND POISON MANAGEMENT

Although recommended for basic poison management for many years, cathartics should not be used routinely in the management of overdosed patients.[5] Intuitively, the advantages of cathartics appear to result from their ability to decrease the potential for constipation or obstruction from AC and hasten the delivery of AC to the small intestine. However, these theoretical advantages have never been demonstrated clinically.

Studies demonstrate that when administered alone, cathartics such as sorbitol or sodium sulfate may decrease peak or total absorption of some xenobiotics, but no study of cathartics alone has achieved results comparable to that of AC alone.[2,17,61,76,101] When comparing the efficacy of a single dose of AC alone with that of AC plus a single dose of cathartic, studies suggest the combination to be equal to,[2,65,74,76,85] slightly better than,[17,42] or even slightly worse than AC alone.[61,101]

WBI with PEG-ELS is currently advocated to hasten the elimination of poorly absorbed xenobiotics or sustained-release medications before they can be absorbed. This approach is theoretically sound and does not produce the fluid and electrolyte complications associated with cathartics. Unfortunately, evidence of efficacy is limited to anecdotal case reports and volunteer studies.

Animal models suggest that WBI may enhance systemic clearance via GI dialysis, much like MDAC.[50] In actuality, low flow rates, the typical delay in administering WBI in actual clinical situations, and the inconvenience of this procedure make it highly unlikely that enhanced systemic clearance can be achieved in humans.

In human volunteer studies, WBI was more effective than single-dose AC or MDAC for enteric-coated acetylsalicylic acid (ASA),[43] decreased peak lithium [Li], and Li AUC (area under the plasma drug concentration versus time curve) compared with controls[87]; decreased the bioavailability of two sustained-release medications[15,48]; and propelled radiopaque markers through the gut more efficiently than controls.[54]

Not unexpectedly, WBI was inferior to AC with regard to prevention of absorption when administered after 650 mg of immediate-release aspirin.[82] Additionally, after the aspirin was absorbed, WBI was unable to enhance systemic clearance.[60] Likewise, only a small, statistically insignificant effect of WBI could be demonstrated on the absorption of extended-release acetaminophen in a human volunteer study.[54] These findings highlight the limited utility of WBI to assist in the prevention of absorption of relatively rapidly absorbed xenobiotics.

Several reports have shown successful use of WBI in the management of overdoses of iron,[26,57,92,93] sustained-release theophylline,[39] sustained-release verapamil,[13] zinc sulfate,[14] lead,[64,66,72,81] arsenic trioxide,[36] mercuric oxide powder,[55] clonidine patch ingestion,[35] arsenic-containing herbicide,[49] delayed-release fenfluramine[67] and in body packers.[34,95,99] Although some clinicians express enthusiasm for the use of WBI for a variety of ingestions, others question its efficacy.[14,83,91] WBI for 5 hours after ingestion of 10 fluorescent coffee beans by each of seven volunteers removed an average of only four beans (range, 1–8).[83] Similar failures were reported with jequirity beans [91] and button batteries.[92] It can be argued that because of their physical characteristics (density, solubility, size), these xenobiotics might not be representative of xenobiotics amenable to WBI. Additionally, the experience of the editors of this text in caring for body packers demonstrates that WBI may not always evacuate all of the drug packets because of inadequate dosing, partial obstruction, or the nature of the procedure. In a recent case, prolonged WBI failed to clear drug in a methamphetamine body stuffer.[32] As a result of these failures, promotility agents were added to WBI and presumably successfully enhanced bowel evacuation in two body packers suspected of having ingested well-constructed drug packets.[96]

ADVERSE EFFECTS OF WHOLE-BOWEL IRRIGATION

Adverse effects resulting from the use of WBI with PEG-ELS include vomiting, particularly after rapid administration, abdominal bloating, fullness, cramping, flatulence, and pruritus ani. Typically, the patient will need to remain on a commode for 4 to 6 hours to complete the procedure. Slow or low-volume administration of PEG-ELS results in sodium absorption. If a total of 500 mL of PEG-ELS were used instead of multiple liters, potentially 1.5 g of sodium may be absorbed.[24] This adverse effect may have resulted in the exacerbation of congestive heart failure in an unstable patient with cardiac and renal dysfunction.[30]

An unusual complication of WBI is colonic perforation, which occurred in a patient with active diverticulitis.[47] Other adverse effects noted by the manufacturer include isolated reports of upper GI bleeding from a Mallory-Weiss tear, esophageal perforation, aspiration pneumonitis after vomiting, and acute lung injury.

Unintentional administration of PEG-ELS by other than the enteral route has occurred. A 4-year-old child inadvertently received 390 mL of PEG-ELS intravenously with no obvious adverse result.[80] In contrast, acute lung injury developed in an 11-year-old child administered PEG-ELS through a nasogastric tube inadvertently inserted in the trachea.[73] In a similar case, a poorly placed nasogastric tube was responsible for PEG-ELS aspiration in a 3-year old boy, with resultant hypoxia and hemodynamic instability requiring endotracheal intubation.[29]

Finally, a recent report of two cases suggests that vomiting and aspiration may be more frequent than previously recognized in hemodynamically unstable patients.[19] Presumably, the patient's hypotension results in GI hypoperfusion and ileus, which with the continued administration of WBI in the presence of decreased GI motility, produces abdominal distention and vomiting.

INTERACTION OF ACTIVATED CHARCOAL AND WHOLE-BOWEL IRRIGATION

Several in vitro studies demonstrate that the addition of PEG-ELS to AC significantly decreases the adsorptive capacity of AC.[8,33,56] Some interactions were affected by pH and magnified by high ratios of PEG-ELS to AC.[7,44,56] The most likely explanation is competition with the AC surface for solute adsorption. Additionally, in an animal model, WBI appeared to have an adverse effect by washing the AC away from the sustained-release theophylline.[15] One recent case report documents rapid increases in carbamazepine concentrations temporally related to the initiation of WBI.[53] Although the patient had received MDAC and hemoperfusion, xenobiotic concentrations were increasing 58 hours after ingestion. It is possible that PEG-ELS competed for carbamazepine binding to AC, displacing some drug and making it available for absorption.

A similar rapidly increasing drug concentration was noted after the initiation of WBI in a patient with a reported 10-g phenytoin overdose.[18] In this case, AC had not been given before the initiation of WBI. One possible explanation is that the massive dose of phenytoin

prevented its own absorption by exceeding its solubility but the administration of WBI provided sufficient diluent to allow phenytoin dissolution before GI emptying with subsequent absorption.

CONTRAINDICATIONS

Contraindications to WBI include prior, current, or anticipated diarrhea; volume depletion; significant GI pathology or dysfunction such as ileus, perforation, colitis, toxic megacolon, hemorrhage, and obstruction; an unprotected or compromised airway; and hemodynamic instability.[4,92]

DOSING

The recommended dose of WBI with PEG-ELS solution is 0.5 L/h or 25 mL/kg/h for small children and 1.5 to 2.0 L/h or 20 to 30 mL/min for adolescents and adults. WBI solution may be administered orally or through a nasogastric tube for 4 to 6 hours or until the rectal effluent becomes clear. An antiemetic such as metoclopramide or a 5HT$_3$ serotonin antagonist may be required for the treatment of nausea or vomiting. In select patients, promotility agents may serve as useful adjuncts.[96] If the xenobiotic being removed is radiopaque, a diagnostic imaging technique demonstrating the absence of the xenobiotic may serve as an initial clinical endpoint (Special Considerations: SC4: Internal Concealment of Xenobiotics). WBI with large volumes of fluid was used successfully in two pregnant women at 38 and 26 weeks of gestation.[98,100]

AVAILABLE FORMS OF PEG-ELS FOR WHOLE-BOWEL IRRIGATION

The original WBI solution was GoLYTELY manufactured by Braintree. This solution contained PEG with electrolytes and sodium sulfate as an added laxative. Colyte is manufactured by Schwartz Pharma and is very similar to GoLYTELY. Braintree later introduced NuLYTELY, a PEG formulation with 52% less total salt than GoLYTELY and no added sodium sulfate. These changes in formulation decreased the salty taste and the risk of fluid- or electrolyte-related complications.[63] NuLYTELY is available in flavors. The three available PEG-ELS products are prepared by filling the container to the 4-L mark with water and shaking it vigorously several times to ensure dissolution. Lukewarm water facilitates dissolution, but subsequent chilling improves palatability. Chilled solutions, however, are not recommended for infants because of the risk of hypothermia. The products are stable with refrigeration for 48 hours after reconstitution.

The three available PEG-ELS products differ in the following manner:

1. GoLYTELY contains 236 g (17.6 mmol/L) of PEG, 22.74 g of sodium sulfate (anhydrous) (sulfate, 40 mmol/L), 6.74 g of sodium bicarbonate (bicarbonate, 20 mmol/L), 5.86 g of sodium chloride (total sodium, 125 mmol/L), and 2.97 g of potassium chloride (potassium, 10 mmol/L and total chloride, 35 mmol/L).

2. Colyte contains 240 g (18 mmol/L) of PEG, 22.72 g of sodium sulfate (anhydrous) (40 mmol/L sulfate), 6.72 g of sodium bicarbonate (bicarbonate, 20 mmol/L), 5.84 g of sodium chloride (total sodium, 125 mmol/L), and 2.98 g of potassium chloride (potassium, 10 mmol/L and total chloride, 35 mmol/L).

3. NuLYTELY contains 420 g of PEG 3350, 5.72 g of sodium bicarbonate, 11.2 g of sodium chloride, and 1.48 g of potassium chloride.

MiraLAX (manufactured by Braintree) contains PEG 3350 powder meant for oral administration after dissolution in water, juice, or soda. It is indicated for occasional constipation, with a recommended dose of 1 heaping teaspoon (17 g) in 240 mL liquid per day. For MiraLAX to be useful in WBI, it would need to be administered at a dose of 2 L/h (8 heaping teaspoons in 2 L of water/h) in adults. This is not recommended for WBI because it does not contain any added electrolytes and may result in an electrolyte imbalance.

SUMMARY

Cathartics should never be considered part of routine management of poisoning and overdose in either children or adults. Cathartics should never be used as an AC substitute when xenobiotics known to be adsorbed to AC are involved. Moreover, when total xenobiotic absorption is evaluated, a single dose of a cathartic given with AC appears to be only about as efficacious as AC given alone.

Investigators have studied the rapidity of stool production resulting from the use of various cathartics, promotility agents, and WBI. Administering a cathartic to produce a faster onset of charcoal stools has never been shown to produce a better clinical outcome. In adults, when large amounts of xenobiotics have been ingested or when desorption from charcoal may be an important consideration, as in the case of aspirin ingestion, a single dose of a cathartic, preferably magnesium citrate or sorbitol, may be given with the AC. When MDAC is administered, if a cathartic is used at all, it should only be given with the first dose. Sufficient oral fluids should always be administered with a cathartic to avoid inspissation and dehydration. Unless contraindicated, WBI is preferable to repetitive dose cathartics for evacuation of sustained-release or poorly soluble xenobiotics not adsorbed to AC.

The precise role of WBI and the interactions between AC and PEG-ELS in overdosed patients remain to be defined. No controlled clinical studies have assessed outcome, although theoretically, ingestions of sustained-release xenobiotics (theophylline, glyburide XL, verapamil, and diltiazem), xenobiotics not adsorbed by charcoal (iron, lead, lithium), and drug packets (in body packers) may be amenable to the use of WBI. An added advantage of using PEG-ELS WBI is that if the patient requires endoscopy, diagnostic imaging, or surgery, the GI tract may be more easily visualized, facilitating the intervention or procedure. AC should be given to patients for whom it is indicated, and if WBI is being performed in conjunction, a comparable dose of AC should be given after the WBI, to prevent or overcome the potential xenobiotic desorption and possible further systemic absorption of the xenobiotic.

CHAPTER 8

PHARMACOKINETIC AND TOXICOKINETIC PRINCIPLES

Mary Ann Howland

Pharmacokinetics is the study of the absorption, distribution, metabolism, and excretion of xenobiotics. *Xenobiotics* are substances that are foreign to the body and include natural or synthetic chemicals, drugs, pesticides, environmental agents, and industrial agents.[49] Mathematical models and equations are used to describe and to predict these phenomena. *Pharmacodynamics* is the term used to describe an investigation of the relationship of xenobiotic concentration to clinical effects. *Toxicokinetics*, which is analogous to pharmacokinetics, is the study of the absorption, distribution, metabolism, and excretion of a xenobiotic under circumstances that produce toxicity. *Toxicodynamics*, which is analogous to pharmacodynamics, is the study of the relationship of toxic concentrations of xenobiotics to clinical effect.

Overdoses provide many challenges to the mathematical precision of toxicokinetics and toxicodynamics because many of the variables, such as dose, time of ingestion, and presence of vomiting, that affect the result are often unknown. In contrast to the therapeutic setting, atypical solubility characteristics are noted, and saturation of enzymatic processes occurs. Intestinal or hepatic enzymatic saturation or alterations in transporters may lead to enhanced absorption through a decrease in first-pass effect. Metabolism before the xenobiotic reaches the blood is referred to as the *first-pass effect*.[2,76] Saturation of plasma protein binding results in more free xenobiotic available in the serum, plasma, and blood. Saturation of hepatic enzymes or active renal tubular secretion leads to prolonged elimination. In addition, age, obesity, gender, genetics, chronopharmacokinetics (diurnal variations), and the effects of illness and compromised organ perfusion all further inhibit attempts to achieve precise analyses.[3,17,40,45,68,72] In addition, various treatments may alter one or more pharmacokinetic and toxicokinetic parameters. There are numerous approaches to recognizing these variables, such as obtaining historical information from the patient's family and friends, performing pill counts, procuring sequential serum concentrations during the phases of toxicity, and occasionally repeating a pharmacokinetic evaluation during therapeutic dosing of that same agent to obtain comparative data.

Despite all of the confounding and individual variability, toxicokinetic principles may nonetheless be applied to facilitate our understanding and to make certain predictions. These principles may be used to help evaluate whether a certain antidote or extracorporeal removal method is appropriate for use, when the serum concentration might be expected to decrease into the therapeutic range (if one exists), what ingested dose might be considered potentially toxic, what the onset and duration of toxicity might be, and what the importance is of a serum concentration. While considering all of these factors, the clinical status of the patient is paramount, and mathematical formulas and equations can never substitute for evaluating the patient. This chapter explains the principles and presents the mathematics in a user-friendly fashion.[79] The application of these principles and mathematical approaches by example and case illustration are found on the website.

ABSORPTION

Absorption is the process by which a xenobiotic enters the body. A xenobiotic must reach the bloodstream and then be distributed to the site or sites of action to cause a systemic effect. Both the rate (k_a) and extent of absorption (F) are measurable and important determinants of toxicity. The rate of absorption often predicts the onset of action and relies on dosage form, and the extent of absorption (*bioavailability*) often predicts the intensity of the effect and depends in part on first-pass effects.[36,37] Figure 8–1 depicts how changes in the rate of absorption may affect toxicity when the bioavailability is held constant versus how toxicity may be affected by changes in bioavailability when the rate of absorption is held constant.

The route by which the xenobiotic enters the body significantly affects both the rate and extent of absorption. As an approximation, the rate of absorption proceeds in the following order from fastest to slowest: intravenous (IV), inhalation > sublingual > intramuscular, subcutaneous, intranasal, oral > cutaneous, rectal. After the oral intake of 200 mg (0.59 mmol) of cocaine hydrochloride, the onset of action is 20 minutes, with an average peak concentration of 200 ng/mL.[71] In marked contrast, smoking 200 mg (0.66 mmol) of cocaine freebase results in an onset of action of 8 seconds and a peak level of 640 ng/mL. When administered IV as 200-mg cocaine hydrochloride, it then has an onset of action of 30 seconds and a peak level of 1000 ng/mL.[71]

A xenobiotic must diffuse through a number of membranes before it can reach its site of action. Figure 8–2 shows the number of membranes through which a xenobiotic typically diffuses. Membranes are predominantly composed of phospholipids and cholesterol in addition to other lipid compounds.[54] A phospholipid is composed of a polar head and a fatty acid tail, which are arranged in membranes so that the fatty acid tails are inside and the polar heads face outward in a mirror image.[58] Proteins are found on both sides of the membranes and may traverse the membrane.[54] These proteins may function as receptors and channels. Pores are found throughout the membranes. The principles relating to diffusion apply to absorption, distribution, certain aspects of elimination, and each instance when a xenobiotic is transported through a membrane.

Transport through membranes occurs via (1) passive diffusion; (2) filtration or bulk flow, which is most important in renal and biliary secretion as the mechanism of transport associated with the movement of molecules with a molecular weight less than 100 daltons, with water directly through aquapores; (3) carrier-mediated active or facilitated transport, which is saturable, and (4) rarely, endocytosis (see Fig. 8–2). Most xenobiotics traverse membranes via simple passive diffusion. The rate of diffusion is determined by the Fick law of diffusion (Eq. 8–1):

$$\text{Rate of diffusion} = \frac{dQ}{dt} = \frac{DAK(C_1 - C_2)}{h} \qquad \text{(Eq. 8–1)}$$

D = diffusion constant
A = surface area of the membrane
h = membrane thickness
K = partition coefficient
$C_1 - C_2$ = difference in concentrations of the xenobiotic at each side of the membrane

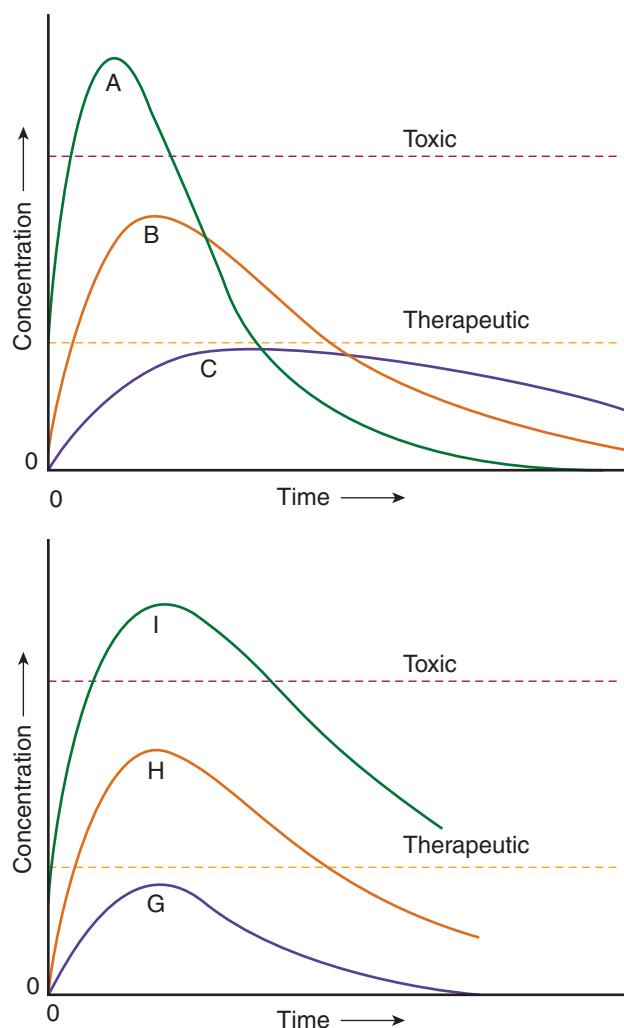
The driving force for passive diffusion is the difference in concentration of the xenobiotic on both sides of the membrane. D is


FIGURE 8–1. Effects of changes in k_a (rate of absorption) and F (bioavailability) on the blood concentration time graph and achieving a toxic threshold. In curves A, B, and C, F is constant as k_a decreases. In curves G, H, and I, k_a is constant as F increases from G to I.[48]

a constant for each xenobiotic and is derived when the difference in concentrations between the two sides of the membrane is 1. The larger the surface area A, the higher the rate of diffusion. Most ingested xenobiotics are absorbed more rapidly in the small intestine than in the stomach because of the tremendous increase in surface area created by the presence of microvilli. The partition coefficient K_e represents the lipid-to-water partitioning of the xenobiotic. To a substantial degree, the more lipid soluble a xenobiotic is, the more easily it crosses membranes. Membrane thickness (h) is inversely proportional to the rate at which a xenobiotic diffuses through the membrane. Xenobiotics that are uncharged, nonpolar, of low molecular weight, and of the appropriate lipid solubility have the highest rates of passive diffusion.

The extent of ionization of weak electrolytes (weak acids and weak bases) affects their rate of passive diffusion. Nonpolar and uncharged molecules penetrate faster. The Henderson-Hasselbalch relationship is used to determine the degree of ionization. An acid (HA), by definition, gives up a hydrogen ion, and a base (B) accepts a hydrogen ion. RCOOH (HA) (ie, aspirin, phenobarbital) and RNH_3^+ (BH^+) are acids

and $RCOO^-$ (A^-), and RNH_2 (B) (amphetamines, tricyclic antidepressants) are bases. The equilibrium dissociation constant K_a can then be described by Equations 8–2A and 8–2B:

$$\text{For weak acids: } HA = H^+ + A^- \quad K_a = \frac{[H^+][A^-]}{[HA]} \quad \text{(Eq. 8–2A)}$$

$$\text{For weak bases: } BH^+ = B + H^+ \quad K_a = \frac{[H^+][B]}{[BH^+]} \quad \text{(Eq. 8–2B)}$$

To work with these numbers in a more comfortable fashion, the negative log of both sides is determined. The results are given in Equations 8–3A and 8–3B.

$$\text{For weak acids:} -\log K_a = -\log[H^+] - \log\frac{[A^-]}{[HA]} \quad \text{(Eq. 8–3A)}$$

$$\text{For weak bases:} -\log K_a = -\log[H^+] - \log\frac{[B]}{[BH^+]} \quad \text{(Eq. 8–3B)}$$

By definition, the negative log of [H^+] is expressed as pH, and the negative log of K_a is pK_a. Rearranging the equations gives the familiar forms of the Henderson-Hasselbalch equations, as shown in Equations 8–4A, 8–4B, and 8–4C:

$$pH = pK_a + \log\frac{\text{Unprotonated species}}{\text{Protonated species}} \quad \text{(Eq. 8–4A)}$$

$$\text{For weak acids: } pH = pK_a + \log\frac{[A^-]}{[HA]} \quad \text{(Eq. 8–4B)}$$

$$\text{For weak bases: } pH = pK_a + \log\frac{[B]}{[BH^+]} \quad \text{(Eq. 8–4C)}$$

Because noncharged molecules traverse membranes more rapidly, it is understood that weak acids cross membranes more rapidly in an acidic environment and weak bases move more rapidly in a basic environment. When the pH equals the pK_a, half of the xenobiotic is charged and half is noncharged. An acid with a low pK_a is a strong acid, and a base with a low pK_a is a weak base. For an acid, whereas a pH less than the pK_a favors the protonated or noncharged species facilitating membrane diffusion, for a base, a pH greater than the pK_a achieves the same result. Table 8–1 lists the pH of selected body fluids, and Figure 8–3 illustrates the extent of charged versus noncharged xenobiotic at different pH and pK_a values.

Lipid solubility and ionization each have a distinct influence on absorption. Figure 8–4 demonstrates these characteristics for three different xenobiotics. Although the three xenobiotics have similar pK_a values, their different partition coefficients result in different degrees of absorption from the stomach.

Specialized transport mechanisms are either adenosine triphosphate (ATP) dependent to transport xenobiotics against a concentration gradient (ie, active transport), or ATP independent and lack the ability to transport against a concentration gradient (ie, facilitated transport). These transport mechanisms are of importance in numerous parts of the body, including the intestines, liver, lungs, kidneys, and biliary system. These same principles apply to a small number of lipid-insoluble molecules that resemble essential endogenous agents.[28,64] For example,
FIGURE 8–2. Illustration of the number of membranes encountered by a xenobiotic in the process of absorption and distribution and the transport mechanisms involved in the passage of xenobiotics across membranes. Examples include diffusion: nonelectrolytes (ethanol) and unionized forms of weak acids (salicylic acid) and bases (amphetamines); endocytosis: Sabin polio virus vaccine; facilitated: 5-fluorouracil, lead, methyldopa, thallium; and active: thiamine and pyridoxine.

5-fluorouracil resembles pyrimidine and is transported by the same system, and thallium and lead are actively absorbed by the endogenous transport mechanisms that absorb and transport potassium and calcium, respectively. Filtration is generally considered to be of limited importance in the absorption of most xenobiotics but is substantially more important with regard to renal and biliary elimination. Endocytosis, which describes the encircling of a xenobiotic by a cellular membrane, is responsible for the absorption of large macromolecules such as the oral Sabin polio vaccine.[64]

Gastrointestinal (GI) absorption is affected by xenobiotic-related characteristics such as dosage form, degree of ionization, partition coefficient, and patient factors (eg, GI blood flow; GI motility; and the presence or absence of food, ethanol, or other interfering substances such as calcium) (Fig. 8–5).

The formulation of a xenobiotic is extremely important in predicting GI absorption. Disintegration and dissolution must precede absorption. Disintegration is usually much more rapid than dissolution except for modified-release products. Modified-release products include delayed-release and extended-release formulations. By definition, extended-release formulations decrease the frequency of drug administration by 50% compared with immediate release-formulations, and they include controlled-release, sustained-release, and prolonged-release formulations. These modified-release formulations are designed to release the xenobiotic over a prolonged period of time to simulate the blood concentrations achieved with the use of a constant IV infusion. These formulations minimize blood level fluctuations, reduce peak-related side effects, reduce dosing frequency, and improve patient compliance. A variety of products use different pharmaceutical strategies, including dissolution control (encapsulation or matrix; Feosol), diffusion control (membrane or matrix; Slow K, Plendil ER), erosion (Sinemet CR), osmotic pump systems (Procardia XL, Glucotrol XL), and ion exchange resins (MS Contin suspension). Overdoses with modified-release formulations often result in a prolonged absorption phase, a delay to peak concentrations, and a prolonged duration of effect.[7] Delayed-release preparations are enteric coated and designed to bypass the stomach and to release drug in the small intestine. Enteric-coated (acetylsalicylic acid [ASA], divalproex

sodium) formulations resist disintegration and delay the time to onset of effect.[6] Dissolution is affected by ionization, solubility, and the partition coefficient, as noted earlier. In the overdose setting, the formation of poorly soluble or adherent masses such as concretions of foreign material termed *bezoars* (verapamil, meprobamate, and bromide) significantly delay the time to onset of toxicity (Table 8–2).[4,11,29,30,60]

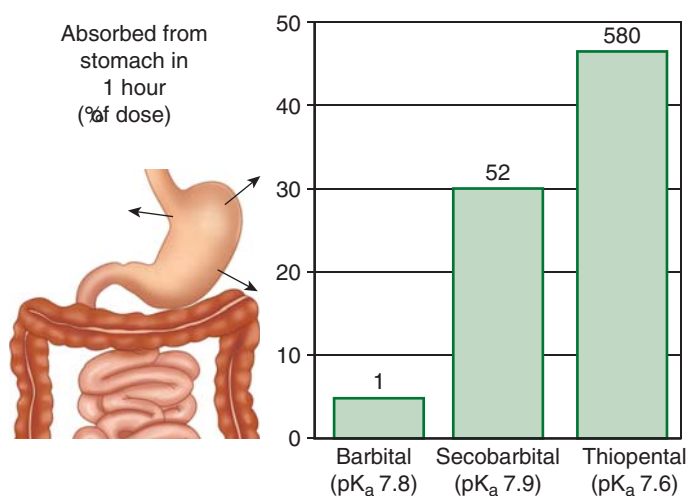
Most ingested xenobiotics are primarily absorbed in the small intestine as a result of the large surface area and extensive blood flow of the small intestines.[59] Critically ill patients who are hypotensive, have a reduced cardiac output, or are receiving vasoconstrictors such as norepinephrine have a decreased perfusion of vital organs, including the GI tract, kidneys, and liver.[3] Not only is absorption delayed, but elimination is also diminished.[57] Total GI transit time can be from 0.4 to 5 days, and small intestinal transit time is usually 3 to 4 hours. Extremely


FIGURE 8–4. Influence of increasing lipid solubility on the amount of xenobiotic absorbed from the stomach for three xenobiotics with similar pK$_a$ values. The number above each column is the oil/water equilibrium partition coefficient.

short GI transit times reduce absorption. This change in transit time is the unproven rationale for use of whole-bowel irrigation (WBI). Delays in emptying of the stomach impair absorption as a result of the delay in delivery to the small intestine. Delays in gastric emptying occur as a result of the presence of food, especially fatty meals; agents with anticholinergic, opioid, or antiserotonergic properties; ethanol; and any agent that results in pylorospasm (salicylates, iron).

Bioavailability is a measure of the amount of xenobiotic that reaches the systemic circulation unchanged (Eq. 8–5).[38] The fractional absorption (F) of a xenobiotic is defined by the area under the plasma drug concentration versus time curve (AUC) of the designated route of absorption compared with the AUC of the IV route. The AUC for each route represents the amount absorbed.

$$F = \frac{(AUC)_{\text{route under study}}}{(AUC)_{IV}} \qquad \text{(Eq. 8–5)}$$

Gastric emptying and activated charcoal are used to decrease the bioavailability of ingested xenobiotics. The oral administration of certain chelators (deferoxamine, D-penicillamine) actually enhances the bioavailability of the complexed xenobiotic. The net effect of some chelators, such as succimer, is a reduction in body burden via enhanced urinary elimination even though absorption is enhanced.[31] Historically, the enteral administration of sodium bicarbonate was used to theoretically reduce the solubility of iron salts; unfortunately, this approach was ineffective and increased toxicity.[15]

Presystemic metabolism may decrease or increase the bioavailability of a xenobiotic or a metabolite.[53] The GI tract contains microbial organisms that can metabolize or degrade xenobiotics such as digoxin and oral contraceptives and enzymes, such as peptidases, that metabolize insulin.[54] However, in rare cases, GI hydrolysis can convert a xenobiotic into a toxic metabolite, as occurs when amygdalin is enzymatically hydrolyzed to produce cyanide, a metabolic step that is not produced after IV amygdalin administration.[27] Xenobiotic metabolizing enzymes and transporters such as P-glycoprotein may also affect bioavailability. Xenobiotic-metabolizing enzymes are found in the lumen of the small intestine and can substantially decrease the absorption of a xenobiotic.[44,73] Some of the xenobiotic that enters the cell can then be removed by the P-glycoprotein transporter out of the cell and back into the lumen to be exposed again to the metabolizing enzymes.[44,73] Venous drainage from the stomach and intestine delivers orally (and intraperitoneally) administered xenobiotics to the liver via the portal vein and avoids direct delivery to the systemic circulation. This venous drainage allows hepatic metabolism to occur before the xenobiotic reaches the blood, and as previously mentioned, is referred to as the *first-pass effect*.[2,76] The hepatic extraction ratio is the percentage of xenobiotic metabolized in one pass of blood through the liver.[47] Xenobiotics that undergo significant first-pass metabolism (eg, propranolol, verapamil) are used at much lower IV doses than oral doses. Some drugs, such as lidocaine and nitroglycerin, are not administered by the oral route because of significant first-pass effect.[4] Instead, sublingual (nitroglycerin), transcutaneous (topical), or rectal administration of drugs is used to bypass the portal circulation and avoid first-pass metabolism.

Disintegration

slowed by:product formulation
such as sustained release,
enteric coating

Dissolution

slowed by:acidic pH
for weak acids,water
insolubility,large
particle size,
concretions,
bezoars

Absorption

slowed by:decreased gastric
emptying,increased ionized drug,
pylorospasm,fast small intestine
transit time,decreased mesenteric
blood flow

First-pass metabolism

enzyme saturation,
P450 or P glycoprotein
inhibitors result in less first
pass metabolism and
increased bioavailability.

Distribution

FIGURE 8–5. Determinants of absorption.

In the overdose setting, presystemic metabolism may be saturated, leading to an increased bioavailability of xenobiotics such as cyclic antidepressants, phenothiazines, opioids, and many β-adrenergic antagonists.[56] Hepatic metabolism usually transforms the xenobiotic into a less-active metabolite but occasionally results in the formation of a more toxic agent such as occurs with the transformation of parathion to paraoxon.[51] Biliary excretion into the small intestine usually occurs for these transformed xenobiotics of molecular weights greater than 350 daltons and may result in a xenobiotic appearing in the feces even though it had not been administered orally.[34,54,67] Hepatic conjugated metabolites such as glucuronides may be hydrolyzed in the intestines to the parent form or to another active metabolite that can be reabsorbed by the enterohepatic circulation.[41,49,52,54] The enterohepatic circulation may be responsible for what is termed a *double-peak phenomenon* after the administration of certain xenobiotics.[64] The double-peak phenomenon is characterized as a serum concentration that decreases and then increases again as xenobiotic is reabsorbed from the GI tract. Other causes include variability in stomach emptying, presence of food, or failure of a tablet dosage form.[64]

DISTRIBUTION

After the xenobiotic reaches the systemic circulation, it is available for transport to peripheral tissue compartments and to the liver and kidney for elimination. Both the rate and extent of distribution depend on many of the same principles discussed with regard to diffusion.

TABLE 8–2. Xenobiotics that Form Concretions or Bezoars, Delay Gastric Emptying, or Result in Pylorospasm	
Anticholinergics	Meprobamate
Barbiturates	Methaqualone
Bromides	Opioids
Enteric-coated tablets	Phenytoin
Glutethimide	Salicylates
Iron	Verapamil

Additional factors include affinity of the xenobiotic for plasma (plasma protein binding) and tissue proteins, acid–base status of the patient (which affects ionization), drug transporters, and physiologic barriers to distribution (blood–brain barrier, placental transfer, blood–testis barrier).[23,35,58] Blood flow, the percentage of free drug in the plasma, and the activity of transporters account for the initial phase of distribution, and xenobiotic affinities determine the final distribution pattern. Whereas the adrenal glands, kidneys, liver, heart, and brain receive from 55 to 550 mL/min/100 g of tissue of blood flow, the skin, muscle, connective tissue, and fat receive 1 to 5 mL/min/100 g of tissue of blood flow.[62] Hypoperfusion of the various organs in critically ill and injured patients affects absorption, distribution, and elimination.[74]

ABC transporters are active ATP-dependent transmembrane protein carriers of which P-glycoprotein was the initial example discovered.[9] Approximately 50 ABC transporters exist, and they are divided into subfamilies based on their similarities. Several members of the ABC superfamily, including P-glycoprotein, are under extensive investigation because of their role in controlling xenobiotic entry into, distribution in, and elimination from the body as well as their contributions to drug interactions.[21,32,73] The discovery of P-glycoprotein resulted from an investigation into why certain tumors exhibit multidrug resistance to many cancer chemotherapy agents. P-glycoprotein (ABCB1) as well as ABCC and ABCG2 are known to be efflux transporters located in the intestines, renal proximal tubules, hepatic bile canaliculi, placenta, and blood–brain barrier and are responsible for the intra- to extracellular transport of various xenobiotics.[16] First-generation transport inhibitors such as amiodarone, ketoconazole, quinidine, and verapamil are responsible for increasing body levels of P-glycoprotein substrates such as digoxin, the protease inhibitors, vinca alkaloids, and paclitaxel. St. John's wort is a transport inducer, and it lowers serum concentrations of these same xenobiotics. Second- and third-generation xenobiotics that will affect transport with a higher affinity and specificity are in development.[18,65] Many of the same xenobiotics that affect cytochrome P450 (CYP) 3A4 also affect P-glycoprotein (Appendix Chapter 12: Cytochrome P450 Substrates Inhibitors and Inducers).

Recently, the organic anion transporting polypeptides (OATPs) have been recognized as another group of transporters found in the liver, kidneys, intestines, brain, and placenta that are also responsible for affecting the absorption, distribution, and elimination of many xenobiotics and contributing to xenobiotic interactions. They include the organic anion transporters (OATs) and the organic cation transporters (OCTs).[18] For example, probenecid increases the serum concentrations

of penicillin by inhibiting the OAT responsible for the active secretion of penicillin by the renal tubular cells, and cimetidine inhibits the OCT responsible for the renal elimination of procainamide and metformin. A variety of OAT inhibitors are being investigated to decrease the hepatic uptake of amatoxins[18] (Chap. 117).

Plasma concentration and *serum concentration* are terms often used interchangeably by medical personnel. When a reference or calculation is made with regard to a concentration in the body, it is actually a plasma concentration. When concentrations are measured in the laboratory, a serum concentration (clotted and centrifuged blood) is often determined. In reality, the laboratory measurements of most xenobiotics in serum or plasma are nearly equivalent. Frequently, this is not the case for whole-blood determination if the xenobiotic distributes into the erythrocyte, such as lead and most other heavy metals.

Volume of distribution (Vd) is the proportionality term used to relate the dose of the xenobiotic that the individual receives and the resultant plasma concentration. Vd is an apparent or theoretic volume into which a xenobiotic distributes. It is a measure of how much xenobiotic is located inside and outside of the plasma compartment because only the plasma compartment is routinely assayed. In a 70-kg man, the total body water (TBW) is 60% of total body weight, or 42 L, with two-thirds (28 L) of the fluid accounted for by intracellular fluid. Of the 14 L of extracellular fluid, 8 L is considered interstitial or between the cells; 3 L, or 0.04 L/kg, is plasma; and 6 L, or 0.08 L/kg, is blood. If 42 g of a xenobiotic is administered and remains in the plasma compartment (Vd = 0.04 L/kg), the concentration would be 15 g/L. If the distribution of the 42 g of xenobiotic approximated TBW (methanol; 0.6 L/kg), the concentration would be 100 mg/dL. These calculations can be performed by using Equation 8–6, where S equals the percent pure drug if a salt form is used.

$$V_d = \frac{S \times F \times Dose\ (mg)}{C_0}$$ (Eq. 8–6)

Experimental determination of Vd involves administering an IV dose of the xenobiotic and extrapolating the plasma concentration time curve back to time zero (C_0). If the determination takes place after steady state has been achieved, the volume of distribution is then referred to as the Vdss. For many xenobiotics, the Vd is known and readily available in the literature (Table 8–3). When the Vd and the dose ingested are known, a maximum predicted plasma concentration can be calculated after assuming all of the xenobiotic is absorbed and no elimination occurred. This assumption usually overestimates the plasma concentration. Distribution is complex, and differential affinities for various storage sites, such as plasma proteins, liver, kidney, fat, and bone, in the body determine where a xenobiotic ultimately resides.

For the purposes of determining the utility of extracorporeal removal of a xenobiotic, a low Vd is often considered to be less than 1 L/kg. For some xenobiotics, such as digoxin (Vd = 7 L/kg) and the cyclic antidepressants (Vd = 10–15 L/kg), the Vd is much larger than the actual volume of the body. A large Vd indicates that the xenobiotic resides outside of the plasma compartment, but again, it does not describe the site of distribution.

The site of accumulation of a xenobiotic may or may not be a site of action or toxicity. If the site of accumulation is not a site of toxicity, then the storage depot may be relatively inactive, and the accumulation at that site may be theoretically protective to the animal or person.[58] Selective accumulation of xenobiotics occurs in certain areas of the body because of affinity for certain tissue-binding proteins. For example, the kidney contains metallothionein, which has a high affinity for metals such as cadmium, lead, and mercury.[23] The retina contains the pigment melanin, which binds and accumulates chlorpromazine, thioridazine,

and chloroquine.[23] Other examples of xenobiotics accumulating at primary sites of toxicity are carbon monoxide binding to hemoglobin and myoglobin and paraquat distributing to type II alveolar cells in the lungs.[55] Dichlorodiphenyltrichloroethane (DDT), chlordane, and polychlorinated biphenyls are stored in fat, which can be mobilized after starvation.[77] Lead sequestered in bone[33] is not immediately toxic, but mobilization of bone through an increase in osteoclastic activity[58] (hyperparathyroidism, possibly pregnancy) may free lead for distribution to sites of toxicity in the central nervous system (CNS) or blood.

Several plasma proteins bind xenobiotics and act as carriers and storage depots. The percentage of protein binding varies among xenobiotics, as do their affinities and potential for reversibility. After it is bound to plasma protein, a xenobiotic with high binding affinity will remain largely confined to the plasma until elimination occurs. However, dissociation and reassociation may occur if another carrier is available with a higher binding affinity. Most plasma measurements of xenobiotic concentration reflect total drug (bound plus unbound). Only the unbound drug is free to diffuse through membranes for distribution or for elimination. Albumin binds primarily to weakly acidic, poorly water-soluble xenobiotics, which include salicylates, phenytoin, and warfarin, as well as endogenous substances, including free fatty acids, cortisone, aldosterone, thyroxine, and unconjugated bilirubin.[62] α_1-Acid glycoprotein usually binds basic xenobiotics, including lidocaine, imipramine, and propranolol.[62] Transferrin, a β_1-globulin, transports iron, and ceruloplasmin carries copper.

Phenytoin is an example of a xenobiotic whose effects are significantly influenced by changes in concentration of plasma albumin. Only free phenytoin is active. When albumin concentrations are in the normal range, approximately 90% of phenytoin is bound to albumin. As the albumin concentration decreases, more xenobiotic is free for distribution, and a greater clinical response to the same serum phenytoin concentration is often observed. The free plasma phenytoin concentration can be calculated based on the albumin concentration. This achieves an appropriate interpretation (adjusted) of total phenytoin within the conventional therapeutic range of 10 to 20 mg/L of free plus bound phenytoin (Eq. 8–7).

$$Adjusted\ phenytoin\ concentration =$$
$$\frac{Actual\ phenytoin\ concentration}{(0.25 \times [albumin]) + 0.1}$$ (Eq. 8–7)

The clinical implications are that a malnourished patient with an albumin of 2 g/dL receiving phenytoin can manifest toxicity with a plasma phenytoin concentration of 14 mg/L. This measurement is total phenytoin (bound + unbound). Because the patient has a reduced albumin concentration, this actually represents a substantially higher proportion and absolute amount of active unbound phenytoin. Substitution into the above equation of 14 mg/L for actual plasma phenytoin concentration and 2 g/dL for albumin gives an adjusted plasma phenytoin concentration of 23.33 mg/L (therapeutic range, 10–20 mg/L).

Although drug interactions are often attributed to the displacement of xenobiotics from plasma protein binding, concurrent metabolic interactions are usually more consequential. Displacement transiently increases the amount of unbound, active drug. This may result in an immediate increase in drug effect. This is followed by enhanced distribution and elimination of unbound drug. Gradually, the unbound plasma concentration returns to predisplacement concentrations.[59]

Saturation of plasma proteins may occur in the therapeutic range for a drug such as valproic acid. Acute saturation of plasma protein binding after an overdose often leads to consequential adverse effects. Saturation of plasma protein binding with salicylates and iron after

TABLE 8–3. Pharmacokinetic Characteristics of Xenobiotics Associated with the Largest Number of Toxicologic Deaths

	Vd (L/kg)	Protein Binding (%)	Renal Elimination (% Unchanged)	Hepatic Metabolism (CYP)	Active Metabolite	Enterohepatic

overdose increase distribution to the CNS (salicylates) or to the liver, heart, and other tissues (iron), increasing toxicity.

Specific therapeutic maneuvers in the overdose setting are designed to alter xenobiotic distribution by inactivating or enhancing elimination to limit toxicity. These therapeutic maneuvers include manipulation of serum or urine pH (salicylates), the use of chelators (lead), and the use of antibodies or antibody fragments (digoxin).

The Vd permits predictions about plasma concentrations and assists in defining whether an extracorporeal method of removal is beneficial for a particular toxin. If the Vd is large (>1 L/ kg), it is unlikely that hemodialysis, hemoperfusion, or exchange transfusion would be effective because most of the xenobiotic is outside of the plasma compartment. Plasma protein binding also influences this decision. If the xenobiotic is more tightly bound to plasma proteins than to activated charcoal, then hemoperfusion is unlikely to be beneficial even if the Vd of the xenobiotic is small. In addition, high plasma protein binding limits the effectiveness of hemodialysis because only unbound xenobiotic will freely cross the dialysis membrane. Exchange transfusion can be effective for a xenobiotic with a small Vd and substantial plasma protein binding because both bound and free xenobiotic are removed simultaneously.

ELIMINATION

Removal of a parent compound from the body (*elimination*) begins as soon as the xenobiotic is delivered to clearance organs such as the liver, kidneys, and lungs. Elimination begins immediately but may not be the predominant kinetic process until absorption and distribution are substantially completed. As expected, the functional integrity of the major organ systems, such as cardiovascular, pulmonary, renal, and hepatic systems, are major determinants of the efficiency of xenobiotic removal and of therapeutically administered antidotes. The xenobiotics themselves (eg, acetaminophen) may cause renal or hepatic failure, subsequently compromising their own elimination. Other factors that influence elimination include age (enzyme maturation), competition or inhibition of elimination processes by interacting xenobiotics, saturation of enzymatic processes, gender, genetics, obesity, and the physicochemical properties of the xenobiotic.[46]

Elimination can be accomplished by biotransformation to one or more metabolites or by *excretion* from the body of unchanged xenobiotic. Excretion may occur via the kidneys, lungs, GI tract, and body secretions (sweat, tears, milk).Because of their water solubility, hydrophilic (polar) or charged xenobiotics and their metabolites are generally excreted via the kidney. The majority of xenobiotic metabolism occurs in the liver, but it also commonly occurs in the blood, skin, GI tract, placenta, or kidneys. Lipophilic (noncharged or nonpolar) xenobiotics are usually metabolized in the liver to hydrophilic metabolites, which are then excreted by the kidneys.[24,51] These metabolites are generally inactive, but if they are active, may contribute to toxicity. Examples of active metabolites include the metabolism of amitriptyline to nortriptyline, procainamide to *N*-acetylprocainamide, and meperidine to normeperidine.

Metabolic reactions catalyzed by enzymes categorized as either phase I or phase II may result in pharmacologically active metabolites; frequently, the latter have different toxicities than the parent compounds. *Phase I* (asynthetic), or preparative metabolism, which may or may not precede phase II, is responsible for introducing polar groups onto nonpolar xenobiotics by oxidation (hydroxylation, dealkylation, deamination), reduction (alcohol dehydrogenase, azo reduction), and hydrolysis (ester hydrolysis). [22,49] *Phase II*, or synthetic reactions, conjugate the polar group with a glucuronide, sulfate, acetate, methyl or glutathione; or amino acids such as glycine, taurine, and glutamic acid, creating less polar metabolites.[14,22,49]

Comparatively, phase II reactions produce a much larger increase in hydrophilicity than phase I reactions. The enzymes involved in these reactions have low substrate specificity, and those in the liver are usually localized to either the endoplasmic reticulum (microsomes) or the soluble fraction of the cytoplasm (cytosol).[49] The location of the enzymes becomes important if they form reactive metabolites, which then concentrate at the site of metabolism and cause toxicity. For example, acetaminophen causes centrilobular necrosis because the CYP 2E1 enzymes, which form *N*-acetyl-*p*-benzoquinoneimine (NAPQI), the toxic metabolite, are located in their highest concentration in that zone of the liver.

The enzymes that metabolize the largest variety of xenobiotics are heme-containing proteins referred to as *CYP monooxygenase enzymes*.[28,49] This group of enzymes, formerly called the *mixed function oxidase system*, is found in abundance in the microsomal endoplasmic reticulum of the liver. These cytochrome P-450 metabolizing enzymes (CYPs) primarily catalyze the oxidation of xenobiotics. Cytochrome P450 in a reduced state (Fe^{2+}) binds carbon monoxide. Its discovery and initial name resulted from spectral identification of the colored CO-bound cytochrome P450, which absorbs light maximally at 450 nm. The cytochrome P450 system is composed of many enzymes grouped according to their respective gene families and subfamilies, of which approximately 57 of these functional human genes have been sequenced. Members of a gene family have more than 40% similarity of their amino acid sequencing, and subfamilies have more than 55% similarity. For example, the *CYP2D6*1a* gene encodes wild-type protein (enzyme) CYP2D6, where 2 represents the family, D the subfamily and 6 the individual gene, and *1a the mutant allele; *CYP2D6.1* represents the most common or wild-type allele.

Toxicity may result from induction or inhibition of CYP enzymes by another xenobiotic, resulting in a consequential drug interaction (Chap. 12) Many of these interactions are predictable based on the known xenobiotic affinities and their capability to induce or inhibit the P450 system.[12,42,49,50,66] However, *polymorphism* (individual genetic expression of enzymes),[1] stereoisomer variability[75](enantiomers with different potencies and isoenzyme affinities), and the capability to metabolize a xenobiotic by alternate pathways contribute to unexpected metabolic outcomes. The pharmaceutical industry is now exploiting the concept of chiral switching (marketing a single enantiomer instead of the racemic mixture) to alter efficacy or side effect profiles. Enantiomers are named either according to the direction in which they rotate polarized light (*l* or – for levorotatory, and *d* or + for dextrorotatory) or according to the absolute spatial orientation of the groups at the chiral center (S or R). *Chiral* means "hand" in Greek, and the latter designations refer to either sinister (left-handed) or rectus (right-handed). There is no direct correlation between levorotatory or dextrorotatory and S and R.[70]

The liver reduces the oral bioavailability of xenobiotics with high extraction ratios. The bioavailabilities of xenobiotics with high extraction ratios are greatly affected by enzyme induction and enzyme inhibition; the reverse is true for xenobiotics with a low extraction ratio. After the xenobiotic is in the blood, the hepatic elimination is affected by blood flow to the liver, the intrinsic hepatic metabolism, and plasma protein binding. If the hepatic metabolism of a xenobiotic is very high, then the only limit to hepatic clearance is blood flow to the liver, and protein binding is not an issue. However, if the intrinsic hepatic metabolism for a xenobiotic is low, then blood flow to the liver is not a consequential factor. Plasma protein binding becomes important because only unbound xenobiotics can be cleared by the liver. Because enzyme inhibition and induction greatly affect intrinsic hepatic metabolism, these factors are also important.

Excretion is primarily accomplished by the kidneys, with biliary, pulmonary, and body fluid secretions contributing to lesser degrees. Urinary excretion occurs through glomerular filtration, tubular secretion, and passive tubular reabsorption. The glomerulus filters unbound xenobiotics of a particular size and shape in a manner that is not saturable (but is subject to renal blood flow and perfusion). Passive tubular reabsorption accounts for the reabsorption of noncharged, lipid-soluble xenobiotics and is therefore influenced by the pH of the urine and the pKa of the xenobiotic. The principles of diffusion discussed earlier permit, for example, the ion trapping of salicylate (pKa = 3.5) in the urine through urinary alkalinization. Tubular secretion is an active process carried out by drug transporters (OATs, OCTs) and subject to saturation and drug interactions (Table 8–4).

Obesity is the accumulation of fat far in excess of that which is considered normal for a person's age and gender. The National Institutes of Health defines obesity as a body mass index (BMI) greater than 30. The BMI is calculated by dividing a person's weight in kilograms by the individual's height in meters squared (m^2). By this criterion, about one-third of the adult US population is obese. Obesity poses problems in determining the correct loading dose and maintenance dose for therapeutic xenobiotics and for the estimation of serum concentrations and elimination times in the overdose setting.[10,26,39,48] A number of formulas have been proposed to classify body size in addition to BMI, but none have been tested adequately in the obese population. Obese patients have not only an increase in adipose tissue but also an increase in lean body mass of 20% to 55% which results in the alteration of the distribution of both lipophilic and hydrophilic xenobiotics. In general, the absorption of xenobiotics in obese patients does not appear to be affected, but distribution is affected. The effect of obesity on hepatic metabolism necessitates additional study, although some studies suggest a nonlinear increase in clearance. Glomerular filtration rate increases in obesity. For example, although aminoglycosides are hydrophilic, because of an increase in fat free mass in obese patients, a dosing weight correction of 40% is used to calculate both the loading dose and the maintenance dose (Dosing body weight = 0.4 × [Actual

TABLE 8–5. Equations for Determining Body Size

$$BMI = \frac{Weight\,(kg)}{Height\,(m^2)}$$

$$BSA\,(m^2) = \frac{\sqrt{Height\,(cm) \times Weight\,(kg)}}{\sqrt{3600}}$$

IBW: Males (kg) = 50 + 2.3 (Height > 60 inches)
IBW: Females (kg) = 45.5 + 2.3 (Height > 60 inches)

$$LBW2005: Males\,(kg) = \frac{9270 \times Weight\,(kg)}{6680 + [(216 \times BMI\,(kg/m^2)]}$$

$$LBW2005: Females\,(kg) = \frac{9270 \times Weight\,(kg)}{8780 + [(244 \times BMI\,(kg/m^2)]}$$

body weight – Ideal body weight] + Ideal body weight). Preliminary studies with propofol, a very lipophilic drug, suggest that induction and maintenance doses correlate better with actual body weight. These equations are found in Table 8–5. One recent hypothesis suggests using LBW2005 to simplify the calculation of maintenance doses.[26]

CLASSICAL VERSUS PHYSIOLOGIC COMPARTMENT TOXICOKINETICS

Models exist to study and describe the movement of xenobiotics in the body with mathematical equations. Traditional *compartmental* models (one or two compartments) are data based and assume that changes in plasma concentrations represent tissue concentrations (Fig. 8–6).[47] Advances in computer technology facilitate the use of the classic concepts developed in the late 1930s.[69] Physiologic models consider the movement of xenobiotics based on known or theorized biologic processes and are unique for each xenobiotic. This allows the prediction of tissue concentrations while incorporating the effects of changing physiologic parameters and affording better extrapolation from laboratory animals.[79] Unfortunately, physiologic modeling is still in its infancy, and the mathematical modeling it entails is often very complex.[19] Regardless, the most commonly used mathematical equations are based on traditional compartmental modeling.

The *one-compartment model* is the simplest approach for analytic purposes and is applied to xenobiotics that rapidly enter and distribute throughout the body. This model assumes that changes in plasma concentrations will result in and reflect proportional changes in tissue concentrations. Many xenobiotics, such as digoxin, lithium, and lidocaine, do not instantaneously equilibrate with the tissues and are better described by a two-compartment model. In the *two-compartment model*, a xenobiotic is distributed instantaneously to highly perfused tissues (central compartment) and then is secondarily, and more slowly, distributed to a peripheral compartment. Elimination is assumed to take place from the central compartment.

Model 2. One-compartment open model with first-order absorption.
Model 3. Two-compartment open model, IV injection.
Model 4. Two-compartment open model with first-order absorption.
FIGURE 8–6. Various classical compartmental models. k_e = pharmacokinetic rate constants; 1 = plasma or central compartment; 2 = tissue compartment; k_{12} = rate constant into tissue from plasma; k_{21} = rate constant into plasma from tissue; k_a = absorption rate constant.

If the rate of a reaction is directly proportional to the concentration of xenobiotic, it is termed *first order or linear*. Processes that are capacity limited or saturable are termed *nonlinear* (not proportional to the concentration of xenobiotic) and are described by the *Michaelis-Menten* equation, which is derived from enzyme kinetics. Calculus is used to derive the first-order equation, as done by Yang and Andersen.[79] Rate is directly proportional to concentration of xenobiotic, as in Equation 8–8.

$$Rate \; \alpha \; concentration(C) \qquad \text{(Eq. 8–8)}$$

An infinitesimal change in concentration of a xenobiotic (dC) with respect to an infinitesimal change in time (dt) is directly proportional to the concentration (C) of the xenobiotic as in Equation 8–9:

$$\frac{dC}{dt} \; \propto \; C \qquad \text{(Eq. 8–9)}$$

The proportionality constant k_e is added to the right side of the expression to mathematically allow the introduction of an equals sign. The constant k_e represents all of the bodily factors, such as metabolism and excretion, that contribute to the determination of concentration (Eq. 8–10).

$$\frac{dC}{dt} = kC \qquad \text{(Eq. 8–10)}$$

Introducing a negative sign to the left-hand side of the equation describes the "decay" or decreasing xenobiotic concentration (Eq. 8–11).

$$-\frac{dC}{dt} = kC \qquad \text{(Eq. 8–11)}$$

This equation is impractical because of the difficulty of measuring infinitesimal changes in C or t. Therefore, the use of calculus allows the integration or summing of all of the changes from one concentration to another beginning at time zero and terminating at time *t*. This relationship is mathematically represented by the integration sign (∫).∫ means to integrate the term from concentration at time zero (C_0) to concentration at a given time *t* (C_t). ∫means the same with respect to time, where t_0 = zero. Prior to this application, the previous equation is first rearranged (Eq. 8–12).

$$-\frac{dC}{C} = kdt$$
$$\int_{C_0}^{C_t} -\frac{dC}{C} = k\int_{t_0}^{t} dt \qquad \text{(Eq. 8–12)}$$

The integration of d*C* divided by *C* is the natural logarithm of *C* (ln *C*) and the integration of dt is *t* (Eq. 8–13).

$$-In\,C \left|\begin{matrix} C_t \\ C_0 \end{matrix}\right. = kt \left|\begin{matrix} t \\ t_0 \end{matrix}\right. . \qquad \text{(Eq. 8–13)}$$

The vertical straight lines proscribe the evaluation of the terms between those two limits. The following series of manipulations are then performed (Eq. 8–14A–D).

$$-(In\,C_t - In\,C_0) = k(t-0) \qquad \text{(Eq. 8–14A)}$$

$$-In\,C_t + In\,C_0 = kt \qquad \text{(Eq. 8–14B)}$$

$$-In\,C_t = -In\,C_0 + kt \qquad \text{(Eq. 8–14C)}$$

$$\underset{Can\;be\;measured}{In\,C_t =} \quad \underset{Constant}{In\,C_0 -} \quad \underset{Can\;be\;selected}{kt} \qquad \text{(Eq. 8–14D)}$$

Equation 8–14D can be recognized as taking the form of an equation of a straight line (Eq. 8–15), where the slope is equal to the rate constant k_e and the intercept is C_0.

$$y = b + mx \qquad \text{(Eq. 8–15)}$$

Instead of working with natural logarithms, an exponential form (the antilog) of Equation 8–14D may be used (Eq. 8–16).

$$C_t = C_0 e^{-kt} \qquad \text{(Eq. 8–16)}$$

Graphing the ln (natural logarithm) of the concentration of the xenobiotic at various times for a first-order reaction is a straight line. Equation 8–16 describes the events when only one first-order process occurs. This is appropriate for a one-compartment model (Fig. 8–7).

In this model, regardless of the concentration of the xenobiotic, the rate (percentage) of decline is constant. The absolute amount of xenobiotic eliminated changes continuously while the percent eliminated remains constant. k_e is reported in h^{-1}. A k_e of 0.10 h^{-1} means that the xenobiotic is being processed (eliminated) at a rate of 10% per hour. k_e is often designated as k_e and referred to as the elimination rate constant. The time necessary for the xenobiotic concentration to be reduced by 50% is called the *half-life*. The half-life is determined by

a rearrangement of Equation 8–14D whereby C_2 becomes C at time t_2 and C_1 becomes C at t_1 and by rearrangement giving Equation 8–17:

$$(t_1 - t_2) = \frac{\left(\ln C_1 - \ln C_2\right)}{k_e} \qquad \text{(Eq. 8–17)}$$

Substitution of 2 for C_1 and 1 for C_2 or 100 for C_1 and 50 for C_2 gives Equations 8–18A and 8–18B:

$$t_{1/2} = \frac{(\ln 2 - \ln 1)}{k_e} \qquad \text{(Eq. 8–18A)}$$

$$t_{1/2} = \frac{0.693}{k_e} \qquad \text{(Eq. 8–18B)}$$

The use of semilog paper facilitates graphing the first-order equation. However, because semilog paper plots log (not ln) versus time, to retain appropriate mathematical relationships the rate constant or slope (k) must be divided by 2.303 (see Fig. 8–7).

The mathematical modeling becomes more complex when more than one first-order process contributes to the overall elimination process. The equation that incorporates two first-order rates is used for a two-compartment model and is Equation 8–19.

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 8–19)}$$

Figure 8–8 demonstrates a two-compartment model where α often represents the distribution phase and β is the elimination phase.

The rate of reaction of a saturable process is not linear (ie, not proportional to the concentration of xenobiotic) when saturation occurs (Fig. 8–9). This model is best described by the Michaelis-Menten

Two-compartment model

$$C_t = Ae^{-\alpha t} + Be^{-\beta t}$$
FIGURE 8–8. Mathematical and graphical forms of a two-compartment classical pharmacokinetic model. k_a represents the absorption rate constant, k_e represents the elimination rate constant, α represents the distribution phase, and β represents the elimination phase.

equation used in enzyme kinetics (Eq. 8–20) in which *v* is the velocity or rate of the enzymatic reaction; *C* is the concentration of the xenobiotic; V_{max} is the maximum velocity of the reaction between the enzyme and the xenobiotic; and K_m is the affinity constant between the enzyme and the xenobiotic.[79]

$$v = \frac{V_{max} \times C}{K_m + C} \qquad \text{(Eq. 8–20)}$$

Application of this equation to toxicokinetics requires *v* to become the infinitesimal change in concentration of a xenobiotic (dC) with respect to an infinitesimal change in time (dt) as previously discussed (see Eq. 8–10). V_{max} and K_m both reflect the influences of diverse biologic processes. The Michaelis-Menten equation then becomes Equation 8–21, in which the negative sign again represents decay:

$$\frac{dC}{dt} = \frac{V_{max} \times C}{K_m + C} \qquad \text{(Eq. 8–21)}$$
FIGURE 8–9. Concentration versus time curve for a xenobiotic showing nonlinear pharmacokinetics where concentrations below 10 mg/mL represent first-order elimination.

TABLE 8–6A. Illustration of 1000 mg of Xenobiotic in Body After First-Order Elimination

Time After Drug Administration (hour)	Amount of Drug in Body (mg)	Amount of Drug Eliminated Over Preceding Hour (mg)	Fraction of Drug Eliminated Over Preceding Hour
0	1000	—	—
1	850	150	0.15
2	723	127	0.15
3	614	109	0.15
4	522	92	0.15
5	444	78	0.15
6	377	67	0.15

When the concentration of the xenobiotic is very low (C <<<K_m), it can be dropped from the bottom right of the equation because its contribution becomes negligible and the resultant equation is described as a first-order process (Eq. 8–22A and 8–22B). Conceptually, this is understandable because at a very low xenobiotic concentration, the process is not saturated.

$$-\frac{dC}{dt} = \frac{V_{max} \times C}{K_m}$$
(Eq. 8–22A)

Because V_{max} divided by K_m is a constant, K, then:

$$-\frac{dC}{dt} = kC$$
(Eq. 8–22B)

However, when the concentrations of the xenobiotic are extremely high and exceed the capacity of the system (C >>> K_m), the rate becomes fixed at a constant maximal rate regardless of the exact concentration of the xenobiotic, termed a *zero-order reaction*. Tables 8–6A and 8–6B compare a first-order reaction with a zero-order reaction. In this particular example, zero order is faster, but if the fraction of xenobiotic eliminated in the first-order example were 0.4, then the amount of xenobiotic in the body would decrease below 100 before the

xenobiotic in the zero-order example. It is inappropriate to perform half-life calculations on a xenobiotic displaying zero-order behavior because the metabolic rates are continuously changing. After an overdose, enzyme saturation is a common occurrence because the capacity of enzyme systems is overwhelmed.

CLEARANCE

Clearance (Cl) is the relationship between the rate of transfer or elimination of a xenobiotic from a reference fluid (usually plasma) to the plasma concentration of the xenobiotic and is expressed in units of volume per unit time mL/min (Eq. 8–23).[25,47,61]

$$Cl = \frac{\text{Rate of elimination}}{Cp}$$
(Eq. 8–23)

The determination of creatinine clearance is a well-known example of the concept of clearance. Creatinine clearance (Cl_{CR}) is determined by Equation 8–24:

$$Cl_{creatinine} = \frac{U \times V}{Cp}$$
(Eq. 8–24)

TABLE 8–6B. Illustration of 1000 mg of Xenobiotic in Body After Zero-Order Elimination

Time After Drug Administration (hour)	Amount of Drug in Body (mg)	Amount of Drug Eliminated Over Preceding Hour (mg)	Fraction of Drug Eliminated Over Preceding Hour
0	1000	—	—
1	850	150	0.15
2	700	150	0.18
3	550	150	0.21
4	400	150	0.27
5	250	150	0.38
6	100	150	0.60

in which U is the concentration of creatinine in urine (mg/mL); V is the volume flow of urine (mL/min); Cp is the plasma concentration of creatinine (mg/mL); and the units for clearance are millimeters per minute. A creatinine clearance of 100 mL/min means that 100 mL of plasma is completely cleared of creatinine every minute. Clearance for a particular eliminating organ or for extracorporeal elimination is calculated with Equation 8–25:

$$Cl = Q_b \times (ER) = Q_b \times \frac{(C_{in} - C_{out})}{C_{in}} \qquad \text{(Eq. 8–25)}$$

Cl = clearance for the eliminating organ or extracorporeal device
Q_b = blood flow to the organ or device
ER = extraction ratio
C_{in} = *xenobiotic concentration in fluid (blood or serum) entering the organ or device*
C_{out} = *xenobiotic concentration in fluid (blood or serum) leaving the organ or device*

Clearance can be applied to any elimination process independent of the precise mechanisms (ie, first-order, Michaelis-Menten) and represents the sum total of all of the rate constants for xenobiotic elimination. Total body clearance ($Cl_{total\ body}$) is the sum of the clearances of all of the individual eliminating processes, as seen in Equation 8–26:

$$Cl_{total\ body} = Cl_{renal} + Cl_{hepatic} + Cl_{intestinal} + Cl_{chelation} + \cdots \qquad \text{(Eq. 8–26)}$$

For a first-order process (one-compartment model), clearance is given by Equation 8–27:

$$Cl = k_e Vd \qquad \text{(Eq. 8–27)}$$

Experimentally, the clearance can be derived by examining the IV dose of xenobiotic in relation to the AUC from time zero to time t (Eq. 8–28). The AUC is calculated using the trapezoidal rule or through integral calculus (units, eg, mg/mL) (Figs. 8–10 and 8–11).

$$Cl = \frac{dose_{IV}}{AUC_{0-t}} \qquad \text{(Eq. 8–28)}$$
FIGURE 8–10. The AUC profile obtained after extravascular administration of a xenobiotic.

Compartment model
Static volume and first-order elimination is assumed. Plasma flow is not considered. $Cl_T = k_e\ V_D$.

Physiologic model
Clearance is the product of the plasma flow (Q_p) and the extraction ratio (ER). Thus, $Cl_T = Q_p\ ER$.

Model independent
Volume and elimination rate constant not defined. $Cl_T = \text{Dose} \div [AUC]_0^\infty$.

FIGURE 8–11. General approaches to clearance.

STEADY STATE

When exposure to a xenobiotic occurs at a fixed rate, the plasma concentration of the xenobiotic gradually achieves a plateau level at a concentration at which the rate of absorption equals the rate of elimination and is termed *steady state*. The time to achieve 95% of steady-state concentration for a first-order process is dependent on the half-life and usually necessitates 5 half-lives. The concentration achieved at steady state depends on the Vd, the rate of exposure, and the half-life.

Iatrogenic toxicity may occur in the therapeutic setting when dosing decisions are based on plasma concentrations determined before achieving a steady state. This adverse event is particularly common when using xenobiotics with long half-lives such as digoxin[78] and phenytoin.

PEAK PLASMA CONCENTRATIONS

Peak plasma concentrations (C_{max}) of a xenobiotic occur at the time of peak absorption. At this point in time, the absorption rate is at least equal to the elimination rate. Thereafter, the elimination rate predominates, and plasma concentrations begin to decline. Whereas the C_{max} depends on the dose, the *rate of absorption* (k_a), and *the rate of elimination* (k_e), the *time to peak* (t_{max}) is independent of dose and only depends on the k_a and k_e. For the same dose of xenobiotic, if the k_e remains constant and the rate of absorption decreases, then the t_{max} (see Table 8–7) will occur later and the C_{max} will be slightly lower. Controlled-release dosage forms and xenobiotics that form concretions and have a decreased rate of absorption may not achieve peak concentrations until many hours after an immediate-release preparation with rapid absorption. The AUC will remain the same. However if the k_a remains constant and the k_e is increased, then the tmax occurs sooner, the C_{max} decreases, and the AUC decreases (Table 8–7).[52]

Values are based on a single oral dose (100 mg) that is 100% bioavailable (F = 1) and has an apparent Vd of 10 L. The drug follows a

TABLE 8–7. Pharmacokinetic Effects of the Absorption Rate Constant and Elimination Rate Constant[a]

Absorption Rate Constant k_a (h^{-1})	Elimination Rate Constant k_e (h^{-1})	t_{max} (h)	C_{max} (µg/mL)	AUC (µg·hr/mL)

one-compartment open model. The AUC is calculated by the trapezoidal rule from 0 to 24 hours.

In the overdose setting, gastric emptying, single-dose activated charcoal, and WBI decrease k_a. Multiple-dose activated charcoal, manipulation of pH to promote ion trapping to facilitate elimination, and certain chelators (ie, succimer, deferoxamine) increase k_e and are likely to decrease C_{max}, t_{max}, and AUC.

INTERPRETATION OF PLASMA CONCENTRATIONS

For plasma concentrations to have significance, there must be an established relationship between effect and plasma concentration. Many medications, such as phenytoin, digoxin, carbamazepine, and theophylline, have an established therapeutic range. However, there are also many drugs (eg, diazepam, propranolol, verapamil) for which there is no established therapeutic range. Some xenobiotics (eg, physostigmine) exhibit *hysteresis* in which the effect increases as the plasma concentration decreases. For many xenobiotics, very little information on toxicodynamics is available. Sequential plasma concentrations often are collected for retrospective analysis in an attempt to correlate plasma concentrations and toxicity. Tolerance to drugs, such as ethanol, also influences the interpretation of plasma concentrations. *Tolerance* is an example of a pharmacodynamic or toxicodynamic effect as a result of cellular adaptation, and it occurs when larger doses of a xenobiotic are necessary to achieve the same clinical or pharmacologic result.

Other factors that influence the interpretation of plasma concentrations include chronicity of dosing (a single dose versus multiple doses); whether absorption is still ongoing and therefore concentrations are still increasing; whether distribution is still ongoing and therefore concentrations are uninterpretable (Fig. 8–12); or whether the value is a peak, trough, or steady-state concentration. Clinical examples in
FIGURE 8–12. A theoretical two-compartment model for digoxin. Assume A-E represents the digoxin serum concentration equilibrium at different t (time) intervals between the plasma compartment and the tissue compartment. Vi (initial volume of distribution) is smaller than Vt (tissue volume of distribution). The myocardium sits in Vt. E represents distribution at 5 half lives and it is assumed that the plasma and tissue compartments are now in equilibrium.[78] (Winter ME: Digoxin. In: Koda-Kimble MA, Young LY, eds. *Basic Clinical Pharmacokinetics,* 3rd ed. Vancouver, WA: Applied Therapeutics; 1994: 198-235.)

which interpretation is dependent on the dosing pattern of a single dose versus multiple doses include theophylline, digoxin, lithium, and acetaminophen. Controlled-release preparations and xenobiotics that delay gastric emptying or form concretions are expected to have prolonged absorptive phases and require serial plasma concentrations to obtain a meaningful analysis of plasma concentrations (Chap. 6). A combination of trough, peak, and minimum inhibitory concentrations is often consequential for monitoring antibiotics such as gentamicin.[8,43]

Pitfalls in interpretation arise when the units for a particular plasma concentration are not obtained or are unfamiliar (eg, mmol/L) to the clinician. In the overdose setting, the type of analysis used is not generally applied to such large concentrations, the laboratory may make errors in dilution, or errors can be inherent in the assay (Chap. 6). In these cases, the director of the laboratory should be consulted for advice with regard to the need for a reference laboratory. The type of collection tube (eg, plasma or serum instead of whole blood for certain metals), or receptacle, or the conditions during delivery of the sample may give rise to inaccurate or inadequate information. When in doubt, the laboratory should be called before sample collection. The laboratory usually measures total xenobiotic (free plus bound), and for agents

that are highly plasma protein bound, reductions in albumin increase free concentrations and alter the interpretation of the reported value (see Eq. 8–7). Active metabolites may contribute to toxicity and may not be measured.[37] Collection of accurate data for analysis requires at least 4 data points during 1 elimination half-life. During extracorporeal methods of elimination, ideal criteria for determining the amount removed require assay of the dialysate or charcoal cartridge or multiple simultaneous serum concentrations going into and out of the device rather than random serum concentrations. Clearance calculations for drugs such as lithium that partition significantly into the red cells are more accurate when measurements are taken on whole blood.[13,20] The patient's weight and height and, when indicated, hemoglobin, creatinine, albumin, and other parameters to assess elimination pathways, may be helpful.

CHAPTER 9
PRINCIPLES AND TECHNIQUES APPLIED TO ENHANCE ELIMINATION

David S. Goldfarb

Enhancing the elimination of a xenobiotic from a poisoned patient is a logical step after techniques to inhibit absorption such as orogastric lavage, activated charcoal, or whole-bowel irrigation have been considered. Table 9–1 lists methods that might be used to enhance elimination. Some of these techniques are described in more detail in chapters that deal with specific xenobiotics. In this chapter, hemodialysis, hemoperfusion, and hemofiltration are considered *extracorporeal therapies* because xenobiotic removal occurs in a blood circuit outside the body. Currently these methods are used infrequently as intensive supportive care because most poisonings are not amenable to removal by these methods. Because these elimination techniques have associated adverse effects and complications, they are indicated in only a relatively small proportion of patients.

EPIDEMIOLOGY

Although undoubtedly an underestimate of true use, enhancement of elimination was used relatively infrequently in a cohort of more than 2.4 million patients reported by the American Association of Poison Control Centers (AAPCC) National Poison Data System (NPDS) in 2007 (Chap. 135)[31]. Alkalinization of the urine was reportedly used 9430 times, MDAC 3114 times, hemodialysis 2106 times, hemoperfusion 16 times, and "other extracorporeal procedures" (most likely continuous venovenous hemofiltration [CVVH]) 24 times. As in the past, there continue to be many instances of the use of extracorporeal therapies that are considered inappropriate, such as in the treatment of overdoses of cyclic antidepressants (CAs) or acetaminophen.[31]

Although data reporting remains important in comparing the most recent data with past reports (Table 9–2), there is a continued increase in the reported use of hemodialysis, paralleling a decline in reports of charcoal hemoperfusion (Chap. 135). Lithium and ethylene glycol were the most common xenobiotics for which hemodialysis was used between 1985 and 2005.

Possible reasons for the decline in use of charcoal hemoperfusion are described in the Charcoal Hemoperfusion section below. Various resins and other sorbents once used for hemoperfusion are not currently available in the United States. Peritoneal dialysis (PD), a slower modality that should have little or no role in any poisonings, is no longer separately reported (Chap. 135). "Other extracorporeal procedures" in the AAPCC reports are probably continuous modalities (discussed below in the section Continuous Hemofiltration and Hemodiafiltration) and may include some cases in which PD was used.

Very few prospective, randomized, controlled clinical trials have been conducted to determine which groups of patients actually benefit from enhanced elimination of various xenobiotics and which modalities are most efficacious. For most poisonings, it is unlikely that such studies will ever be performed, given the relative scarcity of appropriate cases of sufficient severity and because of the many variables that would hinder controlled comparisons. Thus, limited evidence predominates. We must therefore rely on an understanding of the principles of these methods to identify the individual patients for whom enhanced elimination is indicated. Isolated case reports in which the kinetics are studied before, during, and after enhanced elimination are also very useful in establishing the efficacy of a method.

GENERAL INDICATIONS FOR ENHANCED ELIMINATION

Enhanced elimination may be indicated for several types of patients:

- *Patients who fail to respond adequately to full supportive care.* Such patients may have intractable hypotension, heart failure, seizures, metabolic acidosis, or dysrhythmias. Hemodialysis or hemoperfusion are much better tolerated than in the past and may represent potentially life-saving opportunities for patients with life-threatening toxicity caused by theophylline, lithium, salicylates, or toxic alcohols.

- *Patients in whom the normal route of elimination of the xenobiotic is impaired.* Such patients may have renal or hepatic dysfunction, either preexisting or caused by the overdose. For example, a patient with chronic renal insufficiency associated with long-term lithium use is more likely to develop lithium toxicity and then require hemodialysis as therapy.

- *Patients in whom the amount of xenobiotic absorbed or its high concentration in serum indicates that serious morbidity or mortality is likely.* Such patients may not appear acutely ill on initial evaluation. Xenobiotics in this group may include ethylene glycol, lithium, methanol, paraquat, salicylate, and theophylline.

- *Patients with concurrent disease or in an age group (very young or old) associated with increased risk of morbidity or mortality from the overdose.* Such patients are intolerant of prolonged coma, immobility, and hemodynamic instability. An example is a patient with both severe underlying respiratory disease and chronic salicylate poisoning.

- *Patients with concomitant electrolyte disorders that could be corrected with hemodialysis.* An example is the lactic acidosis associated with metformin toxicity discussed in the Hemodialysis section of this chapter.

Ideally, these techniques will be applied to poisonings for which studies suggest an improvement in outcome in treated patients compared with patients not treated with extracorporeal removal. As previously mentioned, these data are rarely available.[25]

The need for extracorporeal elimination is less clear for patients who are poisoned with xenobiotics that are known to be removed by the various modalities of treatment but that cause limited morbidity if supportive care is provided. Relatively high rates of endogenous clearance would also make extracorporeal elimination redundant. Examples of such xenobiotics include ethanol and barbiturates. Both are subject to substantial rates of hepatic metabolism, and neither would be expected to lead to significant morbidity after the affected patient has been endotracheally intubated and is mechanically ventilated. There may be instances of severe toxicity from these two xenobiotics for which enhanced elimination will reduce the length of intensive care unit (ICU) stays and the associated nosocomial risks; extracorporeal elimination may then be a reasonable option.[8,50] Dialysis should be avoided if other more effective modalities are available. For example, patients with acetaminophen overdoses should be treated with *N*-acetylcysteine instead of with hemodialysis.

CHARACTERISTICS OF XENOBIOTICS APPROPRIATE FOR EXTRACORPOREAL THERAPY

The appropriateness of any modality for increasing the elimination of a given xenobiotic depends on various properties of the molecules in question. Effective removal by the extracorporeal procedures and other methods listed in Table 9–1 is limited by a large volume of distribution (Vd). The Vd relates the concentration of the xenobiotic in the blood or serum to the total body burden. The Vd can be envisioned as the apparent volume in which a known total dose of drug is distributed before metabolism and excretion occur:

$$\text{Vd (L/kg)} \times \text{patient weight (kg)} = \text{Dose (mg)/Concentration (mg/L)}$$

The larger the Vd, the less the xenobiotic is available to the blood compartment for elimination. A xenobiotic with a relatively small Vd, considered amenable to extracorporeal elimination, would distribute

TABLE 9–2. Changes in Use of Extracorporeal Therapies[a]

in an apparent volume not much larger than total body water (TBW). TBW is approximately 60% of total body weight, so a Vd equal to TBW is approximately 0.6 L/kg body weight.

Ethanol is an example of a xenobiotic with a small Vd approximately equal to TBW. A substantial fraction of a dose of ethanol could be removed by hemodialysis. In contrast, an insignificant fraction of digoxin with a large Vd (5–12 L/kg of body weight) would be removed by this therapy. Lipid-soluble xenobiotics and those that are highly protein bound have large volumes of distribution, which can exceed TBW or even total body weight. These high apparent volumes of distribution imply that the xenobiotic is not available to extracorporeal removal because only a small portion would be in the blood and therefore the extracorporeal circuit. In addition to the alcohols, other xenobiotics with a relatively low Vd include phenobarbital, lithium, salicylates, bromide and fluoride ions, and theophylline. Conversely, those with a high Vd (≥1 L/kg of body weight), which would not be removed substantially by hemodialysis, include many β-adrenergic antagonists (with the possible exception of atenolol[59]), diazepam, organic phosphorus compounds, phenothiazines, quinidine, and the cyclic antidepressants.

Pharmacokinetics also influence the ability to enhance elimination of a xenobiotic. Kinetic parameters after an overdose may differ from those after therapeutic or experimental doses. For instance, carrier- or enzyme-mediated elimination processes may be overwhelmed by higher concentrations of the xenobiotic in question, making extracorporeal removal potentially more useful. Similarly, plasma protein- and tissue-binding sites may all be saturated at higher concentrations, making extracorporeal removal feasible in instances in which it would have no role in less significant overdoses. An example is valproic acid, which may be poorly dialyzed at nontoxic concentrations because of high rates of protein binding (although dialysis is rarely indicated). However, higher, potentially toxic concentrations saturate protein-binding sites and lead to a higher proportion of the drug free in the serum, amenable to removal by hemodialysis at a clinically relevant rate.[35] Estimates of the expected endogenous rates of elimination of a xenobiotic in the setting of an overdose should be made, wherever possible, from knowledge of the toxicokinetic characteristics derived from obtained in relevant models of toxicity, not after therapeutic doses.

When assessing the efficacy of any technique of enhanced elimination, a generally accepted principle is that the intervention is worthwhile only if the total body clearance of the xenobiotic is increased by at least 30%.[17] This substantial increase is easier to achieve when the xenobiotic has a low endogenous clearance. Examples of xenobiotics with low endogenous clearances (<4 mL/min/kg) include the toxic alcohols (particularly when their metabolism is blocked), atenolol, sotalol, lithium, paraquat, phenytoin, salicylate, and theophylline. Xenobiotics with high endogenous clearances include many β-adrenergic antagonists, lidocaine, opioids, nicotine, and CAs. Enhancement of elimination is expected to contribute more to overall clearance of the former group than to the latter.

The efficacy of any technique of elimination can be directly assessed by comparing the blood or serum concentrations of the xenobiotic at the beginning and the end of the procedure.[69] For example, a xenobiotic such as theophylline, with one-compartment kinetics, is essentially limited to the extracellular space. The difference between the theophylline concentration before the procedure, minus the concentration at the end of the procedure, divided by the concentration at the beginning, is the fraction of the body burden of the xenobiotic that is eliminated. This calculation would not be appropriate to estimate the effect of treatment on the total body burden of a xenobiotic that distributes in a larger Vd because the changes in blood concentration may not reflect the effect of the treatment on the total amount in other compartments.

Certain xenobiotics, such as lithium, distribute in part to the intracellular compartment, and equilibrium is established between the intracellular and extracellular compartments. The latter compartment includes the blood from which xenobiotic elimination occurs. An increase in the elimination rate from the extracellular compartment, such as by hemodialysis, alters this equilibrium. The rate of redistribution of the xenobiotic from the intracellular compartment into the now-dialyzed extracellular compartment may be slower than the rate of clearance across the dialysis membrane. In that case, the serum concentration may become relatively low despite a substantial intracellular burden. This low serum concentration reduces the concentration gradient for diffusion from serum to dialysate so that dialysance (the dialysis clearance) is reduced. Thus, although serum concentrations may decrease precipitously during the procedure, the total-body burden of the xenobiotic may not be affected significantly if it does not move from cells to the dialyzable extracellular volume. An example is a 60-kg patient who ingests 100 25-mg amitriptyline tablets, a TCA.[25] Assuming that the drug is fully absorbed, the 2500-mg distributes in an apparent volume of 40 L/kg of body weight to achieve a serum concentration of 1000 ng/mL, a potentially toxic concentration. If charcoal hemoperfusion is performed with a blood flow rate of 350 mL/min (plasma flow rate of 200 mL/min, assuming a hematocrit of approximately 43%) and the extraction ratio is 100% (see Charcoal Hemoperfusion below), the clearance of drug is 200 mL/min or 200 μg/min. In 4 hours (240 minutes) of treatment, only 48 mg (48,000 μg), or less than 2% of the amount ingested, will be removed. The treatment would not have affected toxicity.

Further evidence that a xenobiotic is in a slowly equilibrating compartment is provided by monitoring the concentrations after discontinuation of the procedure and demonstrating rebounding (serum). This rebound indicates postdialysis redistribution (Fig. 9–1). The magnitude of the rebound depends on total-body stores of the xenobiotic. A postdialysis increase in blood concentrations may also result from ongoing absorption from the gastrointestinal (GI) tract.

When assessing overall efficacy, the evidence of enhanced elimination must be considered in the context of the clinical response. In some instances, observed improvement is not predicted by the kinetics of the parent xenobiotic and may not result from the intervention. For example, in severe cases of CA poisoning, unexpected improvement during hemoperfusion could be fortuitous because the toxicity is manifested early and ameliorates rapidly during the initial distribution phase.

Beginning a procedure during the initial distribution phase may increase the fraction of body burden that can be removed. Later, after the xenobiotic has distributed into fat or has been bound by plasma or tissue proteins, administration of extracorporeal treatment may have much lower clearance rates and benefits. Poisonings with paraquat and hepatotoxic mushrooms are other examples in which only early extracorporeal therapy *may* have benefit.[22] An alternative explanation for unanticipated evidence of improvement in some cases is the removal of small amounts of the xenobiotic and active metabolites from a shallow "toxic effect" compartment. This theory has been advanced to explain the response to hemodialysis of patients overdosed with the antipsychotic chlorprothixene[40] or with a combination of diltiazem and metoprolol.[2] Such effects may lead to transient improvements that are not sustained as drug redistributes from one pool to another, leading to early benefit but eventual recurrence of symptoms. Much of the relevant literature fails to provide long-term follow-up to demonstrate prolongation of benefits after extracorporeal therapy is completed and xenobiotics have redistributed.

Other examples also demonstrate that removal of a xenobiotic is a poor surrogate for clinical benefit. Enhanced elimination of phenobarbital[53] or carbamazepine[73] by MDAC did not affect clinical outcomes compared with those of overdosed, untreated control subjects despite a decrease in their serum concentrations. In another study, no difference was observed between patients with lithium poisoning for whom hemodialysis was done and those for whom it was recommended by a poison control center but not done.[9] The conclusion was that hemodialysis should be considered appropriate only for the more severe cases. In acetaminophen toxicity, the efficacy of administration of *N*-acetylcysteine makes extracorporeal removal unnecessary and not part of the recommended treatment strategy.

TECHNIQUES TO ENHANCE REMOVAL OF XENOBIOTICS

Although the efficacy of or need for removal of many xenobiotics remains controversial, consensus regarding the indications for a number of procedures has developed. This consensus has led to consistent application of several techniques of enhanced elimination for some toxic exposures that occur relatively more frequently. The techniques to enhance xenobiotic elimination most commonly applied over the past decade have been alkalinization of the urine for salicylates and hemodialysis for methanol, ethylene glycol, lithium, and salicylates.

■ FORCED DIURESIS AND MANIPULATION OF URINARY pH

Forced diuresis by volume expansion with isotonic sodium–containing solutions, such as 0.9% NaCl and lactated Ringer solution, may increase renal clearance of some molecules. This therapy would theoretically be most useful for xenobiotics such as lithium for which the glomerular filtration rate (GFR), which is the volume of plasma filtered across the glomerular basement membrane per minute, is an important determinant of excretion. In people with normal extracellular fluid (ECF) volume who have not had loss of sodium via renal, GI, or other routes of excretion, the increase in GFR expected with plasma volume expansion is variable and unpredictable and may not lead to significant increases in xenobiotic elimination. The effect is potentially more important in patients who have had contraction of the ECF volume because of sodium loss. Loss of extracellular volume leads to a reduction
FIGURE 9–1. Repeated serum lithium concentrations after an acute ingestion. *Arrows* indicate beginning (*green arrows*) and end (*red arrows*) of hemodialysis. After a 5-hour hemodialysis treatment, a significant rebound in serum concentration occurred, with recurrence of neurologic impairment. An additional 4-hour hemodialysis treatment was then begun.

of GFR partly as a result of decreased cardiac preload and cardiac output, which, in turn, reduces renal plasma flow. This circumstance is also accompanied by activation of angiotensin II, a small peptide that acts as a pressor and stimulates sodium reabsorption in the proximal tubule. Because small molecules such as lithium are both filtered at the glomerulus and reabsorbed by the proximal tubule, especially when sodium depletion has occurred and angiotensin II has been activated, repletion of ECF volume with isotonic saline will increase GFR and suppress sodium reabsorption. The result is an increase in excretion of low-molecular-weight xenobiotics such as lithium. After the ECF volume is restored, continued infusion of 0.9% NaCl increases urine volume proportionally more than GFR, which may increase excretion of some small molecules such as urea, but which has little efficacy in the case of most poisonings.

The significant risk of this therapy is ECF volume overload, manifested by pulmonary and cerebral edema. This complication may be particularly likely in patients with long-standing lithium use in whom chronic tubulointerstitial disease may lead to renal insufficiency that does not improve with fluid therapy. Other patients with acute kidney injury not mediated by ECF volume depletion are also at risk. Knowing the result of past serum creatinine concentrations may help distinguish acute from chronic renal insufficiency in such cases. Administration of diuretics such as furosemide along with saline may diminish the risk of ECF volume overload but may complicate the therapy, confuse the assessment of ECF volume, and increase the risk of metabolic alkalosis and hypokalemia. The unproven efficacy of forced diuresis in the management of *any* overdose has led most experts to abandon its use. On the other hand, the repletion of ECF volume when it is contracted, as determined by the history and physical examination, is, of course, appropriate.

Many xenobiotics are weak acids or bases that are ionized in aqueous solution to an extent that depends on the pK_a of the compound and the pH of the solution. Knowing these variables, the Henderson-Hasselbalch equation (Chap. 8) may be used to determine the relative proportions of the acids, bases, and buffer pairs. Whereas cell membranes are relatively impermeable to ionized, or polar molecules (eg, an unprotonated salicylate anion), nonionized, nonpolar forms (eg, the protonated, noncharged salicylic acid) may cross more easily. As xenobiotics pass through the kidney, they may be filtered, secreted, and reabsorbed. If the urinary pH is manipulated to favor the formation of the ionized form in the tubular lumen, the xenobiotic is trapped in the tubular fluid and is not passively reabsorbed into the bloodstream. This is referred to as *ion trapping*. Hence, the rate and extent of its elimination can be increased. To make manipulation of urinary pH worthwhile, the renal excretion of the xenobiotic must be a major route of elimination. The 2004 position paper of the American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) emphasizes that, as discussed above for extracorporeal therapies, enhanced removal does not necessarily translate into a clinical benefit with improved outcomes.[55]

Acidification of the urine by systemic administration of HCl or NH_4Cl to enhance elimination of weak bases, such as phencyclidine or the amphetamines, is not useful and is potentially dangerous. The technique has been abandoned because it does not significantly enhance removal of xenobiotics and is complicated by systemic metabolic acidosis.

Alkalinization of the urine to enhance elimination of weak acids has a limited role for xenobiotics such as salicylates,[48] phenobarbital, chlorpropamide, formate, diflunisal, fluoride, methotrexate, and the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D). These weak acids are ionized at alkaline urine pH, and tubular reabsorption is thereby greatly reduced. Alkalinization is achieved by the intravenous (IV) administration of sodium bicarbonate (1 to 2 mEq/kg rapid initial infusion with additional dosing) to increase urinary pH to 7 to 8.

This degree of alkalinization may be difficult, if not impossible, if metabolic acidosis and acidemia are present, as often is the case in patients with salicylate poisoning. In this situation, bicarbonate (administered as the sodium salt) is consumed by titration of plasma protons before it can appear in the urine. On the other hand, salicylate poisoning often causes respiratory alkalosis as well. In that case, when PCO_2 is low, raising serum bicarbonate, equivalent to the induction of metabolic alkalosis, may lead to profound, life-threatening alkalemia. Finally, the risk of ECF volume overload with sodium bicarbonate administration is the same as with the administration of 0.9% NaCl. Hypernatremia may also occur after administration of hypertonic sodium bicarbonate. Bicarbonaturia is also associated with urinary potassium losses, so the patient's serum potassium concentration should be monitored frequently and KCl given liberally as long as GFR is not impaired. A further complication of alkalemia is a decrease of ionized calcium, which becomes bound by albumin as protons are titrated off serum proteins; in this event, tetany may occur.[24] If these complications can be identified and dealt with judiciously and safely, the renal clearance of salicylate may increase fourfold as urine pH increases from 6.5 to 7.5 with alkalinization. Increasing urine pH by decreasing proximal tubular bicarbonate reabsorption via administration of carbonic anhydrase inhibitors such as acetazolamide is not recommended. Although elimination of a xenobiotic may be increased, metabolic acidosis will ensue unless ample sodium bicarbonate is also administered. In the case of salicylates, metabolic acidosis with acidemia may cause increased distribution of drug into the central nervous system. As with $NaHCO_3$ administration, bicarbonaturia is accompanied by urinary potassium losses; hypokalemia may be profound. The role of urinary alkalinization in the management of patients with salicylate poisoning is discussed further in Chapter 35.

Alkalinization is also used to increase the solubility of methotrexate and thereby prevent its precipitation in tubules when patients are given high-dose folinic acid rescue therapy.[15] Precipitation of sulfonamide antibiotics with kidney stones or kidney failure may also be prevented by alkalinization. ECF volume expansion with 0.9% NaCl and $NaHCO_3$ administration also protects the kidneys from the toxic effects of myoglobinuria in patients with extensive rhabdomyolysis. However, because patients with rhabdomyolysis may have acute renal failure, $NaHCO_3$ administration must be used before kidney injury occurs and may lead to ECF volume overload if its administration continues after kidney failure has been established.

■ PERITONEAL DIALYSIS

Theoretically, PD enhances the elimination of a few water-soluble, low-molecular-weight, poorly protein-bound xenobiotics with a low Vd such as the alcohols, lithium, salicylate, and theophylline. Clearance of xenobiotics in the aqueous dialysate is related to dialysate flow rate, the surface area of the peritoneum, and the molecular weight of the compound. The highest clearances are achieved for molecules with molecular weights below 500 daltons. The efficacy of PD is markedly decreased when the patient has hypotension.

Although PD is a relatively simple method to enhance xenobiotic elimination, it is too slow to be clinically useful. Consequently, PD is never the method of choice unless hemodialysis and hemoperfusion are unavailable and transfer to a center that can offer these techniques is not feasible. Besides exchange transfusion, it may be the only practical option in small children when experience with extracorporeal techniques in younger age groups is lacking or until a child can be transported to an appropriate center.

■ HEMODIALYSIS

The utility of hemodialysis for the treatment of patients with toxicity caused by lithium, toxic alcohols, salicylates, or theophylline is unquestionable and is not dealt with here in specific detail. Each of these xenobiotics is described in detail in separate chapters that also review in toxicity and indications for extracorporeal therapies. This section describes the hemodialysis procedure in general and its application to some newer situations.

Prompt consultation with a nephrologist is always indicated in the case of any poisoning with a xenobiotic that might benefit from extracorporeal removal. Annual AAPCC data consistently suggest that some salicylate-related deaths, for example, could have been prevented if hemodialysis had been instituted earlier (Chap. 135).[74] To perform hemodialysis, a nephrologist must be available along with a nurse or technician. The dialysis machine requires preparation, and a vascular access catheter has to be inserted into the patient's circulation. A delay of several hours before hemodialysis can be instituted should be anticipated. If indicated, modalities of treatment such as fomepizole or ethanol for poisoning with toxic alcohols should be administered, and other modalities to enhance elimination, such as urinary alkalinization or oral MDAC, should be used when appropriate.

The technical details of performing hemodialysis for treatment of patients with poisonings do not differ markedly from those used in the treatment of patients with acute kidney failure. Vascular access is best attained via the femoral vein. The subclavian and internal jugular veins are also acceptable but have slightly higher rates of complications such as pneumothorax and arterial puncture.[14] Hemostasis after catheter removal is also more easily achieved at the femoral site. Hemodialysis and hemoperfusion (see sections below) are usually performed using a double-lumen catheter manufactured for dialysis that is made of silicon, polyethylene, polyurethane, or Teflon. Blood is pumped through one lumen, passed through the machine, and returned to the venous circulation through the second lumen. Blood flow rates with these catheters can be as high as 450 to 500 mL/min, although 350 mL/min may sometimes be the maximum rate achievable.

The blood lines and artificial kidney (the dialysis membrane) should be primed with an appropriate volume of fluid to reduce or avoid hypotension when the procedure is started. Larger "high-efficiency" or "high-flux" artificial kidneys should be selected. Full anticoagulation with heparin is usually required. A typical adult heparin dose is 4000 to 5000 units as a bolus followed by 400 to 500 units hourly. Alternatively, periodic flushes of the dialysis membrane with heparinized saline expose the patient to very low doses of heparin and little risk of systemic anticoagulation. Regional anticoagulation of the dialysis circuit with citrate or protamine is possible if heparin is absolutely contraindicated, although these agents complicate the procedure. Use of a dialysate that contains citrate may be adequate for anticoagulation and may allow heparin to be avoided.[1]

In poisoned patients, hemodialysis is usually performed for 4 to 8 hours. Assuming that the patient's serum potassium concentration is normal, a standard bicarbonate-based dialysate with a potassium concentration of 3 or 4 mEq/L and a calcium concentration of 3 mEq/L, flowing at 600 to 800 mL/min, is sufficient. If dialysis is performed in a dialysis unit, the dialysate is a mix of a concentrate with $NaHCO_3$ and highly purified water, usually derived by reverse osmosis or deionization. Dialysis procedures done in ICUs should use portable reverse osmosis machines to generate the water for mixing. Although undesirable, tap water can be used if its chlorine content is less than 0.1 ppm.[7]

During conventional hemodialysis, blood flows through hollow fibers, which are semipermeable membranes. The hollow fibers are bathed by a dialysis solution or dialysate. Xenobiotics diffuse across the membrane from blood into the dialysate down their concentration gradients (Fig. 9–2). Table 9–3 lists the characteristics of xenobiotics
FIGURE 9–2. The comparative schematic layouts of hemodialysis (HD), continuous venovenous hemofiltration (CVVH), continuous venovenous hemofiltration with dialysis (CVHD), and hemoperfusion (HP). *Red circles* ● are high molecular-weight (MW) xenobiotics, such as methotrexate, whose high MW makes them too large to be removed by HD; *Yellow circles* ● are low molecular-weight (MW) diffusible solutes such as urea or methanol. In dialysis, solute moves across a semipermeable membrane (*dashed lines*) from a solution in which it is present in a high concentration (blood) to one in which it is at a low concentration (dialysate). In CVVH and CVVHD, plasma moves across a similar membrane in response to hydrostatic pressures; replacement fluid must be provided. The latter also utilizes a dialysate to augment clearance. The availability of blood pumps has made arteriovenous modalities nearly obsolete. Charcoal hemoperfusion (CH) requires movement of blood through a sorbent-containing cartridge and does not include dialysis or hemofiltration.

TABLE 9–3. Characteristics of Xenobiotics That Allow Clearance by Hemodialysis, Hemoperfusion, and Hemofiltration

For All Three Techniques	For Hemodialysis	For Hemoperfusion	For Hemofiltration
Low Vd (<1 L/kg)	MW <500 daltons	Adsorption by activated charcoal	MW <10,000 or <40,000 daltons,
Single-compartment kinetics	Water soluble	Binding by plasma proteins	depending on filter used
Low endogenous clearance (<4 mL/min/kg)	Not bound to plasma proteins	does not preclude	

MW, molecular weight; Vd, volume of distribution.

that make them amenable to hemodialysis. These requirements greatly reduce the number of xenobiotics that can be expected to be cleared by dialysis. During hemodialysis, clearance of a xenobiotic (Cl_X) can be calculated by:

$$Cl_X = Q_p \times ER$$

where Q_p is the plasma flow rate and ER is the extraction ratio.

$$Q_p = Q_b \times (1 - Hct)$$

where Q_B is blood flow rate and Hct is hematocrit. The extraction ratio (ER) is a measure of the percentage of xenobiotic passing through the artificial kidney or charcoal hemoperfusion cartridge. This can be calculated as:

$$ER = \frac{C_{in} - C_{out}}{C_{in}} \times 100$$

where C_{in} is the concentration of the xenobiotic in blood entering the system and C_{out} is the concentration in blood leaving the system. Then:

$$Cl_X = [Q_p(C_{in} - C_{out})]/C_{in}$$

Several technologic advances now enable patients to tolerate dialysis with better clearances. Although clearance rates reported in the literature of the 1970s and 1980s may significantly underestimate currently achievable clearance rates,[50] these data are still of interest given the relative paucity of more recent reports. Patients undergoing hemodialysis may also experience much less hemodynamic instability than in the past. For instance, the source of base in dialysate is now routinely $NaHCO_3$ rather than sodium acetate; the latter caused hypotension and decreased cardiac output. Computerized machines allow fine control of ultrafiltration rates to limit volume losses; in the past, imprecise calculations and manipulations led to frequent episodes of hypotension. The sodium concentration of the dialysate can be programmed to vary through the course of the procedure, a technique called *sodium modeling*, which may promote hemodynamic stability as well. Better hemodynamic stability and larger dual-lumen catheters allow use of higher blood flows, up to 400 to 500 mL/min. As a result of such innovations, treatment can be delivered in more instances than was previously possible. Hypotension may still occur in critically ill patients. Saline, colloid, vasopressors, or inotropes may also be required in such patients, but if dialysis seems to offer the best chance for the patient's survival, it should usually be attempted.

Dialysis membrane composition has also continually evolved. The hollow-fiber dialyzer, almost universally used today, is composed of thousands of blood-filled capillary tubes held together in a bundle and bathed in the machine-generated dialysate. Older "conventional" dialyzers, much less frequently encountered today, are made of cellulose-derived polymers, most commonly called *cuprophane*. Hemodialysis efficacy for poisonings with low-molecular-weight xenobiotics should improve with the use of larger membranes with larger clearances. The prototypical "middle molecule," the clearance of which is used to express a dialyzer's high-flux dialysance, is β_2-microglobulin (molecular weight, 11,800).

"High-flux," synthetic dialyzers have larger pores that allow more clearance of larger molecules. Because these membranes also have higher water permeability, computerized ultrafiltration control is necessary. These membranes, composed of polysulfone (PS), polyamide, polyacrylonitrile (PAN), and other polymers, have better biocompatibility than older, cellulose-derived membranes. Biocompatibility is measured by the rate of activation or release, after exposure to the membrane, of inflammatory mediators that include white blood cells, platelets, complement, and cytokines. Better biocompatibility means less activation of these potentially damaging mechanisms compared with more bioincompatible membranes.

The influence of biocompatibility on the outcomes of patients receiving long-term hemodialysis for chronic renal failure is still being assessed. Patients with chronic kidney failure are exposed to these membrane materials during at least three treatments a week for many years. It is unlikely that better biocompatibility will affect outcomes for dialysis of poisoned patients who require only one or two treatments.

There are some instances in which high-flux dialyzers might be important in promoting clearance of larger molecules, such as vancomycin, which are not readily removed by conventional low-flux membranes.[26] However, the indications for performing hemodialysis to enhance removal of vancomycin and other xenobiotics with higher molecular weights have not been delineated. Nonetheless, a sound pharmacologic basis for the efficacy of dialysis must still be present; no amount of increased clearance will eliminate a xenobiotic with a large Vd or significant protein or tissue binding.

With that proviso, recent experience suggests a role for high-flux hemodialysis in the clearance of certain xenobiotics that were previously thought to be effectively removed only by charcoal hemoperfusion. The situations in which these modalities are appropriate for these xenobiotics remain exceedingly rare. As valproic acid is increasingly prescribed for neurologic and psychiatric disorders, the incidence of both intentional and unintentional overdoses of this drug will also increase.[68] As discussed previously, valproic acid is largely protein bound at therapeutic serum concentrations. Toxic concentrations saturate protein-binding sites, leading to a higher proportion of unbound drug in the serum and a lower apparent Vd, thereby making the drug more dialyzable. Indeed, several case reports have demonstrated that the clearance of valproic acid with high-flux hemodialysis is at least equivalent to, if not greater than, that of charcoal hemoperfusion.[30,38,39] Although carbamazepine has a low molecular weight and a Vd that would allow for clearance by

hemodialysis, its high protein binding and lack of water solubility are expected to impede the efficacy of hemodialysis. Nonetheless, carbamazepine is also effectively cleared with high-flux hemodialysis.[60,70] In a patient who underwent high-flux hemodialysis followed by charcoal hemoperfusion for carbamazepine toxicity, removal rates were similar for the two modalities. Unlike the case for valproic acid, the rationale for these anecdotal reports for enhanced carbamazepine elimination is unclear. Whether the pharmacokinetics of the drug are altered at toxic serum concentrations, as are those of valproic acid, is not known. Because of its potential efficacy and availability and its insignificant effect on cost and adverse events, high-flux hemodialysis should probably replace charcoal hemoperfusion as the treatment modality of choice when extracorporeal elimination of valproic acid or carbamazepine is to be performed. As stated above, however, effective clearance is not necessarily a surrogate for improved outcomes.

In addition to removing xenobiotics, hemodialysis can correct acid–base and electrolyte abnormalities such as metabolic acidosis or alkalosis, hyperkalemia, and ECF volume overload. Consequently, hemodialysis is preferred, if not essential, for poisonings characterized by these disorders, especially when clearance rates resulting from hemoperfusion and hemodialysis are relatively similar. Examples include salicylate poisoning, which is often associated with metabolic acidosis,[33] and propylene glycol toxicity, which is often associated with lactic acidosis, especially in the presence of renal or hepatic impairment.[52]

A more controversial question is the role of dialysis in the treatment of metformin-associated lactic acidosis in patients with diabetes mellitus. If metformin were not primarily responsible for the lactic acidosis, removal of the drug by hemodialysis would then be unlikely to affect the outcome. An inverse relationship exists between serum metformin concentrations and mortality in patients with metformin-associated lactic acidosis.[42] This finding may indicate that many of those patients determined to have metformin-associated lactic acidosis with lower serum metformin concentrations may have another primary cause for lactate production other than metformin. These include sepsis or bowel ischemia, and often these other diagnoses portend worse outcomes. In cases of metformin-associated lactic acidosis in patients with normal renal function, extracorporeal removal is generally not indicated because endogenous clearance of metformin is quite high and prognosis is good without dialysis.[10] Metformin-associated lactic acidosis in the setting of decreased kidney function may constitute an appropriate indication for hemodialysis.

The more important role for hemodialysis is in cases of metformin-associated lactic acidosis involving acute renal failure such as contrast nephropathy without other causes of lactic acidosis in patients with chronic renal failure who are inappropriately treated with metformin, and in patients who overdose on metformin. Here, the small molecular weight and negligible plasma protein binding of metformin may allow for adequate drug removal despite a relatively large Vd. In addition, hemodialysis would correct acidosis via administration of bicarbonate. Clinical improvement with hemodialysis may result as much or more from correction of the acidosis as from removal of the drug.

Complications of acute hemodialysis are relatively rare. Bleeding or thrombosis at the site used for vascular access, usually the femoral vein, is infrequent with normal hemostasis and adequate postprocedure tamponade of the catheter site. Bleeding in the GI tract and elsewhere, caused by systemic anticoagulation with heparin, can be avoided if low doses of heparin are used. Low-dose heparin is an appropriate choice when dialyzing patients for toxic alcohol and salicylate exposures who are at risk for increased intracerebral bleeding. Nosocomial bacteremia may occur if central lines are left in place for prolonged periods; central lines should be removed after 5 days at most. Femoral venous lines should always be removed in patients who are out of bed.

In addition, hemodialysis increases the elimination of some drugs administered therapeutically, such as folic acid and other water-soluble vitamins and xenobiotics. Doses of these drugs should be increased during dialysis or administered immediately afterward. Similarly, the rate of ethanol infusions used in the treatment of patients with toxic alcohol ingestions must be increased. Fomepizole also has a low molecular weight (molecular weight, 82.1 daltons) and a low Vd (0.6–1.0 L/kg), so it can also be dialyzed, but it is not significantly removed by hemofiltration. If necessary, it should be redosed after dialysis (see Antidotes in Depth: Ethanol and Fomepizole). When fomepizole is not available, ethanol removal can be limited in such cases by enriching the dialysate with ethanol to a concentration of 100 mg/dL.[18] Similarly, hypophosphatemia after more prolonged high-flux hemodialysis can be avoided by adding sodium phosphate salts (eg, Fleet Phospho-Soda) to the dialysate or by administering phosphate intravenously. Angiotensin-converting enzyme inhibitors should never be used if dialysis is performed with PAN membranes because the combination is associated with angioedema.[13]

■ CHARCOAL HEMOPERFUSION

In general, if a xenobiotic is well adsorbed by activated charcoal, charcoal hemoperfusion clearance will exceed that of hemodialysis. During hemoperfusion, blood is pumped through a cartridge containing a very large surface area of sorbent, either activated charcoal or carbon (see Fig. 9–2). The sorbent is coated with a very thin layer of polymer membrane such as cellulose acetate (Adsorba: Gambro, Lakewood, CO), heparin-hydrogel (Biocompatible Hemoperfusion Systems: Clark, New Orleans, LA) or polyHEMA (2-hydroxyl methacrylate or Hemosorba: Asahi, Tokyo, Japan). The membrane prevents direct contact between blood and sorbent, improves biocompatibility, and helps prevent activated charcoal embolization. There may be a further theoretical advantage to the heparin–hydrogel coating to diminish platelet aggregation. The adsorptive capacity of the cartridge is reduced with use because of deposition of cellular debris and blood proteins and saturation of active sites by the xenobiotic in question. Estimation of residual adsorptive capacity by serial serum concentrations is usually not practical because of time delays in obtaining results. The cartridge should therefore be changed after 2 hours of use. As with hemodialysis, patients must be anticoagulated with heparin, and regional heparinization of the cartridge is possible if full anticoagulation is undesirable. The technique can be used in adults[19,74] or children.[16,51] Hemoperfusion is usually performed for 4 to 6 hours at flow rates of 250 to 400 mL/min as tolerated.

The characteristics of xenobiotics that make them amenable to hemoperfusion (summarized in Table 9–3) differ from those for hemodialysis in the important respect that hemoperfusion is not limited by plasma protein binding. This is exemplified in a report in which hemoperfusion but not hemodialysis increased the elimination of the avidly protein-bound oral hypoglycemic agent chlorpropamide.[43] Some xenobiotics are poorly adsorbed by activated charcoal, including the alcohols, lithium, and many metals (see Antidotes in Depth A2: Activated Charcoal), making hemoperfusion inappropriate in their management. Hemoperfusion clearance is calculated in a manner similar to that for hemodialysis. Although hemoperfusion has historically been considered the preferred method to enhance the elimination of carbamazepine, phenobarbital, phenytoin, and theophylline (Table 9–4), recent improvements in hemodialysis technology, such as high-flux membranes, may make older comparisons of hemodialysis and hemoperfusion clearance rates obsolete. Hemodialysis and hemoperfusion have been performed in series for procainamide, thallium, theophylline, and carbamazepine overdoses, with greater apparent clinical efficacy

TABLE 9–4. Properties of Xenobiotics Grouped by Benefit of Extracorporeal Techniques for Elimination

Xenobiotic	MW (daltons)	Water Soluble	Vd (L/Kg)	Protein Binding (%)	Endogenous Clearance (mL/min/kg)	Preferred Method	Comments
Clinically Beneficial							
Bromide	35	Yes	0.7	0	0.1	HD	Falsely elevated chloride measurement
Ethylene glycol	62	Yes	0.6	0	2.0	HD	May have oxaluria
Diethylene glycol	106	Yes	0.5	0	NA	HD	Renal failure
Isopropanol	60	Yes	0.6	0	1.2	HD	No anion gap acidosis
Lithium	7	Yes	0.6–1.0	0	0.4	HD	Cl ↓ in renal failure
Methanol	32	Yes	0.6	0	0.7	HD	Risk CNS hemorrhage
Propylene glycol	76	Yes	0.6	0	1.7	HD	Lactic acidosis, possible acute kidney injury
Salicylate	138	Yes	0.2	50	0.9	HD, HP	Cl and protein binding ↓, with ↑ dose; HD also corrects electrolytes, acid–base disturbance
Theophylline	180	Yes	0.5	56	0.7	HP > HD	HP and HD can also be combined
Valproic acid	144	Yes	0.13–0.22	90	0.1	HD, HP	↑ Concentrations associated with ↓ % protein binding
Possibly Clinically Beneficial							
Amatoxins	373–990	Yes	0.3	0	2.7–6.2	HP	Possibly effective if performed within the first 24 h of exposure
Aminoglycosides	>500	Yes	0.3	1.5	<10	HD, HF	Cl ↓ with renal failure
Atenolol	255	Yes	1.0	2.5	<5	HD, HP	Useful if Cl ↓ caused by renal failure
Carbamazepine	236	No	1.4	74	1.3	HP	Cl ↑ in patients on long-term therapy
Disopyramide	340	No	0.6	1.2	90	HP	Protein binding ↓ as concentration ↑
Fluoride	19	Yes	0.3	50	2.5	HD	Hypocalcemia may be improved by HD; may add little if endogenous renal clearance is preserved
Meprobamate	218	Yes	0.5–0.8	0–30	Low	HP	Most eliminated in 24–36 h
Methotrexate	454	Yes	0.4–0.8	50	1.5	HF	
Paraquat	186	Yes	1.0	6	24.0	HP	Tight tissue binding precludes efficacy unless early in course
Phenobarbital	232	No	0.5	24	0.1	HP	Only for prolonged coma
Phenytoin	252	No	0.6	90	0.3	HP	Cl ↓, as dose ↑
Trichloroethanol	149	Yes	0.6	0.4	0.7	HD	Metabolite of chloral hydrate

Cl, clearance; HD, hemodialysis; HF, hemofiltration; HP, hemoperfusion; MW, molecular weight; NA, not available; Vd, volume of distribution.

than with either procedure alone.[11,21,37] In this technique, blood circulates first through the hemodialysis membrane and then through the charcoal cartridge. If blood traverses the dialysis membrane first, some of the xenobiotic is dialyzed, and the activated charcoal cartridge has less drug to adsorb.[32] The activated charcoal cartridge is exhausted more slowly, and higher extraction ratios are maintained. In a patient who ingested 2 g of propranolol, a hemoperfusion cartridge was inserted into an extracorporeal membrane oxygenation (ECMO) circuit through which the flow rate was less than 3 L/min.[66] The plasma concentrations of propranolol decreased more rapidly during ECMO than after it was discontinued. The high flow rate through the cartridge may have led to substantial clearance of the drug. Hemoperfusion does not correct acid–base and electrolyte disorders, another reason why the combination of the two modalities is attractive for salicylate poisoning.

A practical problem limiting the use of charcoal hemoperfusion is the availability of the cartridges. Many dialysis units do not routinely stock them anymore.[64] The cartridges are expensive ($350–$425 compared with the maximal cost for a high-flux dialysis membrane at about $20–$23). Some have expiration dates, limiting their shelf life. Others, such as the Clark system, have an indefinite shelf life but must be autoclaved before use, which may affect their availability in an emergency. Charcoal cartridges were more available in hemodialysis units when they were more frequently needed for the treatment of patients with chronic aluminum toxicity. The syndromes of aluminum-associated dementia and osteodystrophy were once more prevalent in chronic hemodialysis patients, but aluminum carbonate has been supplanted as a phosphate binder by calcium salts (carbonate and acetate) and sevelamer (Renagel), a phosphate-binding resin. In addition, the most frequent indication for activated charcoal hemoperfusion in the past was theophylline toxicity, and theophylline is rarely used in the treatment of obstructive lung disease and asthma and is consequently less often implicated in acute and chronic poisoning. This accounts for the diminished availability of charcoal cartridges and the relative infrequency with which the procedure is performed. In a survey of New York City hospital dialysis units taking 911 calls, only 10 of 34 units had cartridges. In a recent review of the AAPCC annual data, theophylline was the most common toxin removed by hemoperfusion from 1985 to 2000, but carbamazepine became the most frequent toxin removed by hemoperfusion during 2001 to 2005.[31]

The complications of hemoperfusion are similar to those of hemodialysis. In addition, patients often develop thrombocytopenia, leukopenia, and hypocalcemia. Better membrane encapsulation techniques have made embolization of activated charcoal particles extremely rare. As in the case of hemodialysis, doses of drugs used therapeutically may need to be increased if they are removed by hemoperfusion.

OTHER SORBENTS FOR HEMOPERFUSION

Other adsorptive resins were used for hemoperfusion in the past, such as the synthetic Amberlite XAD-2 and XAD-4 and anion exchange resins such as Dow 1X-2. None of these columns is currently approved or available for use in the United States. The literature regarding their efficacy is scant and relatively anecdotal. Although in vitro evidence suggests that these resins may have greater adsorptive capacities than activated charcoal, there are few, if any, meaningful comparisons in a clinical setting.

A newer concept in sorbents for poisonings is that of albumin dialysis. The procedure is currently available in the United States only for investigational use. The patient's blood flows through a hollow-fiber hemodialyzer. The dialysate bathing the fibers contains human serum albumin that serves as a sorbent to bind the xenobiotic of interest and

maintain levels of the free xenobiotic at zero. A steep concentration gradient from blood to dialysate is established so that even highly protein-bound xenobiotics can be removed from the plasma. The membrane is impermeable to albumin, which remains in the dialysate. The albumin is reprocessed by passing through an activated charcoal cartridge as well as an anion exchanger so that it can then be recirculated.

A current proprietary version of this procedure is called Molecular Adsorbents Recirculating System (MARS). The procedure is used in the management of patients with hepatic encephalopathy and liver failure and as a bridge to hepatic transplantation.[67,47] In this setting, the procedure includes a conventional hemodialysis treatment as well as an albumin-bathed dialysis membrane. The mechanism of the significant benefit of the procedure is not completely understood, although it does remove both water-soluble and protein-bound compounds. It is not known which protein-bound molecules are removed from the blood, such as bile salts and aromatic amino acids, to account for the therapeutic advantage in hepatic failure. The MARS system increases the removal of fentanyl and midazolam in an animal model.[62] One case report suggested potential benefit in a patient treated for toxicity with phenytoin, a drug with significant protein binding and therefore one not expected to be removed by hemodialysis or hemoperfusion.[63] Another case report suggests benefit for theophylline toxicity in a patient with hypotension.[41] Whether this relatively expensive, complicated, and nonspecific procedure would offer benefit in a handful of instances in which protein-binding limits removal of xenobiotics is not known. Devices using powdered sorbent may become available in the United States. The report of the initial use of the device in 10 cases of CA overdoses claimed benefit, although the limitations of extracorporeal therapy for this particular class of drugs is discussed above.[5]

■ MULTIPLE-DOSE ACTIVATED CHARCOAL: "GASTROINTESTINAL DIALYSIS"

Oral administration of multiple doses of activated charcoal increases elimination of some xenobiotics present in the blood. This modality is dealt with in more detail in Antidotes in Depth A2: Activated Charcoal.

■ CONTINUOUS HEMOFILTRATION AND HEMODIAFILTRATION

Hemofiltration is the movement of plasma across a semipermeable membrane in response to hydrostatic pressure. The addition of dialysate on the other side of the membrane further enhances elimination of toxins, whether xenobiotics or endogenous uremic toxins. A recent review of continuous modalities of dialytic therapy concluded that they are still relatively unproven for the treatment of poisoning.[28] These techniques find relatively widespread usage for the treatment of patients with acute renal failure in the ICU, and in this context, they are referred to collectively as modalities of *continuous renal replacement therapy* (CRRT). The clearances of either urea or xenobiotics that are achieved with these techniques are significantly lower than those achieved with hemodialysis. But as continuous modalities, what they lack in clearance they can make up for in time.

There are several possible advantages of continuous modalities. One is the capability to continue therapy for 24 hours every day, permitting hemofiltration to be instituted after hemodialysis or hemoperfusion to further remove a xenobiotic after it redistributes from tissue to blood.[46] This is an attractive modality for slow, continuous removal of drugs, such as lithium, which distribute slowly from tissue-binding sites or from the intracellular compartment (see Fig. 9–1). Other xenobiotics with volumes of distribution that are large enough to preclude use of dialysis or hemoperfusion might also be eliminated with longer courses.

Hemofiltration, or ultrafiltration, refers to the movement of plasma across a semipermeable membrane in response to hydrostatic pressure gradients. Table 9–3 summarizes the properties of xenobiotics that make them amenable to hemofiltration. However, the rate of removal with this form of therapy may be insufficient to benefit critically ill patients. Patients who can tolerate slower clearance rates may not require this enhanced elimination therapy at all. Whether slow treatment to avoid redistribution of intracellularly distributed lithium, for example, is preferable to repeating conventional hemodialysis is unclear.[45,71] Rebound of serum concentrations indicates that the drug is moving out of the intracellular compartment, where it is toxic, into the extracellular compartment, where it is susceptible to removal by hemodialysis. Therefore, although the continuous modalities are touted as preventing rebound, the importance of this property remains unproven. Despite many case reports demonstrating significant xenobiotic clearance, no data have demonstrated that these continuous techniques affect prognosis or mortality in treatment of patients with xenobiotic toxicity. In most cases, hemodialysis should be considered the preferred initial mode of therapy.

The continuous modalities may be best suited for patients with hypotension who cannot tolerate conventional hemodialysis.[12] These modalities may also have a role after hemodialysis to avoid the need for a repeat session after equilibration of the xenobiotics into plasma. These modalities may have a slight advantage over the use of conventional hemodialysis membranes, but not high-flux membranes, in being able to clear larger molecules such as methotrexate (molecular weight, 454.4).[27] Growing evidence suggests that a significant part of the clearance of many molecules occurs because of adsorption of the molecule to synthetic membranes.[20] However, quantification of the contribution of adsorption to total clearance is difficult and is not usually accomplished in published studies. Adsorption of molecules responsible for adverse effects is being studied as a potential benefit in the management of cytokines and liver failure and could be a property useful in the management of poisoning.[57] At present, this property is difficult to quantify and of uncertain benefit. Another practical advantage of CRRT is that the procedure is usually done now in ICUs by ICU nurses, and when available in such units, might not require dialysis personnel. Familiarity of ICU staff with the procedure is critical to having it available when needed; it is most likely to be used effectively in hospitals with higher incidence rates of acute renal failure.

In pure hemofiltration, sometimes called *slow continuous ultra-filtration* (SCUF), there is no dialysate solution on the other side of the dialysis membrane (see Fig. 9–2). Small solutes, such as urea and sodium, are transported across the membrane with plasma water, a mechanism known as *convective transport* or *bulk flow*. Larger solutes, depending on permeability characteristics of the membrane, are excluded. The ECF volume status of the patient determines whether replacement of all or some of the filtered plasma with physiologic electrolyte solution (lactated Ringer's solution or other commercially available preparations) is indicated. Although this technique can be done intermittently using a hemodialysis machine, it has been adapted for use in ICUs as a continuous form of treatment, particularly when removal of ECF is indicated. The clearance of low-molecular-weight solutes such as urea is relatively low.

Solute clearance may be significantly enhanced by adding dialysis, a diffusive mechanism, by having a dialysate solution bathe the blood-filled capillaries running countercurrent to the blood flow. The combination of hemofiltration with dialysis is known as *hemodiafiltration*. Addition of dialysis also usually suffices to treat supervening acute kidney failure or preexisting chronic kidney failure. Hemodiafiltration, similar to hemodialysis, requires that blood perfuse hollow-fiber dialysis membranes made of synthetic plastics such as polysulfone or polyamide.[23] For all of these procedures, the patient usually must be fully anticoagulated, but some hemofilters are available that may not require anticoagulation. Anticoagulation may be achieved either with heparin or citrate. The hydrostatic pressure required for hemofiltration may be derived either endogenously from the patient's own blood pressure or from a blood pump. In continuous arteriovenous hemofiltration (CAVH), blood is pumped through the filter by the patient's arterial pressure via a single-lumen femoral artery catheter returning to a femoral vein catheter. Arteriovenous modalities are less favored now because they require a large (at least 16-French) catheter in the femoral artery while heparin is administered. CVVH differs from CAVH because a blood pump is required to maintain adequate flow rates, and arterial puncture with large-bore catheters is avoided. However, the need for a blood pump also necessitates an experienced ICU team to be continuously present for more than the 4 to 6 hours needed for acute hemodialysis or hemoperfusion. Both the expense and the complexity of the xenobiotic-removal procedure are thereby increased. One large case series found hemodialysis to be less procedurally complicated than CVVH.[65] The addition of a dialysate bathing solution to the hemofiltration apparatus changes CVVH, or hemofiltration, to the augmented CVVHD, or hemodiafiltration (see Fig. 9–2).

Ultrafiltrate flows of 100 to 6000 mL/h across the membrane can be achieved. Fluid and electrolyte losses must be replaced carefully. Depending on the filter, xenobiotics with a molecular weight of up to 40,000 daltons, as well as water, urea, creatinine, and sodium, pass into the ultrafiltrate. Heparin, myoglobin, insulin, and vancomycin are examples of larger molecules cleared with relative efficiency. CVVH seems to be quite effective in the elimination of theophylline, with clearance rates comparable to those of charcoal hemoperfusion.[29] For protein-bound xenobiotics such as theophylline, continuous removal of the free unbound drug from the plasma may shift the equilibrium so that some drug is always moving from plasma protein to plasma. The cellular components and molecules larger than the pore size of the membrane return to the circulation in the venous line. For instance, a hemofilter with a molecular weight cutoff of 40,000 daltons cannot remove digoxin–antibody complexes (molecular weight, 45,000–50,000).[56] Essential electrolytes lost in the ultrafiltrate are replaced by balanced IV fluids.

Attention must be paid to the undesirable removal of therapeutic drugs such as antimicrobials via these continuous modalities. Drug clearances with different synthetic membranes are available in the literature; the doses necessary to maintain therapeutic drug levels can also be determined.[4]

■ PLASMAPHERESIS AND EXCHANGE TRANSFUSION

Plasmapheresis and exchange transfusion are intended to eliminate xenobiotics with large molecular weights that are not dialyzable. This includes xenobiotics and endogenous molecules with molecular weights greater than 150,000 daltons, typified by immunoglobulins. The xenobiotic to be eliminated should also have limited endogenous metabolism to make pheresis or exchange worthwhile.[36] By removing plasma proteins, both techniques offer the consequent potential benefit of removal of protein-bound molecules such as *Amanita* toxins,[32] thyroxine, vincristine, or complexes of digoxin and antidigoxin antibodies. However, there is little evidence that either technique affects the clinical course and prognosis of a patient poisoned by any of these or other xenobiotics.

Pheresis is particularly expensive, and both pheresis and exchange transfusion expose the patient to the risks of infection with plasma- or blood-borne diseases. Replacement of the removed plasma during plasmapheresis can be accomplished with fresh-frozen plasma, albumin, or combinations of both. The former is associated with hypersensitivity

reactions, such as fever, urticaria, wheezing, and hypotension, in as many as 21% of cases.[36]

A different setting in which exchange transfusion may be an appropriate technique is in the management of small infants or neonates in whom dialysis or hemoperfusion may be technically difficult or impossible. Anticoagulation and MDAC may be hazardous and therefore contraindicated in patients in the neonatal nursery, where the risk of intracerebral bleeding and necrotizing enterocolitis is high. In premature neonates, a single volume exchange appeared to alleviate manifestations of theophylline toxicity.[49] The therapy has been successfully used to treat other pediatric patients with poisonings, including severe salicylism.[44]

TOXICOLOGY OF HEMODIALYSIS

Unlike patients who receive acute hemodialysis once or twice in the management of poisoning, patients with chronic renal failure are repeatedly exposed to large volumes of water derived from municipal reservoirs during the course of their hemodialysis treatments. If an "average" regimen consists of three treatments of 4 hours each week, with dialysate flows of 600 mL/min, patients will be exposed to more than 400 L of water separated from them only by a semipermeable membrane designed to allow solute passage in either direction. Problems with dialysate generation therefore have the potential to be lethal to this population by exposing them to significant quantities of toxins. There are two potential sources of dialysate contamination: the municipality's reservoirs and water treatment plants and the dialysis unit.[54] The quality of water used for dialysate generation is regulated in the United States by the Association for the Advancement of Medical Instrumentation (AAMI).[7] This organization regularly revises its guidelines to incorporate new technology and data.

Contamination of dialysate from the municipal water supply may occur as a result of xenobiotic runoff into reservoirs or as a result of inadvertent or intentional addition of a chemical by the municipality. Chlorine and chloramine are frequently added to municipal water supplies to control bacterial populations. However, chlorine may combine with nitrogenous compounds and form chloramine, which may cause nausea, vomiting, methemoglobinemia, and hemolytic anemia.[72] Recently, chloramine was blamed for decreased bone marrow sensitivity to erythropoietin. Aluminum is present in some municipal water supplies, and before it was recognized as a problem, aluminum led to encephalopathy characterized by seizures, myoclonus, and dementia as well as osteomalacia and microcytic anemia.

Water from the municipal supply entering the dialysis unit is first treated with a water softener to remove calcium and magnesium. It is then run through an activated charcoal bed to adsorb chloramine. The potential toxicity (hemolysis and death) from this compound has caused AAMI to mandate a redundancy in the carbon beds; when the active sites in one carbon bed are exhausted, a second will ensure that no toxicity will occur. Most commonly, water for dialysate is then generated by reverse osmosis, a process that requires that water, in response to applied hydrostatic pressure (and against the osmotic gradient), cross a membrane that is relatively impermeable to solutes, leaving them behind. Alternatively, but less commonly, water can also be purified using deionization, a technique that runs water over an exchange resin, releasing hydroxyl ions in exchange for charged species in the water. Deionization is inferior to reverse osmosis for removal of aluminum and may be associated with release of lethal levels of fluoride when exchange sites are exhausted.[3] General water chemistry testing is mandated annually; testing for chlorine and chloramine must be done daily.

Current requirements are that water be highly purified, but not sterile, because bacteria cannot cross from the dialysate into the blood.

However, small quantities of endotoxin (molecular weight, 5–15,000 daltons) can cross, particularly in situations that include the use of high-flux membranes. Endotoxin is suspected of being responsible for activation of circulating cytokines, malnutrition, fever, and other syndromes such as carpal tunnel syndrome, which are associated with chronic inflammation. Recommendations for the frequency of testing for endotoxin and the maximum amounts of endotoxin tolerated are continually debated and have recently become more stringent. Water distribution systems are cleaned at least monthly with bleach, peracetic acid, or other sterilants. Care must be taken that all of these potential toxins are thoroughly flushed from the system before dialysis is restarted. Other products of bacterial metabolism, such as volatile sulfur-containing compounds, generated on the dialysate side of the membrane may be responsible for symptoms in hemodialysis patients.[61]

Unusual microbes have also been associated with serious toxicity. Untreated water at one center in Brazil demonstrated growth of Cyanobacteria (blue-green algae) and production of microcystins, cyclic peptides that cause serious hepatic toxicity; patients dialyzed with the contaminated water had a dramatic rate of death from liver failure.[34] Water contamination should especially be suspected when multiple dialysis patients experience similar symptoms nearly simultaneously. Dialysate distribution systems are always made of polyvinyl chloride (PVC) or other inert plastics, rather than copper, which may also leach into the water and cause hemolytic anemia.

Besides water for dialysate, another potential source of poisoning in hemodialysis units is the process of reusing dialysis membranes. Until recently, up to 70% of dialysis units in the United States reused membranes because of cost considerations. Each dialysis membrane is sterilized with peracetic acid, formaldehyde, or glutaraldehyde. Careful quality assurance programs ensure that there is no significant exposure of the patients to these molecules during the dialysis procedure. Nonetheless, reuse programs are associated with a variety of syndromes such as pyrogenic reactions attributed to patient exposure to germicides or endotoxin caused by inadequate sterilization procedures.[58] Controversial data over the years have suggested, but not proven, higher mortality rates with reuse. Occupational exposure of dialysis personnel to the relevant sterilants has also been monitored closely.

SUMMARY

Further discussions of some of the techniques to enhance elimination that are not discussed here may be found in Chapters 30 (exchange transfusion), SC2 (cerebrospinal fluid drainage and replacement), 64 (toxin-specific antibodies), and 94 (chelation). All of these techniques have limited, very specific indications, and the effect of these interventions on the overall body burden of the intoxicant is usually small.

Urinary alkalinization and many of the other techniques listed in Table 9–1 can be instituted quickly in the emergency department. In contrast, the extracorporeal methods of xenobiotic removal, including hemodialysis, sorbent hemoperfusion, and continuous hemofiltration, all require consultation with a nephrologist or intensivist. Timely use of these techniques requires mobilization of a competent team and preparation of the requisite equipment. Rapid identification of a toxic exposure for which these techniques are appropriate and the presence of more ominous prognostic features should lead to prompt notification of the appropriate consult services so that application of these techniques can proceed in an expeditious manner.

The applicability of these techniques to new xenobiotics should be considered based on the principles discussed here so that these and newer treatment modalities are not used indiscriminately. The relative infrequency of toxicity from specific xenobiotics will continue

to hinder accumulation of useful data and limit the numbers of randomized, controlled trials performed. The literature regarding these techniques in general, and for the treatment of specific xenobiotic exposures in particular, should be read critically and with appropriate skepticism.

CHAPTER 10
USE OF THE INTENSIVE CARE UNIT

Mark A. Kirk

Over the past several decades, the use of the intensive care unit (ICU) and its attendant resources has led to improved patient survival from many serious conditions. This is the direct result of the ability to pay meticulous attention to supportive care, continuously monitor physiologic parameters, and use the most modern medical technology and treatment. Most critically ill poisoned patients have acutely reversible conditions that will clearly benefit from ICU intervention.[55]

Unlike many patients with diseases managed in the ICU, poisoned patients often do not have a well-recognized clinical course or predictable complications. More than almost any other disease managed in the ICU, uncertainties typify toxicologic emergencies. A patient's history is often unreliable with regard to the kind of xenobiotic ingested, time of ingestion, and amount ingested. The xenobiotic may have unknown or unpredictable toxic effects. The therapies, antidotes, and complications of acute poisoning may be unfamiliar to the ICU staff. These uncertainties challenge healthcare providers and influence decisions about admitting patients to the ICU.

Often a patient is admitted to the ICU for observation and monitoring, not for intervention.[71] Of the 12.5 million reported xenobiotic exposures reported in the American Association of Poison Control Centers (AAPCC) National Poison Database System from 2003 to 2007, only 5% were admitted to the hospital (Chap. 135).[7] In addition, fewer than 25% of those hospitalized required specific treatments or antidotes other than gastrointestinal (GI) decontamination.[6,7,71] Many physicians elect to observe poisoned patients in an ICU in anticipation of possible delayed, unrecognized life-threatening toxicity. The ICU provides necessary monitoring and individual nursing care that can help in the early recognition of developing toxicity. ICUs give healthcare providers the best opportunity to minimize morbidity and decrease mortality. However, ICU care is very expensive and has contributed significantly to the escalation of healthcare costs.

The ICU admission guidelines presented in this chapter are intended to encourage effective use of ICU resources without compromising patient care. Effective guidelines must consider the unique characteristics of a xenobiotic, the capabilities of the hospital, and all realistic alternatives for managing and observing poisoned patients without compromising care. Current medical literature allows us to develop only very general guidelines. Future clinical studies addressing the use of healthcare resources for poisoned patients will allow refinement of these guidelines. Although it is impossible to be all-inclusive, this chapter provides a decision-making strategy for most xenobiotics discussed in this text.

CLINICAL OBSERVATIONS AND RISK ASSESSMENT AS THE BASIS FOR ICU ADMISSION

Most critically ill poisoned patients have acutely reversible conditions that will clearly benefit from meticulous supportive care, continuous physiologic monitoring, and the use of the most modern medical technology and treatment. It seems reasonable to assume that a patient's signs and symptoms can be used to decide the need for ICU admission. The presence of certain signs, symptoms, or abnormal diagnostic test results requires ICU observation or intervention, whatever the toxic exposure. This approach is most consistent with the philosophy of "treating the patient and not the poison" and may prove most helpful for patients with polydrug ingestions. Patients with serious central nervous system (CNS), respiratory, cardiovascular, or metabolic manifestations of poisoning need ICU interventions regardless of the exposure. For example, patients with respiratory failure requiring mechanical ventilation, hypotension or cardiac dysrhythmias requiring cardiovascular resuscitation, recurrent seizures requiring airway management and continuous anticonvulsant therapy, or agitation requiring high-dose sedation all require ICU admission.

Beyond managing the obvious end-organ toxicity requiring intervention, the ICU is especially useful for observing for the progression of end-organ effects that may need intervention. Because the natural course of a toxicologic emergency is often unpredictable, consideration must be given to patients at risk of deteriorating to the point that critical care interventions are required.

In acute toxicologic emergencies, the history may be inaccurate or incomplete and the dose uncertain. Therefore, an informal "bedside risk assessment" is a helpful tool for decision making. In this case, "risk assessment" is defined as the process of determining the likelihood of toxicity for an individual after an exposure. This critical care risk assessment takes into account observed clinical effects, estimated dose, pharmacologic and toxicologic characteristics of the suspected xenobiotic, and characteristics of the exposed patient to help determine the need for ICU admission. It is intended to identify patients with conditions requiring meticulous supportive care, physiologic monitoring, or advanced technologic or pharmacologic therapies that can only be provided in the ICU. More importantly, it is needed to predict the likelihood of a patient's deteriorating to the point of needing critical care interventions. This decision-making guide takes into account key clinical observations, current best available evidence from the medical literature, clinical experience, and preferences based on acceptable risks (Table 10–1).

EVIDENCE-BASED CLINICAL CRITERIA FOR ICU ADMISSION

Overcrowded ICUs and escalating healthcare costs have been incentives to develop severity of illness models that predict the benefits of ICU care. The Acute Physiology and Chronic Health Evaluation (APACHE II/III/IV), the Mortality Probability Model (MPM II/III), and the Pediatric Risk of Mortality (PRISM II/III) models are widely studied and generally accepted severity of illness models that score certain physiologic parameters and other factors to estimate risks and predict outcomes in critically ill individuals.[13,61] Additional acute clinical assessment tools, such as the Modified Early Warning Score (MEWS), Simplified Acute Physiology Score (SAPS II), and the Glasgow Coma Score (GCS), are commonly used "bedside" methods of quickly assessing the severity of physiologic derangement and altered neurologic status, respectively.[61,63] These models are most effective for stratifying risks in clinical research trials and comparing quality of care among ICUs. Clinical studies to validate such scoring systems included patients with a variety of medical and surgical conditions, although few trials have validated these scoring systems in large cohorts of poisoned patients. The original APACHE II cohort of 5815 ICU admissions from 13 hospitals included only 153 patients admitted to the ICU with a diagnosis of "drug overdose."[34] APACHE II is limited by its failure

to distinguish between traumatic and nontraumatic causes of altered mental status, a fact of potentially vital import in cases of xenobiotic overdose. The development of APACHE III addressed this shortcoming of its predecessor. However, even this very complicated scoring system with proprietary mathematical modeling has limited value when applied to a wide range of poisoned patients. In fact, when APACHE III was used by its authors to screen a large independent database of almost 40,000 ICU admissions, including 1032 patients admitted with "drug overdose," predicted and actual mortality statistics for these patients were vastly different.[71] Seven deaths (0.7%) were predicted in this cohort, although the actual number turned out to be 25 (2.4%). The difference was highly statistically significant. APACHE IV attempted to further address the shortcomings of its predecessor but it still relies on parameters collected over the first 24 hours in the ICU.[61] Additional articles addressing the usage of severity of illness scoring systems to identify high-risk overdose patients are lacking, although one review of 216 consecutive ICU admissions for intentional overdose found that admission APACHE II and GCS were equally strong predictors of morbidity and mortality.[26] Specifically, a GCS of 12 or less was 88% sensitive and 92% specific in identifying patients at risk of developing morbidity requiring ICU admission.

Results of severity of illness models must be cautiously used.[61] These models lack individual prognostic application, and decisions about individual patients still require clinical judgment. Scores for these models need to be validated for the specific population for which they are to be used. A specific limitation of these models is lead-time bias (ie, pre-ICU care that influences mortality and in which the sole outcome measure is mortality). Therefore, severity of illness models to guide ICU care must be used cautiously when applied specifically to poisoned patients. Few studies have evaluated the use of the ICU for poisoned patients.[6,24,27,29,35,62,65] Prospective studies have focused on mortality rates, use of resources, or types of xenobiotics ingested; other studies, mostly retrospective ones, have focused on patients exposed to a specific xenobiotic. More study is needed before any severity of illness model can be considered reliable in predicting which patients are at the highest risk of developing ICU-requiring morbidity or mortality.

Given the unique characteristics of individual xenobiotics, other authors have attempted to apply severity of illness models in specific instances. APACHE II scores within 24 hours of presentation showed promise as a predictor of mortality when studied prospectively in acetaminophen-induced acute liver failure, revealing similar power to predict a poor outcome when compared against the widely accepted King's College Criteria.[45] Two studies evaluating organic phosphorus

compound poisoning used APACHE II and SAPS II scores demonstrated that high scores were predictive of mortality.[38,57] However, some clinical outcome predictors used in these scoring systems, such as neurologic outcome after cardiac arrest, are unreliable in poisoned patients.[17] Patients with severe poisoning may have clinical characteristics that mimic brain death yet have a complete neurologic recovery. Case reports of poisoning from barbiturates, cyclic antidepressants, baclofen, ethylene glycol, botulism, solvents, and sedative–hypnotics provide specific examples of this observation.[3,50,52,66,68,70] In addition, many toxicologic emergencies occur in young patients who are free of underlying disease. This increases the likelihood of surviving significant insults such as prolonged hypotension or hypoxia. Indeed, one prospective trial involving 286 patients admitted to the ICU with nontraumatic coma found that 91% of the 101 xenobiotic-induced coma patients survived, a much higher rate than those patients whose cause of coma was hypoxia (33%), sepsis (28%), focal cerebral (26%), or a general cerebral insult (17%).[23] Despite negative predictors of outcome, aggressive resuscitation efforts may be justified for poisoned patients. Specifically, prolonged cardiac resuscitation should be provided for victims of cardiac arrest resulting from overdoses of cyclic antidepressant, β-adrenergic antagonists, or calcium channel blockers and those with severe hypothermia.[18,30,43,49,58]

A set of criteria was established to determine whether initial clinical assessment could identify poisoned patients who were at risk of developing serious toxicity, thus needing ICU admission.[6] The specific xenobiotic ingested was not considered in defining risks. Criteria defining high-risk patients were need for intubation; unresponsiveness to verbal stimuli; seizures; PCO_2 above 45 mm Hg; systolic blood pressure below 80 mm Hg; QRS duration above 0.12 seconds; or any cardiac rhythm except normal sinus rhythm, sinus tachycardia, or sinus bradycardia. Patients were classified as low risk when none of the above criteria were present in the emergency department (ED). Retrospectively, 209 cases were analyzed using the above parameters. The most commonly ingested xenobiotics in both the high- and low-risk groups were barbiturates, benzodiazepines, cyclic antidepressants, ethanol, opioids, phenothiazines, and salicylates. None of the 151 patients who were considered at low risk developed complications or required ICU interventions after admission. Of the 58 patients deemed high risk, 35 required ICU interventions such as intubation, treatment of dysrhythmias, treatment of seizures, vasopressors, or hemodialysis or hemoperfusion. Seven patients developed high-risk complications such as hypoxia, respiratory failure, hypotension, or seizures after admission, but all of them had other high-risk criteria in the ED. Although the authors concluded that the clinical course of poisoned patients can be predicted during the initial 2 to 3 hours of observation, xenobiotics with delayed or prolonged toxic effects, such as sustained-release products, lithium, and oral hypoglycemics were not prominent in their study population.

In this study population, 70% of the low-risk patients were admitted to the ICU for observation. Because none of these patients developed complications or required ICU intervention, the authors postulated that applying these criteria would have eliminated 50% of the ICU days without compromising care. The limitations of this study are its retrospective design, relatively small study population, and limited variety of xenobiotic exposures. However, it does suggest that with some clinical judgment, many poisoned patients will not require ICU admission.

Ideally, clinical indicators for ICU care should be established for each xenobiotic. Universal criteria cannot be applied to all poisoned patients because of the unique clinical course of some xenobiotics and the uncertainty regarding which xenobiotics were ingested. In one outcome study of elderly poisoned patients, the authors observed that each category of poisoning has its own special risk profile.[46] Until more

specific predictors of outcome are developed for individual xenobiotics, nothing will be more useful than experience and good clinical judgment in predicting who may benefit from ICU admission. At present, withholding ICU care from poisoned patients based solely on a nonspecific "score" will not result in significant cost savings in the ICU but may increase the risk of morbidity and mortality.

PHYSIOLOGIC MONITORING AND SPECIALIZED TREATMENT AS REQUIREMENTS FOR ICU ADMISSION

The ICU setting offers the most highly skilled staff and modern technology available to manage complex medical problems. It also provides a nurse-to-patient ratio that allows for frequent or continuous monitoring of basic physiologic parameters. These measurements of vital signs, neurologic status, and fluid intake and output measurements, along with continuous cardiac monitoring, make possible early detection of toxicity, recognition of conditions needing active intervention, and prevention of complications. Medical technologic advances now provide a number of invasive and noninvasive capabilities that can signal or provide trends indicating risk of catastrophic deterioration or provide feedback on response to therapy. For example, monitoring hemodynamic parameters are valuable for managing poisoned patients with hypotension, intravascular volume depletion, or respiratory failure from acute lung injury (ALI). Most importantly, clinicians must recognize that no monitoring device improves clinical outcome unless coupled with a treatment that improves outcome.[25]

Most critically ill poisoned patients have acute reversible conditions requiring supportive care measures (ie, ventilator support, vasopressor support, or both) and close monitoring that only ICUs are equipped to provide. Most often, supportive care measures improve the outcome of critically ill poisoned patients more than antidotes and specialized treatments. Focus on supportive care measures, such as maintaining a patent airway, preventing hypoxia with the administration of oxygen, and treatment of shock, decreased the mortality for patients with barbiturate overdoses from 20% in the 1930s to less than 2% in the 1950s.[12] Both adult and pediatric studies report good outcomes in most critically ill overdosed patients treated with only mechanical ventilation, vasopressor support, and careful monitoring.[17,35]

Many antidotes and specific treatments should be administered in the ED and the ICU settings. Although possibly lifesaving, these treatments may have inherent risks. Because these treatments may be unfamiliar to staff and have their own inherent risks, the ICU is the most appropriate environment to administer or continue such treatments. Whereas some xenobiotics are administered in unconventional doses, other familiar xenobiotics should be avoided in treating patients with toxicologic emergencies. In toxicologic emergencies, a familiar xenobiotic may be an antidotal therapy that requires doses that far exceed conventional regimens or indications that deviate from common treatment protocols. High doses of atropine (ie, hundreds of milligrams) may be necessary for the treatment of patients with organic phosphorus insecticide poisoning.[15,21,37] Direct vasopressors such as norepinephrine or phenylephrine are more appropriate for the treatment of those with xenobiotic-induced hypotension.

A false sense of security can result when an antidote reverses toxicity but has a shorter duration of effect than the xenobiotic. An example is a patient, comatose from an opioid overdose who responds to naloxone, awakens, and refuses further treatment. Toxicity may recur when the short duration of effect of naloxone allows opioid toxicity to recur. These patients must be closely observed for the possible need to readminister the antidote. In a retrospective review of patients presenting with opioid overdosage, 31% of 84 naloxone responders experienced resedation necessitating readministration.[67] Resedation is particularly problematic with long-acting opioids such as methadone and controlled-release preparations of oxycodone and morphine.[28]

Extracorporeal methods of eliminating xenobiotics, such as hemodialysis and continuous venovenous hemofiltration, are ideally performed in the ICU. Invasive procedures, such as extracorporeal membrane oxygenation, cardiopulmonary bypass, and intraaortic balloon pump-assisted perfusion, are used successfully in resuscitating critically ill poisoned patients.[16,30,36]

When the need for surgical intervention or specialized wound care is anticipated, patients with toxicologic emergencies are ideally managed in the ICU. Although transplantation becomes necessary in a minority of critically ill acetaminophen-poisoned patients, this treatment can improve survival to discharge by as much as 75%.[2] Compartment syndrome, from muscle compression after prolonged xenobiotic-induced coma, is a rare but limb-threatening occurrence that sometimes results in the need for fasciotomy.[20] Any poisoned patient with significant rhabdomyolysis, whether localized or more widespread, is at risk for the development of compartment syndrome and acute renal failure. If contemplating fasciotomy, monitoring and specialized postoperative care in an ICU is warranted. Plasmapheresis and specialized wound care in an ICU are necessary in cases of toxic epidermal necrolysis (TEN) secondary to xenobiotics. Mortality and morbidity may be reduced by early referral to a specialized burn center for conditions such as TEN or significant dermal burns from caustics.

ADDITIONAL INFORMATION INFLUENCING ICU ADMISSION OF POISONED PATIENTS

End-organ toxicity and specific monitoring or therapeutic interventions are the most important reasons to admit poisoned patients to the ICU. However, restricting ICU admission to those with only end-organ toxicity is inappropriate. Minimally symptomatic or asymptomatic patients may require ICU admission because other factors must be considered. In addition to end-organ toxicity, the xenobiotic and specific patient characteristics should influence ICU admission decisions.

■ XENOBIOTIC CHARACTERISTICS AS A BASIS FOR ICU ADMISSION

Both the known and unknown characteristics of a xenobiotic will assist with ICU admission decisions. Some xenobiotics have proven their capability to cause harm or death to humans. Well-described, expected toxic effects assist in early recognition of poisoning. For other xenobiotics, the consequences after human exposure are not yet reported.

ICU admission is warranted for patients with expected serious toxic effects from an ingested xenobiotic. This is especially true for xenobiotics known to be deadly, such as calcium channel blockers, cyanide, cyclic antidepressants, and salicylates. For example, patients with calcium channel blocker poisoning who exhibit hemodynamic compromise require close attention and meticulous continuous treatment available only in the ICU.

Indicators of toxicity should be identified for individual xenobiotics so that high-risk patients may be closely monitored and aggressively treated. Patients who have ingested cyclic antidepressants develop substantial morbidity and mortality and have been studied in great detail to determine indicators of toxicity. These studies demonstrate that a prolonged QRS duration on a 12-lead electrocardiogram (ECG) is predictive of serious complications such as seizures and dysrhythmias.[4,48] Any patient manifesting ECG abnormalities

(including QRS ≥0.10 seconds), hypotension, or neurologic signs or symptoms requires ICU monitoring.[9] Unlike cyclic antidepressants, most xenobiotics do not have such an extensive literature to define high-risk patients.

Most acetaminophen-poisoned patients can be safely managed outside of the ICU because they exhibit no end-organ toxicity and their hospital management entails only laboratory monitoring and antidotal therapy with *N*-acetylcysteine. However, acetaminophen poisoning can be lethal, and at some point in the clinical course, manifestations of toxicity require close monitoring and treatments available only in the ICU. Predictors of poor outcome have been studied and can be useful guides for selecting patients who need ICU care. The King's College Criteria are well-established indicators of impending hepatic failure and the need for transplantation. Patients with abnormal clinical and laboratory data approaching these criteria are candidates for ICU admission or transfer to a specialized center with advanced ICU resources and transplantation services.

Decisions can be challenging when the characteristics and clinical course of the xenobiotic are unknown. New pharmaceutical and industrial products are introduced every year with little data on toxic exposure doses or human health effects in overdose. Sometimes animal studies provide the only known toxicologic data, and preclinical trials for new xenobiotics may have excluded the populations at risk, such as infants, children, or the elderly. In these cases, the clinician must often make therapeutic decisions and anticipate potential toxicity with little or no reliable data. Because early recognition of serious toxicity may prevent an adverse outcome, expectant observation may be the only rational approach. For example, intentional and unintentional ingestions followed the introduction of fluoxetine. Because, at that time, clinicians lacked experience treating overdoses of this drug and had no data regarding the natural course and toxic dose, many patients were admitted to the ICU to observe for toxic effects. Now that clinicians have experience with this drug and studies are available demonstrating few severe manifestations, ICU resources are seldom needed to treat such patients.[5,60]

Failure to appreciate the potential for serious, delayed toxic effects is a major pitfall in managing poisoned patients. An asymptomatic patient may be a "time bomb" with the potential to deteriorate rapidly. Delayed or continued absorption, slow tissue distribution, interference with cellular function, production of toxic metabolites, or depletion of target organ reserve capacity are causes of delayed onset of clinical effects.

Certain xenobiotics prolong GI absorption, delaying onset of toxicity.[42] Sustained-release pharmaceutical preparations and those with enteric coatings enhance patient compliance but, in overdose, may delay absorption and, in turn, make the onset of toxicity unpredictable.[44] Published cases of overdoses with sustained-release verapamil, bupropion, and enteric-coated aspirin report delayed onset of toxicity (>6 hours), and peak serum concentrations were measured more than 24 hours after ingestion.[19,59,69]

Serial xenobiotic concentrations measurements are necessary to verify peaks and ensure decreasing concentrations. Serial concentrations may, if available, warn of increasing potential for serious toxic effects. When serum concentrations are unobtainable, extended observation, possibly in the ICU, is required for many patients with overdoses of sustained-release and enteric-coated medications.

Clinical effects may be delayed when toxicity depends on alteration of enzyme functions, cellular reproduction, or metabolic function. For example, toxicity from colchicine may not be apparent for many hours after an overdose but then may progress rapidly to severe toxicity such as cardiovascular collapse. Other xenobiotics may take days to exhibit their toxic effects. For example, methotrexate and other chemotherapeutics may cause life-threatening bone marrow suppression days after exposure. When there is potential for serious delayed toxicity, patients necessitate prolonged close monitoring, typically in an ICU setting.

■ PATIENT FACTORS AS CRITERIA FOR ICU ADMISSION

Comorbid medical conditions increase a patient's risk for developing toxicity. Many patients who have chronic medical problems do not tolerate major physiologic stressors without significant compromise. For example, a patient with underlying cardiac disease could develop severe myocardial ischemia from a modest carbon monoxide exposure. An elderly or chronically ill or debilitated patient with chronic salicylism is more likely to have major respiratory or CNS complications than a younger or healthier patient. Conditions that alter xenobiotic metabolism or elimination, such as renal or hepatic disease, may prolong toxicity or produce toxicity after lesser amounts are ingested. For many of these reasons, the morbidity and mortality of acute poisoning are higher in elderly patients.[46]

Patients with physical dependency on ethanol, benzodiazepines, or barbiturates may be admitted to the hospital for acute withdrawal or, during hospitalization, go through a period of abstinence that results in an acute withdrawal syndrome. Withdrawal from ethanol and sedative–hypnotics can have serious consequences and complications. ICU management is frequently indicated because large doses of medications with respiratory depressant effects may be required for treatment.

As many as 80% of recognized suicide attempts involve an overdose of medications.[47] Acute complications of poisoning make it difficult to adequately assess suicidal risks. Patients have an increased rate of suicide after discharge from an ICU for drug overdose.[62] Until suicidal risks are adequately assessed, it must be assumed that an overdosed patient needs close observation.

■ LIFE-THREATENING COMPLICATIONS ASSOCIATED WITH POISONING

Poisoning produces both anticipated and unanticipated complications that can prolong ICU care and decrease survival. Serious complications of poisoning include pulmonary compromise, rhabdomyolysis, compartment syndrome, and anoxic brain injury. Complications such as acute renal or hepatic failure also might prolong an ICU course.

Pulmonary compromise after toxic exposures often develops after several hours or days in the ICU. Pulmonary complications after a toxic exposure include aspiration pneumonitis, ALI, and adult respiratory distress syndrome (ARDS). Aspiration of gastric contents is a common complication after poisoning, especially when a patient's mental status is altered and protective airway reflexes are lost.[11,32] Poisoned patients may aspirate spontaneously while lying unresponsive before being discovered, from stomach dilation secondary to bag-valve-mask ventilation, from GI decontamination procedures such as orogastric lavage, or during insertion of endotracheal or nasogastric tubes.[11,32] In a review of 4562 poisoning admissions, 71 patients clearly has aspiration pneumonitis, giving a rate of 1.6%.[32] In logistic regression analysis older age, a GCS below 15, spontaneous emesis, delayed presentation to the hospital, and ingestion of cyclic antidepressants were associated with aspiration pneumonitis. Not only were the rates of ICU admission and length of stay increased in the patients with aspiration pneumonitis, but mortality was also higher, with a rate of 8.5% compared with 0.4% for those without.

Poisoning may cause global cerebral anoxia from prolonged shock, respiratory failure, or direct toxic metabolic effects. Distinguishing anoxic cerebral injury from reversible encephalopathy can be difficult in poisoned patients. Coma and loss of brainstem reflexes after prolonged, severe cerebral hypoxia indicate a poor prognosis.[39] Although studies are limited in toxicologic patients, newer diagnostic technologies, including diffusion computed tomography, single-photon emission computed tomography, positron emission tomography, cerebral angiography, magnetic resonance imaging, and the use of multimodality evoked potentials,

may prove useful in confirming brain death.[1,14,53] Electroencephalography can be particularly misleading in certain overdoses, such as those involving benzodiazepines or barbiturates, in which the lack of brain electrical activity is a direct effect of the ingested xenobiotic. Angiographic imaging via computer tomography or direct arteriography may prove particularly useful in such cases, although such tests can reveal continued blood flow when intracranial hypertension is absent despite severe axonal injury and brain death.[41] Because clinical predictors of outcome may be unreliable when applied to poisoned patients, the diagnosis of brain death should be made cautiously. Cerebral edema is often a secondary effect of global cerebral anoxia, although some xenobiotics have direct cellular effects. Cerebral edema can be a complication of acetaminophen-induced fulminant hepatic failure and the result of direct neuronal injury from salicylate and lead poisoning.[40,54,64] Aggressive ICU care is preferred to treat patients with xenobiotic-induced cerebral injuries.

ALTERNATIVES TO ICU ADMISSION

Placing patients in the ICU solely for observation often is an ineffective use of this expensive resource. Until further clinical studies are available to define patients who are at risk for serious toxicity or life-threatening complications, many poisoned patients will be admitted to the ICU for observation. When information about the xenobiotic, the patient, and the capabilities of the medical unit are all considered, many patients can be safely observed outside the ICU. Table 10–2 presents some items to consider when making disposition decisions.

Alternatives to ICU admission include a medical or pediatric floor bed, an intermediate care unit, a telemetry-monitored bed, a medical psychiatric unit, or an ED observation unit. Capabilities for managing poisoned patients may vary considerably between institutions and in different types of patient care areas. It is essential to understand the capabilities of the unit where a patient is being considered for admission. If the nursing staff is unfamiliar with the potential for rapid deterioration of the patient or the staffing pattern does not allow for close observation, the patient outcome can be severely compromised. For example, it is unrealistic to expect a nurse to manage intravenous fluids, record hourly intake and output measurements, record frequent vital signs, and check hourly urine pH measurements for a salicylate-poisoned patient while caring for eight other patients. ED observation may be an alternative for the care of select poisoned patients.[8,31] These units are capable of frequent monitoring of vital signs, continuous cardiac monitoring, and maintaining a safe environment for suicidal patients.[22] Patients with a low risk of serious toxicity or life-threatening

---

TABLE 10–2. Considerations for Intensive Care Unit Admission

Xenobiotic Characteristics	Patient Characteristics	Assessing the Capabilities of the Inpatient Unit or Observation Unit
Are there known serious sequelae (eg, cyclic antidepressant cardiotoxicity)?	Does the patient have any signs of serious end-organ toxicity?	Does the admitting healthcare team appreciate the potential seriousness of a toxicologic emergency?
Can the patient deteriorate rapidly from its toxic effects?	Is there progression of the end-organ effects?	Is the nursing staff:
Is the onset of toxicity likely to be delayed (eg, sustained-release preparation, slowed GI motility, or delayed toxic effects)?	Are laboratory data suggestive of serious toxicity?	Familiar with this toxicologic emergency?
	Are xenobiotic concentrations rising?	Familiar with the potential for serious complications?
Does the xenobiotic have cardiac effects that will require cardiac monitoring?	Is the patient at a high risk for complications requiring ICU intervention?	Is the staffing adequate to monitor the patient?
Is the amount ingested a potentially serious or potentially lethal dose?	Seizures	What is the ratio of nurses to patients?
Is the required or planned therapy unconventional (eg, large doses of atropine for treating overdoses of organic phosphorus insecticides)?	Unresponsive to verbal stimuli	Are time-consuming nursing activities required and realistic (eg, hourly urine pH assessments or WBI)?
	Level of consciousness impaired to the point of potential airway compromise	
	PCO_2 >45 mm Hg	
Does the therapy have potentially serious adverse effects?	Systolic blood pressure <80 mm Hg	Can a safe environment be provided for a suicidal patient?
Is there insufficient literature to describe the potential human toxic effects?	Cardiac dysrhythmias	Can a patient have suicide precautions and monitoring with a medical floor bed?
	Abnormal ECG complexes and intervals (QRS duration ≥0.10 seconds; QT prolongation)	Can a one-to-one observer be present in the room with the patient?
Are potentially serious coingestants likely (must take into account the reliability of the history)?	Does the patient have preexisting medical conditions that could predispose to complications?	Can the patient be restrained?
	Chronic alcohol or drug dependence	
	Chronic liver disease	
	Chronic renal failure or insufficiency	
	Heart disease	
	Pregnancy: Is the xenobiotic or the antidote teratogenic?	
	Is the patient suicidal?	
	Is the patient at high risk for complications such as aspiration pneumonitis, anoxic brain injury, rhabdomyolysis, or compartment syndrome?	

complications who require only observation may be ideal candidates for ED observation units.

Many poisoned patients are placed in the ICU because they are suicide risks. Institutions differ on monitoring policies for suicidal patients not admitted on a psychiatric unit. Other than the ICU, many hospitals cannot provide an alternative for observing high-risk suicidal patients. Less-costly alternatives are available, but they must ensure a safe environment for suicidal patients. An ED observation unit, an intermediate care unit, a medical psychiatric unit, or a one-on-one observer can safely monitor these patients.

Future studies must define prognostic factors for poisoning complications. Patients can then be stratified into high- or low-risk groups. The limitations of current studies prevent generalizing the results to individual patients or certain subgroups. Unfortunately, many current clinical guidelines now being used to ration care may be derived from poorly tested models with no scientific basis and may be motivated by financial concerns. Guidelines should be based on sound evidence so they can provide the best care with less intensive use of health care resources.

CRITERIA FOR SAFE TRANSFER OUT OF THE ICU

After the acute toxic effects have resolved, most patients are safe to transfer out of the ICU. Patients with cyclic antidepressant overdoses were studied to determine when it was safe to discontinue monitoring. Concerns arose from case reports of patients developing sudden death as late as several days after a cyclic antidepressant overdose.[9,42,56] In most cases, delayed complications developed in the setting of continued toxicity evidenced by lethargy or sinus tachycardia. Several subsequent studies demonstrate that dysrhythmias do not occur after signs of toxicity have resolved (ie, CNS and cardiac manifestations).[10,51] The authors of these studies suggested cardiac monitoring for an additional 24 hours after normalization of the ECG and resolution of other signs of continued toxicity such as normalization of the mental status and blood pressure.[10] This additional period of monitoring should occur after discontinuation of all specific forms of therapy, such as serum alkalinization.

Most xenobiotics have not received the level of attention given to cyclic antidepressants, making clinical judgments the only basis for deciding when to discharge a patient from the ICU, pending further research and experience. For example, drug-induced QT interval prolongation may increase the risk of developing torsade de pointes.[33] Cardiac monitoring may be required until other clinical signs of toxicity resolve and the QT interval returns to normal.

The same issues previously mentioned may be pitfalls to a patient's safe discharge from an ICU. Carefully consider discharge decisions about patients exposed to xenobiotics, such as colchicine, with serious delayed clinical effects. Also be mindful that the duration of action of the xenobiotic may be longer than the duration of action of the specific treatment or antidote.

Finally, the patient's suicidal intent must be considered before transfer to a less closely monitored hospital unit. Transfer from the ICU should occur after assessment of suicide risk and other important psychosocial issues. Early involvement of psychiatric services, chemical dependency counseling, and social services can expedite ICU disposition. Disposition and treatment options may be considered at a time when the patient is still medically unstable by interviewing his or her family, friends, and outpatient counselors.

SUMMARY

Acute poisoning challenges medical and nursing staff because of its unpredictable clinical course and unfamiliar therapies. Poisoned patients are especially problematic because their clinical history is incomplete and the medical literature is often limited. These potential unknowns create many uncertainties in management. Because the ICU offers the highest level of skilled staff and modern technology available, most seriously poisoned patients should be admitted there. Whether this is clinically justified or is an effective use of resources for a given patient remains a debated issue because admission of poisoned patients continues to be based mostly on clinical judgment and the best available information.

PART B

THE FUNDAMENTAL PRINCIPLES OF MEDICAL TOXICOLOGY

This page intentionally left blank

CHAPTER 11

CHEMICAL PRINCIPLES

Stephen J. Traub and Lewis S. Nelson

Chemistry is the science of matter; it encompasses the structure, physical properties, and reactivities of atoms and their compounds. In many respects, toxicology is the science of the interactions of matter with physiologic entities. Chemistry and toxicology thereby are intimately linked. The study of the principles of inorganic, organic, and biologic chemistry offer important insight into the mechanisms and clinical manifestations of xenobiotics and poisoning, respectively. This chapter reviews many of these tenets and provides relevance to the current practice of medical toxicology.

THE STRUCTURE OF MATTER

■ BASIC STRUCTURE

Matter includes the substances of which everything is made. *Elements* are the foundation of matter, and all matter is made from one or more of the known elements. An *atom* is the smallest quantity of a given element that retains the properties of that element. Atoms consist of a nucleus, incorporating protons and neutrons, coupled with its orbiting electrons. The *atomic number* is the number of protons in the nucleus of an atom, and is a whole number that is unique for each element. Thus, elements with 6 protons are always carbon, and all forms of carbon have exactly 6 protons. However, although the vast majority of carbon nuclei have 6 neutrons in addition to the protons, accounting for an *atomic mass* (i.e., protons plus neutrons) of 12 (^{12}C), a small proportion of naturally occurring carbon nuclei, called *isotopes*, have 8 neutrons and a mass number of 14 (^{14}C). This is the reason that the *atomic weight* of carbon displayed on the periodic table is 12.011, and not 12, as it actually represents the average atomic masses of all isotopes found in nature weighted by their frequency of occurrence. Moreover, ^{14}C is actually a *radioisotope*, which is an isotope with an unstable nucleus that emits radiation (particles or rays) until it achieves a stable state (Chap. 133). The atomic weight, measured in grams per mole (g/mol), also indicates the molar mass of the element. That is, in 1 atomic weight (12.011 g for carbon) there is 1 mole of atoms (6.023×10^{23} atoms).

Elements combine chemically to form *compounds*, which generally have physical and chemical properties that differ from those of the constituent elements. The elements in a compound can only be separated by chemical means that destroy the original compound, as occurs during the burning (ie, oxidation) of a hydrocarbon, which releases the carbon as carbon dioxide. This important property differentiates compounds from *mixtures*, which are combinations of elements or compounds that can be separated by physical means. For example, this occurs during the distillation of petroleum into its hydrocarbon components or the evaporation of seawater to leave sodium chloride. With notable exceptions, such as the elemental forms of many metals or halogens (eg, Cl_2), most xenobiotics are compounds or mixtures.

Dimitri Mendeleev, a Russian chemist in the mid-19th century, recognized that when all of the known elements were arranged in order of atomic weight, certain patterns of reactivity became apparent. The result of his work was the Periodic Table of the Elements (Fig. 11–1), which, with some minor alterations, is still an essential tool today. All of the currently recognized elements are represented; those heavier than uranium are not known to occur in nature. Many of the symbols used to identify the elements refer to the Latin name of the element. For example, silver is Ag, for argentum, and mercury is Hg, for hydrargyrum, literally "silver water."

The reason for the periodicity of the table relates to the electrons that circle the nucleus in discrete orbitals. Although the details of quantum mechanics and electronic configuration are complex, it is important to review some aspects in order to predict chemical reactivity. Orbitals, or quantum shells, represent the energy levels in which electrons may exist around the nucleus. The orbitals are identified by various schemes, but the maximum number of electrons each orbital may contain is calculated as $2x^2$, where x represents the numerical rank order of the orbital. Thus, the first orbital may contain 2 electrons, the second orbital may contain 8, the third may contain 18, and so on. However, the outermost shell (designated by s, p, d nomenclature) of each orbital may only contain up to 8 electrons. This is irrelevant through element 20, calcium, because there is no need to fill the third-level or d shells. Even though the third orbital may contain 18 electrons, once 8 are present the 4s electrons dip below the 3d electrons in energy and this shell begins to fill. This occurs at element 21, scandium, and accounts for its chemical properties and those of the other transition elements. Also, because the inert gas elements, which are also known as noble gases, have complete outermost orbitals, they are unreactive under standard conditions. Transition elements are chemically defined as elements that form at least one ion with a partially filled subshell of d electrons.

In general, only electrons in unfilled shells, or *valence shells*, are involved in chemical reactions. This property relates to the fact that the most stable form of an element occurs when the configuration of its valence shell resembles that of the nearest noble gas, found in group 0 on the periodic table. This state can be obtained through the gaining, losing, or sharing of electrons with other elements and is the basis for virtually all chemical reactions.

INORGANIC CHEMISTRY

■ THE PERIODIC TABLE

Chemical Reactivity Broadly, the periodic table is divided into metals and nonmetals. Metals, in their pure form, are typically malleable solids that conduct electricity, whereas nonmetals are usually dull, fragile,

Symbol	Name	Atomic number	Atomic weight

FIGURE 11–1. The Periodic Table of the Elements.

nonconductive compounds (C, N, P, O, S, Se, halogens). The metals are found on the left side of the periodic table, and account for the majority of the elements, whereas the nonmetals are on the right side. Separating the two groups are the metalloids, which fall on a jagged line starting with boron (B, Si, Ge, As, Sb, Te, At). These elements have chemical properties that are intermediate between the metals and the nonmetals. Each column of elements is termed a family or group, and each row is a period. Although conceived and organized in periods, trends in the chemical reactivity, and therefore toxicity, typically exist within the groups.

The ability of any particular element to produce toxicologic effects relates directly to one or more of its many physicochemical properties, which may, to some extent, be predicted by their location on the periodic table. For example, the substitution of arsenate for phosphate in the mitochondrial production of adenosine triphosphate (ATP) creates adenosine diphosphate monoarsenate (Chap. 12). Because this compound is unstable and not useful as an energy source, energy production by the cell fails; in this manner arsenic interferes with oxidative phosphorylation. Similarly, the existence of an interrelationship between Ca^{2+} and either Mg^{2+} or Ba^{2+} is predictable, although the actual effects are not, that is, under most circumstances Mg^{2+} is a Ca^{2+} antagonist, and patients with hypermagnesemia present with neuromuscular weakness caused by blockade of myocyte calcium channels. Alternatively, Ba^{2+} mimics Ca^{2+} and closes Ca^{2+}-dependent K^+ channels in myocytes, producing life-threatening hypokalemia. Additionally, the physiologic relationship among lithium (Li^+), potassium (K^+), and sodium (Na^+) is consistent with their chemical similarities (all alkali metals in Group IA). However, the clinical similarity between thallium (thallous) ion (Tl^+) and K^+ is not predictable. Other than their monovalent nature (ie, +1 charge), it is difficult to predict the substitution of Tl^+ (Group IIIA, Period 6) for K^+ (Group IA, Period 4) in membrane ion channel functions, until the similarity of their ionic radii is known (Tl^+, 1.47 Å; K^+, 1.33 Å).

Alkali and Alkaline Earth Metals   Alkali metals (Group IA: Li, Na, K, Rb, Cs, Fr) and hydrogen (not an alkali metal on earth) have a single outer valence electron and lose this electron easily to form compounds with a valence of 1+. The alkaline earth metals (Group IIA: Be, Mg, Ca, Sr, Ba, Ra) (between the alkali and rare earth, Group IIIB) readily lose 2 electrons, and their cations have a 2+ charge. In their metallic form, members of both of these groups react violently with water to liberate strongly basic solutions accounting for their group names ($2Na^0 + 2H_2O \rightarrow 2NaOH + H_2$). The soluble ionic forms of sodium, potassium, or calcium, which are critical to survival, also produce life-threatening symptoms following excessive intake (Chap. 16). Xenobiotics may interfere with the physiologic role of these key electrolytes. Li^+ may mimic K^+ and enter neurons through K^+ channels, following which it serves as a poor substrate for the repolarizing Na^+-K^+-ATPase. Thus, Li^+ interferes with cellular K^+ homeostasis and alters neuronal repolarization accounting for the neuroexcitability manifesting as tremor. Similarly, as noted previously, the molecular effects of Mg^{2+} and Ba^{2+} may supplant those of Ca^{2+}. More commonly, though, the consequential toxicities ascribed to alkali or alkaline earth salts actually relate to the anionic component. In the case of NaOH or $Ca(OH)_2$, it is a hydroxide anion (not the hydroxyl radical), while it is a CN^- anion in patients poisoned with potassium cyanide (KCN).

Transition Metals   Unlike the alkali and alkaline earth metals, most other metallic elements are neither soluble nor reactive. This includes the transition metals (Group IB to VIIIB), a large group that contains several ubiquitous metals such as iron (Fe) and copper (Cu). These elements, in their metallic form, are widely used both in industrial and household applications because of their high tensile strength, density, and melting point, which is partly a result of their ability to delocalize

the electrons in the d orbital throughout the metallic lattice. Transition metals also form brightly colored salts that find widespread applications including pigments for paints or fireworks. However, the ionic forms, unlike the metallic form, of these elements are typically highly reactive and toxicologically important. Transition elements are chemically defined as elements which form at least one ion with a partially filled subshell of d electrons. Because the transition metals have partially filled valence shells, they are capable of obtaining several, usually positive, oxidation states. This important mechanism explains the role of transition metals in redox reactions generally as electron acceptors (see Reduction-Oxidation). This reactivity is used by living organisms in various physiologic catalytic and coordination roles, such as at the active sites of enzymes and in hemoglobin, respectively. Expectedly, the substantial reactivity of these transition metal elements is highly associated with cellular injury caused by several mechanisms, including the generation of reactive oxygen species (Fig. 11–2). For example, manganese ion exposure is implicated in the free radical damage of the basal ganglia causing parkinsonism.

Heavy Metals   *Heavy metal* is often loosely used to describe all metals of toxicologic significance, but in reality, the term should be reserved to describe only those metals in the lower period of the periodic table, particularly those with atomic masses greater than 200. The chemical properties and toxicologic predilection of this group vary among the elements, but their unifying toxicologic mechanism is electrophilic interference with nucleophilic sulfhydryl-containing enzymes. Some of the heavy metals also participate in the generation of free radicals through Fenton chemistry (Fig. 11–2). The likely determinant of the specific toxicologic effects produced by each metal is the tropism for various physiologic systems, enzymes, or microenvironments; thus the lipophilicity, water solubility, ionic size, and other physicochemical parameters are undoubtedly critical. Also, because the chemistry of metals varies dramatically based on the chemical form (ie, organic, inorganic, or elemental), as well as the charge on the metal ion, prediction of the clinical effects of a particular metal is often difficult.

Mercury.   Elemental mercury (Hg^0) is unique in that it is the only metal that exists in liquid form at room temperature, and as such is capable of creating solid solutions, or amalgams, with other metals. Although it is relatively innocuous if ingested as a liquid, it is readily volatilized (ie, high vapor pressure), transforming it into a significant pulmonary mucosal irritant upon inhalation. In addition, this change in the route of exposure raises its systemic bioavailability. Absorbed, or incorporated, Hg^0 undergoes biotransformation in the erythrocyte and brain to the mercuric (Hg^{2+}) form, which has a high affinity for sulfhydryl-containing molecules including proteins. This causes a depletion of glutathione in organs such as the kidney, and also initiates lipid peroxidation. The mercurous form (Hg^+) is considerably less toxic than the mercuric form, perhaps because of its reduced water solubility. Organic

$$H_2O_2 \xrightarrow{\text{TM}} OH^- + OH\bullet$$

Fenton

$$H_2O_2 + O_2^{\bullet-} \xrightarrow{\text{TM}} O_2 + OH^- + OH\bullet$$
Haber-Weiss

FIGURE 11–2.   The Fenton and Haber-Weiss reactions, which are the two most important mechanisms to generate hydroxyl radicals, are both mediated by transition metals (TM). Iron (Fe^{2+}) and copper (Cu^+) are typical transition metals.

mercurial compounds, such as methylmercury and dimethylmercury, are environmentally formed by anaerobic bacteria containing the methylating agent methylcobalamin, a vitamin B_{12} analog (Chap. 96).

Thallium.   Another toxicologically important member of the heavy metal group is thallium. Metallic thallium is used in the production of electronic equipment and is itself minimally toxic. Thallium ions, however, have physicochemical properties that most closely mimic potassium ions, allowing them to participate in, and potentially alter, the various physiologic activities related to potassium. This property is clinically used during a thallium-stress test to assess for myocardial ischemia or infarction. Because ischemic myocardial cells lack adequate energy for normal Na^+-K^+-ATPase function, they cannot exchange sodium for potassium (or in this scenario radioactive thallium), producing a "cold spot" in the ischemic areas on cardiac scintigraphy (Chap. 100).

Lead.   Although lead is not very abundant in the Earth's crust (only 0.002%), exposure may occur during the smelting process or from one of its diverse commercial applications. Most of the useful lead compounds are inorganic plumbous (Pb^{2+}) salts, but plumbic (Pb^{4+}) compounds are also used. The Pb^{2+} compounds are typically ionizable, releasing Pb^{2+} when dissolved in a solvent, such as water. Pb^{2+} ions are absorbed in place of Ca^{2+} ions by the gastrointestinal tract and replace Ca^{2+} in certain physiologic processes. This mechanism is implicated in the neurotoxic effect of lead ions. Pb^{2+} compounds tend to be covalent compounds that do not ionize in water. However, some of the Pb^{4+} compounds are oxidants. Although elemental lead is not itself toxic, it rapidly develops a coating of toxic lead oxide or lead carbonate on exposure to air or water (Chap. 94).

Metalloids   Although the metalloids (B, Si, Ge, As, Sb, Te, At) share many physical properties with the metals, they are differentiated because of their propensity to form compounds with both metals and the nonmetals carbon, nitrogen, or oxygen. Thus, metalloids may be either oxidized or reduced in chemical reactions.

Arsenic.   Toxicologically important inorganic arsenic compounds exist in either the pentavalent arsenite (As^{5+}) form or the trivalent arsenate (As^{3+}) form. The reduced water solubility of the arsenate compounds, such as arsenic pentoxide, accounts for its limited clinical toxicity when compared to trivalent arsenic trioxide. The trivalent form of arsenic is primarily a nucleophilic toxin, binding sulfhydryl groups and interfering with enzymatic function (Chaps. 12 and 88).

Nonmetals   The nonmetals (C, N, P, O, S, Se, halogens) are highly electronegative and, unlike the metals, may be toxic in either their compounded or their elemental form. The nonmetals with large electronegativity, such as O_2 or Cl_2, generally oxidize other elements in chemical reactions. Those with lesser electronegativity, such as C, behave as reducing agents.

Halogens.   In their highly reactive elemental form, which contains a covalent dimer of halogen atoms, the halogens (F, Cl, Br, I, At) carry the suffix *-ine* (eg, Cl_2, chlorine). Halogens require the addition of one electron to complete their valence shell; thus, halogens are strong oxidizing agents. Because they are highly electronegative, they form halides (eg, Cl^-, chloride) by abstracting electrons from less electronegative elements. Thus, the halogen ions, in their stable ionic form, generally carry a charge of −1. The halides, although much less reactive than their respective elemental forms, are reducing agents. The hydrogen halides (eg, HCl, hydrogen chloride) are gases under standard conditions, but they ionize when dissolved in aqueous solution to form the hydrohalidic acids (eg, HCl, hydrochloric acid). All hydrogen halides except HF (hydrogen fluoride) ionize nearly completely in water to release H^+ and are considered *strong acids*. Because of its small ionic radius, lack of charge dispersion, and intense electronegativity, HF ionizes poorly and is a *weak acid*. This specific property of HF has important toxicologic implications (Chap. 105).

Group 0: Inert Gases   Inert gases (He, Ne, Ar, Kr, Xe, Rn), also known as noble gases, maintain completed valence shells and are thus entirely unreactive except under extreme experimental conditions. However, despite their lack of chemical reactivity, the inert gases are toxicologically important as simple asphyxiants. That is, because they displace ambient oxygen from a confined space, consequential hypoxia may occur, and the expected warning signs may be completely absent (Chap. 124). During high-concentration exposure, inert gases may produce anesthesia, and xenon is used as an anesthetic agent. Radon, although a chemically unreactive gas, is radioactive, and prolonged exposure is associated with the development of lung cancer.

■ BONDS

Electrons are not generally shared evenly between atoms when they form a compound. Instead, unless the bond is between the same elements, as in Cl_2, one of the elements exerts a larger attraction for the shared electrons. The degree to which an element draws the shared electron is determined by the *electronegativity* of the element (Fig. 11–3). The electronegativity of each element was catalogued by Linus Pauling and relates to the ionic radius, or the distance between the orbiting electron and the nucleus, and the shielding effects of the inner electrons. The electronegativity rises toward the right of the periodic table, corresponding with the expected charge obtained on an element when it forms a bond. Fluoride ion has the highest electronegativity of all elements, which explains many of its serious toxicologic properties.

Several types of bonds exist between elements when they form compounds. When one element gains valence electrons and another loses them, the resulting elements are charged and attract one another in an *ionic,* or *electrovalent,* bond. An example is NaCl, or table salt, in which the electronegativity difference between the elements is 1.9, or greater than the electronegativity of the sodium (see subsequent paragraphs and Fig. 11–3). Thus, the chloride wrests control of the electrons in this bond. In solid form, ionic compounds exist in a crystalline lattice, but when put into solution, as in the serum, the elements may separate and form charged particles, or *ions* (Na^+ and Cl^-). The ions are stable in solution, however, because their valence shells contain 8 electrons and are complete. The properties of ions differ from both the original atom from which the ion is derived and the noble gas with which it shares electronic structure.

It is important to recognize that when a mole of a salt, such as NaCl (molecular weight 58.45 g/mol), is put in aqueous solution, 2 moles of particles result. This is because NaCl essentially ionizes fully in water; that is, it produces 1 mole of Na^+ (23 g/mol) and 1 mole of Cl^- (35.45 g/mol). For salts that do not ionize completely, less than the

FIGURE 11–3. Electronegativity of the common elements. Note that the inert gases are not reactive and thus do not have electronegativity.

intrinsic number of moles are released and the actual quantity liberated can be predicted based on the defined solubility of the compound, or the solubility product constant (K_{sp}). For ions that carry more than a single charge, the term *equivalent* is often used to denote the number of moles of other particles to which one mole of the substance will bind. Thus, an equivalent of calcium ion will typically bind 2 moles (or equivalents) of chloride ions (which are monovalent) because calcium ions are divalent. Alternatively stated, a 10% calcium chloride ($CaCl_2$) aqueous solution contains approximately 1.4 mEq/mL or 0.7 mmol/mL of Ca^{2+}.

Compounds formed by 2 elements of similar electronegativity have little ionic character because there is little impetus for separation of charge. Instead, these elements share pairs of valence electrons, a process known as *covalence*. The resultant molecule contains a *covalent bond*, which is typically very strong and generally requires a high-energy chemical reaction to disrupt it. There is wide variation in the extent to which the electrons are shared between the participants of a covalent bond, and the physicochemical and toxicologic properties of any particular molecule are in part determined by its nature. Rarely is sharing truly symmetric, as in oxygen (O_2) or chlorine (Cl_2). If sharing is asymmetric and the electrons thus exist to a greater degree around one of the component atoms, the bond is *polar*. However, the presence of a polar bond does not mean that the compound is polar. For example, methane contains a carbon atom that shares its valence electrons with 4 hydrogen atoms, in which there is a small charge separation between the elements (electronegativity [EN] difference = 0.40). Furthermore, because the molecule is configured in a tetrahedral formation, there is no notable polarity to the compound; this compound is *nonpolar*. The lack of polarity suggests that methane molecules have little affinity for other methane molecules and they are held together only by weak intermolecular bonds. This explains why methane is highly volatile under standard conditions.

Because the EN differences between hydrogen (EN = 2.20) and oxygen (EN = 3.44) are greater (EN difference = 1.24), the electrons in the HO bonds in water are drawn toward the oxygen atom, giving it a partial negative charge and the hydrogen a partial positive charge. Furthermore, because H_2O is angular, not linear or symmetric, water is a polar molecule. Water molecules are held together by hydrogen bonds, which are stronger than other intermolecular bonds (for example, van der Waals forces; see later). These hydrogen bonds have sufficient energy to open many ionic bonds and *solvate* the ions. In this process, the polar ends of the water molecule surround the charged particles of the dissolved salt. Thus, because there is little similarity between the nonpolar methane and the polar water molecules, methane is not water soluble. Similarly, salts cannot be solvated by nonpolar compounds, and thus a salt, such as sodium chloride, cannot dissolve in a nonpolar solvent, such as carbon tetrachloride.

Alternatively, the stability and irreversibility of the bond between an organic phosphorus insecticide and the cholinesterase enzyme are a result of covalent phosphorylation of an amino acid at the active site of the enzyme. The resulting bond is essentially irreversible in the absence of another chemical reaction.

Compounds may share multiple pairs of electrons. For example, the two carbon atoms in acetylene ($HC{\equiv}CH$) share three pairs of electrons between them, and each shares one pair with its own hydrogen. Carbon and nitrogen share three pairs of electrons in forming cyanide ($C{\equiv}N^-$), making this bond very stable and accounting for the large number of xenobiotics capable of liberating cyanide. Complex ions are covalently bonded groups of elements that behave as a single element. For example, hydroxide (OH^-) and sulfate (SO_4^{2-}) form sodium salts as if they were simply the ion of a single element (such as chloride).

Noncovalent bonds, such as hydrogen or ionic bonds, are important in the interaction between ligands and receptors, and between ion channels and enzymes. These are low-energy bonds and easily broken. Van der Waals forces, also known as London dispersion forces, are intermolecular forces that arise from induced dipoles as a consequence of nonuniform distribution of the molecular electron cloud. These forces become stronger as the atom (or molecule) becomes larger because of the increased polarizability of the larger, more dispersed electron clouds. This accounts for the fact that under standard temperature and pressure, fluorine and chlorine are gases, whereas bromine is a liquid, and iodine is a solid.

■ REDUCTION-OXIDATION

Reduction-oxidation (*redox*) reactions involve the movement of electrons from one atom or molecule to another, and actually comprise two dependent reactions: reduction and oxidation. *Reduction* is the gain of electrons by an atom that is thereby *reduced*. The electrons derive from a *reducing agent*, which in the process becomes *oxidized*. *Oxidation* is the loss of electrons from an atom, which is, accordingly, *oxidized*. An *oxidizing agent* accepts electrons and, in the process, is reduced. By definition, these chemical reactions involve a change in the valence of an atom. It is also important to note that acid–base and electrolyte chemical reactions involve electrical charge interactions but no change in valence of any of the involved components. The implications of redox chemistry for medical toxicology are profound. For example, the oxidation of ferrous (Fe^{2+}) to ferric (Fe^{3+}) iron within the hemoglobin molecule creates the dysfunctional methemoglobin molecule.

Also, elemental lead and mercury are both intrinsically harmless metals, but when oxidized to their cationic forms both produce devastating clinical effects. Additionally, the metabolism of ethanol to acetaldehyde involves a change in the oxidation state of the molecule. In this case, an enzyme, alcohol dehydrogenase, acting as a catalyst oxidizes (ie, removes electrons from) the C-O bond and delivers the electrons to oxidized nicotinamide adenine dinucleotide (NAD^+), reducing it to NADH. As in this last example, *oxidation* is occasionally used to signify the gain of oxygen by a substance. That is, when elemental iron (Fe^0) undergoes rusting to iron oxide (Fe_2O_3), it is said to oxidize. The use of this term is consistent because in the process of oxidation, oxygen derives electrons from the atom to which it is binding.

Reactive Oxygen Species Free radicals are reactive molecules that contain one or more unpaired electrons and are typically neutral but may be anionic or cationic. However, because certain toxicologically important reactive molecules do not contain unpaired electrons, such as hydrogen peroxide (H_2O_2) and ozone (O_3), the term *reactive species* is preferred. The reactivity of these molecules directly relates to their attempts to fill their outermost orbitals by receiving an electron; the result is *oxidative stress* on the biologic system. Molecular oxygen is actually a diradical with two unpaired electrons in the outer orbitals. However, its reactivity is less than that of the other radicals because the unpaired electrons have parallel spins, so catalysts (ie, enzymes or metals) are typically involved in the use of oxygen in biologic processes.

Reactive species are continually generated as a consequence of endogenous metabolism and there is an efficient system for their control. Under conditions of either excessive endogenous generation or exposure to exogenous reactive species, the physiologic defense against these toxic products is overwhelmed. When this occurs, reactive species induce direct cellular damage as well as initiate a cascade of oxidative reactions that perpetuate the toxic damage.

Intracellular organelles, particularly the mitochondria, may also be disrupted by various reactive species. This causes further injury to the cell as energy failure occurs. This initial damage is compounded by the activation of the host inflammatory response by chemokines that are released from cells in response to reactive species-induced

TABLE 11–1. Structure of Important Reactive Species

Peroxynitrite anion	$ONOO^-$
Nitronium cation	NO_2^+

damage. This inflammatory response aggravates cellular damage. The resultant membrane dysfunction or damage causes cellular apoptosis or necrosis.

The most important reactive oxygen species in medical toxicology are derived from oxygen, although those derived from nitrogen are also important. Table 11–1 lists some of the important reactive oxygen and nitrogen species.

This biradical nature of oxygen explains both the physiologic and toxicologic importance of oxygen in biologic systems. Physiologically, the majority of oxygen is used by the body to serve as the ultimate electron acceptor in the mitochondrial electron transport chain (Fig. 11–3). In this situation, 4 electrons are added to each molecule of oxygen to form 2 water molecules ($O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$).

Superoxide is generated within neutrophil and macrophage lysosomes as part of the oxidative burst, a method of eliminating infectious agents and damaged cells. Superoxide may subsequently be enzymatically converted, or "dismutated," into hydrogen peroxide by superoxide dismutase (SOD). Hydrogen peroxide may be subsequently converted into hypochlorous acid by the enzymatic addition of chloride by myeloperoxidase. Both hydrogen peroxide and hypochlorite ion are more potent reactive oxygen species than superoxide. However, this lysosomal protective system may also be responsible for tissue damage following poisoning as the innate inflammatory response attacks xenobiotic-damaged cells. Examples include acetaminophen-induced hepatotoxicity (Chap. 34), carbon monoxide neurotoxicity (Chap. 125), and chlorine-induced pulmonary toxicity (Chap. 124), each of which may be altered, at least in experimental systems, by the addition of scavengers of reactive species.

Although superoxide and hydrogen peroxide are reactive species, it is their conversion into the hydroxyl radical (OH·) that accounts for their most consequential effects. The hydroxyl radical is generated by the Fenton reaction (Fig. 11–2), in which hydrogen peroxide is decomposed in the presence of a transition metal. This catalysis typically involves Fe^{2+}, Cu^+, Cd^{2+}, Cr^{5+}, Ni^{2+}, or Mn^{2+}. The Haber-Weiss reaction (Fig. 11–2), in which a transition metal catalyzes the combination of superoxide and hydrogen peroxide, is the other important means of generating the hydroxyl radical. Alternatively, superoxide dismutase, within the erythrocyte, contains an ion of copper (Cu^{2+}) that participates in the catalytic dismutation (reduction) of superoxide to hydrogen peroxide (SOD was originally called erythrocuprein) and the subsequent detoxification of hydrogen peroxide by glutathione peroxidase or catalase.

Transition metal cations may bind to the cellular nucleus where they locally generate reactive oxygen species, most importantly hydroxyl radical. This results in DNA strand breaks and modification, accounting for the promutagenic effects of many transition metals. In addition to the important role that transition metal chemistry plays following iron or copper salt poisoning, the long-term consequences of chronic transition metal poisoning are exemplified by asbestos. The iron contained in asbestos is the origin of the Fenton-generated hydroxyl radicals that are responsible for the pulmonary fibrosis and cancers associated with long-term exposure.

The most consequential toxicologic effects of reactive oxygen species occur on the cell membrane, and are caused by the initiation by hydroxyl radical of the lipid peroxidative cascade. The alteration of these lipid membranes ultimately causes membrane destruction. Identification of released oxidative products such as malondialdehyde is a common method of assessing lipid peroxidation.

Under normal conditions, there is a delicate balance between the formation and immediate endogenous detoxification of reactive oxygen species. For example, the conversion of the superoxide radical to hydrogen peroxide via SOD is rapidly followed by the transformation of hydrogen peroxide to water by glutathione peroxidase or catalase. Furthermore, in order to minimize the formation of hydroxyl radicals, transition metals exist in "free" form in only minute quantities in biologic systems; that is, cells have developed extensive systems by which transition metal ions can be sequestered and rendered harmless. Ferritin (binds iron), ceruloplasmin (binds copper), and metallothionein (binds cadmium) are specialized proteins that safely sequester transition metal ions. Certain proteins and enzymes such as hemoglobin or SOD have critical biological functions associated with the transition metals at their active sites.

Detoxification of certain reactive species is difficult because of their extreme reactivity. Widespread antioxidant systems typically to trap reactive species before tissue damage occurs. An example is the availability of glutathione, a reducing agent and nucleophile, which prevents both exogenous oxidants from producing hemolysis and the acetaminophen metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI) from damaging the hepatocyte.

The key reactive nitrogen species is nitric oxide. At typical physiologic concentrations, this radical is responsible for vascular endothelial relaxation through stimulation of guanylate cyclase. However, during oxidative burst, high concentrations of nitric oxide are formed from L-arginine. At these concentrations, nitric oxide has primarily both damaging effects and reacts with the superoxide radical to generate the peroxynitrite anion. This is particularly important because peroxynitrite may spontaneously degrade to form the hydroxyl radical. Peroxynitrite ion is implicated in both the delayed neurologic effects of carbon monoxide poisoning and the hepatic injury from acetaminophen.

Redox Cycling. Although transition metals are an important source of reactive species, certain xenobiotics are also capable of independently generating reactive species. Most do so through a process called *redox cycling*, in which a molecule accepts an electron from a reducing agent

and subsequently transfers that electron to oxygen, generating the superoxide radical. At the same time, this second reaction regenerates the parent molecule, which itself can gain another electron and restart the process. The toxicity of paraquat is selectively localized to pulmonary endothelial cells. Its pulmonary toxicity results from redox cycling generation of reactive oxygen species (Fig. 115-3). A similar process, localized to the heart, occurs with anthracycline antineoplastic agents such as doxorubicin.

■ ACID–BASE CHEMISTRY

Water is *amphoteric*, which means that it can function as either an acid or a base, much the same way as the bicarbonate ion (HCO_3^-). In fact, because of the amphoteric nature of water, H^+, despite the nomenclature, does not ever actually exist in aqueous solution; rather, it is covalently bound to a molecule of water to form the hydronium ion (H_3O^+). However, the term H^+, or proton, is used for convenience.

Even in neutral solution, a tiny proportion of water is always undergoing ionization to form both H^+ and OH^- in exactly equal amounts. It is, however, the quantity of H^+ that is of concern, and this is the basis of using the pH to characterize a solution. In a perfect system at equilibrium, the concentration of H^+ ions in water is precisely 0.0000001, or 10^{-7}, moles per liter and that of OH^- is the same. The number of H^+ ions increases when an acid is added to the solution and falls when an alkali is added. In an attempt to make this quantity more practical, the negative log of the H^+ concentration is calculated, which defines the pH. Thus, the negative log of 10^{-7} is 7, and the pH of a neutral aqueous solution is 7. In actuality, the pH of water is approximately 6 because of dissolution of ambient carbon dioxide to form carbonic acid ($H_2O + CO_2 \rightarrow H_2CO_3$), which ionizes to form H^+ and bicarbonate (HCO_3^-).

There are many definitions of acid and base. The three commonly used definitions are those advanced by (1) Svante Arrhenius, (2) Brønsted and Lowry, and (3) Lewis. Because the focus is on physiologic systems, which are aqueous, the original definition by the Swedish chemist Arrhenius is the most practical. In this view, an acid releases hydrogen ions, or protons (H^+), in water. Similarly, a base produces hydroxyl ions (OH^-) in water. Thus, hydrogen chloride (HCl), a neutral gas under standard conditions, dissolves in water to liberate H^+, and is therefore an acid.

For nonaqueous solutions the Brønsted-Lowry definition is preferable. An acid, in this schema, is a substance that donates a proton and a base is one that accepts a proton. Thus, any molecule that has a hydrogen in the 1+ oxidation state is technically an acid, and any molecule with an unbound pair of valence electrons is a base. Because most of the acids or bases of toxicologic interest have ionizable protons or available electrons, respectively, the Brønsted-Lowry definition is most often considered when discussing acid–base chemistry (ie, $HA + H_2O \rightarrow H_3O^+ + A^-$; $B^- + H_2O \rightarrow HB + OH^-$). However, this is not a defining property of all acids or bases. Thus, Lewis offered the least-restrictive definition of such substances. A Lewis acid is an electron acceptor and a Lewis base is an electron donor. Simplistically, acids are sour and turn litmus paper red, whereas bases are slippery and bitter and turn litmus paper blue.

Because acidity and alkalinity are determined by the number of available H^+ ions, it is useful to classify chemicals by their effect on the H^+ concentration. Strong acids ionize completely in aqueous solution and very little of the parent compound remains. Thus, 0.001 (or 10^{-3}) mole of HCl, a strong acid, added to 1 L of water produces a solution with a pH of 3. Weak acids, on the other hand, obtain an equilibrium between parent and ionized forms, and thus do not alter the pH to the same degree as a similar quantity of a strong acid. This chemical notation defines the strength or weakness of an acid and should not be

TABLE 11–2. pH of 0.10 *M* Solutions of Common Acids and Bases Represents the Strength of the Acid or Base

Acid Base	pH
HCl (hydrochloric acid)	1.1
H_2SO_4 (sulfuric acid)	1.2
H_2SO_3 (sulfurous acid)	1.5
H_3PO_4 (phosphoric acid)	1.5
HF (hydrofluoric acid)	2.1
CH_3CO_2H (acetic acid)	2.9
H_2CO_3 (carbonic acid)	3.8
H_2S (hydrogen sulfide)	4.1
HCN (hydrocyanic acid)	5.1
$NaHCO_3$ (sodium bicarbonate)	8.3
NH_4Cl (ammonium chloride)	4.6
$NaCH_3CO_2$ (sodium acetate)	8.9
Na_2HPO_4 (sodium hydrogen phosphate)	9.3
Na_2SO_3 (sodium sulfite)	9.8
NaCN (sodium cyanide)	11.0
NH_4OH (aqueous ammonia)	11.1
Na_2CO_3 (sodium carbonate)	11.6
Na_3PO_4 (sodium phosphate)	12.0
NaOH (sodium hydroxide)	13.0

confused with the concentration of the acid. Thus, the pH of a dilute strong acid solution may be substantially less than that of a concentrated weak acid (Table 11–2).

The degree of ionization of a weak acid is determined by the pK_a, or the negative log of the *ionization constant*, which represents the pH at which an acid is half dissociated in solution. The same relationship applies to the pK_b of an alkali, although by convention the pK_b is expressed as the pK_a ($pK_a = 14 - pK_b$). The lower the pK_a, the stronger the acid; the converse is true for bases. The pK of a strong acid is clinically irrelevant because it is fully ionized under all but the most extreme acid conditions. Knowledge of the pK_a does not itself denote whether a substance is an acid or an alkali. To some extent, this quality may be predicted by its chemical structure or reactivity, or obtained through direct measurement or from a reference source.

Because only uncharged compounds cross lipid membranes spontaneously, the pK_a has clinical relevance. Salicylic acid, a weak acid with a pK_a of 3, is nonionized in the stomach (pH 2) and passive absorption occurs (Fig. 8-3). Because it is predominantly in the ionized form (ie, salicylate) in blood, which has a pH of 7.4, little of the ionized blood-borne salicylate passively enters the tissues. However, because in overdose the serum salicylate rises considerably, enough enters the tissue to have devastating clinical effects. Salicylate, a conjugate base of a weak acid and thus a strong base, equilibrates within the various tissues across the outer mitochondrial membrane. In this intermembrane space (between the inner and outer mitochondrial membrane) abundant protons exist, which are transported there via the electron transport chain of this organelle (Fig. 12-3). Because salicylate is a strong base, it protonates easily in this environment. In this nonionized form, some of the salicylic acid may pass through the inner mitochondrial membrane, into the mitochondrial matrix, and again establish equilibrium

by losing a proton. The process just described uncouples oxidative phosphorylation, by dispersing the highly concentrated protons in the intermembrane space that are normally used to generate adenosine triphosphate (Chap. 12). Uncoupling in the skeletal muscle, for example, produces a metabolic acidosis, and this shifts the blood equilibrium of salicylate toward the nonionized, protonated form, enabling salicylic acid to cross the blood–brain barrier. Presumably, once in the brain, the salicylate uncouples the metabolic activity of neurons with the subsequent development of cerebral edema. This is the rationale for serum alkalinization in patients with aspirin overdose (Chap. 35).

In a similar manner, alkalinization of the patient's urine prevents reabsorption by ionization of the urinary salicylate. Conversely, because cyclic antidepressants are organic bases, alkalinization of the urine reduces their ionization and actually decreases the drug's urinary elimination. However, in the management of cyclic antidepressant poisoning, because the other beneficial effects of sodium bicarbonate on the sodium channel outweigh the negative effect on drug elimination, serum alkalinization is recommended (see Chap. 73).

ORGANIC CHEMISTRY

The study of carbon-based chemistry and the interaction of inorganic molecules with carbon-containing compounds is called *organic chemistry*, because the chemistry of living organisms is carbon based. *Biochemistry* (Chap. 12) is a subdivision of organic chemistry; it is the study of organic chemistry within biologic systems. This section reviews many of the salient points of organic chemistry, focusing on those with the most applicability to medicine and the study of toxicology: nomenclature, bonding, nucleophiles and electrophiles, stereochemistry, and functional groups.

■ CHEMICAL PROPERTIES OF CARBON

Carbon, atomic number 6, has a molecular weight of 12.011 g/mol. With few exceptions (notably cyanide ion and carbon monoxide), carbon forms 4 bonds in stable organic molecules. In organic compounds, carbon is commonly bonded to other carbon atoms, as well as to hydrogen, oxygen, nitrogen, or halide (ie, fluorine, bromine, or iodine) atoms. Under certain circumstances, carbon can be bonded to metals, as is the case with methylmercury.

■ NOMENCLATURE

The most systematic method to name organic compounds is in accordance with standards adopted by the International Union of Pure and Applied Chemistry (IUPAC); these names are infrequently used, especially for larger molecules, and alternative names are common. The complete details of the IUPAC naming system are beyond the scope of this text and can be reviewed elsewhere (www.iupac.org), but a brief description of the fundamentals of this system is included here.

The carbon backbone serves as the basis of the chemical name. Once the carbon backbone has been identified and named, *substituents* (atoms or groups of atoms that substitute for hydrogen atoms) are identified, named, and numbered. The number refers to the carbon to which the substituent is attached. Some of the common substituents in organic chemistry are −OH (hydroxy), −NH_2 (amino), −Br (bromo), −Cl (chloro), and −F (fluoro). Substituents are then alphabetized and placed as prefixes to the carbon chain.

As an example, consider the molecule 2-bromo-2-chloro-1,1, 1-trifluoroethane. The molecule has a 2-carbon backbone (ethane), 3 fluoride atoms on the first carbon, a bromine atom on the second car-
FIGURE 11–4. Nomenclature. (**A**) 2-Bromo-2-chloro-1,1,1-trifluoroethane, or halothane. (**B**) [1R-(exo,exo)]-3-(Benzoyloxy)-8-methyl-8-azabicyclo[3,2,1]-octane-2-carboxylic acid methyl ester, or cocaine.

bon, and a chlorine atom on the second carbon (Fig. 11–4A). A basic understanding of a few simple rules of nomenclature thus allows one to quickly generate the molecular structure of a familiar compound, halothane, from what initially appeared to be an intimidating name.

Although the above-mentioned rules suffice to name simple structures, they are inadequate to describe many others, such as molecules with complex branching or ring structures. The IUPAC rules for naming compounds such as [1R-(exo,exo)]-3-(benzoyloxy)-8-methyl-8-azabicyclo[3,2,1]octane-2-carboxylic acid methyl ester, for example, are too complex to include here. Fortunately, many compounds with complex chemical names have simpler names for day-to-day use; as an example, this molecule is commonly referred to as cocaine (Fig. 11–4B).

Cocaine is an example of a *common* or *trivial* name; one without a systematic basis, but which is generally accepted as an alternative to frequently unwieldy proper chemical names. Common names may refer to the origin of the substance; for example, cocaine is derived from the coca leaf, and wood alcohol (methanol) can be prepared from wood. Alternatively, a common name may refer to the way in which a compound is used; rubbing alcohol is a common name for isopropanol. Common names are often imprecise and may generate some confusion, however, as evidenced by the fact that rubbing alcohol, when commercially marketed, may be ethanol or isopropanol.

An even less precise system of nomenclature is the use of *street* names. A street name is a slang term for a drug of abuse, such as "blow" (cocaine), "weed" (marijuana), or "smack" (heroin). The street name *ecstasy* refers to the stimulant 3,4-methylenedioxymethamphetamine (MDMA), which is most frequently consumed in pill form. It would stand to reason that *liquid ecstasy* might refer to a solution of MDMA, but street names are not necessarily logical. Instead, liquid ecstasy refers to the drug γ-hydroxybutyrate (GHB), a sedative-hypnotic with a completely different pharmacologic and toxicologic profile. Furthermore, there are no standards for the content of ecstasy, and many street pills contain other chemicals or no chemicals at all.

A final consideration must be given to *product names*. Product names are trade names under which a given compound might be marketed, and are frequently different from both the chemical name and common name. Thus, the inhalational anesthetic in Figure 11–4A with the chemical name 2-bromo-2-chloro-1,1,1-trifluoroethane has the common name halothane and the trade name Fluothane.

■ BONDING IN ORGANIC CHEMISTRY

Whereas much of the bonding in inorganic chemistry is ionic or electrovalent, the vast majority of bonding in organic molecules is *covalent*. Whereas electrons in ionic bonds are described as "belonging" to one atom or another, electrons in covalent bonds are shared between two atoms; this type of bonding occurs when the difference in electronegativity between

2 atoms is insufficient for one atom to wrest control of an electron from another. Single bonds are represented by 1, double bonds by 2, and triple bonds by 3 lines between the atoms.

NUCLEOPHILES AND ELECTROPHILES

Many organic reactions of toxicologic importance can be described as the reactions of *nucleophiles* with *electrophiles*. *Nucleophiles* (literally, nucleus-loving) are species with increased electron density, frequently in the form of a lone pair of electrons (as in the cases of cyanide ion and carbon monoxide). Nucleophiles, by virtue of this increased electron density, have an affinity for atoms or molecules which are electron deficient; such moieties are called *electrophiles* (literally, electron-loving). The electron deficiency of electrophiles can be described as absolute or relative. Absolute electron deficiency occurs when an electrophile is charged, as is the case with cations such as Pb^{2+} and Hg^{2+}. Relative electron deficiency occurs when one atom or group of atoms shifts electrons away from a second atom, making the second atom relatively electron deficient. This is the case for the neurotoxin 2,5-hexanedione (Fig. 11–5); the electronegative oxygen of the carbon-oxygen double bond pulls electron density away from the second and fifth carbon atoms of this molecule, making these carbon atoms electrophilic.

The reaction of a nucleophile with an electrophile involves the movement of electrons, by forming or breaking bonds. This movement of electrons is frequently denoted by the use of curved arrows, which better demonstrates how the nucleophile and electrophile interact. The interaction of acetylcholinesterase with acetylcholine, organic phosphorus pesticides, and pralidoxime hydrochloride provides an excellent example of the way in which nucleophiles and electrophiles interact, and of how the use of curved arrow notation can lead to better understanding of the reactions involved.

Under normal circumstances, the action of acetylcholine is terminated when the serine residue in the active site of acetylcholinesterase attacks this neurotransmitter, forming a transient serine–acetyl complex and liberating choline. This serine–acetyl complex is then rapidly hydrolyzed, producing an acetic acid molecule and regenerating the serine residue for another round of the reaction (Fig. 11–6A). In the presence of an organic phosphorus pesticide, however, this serine residue attacks the electrophilic phosphate atom, forming a stable serine–phosphate bond, which is not hydrolyzed (Fig. 11–6B). The enzyme, thus inactivated, can no longer break down acetylcholine, leading to an increase of this neurotransmitter in the synapse, and possibly to a cholinergic crisis.

The enzyme can be reactivated, however, by the use of another nucleophile. Pralidoxime hydrochloride (2-PAM) is referred to as a *site-directed nucleophile.* Because part of its chemical structure (the charged nitrogen atom) is similar to the choline portion of acetylcholine, this antidote is directed to the active site of acetylcholinesterase. Once in position, the nucleophilic oxime moiety (−NOH) of 2-PAM attacks the electrophilic phosphate atom. This displaces the serine residue, regenerating the enzyme (Fig. 11–6C). For a further discussion of organic phosphorus compound toxicity and the use of 2-PAM, see Chap. 113 and Antidotes in Depth A33: Pralidoxime.
FIGURE 11–5. Chemical properties of 2,5-hexanedione. Arrows designate the electrophilic carbon atoms.

A second toxicologically important electrophile is NAPQI (Fig. 11–7). NAPQI is formed when the endogenous detoxification pathways of acetaminophen metabolism (glucuronidation and sulfation) are overwhelmed (Chap. 34). As a result of the electron configuration of NAPQI, the carbon atoms adjacent to the *carbonyl carbon* (a carbonyl carbon is one that is double bonded to an oxygen) are very electrophilic; the sulfur groups of cysteine residues of hepatocyte proteins react with NAPQI to form a characteristic *adduct* (formed when one compound is added to another), 3-(cystein-S-yl)acetaminophen, in a multistep process. These adducts are released as hepatocytes die, and can be found in the blood of patients with acetaminophen-related liver toxicity. Figure 11–7 diagrams the mechanism of the protein–NAPQI reaction (Chap. 34).

Nucleophiles can be described by their strength, which by convention is related to the rate at which they react with the reference electrophile CH_3I. Of more use in pharmacology and toxicology, however, are the descriptive terms "hard" and "soft." Although imprecise, the designations hard and soft help to predict, qualitatively, how nucleophiles and electrophiles interact with one another.

Hard species have a charge (or partial charge) that is highly localized; that is, their charge-to-radius ratio is high. Hard nucleophiles are molecules in which the electron density or lone pair is tightly held; fluoride, a small atom that cannot spread its electron density over a large area, is an example. Similarly, hard electrophiles are species in which the positive charge cannot be spread over a large area; ionized calcium, a small ion, is a hard electrophile.

Soft nucleophiles and electrophiles, on the other hand, are capable of delocalizing their charge over a larger area. In this case the charge to mass ratio is low, either because the atom is large or because the charge can be spread over a number of atoms within a given molecule. Sulfur is the prototypical example of a soft nucleophile and the lead ion, Pb^{2+}, is a typical soft electrophile.

The utility of this classification lies in the observation that hard nucleophiles tend to react with hard electrophiles, and soft nucleophiles with soft electrophiles. For example, a principal toxicity of fluoride ion poisoning (Chap. 105) is hypocalcemia; this is because the fluoride ions (hard nucleophiles) readily react with calcium ions (hard electrophiles). On the other hand, the soft nucleophile lead is effectively chelated by soft electrophiles such as the sulfur atoms in the chelating agents dimercaprol (Antidotes in Depth A26: Dimercaprol [British Anti-Lewisite or BAL]) and succimer (Antidotes in depth A27: Succimer [2,3-Dimercaptosuccinic Acid]).

ISOMERISM

Isomerism describes the different ways in which molecules with the same chemical formula (ie, the same number and types of atoms) can be arranged to form different compounds. These different compounds are called *isomers.* Isomers always have the same chemical formula, but differ either in the way that atoms are bonded to each other (*constitutional isomers*) or in the spatial arrangement of these atoms (*geometric isomers* or *stereoisomers*).

Constitutional isomers are conceptually the easiest to understand, because a quick glance shows them to be very different molecules. The chemical formula C_2H_6O, for example, can refer to either dimethyl ether or ethanol (Fig. 11–8). These molecules have very different physical and chemical characteristics, and have little in common other than the number and type of their atomic constituents.

Stereoisomerism, also referred to as *geometric isomerism,* refers to the different ways in which atoms of a given molecule, with the same number and types of bonds, might be arranged. The most important type of stereoisomerism in pharmacology and toxicology is the stereochemistry around a *stereogenic* (sometimes called *chiral*) *carbon.*

A   **B**

FIGURE 11–8. Two molecules with chemical formula C_2H_6O. (**A**) Dimethylether. (**B**) Ethanol (ethyl alcohol).

Consider the two representations of halothane shown in Figure 11–9. In this figure the straight solid lines and the atoms to which they are bonded exist in the plane of the paper, the solid triangle and the atom to which it is bonded are coming out of the paper, and the dashed triangle and the atom to which it is bonded are receding into the paper. It is clear that, for the molecules in Figure 11–9A and B, no amount of rotation or manipulation will make these molecules superimposable. They are, therefore, different compounds.

The molecules in Figure 11–9A and B are *enantiomers* or *optical isomers*. They differ only in the way in which their atoms are bonded to the chiral carbon. It is important to define the stereochemical configuration of these two molecules, which can be done in one of two ways. In the first classification—the $d(+)/l(-)$ system—molecules are named empirically based on the direction in which they rotate plane-polarized light. Each enantiomer will rotate plane-polarized light in one direction; the enantiomer that rotates light clockwise (to the right) is referred to as $d(+)$, or *dextrorotatory;* the $l(-)$, or *levorotatory* enantiomer rotates plane-polarized light in a counterclockwise fashion (to the left).

Alternatively, enantiomers can be named using an elaborate and formal set of rules known as *Cahn-Ingold-Prelog.* These rules establish priority for substituents, based primarily on molecular weight, and then use the arrangement of substituents to assign a configuration. To correctly assign configuration in this system, the molecule is rotated into a projection in which the chiral carbon is in the plane of the page, the lowest priority substituent is directly behind the chiral carbon (and therefore behind the plane of the page), and the other three substituents are arranged around the chiral carbon. Figure 11–10 assigns Cahn-Ingold-Prelog priority to the halothane enantiomers of Figure 11–9, and rearranges the molecules in the appropriate projections.

If the priority of the substituents increases as one moves clockwise (to the right), the enantiomer is *R* (Latin, *rectus* = right); if it increases as one moves counterclockwise, the enantiomer is *S* (Latin, *sinister* = left). Thus, Figure 11–10A is the *R* enantiomer of halothane and Figure 11–10B is the *S* enantiomer.

Enantiomers have identical physical properties, such as boiling point, melting point, and solubility in different solvents; they differ from each other in only two significant ways. The first, as mentioned before, is that enantiomers rotate plane-polarized light in opposite directions; this point has no practical toxicologic importance. The second is that enantiomers may interact in very different ways with other chiral structures (such as proteins and other cell receptors), which is of both pharmacologic and toxicologic significance.

Perhaps the best analogy to explain the toxicologic and pharmacologic importance of stereochemistry is that of the way a hand (analogous to a molecule of drug or toxin) fits into a glove (analogous to the
FIGURE 11–10. *R* and *S* enantiomers of halothane. (**A**) The substituents increase in a clockwise fashion, so the configuration is *R*. (**B**) The substituents increase in a counterclockwise fashion, so the configuration is *S*. In this projection, hydrogen atoms are directly behind the carbon atoms.

biologic site of activity). Consider the left hand as the *S* enantiomer and the right hand as the *R* enantiomer. There are, qualitatively, three different ways in which the hand can fit into (interact with) a glove.

First, if the glove is very pliable (such as a disposable latex glove), it can accept either the left hand or the right hand without difficulty; this is the case for halothane, whose *R* and *S* enantiomers possess equal activity. Second, if a glove is constructed with greater (but imperfect) specificity, one hand will fit well and the other poorly; this is the case for many substances, such as epinephrine and norepinephrine, whose naturally occurring levorotatory enantiomers are 10-fold more potent than the synthetic dextrorotatory enantiomers. Finally, a glove can be made with exquisite precision, such that one hand fits perfectly, while the other hand does not fit at all. This is the case for physostigmine, in which the $(-)$ enantiomer is biologically active, whereas the $(+)$ enantiomer is inactive.

Even the above analogy is oversimplified, however, as one enantiomer of a drug can be an agonist, while the other enantiomer is an antagonist. Dobutamine, for example, has one stereogenic carbon and thus 2 stereoisomers. At the $\alpha 1$ receptor, *l*-dobutamine is a potent agonist and *d*-dobutamine is a potent antagonist. Because dobutamine is marketed as a *racemic mixture* (a racemic mixture is a 1:1 mixture of enantiomers), however, these effects cancel each other out. Interestingly, at the β_1 receptor, *d*- and *l*-dobutamine have unequal agonist effects, with *d*-dobutamine approximately 10 times more potent than *l*-dobutamine.

■ FUNCTIONAL GROUPS

There is perhaps no concept in organic chemistry as powerful as that of the *functional group*. Functional groups are atoms or groups of atoms that confer similar reactivity on a molecule; of less importance is the molecule to which it is attached. *Alcohols, carboxylic acids,* and *thiols* are functional groups; *hydrocarbons* are generally not considered functional groups per se, but rather are the structural backbone to which functional groups are attached The functional groups discussed below are included because they illustrate important principles, not because this represents an exhaustive list of important functional groups in toxicology.

Hydrocarbons, as their name implies, consist of only carbon and hydrogen. *Alkanes* are hydrocarbons that contain no multiple bonds; they may

FIGURE 11–9. The graphic representation of the enantiomers of halothane.
FIGURE 11–11. Two isomers of the 4 carbon alkane, butane. (**A**) *n*-Butane. (**B**) Isobutane.

be straight chain, usually designated by the prefix *n*- (Fig. 11–11A) or, branched (isobutane, Fig. 11–11B); cyclical *Alkenes* contain carbon–carbon double bonds. *Alkynes*, which contain carbon–carbon triple bonds, are of limited toxicologic importance. Butane (lighter fluid) is an alkane, and gasoline is a mixture of alkanes.

Hydrocarbons are of toxicologic importance for two reasons: they are widely abused as inhalational drugs for their CNS depressant effects, and they can cause profound toxicity when aspirated. Although these effects are physiologically disparate, they are readily understood in the context of the chemical characteristics of the hydrocarbon functional group.

Hydrocarbons do not contain *polar groups*, or groups that introduce full or partial charges into the molecule; as such, they interact readily with other nonpolar substances, such as lipids or lipophilic substances. Hydrocarbons readily interact with the myelin of the CNS, disrupting normal ion channel function and causing CNS depression. When aspirated, hydrocarbons interact with the fatty acid tail of surfactant, dissolving this protective substance and contributing to acute lung injury (Chap. 106).

Alcohols possess the hydroxyl (–OH) functional group, which adds polarity to the molecule and makes alcohols highly soluble in other polar substances, such as water. For example, ethane gas (CH_3CH_3) has negligible solubility in water, whereas ethanol (CH_3CH_2OH) is *miscible*, or infinitely soluble, in water. In biologic systems, alcohols are generally CNS depressants, but they can also act as nucleophiles. Ethanol may react with cocaine to form cocaethylene, a longer-acting and more vasoactive substance than cocaine itself (Fig. 11–12; see Chap. 76 for clinical details).
FIGURE 11–12. Reaction of cocaine with ethanol (**A**) to form cocaethylene and methanol (**B**).

Alcohols can be primary, secondary, or tertiary, in which the reference carbon is bonded to 1, 2, or 3 carbons in addition to the hydroxyl group. Methanol, in which the reference carbon is bonded to no other carbons, is not a primary alcohol per se but shares many of the reactivity patterns of primary alcohols. The difference between primary, secondary, and tertiary structures is important, because although the alcohol functional group imparts many qualities to the molecule, the degree of substitution can affect the chemical reactivity. Primary alcohols can undergo multistep oxidation to form carboxylic acids, whereas secondary alcohols generally undergo one-step metabolism to form ketones, and tertiary alcohols do not readily undergo oxidation. This is a point of significant toxicologic importance, and is discussed in more detail later.

Alcohols can be named in many ways; the most common is to add *-ol* or *-yl alcohol* to the appropriate prefix. If the alcohol group is bonded to an interior carbon, the number to which the carbon is bonded precedes the suffix.

Carboxylic acids contain the functional group –COOH. As their name implies, they are weakly acidic, and the pK_a of carboxylic acids are generally 4 or 5, depending on the substitution of the molecule. Carboxylic acids are capable of producing a significant anion gap metabolic acidosis, which is true whether the acids are endogenous or exogenous. Examples of endogenous acids are β-hydroxybutyric acid and lactic acid; examples of exogenous acids are formic acid (produced by the metabolism of methanol) and glycolic, glyoxylic, and oxalic acids (produced by the metabolism of ethylene glycol). Carboxylic acids are named by adding *-oic acid* to the appropriate prefix; the four-carbon straight-chain carboxylic acid is thus butanoic acid.

Thiols contain a sulfur atom, which usually functions as a nucleophile. The sulfur atom of *N*-acetylcysteine can regenerate glutathione reductase, and can also react directly with NAPQI to detoxify this electrophile. The sulfur atoms of many chelators, such as dimercaprol and succimer, are nucleophiles that are very effective at chelating electrophiles such as heavy metal ions. Thiols are generally named by adding the word *thiol* to the appropriate base. Thus, a 2-carbon thiol is ethane thiol.

As noted above, molecules with a given functional group often have more in common with molecules within the same functional group than they have in common with the molecules from which they were derived. The alkanes methane, ethane, and propane are straight-chain hydrocarbons with similar properties. All are gases at room temperature, have almost no solubility in water, and have similar melting and boiling points. When these molecules are substituted with one or more hydroxide functional groups, they become alcohols: examples are methanol, ethanol, ethylene glycol (a *glycol* is a molecule that contains 2 alcohol functional groups), the primary alcohol 1-propanol, and the secondary alcohol 2-propanol (isopropanol). Each of these alcohols is a liquid at room temperature, and all are very water soluble. All have boiling points that are markedly different from the alkane from which they were derived, and quite close to each other.

In addition to conferring different physical properties on the molecule, the addition of the alcohol functional group also confers different chemical properties and reactivities. For example, methane, ethane, and propane are virtually incapable of undergoing oxidation in biologic systems. The alcohols formed by the addition of one or more hydroxyl groups, however, are readily oxidized by alcohol dehydrogenase (Fig. 11–13).

As Figure 11–13 indicates, the oxidation of the primary alcohols methanol and ethanol results in the formation of *aldehydes* (functional groups in which a carbon atom contains a double bond to oxygen and a single bond to hydrogen), whereas the oxidation of the secondary alcohol isopropanol results in the formation of a *ketone* (a functional group in which a carbon is double-bonded to an oxygen atom and
FIGURE 11–13. Oxidative metabolism of (**A**) methanol, (**B**) ethanol, and (**C**) isopropanol. Note that acetone does not undergo further oxidation in vivo. ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase.

single-bonded to two separate carbon atoms). Although both aldehydes and ketones contain the *carbonyl group* (a carbon-oxygen double bond), aldehydes and ketones are distinctly different functional groups, and have different reactivity patterns. For instance, aldehydes can undergo enzymatic oxidation to carboxylic acids (Figs. 11–13A and B), whereas ketones cannot (Fig. 11–13C).

It is here that recognition of functional groups helps to understand the potential toxicity of an alcohol. Methanol, ethanol, and isopropanol are all alcohols; as such, their toxicity before metabolism is expected to be (and in fact is) quite similar to that of ethanol, producing CNS sedation.

Because these toxins are primary and secondary alcohols, all three can be metabolized to a carbonyl compound, either an aldehyde or a ketone. Here, however, the functional groups on the molecules have changed; whereas aldehydes can be metabolized to carboxylic acids (which can, in turn, cause an anion gap acidosis), ketones cannot. It is for this reason that methanol and ethylene glycol can cause an anion gap acidosis, and isopropanol cannot (Chap. 107).

The concept of functional groups, however useful, has limitations. For example, although both formic acid and oxalic acid are organic acids, they cause different patterns of organ system toxicity. Formic acid is a mitochondrial toxin and exerts effects primarily in areas (such as the retina or basal ganglia) that poorly tolerate an interruption in the energy supplied by oxidative phosphorylation. Conversely, oxalic acid readily precipitates calcium and is toxic to renal tubular cells, which accounts for the hypocalcemia and nephrotoxicity that are characteristic of severe ethylene glycol poisoning. The concept of the functional group is thus an aid to understanding chemical reactivity, but not a substitute for a working knowledge of the toxicokinetic or toxicodynamic effects of xenobiotics in living systems.

SUMMARY

Understanding key principles in inorganic and organic chemistry provides insight into the mechanisms by which xenobiotics act. The periodic table forms the basis for inorganic chemistry and provides insight into the expected reactivity, and to a large extent the clinical effects, of any element. A growing understanding of how reactive species are formed and how they interfere with physiologic processes has led to new insights in the pathogenesis and treatment of toxin-mediated diseases. Organic chemistry forms the basis of life, and is essential to an understanding of biochemistry and pharmacology. Because many xenobiotics are organic compounds there is direct relevance to medical toxicology.

CHAPTER 12
BIOCHEMICAL AND METABOLIC PRINCIPLES

Kurt C. Kleinschmidt and Kathleen A. Delaney

Xenobiotics are compounds that are foreign to a living system. Toxic xenobiotics interfere with critical metabolic processes, causing structural damage to cells or altering the cellular genetic material. The specific biochemical sites of actions that disrupt metabolic processes are well characterized for many xenobiotics although mechanisms of cellular injury are not. This chapter reviews the biochemical principles that are relevant to an understanding of the damaging effects of toxic xenobiotics and the biotransformation enzymes and their clinical implications.

The capacity of a xenobiotic to produce injury is affected by many factors including its absorption, distribution, elimination, site of activation or detoxification, site of action, and capability of cross membranes to access a particular organ. Sites of action include the active sites of enzymes, DNA, and lipid membranes. The route of exposure to a xenobiotic may confine damage primarily to one organ, for example, pulmonary injury that follows inhalation or GI injury that follows a caustic ingestion. Hepatocellular injury results when a toxic xenobiotic is delivered to the liver, either by the portal venous system following ingestion or by the hepatic artery carrying blood with xenobiotics absorbed from other sites of exposure. Various factors affect the ability of a xenobiotic to access a particular organ. For example, many potentially toxic xenobiotics fail to produce CNS injury because they cannot cross the blood–brain barrier. The negligible CNS effects of the mercuric salts when compared with organic mercury compounds are related to their inability to penetrate the CNS. Two potent biologic xenobiotics—ricin (from *Ricinus communis*) and α-amanitin (from *Amanita phalloides*)—block protein synthesis through the inhibition of RNA polymerase. However, they cause different clinical effects because of access to different tissues. Ricin has a special binding protein that enables it to gain access to the endoplasmic reticulum in GI mucosal cells, where it inhibits cellular protein synthesis and causes severe diarrhea.[4] α-Amanitin is transported into hepatocytes by bile salt transport systems, where inhibition of protein synthesis results in cell death.[50,55] The electrical charge on a toxin also affects its ability to enter a cell. Unlike the ionized (charged) form of a xenobiotic, the uncharged form is lipophilic and passes easily through lipid cell membranes to enter the cells. The pK_a of an acidic xenobiotic ($HA \leftrightarrow A^- + H^+$) is the pH at which 50% of the molecules are charged (A^- form) and 50% are uncharged (HA form). A xenobiotic with a low pK_a is more likely to be absorbed in an acidic environment where the uncharged form predominates.

GENERAL ENZYME CONCEPTS

The capability to detoxify and eliminate both endogenous toxins and xenobiotics is crucial to the maintenance of physiologic homeostasis and normal metabolic functions. A simple example is the detoxification of cyanide, a potent cellular poison that is common in the environment and is also a product of normal metabolism. Mammals have evolved the enzyme rhodanese, which combines cyanide with thiosulfate to create the less toxic, renally excreted compound thiocyanate.[6]

Most xenobiotics have lipophilic properties that facilitate absorption across cell membranes in organs that are portals of entry into the body: the skin, GI tract, and lungs. The liver has the highest concentration of enzymes that metabolize xenobiotics. Enzymes found in the liquid matrix of hepatocytes, the cytosol, that are specific for alcohols, aldehydes, esters, or amines act on many different substrates within these broad chemical classes. Enzymes that act on more lipophilic xenobiotics, including the cytochrome P450 (CYP) enzymes, are embedded in the lipid membranes of the cytosol-based endoplasmic reticulum. When cells are mechanically disrupted and centrifuged, these membrane bound enzymes are found in the pellet, or microsomal fraction, hence they are called *microsomal enzymes*. Enzymes located in the liquid matrix of cells are called *cytosolic enzymes* and are found in the supernatant when disrupted cells are centrifuged.[19]

BIOTRANSFORMATION OVERVIEW

The study of xenobiotic metabolism was established as a scientific discipline by the seminal publication of Williams in 1949.[94] Biotransformation is the physiochemical alteration of a xenobiotic, usually as a result of enzyme action. Most definitions also include that this action converts lipophilic substances into more polar, excretable substances.[56,87] The chemical nature of the xenobiotic determines whether it will undergo biotransformation; however, most undergo some degree of biotransformation. The hydrophilic nature of ionized compounds such as carboxylic acids enables the kidneys to rapidly eliminate them. Very volatile compounds, such as enflurane, are expelled promptly via the lungs. Neither of these groups of xenobiotics undergo significant enzymatic metabolism.

Biotransformation usually results in "detoxification," a reduction in the toxicity, by the conversion to hydrophilic metabolites of the xenobiotic that can be renally eliminated.[56] However, this is not always the case. Many parent xenobiotics are inactive and must undergo "metabolic activation," a classic concept introduced in 1947.[59] When metabolites are more toxic than the parent xenobiotic, biotransformation has resulted in "toxification."[87] Biotransformation via acetylation or methylation may enhance the lipophilicity of a xenobiotic. Biotransformation is done by impressively few enzymes, reflecting broad substrate specificity. The predominant pathway for the biotransformation of an individual xenobiotic is determined by many factors including the availability of cofactors, changes in the concentration of the enzyme caused by induction, and the presence of inhibitors. The predominant pathway is also affected by the rate of substrate metabolism, reflected by the K_m (Michaelis-Menten dissociation constant) of the biotransformation enzyme.[87] (Chap. 8)

Biotransformation is often divided into phase I and phase II reactions, terminology first introduced in 1959.[95] Phase I reactions prepare lipophilic xenobiotics for the addition of functional groups or actually add the groups, converting them into more chemically reactive metabolites. This is usually followed by phase II synthetic reactions that conjugate the reactive products of phase I with other molecules that render them more water soluble, further detoxifying the xenobiotics and facilitating their elimination. However, biotransformation often does not follow this stepwise process and it has been suggested that phase I and II terminology be eliminated.[42] Some xenobiotics undergo only a phase I or a phase II reaction prior to elimination. Phase II reactions can precede phase I. While virtually all phase II synthesis reactions cause inactivation, a classic exception is fluoroacetate being metabolized to fluorocitrate, a potent inhibitor of the tricarboxylic acid cycle.[70]

Biotransformed xenobiotics cannot be eliminated until they are moved back across cell membranes, out of the cells. Membrane transporters are proteins that move agents across the membranes without

altering their chemical compositions, a process called a phase III reaction because it typically occurs after biotransformation.[42] However, membrane transport does not always occur after phase I or II reactions. Some parent compounds are transported across membranes without any biotransformation at all.

PHASE I BIOTRANSFORMATION REACTIONS

Oxidations are the predominant phase I reactions, adding reactive functional groups suitable for conjugation during phase II. These groups include hydroxyl (–OH), sulfhydryl (–SH), amino (–NH$_2$), aldehyde (–COH), or carboxyl (–COOH) moieties. Noncarbon elements such as nitrogen, sulfur, and phosphorus are also oxidized in phase I reactions. Other phase I reactions include hydrolysis (the splitting of a large molecule by the addition of water that is divided among the 2 products), hydration (incorporation of water into a complex molecule), hydroxylation (the attachment of –OH groups to carbon atoms), reduction, dehalogenation, dehydrogenation, and dealkylation.[56,87]

The CYP enzymes are the most numerous and important of the phase I enzymes. A common oxidation reaction catalyzed by CYP enzymes is illustrated by the hydroxylation of a xenobiotic R–H to R–OH (Fig. 12–1).[25] Membrane-bound flavin monooxygenase (FMO), an NADPH-dependent oxidase located in the endoplasmic reticulum, is an important oxidizer of amines and other compounds containing nitrogen, sulfur, or phosphorus.[56]

The alcohol, aldehyde, and ketone oxidation systems use predominantly cytosolic enzymes that catalyze these reactions using NADH/NAD$^+$.[53,87] Two classic phase I oxidation reactions are the metabolism of ethanol to acetaldehyde by alcohol dehydrogenase (ADH) followed by the metabolism of acetaldehyde to acetic acid by aldehyde dehydrogenase (ALDH) (Fig. 12–2). Alcohol dehydrogenase, which oxidizes many different alcohols, is found in the liver, lungs, kidney, and gastric mucosa.[53] Women have less ADH in their gastric mucosa than men. This results in decreased first-pass metabolism of alcohol and increased alcohol absorption. Some populations, particularly Asians, are deficient in ALDH, resulting in increased acetaldehyde concentrations and symptoms of the acetaldehyde syndrome[53] (Chap. 79).

OXIDATION OVERVIEW

Biotransformation often results in the oxidation or reduction of carbon. A substrate is oxidized when it transfers electrons to an electron-seeking (electrophilic or oxidizing) molecule, leading to reduction of the electrophilic molecule. These oxidation-reduction reactions are usually coupled to the cyclical oxidation and reduction of a cofactor, such as the pyridine nucleotides, nicotinamide adenine dinucleotide phosphate (NADPH/NADP$^+$) or nicotinamide adenine dinucleotide (NADH/NAD$^+$). The nucleotides alternate between their reduced (NADPH, NADH) and oxidized (NADP$^+$, NAD$^+$) forms. Since xenobiotic oxidation is the most common phase I reaction, the reduced cofactors must have a place to unload their electrons; otherwise, biotransformation ends. The electron transport chain is the major electron recipient.

Electrons resulting from the catabolism of energy sources are extracted primarily by NAD$^+$, forming NADH. Within the mitochondria,
FIGURE 12–1. A common oxidation reaction catalyzed by CYP enzymes: the hydroxylation of Drug-H to Drug-OH.
FIGURE 12–2. Conversion of ethanol to acetaldehyde by CYP2E1 that uses NADPH and oxygen and by alcohol dehydrogenase that uses NAD$^+$. This illustrates how NAD and NADP can function in oxidation reactions in both their oxidized and reduced forms. Alcohol dehydrogenase has a low K$_m$ for ethanol and is the predominant metabolic enzyme in moderate drinkers.

NADH transports its electrons to the cytochrome-mediated electron transport chain. This results in the production of adenosine triphosphate (ATP), the reduction of molecular oxygen, and the regeneration of NAD$^+$—all parts critical to the maintenance of oxidative metabolism. NADPH, created within the hexose monophosphate shunt, is used in the synthetic (anabolic) reactions of biosynthesis (especially fatty acid synthesis). NADPH is also coupled to the reduction of glutathione, which plays an important role in the protection of cells from oxidative damage.

The oxidation state of a specific carbon atom is determined by counting the number of hydrogen and carbon atoms to which it is connected. The more reduced a carbon, the higher the number of connections. For example, the carbon in methanol (CH$_3$OH) has three carbon-hydrogen bonds and is more reduced than the carbon in formaldehyde (H$_2$C=O), which has two. Carbon–carbon double bonds count as only one connection.

CYTOCHROME ENZYMES–AN OVERVIEW

Cytochromes are a class of hemoprotein enzymes whose function is electron transfer, using a cyclical transfer of electrons between oxidized (Fe^{3+}) or reduced (Fe^{2+}) forms of iron. One type of cytochrome is cytochrome P450 (CYP) whose nomenclature derives from the spectrophotometric characteristics of its associated heme molecule. When bound to carbon monoxide, the maximal absorption spectrum of the reduced CYP (Fe^{2+}) enzyme occurs at 450 nm.[63] CYP enzymes, which incorporate one atom of oxygen into the substrate and one atom into water, were once called *mixed-function oxidases*. This activity is now referred to as a *microsomal monooxygenation reaction*.[63,87]

Cytochrome enzymes perform many functions. The biotransformation CYP enzymes are bound to the lipid membranes of the smooth endoplasmic reticulum. They execute 75% of all xenobiotic metabolisms and most phase I oxidative biotransformations of xenobiotics.[34] A second role for CYP enzymes is synthetic: biotransforming endobiotics (chemicals endogenous to the body) to cholesterol, steroids, bile acids, fatty acids, prostaglandins, and other important lipids. Cytochromes also act as electron transfer xenobiotics within the mitochondrial electron transport chain.[36,63]

While over 6000 CYP genes exist in nature, the human genome project completed in 2003 set the number of human CYP genes at 57.[63] CYP enzymes are categorized according to the similarities of their

amino acid sequences. They are in the same "family" if they are more than 40% comparable and same "subfamily" if they are more than 55% similar. Families are designated by an Arabic numeral, subfamilies by a capital letter, and each individual enzyme by another numeral, resulting in the nomenclature CYPnXm for each enzyme. For example, CYP3A4 is enzyme number 4 of the CYP3 family and of the CYP3A subfamily.[32,61] Most xenobiotic metabolism is done by the CYP1, CYP2, and CYP3 families, with a small amount done by the CYP4 family.[12,92] While 15 CYP enzymes metabolize xenobiotics,[69] nearly 90% is done by 6 CYP enzymes: 1A2, 2C9, 2C19, 2D6, 2E1, and 3A4 (Table 12–1).[63]

Most CYP enzymes are found in the liver, where they comprise 2% of total microsomal protein.[69] High concentrations are also in extrahepatic tissues, particularly the gastrointestinal tract and kidney.[21,64] The lungs,[97] heart,[66] and brain[22] have the next highest amounts. Each tissue has a unique profile of CYP enzymes that determines its sensitivity to different xenobiotics.[21] The CYP enzymes in the enterocytes of the small intestine actually contribute significantly to "first-pass" metabolism of some xenobiotics.[44,63] Corrected for tissue mass, the CYP enzyme system in the kidneys is as active as that in the liver. The activity of the renal CYP enzymes is decreased in patients with chronic renal failure, with relative sparing of CYPs 1A2, 2C19, and 2D6 compared with 3A4 and 2C9.[12]

■ CYTOCHROME P450 ENZYME SPECIFICITY FOR SUBSTRATES

In vitro models have been used to define the specificities of CYP enzymes for their substrates and inhibitors. However, activity in a test tube does not always correlate with that in a cell. These models use substrate and inhibitor concentrations that are much higher than would be encountered in vivo, and the mathematical models that extrapolate to clinically relevant processes yield conflicting results. This has resulted in discrepancies in reported substrates, inhibitors, and inducers of specific CYP enzymes.[93]

The substrate specificity of a CYP enzyme greatly affects its role in biotransformation.[34] CYP enzymes involved in endobiotic biotransformation are highly selective. For example, CYP1A2 specifically catalyzes only the 21-hydroxylation of progesterone, an important step in steroid synthesis.[35] Most CYP enzymes involved in xenobiotic biotransformation have broad substrate specificity and can metabolize many xenobiotics.[34] This is fortunate because the number of xenobiotic substrates may exceed 200,000.[52] Broad substrate specificity often results in multiple CYP enzymes being able to biotransform a xenobiotic. This enables the ongoing biotransformation despite an inhibition or deficiency of an enzyme. When a substrate can be biotransformed by more than one enzyme, the one that has the highest affinity for the substrate usually predominates at low substrate concentrations, while enzymes with lower affinity may be very important at high concentrations. This transition is usually concomitant with, but not dependent on, the saturation of the catalytic capacity of the primary enzyme as it reaches its maximum rate of activity.[34] The K_m, which is defined as the concentration of enzyme that results in 50% of maximal enzyme activity, describes this property of enzymes. For example, ADH in the liver has a very low Km for ethanol, making it the primary metabolic enzyme for ethanol when concentrations are low.[53] Ethanol is also biotransformed by the CYP2E1 enzyme, which has a high K_m for ethanol and only functions when concentrations are high. The CYP2E1 enzyme metabolizes little ethanol in moderate drinkers but accounts for significantly more

---

TABLE 12–1. Characteristics of Different Cytochrome P450 Enzymes[1,12,21,25,51,63,67]

Enzyme	1A2	2C9	2C19	2D6	2E1	3A4
Percent of liver CYPs	2%	10%–20%	10%–20%	30%	7%	40%–55%
Contribution to enterocyte CYPs	Minor	Minor	Minor	Minor	Minor	70%
Organs other than liver with enzyme	Lung	Small intestine, nasal mucosa, heart	Small intestine, nasal mucosa, heart	Small intestine, kidney, lung, heart	Lung small intestine, kidney	Much in small intestine; some in kidney, nasal mucosa, lung, stomach
Percent of metabolism of typically used drugs	2%–15%	10%–15%		25%–30%		50%–60%
Polymorphism[a]	No	Yes	Yes	Yes	No	No
Poor metabolizer						
African American		1%–2%	20%	2%–8%		
Asian		1%–2%	15%–20%	>1%		
White		1%–3%	3%–5%	5%–10%		
Ultra extensive metabolizer						
Asian				1%		
Ethiopian				30%		
Northern Europeans				1%–2%		
Southern Europeans				10%		

[a] Enzyme variations exist even in those listed as "No" for polymorphism.

biotransformation in alcoholics. As another example, diazepam is metabolized by both CYP2C19 and CYP3A4 enzymes. However, the affinity of CYP3A4 for diazepam is so low (ie, the K_m is high) that most diazepam is metabolized by CYP2C19.[37]

The substrate selectivity of some CYP enzymes is determined by molecular, and physicochemical properties of the substrates. The CYP1A subfamily has greater specificity for planar polyaromatic substrates such as benzo[*a*]pyrene. The CYP2E enzyme subfamily targets low-molecular-weight hydrophilic xenobiotics, whereas the CYP3A4 enzyme has increased affinity for lipophilic compounds. Substrates of CYP2C9 are usually weakly acidic, whereas those of CYP2D6 are more basic.[51] High specificity can also result from key structural considerations such as stereoselectivity. Some xenobiotics are racemic mixtures of stereoisomers. These may be substrates for different CYP enzymes and have distinct affinities for the enzymes, resulting in different rates of metabolism. For example, R-warfarin is biotransformed by CYP3A4 and CYP1A2, whereas S-warfarin is metabolized by CYP2C9.[78,87]

The CYP enzymes that biotransform a specific xenobiotic cannot be predicted by its drug class. Whereas fluoxetine and paroxetine are both major substrates and potent inhibitors of CYP2D6, sertraline is not extensively metabolized and exhibits minimal interaction with other antidepressants.[5] Most β-hydroxy-β-methylglutarylcoenzyme A (HMG-CoA) reductase inhibitors are metabolized by CYP3A4 (lovastatin, simvastatin, and atorvastatin); however, fluvastatin is metabolized by CYP2D6 and pravastatin undergoes virtually no CYP enzyme metabolism at all.[32] Among angiotensin-II receptor blockers, losartan and irbesartan are metabolized by CYP2C9, while valsartan, eprosartan, and candesartan are not substrates for any CYP enzyme. In addition, losartan is a prodrug whose active metabolite provides most of the pharmacologic activity, while irbesartan is the primary active compound. For these two drugs the inhibition of CYP2C9 is predicted to have opposite effects.[28]

◼ CYTOCHROME P450 AND DRUG–DRUG/DRUG–CHEMICAL INTERACTIONS

Adverse reactions to medications and drug–drug interactions are common causes of morbidity and mortality in hospitalized patients, the risk of which increases with the number of drugs taken (Chaps. 138 and 139). Fifty percent of adverse reactions may be related to pharmacogenetic factors.[30] The most significant interactions are mediated by CYP enzymes.[63] The impact of genetic polymorphism and enzyme induction or inhibition are addressed below.

CYP enzymes are involved in many types of drug interactions. The ability of potential new drugs to induce or inhibit enzymes is an important consideration of industry. Drug development focuses on the potential of new xenobiotics to induce or inhibit during the drug discovery phase. Various in vitro models have been created to enable this early determination.[54]

Many xenobiotics interact with the CYP enzymes. St. John's wort, an herb marketed as a natural antidepressant, induces multiple CYP enzymes including 1A2, 2C9, and 3A4. The induction of CYP3A4 by St. John's wort is associated with a 57% decrease in effective serum concentrations of indinavir when given concomittantly.[71] Xenobiotics contained in grapefruit juice, such as naringin and furanocoumarins, are both substrates and inhibitors of CYP3A4. They inhibit the first-pass metabolism of CYP3A4 substrates by inhibiting CYP3A4 activity in both the gastrointestinal tract and the liver.[18] Polycyclic hydrocarbons found in charbroiled meats and in cigarette smoke induce CYP1A2. For smokers who drink coffee, concentrations of caffeine, a CYP1A2 substrate, will be increased following cessation of smoking.[25]

◼ GENETIC POLYMORPHISM

There is much variation in response to xenobiotics and to coadministration of inhibitory or inducing xenobiotics. The translation of DNA sequences into proteins results in the phenotypic expression of the genes. When a genetic mutation occurs, the changed DNA may continue to exist, be eliminated, or propagate into a polymorphism. A polymorphism is a genetic change that exists in at least 1% of the human population.[30] A polymorphism in a biotransformation enzyme may change its rate of activity. The heterogeneity of CYP enzymes contributes to the differences in metabolic activity between patients.[30] Differences in biotransformation capacity that lead to toxicity, once thought to be "idiosyncratic" drug reactions, are likely caused by these inherited differences in the genetic complement of individuals.

The normal catalytic speed of CYP enzyme activity is called *extensive*. There are 2 major metabolizer phenotypes due to polymorphism: poor (slow) and ultraextensive (rapid).[61,30] The CYP2C19 and CYP2D6 genes are highly polymorphic (Table 12–1).[41] The CYP2D6 gene, which has 76 different alleles, is associated with both ultraextensive and poor metabolism. The CYP2C19 and CYP2C9 genes are both associated with poor metabolizers.[12,63]

The clinical implications of polymorphisms are vast. A prodrug may not be bioactivated because the patient is a poor metabolizer. Conversely, a drug may not reach a therapeutic concentration because the patient is an ultraextensive metabolizer.[30]

Polymorphisms exist for enzymes other than CYP enzymes. A classic one is the inheritance of rapid or slow "acetylator" phenotypes. Acetylation is important for the biotransformation of amines (R–NH_2) or hydrazines (NH_2–NH_2). Slow acetylators are at increased risk of toxicity associated with the slower biotransformation of certain nitrogen-containing xenobiotics such as isoniazid, procainamide, hydralazine, and sulfonamides.[24,80]

Polymorphic genes that code for enzymes in important metabolic pathways affect the toxicity of a xenobiotic by altering the response to or the disposition of the xenobiotic. An example occurs in glucose-6-phosphate dehydrogenase (G6PD) deficiency. G6PD is a critical enzyme in the hexose monophosphate shunt, a metabolic pathway located in the red blood cell (RBC) that produces NADPH, which is required to maintain RBC glutathione in a reduced state. In turn, reduced glutathione prevents hemolysis during oxidative stress.[14] In patients deficient in G6PD, oxidative stress produced by electrophilic xenobiotics results in hemolysis.

◼ INDUCTION OF CYP ENZYMES

Biotransformation by induced CYP enzymes results in either increased activity of prodrugs or enhanced elimination of drugs. Stopping an inducing agent may result in the opposite effects. Either way, maintaining therapeutic concentrations of affected drugs is difficult, resulting in either toxicity or subtherapeutic concentrations. Interestingly, not all CYP enzymes are inducible. Inducible ones include CYP2A, CYP2B, CYP2C, CYP2E, and CYP3A.[54]

While varied mechanisms of induction exist, the most common and significant is nuclear receptor (NR)-mediated increase in gene transcription.[54] Nuclear receptors are the largest group of transcription factors, proteins that switch genes on or off.[90] They regulate reproduction, growth, and biotransformation enzymes, including CYP enzymes.[88] Nuclear receptors exist mostly within the cytoplasm of cells. The CYP families 2 and 3 both have gene activation triggered through the nuclear receptors pregnane X receptor (PXR) and constitutive androstane receptor (CAR). The CYP 1A subfamily uses the aryl hydrocarbon receptor (AhR) as its NR. Ligands, molecules that bind to and affect the reactivity of a central molecule, are typically small and lipophilic,

enabling them to enter cells. Many xenobiotics are ligands. Ligands bind the NRs, resulting in structural changes that enable the NR-ligand complexes to be translocated into the cell nucleus. Within the nucleus, NR-ligand complexes bind to a heterodimerization partner such as retinoid X receptor (RXR), shared by PXR and CAR, or AhR nuclear translocator (Arnt), by AhR. This new complex then interacts with specific response elements of DNA, initiating the transcription of a segment of DNA, and resulting in the phenotypic expression of the respective CYP enzyme.

The ligand binding domain of the PXR receptor is very hydrophobic and flexible, enabling this pocket to bind many substrates of varied sizes and reflecting why PXR can be activated by such a broad group of ligands.[67,88] For example, xenobiotic ligands that bind the NR PXR that targets the *CYP3A4* gene include rifampin, omeprazole, carbamazepine, and troleandomycin. Phenobarbital, a classic inducing agent, is a ligand that binds CAR.[90] The induction of CYP1A subfamily enzymes is through the interaction with the NR AhR. Exogenous AhR ligands are hydrophobic, cyclic, planar molecules. Classic AhR ligands include polycyclic hydrocarbons such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin and benzo[*a*]pyrene.[67]

Induction requires time to occur because it involves de novo synthesis of new proteins. Similarly, withdrawal of the inducer results in a slow return to the original enzyme concentration.[54] Polyaromatic hydrocarbons (PAHs) result in CYP1A subfamily induction within 3 to 6 hours with maximum effect within 24 hours.[84] The inducer rifampin does not affect verapamil trough concentrations maximally until 1 week; followed by a 2-week return to baseline steady state after withdrawal of rifampin.[54] Xenobiotics with long half-lives require longer periods to reach steady-state concentrations that maximize induction. Phenobarbital or fluoxetine, which have long half-lives, may fully manifest induction only after weeks of exposure. Conversely, xenobiotics with short half-lives, such as rifampin or venlafaxine, can reach maximum induction within days.[12,32]

Inconsistency in CYP induction exists between individuals. This variability exists for CYP enzymes in all organs.[54,67] In an in vitro study of inducers on 60 livers, differences in enzyme induction ranged from 5-fold for CYP3A4 and CYP2C up to more than 50-fold for CYP2A6 and CYP2D6.[54] The inconsistency likely results from multiple environmental factors including diet, tobacco, and pollutants.[54] There is variation in the extent to which inducers can generate new CYP enzymes. Identical dosing regimens with rifampin have resulted in induction of in vivo hepatic CYP3A4 with up to 18-fold differences between subjects.[54] There is an inverse correlation of the degree of inducibility of an enzyme and the baseline enzyme concentration. Patients with a relatively low baseline concentration of a CYP enzyme will be more inducible than those with a high baseline concentration. Interestingly, the maximum concentrations of CYP enzymes seem to be quantitatively similar among individuals, suggesting a limit to which enzymes can be induced.[54]

While the focus of this section is on CYP enzymes, it appears that all phases of xenobiotic metabolism are regulated by nuclear receptors.[9] Also, just as genetic polymorphisms exist for CYP enzymes, they exist for nuclear receptors including AhR, CAR, and PXR. This results in varied sensitivities to the ligands that complex with the nuclear receptors, ultimately resulting in differences in CYP enzyme induction.[54,90]

■ INHIBITION OF CYP ENZYMES

CYP enzyme inhibition can result in increased bioavailability of a drug or decreased activity of a prodrug that is no longer able to be metabolically activated.[69] Inhibition of CYP enzymes is the most common cause of harmful drug–drug interactions.[69] Inhibition of CYP enzymes by coadministered xenobiotics has resulted in the removal of many medications from the market in recent years including terfenadine, mibefradil, bromfenac, astemizole, cisapride, cerivastatin, and nefazodone.[93] The appendix at the end of this chapter includes a comprehensive listing of cytochrome P450 substrates, inhibitors, and inducers.

Inhibition mechanisms include irreversible (mechanism-based inhibition) and the more common reversible processes. The most common type of reversible inhibition is competitive, where the substrate and inhibitor both bind the active site of the enzyme.[69,93] Binding is weak and is formed and broken down easily, resulting in the enzyme becoming available again. It occurs rapidly, usually beginning within hours.[12] Because the degree of inhibition varies with the concentration of the inhibitor, the time to reach the maximal effect correlates with the half-life of the xenobiotic in question.[12] A competitive inhibitor can be overcome by increasing the substrate concentration. Each substrate of a CYP enzyme is an inhibitor of the metabolism of all the other substrates of the same enzyme, thereby increasing their concentrations and half life. Noncompetitive inhibition occurs when an inhibitor binds a location on an enzyme that is not the active site, resulting in a structural change that inhibits the active enzyme site. For example, noncompetitive inhibitors of CYP2C9 include nifedipine, tranylcypromine, and medroxyprogesterone acetate.[79] Another reversible mechanism results from competition between one xenobiotic and a metabolite of a second xenobiotic at its CYP enzyme substrate binding site. For example, the metabolites of clarithromycin and erythromycin produced by CYP3A inhibit further CYP3A activity. The effect is reversible and usually increases with repeated dosing.[79] Some reversible inhibitors bind so tightly to the enzyme that they essentially function as irreversible inhibitors.[69]

Irreversible inhibitors have reactive groups that covalently bind the enzyme, permanently. They display time-dependent inhibition because the amount of active enzyme at a given concentration of irreversible inhibitor will be different depending on how long the inhibitor is preincubated with the enzyme. Because the enzyme will never be reactivated, inhibition lasts until new enzyme is synthesized.[69] A relatively rare form of irreversible inhibition occurs when a reactive metabolite of a xenobiotic inhibits further metabolism of the substrate. This so-called suicide inhibition results in the destruction of the bound CYP enzyme.[28,77]

One measure of inhibitor potency is the inhibitory concentration, K_i, the concentration of the inhibitor that produces 50% inhibition of the enzyme. The more potent the inhibitor, the lower the value.[84] Values below 1 μmol/L are regarded as potent.[65] The azole antifungals are very potent with K_i values of 0.02 μmol/L.[84]

The impact of an inhibitor is also affected by the fraction of the substrate that is cleared by the inhibited, target enzyme. The inhibition of a CYP enzyme will have little impact if the enzyme only metabolizes a fraction of the affected drug.[65] Conversely, drugs that are primarily metabolized by a single CYP enzyme are more susceptible to interactions.[69] Astemizole and simvastatin are mainly biotransformed by CYP3A4. The potent and specific CYP3A inhibitor itraconazole prevents their metabolism, resulting in torsade de pointes dysrhythmias or rhabdomyolysis, respectively.[1]

■ SPECIFIC CYP ENZYMES

CYP1A1 and 1A2   While 1A1 is located primarily in extrahepatic tissue, 1A2 is a hepatic enzyme and is involved in the metabolism of 10 to 15% of all pharmaceuticals used today.[12,54] They both are very inducible by polycyclic aromatic hydrocarbons including those in cigarette smoke and charred food. They bioactivate several procarcinogens including benzo[*a*]pyrene.[45] Xenobiotics activated by the CYP1 enzyme family in the gastrointestinal tract are linked to colon cancer.[63]

CYP2C9 Approximately one-third of human CYP enzymes are in the CYP2 enzyme family, which, with 76 alleles, exhibits the greatest degree of genetic polymorphism.[25] The CYP2C9 enzyme is the most abundant enzyme of the CYP2C enzyme subfamily, which with CYP2C19, comprises approximately 10%–20% of the CYP enzymes in the liver.[25] This enzyme is associated with polymorphisms (Table 12–1).[12,63] This enzyme biotransforms S-warfarin, the more active isomer of warfarin. There is an association between slow metabolism and an increased risk of bleeding in patients on warfarin.[78]

CYP2D6 Twenty-five percent of all drugs used today, including 50% of the commonly used antipsychotics, are substrates for CYP2D6. It is sometimes called debrisoquine hydrolase as it was first identified with studying the metabolism of the antihypertensive agent debrisoquine.[12,41,63]

CYP2E1   This enzyme comprises 7% of the total CYP enzyme content in the human liver.[62] It metabolizes small organic compounds including alcohol, carbon tetrachloride, and halogenated anaesthetic agents.[84] It also biotransforms low-molecular-weight xenobiotics including benzene, acetone, and N-nitrosamines.[84] Some of these substrates are procarcinogens which are bioactivated by CYP2E1. Besides CYP1A2, this is the only other CYP enzyme linked to cancer.[63] The assessment for a relationship to cancer is particularly intense because many of its substrates are environmental xenobiotics. The induction of CYP2E1 is associated with increased liver injury by reactive metabolites of carbon tetrachloride and of bromobenzene[37] (Chap. 26). During the metabolism of substrates that include carbon tetrachloride, ethanol, acetaminophen, aniline, and N-nitrosomethylamine, CYP2E1 actively produces free radicals and other reactive metabolites associated with adduct formation and lipid peroxidation[15] (Chaps. 8 and 34). CYP2E1 is inhibited by acute elevations of ethanol, an effect illustrated by the capacity of acute administration of ethanol to inhibit the metabolism of acetaminophen.[10] The chronic ingestion of ethanol hastens its own metabolism through enzyme induction.

CYP3A4 CYP3A4 is the most abundant CYP in the human liver, comprising 40% to 55% of the mass of hepatic CYP enzymes.[12,25] The CYP3A4 enzyme is the most common one found in the intestinal mucosa and is responsible for much first-pass drug metabolism.[12] Numerous xenobiotics are metabolized by CYP3A4. It is involved in the biotransformation of 50% to 60% of all pharmaceuticals.[62,98] It has such broad substrate specificity because it accommodates especially large lipophilic substrates and can adopt multiple conformations. It can even simultaneously fit two relatively large compounds (ketoconazole, erythromycin) in its active site.[77]

An example of an adverse drug interaction related to this enzyme is the QT interval prolongation and torsades de pointes that occurred in patients taking terfenadine or astemizole in combination with ketoconazole or erythromycin.[68,75] Ketoconazole inhibits CYP3A4, causing a 15-fold to 72-fold increase in serum concentrations of terfenadine.[63] Bioflavonoids in grapefruit juice decrease metabolism of some substrates by 5-fold to 12-fold.[12,63] The CYP3A4 enzyme does not exhibit genetic polymorphism; however, there are large interindividual variations in enzyme concentrations.[98]

■ PHASE II BIOTRANSFORMATION REACTIONS

Phase II biotransformation reactions are synthetic, catalyzing conjugation of the products of phase I reactions or molecules with sites amenable to conjugation. Conjugation usually terminates the pharmacologic activity of the xenobiotic and greatly increases their water solubility and excretability.[56,87,96] Conjugation occurs most commonly with glucuronic acid, sulfates, and glutathione. Less common phase II reactions include amino acid conjugation, such as glycine, glutamic acid, and taurine; acetylation; and methylation.

Glucuronidation is the most common phase II synthesis reaction.[56] It occurs only within microsomal membranes. Glucuronyl transferase has relatively low substrate affinity but it has high capacity at higher substrate concentrations.[96] The glucuronic acid, donated by uridine diphosphate glucuronic acid (UDPG), is conjugated with the nitrogen, sulfhydryl, hydroxyl, or carboxyl groups of substrates. Smaller conjugates usually undergo renal elimination, whereas larger ones undergo biliary elimination.[51]

Sulfation complements glucuronidation because it is a high affinity but low capacity reaction that occurs primarily in the cytosol. For example, the affinity of sulfate for phenol is very high (the K_m is low), so that when low doses of phenol are administered, the predominant excretion product is the sulfate ester. Because the capacity of this reaction is readily saturated, glucuronidation becomes the main method of detoxification when high doses of phenol are administered.[56,96] Sulfate conjugates are highly ionized and very water soluble. Of note, sulfation is reversible by the action of sulfatases within the liver. The resultant metabolites may be resulfated and the cycle may repeat itself further.[96]

Glutathione *S*-transferases are important because they catalyze the conjugation of the tripeptide glutathione (glycine-glutamate-cysteine, or GSH) with a diverse group of reactive, electrophilic metabolites of phase I CYP enzymes. The reactive compounds initiate an attack on the sulfur group of cysteine, resulting in conjugation with GSH that detoxifies the reactive metabolite. Of the three phase II reactions addressed, hepatic concentrations of glutathione by far account for the greatest amount of cofactors used. While intracellular glutathione is difficult to deplete, when it does occur, severe hepatotoxicity often follows.[96] Some GSH conjugates are directly excreted. More commonly, the glycine and glutamate residues are cleaved and the remaining cysteine is acetylated to form an *N*-acetylcysteine (mercapturic acid) conjugate that is readily excreted in the urine. A familiar example of this detoxification is the avid binding of *N*-acetyl-*p*-benzoquinoneimine (NAPQI), the toxic metabolite of acetaminophen, by glutathione.[5,11]

As with the CYP enzymes, many phase II enzymes are inducible. For example, UDP-glucuronosyltransferase which executes glucuronidation is inducible via PXR, CAR, and AhR nuclear receptors after binding with rifampin, phenobarbital, and PAHs, respectively. Its activity varies 6-fold to 15-fold in liver microsomes.[90]

■ MEMBRANE TRANSPORTERS

While the focus on drug disposition has traditionally been on biotransformation, membrane transporters also impact drug disposition.[38] Because they usually occur after phase I and II biotransformation, their actions are sometimes called phase III metabolism.[42] Their physiologic role is to transport sugars, lipids, amino acids, and hormones so as to regulate cellular solute and fluid balance. However, they affect drug disposition just as do biotransformation processes by facilitating or preventing the passage of xenobiotics through membranes.[46] Uptake transporters translocate drugs into cells while efflux transporters export xenobiotics, often against concentration gradients, out of cells. Most transporters are in the adenosine triphosphate binding cassette (ABC) family of transmembrane proteins that use energy from ATP hydrolysis.[13,38] This family includes the P-glycoprotein family. Some transporters move substrates both into and out of cells. Organs important for drug disposition have multiple transporters that have overlapping substrate capabilities, a redundancy that enhances protection. In the small intestine, P-glycoprotein is important because it can actively extrude xenobiotics back into the intestinal lumen.[13] The degree of phenotypic expression of P-glycoprotein affects the bioavailability of many xenobiotics including paclitaxel, digoxin, and protease inhibitors. Hepatocyte efflux transporters move biotransformed xenobiotics into bile. Transporters in endothelial cells of the blood–brain barrier prevent

CNS entry of substrate xenobiotics.[13,38] As with biotransformation enzymes and nuclear receptors, membrane transporters may be inhibited or induced. Digoxin, a high affinity substrate for P-glycoprotein, has increased bioavailability when administered with P-glycoprotein inhibitors such as clarithromycin or atorvastatin.[38] Loperamide is a substrate for P-glycoprotein that limits its intestinal absorption or CNS entry. Coadministration with quinidine, a P-glycoprotein inhibitor, results in increased opioid CNS effects of loperamide.[38] As with the biotransformation enzymes, polymorphisms exist for membrane transporters. However, the clinical significance of these is not clear.[17]

MECHANISMS OF CELLULAR INJURY

Ideally and commonly, potentially toxic metabolites produced by phase I reactions are detoxified during phase II reactions. However, detoxification does not always occur. This section reviews mechanisms of cellular injury related to xenobiotic biotransformation.

■ SYNTHESIS OF TOXINS

Sometimes a xenobiotic is mistaken for a natural substrate by synthetic enzymes that biotransform it into an injurious compound. The incorporation of the rodenticide fluoroacetate into the tricarboxylic acid cycle is an example of this mechanism of toxic injury (Fig. 12–3).[70]

Another example is illustrated by analogs of purine or pyrimidine bases that are phosphorylated and inserted into growing DNA or RNA chains, resulting in mutations and disruption of cell division. This mechanism is used therapeutically with 5-fluorouracil (5-FU), an antitumor, pyrimidine base analog. When phosphorylated to 5-fluoro-dUTP and incorporated into growing DNA chains, it causes structural instability of the cellular DNA and inhibits tumor growth.[75]

■ INJURY BY METABOLITES OF BIOTRANSFORMATION

Many toxic products result from metabolic activation (Table 12–2).[43] The CYP enzymes most associated with bioactivation are 1A1, 1B1, 2A6, and 2E1 while 2C9 and 2D6 yield little toxic activation.[34]

Highly reactive metabolites exert damage at the site where they are synthesized; reacting too quickly with local molecules to be transported elsewhere. This commonly occurs in the liver, the major site of biotransformation of xenobiotics[33,82] (Chap. 26). However, the lungs, skin, kidneys, gastrointestinal tract, and nasal mucosa can also create toxic metabolites that cause local injury.[11,49] Overdoses of acetaminophen lead to excessive hepatic production of the highly reactive electrophile NAPQI, which initiates a damaging covalent bond with hepatocytes[5,10] (Chap. 34). Acute renal tubular necrosis also occurs in patients with overdose of acetaminophen, attributed to its biotransformation by
FIGURE 12–3. Pyruvate is converted to acetylcoenzyme A (acetyl-CoA), which enters the Krebs cycle as shown. Reducing equivalents, in the form of NADH, and FADH, donate electrons to a chain of cytochromes beginning with NADH dehydrogenase. These reactions "couple" the energy released during electron transport to the production of ATP. Ultimately, electrons combine with oxygen to form water. The sites of action of xenobiotics that inhibit oxidative metabolism are shown. The sites where thiamine functions as a coenzyme are also illustrated. DH = dehydrogenase.

TABLE 12–2. Examples of Xenobiotics Activated to Toxins by Human Cytochrome P450 Enzymes

CYP Enzyme	Substrate	Toxicity	CYP Enzyme	Substrate	Toxicity
1A1	Benzo[*a*]pyrene (PAH)	IARC Group 1	2E1	Carbon tetrachloride	IARC Group 2B
1A2	Acetaminophen	Hepatotoxicity		Chloroform	IARC Group 2B

prostaglandin H synthase within renal tubular cells to a highly reactive semiquinoneimine.[23,48]

Monoamine oxidases (MAOs) are mitochondrial enzymes present in many tissues. They oxidize many amines, including dopamine, epineph-rine, and serotonin, and xenobiotics such as primaquine and haloperidol. The metabolic activity of MAOs was responsible for the outbreak of parkinsonism associated with the use of methylphenyltetrahydropyridine (MPTP), an unintended by-product of attempts to synthesize a "designer" analog of meperidine, methylphenylpropionoxypiperidine (MPPP). After crossing the blood–brain barrier, MPTP is biotransformed by MAO in glial cells to methylphenyldihydropyridine (MPDP$^+$), which is nonen-zymatically converted to MPP$^+$. The MPP$^+$ is subsequently taken up by specific dopamine transport systems into dopaminergic neurons in the substantia nigra, resulting in inhibition of oxidative phosphorylation and subsequent neuronal death.[31]

■ FREE RADICAL FORMATION

Within an atom, it is energetically favorable for electrons to exist in lone pairs or as a part of a chemical bond. An element or compound with an unpaired electron, called a *radical* or *free radical*, is very reactive and it generally does not exist for long. It rapidly seeks other species in order to obtain another electron. Radicals include the superoxide anion $O_2 \bullet^-$, which is produced by adding an electron to O_2, and the highly reactive hydroxyl radical HO•, which is produced by splitting the H_2O_2 molecule into two. The H_2O_2 molecule itself is reactive and is also associated with injury. The superoxide and hydroxyl radicals react with other molecules in order to stabilize; however, by taking an electron in order to do so, they generate new free radical species, potentially initiating a chain reaction. The production of radicals is a normal occurrence and the human body has defense mechanisms. Some xenobiotics promote the formation of reactive oxidizing species to the extent that defensive mechanisms against oxidants are overwhelmed, a condition called *oxidative stress*. Oxidizing species are called such because, by reduc-ing themselves by taking away electrons, they oxidize the species from which they took the electrons.[7]

While oxidative stress may result in oxidative damage to nucleic acids and proteins, other classic targets are polyunsaturated fatty acids (PUFA) in cellular membranes, resulting in lipid peroxidation (the oxidative destruction of lipids). This attack removes the particularly reactive hydrogen atom, with its lone electron, from a methylene car-bon of a PUFA; leaving an unpaired electron and causing the formation of a lipid radical. This lipid radical attacks other PUFA, causing a chain reaction that destroys the cellular membrane. Membrane degradation products initiate inflammatory reactions in the cells, resulting in fur-ther damage.[82,7]

Molecular oxygen (O_2) has a lone pair of electrons in its orbit. Because oxygen is a relatively weak univalent electron acceptor (and most organic molecules are weak univalent electron donors), oxygen cannot efficiently oxidize amino acids and nucleic acids. However, the unpaired electrons of O_2 readily interact with the unpaired electrons of transition metals and organic radicals. Metals frequently catalyze

the creation of oxygen free radicals. The following is an example of hydroxyl radical formation: (1) A first step is the addition of an electron to O_2 to create the superoxide ion. (2) The very reactive superoxide combines with hydrogen and another electron to produce hydrogen peroxide. (3) In the presence of a metal ion catalyst such as iron, hydrogen peroxide undergoes various reactions to produce the hydroxyl radical. The dot in these formulas represents an unpaired electron, the hallmark of a free radical.[40,35,56]

$$(1)\ O_2 + e^- \rightarrow O_2^{\overline{\bullet}}$$

$$(2)\ O_2^{\overline{\bullet}} + 2H^+ + e^- \rightarrow H_2O_2$$

$$(3)\ H_2O_2 \xrightarrow[Fe^{2+}]{} OH^- + OH\bullet\ (Fenton)$$

$$H_2O_2 + O_2^{\overline{\bullet}} \xrightarrow[Fe^{2+}]{} O_2 + OH^- + OH\bullet\ (Haber\text{-}Weiss)$$
The damaging effects of the free radicals are decreased by reaction with antioxidants such as ascorbate, tocopherols, and glutathione.[56] Deficiencies of antioxidants, especially glutathione, are associated with increased oxidative damage. Free radicals are also neutralized by several enzymes, including peroxidase, superoxide dismutase, and catalase.

The ethanol-inducible CYP2E1 enzyme produces significant amounts of superoxide and peroxide free radicals, and, in the presence of iron, hydroxyl free radicals that readily initiate lipid peroxidation. This has been studied extensively in models of the metabolism of carbon tetrachloride, ethanol, and acetaminophen.[20] The formation of free radicals is implicated in the pulmonary injury caused by paraquat, the myocardial injury caused by doxorubicin, and the liver injury caused by carbon tetrachloride.[60,72] Paraquat reacts with NADPH to form a pyridinyl free radical, which, in turn, reacts with oxygen to generate the superoxide anion radical. Doxorubicin is metabolized to a semiquinone free radical in the cardiac mitochondria, which, in the presence of oxygen, forms a superoxide anion radical that initiates myocardial lipid peroxidation.[60] Carbon tetrachloride (CCl_4) is metabolized to the trichloromethyl radical ($\bullet CCl_3$) that binds covalently to cellular macromolecules. In the presence of oxygen, this is converted to the trichloromethylperoxyl radical ($\bullet CCl_3O_2$) that can initiate lipid peroxidation (Fig. 12–4).[73] See Chap. 106 for a more extensive discussion.
FIGURE 12–4. Carbon tetrachloride metabolism by the hepatocyte. Under hypoxic conditions, the CCl_3 radical is the predominant species formed. At higher oxygen tensions, CCl_3 radical is oxidized to the CCl_3OO radical, which is more readily detoxified by glutathione. Both free radicals bind to hepatocytes and cause cellular injury.

CRITICAL BIOCHEMICAL PATHWAYS AND XENOBIOTICS THAT AFFECT THEM

Energy metabolism is the foundation of cellular function. It provides high-energy fuel, predominantly in the form of ATP, for all energy-dependent cellular processes such as synthesis, active transport, and maintenance of electrolyte balance and membrane integrity. Numerous pathways interconnect glycogen, fat, and protein reserves in many tissues that store and retrieve ATP and glucose. The brain and red blood cells are entirely dependent on glucose for energy production, while other tissues can also use ketone bodies and fatty acids to synthesize ATP. Rapid cell death occurs if the production or use of ATP is inhibited, thus the goal of many metabolic processes is the production and mobilization of cellular energy.

Catabolic pathways that produce cellular energy include glycolysis, the tricarboxylic acid (citric acid, or Krebs) cycle, and oxidative phosphorylation via the electron transport chain. Citric acid occurs in the cytosol while the citric acid cycle and the electron transport chain are located within the mitochondria. Glycolysis produces small amounts of ATP through the anaerobic metabolism of glucose. Pyruvate, the end product of glycolysis, yields far more ATP when it is converted to acetylcoenzyme A (acetyl-CoA) and "processed" in the citric acid cycle (Fig. 12–3). Fat and protein yield their energy through their conversion to acetyl-CoA and other intermediates of the citric acid cycle. The citric acid cycle and oxidative phosphorylation, via the electron transport chain, result in most ATP synthesis. Oxidative phosphorylation disposes of electrons or "reducing equivalents" and converts their energy to ATP. A lack of oxygen stops the electron transport chain and ATP production. Oxidative metabolism is highly energy efficient, producing 36 moles of ATP for each mole of glucose metabolized, compared to the 2 moles of ATP produced by glycolysis. The following sections review the basics of cellular energy metabolism and several important xenobiotics that affect these critical metabolic functions (Table 12–3). [47,25]

■ GLYCOLYSIS

Glycolysis is the first biochemical pathway in the metabolism of glucose. Other sugars enter the glycolytic pathway after conversion to glycolytic intermediates (Fig. 12–5). The glycolytic process converts 1 molecule of glucose to 2 pyruvate molecules + 2 ATP + 2 NADH. Pyruvate may follow many paths. Under anaerobic conditions, the 2 pyruvates produced from 1 glucose molecule are reduced by lactate dehydrogenase to 2 lactate molecules in an NADH-requiring step that regenerates NAD^+. Thus, anaerobic glycolysis yields 2 molecules of lactate + 2 ATP. When NAD^+ and oxygen are available, pyruvate is converted by pyruvate decarboxylase to acetyl-CoA, which is transported from the cytosol into the mitochondria and condenses with oxaloacetate within the citric acid cycle to form citrate (Fig. 12–3).[47,25] In energy rich conditions, pyruvate is used for fatty acid synthesis.

Arsenate has a toxic effect at the glycolytic step where 3-phosphoglyceraldehyde dehydrogenase (3-PGA) catalyzes the oxidation of glyceraldehyde-3-phosphate to 1,3-diphosphoglycerate; a reaction that preserves a high-energy phosphate bond used to synthesize ATP in the next step of glycolysis (Fig. 12–5).[39] Arsenate acts as an analog of phosphate at this step. While glycolysis continues, the resultant unstable arsenate intermediate is rapidly hydrolyzed, preventing the subsequent synthesis of ATP.[39]

■ CITRIC ACID CYCLE

The citric acid cycle uses acetyl-CoA derived from glycolysis, fat, or protein to regenerate NADH from NAD^+. The cycle is a major source of

TABLE 12–3. Inhibitors of Glucose Metabolism and ATP Synthesis

Step/Location	Action	Examples	
Glycolysis	Inhibits NADH production	Iodoacetate (at GAPDH)	
		NO^+ (at GAPDH)	
	Bypasses ATP producing step	Arsenate, As^{5+}	
Gluconeogenesis	Inhibits NADH production	4-(Dimethylamino)phenol *p*-benzoquinone	
		Hypoglycin A	
Fatty acid metabolism	Inhibits NADH production	Aflatoxin	Protease inhibitors

FIGURE 12–5. During glycolysis, the anaerobic metabolism of 1 mole of glucose to 2 moles of pyruvate results in the net production of 2 moles of ATP. Arsenic inhibits 3-phosphoglycerate dehydrogenase, which catalyzes the oxidation of glyceraldehyde-3-phosphate to 1,3-biphosphoglycerate.

electrons (in the form of NADH) and is critical to the aerobic production of ATP (Fig. 12–3). Each acetyl-CoA molecule that is oxidized within the citric acid cycle ultimately forms one molecule each of CO_2 and guanosine triphosphate (GTP), and more importantly, 3 molecules of NADH and one molecule of flavin adenine dinucleotide ($FADH_2$) (reduced form), which enter the electron transport chain, producing a total of 15 molecules of ATP. In addition, the citric acid cycle provides important intermediates for amino acid synthesis and for gluconeogenesis.[47]

Various xenobiotics inhibit the citric acid cycle. The rodenticides, sodium fluoroacetate and fluoroacetamide, are combined with coenzyme A, CoASH, to create fluoroacetyl CoA (FAcCoA). The FAcCoA substitutes for acetyl CoA, entering the TCA cycle by condensation with oxaloacetate to form fluorocitrate, which inhibits citrate metabolism, resulting in inhibition of the cycle and termination of oxidative metabolism (Fig. 12–3) (Chap. 108).[70]

Thiamine is an important cofactor for 2 citric acid cycle enzymes: the conversion of pyruvate to acetyl-CoA by pyruvate decarboxylase and for the conversion of α-ketoglutarate to succinyl-CoA by α-ketoglutarate dehydrogenase (Fig. 12–3).[25] The life-threatening effects of thiamine deficiency are likely related to impairment of these enzyme functions (see Antidotes in Depth: Thiamine Hydrochloride). Arsenite inhibits these thiamine-dependent enzymes within the citric acid cycle.

■ **THE ELECTRON TRANSPORT CHAIN**

The electron transport chain is the location where the "phosphorylation" of oxidative phosphorylation occurs. Oxidative phosphorylation is the creation of high energy bonds by phosphorylation of ADP to ATP, "coupled" to the transfer of electrons from reduced coenzymes to molecular oxygen via the electron transport chain. The success of aerobic metabolism requires the disposal of electrons within NADH and FADH, generated by oxidative metabolism within the citric acid cycle. The electron transport chain consists of a series of cytochrome–enzyme complexes within the inner mitochondrial membrane (Fig. 12–3). Within these complexes, NADH is split into NAD^+ + H^+ + 2 electrons at complex I at the beginning of the chain while $FADH_2$ is split into FADH + H^+ + 2 electrons at complex II. These splits have 2 results. First, the regenerated NAD^+ and FADH are recycled back to the citric acid cycle, enabling oxidative metabolism to continue. Second, these actions provide the energy required to pump protons (H^+) from the mitochondrial matrix into the intermembrane space. This action causes the matrix to become relatively alkaline compared to the now acidified intermembrane space, resulting in a proton gradient across the inner mitochondrial membrane. This gradient provides the energy needed to create the high-energy bonds of ATP at complex V. The final step in oxidative phosphorylation is the reduction of molecular oxygen to water by cytochrome a-a_3 (Fig. 12–3).[47,25]

Mitochondria oxidize substrates, consume oxygen, and make ATP. Xenobiotics that interrupt oxidative phosphorylation impair ATP production by either inhibiting specific electron chain complexes or by acting as "uncouplers." Both of these mechanisms result in rapid depletion of cellular energy stores, followed by failure of ATP-dependent active transport pumps, loss of essential electrolyte gradients, and increases in cell volume.[27]

Inhibitors of specific cytochromes block electron transport and cause an accumulation of reduced intermediates proximal to the site of inhibition. This stops the regeneration of oxidized substrates for the citric acid cycle, particularly NAD^+ and FAD, further impairing oxidative metabolism. Cyanide, carbon monoxide, and hydrogen sulfide block the cytochrome a-a_3–mediated reduction of O_2 to H_2O. The very dramatic clinical effects of a significant cyanide exposure illustrate the importance of aerobic metabolism (Chaps. 125, 126). Other xenobiotics are less commonly associated with inhibition of the electron transport chain (Table 12–3).[91]

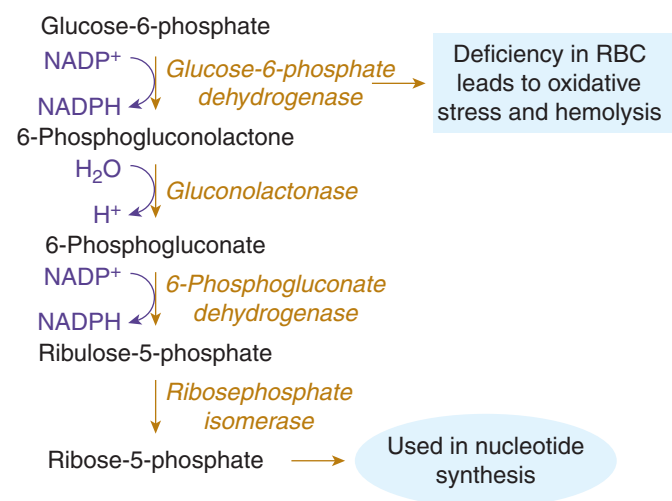
Severe metabolic acidosis is a clinical manifestation of xenobiotics that inhibits aerobic respiration. This metabolic acidosis is primarily caused by the accumulation of protons in the mitochondrial matrix that are not used in the production of ATP. While lactic acid accumulates, it is only a marker for metabolic acidosis associated with the impairment of oxidative metabolism.[76]

Xenobiotics that uncouple oxidative phosphorylation, like inhibitors of the electron transport chain, stop ATP synthesis. However, protons continue to be pumped into the intermembrane space, electrons continue to flow down the chain to reduce oxygen, and substrate consumption continues. Uncoupling xenobiotics destroy the proton gradient across the mitochondrial inner membrane. They allow the protons to cross back into the mitochondrial matrix, causing the loss of the proton gradient across the inner mitochondria membrane. Since it is the proton gradient that drives the production of ATP at complex V, ATP production is stopped. Thus, oxygen consumption is "uncoupled" from ATP production. The redox energy created by electron transport that cannot be coupled to ATP synthesis is released as heat. Various xenobiotics uncouple ATP synthesis (Table 12–3). A classic one is dinitrophenol, used in the past as an herbicide and as a weight-loss product (Chap. 39). Xenobiotics that are capable of carrying hydrogen ions across membranes are generally lipophilic weak acids. These xenobiotics must have an acid-dissociable group to carry the proton and a bulky lipophilic group to cross a membrane.[91] Dinitrophenol is able to carry its proton from

the cytosol into the more alkaline mitochondrial matrix where it dissociates, acidifying the matrix and destroying the proton gradient across the inner mitochondrial membrane. Interestingly, the phenolate anion of dinitrophenol is relatively lipophilic and can cross back out to the cytosol where it gains a new proton and starts the process over again. Long-chain fatty acids uncouple oxidative phosphorylation by a similar mechanism.[91] Fatal exposures to dinitrophenol and to pentachlorophenol, a wood preservative, are associated with severe hyperthermia attributed to heat generation by uncoupled oxidative phosphorylation.[58] Rats develop fatal hyperthermia following oral ingestion of dinitrophenol.[83] The hyperthermia and acidosis associated with severe salicylate poisoning are attributed to its uncoupling of oxidative phosphorylation.[81]

■ HEXOSE MONOPHOSPHATE SHUNT

The hexose monophosphate (HMP) shunt provides the only source of cellular NADPH. NADPH is used in biosynthetic reactions, particularly fatty acid synthesis, and is an important source of reducing power for the maintenance of sulfhydryl groups that protect the cell from free radical injury.[8,40] As noted earlier, G6PD is a key enzyme in the pathway (Fig. 12–6). Reduced glutathione, which is quantitatively the most important antioxidant in cells, depends on the availability of NADPH. Red blood cells (RBCs) are especially vulnerable to deficiency of NADPH, which results in hemolysis during oxidative stress.

Another manifestation of oxidative stress in RBCs is the oxidation of the iron in hemoglobin from Fe^{2+} to Fe^{3+}, producing methemoglobin that occurs both spontaneously and as a response to xenobiotics such as nitrites and aminophenols. Because most reduction of methemoglobin is done by NADH-dependent methemoglobin reductase, which is not deficient in persons who lack G6PD, such persons do not develop methemoglobinemia under normal circumstances. However, when oxidative stress is severe and methemoglobinemia develops, people who have G6PD deficiency have limited ability to use the alternative NADPH-dependent methemoglobin reductase (Chap. 127).[89]


■ GLUCONEOGENESIS

Gluconeogenesis facilitates the conversion of amino acids and intermediates of the citric acid cycle to glucose. It occurs primarily in the liver but also in the kidney. It is an important source of glucose during fasting and enables maintenance of glycogen stores. Most of the steps in the synthesis of glucose from pyruvate are simply the reverse of glycolysis, with three irreversible exceptions: (1) the conversion of glucose-6-phosphate to glucose; (2) the conversion of fructose-1,6-diphosphate to fructose-6-phosphate; and (3) the synthesis of phosphoenolpyruvate from pyruvate. The synthesis of phosphoenolpyruvate from pyruvate is especially complex. Pyruvate is first converted to oxaloacetate within the mitochondria, then to malate, which is transported out of the mitochondria and converted in the cytosol back to oxaloacetate, and then to phosphoenolpyruvate (Fig. 12–7). Certain amino acids—notably alanine, glutamate, and aspartate—are readily converted to citric acid cycle intermediates and can be used in the synthesis of glucose through this cycle.[47] Glycerol, produced by the breakdown of triglycerides in adipose tissue, is another substrate for gluconeogenesis.

The regulation of gluconeogenesis is opposite to that of glycolysis, stimulated by glucagon and catecholamines but inhibited by insulin. Gluconeogenesis requires the cytosolic NAD^+ and mitochondrial NADH. It is impaired by processes that increase the cytosol-reducing potential as measured by the cytosol $NADH/NAD^+$ ratio (see discussion below).

A number of xenobiotics impair gluconeogenesis, resulting in hypoglycemia when glycogen stores are depleted (Table 12–3). Hypoglycin A, an unusual amino acid found in unripe ackee fruit that is the cause of Jamaican vomiting sickness, produces profound hypoglycemia.[26,81,85] Its metabolite methylenecyclopropylacetic acid (MCPA) indirectly inhibits gluconeogenesis by blocking the oxidation of long-chain fatty acids, an important source of NADH in mitochondria. It also inhibits the metabolism of several glycogenic amino acids including leucine, isoleucine, and tryptophan; and blocks their entrance into the citric acid cycle. MCPA may also prevent the transport of malate out of the mitochondria.[74,85,86] Hypoglycemia also occurs in fasting patients with elevated ethanol concentrations.[3,29,49] This is likely a result of the impairment of gluconeogenesis by the increased cytosolic $NADH:NAD^+$ ratio associated with the metabolism of ethanol. This inhibits the two cytosolic steps that require NAD^+—the conversions of lactate to pyruvate and of malate to oxaloacetate.[2,49,73]

■ FATTY ACID METABOLISM

Fatty acid metabolism occurs primarily in hepatocytes. Fatty acids mobilized in adipose tissue enter hepatocytes by passive diffusion. Fatty acid synthesis is stimulated by insulin and inhibited by glucagon and epinephrine. Acetyl-CoA is the primary building block of free fatty acids (FFAs). In energy-repleted cells, fatty acids are combined with glycerol phosphate to form triacylglycerol (triglycerides), the first step in the synthesis of fat for storage. Hepatic triglycerides are bound to lipoprotein to form very-low-density lipoprotein (VLDL), then transported and stored in adipocytes. When hepatocytes are energy depleted, triglycerides are broken down to FFA and glycerol. This process is suppressed by insulin but supported by glucagon or epinephrine. FFAs undergo β-oxidation in the mitochondria, a process that breaks the FFA into acetyl-CoA molecules that can then enter the citric acid cycle. FFAs require activation before transport into the mitochondria. This is accomplished by acylcoenzyme A (acyl-CoA) synthetase, which adds a CoA group to the FFA in an energy-dependent synthetic reaction. These are transported into the

FIGURE 12–6. The oxidation reactions of the hexose monophosphate shunt are an important source of NADPH for reductive biosynthesis and for protection of cells against oxidative stress. Deficiency of G6PD, the first enzyme in the pathway, may result in RBC hemolysis during oxidative stress.

FIGURE 12–7. Gluconeogenesis reverses the steps of glycolysis, with the exception of the bypass of the three irreversible steps shown. The step from pyruvate to phosphoenolpyruvate involves both cytosolic and mitochondrial reactions that use ATP. Hypoglycin A inhibits the intramitochondrial conversion of oxaloacetate to malate by depleting NADH through interference with β-oxidation of fatty acids. Ethanol decreases cytosolic supplies of NAD⁺. Pyruvate kinase (PK) and phosphofructokinase (PFK), the enzymes whose activities are regulated by glucagon via cyclic adenosine monophosphate (cAMP)-dependent phosphokinase, are shown.

FIGURE 12–8. Steatosis, an accumulation of fat, results when xenobiotics interfere with the oxidation of fatty acids. Other processes that may be associated with intracellular accumulation of fat include: impaired lipoprotein synthesis; impaired lipoprotein release; increased mobilization of free fatty acids; increased uptake of circulating lipids; and increased production of triglycerides. β-Oxidation takes place in the mitochondria after transport of fatty acids from the cellular cytosol across the mitochondrial membrane. The enzymes involved are (a) acyl-CoA synthetase; (b) carnitine palmitoyltransferase I; (c) carnitine acylcarnitine translocase; and (d) carnitine palmitoyltransferase II. Acyl-CoA is the intramitochondrial substrate for β-oxidation. Potential mechanisms of inhibition of β-oxidation include induction of carnitine deficiency, inhibition of the transferase or translocase, and increased NADH:NAD⁺ ratio via increased use of NAD⁺ or by inhibition of NADH use. The specific site of action is not defined for many toxins that cause steatosis.

mitochondria by a process that utilizes cyclical binding to carnitine, a "carnitine shuttle" (Fig. 12–3). Once inside the mitochondria, FFAs are converted to acetyl-CoA by β-oxidation, involving the sequential removal of 2-carbon fragments, each time acting at the second carbon (the β carbon) position of the fatty acid. Each 2-carbon molecule removed from the FFA produces one NADH and one FADH₂, which are oxidized in the electron transport chain, and one mole of acetyl-CoA, which enters the TCA cycle. This process produces 1.3 times more ATP per molecule of carbon metabolized than does the oxidative metabolism of glucose or other carbohydrates.[47]

Many xenobiotics interrupt fatty acid metabolism at various steps, resulting in accumulation of triglycerides in the liver (Table 12–3; Fig. 12–8). The mechanisms of disruption of fatty acid metabolism are poorly defined.[16] Some xenobiotics, including ethanol, hypoglycin, and nucleoside analogs (Chap. 56); inhibit β-oxidation, at least indirectly, through effects on NADH concentrations. Protease inhibitors are associated with a syndrome of peripheral fat wasting, central adiposity, hyperlipidemia, and insulin resistance.

The condition of alcoholic ketoacidosis is related in part to inhibition of gluconeogenesis in the alcoholic patient and in part to an exuberant response to nutritional needs by the fatty acid machinery. Vomiting in the alcoholic patient leads to decreased intake of carbohydrate, which stimulates a starvation response with increases in serum glucagon, cortisol, growth hormone, and epinephrine concentrations, and decreases in serum insulin. When the need for carbohydrate is not met by gluconeogenesis, lipolysis, which is normally inhibited by insulin, is intensified and fatty acid mobilization progresses. Glucagon stimulates mitochondrial carnitine acyltransferase, and β-oxidation of fatty acids is increased. The increased mitochondrial NADH:NAD⁺ ratio favors the production of β-hydroxybutyrate over acetoacetate, its oxidized form. The administration of fluids, dextrose, and thiamine to the alcoholic patient leads to correction of this process.[57]

SUMMARY

Humans are exposed to a wide variety of xenobiotics. Some, including therapeutic drugs, are harmless at low doses and toxic only at high doses. The toxicity of those xenobiotics that interrupt important

biologic functions or cause cellular injury is dose related and often rapidly evident. The diverse mechanisms of toxic injury have been discussed in general terms. The capacity of xenobiotics to cause injury is clearly a function of many factors specific to the xenobiotic, the tissue injured, and the individual.

APPENDIX
Common Cytochrome P450 Substrates, Inhibitors, and Inducers[1]

	SUBSTRATES		INHIBITORS		INDUCERS
1A2	**Analgesics** Acetaminophen Naproxen **Antidepressants** Amitriptyline Clomipramine Duloxetine[2] Fluvoxamine Imipramine Mirtazapine **Antipsychotics** Clozapine Haloperidol Olanzapine Thioridazine	**Cardiovascular** Mexiletine Propranolol Verapamil **Hormones** Estradiol Flutamide **Other Medications** Caffeine Cyclobenzaprine Ondansetron Theophylline[3] Tizanidine[3] Warfarin-R Zolmitriptan	**Antibiotics** **(Fluoroquinolones)** Ciprofloxacin Norfloxacin **Antibiotics** **(Macrolides)** Clarithromycin Erythromycin Troleandomycin **Antidepressants** Duloxetine Fluvoxamine	**Cardiovascular** Amiodarone Mexiletine Mibefradil[4] Verapamil **Other Medications** Acyclovir Cimetidine Famotidine Grapefruit juice	**Anticonvulsants** Carbamazepine Phenobarbital Phenytoin **Proton Pump** **Inhibitors** Lansoprazole Omeprazole **Other** Nafcillin Polycyclic hydrocarbons (chargrilled meat, cigarette smoke) Rifampicin Rifampin Ritonavir[5]
3A4	**Antibiotics** Clarithromycin Dapsone Erythromycin Rifabutin Telithromycin **Antidepressants** (Minor for most) Amitriptyline Buspirone[2] Citalopram Clomipramine Escitalopram Imipramine Mirtazapine Nefazodone Sertraline Trazodone **Antidysrhythmics** Amiodarone Disopyramide Quinidine[3] **Antifungals** Itraconazole Ketoconazole Voriconazole	**Immune** **Modulators** Cyclosporine[3] Sirolimus[3] Tacrolimus[3] Tamoxifen **Opioids** Alfentanil[3] Buprenorphine Codeine Dextromethorphan Fentanyl[3] Meperidine Methadone Morphine Oxycodone Propoxyphene Sufentanyl Tramadol **Protease** **Inhibitors** Indinavir Nelfinavir Ritonavir Saquinavir[2]	**Antidepressants** Fluoxetine Fluvoxamine Nefazodone Norfluoxetine Sertraline **Antibiotics** **(Macrolide)** Clarithromycin Erythromycin Telithromycin **Antibiotics** Chloramphenicol Ciprofloxacin Isoniazid Norfloxacin **Antifungals** Fluconazole Itraconazole Ketoconazole Voriconazole	**Calcium** **Channel** **Blockers** Diltiazem Mibefradil[4] Nifedipine Verapamil **Protease** **Inhibitors** Amprenavir Atazanavir Fosamprenavir Indinavir Nelfinavir[1] Ritonavir[5] Saquinavir **Other** Amiodarone Cimetidine Cisapride Cocaine Cyclosporine Ergotamines Felbamate Grapefruit juice[1]	**Antibiotics** Rifabutin Rifampicin Rifampin Rifapentine **Protease** **Inhibitors** Amprenavir Efavirenz Nelfinavir[1] Nevirapine Ritonavir[5] **Anticonvulsants** Carbamazepine Felbamate Oxcarbazepine Phenobarbital Phenytoin Topiramate **Steroids** Dexamethasone Methylprednisolone Prednisolone **Other** St. John's wort

	SUBSTRATES		INHIBITORS		INDUCERS
	Antihistamines Astemizole[4] Chlorpheniramine Desloratidine Loratidine Terfenadine[4] **Antipsychotics** (Minor for most) Aripiprazole Clozapine Haloperidol Quetiapine Risperidone Thioridazine Ziprasidone **Benzodiazepines** Alprazolam Clonazepam Diazepam Midazolam[2] Triazolam[2] **Calcium Channel Blockers** Amlodipine Diltiazem Felodipine[2] Nicardipine Nifedipine Nimodipine Nisoldipine Verapamil	**Proton Pump Inhibitors** (Minor for most) Esomeprazole Lansoprazole Omeprazole Pantoprazole Rabeprazole **Statins** Atorvastatin Cerivastatin[4] Lovastatin[2] Simvastatin[2] **Steroids and Hormones** Dexamethasone Estradiol Fluticasone[2] Hydrocortisone Methylprednisolone Prednisone Progesterone **Other Medications** Carbamazepine Cisapride Cyclobenzaprine Diclofenac Ergotamines[3] Losartan Ondansetron Pioglitazone Propranolol Salmeterol Sildenafil[2] Vardenafil[2] Warfarin-R Zaleplon Zolpidem				
2C9	**Angiotensin II Blockers** Irbesartan Losartan **Hypoglycemics** Chlorpropamide Glimepiride Glipizide Glyburide Tolbutamide **NSAIDs** Celecoxib Diclofenac Flurbiprofen Ibuprofen Indomethacin Meloxicam Naproxen Piroxicam	**Other Medications** Amitriptyline Fluoxetine Fluvastatin Phenobarbital Phenytoin[3] Rosiglitazone Tamoxifen Sertraline Rosuvastatin Warfarin-S[3]	**Antibiotics (Macrolide)** Clarithromycin Erythromycin Troleandomycin **Antibiotics** Isoniazid Metronidazole Sulfamethoxazole **Antidepressants** Fluoxetine Fluvoxamine Paroxetine Sertraline	**Antifungals (Azoles)** Fluconazole Itraconazole Ketoconazole Voriconazole **Other** Amiodarone Cimetidine Ritonavir[5] Grapefruit juice Valproic acid	**Anticonvulsants** Carbamazepine Phenobarbital Phenytoin **Other** Nelfinavir Rifampicin Rifampin Rifapentine Ritonavir[5] St. John's wort

	SUBSTRATES		INHIBITORS		INDUCERS
2C19	**Antidepressants** Amitriptyline Citalopram Clomipramine Desipramine Doxepin Escitalopram Fluoxetine Imipramine **Anticonvulsants** Diazepam Phenobarbital Phenytoin	**Proton Pump Inhibitors** (Major for most) Esomeprazole Lansoprazole Omeprazole[2] Pantoprazole Rabeprazole **Other Medications** Atomoxetine Carisoprodol Clopidogrel Cyclophosphamide Indomethacin Nelfinavir Olanzapine Methadone Progesterone Propranolol Voriconazole Warfarin-R	**Antibiotics (Macrolide)** Clarithromycin Erythromycin Troleandomycin **Antidepressants (SSRI)** Citalopram Fluoxetine Fluvoxamine Paroxetine Sertraline **Antifungals (Azoles)** Fluconazole Ketoconazole Voriconazole	**Anticonvulsants** Felbamate Oxcarbazepine Topiramate **Other Medications** Chloramphenicol Cimetidine Grapefruit juice Indomethacin Isoniazid Ritonavir[5] Ticlopidine **Proton Pump Inhibitors** Lansoprazole Omeprazole Pantoprazole Rabeprazole	**Anticonvulsants** Carbamazepine Phenobarbital Phenytoin **Other** Prednisone Rifampicin Rifampin Rifapentine Ritonavir[5] St. John's wort
2D6	**Antidepressants (SSRI)** Escitalopram Fluoxetine Fluvoxamine Paroxetine Sertraline **Antidepressants (Other)** (Major for most) Amitriptyline Clomipramine Desipramine[2] Doxepin Duloxetine Escitalopram Imipramine Maprotiline Mirtazapine Nortriptyline Venlafaxine **Antidysrhythmics** Flecainide Mexiletine Quinidine **Antihistamines** Chlorpheniramine Desloratidine Diphenhydramine Loratadine	**Antipsychotics** (Major for most) Aripiprazole Chlorpromazine Fluphenazine Haloperidol Perphenazine Promethazine Risperidone Thioridazine[3] **β-Adrenergic Antagonists** Metoprolol Pindolol Propranolol Timolol **Opioids** Codeine Dextromethorphan Hydrocodone Oxycodone Tramadol **Other Medications** Amphetamine Atomoxetine Cyclobenzaprine Debrisoquine Metoclopramide Ondansetron Tamoxifen	**Antidepressants** Bupropion Citalopram Duloxetine Escitalopram Fluoxetine Paroxetine Sertraline **Antihistamines** Chlorpheniramine Cimetidine Diphenhydramine Hydroxyzine Ranitidine **Antipsychotics** Chlorpromazine Haloperidol Perphenazine Promethazine Thioridazine	**Other Medications** Amiodarone Celecoxib Chloramphenicol Chloroquine Cocaine Doxorubicin Ticlopidine Methadone Ritonavir[5]	Dexamethasone Rifampicin Rifampin Ritonavir[5] Tramadol

	SUBSTRATES		INHIBITORS	INDUCERS
2E1	Acetaminophen Chlorzoxazone Ethanol Theophylline Isoniazid	**Inhaled Anesthetics** Enflurane Halothane Isoflurane Methoxyflurane	Disulfiram Fomepizole	Ethanol Isoniazid St. John's wort

[1] This list is not complete and may reflect some variation in author opinions as to whether a xenobiotic is a substrate, inhibitor, or inducer. Many drugs are metabolized by several isoenzymes with some representing major pathways and others minor pathways.

[2] The area-under-the-curve of this substrate has been shown to increase 5-fold or more when coadministered with a known CYP3A inhibitor.

[3] This substrate has a narrow therapeutic range and safety concerns occur when coadministered with an inhibitor.

[4] These medications were withdrawn from the market due to complications associated with drug–drug interactions.

[5] Ritonavir has paradoxical dose- and time-dependent inhibitory and induction effects.

NSAID – Non-steroidal anti-inflammatory drugs; PPI – proton pump inhibitors.

CHAPTER 13

NEUROTRANSMITTERS AND NEUROMODULATORS

Steven C. Curry, Kirk Charles Mills, Anne-Michelle Ruha, and Ayrn D. O'Connor

This chapter reviews the normal physiology of neurotransmission, the molecular action and biochemistry of several major neurotransmitters and their receptors, and the toxicologic mechanisms by which numerous xenobiotics act at the molecular level. Acetylcholine, norepinephrine, epinephrine, dopamine, serotonin, γ-aminobutyric acid (GABA), γ-hydroxybutyrate (GHB), glycine, glutamate, and adenosine are the neurotransmitters and neuromodulators of toxicologic interest that are discussed in this chapter.

When examining molecular actions of xenobiotics on neurotransmitter systems, it quickly becomes apparent that substances rarely possess single pharmacologic actions. As examples, doxepin, in part, antagonizes voltage-gated sodium channels, histaminic H_1 and H_2 receptors, α-adrenoceptors, muscarinic acetylcholine receptors, dopamine D_2 receptors, and $GABA_A$ receptors; prevents potassium efflux; and inhibits norepinephrine, serotonin, and adenosine uptake. And carbamazepine blocks voltage-gated sodium channels; inhibits uptake of norepinephrine, adenosine, and serotonin; antagonizes adenosine and muscarinic receptors; and activates $GABA_B$ and mitochondrial benzodiazepine receptors. For obvious reasons, then, this chapter cannot include every action of every xenobiotics on the nervous system. Nor is it meant to be a complete discussion of toxic syndromes produced by various xenobiotics, as these are discussed in specific chapters. Rather, it provides a general and basic understanding of the mechanisms of action of various xenobiotics affecting neurotransmitter function and receptors, especially in the central nervous system. With this focus, the clinical effects produced are more easily understood and predicted, and specific treatments can be rationally undertaken. Given the complexity of the nervous system and the numerous actions of a given xenobiotic, it is not always clear which neurotransmitter system is producing an observed effect. Therefore, specific xenobiotics may be found in several sections. An attempt is made to note a xenobiotics main mechanism of action, although other actions are noted when possible.

NEURON PHYSIOLOGY AND NEUROTRANSMISSION

■ MEMBRANE POTENTIALS, ION CHANNELS, AND NERVE CONDUCTION

Membrane-bound sodium–potassium adenosine triphosphatase (ATPase) moves three sodium ions (Na^+) from inside the cell to the interstitial space while pumping two potassium ions (K^+) into the cell. Because the cell membrane is not freely permeable to large, negatively charged intracellular molecules, such as proteins, an equilibrium results in which the inside of the neuron is negative with respect to the outside. This typical neuronal resting membrane potential is –65 mV.

Sodium, calcium (Ca^{2+}), K^+, and chloride (Cl^-) ions move into and out of neurons through ion channels. Ions always move passively down electrochemical gradients through ion channels, which are long polypeptides comprising several subunits that span the plasma membrane several times. Many different ion channels are structurally comparable, sharing similar amino acid sequences.[15] Channels for a specific ion can also vary in structure, depending on the specific subunits that have combined to form the channel. Because of structural similarity of different channels, it is not surprising that many xenobiotic are able to bind to more than one type of ion channel.

More than 40 different ion channels have been described in various nerve terminals,[102] and it is estimated that a human being contains hundreds of different varieties of ion channels for Na^+, Cl^-, Ca^{2+}, and K^+. Most ion channels fall into two general classes: voltage-gated (voltage-dependent) ion channels and ligand-gated ion channels.[102] Voltage-gated channels open or close in response to changes in membrane potential. Ligand-gated channels open or close when a ligand (eg, neurotransmitter) binds to the channel to change its configuration.

A commonly accepted model describes voltage-gated Na^+ channels and some other voltage-gated ion channels in 3 possible states. Using Na^+ channels as an example, the Na^+ channel is closed at rest and impermeable to Na^+, preventing Na^+ from moving into the cell. When the channel undergoes activation, the channel opens, allowing Na^+ to move intracellularly, down its electrochemical gradient. The channel then undergoes a third conformational change by becoming inactivated, preventing further influx of Na^+. The term *recovery* describes the conversion of inactive channels back to the resting state, a process that requires repolarization of the cell membrane.

Depolarization of a neuron usually results from an initial inward flux of cations (Na^+ or Ca^{2+}), or prevention of K^+ efflux. The fall in membrane potential (movement toward 0 mV) results in further activation of these voltage-dependent Na^+ channels, allowing yet a greater influx of cations. When the membrane potential falls to threshold, Na^+ channels are activated en masse, and there is a large influx of Na^+.

Depolarization of a segment of the neurolemma causes the adjacent neuronal membrane to reach threshold, resulting in the propagation of an action potential down the neuron. Sodium channel activation is quickly followed by inactivation, ending depolarization. Over the short-term, repolarization of the neuron subsequently occurs mainly from efflux of K^+ and some influx of Cl^-.

■ NEUROTRANSMITTER RELEASE

Neurotransmitters are chemicals that are released from nerve endings into the synapse, where they produce effects by binding to receptors on postsynaptic or presynaptic cell membranes. The receptors may be on either other neurons or effector organs such as smooth muscle. Concentrations of neurotransmitters in cytoplasm are usually low because of rapid enzymatic degradation and diffusion out of the nerve ending. To provide a source of neurotransmitters that is protected from degradation and that can rapidly be released, neurotransmitters are concentrated and stored within vesicles in the axonal nerve terminal. As a wave of depolarization from Na^+ influx reaches the nerve ending, the membrane depolarization causes voltage-gated Ca^{2+} channels to open, allowing Ca^{2+} to move rapidly into the cell. This influx of Ca^{2+} triggers exocytosis of vesicle contents into the synapse. The voltage-gated Ca^{2+} channels responsible for inward Ca^{2+} currents that trigger neurotransmitter release are members of the Ca_v2 subfamily (N, P/Q, and R subtypes).[106,129] Ziconotide is a derivative of a conotoxin that is used for analgesia; it blocks N-type calcium channels on nociceptive neurons in the dorsal root to prevent neurotransmitter release. Cardiovascular calcium channel blockers used in clinical practice do not block these subtypes of voltage-dependent Ca^{2+} channels, but block the L-subtype. However, L-subtype Ca^{2+} channels reside elsewhere on

neurons, which explains the ability of traditional Ca^{2+} channel blockers to affect some neurologic functions.

■ VESICLE TRANSPORT OF NEUROTRANSMITTERS

The pH inside neurotransmitter vesicles is about 5.5, which is lower than that in the cytoplasm. A vacuolar ATPase (V-ATPase) in the vesicular membrane is responsible for movement of protons into the vesicular lumen at the expense of ATP hydrolysis. Vesicular uptake pumps (transporters) that move neurotransmitters or their precursors from the cytoplasm into the vesicle lumen, in turn, are powered by the electrochemical H^+ gradient; that is, the movement of an H^+ out of the vesicle into the cytoplasm is coupled to the movement of a neurotransmitter from the cytoplasm into the vesicle.

Various vesicular transporters for neurotransmitters have been sequenced to date. VGAT transports GABA and glycine. VMAT2 transports all three monoamines, dopamine, norepinephrine, and serotonin (VMAT1 transports monoamines into nonneuronal vesicles). VAChT is responsible for acetylcholine (ACh) transport, and 3 VGluTs (VGluT1-3) move glutamate into vesicles.

Neurotransmitters are confined within the vesicle, to a great extent, by ion trapping, as they are more ionized and less able to diffuse back out of the vesicle at the lower pH. Anything that causes a decrease in the pH gradient across the vesicle membrane results in the movement of neurotransmitters into the cytoplasm.[155] For example, amphetamines move into vesicles, where they buffer protons, causing the movement of monoamine neurotransmitters out of vesicles, and raising cytoplasmic concentrations of neurotransmitters, and ultimately raising the synaptic monoamine concentration.[155,156]

■ NEUROTRANSMITTER UPTAKE

Although acetylcholine is inactivated in the synapse by enzymatic degradation, other neurotransmitters have their synaptic effects terminated by active uptake into neurons or glial cells. These plasma membrane neurotransmitter transporters are distinct from those transporters responsible for movement of neurotransmitters into vesicles. Cell membrane transporters (uptake pumps) for different neurotransmitters are Na^+-dependent transport proteins, during which the uptake of neurotransmitters is accompanied by the movement of Na^+ across the synaptic membrane.[1]

Neurotransmitter uptake transporters have been subdivided into two main families.[1] One family (SLC6) includes structurally similar uptake pumps for GABA, glycine, norepinephrine, dopamine, and serotonin. They generally comprise 600–700 amino acids and form loops spanning the plasma membrane 12 times. Four GABA uptake transporters (GAT-1 through GAT-4) transport GABA into neurons and glial cells. DAT, SERT, and NET are responsible for uptake of dopamine, serotonin, and norepinephrine, respectively. GLYT-1 and GLYT-2 are responsible for glycine uptake into neurons or astrocytes.

The second family (SLC1) comprises 5 glutamate uptake transporters (excitatory amino acid transporters; EAATs), which appear to traverse the plasma membrane 10 times and move glutamate from the synapse into glial cells and neurons.

Several properties make transporter proteins of particular toxicologic significance. First, they are capable of moving neurotransmitters in either direction; when cytoplasmic neurotransmitter concentrations are significantly elevated, neurotransmitters can be transported back into the synapse. Second, these transporters are not always completely specific. For instance, the uptake transporter for norepinephrine can pump dopamine and other biogenic amines into the neuron. Third, a xenobiotic that acts at the level of the membrane transporter may affect functions of several different neurotransmitters, depending on

its specificity for a particular transporter. As an example, fluoxetine is fairly specific at inhibiting uptake of serotonin, whereas cocaine inhibits the uptake of serotonin, norepinephrine, and dopamine.

■ NEUROTRANSMITTER RECEPTORS

Channel Receptors The first general class of neurotransmitter receptors comprises ligand-gated ion channels (channel receptors or ionotropic receptors), in which the receptor for the neurotransmitter is part of an ion channel. These channels comprise multiple subunits which combine in various combinations to create channels that vary in their response to a given neurotransmitter or other agonist/antagonist. By binding to its receptor, the neurotransmitter allosterically changes the configuration of the ion channel so that ions traverse the channel in greater quantities per unit time. As an example, the acetylcholine nicotinic receptor at the neuromuscular junction is a ligand-gated Na^+ channel. When acetylcholine binds to the nicotinic receptor, the channel's configuration changes, allowing Na^+ to move into the cell and trigger an action potential. (The action potential then propagates down muscle via voltage-gated Na^+ channels.) Table 13–1 lists other examples of channel receptors.

G Protein–Coupled Receptors The second general class of neurotransmitter receptors are linked to G proteins, which are part of a superfamily of proteins with guanosine triphosphatase (GTPase) activity responsible for signal transduction across plasma membranes.[146] G proteins comprise three polypeptide subunits: α, β, and γ chains. These chains span the plasma membrane several times, and they associate with a separately transcribed neurotransmitter receptor that spans the cell membrane 7 times, with an external binding site for neurotransmitters. Some receptors (eg, $GABA_B$ receptor) coupled to G proteins are dimers comprising 2 separate proteins, both of which must be present for activity.

Both the α subunit and the βγ subunit of a G protein may account for activity resulting from a neurotransmitter binding to its receptor. The α chain normally binds guanosine diphosphate (GDP) in the cytoplasm and is inactive. When a neurotransmitter binds to its receptor on the outside of the cell membrane, GDP dissociates from the α chain and guanosine triphosphate (GTP) binds in its place, activating the α subunit. The activated chain then dissociates from receptor and from the β and γ chains. Both the activated α subunit and βγ subunits modulate effectors in the plasma membrane.[146] The effector influenced by α or βγ subunits may be an enzyme that

TABLE 13–1. Types of Neurotransmitter and Neuromodulator Receptors

Ion Channel	G Protein-Coupled Receptor
ACh nicotinic	ACh muscarinic
$GABA_A$, $GABA_C$	$GABA_B$
Glycine (inhibitory)	Dopamine
Glutamate AMPA	Norepinephrine
Glutamate NMDA	$5-HT_{1,2,4-7}$
Glutamate kainate	Adenosine
$5-HT_3$	Glutamate metabotropic

ACh = acetylcholine; AMPA = amino-3-hydroxy-5-methyl-4-isoxazole propionate; GABA = γ-aminobutyric acid; 5-HT = 5-hydroxytryptamine (serotonin); NMDA = N-methyl-D-aspartate.

the subunits stimulate or inhibit (eg, adenylate cyclase) or an ion channel that is opened or closed directly or through other chemical reactions (eg, channel phosphorylation).[30] Intrinsic GTPase activity in the α chain eventually converts the GTP to GDP, inactivating the α subunit and allowing it to reassociate with the βγ chains and the neurotransmitter receptor, terminating consequences of neurotransmitter binding.[146]

G proteins are mainly categorized by the type of α chain they contain. The three main families of G proteins coupled to neurotransmitter receptors are G_s (containing the α subunit $α_s$), $G_{i/o}$ (containing $α_i$ or $α_o$), and G_q (containing $α_q$). G_s stimulates membrane-bound adenylate cyclase; activation of a neurotransmitter receptor coupled to G_s causes a rise in intracellular 3′,5′-cyclic adenosine monophosphate (cAMP) concentration.[86] Neurotransmitter receptors activating G_i may inhibit adenylate cyclase or modulate K^+ and Ca^{2+} channels. Receptors coupled to G_q act through membrane-bound phospholipase C to increase intracellular calcium concentrations. Table 13–1 lists the neurotransmitter receptors coupled to G proteins. A given neurotransmitter can activate different classes of receptors (eg, ion-channel and G protein) or different types of receptors in the same class. For example, $GABA_A$ receptors are Cl^- channels, whereas $GABA_B$ receptors are coupled to G proteins. Dopamine D_1–like receptors are linked to G_s, whereas D_2–like receptors are linked to G_i or G_o.

Importantly, a single G protein–coupled receptor may activate more than one type of G protein in the same cell, depending on various circumstances, including duration of receptor activation. Receptor downregulation occurs at various levels. For example, prolonged receptor activation results in receptor phosphorylation by G protein kinases (GPKs) which causes receptor binding to a family of proteins, the arrestins, preventing further activation of the G protein by the receptor, and eventually triggers receptor endocytosis.[83,175]

■ NEURONAL EXCITATION AND INHIBITION

Excitatory neurotransmitters usually act postsynaptically by causing Na^+ or Ca^{2+} influx, or by preventing K^+ efflux, triggering depolarization and an action potential (Fig. 13–1). These effects may be mediated by channel or G protein–coupled receptors.

Postsynaptic inhibition can be mediated by channel receptors or by receptors coupled to G proteins (Fig. 13–1). Inhibition is usually accomplished by neuronal influx of Cl^- or efflux of K^+ to hyperpolarize the neuron and move membrane potential farther away from threshold, making it more difficult for a given stimulus to depolarize the membrane to threshold voltage.

Presynaptic inhibition, the prevention of neurotransmitter release, is usually mediated by receptors coupled to G proteins. When a neurotransmitter released from a neuron binds to a receptor on that same neuron to limit further neurotransmitter release, the receptor is termed an *autoreceptor*.[139] Autoreceptors reside on dendrites, cell bodies, axons, and presynaptic terminals. Autoreceptors on dendrites and cell bodies (somatodendritic autoreceptors) usually inhibit further neurotransmitter release by increasing K^+ efflux, thereby hyperpolarizing the neuron away from threshold (Fig. 13–2). However, activation of autoreceptors found on presynaptic terminals (terminal autoreceptors) usually limits increases in intracellular Ca^{2+} concentration by limiting Ca^{2+} influx or preventing Ca^{2+} release from intracellular stores, impairing exocytosis of neurotransmitter vesicles (Fig. 13–2). Types of neurotransmitter receptors that serve as autoreceptors also usually reside postsynaptically, where they may mediate different physiologic effects.

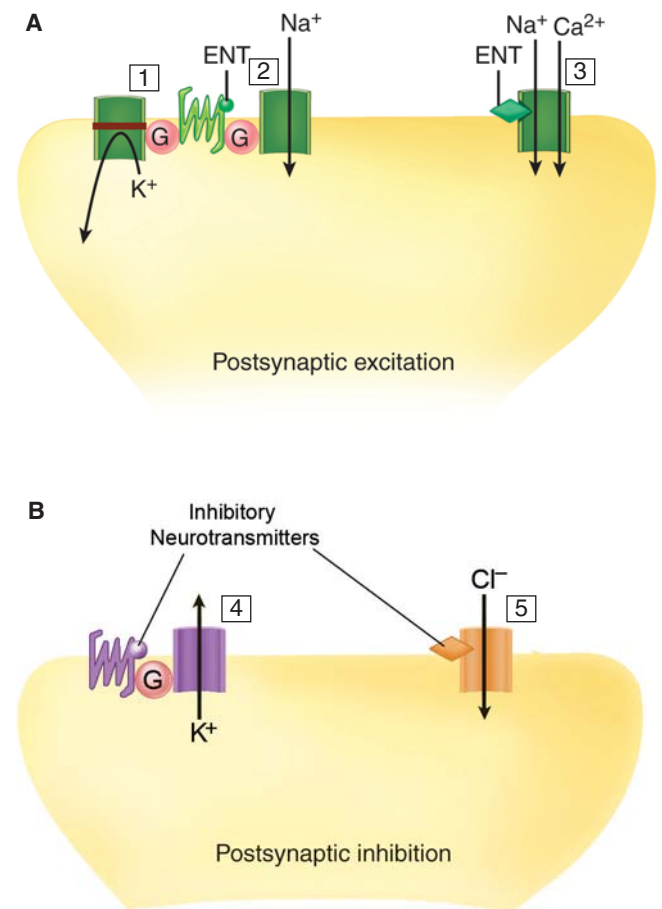
Presynaptic nerve terminal inhibition of neurotransmitter release is not limited to actions by autoreceptors. Presynaptic terminal inhibitory


FIGURE 13–1. Common mechanisms of postsynaptic excitation and inhibition. (**A**) An excitatory neurotransmitter (ENT) binds to receptors linked to G proteins to prevent K^+ efflux [1] or to allow Na^+ influx [2], producing membrane depolarization. An ENT may bind to and activate a cation channel [3] to allow Na^+ and/or Ca^{2+} influx with resultant membrane depolarization. (**B**) An inhibitory neurotransmitter hyperpolarizes the membrane (makes membrane potential more negative) by binding to receptors linked to G proteins to enhance K^+ efflux [4], or to Cl^- channels to allow Cl^- influx [5]. Some Cl^- channels are regulated by G proteins as well. G = G protein.

receptors for various neurotransmitters may be found on a single neuron (heteroreceptors). For example, stimulation of presynaptic $α_2$ receptors found on postganglionic parasympathetic nerve terminals prevents acetylcholine release.

Finally, stimulation of receptors on presynaptic nerve endings may enhance, rather than inhibit, neurotransmitter release. Such receptors also are usually coupled to G proteins. For example, stimulation of a $β_2$ receptor on an adrenergic nerve terminal enhances norepinephrine release.

ACETYLCHOLINE

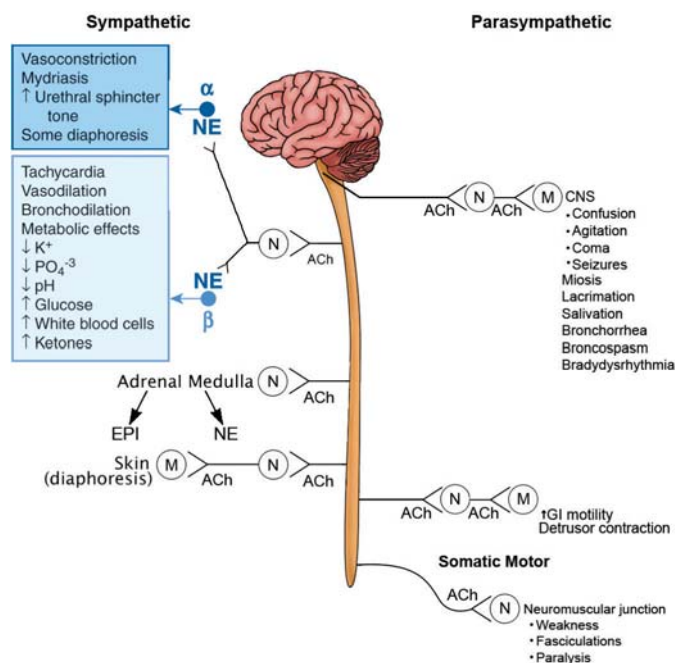
Acetylcholine (ACh) is a neurotransmitter of the central and peripheral nervous system. Centrally, it is found in both brain and spinal cord; cholinergic fibers project diffusely to the cerebral cortex. Peripherally, ACh serves as a neurotransmitter in autonomic and somatic motor fibers (Fig. 13–3).
FIGURE 13–2. Common mechanisms of presynaptic inhibition (the inhibition of neurotransmitter [NT] release). A neuron releases NT (green dots), which returns to activate receptors on the cell body or dendrites (somatodendritic autoreceptors), or on the axonal terminal (terminal autoreceptors). Such activation limits further release of NT by completing a negative feedback loop. At somatodendritic autoreceptors, NT binding produces activation of G proteins, which promote either K^+ efflux or Cl^- influx; both processes hyperpolarize the neuron away from threshold. At terminal autoreceptors, NT binding activates G proteins, which, through various mechanisms, lower intracellular Ca^{2+} concentrations to prevent exocytosis of NT vesicles, despite depolarization. Presynaptic inhibitory receptors for other types of NTs (heteroreceptors) are also shown. Excitatory axonal terminal autoreceptors and heteroreceptors that serve to enhance neurotransmitter release are not illustrated. G = G protein.


FIGURE 13–3. Diagram of the cholinergic nervous system, including adrenergic involvement in the autonomic nervous system. ACh binds to various nicotinic receptors (N) in CNS, in sympathetic and parasympathetic ganglia, and the adrenal glands. All nicotinic receptors shown are neuronal nicotinic receptors (nnAChRs) except for those at skeletal muscle, which are neuromuscular junction nicotinic receptors (NMJ nAChRs). ACh also binds to various subtypes of muscarinic (M) receptors in the CNS and on effector organs innervated by postsynaptic parasympathetic neurons and to most sweat glands. NE and/or EPI released in response to ACh stimulation of nnAChRs activates α- and β-adrenoceptors. ACh = acetylcholine; CNS = central nervous system; EPI = epinephrine; NE = norepinephrine.

■ SYNTHESIS, RELEASE, AND INACTIVATION

Acetylcholine is synthesized from acetylcoenzyme A and choline by choline acetyltransferase. Acetylcholine moves into synaptic vesicles via the vesicular membrane transporter, VAChT, where it is stored before release into the synapse by Ca^{2+}-dependent exocytosis. ACh undergoes degradation in the synapse to choline and acetic acid by acetylcholinesterase. A Na^+-dependent transporter in the neuronal membrane (ChT) then pumps choline back into the cytoplasm to be used again as a substrate for ACh synthesis (Fig. 13–4). Pseudocholinesterase (plasma cholinesterase) is made in the liver and plays no role in the degradation of synaptic ACh. However, it does metabolize some xenobiotics, including cocaine and succinylcholine.

■ ACETYLCHOLINE RECEPTORS

Nicotinic Receptors After release from cholinergic nerve endings, ACh activates two main types of receptors: nicotinic and muscarinic.[84] Nicotinic receptors (nAChRs) reside in the CNS (mainly in spinal cord), on postganglionic autonomic neurons (both sympathetic and parasympathetic), and at skeletal neuromuscular junctions, where they mediate muscle contraction (Fig. 13–3).

Nicotinic receptors at neuromuscular junctions (NMJ nAChRs) are part of a Na^+ channel made of five protein subunits and are thus channel receptors. Stimulation of these receptors by ACh results mainly in Na^+ influx, depolarization of the endplate, and triggering of an action potential that is propagated down the muscle by voltage-gated Na^+ channels.

Nicotinic receptors on central or peripheral neurons or in the adrenal gland are termed neuronal nAChRs. Neuronal nAChRs are also ion channels, although in some cases Ca^{2+} influx through the receptor may be more important than Na^+ influx. Neuronal nAChRs also comprise five subunits.
FIGURE 13–4. Cholinergic nerve ending. Activation of postsynaptic muscarinic receptors (mAChR) hyperpolarizes the postsynaptic membrane through G-protein-mediated enhancement of K^+ efflux. Several subtypes of muscarinic receptors coupled to various G proteins exist–a muscarinic receptor coupled to a G protein that opens K^+ channels is shown only as an example [2]. Postsynaptic nicotinic receptor (nAChR) activation causes Na^+ influx and membrane depolarization [3]. Ca^{2+} influx appears to be the main cation involved with some neuronal nicotinic receptors. Presynaptic muscarinic and α_2-adrenoceptor activation prevents ACh release through lowering of intracellular Ca^{2+} concentrations. The agents listed in Table 13-2 may act to enhance or prevent release of ACh [1]; activate or antagonize postsynaptic muscarinic (M) receptors [2]; activate or antagonize nicotinic (N) receptors [3]; inhibit acetylcholinesterase [4]; prevent ACh release by stimulating presynaptic muscarinic autoreceptors [5] or α_2-adrenergic heteroreceptors [6]; or enhance ACh release by antagonizing presynaptic autoreceptors [5] or by antagonizing presynaptic α_2-adrenergic heteroreceptors [6] (on parasympathetic postganglionic terminals). ACh = acetylcholine; AChE = acetylcholinesterase; G = G protein; VAChT = vesicular transporter for ACh. Norepinephrine is shown as light blue dots.

Muscarinic Receptors Muscarinic receptors reside in the CNS (mainly in the brain), on end organs innervated by postganglionic parasympathetic nerve endings, and at most postganglionic sympathetically innervated sweat glands (Fig. 13–4). At least five subtypes of muscarinic receptors, M_{1-5}, are recognized and linked to several G proteins. For example, in the heart, ACh released from the vagus nerve binds to M_2 receptors linked to G_i. G_i opens K^+ channels, allowing efflux of K^+ down its concentration gradient, which makes the inside of the cell more negative and more difficult to depolarize, slowing heart rate. Different subtypes of muscarinic receptors also act as autoreceptors in various locations, M_1 being the most common.

■ XENOBIOTICS

Table 13–2 provides examples of xenobiotics that affect cholinergic neurotransmission.

Modulators of Acetylcholine Release Figure 13–4 illustrates sites of actions of numerous xenobiotics that influence the cholinergic nervous

TABLE 13–2. Examples of Xenobiotics That Affect Cholinergic Neurotransmission

Cholinomimetics	Cholinolytics
Cause ACh release	Direct nicotinic antagonists
α_2-Adrenergic antagonists[a]	α-Bungarotoxin[c]
Aminopyridines	Nondepolarizing neuromuscular
Black widow spider venom	blockers
Carbachol	Trimethaphan
Guanidine	Indirect neuronal
Anticholinesterases	nicotinic antagonists
Donepezil	Physostigmine
Edrophonium	Tacrine
N-methylcarbamate insecticides	Galantamine
Organic phosphorus insecticides	Direct muscarinic antagonists
Physostigmine	Antihistamines
Rivastigmine	Atropine
Direct nicotinic agonists	Benztropine
Carbachol	Clozapine
Coniine	Cyclic antidepressants
Cytisine	Cyclobenzaprine
Nicotine	Disopyramide
Succinylcholine[b]	Orphenadrine
Varenicline	Phenothiazines
Indirect neuronal nicotinic agonists	Procainamide
Chlorpromazine	Scopolamine
Ethanol	Trihexyphenidyl
Ketamine	Inhibit ACh release
Local anesthetics	α_2-Adrenergic agonists[d]
Phencyclidine	Botulinum toxins
Volatile anesthetics	Crotalinae venoms
Direct muscarinic agonists	Elapidae β-neurotoxins
Arecoline	Hypermagnesemia
Bethanechol	
Carbachol	
Cevimeline	
Methacholine	
Muscarine	
Pilocarpine	

ACh = acetylcholine

[a] Antagonism of α_2-adrenoceptors enhances ACh release from parasympathetic nerve endings.

[b] Depolarizing neuromuscular blockers.

[c] α-Bungarotoxin exemplifies many elapid α-neurotoxins that produce paralysis and death from respiratory failure.

[d] Stimulation of presynaptic α_2-adrenoceptors on parasympathetic nerve endings prevents ACh release.

system. Botulinum toxins, some neurotoxins from pit vipers, and elapid β-neurotoxins prevent release of ACh from peripheral nerve endings.[58] This results in ptosis, other cranial nerve findings, weakness, and respiratory failure. Hypermagnesemia also inhibits ACh release, probably by inhibiting Ca^{2+} influx into the nerve endings.[84]

Guanidine, aminopyridines, and black widow spider venom enhance the release of ACh from nerve endings. Aminopyridines in part block voltage-gated K^+ channels to prevent K^+ efflux; the resultant action potential widening (delayed repolarization) causes prolongation of Ca^{2+} channel activation, enhancing influx of Ca^{2+} and promoting

neurotransmitter release. Aminopyridines have been used therapeutically in Lambert–Eaton syndrome, myasthenia gravis, multiple sclerosis, and experimentally in calcium channel blocker overdose.

Black widow spider venom causes ACh release with resultant muscle cramping and diaphoresis.[5]

Nicotinic Receptor Agonists and Antagonists Xenobiotics that bind to and activate nicotinic receptors may stimulate postganglionic sympathetic and parasympathetic neurons, skeletal muscle end-plates, and neurons within the CNS (Fig. 13–3). Prolonged depolarization at the receptor eventually causes diminution of responses to receptor occupancy.[118] For example, poisoning by nicotine, both a neuronal and NMJ nAChR agonist, may produce hypertension, tachycardia, vomiting, diarrhea, muscle fasciculations, and convulsions, followed by hypotension, bradydysrhythmias, paralysis, and coma. Succinylcholine is a neuromuscular blocking agent that initially stimulates and then blocks through prolonged depolarization of NMJ nAChRs.

Xenobiotics that block NMJ nAChRs without stimulation at skeletal neuromuscular junctions produce weakness and paralysis. Examples include curare and atracurium. α-Neurotoxins from elapids (eg, α-bungarotoxin) directly antagonize NMJ nAChRs, producing ptosis, weakness, and respiratory failure from paralysis.[169]

Peripheral neuronal nAChR blockade produces autonomic ganglionic blockade. Trimethaphan was used as a pharmacologic ganglionic blocker; however, it is not entirely specific for neuronal nAChRs. Occasionally, timethaphan may cause weakness and paralysis from NMJ nAChR blockade.

Recent studies demonstrate that the function of neuronal nAChRs can be modulated by a variety of xenobiotics that do not bind to the ACh binding site, but bind instead to a number of distinct allosteric sites on the neuronal nAChR. For example, aside from their ability to inhibit acetylcholinesterase, physostigmine, tacrine, and galantamine bind to a noncompetitive allosteric activator site on neuronal nAChRs to enhance channel opening and ion conductance (there is evidence suggesting that serotonin may bind here as well). Furthermore, a diverse range of xenobiotics, including chlorpromazine, phencyclidine, ketamine, local anesthetics, and ethanol bind to a noncompetitive negative allosteric site(s) to inhibit inward ion fluxes without directly affecting ACh binding. Steroids can desensitize neuronal nAChRs by binding to yet an additional allosteric site.[120]

Muscarinic Receptor Agonists and Antagonists Peripheral muscarinic agonists produce bradycardia, miosis, salivation, lacrimation, vomiting, diarrhea, bronchospasm, bronchorrhea, and micturition. Central muscarinic agonists produce sedation, extrapyramidal dystonias, rigidity, coma, and convulsions. Anticholinergic poisoning syndrome results from blockade of muscarinic receptors and is more appropriately referred to as antimuscarinic poisoning syndrome.[141] Central nervous system muscarinic blockade produces confusion, agitation, myoclonus, tremor, picking movements, abnormal speech, hallucinations, and coma. Peripheral antimuscarinic effects include mydriasis, anhidrosis, tachycardia, and urinary retention. Muscarinic antagonists number in the hundreds; Table 13–2 lists examples.

Acetylcholinesterase Inhibition Xenobiotics inhibiting acetylcholinesterase raise ACh concentrations at both nicotinic and muscarinic receptors, producing a variety of CNS, sympathetic, parasympathetic, and skeletal muscle signs and symptoms.[32] Anticholinesterases include organic phosphorus compounds and *N*-methylcarbamates. Organic phosphorus compounds are usually encountered as insecticides, although topical medicinal organic phosphorus compounds are used for the treatment of glaucoma and lice. *N*-methylcarbamates are found as insecticides and pharmaceuticals. Medicinal *N*-methylcarbamates include physostigmine, pyridostigmine, rivastigmine, and neostigmine.

Edrophonium, galantamine, tacrine, donepezil, and metrifonate are noncarbamate, reversible anticholinesterases.

α₂-Adrenoceptor Agonists and Antagonists Agonists and antagonists of α_2-adrenoceptors are discussed in detail below. Briefly, stimulation of presynaptic α_2-adrenoceptors on postganglionic parasympathetic nerve endings decreases ACh release. Conversely, presynaptic α_2 antagonism increases ACh release (Fig. 13–4).

NOREPINEPHRINE AND EPINEPHRINE

Norepinephrine (NE), epinephrine (EPI), dopamine (DA), and serotonin (5-hydroxytryptamine; 5-HT) have historically been referred to as biogenic amines, and their neurotransmitter systems are similar in many respects. Neurotransmitter synthesis, vesicle transport and storage, uptake, and degradation share many enzymes and structurally similar transport proteins. Cocaine, reserpine, amphetamines, and monoamine oxidase inhibitors (MAOIs) affect all four types of neurons. In addition, these xenobiotics produce several different effects in the same system. For example, in the noradrenergic neuron, amphetamines work mainly by causing the release of cytoplasmic NE, but they also inhibit NE uptake, and their metabolites inhibit monoamine oxidase. Actions of xenobiotics that affect all biogenic amine neurotransmitters are described in the most detail for noradrenergic neurons. For the sake of brevity, similar mechanisms of action are simply noted in discussions of dopaminergic and serotonergic neurotransmission.

Norepinephrine is released from postganglionic sympathetic fibers (Fig. 13–3) and is also found in the CNS. The adrenal gland, acting as a modified sympathetic ganglion, releases EPI and lesser amounts of NE in response to stimulation of neuronal nAChRs. Epinephrine-containing neurons also reside in the brainstem.

The locus ceruleus is the main noradrenergic nucleus and resides in the floor of the fourth ventricle on each side of the pons. Axons radiate from this nucleus out to all layers of the cerebral cortex, to the cerebellum, and to other structures. Norepinephrine demonstrates both excitatory and inhibitory actions in the CNS. Norepinephrine released from locus ceruleus projections in the hippocampus increases cortical neuron activity through β-adrenoceptor activation and G protein–mediated inhibition of K⁺ efflux. Norepinephrine released in outer cortical areas produces inhibitory effects mediated by α₂-adrenoceptor agonism. Consistent with this, NE demonstrates anticonvulsant actions in animals. Carbamazepine's anticonvulsant action may be partly a result of inhibition of NE uptake.[44] Despite antagonistic actions on different cortical neurons, electrical stimulation of the locus ceruleus produces widespread cortical activation and excitation. This overall effect probably explains a great deal of the hyperattentiveness and lack of fatigue that accompanies use of xenobiotics that mimic or increase noradrenergic activity in the brain. Locus ceruleus neuronal firing increases during waking and dramatically falls during sleep.

■ SYNTHESIS, RELEASE, AND UPTAKE

Figure 13–5 is a representation of a noradrenergic neuron. Tyrosine hydroxylase is the rate-limiting enzyme in NE synthesis and is sensitive to negative feedback by NE. This enzyme requires Fe^{2+} as a cofactor and exists as a homotetramer and is upregulated by chronic exposure to caffeine and nicotine. Under normal dietary conditions tyrosine hydroxylase is completely saturated by tyrosine, and increasing dietary tyrosine does not appreciably increase dopa synthesis. Dopa undergoes decarboxylation by L-amino acid decarboxylase to DA. L-Amino acid decarboxylase (dopa decarboxylase) is not specific for dopa. For example, it also catalyzes the formation of serotonin from 5-HT.
FIGURE 13–5. Noradrenergic nerve ending. The postsynaptic membrane may represent an end organ or another neuron in the CNS. Brief examples of effects resulting from postsynaptic receptor activation are shown. Agents in Tables 13-4 and 13-5 produce effects by inhibiting transport of dopamine (DA) or norepinephrine (NE) into vesicles through VMA2 [1]; causing movement of NE an DA from vesicles into the cytoplasm [2]; activating or antagonizing postsynaptic α- and β-adrenoceptors [3 -5]; modulating NE release by activating or antagonizing presynaptic α_2-autoreceptors [6], dopamine$_2$ (D$_2$) heteroreceptors [10], or β_2-autoreceptors [11]; blocking uptake of NE (NET inhibition) [7]; causing reverse transport of NE from the cytoplasm into the synapse via NET by raising cytoplasmic NE concentrations [8]; inhibiting monoamine oxidase (MAO) to prevent NE degradation [9]; or inhibiting COMT to prevent NE degradation [12]. AADC = aromatic L-amino acid decarboxylase; β-hydroxylase = dopamine-β-hydroxylase; COMT = catechol-*O*-methyltransferase; CNS = central nervous system; DOPGAL = 3,4-dihydroxyphenylglycoaldehyde; G = G protein; NET = membrane NE uptake transporter; NME = normetanephrine; VMA2 = vesicle uptake transporter for NE.

About one-half of cytoplasmic DA is actively pumped into vesicles by VMAT2. The remaining DA is quickly deaminated.

In the vesicle, DA is converted to NE by dopamine-β-hydroxylase. Vesicles isolated from peripheral nerve endings contain DA, NE, dopamine-β-hydroxylase, and ATP, and all of these substances are released into the synapse during Ca²⁺-dependent exocytosis triggered by neuronal firing. In neurons containing EPI as a neurotransmitter, NE is released from vesicles into the cytoplasm, where it is converted to EPI by phenylethanolamine-*N*-methyl-transferase. Epinephrine is then transported back into vesicles before synaptic release.[84]

Norepinephrine is removed from the synapse, mainly by uptake into the presynaptic neuron by the NE transporter (NET). Although this transporter has great affinity for NE, it also transports other amines, including DA, tyramine, MAOIs, and amphetamines. Once pumped back into the cytoplasm, NE can either be transported back into vesicles for further storage and release, or can be quickly degraded by monoamine oxidase (MAO), an enzyme expressed on the outer mitochondrial membrane.

MAO is present in all human tissues except red blood cells. It exists as 2 isozymes, MAO-A and MAO-B,[101] each with relatively separate affinities for various substrates (Table 13–3). Neuronal MAO degrades cytoplasmic amines, including neurotransmitters, to prevent elevated cytoplasmic concentrations of biogenic amines. Hepatic and intestinal MAO prevent large quantities of dietary bioactive amines from entering the circulation and producing systemic effects.

Catechol-*O*-methyltransferase (COMT) is an intracellular enzyme widely distributed throughout the body, including the central nervous system, that is responsible for metabolism of DA, L-Dopa, NE, and EPI.

TABLE 13–3. Characteristics of Monoamine Oxidase (MAO) Isozymes

	MAO Isozymes	
	MAO-A	MAO-B
Location		
Brain	+	+++

In extraneuronal tissue, COMT metabolizes catecholamines, including those that have entered the systemic circulation.

ADRENERGIC RECEPTORS

The 2 main types of adrenoceptors are α-adrenoceptors and β-adrenoceptors. All adrenoceptors are linked to G proteins.

β-Adrenoceptors β-Adrenoceptors are divided into 3 major subtypes (β_1, β_2, and β_3), depending on their affinity for various agonists and antagonists.[25,65,68,86] β_1-adrenoceptors and β_2-adrenoceptors are linked to G_s, and their stimulation raises cAMP concentration and/or activates protein kinase A which, in turn, produces several effects, including regulation of ion channels. At least some β_3-adrenoceptors may be coupled not only to G_s, but also to receptors for $G_{i/o}$ proteins. Prolonged activation of β_2 receptors in the heart causes them to become coupled to G_i.[175]

The β-adrenoceptors are polymorphic, with genetic variation in humans.[23] Polymorphism influences response to medications, regulation of receptors, and clinical course of disease.[23,68,86] In general, peripheral β_1-adrenoceptors are found mainly in the heart (along with β_2 receptors), whereas peripheral β_2-adrenoceptors also mediate additional adrenergic effects.[68] Presynaptic β_2-adrenoceptor activation causes release of NE from nerve endings (positive feedback). β_3-Adrenoceptors reside mainly in fat, but they also reside in skeletal muscle, gallbladder, and colon where they regulate metabolic processes. β_3-Adrenoceptors' polymorphism may contribute to clinical expressions of non–insulin-dependent diabetes and obesity.[23,154,171]

α-Adrenoceptors α-Adrenoceptors are linked to G proteins that inhibit adenylate cyclase to lower cAMP levels, affect ion channels, increase intracellular Ca^{2+} through inositol triphosphate and diacylglycerol production, or produce other actions. These receptors are divided into two main types, α_1 and α_2, and at least six subtypes—α_{1A}, α_{1B}, α_{1D}, α_{2A}, α_{2B}, and α_{2C}—are described.[39,65] Most α_1 adrenoceptors are coupled to G_q, whereas most α_2 adrenoceptors are coupled to G_i.

In peripheral tissue, α_1-adrenoceptors reside on the postsynaptic membrane in continuity with the synaptic cleft. Stimulation of these receptors on blood vessels commonly results in vasoconstriction.

α_2-Adrenoceptors reside on both sides of the synapse. Presynaptic α_2-adrenoceptor activation mediates negative feedback, limiting further release of NE (Fig. 13–5). Postganglionic parasympathetic neurons (cholinergic) also contain presynaptic α_2-adrenoceptors that, when stimulated, prevent release of ACh (Fig. 13–4).

Postsynaptic α_2-adrenoceptors on vasculature also can mediate vasoconstriction. Initially, it was suggested that postsynaptic α_2-adrenoceptors resided mainly outside of the synapse and mediated vasoconstrictive responses to circulating α agonists such as NE, whereas postsynaptic α_1-adrenoceptors responded to NE released from nerve endings. However, it has been demonstrated that in at least some tissues (eg, saphenous vein), NE released following nerve stimulation produces vasoconstriction through action at α_2-adrenoceptors, making the previous differentiation not as distinct.[39,76] Because both α_1-adrenoceptors and α_2-adrenoceptors on noncerebral vasculature mediate vasoconstriction, a patient with hypertension from high concentrations of circulating catecholamines (eg, pheochromocytoma or clonidine withdrawal) or from extravasation of NE from an intravenous line commonly needs both α_1-adrenoceptor and α_2-adrenoceptor blockade to vasodilate adequately (eg, phentolamine). Stimulation of postsynaptic α_2-adrenoceptors in the brainstem inhibits sympathetic output and produces sedation (Fig. 13–6). In fact, dexmedetomidine, an imidazole and potent α_{2A}-adrenoceptor agonist, is used for sedation in intensive care patients, although hypotension and bradycardia occur as expected side effects.[13]

XENOBIOTICS

Xenobiotics producing pharmacologic effects that result in or mimic increased activity of the adrenergic nervous system are *sympathomimetics* (Table 13–4). Those with the opposite effect are *sympatholytics* (Table 13–5).

Sympathomimetics *Direct-Acting Agents.* Xenobiotics whose sympathomimetic actions result from direct binding to α-adrenoceptors or β-adrenoceptors are called *direct-acting sympathomimetics*. Most do not cross the blood–brain barrier in significant quantities.

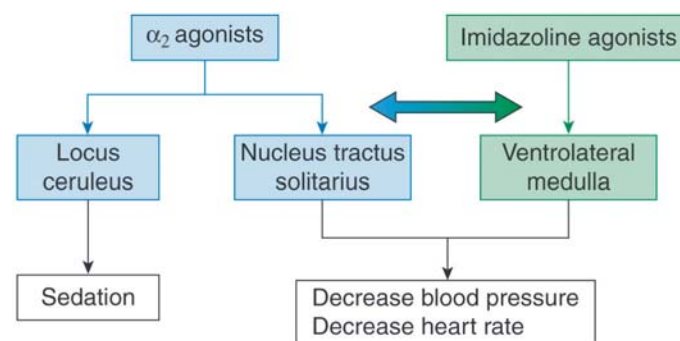
Indirect-Acting Agents. Xenobiotics that produce sympathomimetic effects by causing the release of cytoplasmic NE from the nerve ending in the absence of vesicle exocytosis are called *indirect-acting sympathomimetics*. Amphetamine is the prototype of indirect-acting sympathomimetics and is used for the discussion of what is known about their mechanism of action. In general, mechanisms of indirect release of NE


FIGURE 13–6. Central action of agents that activate α_2-adrenoceptors or that bind to type 1 imidazoline binding sites. There are poorly understood interactions between imidazoline binding sites and α_2-adrenoceptors that make delineation of specific effects difficult to attribute to specific receptor activation.

TABLE 13–4. Examples of Sympathomimetics

Direct acting	Selective α_2-adrenoceptor
α-*Adrenoceptor agonists*	antagonists
Epinephrine	Idazoxan
Ergot alkaloids	Efaroxan
Methoxamine	Yohimbine
Midodrine	Imidazoline binding-site antagonists
Norepinephrine	Idazoxan
Phenylephrine	Efaroxan
β-*Adrenoceptor agonists*	MAOIs
Albuterol	Amphetamine metabolites
Dobutamine	Clorgyline
Epinephrine	Isocarboxazid
Isoproterenol	Linezolid
Metaproterenol	Moclobemide
Norepinephrine	Pargyline
Terbutaline	Phenelzine
Indirect acting	Rasagiline
Amphetamine	Selegiline
Cocaine	Tranylcypromine
Fenfluramine	Inhibit norepinephrine Uptake
MAOIs	Amphetamine
Methylphenidate	Atomoxetine
Pemoline	Benztropine
Phenmetrazine	Bupropion
Propylhexedrine	Carbamazepine
Tyramine	Cocaine
Mixed acting	Cyclic antidepressants
Dopamine	Diphenhydramine
Ephedrine	Duloxetine
Mephentermine	Orphenadrine
Metaraminol	Pemoline
Phenylpropanolamine	Reboxetine
Pseudoephedrine	Tramadol
	Trihexyphenidyl
	Venlafaxine

MAOIs = monoamine oxidase inhibitors.

TABLE 13–5. Examples of Sympatholytics

α-Adrenoceptor antagonists	α_2-Adrenoceptor agonists[b]
Clozapine	α-Methyldopa[c]
Cyclic antidepressants	Clonidine
Doxazosin	Dexmedetomidine
Ergot alkaloids	Guanabenz
Olanzapine	Guanfacine
Phenothiazines	Moxonidine
Phenoxybenzamine	Naphazoline
Phentolamine	Oxymetazoline
Prazosin	Rilmenidine
Risperidone	Tetrahydrolozine
Terazosin	Tizanidine
Tolazoline	Xylometazoline
Trazodone	Imidazoline binding-site agonists[b]
Inhibit dopamine-β-hydroxylase	Clonidine
Diethyldithiocarbamate	Guanabenz
Disulfiram	Guanfacine
MAOIs	Moxonidine
β-Adrenoceptor antagonists	Naphazoline
Atenolol	Oxymetazoline
Esmolol	Rilmenidine
Labetalol	Inhibitors of vesicle uptake
Nadolol	Reserpine
Pindolol[a]	Tetrabenazine
Practolol[a]	
Propranolol	
Sotalol	

MAOIs = monoamine oxidase inhibitors.

[a] Partial β-agonist.

[b] Xenobiotics in these categories vary in their relative selectivity for α_2-adrenoceptors or imidazoline binding sites.

[c] Metabolized to α-methylnorepinephrine, which activates α_2-adrenoceptors.

---

by amphetamines, cocaine, phencyclidine, MAOIs, and mixed-acting xenobiotics noted in Table 13–4 are similar in that their actions depend on their ability to produce elevated cytoplasmic NE concentrations.

Amphetamine and structurally similar indirect-acting sympathomimetics move into the neuron mainly by the membrane transporter that pumps NE into the neuron. (Lipophilic indirect-acting sympathomimetics move into the neuron by diffusion.) From the cytoplasm, amphetamines are transported into neurotransmitter vesicles, where they buffer protons to raise intravesicular pH. As noted earlier, much of the vesicle's ability to concentrate NE (and other neurotransmitters) is a result of ion trapping of NE at the lower pH. The rise in intravesicle pH produced by amphetamines causes NE to leave the vesicle and move into the cytoplasm.[155,156] Such movement may be caused by diffusion or reverse transport of NE by VMAT2. In the cytoplasm, amphetamines also compete with NE and DA for transport into vesicles, which further contributes to elevated cytoplasmic NE concentrations. In the case of amphetamine, the rise in cytoplasmic concentrations of NE may be enhanced by the ability of amphetamine metabolites to inhibit MAO, which impairs NE degradation.

Every time the Na^+-dependent uptake transporter, NET, moves a bioactive amine (eg, tyramine) into the neuron where it is released, a binding site for NE on NET transiently faces inward and becomes available for reverse transport of NE out of the neuron. The normally low concentration of cytoplasmic NE prevents significant reverse transport. In the face of elevated cytoplasmic NE concentrations produced by indirect-acting sympathomimetics, NET moves NE out of the neuron and back into the synapse, where the neurotransmitter stimulates adrenoceptors (indirect action). This process is sometimes referred to as facilitated exchange diffusion, or displacement, of NE from the nerve ending. Evidence supporting reverse transport produced by amphetamines is that inhibitors of the transporter (eg, tricyclic antidepressants) prevent amphetamine-induced NE release.

While all indirect-acting smypathomimetics cause reverse NE transport by increasing cytoplasmic NE concentrations, those that move into the neuron by the membrane transporter (eg, amphetamines, MAOIs, DA, tyramine) further enhance reverse transport because their uptake may cause more NE binding sites on NET to face inward per unit time.

Although cocaine does inhibit NET, it also causes some NE release. In fact, cocaine similarly lessens pH gradients across vesicle membranes[156] to raise cytoplasmic concentrations of NE. That cocaine

produces less NE release than amphetamines is partly explained by cocaine-induced inhibition of the membrane transporter and by the fact that cocaine does not move into the neuron by active uptake (ie, does not increase the number of NE binding sites facing inward), but diffuses into the neuron. (Most of cocaine's severe sympathomimetic effects probably result from its action on the brain rather than peripheral nerve endings.[162])

Phencyclidine (PCP) is a hallucinogen that possesses multiple pharmacologic actions. Like toxicity from many hallucinogens, PCP toxicity is accompanied by increased adrenergic activity, which results, in part, from PCP-induced decreases in pH gradients across the vesicle membrane[156] and indirect release of NE. Like cocaine, PCP moves into the neuron by diffusion rather than uptake through the membrane transporter, at least partly explaining less PCP-induced NE release than typically occurs in amphetamine poisoning.

In addition to causing ACh release, black widow spider venom causes vesicle exocytosis of NE, producing hypertension and diaphoresis over the palms, soles, upper lip, and nose. All of the aforementioned indirectly acting sympathomimetics, except black widow spider venom, enter the CNS.

Mixed-Acting Xenobiotics. Mixed-acting sympathomimetics act directly and indirectly. For example, large doses of phenylpropanolamine indirectly cause NE release and act directly as α-adrenoceptor agonists. Intravenously administered DA indirectly causes NE release, explaining most of its vasoconstricting activity, but also directly stimulates dopaminergic and β-adrenoceptors. Direct α-agonism occurs at high doses. Except for DA, these xenobiotics cross the blood–brain barrier to produce central effects.

Uptake Inhibitors. Inhibitors of NE uptake raise concentrations of NE in the synapse to produce excessive stimulation of adrenoceptors.

There are 2 main mechanisms of action for inhibitors of biogenic amine uptake: competitive and noncompetitive. Noncompetitive inhibitors, such as cyclic antidepressants, carbamazepine, venlafaxine, methylphenidate, and cocaine, bind at or near the carrier site on NET to prevent NET from moving NE and similar xenobiotics into or out of the neuron. These inhibitors are not transported into the neuron by this mechanism. Various xenobiotics used for their antimuscarinic effects also block NET noncompetitively. These include benztropine, diphenhydramine, trihexyphenidyl and orphenadrine.[108] Atomexetine also inhibits NET.

The second mechanism, competitive inhibition of NET, characterizes most indirect-acting sympathomimetics, including amphetamines and structurally similar xenobiotics (eg, mixed-acting agents, MAOIs). These xenobiotics prevent NE uptake by competing with synaptic NE for binding to the carrier site on NET, the mechanism by which they move into the neuron. In fact, an additional adrenergic action of amphetamines, mixed-acting agents, MAOIs, and tyramine is to raise synaptic NE concentrations by competing for uptake, thereby compounding their indirect or direct actions.

MAOIs. MAOIs are transported by NET into the neuron, where they act through several mechanisms.[101] Inhibition of MAO, their main pharmacologic effect, results in increased cytoplasmic concentrations of NE and some indirect release of neurotransmitter into the synapse. As a minor effect they also may displace NE from vesicles by raising pH in a manner similar to amphetamines. These actions explain the initial hyperadrenergic findings following MAOI overdose and probably also account for occasional and unpredictable adrenergic crises that occur despite dietary compliance.

Nonspecific MAOIs inhibit both isozymes of MAO, preventing intestinal and hepatic degradation of bioactive amines. A person taking such an MAOI who then is exposed to indirect-acting sympathomimetics (eg, tyramine in cheese, phenylpropanolamine, DA, amphetamines) has a much larger cytoplasmic concentration of NE to transport into the synapse and may, therefore, develop central and peripheral hyperadrenergic findings. MAOIs specific for the MAO-B isozyme are less likely to predispose to food or drug interactions by maintaining significant hepatic and intestinal MAO activity. Furthermore, reversible MAO-A specific inhibitors are also less likely to provoke this reaction because their reversibility allows competition of exogenous amines with the inhibitor, resulting in its displacement from the enzyme and normal metabolism of the bioactive amines.[177] Isozyme specificity is lost as the dose of the MAOI is increased. In fact, selegiline, currently marketed as a selective MAO-B inhibitor, partially inhibits MAO-A activity at therapeutic doses. Specificity might lack importance when indirect-acting agents are administered parenterally (eg, intravenous DA or amphetamines). Linezolid is an antibiotic that produces weak MAO inhibition.

Occasionally, patients suffering from refractory depression respond to a combination of MAOIs and tricyclic antidepressants. This combination therapy is usually unaccompanied by excessive adrenergic activity because the inhibition of the membrane uptake transporter by the tricyclic antidepressant attenuates excessive reverse transport of elevated cytoplasmic NE concentrations produced by MAOIs.

COMT Inhibitors. Inhibitors of COMT are administered in the treatment of Parkinson disease to prevent the catabolism of concomitantly administered L-dopa. Entacapone only acts peripherally, whereas tolcapone also crosses the blood–brain barrier.

α₂-Adrenoceptor Antagonists. Yohimbine blocks $α_2$-adrenoceptors to produce a mixed clinical picture. Peripheral postsynaptic $α_2$ blockade produces vasodilation. Blockade of presynaptic $α_2$-adrenoceptors on cholinergic nerve endings (Fig. 13–4) enhances ACh release, occasionally producing bronchospasm[82] and contributing to diaphoresis. Similar presynaptic actions on peripheral noradrenergic nerves enhance catecholamine release (Fig. 13–5). Antagonism of central $α_2$-adrenoceptors in the locus ceruleus results in CNS stimulation, whereas blockade of postsynaptic $α_2$-adrenoceptors in the nucleus tractus solitarius may enhance sympathetic output (Fig. 13–6). The final result includes hypertension, tachycardia, anxiety, fear, agitation, mania, mydriasis, diaphoresis, and bronchospasm.[87]

Sympatholytics *Direct Antagonists.* Direct α-adrenoceptor and β-adrenoceptor antagonists are noted in Table 13–5. After overdose, β-adrenoceptor selectivity may be less significant. Some β-adrenoceptor antagonists also are partial agonists.

Xenobiotics That Prevent Norepinephrine Release. Xenobiotics that block the vesicle uptake transporter prevent the movement of NE into vesicles and deplete the nerve ending of this neurotransmitter, also preventing NE release after depolarization. Reserpine and ketanserin inhibit both VMAT1 and VMAT2, whereas tetrabenazine only inhibits VMAT2. Like guanethidine, reserpine causes transient NE release with the initial dose or early in overdose. β-Adrenoceptor antagonists block presynaptic $β_2$-adrenoceptors to limit catecholamine release from nerve endings, although this does not appear to be their main mechanism of action.

Imidazoline and α₂-Adrenoceptor Agonists. Numerous imidazoline derivatives (eg, clonidine) and structurally similar xenobiotics are used as centrally acting antihypertensives or long-acting topical vasoconstrictors. They are currently divided into first-generation agents (eg, clonidine) that are thought to act at both $α_{2A}$-adrenoceptor and imidazoline binding sites, and second-generation agents (eg, rilmenidine) that express much greater affinity for imidazoline binding sites than for $α_{2A}$-adrenergic receptors.

The ventromedial (depressor) and the rostral-ventrolateral (pressor) areas of the ventrolateral medulla (VLM) are responsible for the central regulation of cardiovascular tone and blood pressure. They receive

afferent fibers from the carotid and aortic baroreceptors, which form the tractus solitarius via the nucleus tractus solitarius (NTS).[75]

The hypotensive actions of α_2-adrenoceptor agonists were previously attributed entirely to brainstem α_2-adrenoceptor activation, because stimulation of postsynaptic α_2-adrenoceptors in the NTS decreased sympathetic output (Fig. 13–6).[19] The discovery of imidazoline binding sites, however, led to a more complicated analysis. It was discovered that imidazolines and related xenobiotcis produced hypotension when applied to the VLM, whereas catecholamines capable of activating α_2-adrenoceptors were claimed to be incapable of producing effects at this site. This led to the hypothesis that receptors specific for imidazolines, different from α_{2A}-adrenoceptors, must exist. Decreased sympathetic output could result from activation of imidazoline binding sites in the VLM and from α_2-adrenoceptor activation in the NTS; sedation and respiratory depression were attributed to α_2-adrenoceptor activation in the locus ceruleus.[46]

Imidazoline binding sites have been characterized and subdivided into I_1, I_2 (with subtypes), and I_3.[41] I_1 binding sites reside on neuronal plasma membranes and are involved in controlling systemic blood pressure. I_2 sites are allosteric sites found on the external membrane of mitochondria and modulate MAO-A and MAO-B.[19,41] The putative I_3 sites are thought to modulate insulin secretion via ATP-sensitive potassium channels in β-islet cells.

The molecular structure of the imidazoline binding sites has not been identified. Endogenous ligands for these binding sites have been discovered: agmatine, imidazole-acetic acid ribotide, harmane, and other β-carbolines.[10,60,132]

Functional evidence suggests that there is significant interaction between the imidazoline sites and α_{2A}-adrenoceptors, and that this interaction is necessary to trigger hypotensive effects.[18,46] As examples, there appears to be a close relationship between "presynaptic" imidazoline sites and "downstream" α_{2A}-adrenoceptors in the VLM mediating hypotension;[59] α_{2A}-adrenoceptors in the VLM appear to be activated as a consequence of imidazoline site activation. Although second-generation agents (rilmenidine and moxonidine) preferentially act via imidazoline binding sites, and although α_{2A}-adrenoceptors are important for the hypotension produced by first-generation agents (clonidine and α-methyldopa), hypotension produced by all of these xenobiotics is dependent on central noradrenergic pathways.[18,59] Some studies report that yohimbine, an α_2-adrenoceptor antagonist, reverses the hypotensive effect of both clonidine and rilmenidine-like drugs when given at high doses. Thus, it appears that there is significant interaction between imidazoline sites and α_{2A}-adrenoceptors, and that centrally acting antihypertensive agents with relatively high affinity for imidazoline binding sites may require both imidazoline specific sites and functional α_{2A}-adrenoceptors to produce their hypotensive actions.

Ingestions of xenobiotics that activate α_{2A}-adrenoceptors and imidazoline binding sites (Table 13–5) produce a mixed clinical picture. Peripheral postsynaptic α_2-adrenoceptor stimulation produces vasoconstriction, pallor, and hypertension, often with reflex bradycardia (Fig. 13–5). Peripheral presynaptic α_2-adrenoceptor stimulation prevents NE release (Fig. 13–5), whereas central α_2-adrenoceptor stimulation in the locus ceruleus accounts for CNS and respiratory depression (Fig. 13–6). Stimulation of postsynaptic α_2-adrenoceptors in the NTS and of central I_1 receptors in the VLM are thought to inhibit sympathetic output and enhance parasympathetic tone, explaining hypotension with bradycardia (Fig. 13–6).[75] Both first-generation and second-generation agents produce dry mouth.[19,41]

Dopamine-β-Hydroxylase Inhibition. Inhibition of dopamine-β-hydroxylase, a copper-containing enzyme (Fig. 13–5), prevents the conversion of DA to NE, resulting in less NE release and less α-adrenoceptor

and β-adrenoceptor stimulation with neuronal firing. Disulfiram and diethyldithiocarbamate, copper chelators, produce such inhibition.[43] Because NE release mediates most of DA's ability to cause vasoconstriction, NE is the vasopressor of choice in a hypotensive patient taking disulfiram. MAOIs and α-methyldopa also inhibit dopamine-β-hydroxylase, although this is not their main mechanism of action.[101]

Dopamine is relatively contraindicated in hypotensive patients who have overdosed on MAOIs. First, DA acts indirectly and its administration might produce excessive adrenergic activity and exaggerated rises in blood pressure. Second, even if an adrenergic storm does not occur, most of dopamine's α-mediated vasoconstriction is secondary to NE release. In the presence of MAOIs, NE synthesis may be impaired from concomitant dopamine-β-hydroxylase inhibition, and DA may not reliably raise blood pressure if cytoplasmic and vesicular stores have been depleted. In the presence of impaired NE release or α-adrenoceptor blockade by any cause, unopposed dopamine-induced vasodilatation from action on peripheral DA and β-adrenoceptors may paradoxically lower blood pressure further. Norepinephrine and EPI can be used to support blood pressure relatively safely in patients taking MAOIs, because they have little or no indirect action and are metabolized by COMT when given intravenously.

DOPAMINE

Because DA is the direct precursor of NE, noradrenergic vesicles contain DA. The release of NE from peripheral sympathetic nerves, therefore, always results in release of some DA (Fig. 13–5), as does the release of NE and EPI from the adrenal gland, explaining most of DA in blood. In peripheral tissues, activation of DA receptors causes vasodilatation of renal mesenteric, and coronary vascular beds. Dopamine can also stimulate β-adrenoceptors and, at high doses, can directly stimulate α-adrenoceptors. When DA is administered intravenously, most vasoconstriction is caused by dopamine-induced NE release.

Dopamine accounts for about one-half of all catecholamines in the brain and is present in greater quantities than NE or 5-HT. In contrast to the diffuse projections of noradrenergic neurons, dopaminergic neurons and receptors are highly organized and concentrated in several areas, especially in the basal ganglia and limbic system.[81,140]

Excessive dopaminergic activity in the neostriatum and/or other areas from any cause (eg, increased release, impaired uptake, increased receptor sensitivity) can produce acute choreoathetosis[77] and acute Gilles de la Tourette syndrome, with tics, spitting, and cursing. Excessive dopaminergic activity in the limbic system and, perhaps, in other areas produces paranoid psychosis and is thought responsible for much of the drug craving and addictive behavior in patients abusing sympathomimetics, opioids, alcohol, and nicotine. Diminished dopaminergic tone (eg, impaired release, receptor blockade) in the neostriatum produces various extrapyramidal disorders such as acute dystonias and parkinsonism.[131,151,165]

■ SYNTHESIS, RELEASE, AND UPTAKE

The steps of DA synthesis and vesicle storage are the same as those for NE, except that DA is not converted to NE after transport into vesicles (Fig. 13–7). Dopamine is removed from the synapse via uptake by DAT, the membrane-bound DA transporter. DAT and NET exhibit 66% homology in their amino acid sequences. Like NET, DAT is not completely specific for DA and transports amphetamines and other structurally similar sympathomimetics. Cytoplasmic DA has a fate similar to NE. It is pumped back into vesicles by VMAT2 (brain) and VMAT1 (neuroendocrine tissue, adrenal glands) or degraded by MAO and COMT.
FIGURE 13–7. A dopaminergic nerve ending and postsynaptic membrane. Dopamine (DA) released from nerve endings binds to various postsynaptic DA receptors (D) on neurons or peripheral end organs. Stimulation of presynaptic D_2 receptors [9] lessens DA release. Agents in Table 13-6 may act to inhibit vesicle uptake [1]; cause DA to leave the vesicle and move into the cytoplasm [2]; activate or antagonize DA receptors [3, 4, 9]; inhibit DAT to prevent DA uptake [5]; cause reverse transport of cytoplasmic DA (via DAT) into the synapse by raising cytoplasmic DA concentrations [6]; prevent DA degradation by inhibiting monoamine oxidase (MAO) [7]; or prevent DA degradation by inhibiting catechol-O-methyltransferase (COMT) [8]. (Both DA and dopa are substrates for COMT.) AADC = L-aromatic amino acid decarboxylase; DAT = membrane DA uptake transporter; DOPAC = 3,4-dihydroxyphenylacetic acid; VMA2 = vesicle membrane uptake transporter.

DOPAMINE RECEPTORS

All DA receptors are coupled to G proteins and are divided into two main groups, depending on whether they raise or lower cAMP concentrations. Dopamine D_1-like receptors (D_1 and D_5) are expressed as various subtypes and are linked to G_s to stimulate adenylate cyclase and to raise cAMP concentrations.[81] D_1 receptors are found in the basal ganglial nuclei and cerebral cortex, and D_5 receptors are concentrated in the hippocampus and hypothalamus. Dopamine is 5 to 10 times more potent at D_5 receptors than it is at D_1 receptors.

D_2-like receptors (D_2, D_3, D_4) are linked to $G_{i/o}$ to produce several actions, including inhibition of adenylate cyclase and the lowering of cAMP levels. Again, numerous subtypes of receptors exist (eg, D_{2s}, D_{2L}). D_2 receptors are concentrated in the basal ganglia and limbic system.

Some D_2 receptors also reside on presynaptic membranes, where their activation limits neurotransmitter release, including the peripheral release of NE (Figs. 13–5 and 13–7). D_3 receptors are concentrated in the hypothalamic and limbic nuclei, whereas D_4 receptors are concentrated in the frontal cortex and limbic nuclei (rather than basal ganglia nuclei). Most agonists bind to the D_3 receptors with higher affinity than to D_2 receptors, whereas most antagonists bind preferentially to D_2 receptors.[81,140] Most agonists and antagonists express a lower affinity for D_4 receptors than they express for D_2 receptors; a notable exception is clozapine.

■ XENOBIOTICS

Table 13–6 provides examples of xenobiotics that affect dopaminergic neurotransmission.

TABLE 13–6. Examples of Xenobiotics That Affect Dopaminergic Neurotransmission

Dopamine agonism	Increase dopamine receptor sensitivity
Direct stimulation of	Amphetamine
dopamine receptors	Antipsychotics
Apomorphine	Metoclopramide
Bromocriptine	Phenytoin
Cabergoline[a]	Dopamine antagonism
L–Dopa[b]	Block dopamine receptors
Fenoldopam	Amoxapine
Lisuride	Aripiprazole
Pramipexole	Buspirone
Ropinirole	Butyrophenones
Inhibit dopamine metabolism	Clozapine
MAOIs	Cyclic antidepressants
COMTs	Domperidone
Indirect acting	Loxapine
Amantadine	Metoclopramide
Amphetamine	Olanzapine
Benztropine	Phenothiazines
Diphenhydramine	Pimozide
MAOIs	Quetiapine
Methylphenidate	Risperidone
Pemoline	Thioxanthenes
Trihexyphenidyl	Ziprasidone
Inhibit dopamine uptake	Destroy dopaminergic neurons
Amantadine	MPTP/MPP+
Amphetamine	Prevent vesicle dopamine uptake
Benztropine	Reserpine
Bupropion	Tetrabenazine
Cocaine	
Diphenhydramine	
Methylphenidate	
Orphenadrine	
Trihexyphenidyl	

COMTs = catechol-*o*-methyltransferase inhibitors; MAOIs = monoamine oxidase inhibitors; MPTP = 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine. MPP+ = 1-methyl-4-phenylpyridinium.

[a] Associated with fibrotic vavlulopathy due to 5HT$_{2B}$ agonism.

[b] Metabolized to dopamine, which acts as an agonist.

Dopamine Agonism *Indirect-Acting and Mixed-Acting Xenobiotics.* Most indirect-acting and mixed-acting sympathomimetics cause DA release. The mechanism of action is similar to that causing NE release. These xenobiotics diffuse into the neuron or undergo uptake by DAT before being transported into vesicles by VMAT2 where they buffer protons and displace DA into the cytoplasm for reverse transport by DAT into the synapse. Benztropine, diphenhydramine, trihexyphenidyl, and orphenadrine also cause DA release, perhaps contributing to their abuse potential, which is noted below.[108] Excessive dopaminergic activity following therapeutic doses or overdoses of decongestants (eg, pseudoephedrine), amphetamines, methylphenidate, and pemoline can produce acute choreoathetosis ("crack dancing") and Tourette syndrome.[22,92] Ingestion of excessive doses of L-dopa (which is converted to DA) may present with similar symptoms.

Direct Agonists. Bromocriptine is an ergot derivative that directly activates DA receptors (mainly D$_2$). Toxic effects include those described above for indirect-acting agents. Apomorphine directly activates D$_2$ receptors.

Such action at the chemoreceptive triggering zone produces vomiting, whereas agonism in the basal ganglia explains the use of apomorphine in the treatment of Parkinson disease. Fenoldopam is a D$_1$ agonist used as a vasodilator in the treatment of hypertensive emergencies.

D$_1$-like and D$_2$-like receptor activation is the predominant mediator of locomotor effects from DA agonists. Activation of either D$_1$-like or D$_2$-like receptors produces antiparkinsonian effects.[63,140] Cabergoline, ropinirole, and pramipexole are D$_2$-like agonists used to treat Parkinson disease.[8,41,57] Dihydrexidine is a D$_1$-like agonist that has been used for the same purpose.

Uptake Inhibition. Xenobioitics inhibiting DAT prevent DA uptake and include cocaine, amphetamines, methylphenidate, and probably amantadine. Increased dopaminergic activity from cocaine toxicity may produce choreoathetosis and Tourette syndrome. In general, antidepressants are not strong DA uptake blockers. However, bupropion appears to be more active in this regard.[136]

As noted earlier, much of the craving and addiction produced by sympathomimetics probably results from excessive dopaminergic activity in the mesolimbic system.[151] Interestingly, the anticholinergic drugs benztropine, diphenhydramine, trihexyphenidyl, and orphenadrine are also DA uptake inhibitors, possibly explaining their abuse.[108,147] In fact, benztropine is one of the most potent DA uptake inhibitors known. Amantadine, an antiparkinsonian agent that causes DA release and some inhibition of DA uptake (as well as being anticholinergic), is also abused.

Increase of Receptor Sensitivity. Several xenobiotics are thought to increase sensitivity of DA receptors, resulting in choreoathetosis, even with therapeutic doses (eg, phenytoin). Evidence exists that increased DA receptor sensitivity may be responsible for movement disorders resulting from amphetamines.[26] Tardive dyskinesia (discussed below) may also result from increased DA receptor sensitivity and occurs following chronic administration of D$_2$ receptor antagonists.

MAO Inhibition. MAOIs inhibit the breakdown of cytoplasmic DA. Some of the food and drug interactions with MAOIs results from excessive release of DA from nerve endings.

COMT Inhibition. Peripheral COMT inhibitors (eg, entacapone, tolcapone) are given with levodopa to patients with Parkinson disease to prevent peripheral degradation of levodopa to 3-*O*-methyldopa. This allows more levodopa to traverse the blood–brain barrier and to be converted to DA by neuronal dopa decarboxylase. Tolcapone also inhibits COMT in the brain.[71] Other substrates of COMT include dopa, DA, NE, EPI, and their hydroxylated metabolites. COMT inhibitors might potentiate the effects of these drugs when administered intravenously.[71]

Dopamine Antagonism *Direct Receptor Blockade.* Blockade of DA receptors is the specific aim when using many therapeutic agents. The neuroleptic actions of butyrophenones, phenothiazines, and other antipsychotics mainly correlate with their ability to block D$_2$-like receptors. Many phenothiazines block both D$_1$-like and D$_2$-like receptors, whereas haloperidol mainly blocks D$_2$-like receptors. Unfortunately, antipsychotics and metoclopramide also block DA receptors in the striatum, producing various extrapyramidal symptoms, including acute parkinsonism and dystonias.

In the last decade, several "atypical" antipsychotics have been marketed that produce fewer extrapyramidal effects and are thought to carry less risk of producing tardive dyskinesia.[134] The relative affinity of an antipsychotic for 5-HT$_{2A}$ receptors over D$_2$ receptors has predictive value for atypical agents with a lower risk of extrapyramidal symptoms.[124] These include clozapine, olanzapine, quetiapine, risperidone, and ziprasidone.

The ratio of muscarinic (M$_1$) blockade to D$_2$-receptor blockade is also important in limiting extrapyramidal symptoms. Antipsychotics

exhibiting strong antimuscarinic effects (eg, olanzapine, clozapine, thioridazine) are also less likely to induce extrapyramidal symptoms.[134]

Buspirone, an anxiolytic, antagonizes D_2 receptors, which explains occasional extrapyramidal reactions. Various cyclic antidepressants, especially amoxapine, block D_2 receptors to some extent.

The chronic use of dopamine-blockers causes upregulation of DA receptors. The continued use or, especially, withdrawal of DA antagonists (antipsychotics, metoclopramide, and occasionally antidepressants) can result in excessive dopaminergic activity and tardive dyskinesia, characterized by choreiform movements typical of excessive dopaminergic influence in the neostriatum.

The blockade of DA receptors by numerous xenobiotics, including butyrophenones, phenothiazines, and metoclopramide, can produce a poorly understood disorder called *neuroleptic malignant syndrome.* Neuroleptic malignant syndrome may rarely follow acute withdrawal of DA agonists (eg, stopping L-dopa, bromocriptine, or tolcapone in a patient prior to surgery). Neuroleptic malignant syndrome is characterized, in part, by mental status changes, autonomic instability, rigidity, and hyperthermia.

Indirect Antagonism.   Reserpine and tetrabenazine inhibit VMAT to prevent transport of DA into storage vesicles and deplete nerve endings of DA. In fact, reserpine was used as an antipsychotic before the introduction of phenothiazines. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a meperidine analog, undergoes activation by MAO to a metabolite, 1-methyl-4-phenylpyridinium (MPP$^+$), that causes death of dopaminergic neurons. Both MPTP and its metabolite undergo uptake not only by DAT, but also by NET and SET, making their way into all biogenic amine neurons. The reasons that dopaminergic neurons are selectively damaged remain unknown. Both MAOIs and inhibitors of DA transporters prevent MPTP-induced destruction of dopaminergic neurons.

SEROTONIN

Serotonin (5-HT, 5-OH-tryptamine) is an indole alkylamine found throughout nature (animals, plants, venoms) and has the most complex receptor family of all known neurotransmitters. In the CNS, several hundred thousand serotonergic neurons lie in or in juxtaposition to numerous midline nuclei in the brainstem (raphe nuclei), from which they project to virtually all areas of the brain, including the basal ganglia. Serotonin is involved with mood, emotion, learning, memory, personality, affect, appetite, aggression, motor function, temperature regulation, sexual activity, pain perception, sleep induction, other basic functions. Serotonin is not essential for any of these processes, but modulates their quality and extent. A number of psychiatric disorders, including depression, anxiety, obsessive-compulsive disorder, dementia, schizophrenia, and eating disorders, are linked to altered serotonin function. Consequently, modification of serotonergic neurotransmission is an integral part of the treatment plan for most of these conditions.

The serotonergic system is extremely diverse, with 14 types of receptors that act to stimulate or inhibit neurons, including those of other neurotransmitter systems. Serotonin is also the precursor for the pineal hormone, melatonin. Despite the important role 5-HT plays in the CNS, less than 5% of the body's 5-HT is found within the CNS, with the great majority of 5-HT being located within enterochromaffin cells of the intestines and a small amount of serotonin sequestered by platelets.[110]

Peripherally, 5-HT is released by enterochromaffin cells in response to intestinal stimulation, which contributes to peristalsis and fluid secretion. Most of this activity is performed automatically at the unconscious level. However, there are two pathways via vagal nerve and spinal cord afferent projections to the CNS that allow for conscious input and feedback between these two systems.[33] Platelets take up 5-HT

while passing through the enteric circulation. Serotonin is released from activated platelets to interact with other platelet membranes (promote aggregation) and with vascular smooth muscle.[110]

Experimentally, 5-HT exhibits diverse effects on the cardiovascular and peripheral nervous systems, although the importance of these actions remains uncertain in the normal physiologic state. Serotonin vasoconstricts (stimulation of 5-HT_2, 5-HT_{1B}, and 5-HT_{1D} receptors) most vascular beds, except for coronary arteries and skeletal muscle, where it produces vasodilation in the presence of intact endothelium. 5-HT_{1B} and 5-HT_{1D} agonists (eg, sumatriptan) produce coronary vasoconstriction as an adverse effect to their desired actions on cranial vasculature.[113]

Centrally, it is particularly difficult to ascribe a specific symptom or physical finding to serotonergic neurons because of the diversity of their physiologic actions. However, 5-HT definitely plays an important role in the action of many hallucinogenic or illusionogenic drugs, which act as partial agonists at cortical 5-HT_2 receptors. Proserotonergics are used to treat depression, whereas 5-HT receptors (5-HT_2) antagonists have greater importance in the management of schizophrenia.[51,161]

Generally, in areas where they overlap, 5-HT acts in opposition to DA. For example, 5-HT serves to increase prolactin, adrenocorticotropic hormone (ACTH), and growth hormone secretion, whereas DA decreases prolactin secretion. As another example, activation of basal ganglial 5-HT_{2A} receptors inhibits DA release.[51,161] However, well-known exceptions exist, such as cortical 5-HT_3 receptors[28] and 5-HT_{1A} receptors that are capable of promoting DA release under certain circumstances.[112]

■ SYNTHESIS, RELEASE, AND UPTAKE

Figure 13–8 illustrates 5-HT synthesis. Tryptophan-5-hydroxylase is the rate-limiting enzyme of 5-HT synthesis. Increases in tryptophan are predictably accompanied by increased 5-HT production. L-Amino acid decarboxylase (dopa decarboxylase) converts 5-hydroxytryptophan to 5-HT. Cytoplasmic 5-HT is transported into vesicles by VMAT2, where it is concentrated by ion trapping before release by Ca^{2+}-dependent exocytosis. In contrast to vesicles containing DA or NE, 5-HT vesicles contain almost no ATP. After release into the synapse, a transporter (SERT) in the neuronal membrane moves 5-HT back into the neuron, where it reenters vesicles or is degraded by MAO.[110]

Serotonin is preferentially metabolized by the MAO-A isozyme. Paradoxically, the serotonergic nerve terminal is almost devoid of MAO-A, but contains abundant amounts of MAO-B. It has been hypothesized that the large amounts of MAO-B metabolize other xenobiotics that might inappropriately promote 5-HT release (eg, dopamine). However, the small amount of MAO-A found in serotonergic neurons provides adequate degradation of 5-HT.[110]

■ SEROTONIN RECEPTORS

Most authors identify seven major functioning receptors (5-HT_1 through 5-HT_7) and numerous subtypes.

5-HT_1 Receptors   Receptors in the 5-HT_1 class are coupled to G proteins and commonly increase K$^+$ efflux and decrease cAMP concentrations. Members of the 5-HT_1 receptor class express greatest affinity for 5-HT and are thus biologically active under normal physiologic conditions. 5-HT_{1A} receptors reside predominantly on raphe nuclei, where they act as somatodendritic autoreceptors.[104,116] Hippocampal 5-HT_{1A} receptors reside postsynaptically, where they also inhibit through similar mechanisms.[116]

Central 5-HT_{1D} and 5-HT_{1B} receptors primarily act as inhibitory terminal autoreceptors and heteroreceptors. They are found less commonly on postsynaptic membranes.[116] Originally 5-HT_{1B} receptors were not believed to exist in humans. However, most of the actions described in older literature regarding 5-HT_{1D} receptors can now be
FIGURE 13–8. A serotonergic nerve ending and postsynaptic membrane. Tryptophan hydroxylase [1] converts tryptophan to 5-hydroxytryptophan (5-OH-tryptophan). Aromatic L-amino acid decarboxylase (AADC) then metabolizes 5-OH-tryptophan to serotonin (5-HT). Serotonin is concentrated within vesicles through uptake by VMA2 before exocytosis [2]. After uptake into the neuron by SERT [7], 5-HT is transported back into vesicles or undergoes degradation by monoamine oxidase (MAO) to an intermediate compound, which is converted to 5-hydroxyindoleacetic acid (5-HIAA) [8]. 5-HT$_{1,2,4,6,7}$ receptors [3,9,10] are coupled to G proteins, while 5-HT$_3$ receptors [4] are ligand-gated cation channels that may conduct Na$^+$ and/or Ca^{2+} (only Na$^+$ is illustrated). 5-HT$_3$ cation channels also appear to be blocked by Mg^{2+} until the cell is depolarized, allowing Mg^{2+} to dissociate—a mechanism similar to that found at NMDA glutamate receptors. In addition to residing on postsynaptic membranes, 5-HT$_{1A}$, 5-HT$_{1B}$, and 5HT$_{1D}$ receptors serve as presynaptic autoreceptors that, when stimulated, decrease further release of 5-HT [9,10]. Presynaptic 5-HT1A receptors mainly serve as somatodendritic autoreceptors, whereas presynaptic 5-HT1B, and 5-HT1D receptors serve as terminal autoreceptors. Agents in Table 13-7 act to enhance 5-HT synthesis [1]; inhibit VMA2 to prevent vesicle uptake of 5-HT [2]; raise cytoplasmic concentrations of 5-HT, resulting in reverse transport of 5-HT into the synapse by SERT [6]; by displacing 5-HT from vesicles [5] or inhibiting MAO [8]; activate or antagonize 5-HT receptors [3,4,9,10]; or by inhibiting 5-HT uptake [7]. G = G protein; SERT = membrane 5-HT uptake transporter; VMA2 = vesicle membrane uptake transporter.

the cerebral cortex, where they serve as excitatory postsynaptic receptors. Their activation increases glutamate release from pyramidal cells, but also can lead to release of GABA.[161] 5-HT$_{2A}$ receptors also reside on platelets, where their activation produces platelet aggregation. 5-HT$_{2C}$ receptors (previously 5-HT$_{1C}$) reside on the choroid plexus, where they regulate cerebrospinal fluid production. Activation of 5-HT$_{2B}$ receptors in the GI tract promotes stomach contraction.[110] At least some xenobiotics that activate 5-HT$_{2B}$ receptors on cardiac valves cause a valvulopathy identical to that of carcinoid syndrome, though both sides of the heart can be involved with drug-induced 5-HT$_{2B}$ agonism.

5-HT$_3$ Receptors 5-HT$_3$ receptors are isopentameric ligand-gated cation channels that are structurally similar to ACh nicotinic receptors, GABA$_A$ Cl$^-$ channels, glycine, and NMDA glutamate receptors.[28] They are localized to both presynaptic and postsynaptic membranes. Upon activation, they stimulate the neuron by opening the channel to cause depolarization through Na$^+$ and/or Ca^{2+} influx. In addition, these channels are normally blocked by Mg^{2+} in a voltage-dependent manner similar to glutamatergic NMDA receptors (see Glutamate later). Centrally, 5-HT$_3$ receptors are expressed diffusely, but are especially concentrated in the chemoreceptive triggering zone, where their activation induces emesis.[33] In the cerebral cortex, their activation leads to increased release of DA and decreased release of ACh.[28] Cortical 5-HT$_3$ receptors are frequently identified on GABA interneurons where they increase inhibitory, GABAergic tone. In contrast to cerebral actions, activation of peripheral 5-HT$_3$ receptors on cholinergic nerves in the gut enhances ACh release to increase gastrointestinal motility.[33]

5-HT$_4$ Receptors 5-HT$_4$ receptors are coupled to G proteins (G$_s$). Their activation leads to increased cAMP concentrations. 5-HT$_4$ receptors are scattered diffusely throughout the brain, and their exact role remains undefined, although they are known to increase the release of ACh.[161] Peripheral 5-HT$_4$ receptors reside in the heart, intestines, and adrenal gland where their activation can be demonstrated to produce tachycardia, aldosterone and cortisol release, and contraction of gut and bladder smooth muscle. Whether these actions are important under normal physiologic conditions is not clear, but peripheral 5-HT$_4$ receptors promote the release of ACh and increase gut motility.[33]

attributed to 5-HT$_{1B}$ receptors.[116] Cranial blood vessels (eg, meninges) possess 5-HT$_{1D}$ and 5-HT$_{1B}$ receptors, whose activation produces vasoconstriction and decreased inflammation.[113]

5-HT$_{1E}$ and 5-HT$_{1F}$ receptors are more recently discovered members of the 5-HT$_1$ receptor class. Their functional activity is yet to be determined.

5-HT$_2$ Receptors The three subtypes of 5-HT$_2$ receptors are coupled to G proteins, thus serving to decrease K$^+$ efflux and/or increase intracellular Ca^{2+} concentration by raising concentrations of inositol triphosphate and diacylglycerol.[104] The three subtypes of 5-HT$_2$ receptors are so similar in characterization that investigational probes have great difficulty in distinguishing the subtypes. 5-HT$_{2A}$ receptors are most concentrated in

5-HT$_5$ Receptors 5-HT$_5$ receptors exist in the form of at least two subtypes, one of which may be coupled to G$_{i/o}$. The 5-HT$_{5a}$ subtype may act as a somatodendritic autoreceptor, but the functionality of this role is unknown, in contrast to the predominant importance of 5-HT$_{1a}$ autoreceptors.[104]

5-HT$_6$ and 5-HT$_7$ Receptors 5-HT$_6$ and 5-HT$_7$ receptors are positively coupled to cAMP formation through G proteins.[104] Their distribution

is poorly defined. However, many antidepressants and antipsychotics antagonize these receptors. They are currently a source of great interest because of the possibility of avoiding DA blockade to achieve antipsychotic activity. The 5-HT$_7$ receptor may be particularly important in regulating circadian rhythms.[161]

■ XENOBIOTICS

Table 13–7 provides examples of xenobiotics that affect serotonergic neurotransmission.

TABLE 13–7. Examples of Xenobiotics That Affect Serotonergic Neurotransmission

Serotonin agonism	Escitalopram
Enhance 5-HT synthesis	Fluoxetine
ʟ-Tryptophan	Fluvoxamine
5-Hydroxytryptophan	Lamotrigine
Direct 5-HT agonists	Meperidine
Buspirone	Nefazodone
Cisapride	Sertraline
Ergots and indoles	Tramadol
Hallucinogenic substituted	Trazodone
amphetamines	Venlafaxine
mCPP	Serotonin Antagonism
Lisuride	Direct 5-HT antagonists
Mescaline	Aripiprazole
Metoclopramide	Clozapine
Triptans	Cyclic antidepressants
Increase 5-HT release	Cyproheptadine
Amphetamine	Ergots and indoles (eg, LSD)
Cocaine	Haloperidol
Dexfenfluramine	Ketanserin
Dextromethorphan	Mescaline
ʟ-Dopa	Methysergide
Fenfluramine	Metoclopramide
MDMA	Mirtazapine
Mirtazapine	Nefazodone
Reserpine (initial)	Olanzapine
Increase 5-HT tone by	Ondansetron
unknown mechanism	Paliperidone
Lithium	Phenothiazines
Inhibit 5-HT breakdown	Phentolamine
MAOIs	Propranolol
Inhibit 5-HT uptake	Quetiapine
Amoxapine	Risperidone
Amphetamines	Trazodone
Atomoxetine	Ziprasidone
Carbamazepine	Enhance 5-HT uptake
Citalopram	Tianeptine
Clomipramine[a]	Inhibit vesicle uptake
Cocaine	Reserpine
Cyclic antidepressants	Ketanserin
Dextromethorphan	Tetrabenazine
Duloxetine	

5-HT = serotonin; LSD = lysergic acid diethylamide; MAOIs = monoamine oxidase inhibitors; mCPP = *m*-chlorophenylpiperazine (metabolite of trazodone and nefazodone); MDMA methylenedioxymethamphetamine.

[a]Clomipramine is the most potent 5-HT uptake inhibitor of the tricyclic antidepressants.

Serotonin Agonists   The body rapidly metabolizes orally administered 5-HT via intestinal and hepatic MAO. However, L-tryptophan is an amino acid precursor to 5-HT, which is readily absorbed by the intestinal tract and able to cross the blood–brain barrier. This method of augmenting CNS 5-HT production was previously used as an unproved sleep aid until it was associated with the eosinophilia myalgia syndrome in 1990. 5-Hydroxytryptophan (5-HTP) is the immediate precursor to 5-HT. 5-HTP is commonly available without a prescription. The anxiolytics buspirone, gepirone, and ipsapirone act as partial agonists at somatodendritic and postsynaptic 5-HT$_{1A}$ receptors. Sumatriptan, an antimigraine agent, mainly activates 5-HT$_{1D}$ and 5-HT$_{1B}$ receptors.[113] The action of sumatriptan action may result from vasoconstriction of meningeal and other cranial, extracerebral vasculature; no impairment of cerebral blood flow follows its use. Other members of the triptan class include rizatriptan, zolmitriptan, and naratriptan.

Metoclopramide and tegaserod are prokinetic drugs that activate 5-HT$_4$ receptors to increase gut motility.[33] Because 5-HT$_4$ receptors are also found in the heart and urinary bladder detrusor muscle, 5-HT$_4$ agonists occasionally produce bladder incontinence and tachycardia.

Numerous indoles and phenylalkylamines, including ergot alkaloids, lysergic acid diethylamide (LSD), psilocybin, and mescaline, exhibit both agonistic and antagonistic properties at multiple 5-HT receptors. Their hallucinogenic/illusionogenic action is best explained by partial agonism at 5-HT$_{2A}$ receptors.[51] Some substituted amphetamines (eg, methylenedioxymethamphetamine, MDMA) directly stimulate 5-HT receptors.[157]

Cocaine and indirect-acting sympathomimetics, especially amphetamines, cause 5-HT release as previously described.[157] Centrally, DA undergoes uptake into serotonergic neurons to displace 5-HT from the neuron. Ingestion of L-dopa or other agents that increase CNS DA concentrations can cause 5-HT release.[104]

Inhibitors of 5-HT uptake include amphetamines, cocaine, various antidepressants, meperidine, and dextromethorphan. Several antidepressants specifically inhibit 5-HT uptake. Examples of selective 5-HT reuptake inhibitors (SSRIs) include fluoxetine, sertraline, paroxetine, and citalopram. The use of SSRIs sometimes produces extrapyramidal side effects for reasons that remain unclear because of the numerous actions of 5-HT in the basal ganglia.[61] Two anticonvulsants, carbamazepine and lamotrigine, appear to inhibit 5-HT uptake.[150] Again, reserpine and tetrabenazine prevent 5-HT uptake into vesicles.

MAO-A accounts for most 5-HT degradation, and nonspecific MAOIs and MAO-A inhibitors (clorgyline, moclobemide) raise 5-HT concentrations and, through indirect action, probably cause 5-HT release.

Serotonin Antagonists   Trazodone and nefazodone act mainly as antagonists at 5-HT$_2$ receptors, but are also weak uptake inhibitors. Both undergo metabolism to *m*-chlorophenylpiperazine (mCPP), which activates most 5-HT receptors, but is especially active at 5-HT$_{2C}$ receptors. Ketanserin and ritanserin specifically antagonize 5-HT$_{2C}$ receptors, while methysergide and cyproheptadine antagonize 5-HT$_1$ and 5-HT$_2$ receptors.[110]

Mirtazapine exhibits complex actions, including antagonism of 5-HT$_{2A}$, 5-HT$_{2C}$, and 5-HT$_3$ receptors.[53] It also indirectly increases 5-HT$_{1A}$ activity and enhances release of NE through antagonism of α$_2$-adrenoceptors. Mirtazapine demonstrates potent antagonism of histaminic and muscarinic receptors.[53]

Most antipsychotics and tricyclic antidepressants antagonize 5-HT$_{2A}$ and, to a lesser extent, 5-HT$_{2C}$ receptors. In fact, investigators are interested in developing antipsychotic agents similar to risperidone that possess potent antagonistic properties at 5-HT$_2$ receptors, without accompanying DA receptor antagonism, in order to limit extrapyramidal side effects. These investigations have resulted in the introduction of olanzapine, sertindole, ziprasidone, zotepine, quetiapine, and amisulpride.[161]

Ondansetron, granisetron, tropisetron, dolasetron, and alosetron antagonize 5-HT$_3$ receptors.[33] Their antiemetic action is thought to be

explained by several mechanisms. Central antagonism at the chemore-ceptor-triggering zone lessens vomiting. Peripheral 5-HT$_3$ receptor antagonism in the gut prevents ACh release, decreasing gut motility. Finally, antagonism of vagal 5-HT$_3$ receptors decreases afferent stimu-latory signals to the vomiting center in the brainstem. Metoclopramide antagonizes 5-HT$_3$ and D$_2$ receptors.[33] Ondansetron and other experi-mental 5-HT$_3$ antagonists are being studied in the treatment of schizo-phrenia because of their ability to prevent DA release.

Tianeptine is an antidepressant that enhances 5-HT uptake, thus lowering synaptic 5-HT concentrations.[128]

Serotonin Syndrome Serotonin syndrome represents an iatrogenic and largely idiosyncratic condition that is most commonly caused by the combination of two or more 5-HT agonists, although it can happen following single 5-HT agonists in overdose or at therapeu-tic dosages.[107] Animal models indicate that serotonin syndrome can be prevented by the blockade of 5-HT$_{1A}$ receptors and 5-HT$_{2A}$ receptors.[21,110,112] Serotonin syndrome is characterized by alterations in mentation and cognition, autonomic nervous system dysfunction, and neuromuscular abnormalities. Symptoms may include confu-sion, agitation, convulsions, coma, tachycardia, diaphoresis, hyper-thermia, hypertension, shivering, myoclonus, tremor, hyperreflexia, and muscle rigidity (especially of legs).[107] Serotonin syndrome is often confused with neuroleptic malignant syndrome in its more severe presentation due to their similar manifestations. Serotonin syndrome usually responds to supportive care alone but may improve with 5-HT$_{1a}$ and 5-HT$_{2a}$ receptor inhibitors such as cyproheptadine.[21,107] Serotonin syndrome can be caused by xenobiotics that increases CNS 5-HT neurotransmission (Table 13–7). In addition, xenobiotics that act to increase CNS DA concentrations, such as levodopa and bromocriptine, have potential to precipitate serotonin syndrome by indirectly causing 5-HT release (Chap. 72).

■ γ-AMINOBUTYRIC ACID

GABA is one of two main inhibitory neurotransmitters of the central nervous system (glycine is discussed later; see Glycine as an Inhibitory Neurotransmitter). Xenobiotics that enhance GABA activity are gener-ally used as anticonvulsants, sedative-hypnotics, anxiolytics, and gen-eral anesthetics. Xenobiotics that antagonize GABA activity typically produce CNS excitation and convulsions. GABA is synthesized from glutamate, the brain's main excitatory neurotransmitter.

In general, GABA inhibition predominates in the brain. In the spinal cord, through monosynaptic and polysynaptic reflex pathways, GABA mediates a number of physiologically minor peripheral effects outside the CNS (eg, vasodilatation, bladder relaxation). Spinal cord GABA is important in attenuating skeletal muscle reflex arcs.[97]

■ SYNTHESIS, RELEASE, AND UPTAKE

Figure 13–9 illustrates GABA synthesis. Glutamate is converted to GABA via glutamic acid decarboxylase (GAD) which requires pyridoxal phosphate (PLP) as a cofactor. Pyridoxal phosphate is synthesized from pyridoxine (vitamin B$_6$) by the enzyme pyridoxine kinase (PK).[105] VGAT, a vesicle-bound transporter, transports GABA into vesicles from where it is released through Ca^{2+}-dependent exocytosis into the synapse.[97] Uptake of GABA from the synapse back into the presynaptic neurons is mediated by the Na$^+$-dependent transporter, GAT-1, whereas uptake into glial cells and possibly postsynaptic neurons is mediated by GAT-2, GAT-3, and GAT-4. Evidence also suggests that GABA is released into the synapse from cytoplasm by reverse transport under some condi-tions. In glial cells, cytoplasmic GABA can undergo degradation by GABA-transaminase (GABA-T) to succinic semialdehyde (SSA), part

of which then undergoes oxidation to succinate. GABA-T also requires PLP as a cofactor.[115] The transamination of GABA to SSA by GABA-T results in the conversion of α-ketoglutarate to glutamate, which then moves back into neurons to be used for resynthesis of GABA.

■ GABA RECEPTORS

There are three main types of GABA receptors (Table 13–8).[17] GABA$_A$ receptors are Cl$^-$ channels that mediate inhibition by allowing Cl$^-$ to move into and hyperpolarize the neuron. The majority of GABA$_A$ receptors are located postsynaptically and mediate fast or *phasic* inhi-bition. About 5% to 10% of GABA$_A$ receptors are located outside the synapse and are responsible for slower *tonic* current that is present at resting membrane potential.[60,91,109,137] Situated at various sites in relation to the GABA recognition site on the Cl$^-$ channel are sites for exogenous and endogenous modulators (Fig. 13–10) where numerous excitatory and depressant xenobiotics bind, and through which GABA$_A$ receptor responsiveness is regulated under normal physiologic conditions. The common denominator for modulation at the GABA$_A$ complex is an increase or decrease in inward Cl$^-$ current.

Throughout the CNS there are regional variations in expressions of multiple subunit genes for the GABA$_A$ complex. GABA$_A$ receptors exist as pentamers, composed most commonly of two α subunits, two β subunits, and either a γ or δ subunit. Multiple isoforms of subunits exist (eg, α$_1$–α$_6$), but within a single receptor, the isoforms of individual sub-units appear to be identical. While the large numbers of isoforms and different combinations of subunits could theoretically produce more than 2000 different GABA$_A$ Cl$^-$ channels, only a few dozen combina-tions exist naturally.[35,109] The most common is α$_1$β$_2$γ$_2$.[8,145]

The second type of GABA receptor, GABA$_B$, is found on both presyn-aptic and postsynaptic membranes. The GABA$_B$ receptors are heterodi-mers, with companion proteins linked to the receptors, and are coupled to G proteins (probably G$_{i/o}$) that mediate both presynaptic and postsyn-aptic inhibition.[20] Presynaptic inhibition results from preventing Ca^{2+} influx so as to impair exocytosis of neurotransmitter vesicles, including those containing excitatory amino acids (eg, glutamate). Postsynaptic inhibition is mediated by increasing K$^+$ efflux through K$^+$ channels, resulting in hyperpolarization of the membrane away from threshold. Through presynaptic actions, GABA$_B$ receptors also serve as autorecep-tors, where their activation in response to synaptic GABA provides feed-back inhibition of further neurotransmitter release (Fig. 13–9).

A third GABA receptor, GABA$_C$, is a Cl$^-$ channel that, when acti-vated, allows increased Cl$^-$ influx. The GABA$_C$ receptors are thought to comprise 5 ligand binding sites, whereas GABA$_A$ receptors have 2 ligand binding sites.[17] GABA$_C$ receptors are composed of ρ subunits (ρ$_1$–ρ$_3$). ρ$_1$ subunits are located in the mammalian retina, ρ$_2$ subunits are present in most brain regions, and ρ$_3$ subunits are found in the hip-pocampus. ρ$_1$ and ρ$_2$ receptors have also been found outside the CNS.[69] GABA$_C$ receptors are sensitive to *cis*-4-aminocrotonic acid (CACA), are insensitive to baclofen, bicuculline, benzodiazepines, and barbitu-rates, and are less sensitive to neuroactive steroids and to picrotoxin (Table 13–8).[69] GABA$_C$ receptors are activated at 40-fold lower GABA concentrations than GABA$_A$ receptors, are less liable to desensitization, and remain open longer than GABA$_A$ Cl$^-$ channels.

■ XENOBIOTICS

Table 13–9 provides examples of xenobiotics that affect GABAergic neurotransmission.

Modulation of GABA Production and Degradation Isoniazid (INH) and other hydrazines (eg, monomethylhydrazine from mushrooms) lower CNS GABA concentrations by several mechanisms. Most important,
FIGURE 13–9. GABAergic neurotransmission. GABA (γ-aminobutyric acid) released from a presynaptic neuron (B) binds to postsynaptic $GABA_A$, $GABA_B$, or $GABA_C$ receptors to hyperpolarize and inhibit neuron D [5,6] or to presynaptic $GABA_B$ heteroreceptors on neuron C [7] to inhibit neurotransmitter release by blocking Ca^{2+} influx (an excitatory glutamatergic neuron is shown as an example). Stimulation of $GABA_B$ autoreceptors on neuron B [8] also reduces further release of GABA. Synaptic GABA undergoes uptake into the presynaptic neuron by GAT-1, and uptake into glial cells and possibly postsynaptic neurons by GAT-2, GAT-3, and GAT-4 (GAT-2 is shown mediating uptake into glial cell A as an example.) Acute falls in pyridoxal phosphate (PLP) lead to impaired glutamic acid decarboxylase (GAD) activity and low GABA concentrations. Although GABA-transaminase (GABA-T) also requires PLP, acute falls in PLP do not affect this enzyme as dramatically because of tight PLP binding to the GABA-T complex. Agents in Table 13 -9 act to impair PLP formation by inhibiting pyridoxine kinase (PK) [1]; to increase GABA concentrations by either stimulating GAD [2] or inhibiting SSAD [3]; to inhibit GABA uptake [4]; to stimulate or block GABA receptors [5 -8]; to cause GABA release [9]; or to inhibit GABA-T [10]. Glutamic-oxaloacetic transaminase (GOT), GABA-T, and SSAD are mitochondrial enzymes. G = G protein; GAT = membrane GABA uptake transporter; SA = succinic acid; SSA = succinic semialdehyde; SSAD = SSA dehydrogenase; VGAT = vesicle membrane GABA uptake transporter.

they compete with pyridoxine for binding to PK, impairing PLP pro-duction.[105] Pyridoxal phosphate binding to the GAD complex is easily reversible.[115] The acute decrease in PLP concentration, then, is rapidly accompanied by impaired GABA synthesis and a decrease in GABA concentration. Lack of normal GABA inhibition produces seizures typi-cal of hydrazine toxicity. Although PLP is also required for GABA deg-radation by GABA-T, acute decreases in PLP do not affect this enzyme nearly as much, because PLP is more tightly bound to the GABA-T complex and remains associated with the enzyme.[115] To a lesser extent, isoniazid binds to the GAD-PLP complex to prevent GABA formation.

Cyanide inhibits numerous enzymes besides cytochrome oxidase. Inhibition of GAD with a resultant fall in GABA concentration may partly explain seizures that occur in cyanide-poisoned patients. Domoic acid (see Glutamate later) may also inhibit GAD.[36]

In vitro studies demonstrate valproate's ability to increase brain GABA concentrations, either by inhibition of succinic semialdehyde dehydroge-nase or by activation of GAD.[70] Gabapentin may increase the rate of GABA synthesis in the brain by stimulating GAD, though gabapentin's main mechanism of action is to bind to calcium channels.[160] Vigabatrin, an anticonvulsant, acts by irreversibly inhibiting GABA-T.[153]

TABLE 13–8. GABA Receptors and Their Characteristics

	GABA$_A$	GABA$_B$	GABA$_C$
Receptor	Cl⁻ channel	G protein-coupled	Cl⁻ channel
Bicuculline antagonism	Yes	No	No
Baclofen agonism	No	Yes	No
Benzodiazepine agonism	Yes	No	No
Barbiturate agonism	Yes	No	No
Picrotoxin antagonism	Yes	No	Slight

GABA$_A$ Agonism Figure 13–10 schematically illustrates the GABA$_A$ receptor complex. In general, GABA$_A$ agonists cause CNS depression, ranging from mild sedation and nystagmus to ataxia, stupor, coma, and even general anesthesia. Many indirect agonists that bind to the GABA$_A$ complex have no activity in the absence of GABA. With some exceptions, their pharmacologic actions require the binding of GABA to its receptor and do not result from a direct effect on Cl⁻ conductance exclusive of GABA binding. Many of these xenobiotics demonstrate additional actions that are not mediated through the GABA$_A$ complex.

Direct GABA Agonists. The main direct GABA agonist of toxicologic interest is muscimol, found in some poisonous mushrooms. Muscimol binds to the GABA receptor on the GABA$_A$ complex to mimic the action of GABA.[117] Ibotenic acid, a direct glutamate agonist found in the same mushrooms, is decarboxylated to muscimol just as glutamate is decarboxylated to GABA.
FIGURE 13–10. Representation of the GABAA Cl⁻ channel receptor complex. Benzodiazepines (BENZOs), barbiturates, picrotoxin, steroids, and GABA (γ-aminobutyric acid) clearly bind to different sites on the channel. Although separate circles represent different agents capable of binding to and of modulating Cl⁻ influx through the GABA$_A$ receptor complex, it is not always apparent where these agents bind on the channel. For example, general anesthetics and ethanol may produce their effects by interacting with the steroid binding site. Chloral hydrate undergoes metabolism to trichloroethanol, which interacts with the GABA$_A$ receptor complex. Zolpidem, zopiclone, and zaleplon are nonbenzodiazepines that bind to the benzodiazepine site. Given the structural similarity of glutethimide and methyprylon to barbiturates, it is speculated that their action may be mediated at GABA$_A$ receptors.

TABLE 13–9. Examples of Xenobiotics That Affect GABAergic Neurotransmission

GABA agonism	GABA antagonism
Stimulate GAD	Direct GABA$_A$ antagonists
Valproate	Bicuculline
Direct GABA$_A$ agonists	Cephalosporins
Muscimol	Ciprofloxacin
Progabide[a]	Enoxacin
Indirect GABA$_A$ agonists	Imipenem
Avermectin	Nalidixic acid
Barbiturates	Norfloxacin
Benzodiazepines	Ofloxacin
Chloral hydrate	Penicillins
Clomethiazole	Indirect GABA$_A$ antagonists
Ethanol	Aztreonam
Etomidate	Clozapine
Felbamate	Cyclic antidepressants
Ivermectin	Flumazenil
Meprobamate	Lindane
Methaqualone	MAOIs
Propofol	Maprotiline
Steroids	Organic chlorine insecticides
Topiramate	Penicillins
Trichloroethanol	Pentylenetetrazol
Volatile anesthetics	Picrotoxin
Zaleplon	Inhibit GAD
Zolpidem	Cyanide
Zopiclone	Domoic acid
Direct GABA$_B$ agonists	Hydrazines
Baclofen	Isoniazid
GHB	Direct GABA$_B$ antagonists
Inhibit GABA-T	Phaclofen[b]
Vigabatrin	Saclofen[b]
Inhibit GABA uptake	Inhibit PK
Tiagabine	Hydrazines[c]
Valproate	Isoniazid[c]

GABA = γ-aminobutyric acid; GABA-T = GABA transaminase; GAD = glutamic acid decarboxylase; GHB = γ-hydroxybutyric acid; PK = pyridoxine kinase; MAOIs = monoamine oxidase inhibitors.

[a] Directly activates GABA$_A$ and GABA$_B$ receptors as well as being metabolized to GABA.

[b] Thought not to cross blood–brain barrier in meaningful amounts.

[c] Major site of action is PK inhibition, though some direct GAD inhibition occurs.

Indirect GABA Agonists. Benzodiazepines bind to benzodiazepine receptors on GABA$_A$ complexes to increase the affinity of GABA for its receptor and to increase the frequency of Cl⁻ channel opening in response to GABA binding.[144] The benzodiazepine binding site on the GABA$_A$ receptor is located in a pocket between an α subunit and a γ$_2$ subunit.[166] Benzodiazepines also inhibit adenosine uptake apart from GABA$_A$ activity (see Adenosine later).

Various isoforms of GABA$_A$ Cl⁻ channels differ in their affinity for different benzodiazepines. GABA$_A$ receptors containing γ$_2$ subunits are more sensitive to benzodiazepines than are GABA$_A$ receptors containing γ$_1$ and γ$_3$ subunits. Sensitivity and response to benzodiazepine binding is also highly dependent on the specific α subunit composition of the GABA$_A$ receptor. GABA$_A$ receptors containing an α$_4$ or α$_6$ subunit are completely insensitive to and will not bind benzodiazepines,

whereas $GABA_A$ receptors containing α_1, α_2, α_3, or α_5 subunits are sensitive to benzodiazepine binding. This has important implications in that the development of tolerance to ethanol confers cross tolerance to benzodiazepines through a change in α subunits (see Chaps. 14 and A24). In addition, specific subunits may mediate different effects of benzodiazepines. For example, sedative effects are mediated through binding to α_1 subunits while anxiolytic effects appear to be mediated by binding to α_2 subunits.[47]

Zolpidem, an imidazopyridine, zaleplon, a pyrazolopyrimidine, and zopiclone are nonbenzodiazepines that act as agonists at the benzodiazepine binding site on the $GABA_A$ receptor. They exhibit a high selectivity for the α_1 subunit and low selectivity for α_2, α_3, and α_5 subunits.[148,166] This selective binding to α_1 subunits is thought to account for their relatively selective sedative properties at therapeutic doses, and lack of anxiolysis, as compared to benzodiazepines.

Numerous steroids, such as alphaxalone and naturally occurring analogs, bind to the $GABA_A$ complex to inhibit or enhance the action of GABA.[50,144] The synthesis of neuroactive steroids is partly regulated by benzodiazepine binding to mitochondrial benzodiazepine receptors (also known as TSPO [translocator proteins]) apart from the $GABA_A$ complex.[79,144] These mitochondrial benzodiazepine binding sites are found both within and outside the CNS and were originally called peripheral benzodiazepine receptors. On binding, benzodiazepines appear to enhance the movement of cholesterol into mitochondria to begin steroid synthesis. Some of carbamazepine's action may be a result of binding at mitochondrial benzodiazepine receptors.[44]

Barbiturates bind to the $GABA_A$ complex to produce several effects.[78,144] All barbiturates enhance the action of GABA by producing more Cl^- influx for a given amount of GABA binding by increasing the duration of Cl^- channel opening. Whereas phenobarbital does not change the affinity of GABA or benzodiazepines for their binding sites, depressant barbiturates, such as pentobarbital, do increase GABA and benzodiazepine receptor affinities for their ligands, further enhancing inward Cl^- currents. At high concentrations, at least some barbiturates directly open Cl^- channels to cause Cl^- influx.[78] Phenobarbital can directly open the Cl^- channel at antiepileptic concentrations. In addition, barbiturates possess other actions that depress all excitable membranes, including cardiac and smooth muscle.

The intravenous anesthetics propofol and etomidate enhance inward $GABA_A$ Cl^- currents, and at high concentrations they directly open chloride channels in the absence of GABA.[7] The respiratory depressant and immobilizing effects of etomidate and propofol are mediated by β_3 subunits, while the sedative effects of these agents are mediated through agonism at β_2 subunits.[149,178] Volatile general anesthetics also directly activate $GABA_A$ Cl^- channels.

Some of ethanol's action is mediated through binding to the $GABA_A$ complex. The degree to which ethanol enhances the effect of GABA on Cl^- influx depends on the $GABA_A$ receptor subunit composition. For example, receptors with an α_4 or α_6 subunit and a δ subunit respond to very low concentrations of ethanol.[158,168]

Methaqualone produces at least part of its pharmacologic effect through indirect $GABA_A$ activity. Little is known of the mechanisms of action of glutethimide and methyprylon. Their structural similarities to barbiturates suggest that they have activity at the $GABA_A$ receptor. Trichloroethanol, a metabolite of chloral hydrate, and clomethiazole interact at the $GABA_A$ complex in a manner similar to barbiturates, although it is not clear whether they are binding to an identical site on the Cl^- channel.[172] Ivermectin, an antihelminthic, activates $GABA_A$ Cl^- channels by increasing GABA binding. Meprobamate displays barbiturate-like action at the $GABA_A$ receptor and, at high concentrations, is able to cause Cl^- influx in the absence of GABA.[133] High concentrations of felbamate also cause inward Cl^- currents in the presence of GABA, although this seems unimportant at therapeutic doses.[133]

Part of topiramate's anticonvulsant action may result from enhanced Cl^- influx through binding to $GABA_A$ receptors.[142]

Inhibition of GABA Uptake. Valproate and the anticonvulsants guvacine and tiagabine work, in part, by inhibiting GABA uptake. Although valproate is structurally similar to GABA, its inhibition of the GABA transporter does not appear to be competitive.[114]

$GABA_A$ Antagonism *Direct $GABA_A$ Antagonists.* Xenobiotics that act by any mechanism to decrease $GABA_A$ activity can cause CNS excitation and convulsions by decreasing inhibitory inward Cl^- currents. Direct antagonists bind to the same site as GABA to prevent GABA binding, the prototype being the convulsant bicuculline. Various antibiotics interact with the $GABA_A$ receptor to antagonize the action of GABA. In a dose-dependent manner, both imipenem and cephalosporins appear to directly antagonize GABA binding and can produce seizures at high doses or at therapeutic doses in susceptible individuals.[167] Evidence suggests that penicillin may also directly antagonize GABA binding. Electrophysiologic and radioligand binding studies indicate that norfloxacin, ciprofloxacin, ofloxacin, and enoxacin combine with the GABA binding site to prevent GABA binding.[167] Theophylline and at least some NSAIDs markedly enhance GABA antagonism by some fluoroquinolones in vitro.[167] Virol A, from *Cicuta virosa*, appears to directly antagonize binding of GABA to its receptor on the $GABA_A$ complex.[163]

Indirect $GABA_A$ Antagonists. Penicillin is well known for producing convulsions at high doses (eg, >20 million units of penicillin per day with renal insufficiency), and both penicillin and aztreonam, a monobactam, appear to block the Cl^- channel to prevent GABA-mediated inward Cl^- currents.[167]

Picrotoxin, from *Anamirta cocculus* (fish berries), and the experimental convulsant pentylenetetrazol bind to the picrotoxin site of the $GABA_A$ receptor complex to inhibit the action of GABA. Excessive doses produce CNS excitation and convulsions. Some organochlorine insecticides (eg, lindane) also inhibit the action of GABA by binding to what appears to be the picrotoxin site and cause convulsions.[93] Both α-thujone, the active component in wormwood oil, and cicutoxin from the water hemlock noncompetitively antagonize $GABA_A$ activity.[64,164]

Flumazenil competitively antagonizes benzodiazepines, zolpidem, zaleplon, and zopiclone at their receptors to reverse their pharmacologic effects.[17,145] Paradoxically, large doses of flumazenil exhibit anticonvulsant activity in animals. This is explained, at least in part, by flumazenil's ability to inhibit adenosine uptake.[123]

Cyclic antidepressants, including amoxapine and maprotiline, and at least two MAOIs (isocarboxazid and tranylcypromine) inhibit GABA-mediated Cl^- influx at $GABA_A$ receptors.[96,152] Their potency at inhibiting Cl^- influx correlates with the frequency of seizures that occur in patients taking therapeutic doses of these medications. Impaired $GABA_A$ activity may contribute to or be primarily responsible for seizures that occur in patients who overdose on these xenobiotics. Their exact binding on the $GABA_A$ receptor complex remains unknown, although some evidence suggests at least indirect activity at the picrotoxin binding site.

Some subtypes of $GABA_A$ receptors are susceptible to inhibition by zinc ions.[144] What role this plays in normal physiology or toxicology is not established.

$GABA_A$ Withdrawal. Acute withdrawal from all $GABA_A$ direct and indirect agonists appears almost identical except for time course; the common denominator is impaired Cl^- influx. Withdrawal of all $GABA_A$ agonists can cause tremor, hypertension, tachycardia, respiratory alkalosis, diaphoresis, agitation, hallucinations, and convulsions. When $GABA_A$ receptors are chronically exposed to an agonist, changes in gene expression of receptor subunits occur, which lessens

Cl$^-$ influx in response to GABA or drug binding, producing tolerance. Importantly, withdrawal of the agonist produces yet further changes in subunit expression. For example, benzodiazepine-insensitive α_4-subunit expression is increased following withdrawal of many GABA agonists, including benzodiazepines, zolpidem, zopiclone, zaleplon, neurosteroids, and ethanol. (Expression of other subunits, including α_1, γ_2, β_2, and β_1 also change in response to exposure and/or withdrawal of GABA$_A$ agonists.[47]) Alterations in GABA$_A$ receptor subunit composition following chronic exposure to and withdrawal of an agonist can, therefore, affect the ability to successfully treat withdrawal symptoms. While any GABA$_A$ receptor agonist may be used to treat withdrawal from another, some agents work better than others in different clinical settings. For example, patients experiencing severe alcohol withdrawal may have an increased proportion of GABA$_A$ receptors containing benzodiazepine-insensitive α_4 subunits, and contain fewer GABA$_A$ receptors with benzodiazepine-sensitive α_1 subunits.[24] Even extremely high doses of benzodiazepines in these patients may not effectively control severe alcohol withdrawal. A better treatment option in such a setting would be GABA$_A$ agonists such as propofol or phenobarbital that either act on a different site on the GABA$_A$ receptor or directly open the Cl$^-$ channel.[7,24] Phenytoin and carbamazepine do not stop GABA$_A$ withdrawal seizures because their pharmacologic effects are independent of GABA$_A$ agonism.

GABA$_B$ Agonists. The main GABA$_B$ receptor agonist of toxicologic significance is baclofen. Coma, hypothermia, hypotension, bradydysrhythmias, and seizures characterize its toxicity. The convulsions that occur in patients with baclofen overdose are thought to result from disinhibition (inhibition of inhibitory neurons). Carbamazepine's activation of GABA$_B$ receptors has been demonstrated, although this is not thought to explain most of its anticonvulsant action. Some of γ-hydroxybutyrate's actions following pharmacologic doses may be mediated through activation of GABA$_B$ receptors.

GABA$_B$ Withdrawal. Baclofen withdrawal is similar clinically to GABA$_A$ withdrawal. Hallucinations, agitation, tremor, increased sympathetic activity, and convulsions are the main characteristics of baclofen withdrawal. Withdrawal from chronic intrathecal baclofen administration may also be accompanied by large swings in autonomic tone (hypotension, hypertension, tachycardia, bradycardia) and transient cardiomyopathy and shock. Reinstitution of oral baclofen therapy following oral withdrawal, or intrathecal baclofen following intrathecal withdrawal, when possible, is the treatment of choice.[97]

GAMMA-HYDROXYBUTYRATE

γ-Hydroxybutyrate (GHB; γ-hydroxybutyric acid) exists endogenously, but toxicologic interest stems from its use as a drug of abuse and as a treatment for narcolepsy.[11,45,85] GHB is rapidly absorbed and freely crosses the blood–brain barrier. Toxicity resulting from ingestion of GHB is explained by GHB receptor and GABA$_B$ receptor activation, and comprises agitation, tremor, rapid onset of coma, vomiting, bradycardia, hypotension, hypotonia, and apnea that usually resolve within several hours. Although seizure activity has been noted in experimental animals, it is debated whether GHB causes true convulsive activity in human beings. Human experiments with "therapeutic" doses of GHB have not found EEG changes consistent with seizure activity.[85] Some authors have reported "generalized seizures" occurring in patients presenting after GHB overdose. Interestingly, patients with the rare inborn error of metabolism, succinic semialdehyde dehydrogenase (SSAD) deficiency, have elevated GHB concentrations and tend to experience seizures.[52] Valproate similarly elevates endogenous GHB concentrations by inhibiting SSAD.

Controversy exists as to whether GHB should be considered a neurotransmitter or simply a neuromodulator because it is unclear whether this substance is concentrated within vesicles for synaptic release. There is evidence demonstrating a sodium-dependent up-take transporter for GHB.

GHB receptors appear to be heterogeneously distributed throughout the brain, with highest concentrations in the hippocampus, cortex, limbic areas, and thalamus, as well as in regions innervated by dopaminergic terminals and dopaminergic nuclei. GHB receptors exist on neurons, mainly at the synaptic level, but are absent from glial or peripheral cells. At least two general GHB receptors have been described thus far, based on binding affinity for GHB and other ligands. Although γ-butyrolactone (GBL) does not express affinity for GHB binding sites, GBL rapidly undergoes hydrolysis to form GHB by peripheral γ-lactonase.[11,95] 1,4-Butanediol undergoes conversion to GHB via alcohol dehydrogenase and aldehyde dehydrogenase.

Several proposed pathways for endogenous GHB formation exist (Fig. 13–11).[11] Evidence exists for GHB's metabolism back to GABA, although this appears minimal at physiologic GHB concentrations.[45] However, effects resulting from pharmacologic doses of GHB may result, in part, from secondary GABA formation.
FIGURE 13–11. Potential pathways of GHB (γ-hydroxybutyrate) synthesis and degradation. GABA = γ-aminobutyric acid; GBL = γ-butyrolactone; SSA = succinic semialdehyde; [1] = glutamic acid decarboxylase; [2] = GABA-transaminase; [3] = succinic semialdehyde dehydrogenase; [4] = specific succinic semialdehyde reductase and/or nicotinamide adenine dinucleotide phosphate (NADPH)-dependent aldehyde reductase 2; [5] = mitochondrial β oxidation; [6] = alcohol dehydrogenase and aldehyde dehydrogenase; [7] = GHB dehydrogenase; [8] = γ-lactonase.

Although normal endogenous GHB concentrations are probably not high enough to activate GABA$_B$ receptors, such receptor activation may occur with exogenous administration of GHB. Furthermore, there appears to be functional interplay between GHB and GABA$_B$ receptors.[11]

Specific interactions between GHB and DA are complex and not fully delineated. Treatment with GHB appears to inhibit DA release, probably via stimulation of GABA$_B$ receptors.[173] GHB also affects the firing rates of dopaminergic neurons, DA synthesis, and levels of DA and its major metabolites. GHB is thought to affect sleep cycles, temperature regulation, cerebral glucose metabolism and blood flow, memory, and emotional control, and it may be neuroprotective.

Although GHB can suppress alcohol withdrawal, it is also addictive, and both tolerance and a withdrawal syndrome have been described. Withdrawal is characterized, in part, by insomnia, cramps, paranoia, hallucinations, tremor, and anxiety.

GLYCINE AS AN INHIBITORY NEUROTRANSMITTER

Glycine acts as an inhibitory neurotransmitter in the spinal cord and lower brainstem. In the CNS, serine is converted to glycine by serine hydroxymethyltransferase (SHMT).

■ RELEASE AND UPTAKE

Glycine is transported into storage vesicles by VGAT and undergoes Ca^{2+}-dependent exocytosis upon neuronal depolarization (Fig. 13–12). Glycine is removed from the synapse through uptake by a Na$^+$-dependent transporter into presynaptic neurons and into glial cells. Two glycine membrane transporters have been cloned and share homology with GABA uptake transporters. GLYT-1 is found both in astrocytes and neurons, whereas GLYT-2 is localized on axons and terminal boutons of neurons
FIGURE 13–12. Inhibitory glycinergic neurotransmission. Glycine is concentrated within vesicles by uptake via VGAT, the vesicle membrane transporter. Signals from the afferent limb of a reflex arc (top right) cause the release of an excitatory neurotransmitter (ENT) that crosses the synapse to bind to a neuron in the efferent limb of the reflex arc [1]. To prevent excessive neuronal firing and motor activity, glycine (Gly) released from a glycinergic inhibitory neuron [2] binds to glycine Cl$^-$ channel receptors [3] and causes inhibition by hyperpolarization through Cl$^-$ influx. Synaptic glycine is transported back into the neuron by at least two subtypes of membrane glycine transporters, GLYT-1 and GLYT-2 [4]. Strychnine binds to the glycinergic Cl$^-$ channel to decrease glycine's binding, which prevents Cl$^-$ influx. Although strychnine is shown to bind to a separate site from glycine, there is evidence that these sites may overlap. GLYT = glycine uptake transporter.

that contain vesicular glycine. Although both transporters are found associated with glycinergic neurons in the brainstem and spinal cord, GLYT-1 is also found in the forebrain in regions devoid of glycinergic neurotransmission. At the latter location, GLYT-1 may regulate extracellular glycine that is available for NMDA receptor activation, and GLYT-1 inhibitors could then enhance NMDA responses (see NMDA Receptor Antagonists). Glycine transporters can also function in reverse, moving glycine out of the cell when the intracellular sodium concentrations rise.[3]

■ GLYCINE RECEPTORS

The glycine receptor is a Cl^- channel that shares significant amino acid homology with the $GABA_A$ Cl^- channel. Glycine receptors are pentameric proteins made up of α and β subunits. Four isoforms of the α subunit and one isoform of the β subunit have been described.[103] An anchoring protein, gephyrin, binds to the β subunit and allows for clustering of glycine receptors at postsynaptic membranes. Glycine receptors may also be found outside the synapse, although the function of these receptors is not well understood.[170] Glycine receptor activation causes an inward Cl^- current that hyperpolarizes the membrane. Glycine binding is also important for functioning of the NMDA receptor as discussed later.

■ XENOBIOTICS

Table 13–10 provides examples of xenobiotics that affect inhibitory glycine Cl^- channels. The amino acids D-alanine, taurine, L-alanine, L-serine, and proline can activate glycinergic Cl^- channels. Both ethanol and propofol potentiate glycine-mediated inward Cl^- currents, just as they do at $GABA_A$ Cl^- channels.[99,103] Volatile halogenated anesthetics, ivermectin, Δ-9-tetrahydrocannabinol, and chloromethiazole also potentiate glycinergic transmission.[170] Clozapine inhibits glycine uptake.[67]

Strychnine is the main toxicant affecting glycinergic transmission. Strychnine binds to the α subunit of the glycine receptor to prevent glycine's action on Cl^- influx,[2] at least in part by decreasing glycine's binding to its receptors. This physiologic antagonism of glycine's action produces increased muscle tone, rigidity, opisthotonus, trismus, rhabdomyolysis, and death from respiratory failure. Given the similarity in Cl^- channels, it is not surprising that strychnine binds to the $GABA_A$ complex in vitro. However, strychnine's affinity for this complex is less than that for glycine receptors, and most of its toxicologic action is a result of physiologic antagonism of glycine's inhibitory action.

Picrotoxin binds to the glycine receptor to impair Cl^- influx.[94] Evidence exists for picrotoxin's direct antagonism at the glycine binding site(s), in contrast to $GABA_A$ Cl^- channels, where it acts at a site separate from where GABA binds. Ginkgolide B appears to inhibit the glycine receptor by directly blocking the Cl^- channel.[170] Tetanus toxin produces rigidity and trismus by preventing glycine release from nerve endings in the spinal cord and brainstem.

TABLE 13–10. Examples of Xenobiotics That Affect Inhibitory Glycine Chloride Channels

Glycine agonists	Glycine antagonists
Ethanol	Ginkogolide B
Halogenated anesthetics (volatile)	Picrotoxin
Propofol	Strychnine
D-Serine	Glycine uptake inhibitor
	Clozapine

GLUTAMATE

Glutamate is the main excitatory neurotransmitter in the CNS. It also serves as the immediate precursor to the main inhibitory neurotransmitter, GABA. This exquisite balance between glutamate neuronal stimulation and neuronal inhibition by GABA is essential for the normal functioning and protection of the CNS. Two-thirds of all brain energy expenditure is dedicated to uptake and recycling of glutamate, which insures that glutamate activity is tightly regulated.[67] Glutamate is essential for memory, learning, perception, and locomotion. Although aspartate displays similar actions as glutamate in experimental models, its role as a neurotransmitter in mammalian brains is doubtful, as it is only active at certain types of glutamate receptors and is not a substrate for glutamate neuronal vesicular transporters.[48] Glutamate and aspartate are commonly referred to as excitatory amino acid (EAA) neurotransmitters.

Glutamatergic neurotransmission has been a subject of intense research because of its role in mediating neuronal damage in degenerative neurologic diseases and during trauma, ischemia, hypoglycemia, and status epilepticus.[100] Although glutamate receptor stimulation is necessary for normal brain activity, excessive glutamate receptor activation endogenously or by glutamate agonists can produce convulsions, neuronal damage, and death. Similarly, glutamate antagonists demonstrate anticonvulsant activity and neuroprotective action in animal models of brain and spinal cord injury. A number of psychiatric and neurologic disorders have been identified with altered glutamatergic function, such as schizophrenia, depression, anxiety, posttraumatic stress disorder, and Alzheimer dementia.[67] Glutamate may also play an important role in the development of drug abuse and subsequent withdrawal symptoms. Glutamate antagonists decrease drug craving and withdrawal symptoms in patients addicted to ethanol, benzodiazepines, and opioids.[73]

■ SYNTHESIS, RELEASE, AND UPTAKE

Glutamate must be synthesized from products of glucose metabolism or other precursors within the CNS because glutamate does not cross the blood–brain barrier. Glutamate is primarily synthesized from glutamine by the enzyme glutaminase located within the mitochondrial compartment.[48] Glutamate is stored within vesicles and then released into the synapse by Ca^{2+}-dependent exocytosis. Synaptic glutamate transported into glial cells undergoes conversion back to glutamine by the enzyme glutamine synthase. Glial cells then release glutamine which is taken up by neurons before conversation back to glutamate and subsequent transport into vesicles (Fig. 13–13). Reverse transport of glutamate from the cytoplasm into the synapse by the membrane transporter may occur under some circumstances.[6] There are five different cell surface excitatory amino acid transporters (EAAT) that differ in their predominant CNS locations. EAAT1 is primarily found on forebrain glial cells. EEAT2 is located on astrocytes and is responsible for 80% of all glutamate update. EAAT3 is located on glutamatergic neurons in the forebrain. EAAT4 serves the same purpose in the cerebellum. EAAT5 is limited to the retina.[74]

■ GLUTAMATE RECEPTORS

The EAA receptor system is extremely complex, consisting of 11 different receptors. Three of these receptors are ionotropic cation channels, which are responsible for fast excitatory glutamatergic activity. There are eight metabotropic receptors linked to G proteins whose actions are slower, more diverse, and longer lasting than the inotropic receptors.[74] A single neuron may express numerous types of glutamate receptors.
FIGURE 13–13. Glutamatergic neurotransmission. Glutamic oxaloacetic transaminase (GOT) converts α-ketoglutarate to glutamate in mitochondria. Glutamate also forms from glutamine via mitochondrial glutaminase. Glutamate is transported into vesicles [6] by VGlut1 (or possibly other subtypes) for exocytotic release into the synapse. Synaptic glutamate activates four main types of receptors. AMPA [2], kainate [3], and NMDA [4] receptors are cation channels. Membrane depolarization in response to their activation causes neuronal excitation through cation influx. Metabotropic receptors (mGluR) [1,8] are coupled to G proteins and are expressed on pre- and postsynaptic membranes. In addition, some mGluRs reside outside of the synapse. Postsynaptic mGluR excitation in this example [1] results from preventing K+ efflux, but other mechanisms of excitation exist. Presynaptic mGluRs act to inhibit [8] glutamate (and other neuro-transmitter) release through modulating intracellular Ca2+ concentrations, as do presynaptic GABA$_B$ receptors in response to GABA binding [9]. Figure 13 -14 provides a more detailed illustration of the NMDA receptor. Excessive influx of Ca2+ through NMDA receptors (and through some AMPA and kainate receptors) causes neuronal damage and cell death. A Mg2+ ion normally blocks the NMDA receptor channel to prevent Ca2+ influx despite glutamate binding. However, depolarization of the neuronal membrane by cation influx resulting from activation of any of the other receptor types causes Mg2+ to dissociate from the NMDA receptor and to allow potentially damaging inward Ca2+ currents in response to glutamate binding. Glutamate undergoes uptake by neurons and glial cells by various subtypes of EEAT, the membrane bound glutamate transporter [5]. In glial cells, glutamate is converted to glutamine by glutamine synthase, and glutamine is transported out of glial cells by system N-1 (SN1), a Na+- and H+-dependent pump that is structurally similar to VGAT, the vesicle membrane GABA transporter. Glutamine then moves back into neurons [7] where it undergoes conversion back to glutamate. Various agents in Table 13 -11 affect glutamatergic neurotransmission, in part, by stimulating or blocking the various glutamate receptors [1 -4,8] or by preventing glutamate uptake [5]. G = G protein.

Also, every type of glutamate receptor has been identified on both presynaptic and postsynaptic membranes, but many of these receptors are not active under normal physiologic conditions. This complexity is necessary for protection against the devastating effects of uncontrolled excitatory neurotransmission. Presynaptic terminal glutamate receptors modulate the release of various neurotransmitters, including glutamate,

while postsynaptic glutamate receptors are usually excitatory, although some inhibitory actions have been demonstrated (Fig. 13–13).[125]

Ionotropic Glutamate Receptors All three types of ionotropic glutamate receptors allow for neuronal excitation through cation influx. These receptors are further categorized and named by their abilities to be activated or antagonized by various substances: kainic acid,

α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA), and *N*-methyl-D-aspartate (NMDA).[74,125]

Kainate receptors are named for their affinity for kainic acid, found in seaweed, and comprise GluR5–7, KA1, and KA2 subunits.[135] Activation allows Na^+ influx and a small amount of K^+ efflux, resulting in neuronal depolarization. Some kainate receptors allow for the passage of Ca^{2+}.[27] Kainate receptors are found both presynaptically and postsynaptically. Their presynaptic behavior is complex in that they initially stimulate neurotramsitter release, but ultimately act more like metabotropic receptors, with the net effect of functioning as autoreceptors, modulating subsequent glutamate release and acting as heteroreceptors via stimulation of presynaptic $GABA_B$ receptors to limit GABA release.[27,135] Postsynaptic kainite receptors contribute to excitability of postsynaptic neurons.

The AMPA receptor is an ion channel structurally similar to the kainate receptor that also mediates Na^+ influx (and lesser amounts of K^+ efflux) on presynaptic and postsynaptic membranes, triggering neuronal depolarization. AMPA receptors comprise GluR1–4 subunits.[27] The AMPA receptor is the most common ionotropic glutamate receptor found in the brain. AMPA receptors appear to be responsible for most glutamatergic excitation under normal conditions.[27]

The NMDA receptor, the most studied of all glutamate receptors, is a Ca^{2+} channel whose activation allows for inward Ca^{2+} and Na^+ currents (and some K^+ efflux), resulting in neuronal depolarization and excitation (Fig. 13–14). NMDA receptors comprise NR1, $NR2_{A-D}$, and $NR3_{A-B}$ subunits.[72] Excessive stimulation of NMDA receptors by glutamate released during ischemia, trauma, hypoglycemia, or convulsions triggers damaging rises in intracellular Ca^{2+} concentrations, activation of numerous enzymes, and free radical formation, all of which incite cell death.[100] Antagonists of NMDA Ca^{2+} channels are anticonvulsants and neuroprotectants.

The NMDA Ca^{2+} channel is normally blocked by Mg^{2+} in a voltage-dependent manner, preventing Ca^{2+} influx despite glutamate binding (Fig. 13–14).[67,72] Only when the neuronal membrane is depolarized by at least 20–30 mV through some other mechanism (eg, activation of another type of glutamate receptor) will Mg^{2+} leave the channel and allow Ca^{2+} influx in response to glutamate binding. Thus, the NMDA glutamate receptor is both a ligand-gated and voltage-gated ion channel. Many neurons express both NMDA and non-NMDA receptors for glutamate. Excessive stimulation of kainate or AMPA receptors

FIGURE 13–14. Representation of the NMDA glutamate receptor. The NMDA receptor is a voltage-gated and ligand-gated Ca^{2+} channel. Glutamate binds to its receptor on the channel [2] to open the Ca^{2+} channel and to allow Ca^{2+} and Na^+ influx and lesser amounts of K^+ efflux. Mg^{2+} normally blocks the Ca^{2+} channel, preventing cation influx in response to glutamate binding. Mg^{2+} leaves the channel when the membrane is depolarized by 20 -30 mV. Glycine must also bind to its site on the NMDA receptor complex for successful glutamate agonism. Polyamines bind on the extracellular surface of the receptor [5]. Zn^{2+} binds [4] to inhibit Ca^{2+} influx. The phencyclidine (PCP) binding site [3] lies within the channel. Agents in Table 13 -11 may antagonize glycine binding [1]; block the Ca^{2+} channel by binding to the PCP binding site [3]; bind to the polyamine binding site [5]; or directly stimulate the glutamate binding site [2].

by glutamate causes cell damage through Na^+ (and in some instances, Ca^{2+}) influx, because the membrane depolarization they produce causes Mg^{2+} to leave the NMDA receptor and allows for potentially damaging inward Ca^{2+} currents.[38] Calcium ion influx through voltage-gated ion channels (including the L-subtype) on cell bodies that open in response to depolarization also contributes to accumulation of intracellular calcium and cell damage.[72]

Glutamate, alone, is incapable of triggering Ca^{2+} influx after binding to NMDA receptors, even after Mg^{2+} has dissociated from the ion channel. Glycine also must bind to its specific receptor on the NMDA receptor complex for successful glutamate agonism (Fig. 13–14), making glycine an indirect agonist of excitatory neurotransmission.[72] Strychnine, a glycine antagonist at neuronal glycine receptors, does not antagonize glycine's excitatory action at NMDA receptors, explaining why glycine NMDA receptors are also known as strychnine-insensitive glycine receptors.

Zinc ions normally bind to the NMDA receptor complex to antagonize the action of glutamate. Binding of spermine or spermidine to a polyamine binding site on the extracellular side of the NMDA receptor results in increased affinity of glycine and glutamate for their binding sites. However, polyamine agonism is not essential for glutamate activation of NMDA receptors.[72]

Metabotropic Glutamate Receptors Metabotropic glutamate receptors (mGluRs) are linked to various G proteins on postsynaptic and presynaptic membranes (Fig. 13–13). Eight different receptors have been isolated. In contrast to ionotropic glutamate receptors, mGluRs may excite or inhibit at postsynaptic membranes, and appear mainly to inhibit at presynaptic locations. Postsynaptic excitation most commonly results from prevention of K^+ efflux or activation of phospholipase C, which serves to raise intracellular Ca^{2+} concentration. Postsynaptic inhibition usually results from enhanced K^+ efflux.[159]

Metabotropic glutamate receptors are commonly subdivided into three main groups based on their sequence homology, intracellular signaling mechanisms, and response to specific experimental agonists.[159] As a general rule, group I receptors (mGlu1, mGlu5) reside postsynaptically; activation produces excitation through blockade of K^+ efflux or by activating phospholipase C, producing rises in intracellular Ca^{2+}. The mGlu5 receptor is the most common and active of the group I receptors. In animal experiments, agonists of group I receptors produce convulsions, while antagonists display anticonvulsant effects.[90]

Groups II (mGlu2, mGlu3) and III (mGlu4, mGlu6, mGlu7, mGlu8) receptors most commonly serve as presynaptic autoreceptors and heteroreceptors and, when activated, inhibit adenylate cyclase activity.[125,159] This, in turn, prevents Ca^{2+} influx and serves to inhibit release of neurotransmitters, including glutamate, GABA, DA, and adenosine. Group II presynaptic autoreceptors may play an especially important role in decreasing further glutamate release during pathologic conditions, when the extracellular concentration of glutamate exceeds normal physiologic levels. They are positioned outside the synaptic active zone and, therefore, only become activated when glutamate spills out of the synapse.[125] The mGlu7 receptor is positioned within the active zone of the synapse, but has a low affinity for glutamate, allowing for a continuous but mild inhibitory effect on glutamate release.[125,159] Agonists of groups II and III metabotropic receptors produce anticonvulsant effects in animals.[98]

■ XENOBIOTICS

Table 13–11 provides examples of xenobiotics that affect glutamatergic neurotransmission.

Glutamate Agonism Domoic acid produces amnestic shellfish poisoning, partly characterized by confusion, agitation, convulsions, memory disturbance, neuronal damage, and death.[62] The structural similarity

TABLE 13–11. Examples of Xenobiotics That Affect Glutamatergic Neurotransmission

Glutamate agonism	Riluzole
Direct glutamate receptor agonists	Sulfasalazine
BMAA	Increase glutamate reuptake
BOAA	Ceftriaxone
Domoic acid	Riluzole
Homoquinolinic acid	AMPA receptor antagonists
Ibotenic acid	Quinoxalinediones
Quisqualate	Topiramate
Willardine	NMDA receptor antagonists
AMPA receptor modulators	Amantadine
BMAA	Buprenorphine
BOAA	Dextrorphan
Cyclothiazide	Dizocilpine (MK801)
Dysiherbaine	Ethanol[a]
Racetams	Ketamine
Kainate receptor modulators	Memantine
Concavanalin A	Meperidine
Domoic acid	Methadone
Dysiherbaine	Orphenadrine
Glycine NMDA receptor agonists	Pentamidine
D-Cycloserine	Phencyclidine
Kynerenic acid	Tramadol
Milacemide	NMDA glycine antagonists
Glutamate uptake inhibitor	Felbamate
Clozapine	Kynurenic acid
Nitropropionic acid	Meprobamate
Polyamine aonists	Kainate receptor antagonists
Neomycin	Quinoxalinediones
Glutamate antagonism	Topiramate
Prevent glutamate release	Polyamine antagonists
Diazoxide	Diethylenetriamine
Felbamate	Ifenprodil
Lamotrigine	Eliprodil
Nimodipine	

BMAA = α-amino-β-methylaminopropionic acid; BOAA = β-N-oxalylamino-L-alanine; NMDA = N-methyl-D-aspartate.

[a]Ethanol antagonizes glutamate's action at NMDA receptors through an unknown mechanism.

between domoic acid and glutamate is thought to explain excessive activation of kainate receptors with secondary NMDA receptor activation and resultant neuronal dysfunction and damage.

Investigators hypothesize that other naturally occurring glutamate receptor agonists produce additional neurologic diseases. The neurogenic form of lathyrism results from using chickling peas (*Lathyrus sativus*) as a food staple. Chickling peas contain β-N-oxalylamino-L-alanine (BOAA), an agonist of AMPA receptors.[80] Neurogenic lathyrism was common in German concentration and prisoner of war camps during World War II and still occurs regularly in some parts of the world. Ibotenic acid, from poisonous mushrooms, activates NMDA and some metabotropic glutamate receptors. It undergoes decarboxylation to muscimol, a direct agonist at GABA$_A$ receptors. Clozapine inhibits glutamate uptake.[67]

Because noncompetitive NMDA receptor antagonism reproduces many signs and symptoms of schizophrenia, investigators are directing efforts at increasing glutamate's activity at NMDA channels in an effort

to treat the disease.[143] After crossing the blood–brain barrier, milacemide undergoes conversion to glycine, which is required for NMDA receptor activation.[143] D-Cycloserine also crosses the blood–brain barrier to stimulate glycine receptors on NMDA calcium channels.[72]

Glutamate Antagonism *Prevention of Glutamate Release.* Riluzole, used for the treatment of amyotrophic lateral sclerosis, indirectly prevents release of glutamate by blocking Na$^+$ channels. It also stimulates EAAT activity, thereby facilitating reuptake of glutamate from the synapse.[72] Lamotrigine diminishes glutamate release through blockade of voltage-gated Na$^+$ channels.[67] Blockade of voltage-gated Ca^{2+} channels by nimodipine also appears to impair glutamate release.[55]

NMDA Receptor Antagonists. Although some experimental xenobiotics antagonize the action of glutamate, most of our knowledge concerns antagonism at NMDA receptors. Phencyclidine and ketamine appear to bind within the ion channel (PCP binding site) to block Ca^{2+} influx following glutamate binding (Fig. 13–14).[67,72] Both possess other pharmacologic actions and can produce convulsions in overdose.

Dextromethorphan and its first-pass metabolite, dextrorphan, exhibit anticonvulsant activity in animals. Dextrorphan's anticonvulsant activity results, in part, from blockade of NMDA receptor Ca^{2+} channels by binding to the PCP binding site. Dextromethorphan does not bind to the NMDA complex but, like dextrorphan, can directly block N-subtype and L-subtype voltage-dependent Ca^{2+} channels.[72]

Dizocilpine (MK-801) is an NMDA receptor antagonist that binds to the PCP binding site in the NMDA Ca^{2+} channel.[40] Human trials of dizocilpine resulted in adverse effects similar to those produced by phencyclidine, preventing further use in humans as a neuroprotective agent. Amantadine, memantine, and orphenadrine act as low-affinity antagonists at the PCP site, but are not associated with insurmountable psychotomimetic adverse effects.[72] Part of amantadine's effectiveness in the treatment of Parkinson disease may be related to NMDA antagonism. Pentamidine also antagonizes glutamate binding at NMDA channels.[40]

Tramadol displays multiple mechanisms of action as an analgesic, including a weak affinity for the opioid receptors, inhibition of monoamine reuptake, and inhibition of NMDA glutamtergic activity at clinically relevant concentrations by an unknown mechanism.[56] Methadone, meperidine, and buprenorphine are opioid analgesics that antagonize NMDA receptors at therapeutic doses, and this mechanism of action may contribute to their analgesic effect.[37]

Ethanol competitively inhibits NMDA receptor activation by an unknown mechanism, resulting in upregulation of this glutamatergic system. It does not appear to act through currently recognized binding sites.[174] In some animal models of ethanol withdrawal seizures, NMDA receptor antagonists demonstrate better anticonvulsant action than GABA$_A$ agonists.

Glycine Antagonists. Felbamate's anticonvulsant activity may result, in part, from antagonism of glycine at NMDA receptors.[122,176] Kynurenic acid, a metabolite of L-tryptophan, prevents NMDA activation through glycine antagonism. Meprobamate also antagonizes NMDA glutamate receptors by a yet-to-be-determined mechanism.[122] However, given the structural similarity to felbamate, meprobamate may act by antagonizing the action of glycine.

Polyamine Antagonism. Ifenprodil and eliprodil antagonize glutamate's action at NMDA channels by preventing polyamine binding.[54]

ADENOSINE

Adenosine is an important modulator of brain activity and body physiology. Adenosine receptors are vastly distributed throughout the body, which emphasizes the pivotal role adenosine plays in neurotransmission and metabolic activity. The overall action of adenosine is to lessen

oxygen requirements and to increase oxygen and substrate delivery. Adenosine can be found in small concentrations in most extracellular fluids as a consequence of ATP metabolism. This is in contrast to classical neurotransmitters, which are secreted in discrete quanta upon stimulation of presynaptic neurons. In the brain, adenosine primarily limits glutamate and ACh release, thereby preventing excessive postsynaptic neuronal stimulation. Adenosine also counterbalances the effects of DA stimulation in the basal ganglia.[126] Adenosine contributes to temperature regulation, sleep, anxiety reduction, locomotion, pain perception, and seizure inhibition.[89] Peripheral effects of adenosine include bradycardia, decreased myocardial contractility, vasodilation, bronchoconstriction, decreased glomerular filtration, suppression of overactive immune responses, and anti-inflammatory activity.[66]

■ SYNTHESIS, RELEASE, AND UPTAKE

Adenosine is derived from the breakdown of ATP, which is commonly co-released with other neurotransmitters (eg, NE, ACh, glutamate) into the synapse before subsequent degradation by ectonucleotidases

(Fig. 13–15). During times of adequate oxygen delivery and oxidative phosphorylation, intracellular ATP concentrations are many times greater than those of adenosine, with normal intracellular adenosine concentrations ranging from 50 to 300 nM. Intracellular adenosine concentrations increase rapidly during ischemia, hypoxia, or elevated metabolic activity (eg, seizures).[9] A bidirectional Na$^+$-dependent purine uptake transporter typically moves adenosine from the synapse back into the neuron under normal conditions, but can reverse adenosine transport when intracellular adenosine concentrations become elevated (Fig. 13–15). The overall cellular preference is to convert adenosine back to ATP via adenosine kinase, but adenosine also undergoes conversion to inosine by adenosine deaminase.[89] Synaptic adenosine then activates adenosine receptors on neuronal and non-neuronal tissue (eg, vasculature). Adenosine's actions are terminated by uptake into glial cells and neurons (Fig. 13–15).[9,89] Exogenously administered adenosine used in the treatment of supraventricular tachycardia does not cross the blood–brain barrier and, therefore, is not centrally active. The half-life of adenosine in the blood is less than 10 seconds.
FIGURE 13–15. Adenosine's role in regulating excitatory neurotransmission, using glutamate as an example. In this example, glutamate excites a postsynaptic neuron by activating metabotropic glutamate receptors (mGluR1) [1]. ATP enters the synapse when glutamate is released. Adenosine formed from metabolism of ATP within the synapse [3] binds to postsynaptic A$_1$ receptors [2], which open K$^+$ channels to inhibit the neuron through hyperpolarization. Adenosine also activates presynaptic A$_1$ receptors [4] to lower intracellular Ca^{2+} concentrations, thereby impairing further glutamate release. After uptake [5], adenosine is acted upon either by adenosine kinase (AK) [7] to form AMP, or by adenosine deaminase (ADA) [6] to form inosine. Adenosine also binds to neuronal A$_2$ receptors (especially in the striatum) and to vascular A$_2$ receptors to cause vasodilatation [8]. A$_3$ receptors [9] are not activated by normal concentrations of adenosine. During times of excessive catabolism (e.g., seizures, hypoglycemia, stroke) when intracellular adenosine concentrations rise markedly, adenosine moves into the synapse through reverse transport via the purine uptake transporter [10]. Resultant stimulation of A$_1$ and A$_2$ receptors results in inhibitory actions to decrease oxygen requirements and to increase substrate delivery through vasodilatation as described above. However, the resultant stimulation of A$_3$ receptors [9] may contribute to neuronal damage and death. Agents in Table 13-12 act to inhibit adenosine uptake [5]; to inhibit ADA [6]; to inhibit AK [7]; to increase adenosine release; and to antagonize A$_1$ [2,4] and A$_2$ [8] receptors. ADP = adenosine diphosphate; ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; G = G protein; IP$_3$ = inositol triphosphate.

ADENOSINE RECEPTORS

The purine P_1 receptor family comprises 4 adenosine receptor subtypes linked to G proteins: A_1, A_{2A}, A_{2B}, and A_3.[9,66,89,138] Postsynaptic A_1 stimulation results in K^+ channel opening and K^+ efflux, with subsequent hyperpolarization of the neuron (Fig. 13–15). Evidence suggests that G protein–mediated Cl^- influx may explain postsynaptic hyperpolarization by A_1 activation in some cases. Presynaptic A_1 stimulation modifies voltage-dependent Ca^{2+} channels, lessening Ca^{2+} influx during depolarization, which limits exocytosis of neurotransmitter. Therefore, activation of A_1 receptors prevents release of neurotransmitters presynaptically and inhibits their responses postsynaptically.[9]

In the central and autonomic nervous systems, A_1 receptors reside on presynaptic and postsynaptic membranes, where they serve as inhibitory modulators for numerous neurotransmitter systems; they are particularly prevalent in association with glutamatergic neurons in the CNS.[126] The A_1 receptor is prevalent throughout the central nervous system, with high levels in the cerebral cortex, hippocampus, cerebellum, thalamus, brain stem, and spinal cord. A_1 receptor stimulation also produces sedation and is important in sleep regulation. Other functions attributed to A_1 receptors include neuroprotection, anxiolysis, temperature reduction, anticonvulsant activity, and spinal analgesia.[9]

Peripheral A_1 receptor activation produces bronchoconstriction, decreased glomerular filtration, decreased heart rate, slowed atrioventricular conduction, and decreased atrial myocardial contractility.[66]

In the CNS, A_{2A} receptors demonstrate limited distribution. They are concentrated on cerebral vasculature and produce vasodilation when stimulated.[66] Additionally, A_{2A} receptors are especially prevalent on neurons in the striatum, where they inhibit the activity of D_2 receptors.[126] Antagonism of A_{2A} receptors in the striatum increases dopamine-mediated motor activity without the dyskinesia that commonly occur with DA agonists.[126] Some A_{2A} receptors are found presynaptically located as heteromers with A_1 receptors. They act to diminish the inhibition of presynaptic A_1 receptors when adenosine concentrations increase.[29] Under normal conditions the presynaptic A_{2A} receptors are relatively inactive.

A_{2B} receptors are expressed diffusely throughout the brain, and are most commonly identified on glial cells. A_{2B} receptors demonstrate low affinity for adenosine, and little is known of their physiologic role.[9,89] At least some A_{2A} and A_{2B} receptors are coupled to G_s. The rise in cAMP concentration resulting from A_{2A} activation on cerebral vasculature and elsewhere explains vasodilatation.[130] For example, peripheral A_2 receptor activation also results in coronary artery vasodilation.[138]

A_3 receptors express low affinity for adenosine. In the CNS, A_3 receptors are expressed primarily in the hippocampus and thalamus. A_3 receptors act through G proteins to decrease adenylate cyclase activity and increase phospholipase C activity.[9] The low concentrations of adenosine found during normal metabolism minimally activate A_3 receptors to produce inhibitory effects. During times of excessive ATP degradation (eg, hypoxia, seizures), adenosine accumulates at and activates A_3 receptors to produce complex responses that appear to enhance ischemic cellular injury and death, at least in part through disinhibition of presynaptic metabotropic glutamate receptor responses. Thus, A_3 receptor antagonists are being examined for neuroprotective actions.[66]

ADENOSINE AND SEIZURE TERMINATION

In humans and in animal models of status epilepticus, including those from xenobiotics, there are two alternating phases of electrical activity noted on electroencephalography. Periods of high-frequency spike activity (ictal) are accompanied by marked increases in cerebral oxygen consumption and metabolic requirements and alternate with interictal periods of isolated spike waves during which metabolic demands are less. The high-frequency phase lasts only a few minutes before suddenly terminating, sometimes with a few seconds of electrocerebral silence. A gradual increase in electrical activity during the interictal phase eventually leads to a recurrence of high-frequency spike activity.[4]

These periodic, spontaneous self-terminations of high-frequency electrical activity initially occur before neurons exhaust oxygen and energy supplies and result from adenosine released from depolarizing neurons (and probably glial cells).[4,16] Adenosine acts on presynaptic receptors to prevent further release of excitatory neurotransmitters and acts on postsynaptic receptors to inhibit their actions.[16]

Any xenobiotic that directly or indirectly enhances adenosine's action at A_1 receptors in the brain will usually exhibit anticonvulsant activity. Conversely, A_1 receptor antagonists lower the seizure threshold and make seizure termination more difficult and less likely to respond to anticonvulsants. Xenobiotics that antagonize A_{2A} receptors produce cerebral vasoconstriction and may limit oxygen delivery during times of increased demand.[4,16]

XENOBIOTICS

Table 13–12 provides examples of xenobiotics that affect adenosine receptors.

Direct Adenosine Agonists ADAC (adenosine amine congener) is a direct A_1 receptor agonist used in the treatment of Huntington disease.[9] Tecadenoson is a selective A_1 receptor agonist that is used for treatment of supraventricular tachycardia.[42]

Indirect Adenosine Agonists Papaverine and dipyridamole inhibit adenosine uptake.[49] Like other adenosine agonists, papaverine and dipyridamole demonstrate anticonvulsant activity when injected into the CNS. Such actions are not achievable with safe systemic doses.

In addition to their actions at $GABA_A$ receptors, benzodiazepines inhibit adenosine uptake.[88] This may explain observations that methylxanthines, potent adenosine receptor antagonists, have reversed benzodiazepine-induced sedation in humans. The potencies of benzodiazepines as inhibitors of adenosine uptake show good correlation with clinical anxiolytic and anticonflict potencies, suggesting that such inhibition contributes to their action. The anticonvulsant effect of large doses of flumazenil also results, at least in part, from inhibition of adenosine uptake. Carbamazepine inhibits adenosine uptake, although this is not thought to account for most anticonvulsive action.

TABLE 13–12. Examples of Xenobiotics That Affect Adenosine Receptors

Adenosine agonism	Inhibit adenosine deaminase
Direct agonists	Acadesine
Adenosine	Dipyridamole
ADAC (adenosine amine congener)	Pentostatin
Tecadenoson	Inhibit adenosine kinase
Inhibit uptake	Acadesine
Acadesine	Increase adenosine release
Acetate[a]	Opioids
Benzodiazepines	Adenosine antagonism
Calcium channel blockers	A_1 blockade
Carbamazepine	Caffeine
Cyclic antidepressants	Carbamazepine
Dyridamole	Theophylline
Ethanol[a]	A_2 blockade
Indomethacin	Caffeine
Papaverine	Theophylline

[a] Ethanol is metabolized to acetate, which inhibits adenosine uptake.

Adenosine may mediate many of the acute and chronic motor effects of ethanol on the brain. Ethanol, probably through its metabolite, acetate, prevents adenosine uptake, raising synaptic adenosine concentrations.[12] Excessive stimulation of several adenosine receptors in the cerebellum may explain much of the motor impairment from low ethanol concentrations. In fact, animals made tolerant to ethanol develop cross-tolerance to adenosine agonists. In mice, adenosine receptor agonists increase ethanol-induced incoordination, while adenosine antagonists decrease this intoxicating response.[127]

There are numerous inhibitors of adenosine uptake, including propentofylline, nimodipine, cyclic antidepressants, and other calcium channel blockers.[119,121] A_1 receptors located at the spinal cord are important modulators of pain transmission. Cyclic antidepressant-induced inhibition of adenosine uptake may explain some of their effectiveness in treating neuropathic pain.[49] The analgesic effectiveness of opioids can be partially attributed to their ability to increase the release of adenosine within the spinal cord.[9,49]

Dipyridamole inhibits adenosine deaminase, raising adenosine concentrations. During times of elevated adenosine concentrations that occur with cardiac or cerebral ischemia, acadesine further enhances adenosine's beneficial actions by three mechanisms: inhibition of adenosine kinase, inhibition of adenosine deaminase, and inhibition of adenosine uptake.[111]

Adenosine Antagonists The main adenosine antagonists of toxicologic concern are methylxanthines. Theophylline and caffeine are selective P_1 antagonists, blocking both A_1 and A_2 receptors.[9] The response to methylxanthines by A_3 receptors varies widely, depending on the species. Human A_3 receptors demonstrate very low affinity for methylxanthines.[89]

Peripherally, methylxanthines produce excessive release of catecholamines from peripheral nerve endings (and probably the adrenal gland) by blocking presynaptic A_1 receptors. In turn, catecholamine-mediated responses are exaggerated by blockade of inhibitory postsynaptic A_1 receptors on end organs.[4]

Centrally, enhanced release and actions of excitatory neurotransmitters (eg, glutamate) explain methylxanthine-induced convulsions that are frequently refractory to anticonvulsants. The reasons why theophylline convulsions carry such a high mortality stem from lack of A_1-mediated self-termination (continual high-frequency spike activity and large metabolic demands), compounded by vasoconstriction caused by blockade of A_2 receptors. $GABA_A$ receptor agonism, especially by barbiturates, most effectively prevents and terminates methylxanthine-induced seizures. Phenytoin not only is ineffective in treating theophylline-induced seizures, but may actually increase the likelihood of seizures and mortality.[14]

Like phenytoin, carbamazepine's major anticonvulsant effect results from Na^+ channel blockade. Unlike phenytoin, carbamazepine antagonizes A_1 receptors.[31,34] This may explain the higher frequency of seizures after carbamazepine overdose than after phenytoin overdose. The absence of A_2 blockade by carbamazepine theoretically allows for increases in cerebral blood flow to meet metabolic demands of the seizing brain.

SUMMARY

Neurotransmitter systems share common physiologic features, including neurotransmitter uptake, vesicle membrane pumps, ion trapping of neurotransmitters within vesicles, calcium-dependent exocytosis, and receptors coupled to either G proteins or to ion channels. It is not surprising, then, that a single pharmacologic agent frequently produces effects on several different neurotransmitter systems.

As the number of new xenobiotics encountered by man continues to grow, an understanding of their molecular actions in the nervous system helps the physician to anticipate and better understand various pharmacologic and adverse effects resulting from therapeutic or toxic doses.

CHAPTER 14
WITHDRAWAL PRINCIPLES

Richard J. Hamilton

In the central nervous system (CNS), excitatory neurons fire regularly, and inhibitory neurons inhibit the transmission of these impulses. Whenever action is required, the inhibitory tone diminishes, permitting the excitatory nerve impulses to travel to their end organs. Thus, all action in human neurophysiology can be considered to result from disinhibition.[56,104,108]

Tonic neurological activity of a xenobiotic produces an adaptive change in affected neurons. For example, tonic stimulation of inhibitory neurons reduces their activity so that the baseline level of function is regained. A withdrawal syndrome occurs when the constant presence of this xenobiotic is removed or reduced and the adaptive changes persist. In this example withdrawal produces a dysfunctional condition in which inhibitory neurotransmission is significantly reduced, essentially producing excitation (Fig. 14–1). Every withdrawal syndrome has two characteristics: (1) a pre-existing physiologic adaptation to a xenobiotic, the continuous presence of which prevents withdrawal, and (2) decreasing concentrations of that xenobiotic. In contrast, simple tolerance to a xenobiotic is characterized as a physiologic adaptation that shifts the dose–response curve to the right; that is, greater amounts of a xenobiotic are required to achieve a given effect. Patients with withdrawal syndromes have often developed tolerance, but tolerance does not require the continued presence of the xenobiotic to prevent withdrawal.[41,93]

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) provides a helpful and descriptive set of criteria that mesh with our understanding of the pathophysiology of withdrawal syndromes.[32] According to DSM-IV, withdrawal is manifested by either of the following: (1) a characteristic withdrawal syndrome for the substance or (2) the same (or a closely related) substance is taken to relieve withdrawal symptoms. Note that either criterion fulfills this definition. Logically, all syndromes have the first criterion, so it is the presence of the second criterion that is critical to understanding physiology and therapy.

For the purposes of defining a unifying pathophysiologic pattern of withdrawal syndromes, this chapter considers syndromes in which both features are present. An analysis from this perspective distinguishes xenobiotics that affect the inhibitory neuronal pathways from those that affect the excitatory neuronal pathways, such as cocaine. According to this definition, cocaine does not produce a withdrawal syndrome but rather a postintoxication syndrome that often results in lethargy, hypersomnolence, movement disorders, and irritability. This syndrome does not meet the second of the DSM-IV criteria for a withdrawal syndrome because the same (or a closely related) substance is not taken to relieve or avoid withdrawal symptoms. This postintoxication syndrome, the so-called "crack crash" or "washed-out syndrome," is caused by prolonged use of cocaine, and patients ultimately return to their premorbid function without intervention.[81,94,107] This distinction is important for toxicologists, because (1) withdrawal syndromes that demonstrate both features of the DSM-IV criteria are treated with reinstatement and gradual withdrawal of a xenobiotic that has an effect on the receptor and (2) withdrawal syndromes that do not demonstrate the second feature require only supportive care and resolve spontaneously.

Finally, withdrawal syndromes are best described and treated according to the class of receptors that is primarily affected because this concept also organizes the approach to patient care. For each receptor and its agonists, research has identified genomic and nongenomic effects that produce neuroadaptation and withdrawal syndromes. Six mechanisms appear to be involved: (1) genomic mechanisms via mRNA; (2) second-messenger effects via protein kinases, cyclic adenosine monophosphate (cAMP),[47,49] and calcium ions; (3) receptor endocytosis; (4) expression of various receptor subtypes depending on location within the synapse (synaptic localization); (5) intracellular signaling via effects on other receptors; and (6) neurosteroid modulation. Some or all of these mechanisms are demonstrated in each of the known withdrawal syndromes.[57] These mechanisms develop in a surprisingly rapid fashion and modify the receptor and its function in such complex ways as to depend on the continued presence of the xenobiotic to prevent dysfunction.[55,70,74,76,92,109,112]

GABA$_A$ RECEPTORS (BARBITURATES, BENZODIAZEPINES, ETHANOL, VOLATILE SOLVENTS)

γ-Aminobutyric acid type A (GABA$_A$) receptors have separate binding sites for GABA, barbiturates, benzodiazepines, and picrotoxin, to name only a few xenobiotics (Chap. 13). Barbiturates and benzodiazepines bind to separate receptor sites and enhance the affinity for GABA$_A$ at its receptor site. GABA$_A$ receptors are part of a superfamily of ligand-gated ion channels, including nicotinic acetylcholine receptors and glycine receptors, that exist as pentamers arranged around a central ion channel.[96] When activated, they hyperpolarize the postsynaptic neuron by facilitating an inward chloride current (without a G protein messenger), decreasing the likelihood of the neuron firing an action potential.[56,87]

The GABA receptor is a pentamer comprised of 2 α subunits, 2 β subunits, and 1 additional subunit, most commonly γ, which is a key element in the benzodiazepine binding site. Each receptor has 2 GABA binding sites that are located in a homologous position to the benzodiazepine site between the α and β subunits. Although the mechanism is unclear, benzodiazepines have no direct functional effect without the presence of GABA. Conversely, certain barbiturates (perhaps all, in a dose-dependent manner) can directly increase the duration of channel opening, thereby producing a net increase in current flow without GABA binding.[39,74] This process has therapeutic implications and accounts for why high dose barbiturates are universally successful in stopping status epilepticus and treating severe withdrawal.

Recent evidence demonstrates that this prototypical pentameric GABA$_A$ receptor assembly is derived from permutations and combinations of 2, 3, 4, or even 5 different subunits. The subtypes of GABA receptors can even vary on the same cell.[74] In fact, GABA receptors are heterogeneous receptors with different subunits and distinct regional distribution. Although the preponderance of subtypes $α_1β_2γ_2$, $α_2β_3γ_2$, and $α_3β_3γ_2$ account for 75% of GABA receptors, there are at least 16 others of import.[112] The recognition of additional subunits of GABA$_A$ receptors, has permitted the development of targeted pharmaceuticals.[6] For example, the drug zolpidem achieves its effect of hastened onset of sleep by targeting the BZ$_1$ receptor subunit of GABA$_A$.[91]

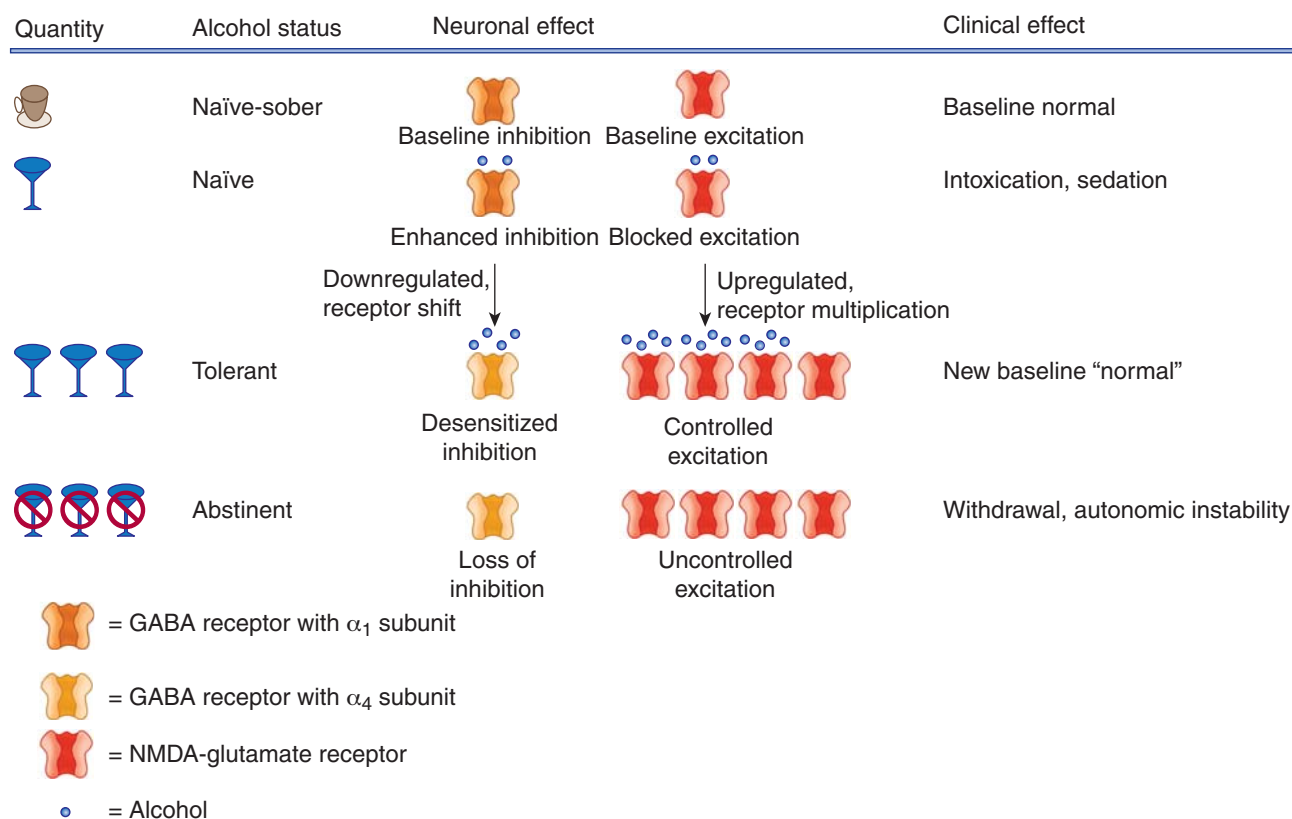
Previously, ethanol was thought to have GABA receptor activity, although a clearly identified binding site was not evident. Traditional explanations for this effect included (1) enhanced membrane fluidity and allosteric potentiation (so-called cross-coupling) of the 5 proteins that construct the GABA$_A$ receptor; (2) interaction with a portion of the receptor; and/or (3) enhanced GABA release.[20,56,58,90] Research


FIGURE 14–1. Alcohol intoxication, tolerance, and withdrawal. Alcohol consumption in alcohol-naive persons produces intoxication and sedation by simultaneous agonism at the γ-aminobutyric acid (GABA) receptor–chloride channel complex and antagonism at the *N*-methyl-D-aspartate (NMDA)-glutamate receptor. Continuous alcohol consumption leads to the development of tolerance through changes in both the GABA receptor–chloride channel complex (a subunit shift from α_1 to α_4 results in reduced sensitivity to the sedating effects of alcohol) and the NMDA subtype of glutamate receptor (upregulation in number, resulting in enhanced wakefulness). There is conceptually a concentration at which the tolerant patient may appear clinically normal despite having an elevated blood alcohol concentration. Tolerant patients who are abstinent lose the tonic effects of alcohol on these receptors, resulting in withdrawal.

with chimeric reconstruction of GABA$_A$ and *N*-methyl-D-aspartate (NMDA) channels demonstrates highly specific binding sites for high doses of ethanol that enhance GABA$_A$ and inhibit NMDA receptor-mediated glutamate neurotransmission.[75] However, research has not clarified whether ethanol at low doses is a direct agonist of GABA$_A$ receptors or a potentiator of GABA$_A$ receptor binding.[59,74,80,83]

Ethanol exhibits all 6 mechanisms of adaptation to chronic exposure and is the prototypical xenobiotic for studying neuroadaptation and withdrawal.[57] These 6 mechanisms appear to apply to benzodiazepines as well.[3,54,80,83] The mechanisms are (1) altered GABA$_A$ receptor gene expression via alterations in mRNA and peptide concentrations of GABA$_A$ receptor subunits in numerous regions of the brain (genomic mechanisms); (2) posttranslational modification through phosphorylation of receptor subunits with protein kinase C (second-messenger effects); (3) subcellular localization by an increased internalization of GABA$_A$ receptor α_1-subunit receptors (receptor endocytosis); (4) modification of receptor subtypes with differing affinities for agonists to the synaptic or nonsynaptic sites (synaptic localization); (5) regulation via intracellular signaling by the NMDA, acetylcholine, serotonin, and β-adrenergic receptors; and (6) neurosteroidal modulation of GABA receptor sensitivity and expression.[12,19,34,37,47,52,58-60,85,110] Furthermore, changes in GABA$_A$ subunit composition and function are evident within 1 hour of administration of a single dose of ethanol.[62]

Intracellular signaling via the NMDA subtype of the glutamate receptor appears to explain the "kindling" hypothesis, in which successive withdrawal events become progressively more severe.[8,11,14,17,36,63,111] The activity of an excitatory neurotransmission increases the more it fires, a phenomenon known as *long-term potentiation*, and is the result of increased activity of mRNA and receptor protein expression, a genomic effect of intracellular signaling.[41,102] As NMDA receptors increase in number and function (upregulation) and GABA$_A$ receptor activity diminishes, withdrawal becomes more severe.[30,46,63,72,85,99] The dizocilpine (MK-801) binding site of the NMDA receptor appears to be the major contributor, and this effect is recognized in neurons that express both NMDA and GABA$_A$ receptors.[4,110,115] Interestingly, animal models suggest that chronic ethanol use induces alterations in the receptor subunit composition of the GABA$_A$ receptor, which may be partly responsible for the development of ethanol tolerance, withdrawal, and kindling.[22,63]

GABA$_A$ agonists induce modulatory changes in the receptors through genomic and nongenomic mechanisms that ultimately alter their function. In this way, withdrawal symptoms represent the clinical manifestation of a change in GABA receptor–complex characteristics.[21,50] When alcohol or any xenobiotic with GABA agonist activity is withdrawn, inhibitory control of excitatory neurotransmission, such as that mediated by the now upregulated NMDA receptors, is lost.[37,70,88]

This loss results in the clinical syndrome of withdrawal: CNS excitation (tremor, hallucinations, seizures), and autonomic stimulation (tachycardia, hypertension, hyperthermia, diaphoresis) (Chap. 78).[42,56,92]

Volatile solvents, such as gasoline, diethyl ether, and toluene, are widely abused xenobiotics whose effects appear to be mediated by the GABA receptor.[84,98] These solvents can produce CNS inhibition and anesthesia at escalating doses via the $GABA_A$ receptor in a fashion similar to that of ethanol.[7,9,48,113]

GABA$_B$ RECEPTORS (GHB AND BACLOFEN)

GABA$_B$ agonists such as γ-hydroxybutyric (GHB) acid and baclofen have similar clinical characteristics with regard to adaptation and withdrawal.[13,24,40,114] The GABA$_B$ receptor is a heterodimer of the $GABA_{B(1)}$ and $GABA_{B(2)}$ receptors. Unlike GABA$_A$, the GABA$_B$ receptor couples to various effector systems through a signal-transducing G protein.[15,69,114] GABA$_B$ receptors mediate presynaptic inhibition (by preventing Ca^{2+} influx) and postsynaptic inhibition (by increasing K^+ efflux). The postsynaptic receptors appear to have an inhibitory effect similar to that of the GABA$_A$ receptors, though the mechanism differs. The presynaptic receptors provide feedback inhibition of GABA release.

GHB is a naturally occurring inhibitory neurotransmitter with its own distinct receptor.[5] Physiologic concentrations of GHB activate at least 2 subtypes of a distinct GHB receptor (antagonist-sensitive and antagonist-insensitive). However, at supraphysiologic concentrations, such as those that occur after overdose and abuse, GHB binds directly to the GABA$_B$ receptor and is metabolized to GABA (which then activates the GABA$_B$ receptor). The GHB withdrawal syndrome clinically resembles the withdrawal syndrome noted from ethanol and benzodiazepines and can be severe.[24] In most cases, distinctive clinical features of GHB withdrawal are the relatively mild and brief autonomic instability and the persistence of psychotic symptoms.[106]

Baclofen is also a GABA$_B$ agonist. The presynaptic and postsynaptic inhibitory properties of baclofen allow it, paradoxically, to cause seizures in cases of both acute overdose (because of decreased release of presynaptic GABA via autoreceptor stimulation) and withdrawal. Withdrawal is probably a result of the loss of the chronic inhibitory effect of baclofen on postsynaptic GABA$_B$ receptors. Discontinuation of baclofen produces hyperactivity of neuronal Ca^{2+} channels (N, P/Q type),[29] leading to seizures, hypertension, hallucinations, psychosis, and coma. However, these manifestations may not differ from the withdrawal symptoms of GABA$_A$ agonists.[86,100]

Typically, the development of a baclofen withdrawal syndrome occurs 24 to 48 hours after discontinuation or a reduction in the dose of baclofen. Case reports highlight the development of seizures, hallucinations, psychosis, dyskinesias, and visual disturbances. The intrathecal baclofen pump has become an effective replacement for oral dosing, but withdrawal can occur following use of this modality as well. Reinstatement of the prior baclofen-dosing schedule appears to resolve these symptoms within 24 to 48 hours. Benzodiazepines and GABA$_A$ agonists (not phenytoin) are the appropriate treatment for seizures induced by baclofen withdrawal.[79]

OPIOID RECEPTORS (OPIOIDS)

Similar to the behavior of ethanol and GABA$_A$ receptors, opioid binding to the opioid receptors results in a series of genomic and nongenomic neuroadaptations, especially via second-messenger effects. When opioids bind to opioid receptors they alleviate pain by inhibiting neurons, while activating G_s proteins and stimulating K^+ efflux currents.

The opioid receptors are also linked to the $G_{i/o}$ proteins. They act through adenyl cyclase and activate inward Na^+ current, thus enhancing the intrinsic excitability of a neuron (Chap. 38).[25]

Chronic use of opioids, all xenobiotics with opioid-receptor affinity, results in a decreased efficacy of the receptor to open potassium channels by genomic mechanisms and second-messenger effects. Following chronic opioid use, the expression of adenyl cyclase increases through activation of the transcription factor known as *cAMP response element–binding protein* (*CREB*) (Fig. 14–2).[45,71,77] This situation results in an upregulation of cAMP-mediated responses such as the inward Na^+ channels responsible for intrinsic excitability. The net effect is that only higher concentrations of opioids result in analgesia and other opioid effects. In the dependent patient, when opioid concentrations drop, inward Na^+ flux occurs unchecked, and the patient experiences the opioid withdrawal syndrome. The clinical findings associated with this syndrome are largely a result of uninhibited activity at the locus ceruleus.[23,55,71,73,77]

Furthermore, opioid receptors and central α$_2$-adrenergic receptors both exert a similar effect on the potassium channel in the locus ceruleus. Clonidine binds to the central α$_2$-adrenergic receptor and stimulates potassium efflux, as do opioids, and produces similar clinical findings,[2] which explains why clonidine has some efficacy in treating the opioid withdrawal syndrome. In addition, the antagonistic effect of naloxone at the opioid receptor seems to partially reverse the effect of clonidine on this shared potassium efflux channel.[2,38,43]

Rapid opioid detoxification is a form of iatrogenic withdrawal that uses opioid antagonist activity to accelerate a return to premorbid receptor physiology. In theory, inducing opioid withdrawal under general anesthesia with high-dose opioid antagonists permits the transition from drug dependency to naltrexone maintenance without drug withdrawal symptoms.[64-66,95] Naltrexone blocks the euphoric effects of continued opioid use and discourages recidivism by blunting drug craving.[53,65,67,68] Although the mechanism by which naltrexone blocks drug craving is not entirely clear, the speculation is that mere receptor occupancy by an antagonist is sufficient to blunt cravings.[33] However, withdrawal symptoms may still be intense and persist for up to one week after rapid detoxification, suggesting that clinical recovery from the changes induced by chronic opioid use is slow.[26,44,91,97,103]

α$_2$-ADRENERGIC RECEPTORS (CLONIDINE)

α$_2$-Adrenergic receptors are located in the central and peripheral nervous systems. Clonidine is a central and peripheral α$_2$-adrenergic agonist. Stimulation of central presynaptic α$_2$-adrenergic receptors inhibits sympathomimetic output and results in bradycardia and hypotension.[35] Within 24 hours after the discontinuation of clonidine, norepinephrine concentrations rise as a result of enhanced efferent sympathetic activity.[89] This increase results in hypertension, tachycardia, anxiety, diaphoresis, and hallucinations.[18]

ADENOSINE (A) RECEPTORS (CAFFEINE)

The release of neurotransmitters is accompanied by the passive release of adenosine as a by-product of adenosine triphosphate (ATP) breakdown. The released adenosine binds to postsynaptic A$_1$ receptors where it typically has inhibitory effects on the postsynaptic neuron. It also binds to presynaptic A$_1$ autoreceptors to limit further release of neurotransmitters. A$_2$ receptors are found on the cerebral vasculature and peripheral vasculature where stimulation promotes vasodilation.[28,51] Caffeine and other methylxanthines, such as theophylline, antagonize the inhibitory effect of adenosine, primarily on postsynaptic A$_1$ receptors.
FIGURE 14–2. Immediate and long-term effects of opioids. The immediate effects of both opioids and α_2-adrenergic agonists are to increase inhibition through enhanced potassium efflux and inhibited sodium influx. Long-term effects alter gene expression to enhance sodium influx and restore homeostasis. CREB = cAMP response element-binding protein; AC = adenyl cyclase; PKC = protein kinase C; (ᴍ) = Beta-adrenergic receptor.

As a result, acute use results in increases in heart rate, ventilation, gastrointestinal motility, gastric acid secretion, and motor activity. Chronic caffeine use results in tolerance and the above symptoms diminish.[31] Chronic caffeine use upregulates A_1 receptors by a variety of mechanisms, including increases in receptor number, increases in receptor affinity, enhancement of receptor coupling to the G protein, and increases in G protein–stimulated adenyl cyclase.[61] The results of an animal study demonstrate that the adenosine receptor has a threefold increase in affinity for adenosine at the height of withdrawal symptoms. This model suggests that long-term caffeine administration results in an increase in receptor affinity for adenosine, thus restoring a state of physiologic balance (normal motor inhibitory tone). When caffeine is withdrawn, the enhanced receptor affinity results in a strong adenosine effect and clinical symptoms of withdrawal: headache (cerebral vasodilation), fatigue, and hypersomnia (motor inhibition).[76,101,105]

ACETYLCHOLINE RECEPTORS (NICOTINE)

A nicotinic receptor is a type of acetylcholine receptor located in the autonomic ganglia, adrenal medulla, CNS, spinal cord, neuromuscular junction, and carotid and aortic bodies. Nicotinic receptors are fast-response cation channels that are not coupled to G proteins which distinguishes them from muscarinic receptors, which are coupled to G proteins. Nicotinic acetylcholine receptors have both excitatory and inhibitory effects. As in other withdrawal syndromes, changes brought on by chronic use of nicotinic agonists, such as nicotine in cigarettes, appear to be related to selective upregulation of cAMP.[10,78,109]

SSRI DISCONTINUATION SYNDROME

Upon discontinuation of chronic selective serotonin reuptake inhibitor (SSRI) therapy, patients develop characteristic signs and symptoms.

The syndrome complies with the definition of withdrawal syndromes in that symptoms begin when xenobiotic concentrations drop, and the syndrome abates when the xenobiotic is reinstated. Headache, nausea, fatigue, dizziness, and dysphoria are commonly described symptoms. The condition appears to be uncomfortable but not life threatening, rapidly resolves with reinstatement of a xenobiotic of the same class, and slowly resolves when the drug is discontinued after a more gradual taper (Chap. 72).[1,16,24,27,82]

SUMMARY

The understanding of the mechanisms of withdrawal for varied xenobiotics has permitted a more logical approach to these states of altered inhibition of neuronal pathways and those affecting excitatory neuronal pathways. This chapter addresses the related neurophysiologic mechanisms, the characteristics of withdrawal associated with the xenobiotic in question, and the xenobiotic or the types of xenobiotics effective in relieving the withdrawal symptoms.

CHAPTER 15
THERMOREGULATORY PRINCIPLES

Susi U. Vassallo and Kathleen A. Delaney

Despite exposure to wide fluctuations of environmental temperatures, human body temperature is maintained within a narrow range.[23,131] Elevation or depression of body temperature occurs when (1) thermoregulatory mechanisms are overwhelmed by exposure to extremes of environmental heat or cold; (2) endogenous heat production is either inadequate, resulting in hypothermia, or exceeds the physiologic capacity for dissipation, resulting in hyperthermia; or (3) disease processes or xenobiotic effects interfere with normal thermoregulatory responses to heat or cold exposure.

METHODS OF HEAT TRANSFER

Heat is transferred to or away from the body through radiation, conduction, convection, and evaporation. *Radiation* involves the transfer of heat from a body to the environment, and from warm objects in the environment, for example, from the sun to a body. *Conduction* involves the transfer of heat to solid or liquid media in direct contact with the body. Water immersion conducts significant amounts of heat away from the body. This effect facilitates cooling in a swimming pool on a hot summer day, or may lead to hypothermia despite moderate ambient temperatures on a rainy day. The amount of heat lost through conduction and radiation depends on the temperature gradient between skin and surroundings, cutaneous blood flow, and insulation such as subcutaneous fat, hair, clothing, or fur in lower animals.[148] In the respiratory tract, heat is lost by conduction to water vapor or gas. In animals unable to sweat, this represents the primary method of heat loss. The amount of heat lost through the respiratory tract depends on the temperature gradient between inspired air and the environment, as well as the rate and depth of breathing.[148] *Convection* is the transfer of heat to the air surrounding the body. Wind velocity and ambient air temperature are the major determinants of convective heat loss. *Evaporation* is the process of vaporization of water, or sweat. Large amounts of heat are dissipated from the skin during this process, resulting in cooling. Ambient temperature, rate of sweating, air velocity, and relative humidity are important factors in determining how much heat is lost through evaporation. On a very humid day, sweat may pour off, rather than evaporate from a person exercising in a hot environment, thereby accomplishing little heat loss. In very warm environments, thermal gradients may be reversed, leading to transfer of heat to the body by radiation, conduction, or convection.[164]

PHYSIOLOGY OF THERMOREGULATION

In the normal human, stimulation of peripheral and hypothalamic temperature-sensitive neurons results in autonomic, somatic, and behavioral responses that lead to the dissipation or conservation of heat. Thermoregulation is the complex physiologic process that serves to maintain hypothalamic temperature within a narrow range of 98.6 ± 0.8°F (37 ± 0.4°C) known as the set point.[131] This hypothalamic set point is influenced by factors including diurnal variation and the menstrual cycle. Maintaining, raising, or lowering the set point results in many outwardly visible physiologic manifestations of thermoregulation such as sweating, shivering, flushing, or panting. In the central nervous system, thermosensitive neurons are located predominantly in the preoptic area of the anterior hypothalamus, although some are found in the posterior hypothalamus. These neurons may be divided into those that are warm sensitive, cold sensitive, or temperature insensitive. Approximately 30% of preoptic neurons are warm sensitive. These increase their firing rate during warming and decrease their firing rate during cooling.[36] Warming of the hypothalamus in conscious animals results in vasodilation, hyperventilation, salivation, and increases in evaporative water loss, as well as a reduction of cold-induced shivering and vasoconstriction.[131] Cooling of the hypothalamus in conscious animals causes shivering, vasoconstriction, and increased metabolic rate, even if the environment is hot.[123] How these temperature-sensitive neurons of the hypothalamus detect temperature changes and effect neuronal transmission is unclear. Altered action potential initiation and propagation caused by temperature-dependent changes in membrane potential, changes in the ratios of Na^+ to Ca^{2+} which alter neuronal excitability and neurotransmitter release, or effects on the Na^+K^+-ATPase (adenosine triphosphatase) pump may be involved.[148] Xenobiotics that increase intracellular cyclic adenosine monophosphate (cAMP) concentrations increase the thermosensitivity of warm-sensitive neurons.[36] In the brainstem, warm-sensitive and cold-sensitive neurons are located in the medullary reticular formation, where information from cutaneous receptors, spinal cord, and preoptic area of the anterior hypothalamus is integrated.[137]

The spinal cord also manifests thermosensitivity. Heat-sensitive and cold-sensitive ascending spinal impulses are conducted in the spinothalamic tract. As in the hypothalamus, local heating or cooling of the spinal cord results in thermoregulatory responses.[131] In addition to the hypothalamus, brainstem, and spinal cord, there is evidence of thermosensitivity in the deep abdominal viscera.[119,131,241] Intraabdominal heating or cooling results in thermoregulatory responses. Cold-sensitive and warm-sensitive afferent impulses can be recorded from the splanchnic nerves in animals.[119,243] Finally, the skin also contains heat and cold thermosensitive neurons. Cold receptors are free nerve endings that protrude into the basal epidermis, whereas warm-sensitive receptors protrude into the dermis.[130,132] Cutaneous thermoreceptor output is affected by the absolute temperature of the skin, rate of temperature change, and area of stimulation.[131] Cutaneous cold
FIGURE 15–1. A representation of the cutaneous thermoreceptive neurons responsive to external temperature change that functions as an early warning to the central nervous system.

receptors are Aδ and C nociceptor afferent fibers. Aδ fibers are small-diameter thinly myelinated fibers that conduct at 5–30 m/sec, and C fibers are small-diameter unmyelinated fibers that conduct at 0.5–2 m/sec.[119] Afferents from heat receptors are primarily C fibers. Cutaneous thermoreceptive neurons respond to external temperature change as well as rate of temperature change, sending early warning to the CNS via afferent impulses. This allows rapid and transient thermoregulatory responses before brain temperature changes (Fig. 15–1).

VASOMOTOR AND SWEAT GLAND FUNCTION

Vasomotor responses to thermoregulatory input differ according to location. The normal thermoregulatory response to heat stress is mediated primarily by heat-sensitive neurons in the hypothalamus. Increased body core temperature results in active vasodilation in the extremities and is under noradrenergic control. Increasing sympathetic stimulation results in vasoconstriction, and decreasing sympathetic stimulation results in vasodilation. Vasodilation in the head, trunk, and proximal limbs is not a result of decreased sympathetic tone; instead, it is a result of an active process that is under the influence of cholinergic sudomotor nerves and local effects of temperature on venomotor tone. Sweat glands release local transmitters, such as vasoactive intestinal polypeptide (VIP) or bradykinins, and vasodilation results. Areas of the body such as the forehead, where sweating is most prominent during heat stress, correspond to areas where active vasodilation is greatest. The neurotransmitters involved in the regulation of relationships between vasodilation and sweating as a response to heat stress are not fully elucidated, but animal evidence suggests the presence of specific vasodilator nerves.[131]

Sweat glands are controlled by sympathetic postganglionic nerve fibers, which are cholinergic, and large amounts of acetylcholinesterase as well as other peptides are involved in neural transmission.[130,131]

NEUROTRANSMITTERS AND THERMOREGULATION

The neurotransmitters involved in thermoregulation include serotonin, norepinephrine, acetylcholine, dopamine, prostaglandins, β-endorphins, and intrinsic hypothalamic peptides such as arginine vasopressin, adrenocorticotropic hormone, thyrotropin-releasing hormone, and melanocyte–stimulating hormone.[56,228] Studies on the effects of individual neurotransmitters in thermoregulation yield contradictory results, depending on the animal species and the route of administration of the exogenous neurotransmitter. Refinements in techniques of microinjection of neurotransmitters into the hypothalamus of animals, rather than intraventricular instillation, have elucidated microanatomic sites where neurotransmitters are active. More research is needed, however, as interspecies variations and theoretical differences in response to exogenous versus endogenous peptides makes this area of study complex.

Apomorphine is a mixed dopamine agonist that causes hypothermia in animals. Studies using selective D_1-receptor and D_2-receptor agonists and antagonists suggest that the hypothermic effect of apomorphine is a result of its effects on D_2 receptors, with some modulation by D_1 receptors in the hypothalamus.[204] Stimulation of D_2 receptors appears to mediate the hypothermia induced by the peptide sauvagine.[40] Stimulation of D_3 by specific agonists caused hypothermia in an animal model.[205,206] There appears to be a link between dopamine D_2 receptors and norepinephrine receptors in the hypothalamus, perhaps leading to vasodilation and hypothermia. The effect of clozapine in producing hypothermia in the rat is caused by D_1 and D_3 stimulation.[206,255] Lesser-known peptides appear to be involved in thermoregulation. For example, neuropeptide Y is an amino acid neurotransmitter that occurs in high concentrations in the preoptic area of the anterior hypothalamus. Administration of neuropeptide Y caused a reduction in core temperature when administered with adrenoceptor antagonists such as prazosin, an α_1-adrenergic antagonist, propranolol, a β-adrenergic antagonist, and clonidine, a central α_2-adrenergic agonist.[90,253] The administration of synthetic cannabinoids induces hypothermia in animals, an effect that is antagonized by adrenergic agonists and enhanced by adrenergic antagonists.[236] Studies on muscarinic receptors suggest the involvement of muscarinic M_2 and M_3 receptors in the production of hypothermia when agonists to these receptors are administered centrally.[256] Blockers of adenosine triphosphate sensitive K^+ channels can reverse the effect of cholinomimetic drugs in producing hypothermia.[238] Finally, studies of the neuroprotective effects of induced hypothermia may better define the role of other neurotransmitters in unintentional hypothermia.[311]

XENOBIOTIC EFFECTS ON THERMOREGULATION

Many xenobiotics have pharmacologic effects that interfere with thermoregulatory responses (Tables 15–1 and 15–2).[188,190,293] α-Adrenergic agonists prevent vasodilation in response to heat stress. Increased endogenous heat production in the setting of increased motor activity also occurs in patients poisoned with cocaine or amphetamines.

TABLE 15–1. Effects of Xenobiotics that Predispose to Hyperthermia

Impaired cutaneous heat loss
Vasoconstriction through α-adrenergic stimulation
    Amphetamine and derivatives
    Cocaine
    Ephedrine
    Phenylpropanolamine
    Pseudoephedrine
Sweat gland dysfunction
    Antihistamines
    Belladonna alkaloids
    Cyclic antidepressants
    Topiramate
    Zonisamide
Myocardial depression
Decreased cardiac output
    Antidysrhythmics
    β-Adrenergic antagonists
    Calcium channel blockers
Reduced cardiac filling by salt and winter depletion
    Diuretics
    Ethanol
Hypothalamic depression
Antipsychotics
Impaired behavioral response
Cocaine
Ethanol
Opioids
Phencyclidine
Sedative-hypnotics
Uncoupling of oxidative phosphorylation
Dinitrophenol
Pentachlorophenol
Salicylates
Increased muscle activity through agitation, seizures, or rigidity
Amphetamines
Caffeine
Cocaine
Isoniazid
Lithium
Monoamine oxidase inhibitors
Phencyclidine
Strychnine
Sympathomimetics
Dystonia
Butyrophenones
Phenothiazines
Withdrawal
Dopamine agonists
Ethanol
Sedative-hypnotics

TABLE 15–2. Effects of Xenobiotics that Predispose to Hypothermia

Impaired nonshivering thermogenesis
    β-Adrenergic antagonists
    Cholinergics
    Hypoglycemics
Impaired perception of cold
    Carbon monoxide
    Ethanol
    Hypoglycemics
    Opioids
    Sedative-hypnotics
Impaired shivering by hypothalamic depression
    Carbon monoxide
    Ethanol
    General anesthetics
    Opioids
    Phenothiazines
    Sedative-hypnotics
Impaired vasoconstriction
    α-Adrenergic antagonists
    Ethanol
    Phenothiazines

Life-threatening hyperthermia is associated with the use of these xenobiotics. α-Adrenergic antagonists and calcium channel blockers diminish the cardiac reserve available to compensate for heat-induced vasodilation, whereas diuretics decrease cardiac reserve through their effects on intravascular volume.[70] β-Adrenergic antagonists also interfere with the capacity to maintain normothermia under conditions of cold stress, possibly related to their interference with the mobilization of substrates required for thermogenesis.[131,190] Opioids and diverse sedative-hypnotics depress hypothalamic function and predispose to hypothermia in the overdose setting.[92] Carbon monoxide poisoning must also be considered in the hypothermic patient. Organic phosphorous insecticides and other xenobiotics that cause cholinergic stimulation cause hypothermia by stimulation of inappropriate sweating and possibly through depression of the endogenous use of calorigenic substrates.[190] Xenobiotics with anticholinergic effects decrease sweating and predispose to hyperthermia during environmental heat exposure or exercise. Phenothiazines appear to interfere with normal response to both heat and cold. Severe hyperthermia associated with the absence of sweating is frequently described in patients using phenothiazines and may be a consequence of their anticholinergic effects.[257,310] Effects on cold tolerance are attributed to their α-adrenergic antagonist effects, which prevent vasoconstriction in response to cold stress.[189] In addition, hyperthermia associated with severe extrapyramidal rigidity may occur in patients on antipsychotics.[181] This rigidity is attributed to the dopamine-blocking effects of this class of drugs.

ETHANOL

Ethanol is the xenobiotic most commonly related to the occurrence of hypothermia in an urban setting.[68,300,301] The mechanisms by which

ethanol predisposes to hypothermia are said to be due to its effects on CNS depression, cutaneous vasodilation, and blunting of behavioral responses to cold. However, thermoregulatory dysfunction associated with ethanol intoxication is undoubtedly more complex.

Ethanol leads to hypothermia in animal models, the extent of which is partly dependent on ambient temperature.[222,244,245] In mice, as the dose of ethanol increased, body temperature decreased. The rate of this decline in body temperature was faster at higher ethanol doses.[217] The decline in body temperature could be reversed by increasing ambient temperature to 96.8°F (36°C) which caused an immediate rise in the body temperature.[217] The poikilothermic effect of ethanol was not a result of hypoglycemia. Poikilothermia is the variation in body temperature greater than ±3.6°F (±2°C) on exposure to environmental temperature changes. Rats treated with equipotent amounts of sodium pentobarbital showed the same effects on body temperature as rats treated with ethanol, suggesting a similar central mechanism of CNS depression resulting in altered thermoregulation.[217]

Numerous mechanisms are involved in the ethanol-induced depression of CNS function.[250] Genetic factors influence the role of ethanol in the production of hypothermia. Mice can be selectively bred for genetic sensitivity or insensitivity to acute ethanol-induced hypothermia, and the differences appear to be mediated by the serotonergic systems.[93,106,209,217] Histidyl-proline–like topiperazine (cyclo His-Pro, or CHP), another neurotransmitter that is found in many animal species, acts at the preoptic-anterior hypothalamus to modulate body temperature.[46,141] Exogenous administration of this neuropeptide produced a dose-dependent decrease in ethanol-induced hypothermia. Attenuation of hypothermia resulted from passive immunization with CHP antibody.[46,141] Ethanol effects may be mediated through modulation of endogenous opioid peptides, as high-dose (10 mg/kg) naloxone reverses ethanol-induced hypothermia in animals.[233]

Pharmacokinetic characteristics of ethanol metabolism change in the presence of hypothermia. Hypothermic piglets infused with ethanol showed slower ethanol metabolism and a smaller volume of distribution and, as a result, higher ethanol concentrations than normothermic controls. Ethanol elimination and metabolism decreased as temperature fell.[169]

Tolerance develops to the ability of ethanol to produce hypothermia in all species.[95,222] The degree of tolerance is proportional to the dose and duration of treatment with ethanol and is not explained by the increased rate of metabolism with chronic exposure.[148] Age is a factor in the development of tolerance; older animals do not display the same degree of tolerance to the hypothermic effects of chronic ethanol administration as do younger animals.[214,231,308] The development of tolerance to ethanol-induced hypothermia is affected by genetic factors. Experimentally, tolerance to ethanol-induced hypothermia increases the incorporation of certain amino acids into proteins in the rat brain. The formation of new proteins in ethanol-tolerant rats suggests stimulation of gene expression related to the tolerant state.[148,296] Deficits in *N*-methyl-D-aspartate (NMDA) receptor systems may also be implicated in the development of ethanol tolerance. In addition, altered nicotinamide adenine dinucleotide (NADH) oxidation to NAD$^+$, diminished blood flow to the liver, or slowing of metabolism through the microsomal enzyme system may be involved.[250]

Hypothermia alters the breath–ethanol partition in the alveolus, and the temperature of expired breath alters breath–ethanol analysis results. In patients with mild hypothermia, ethanol breath analysis results in lower values by 7.3% per degree centigrade (or 1.8°F) decrease in body temperature.[98] Whether breath–ethanol analysis is also affected by hyperthermia in the test subject remains to be studied.[98]

DISEASE PROCESSES AND THERMOREGULATION

Many disease processes interfere with normal thermoregulation, limiting an individual's capacity to prevent hypothermia or hyperthermia. Extensive dermatologic disease or cutaneous burns impair sweating and vasomotor responses to heat stress.[42] Patients with autonomic disturbances such as diabetes mellitus or peripheral vascular disease also have altered vasomotor responses that impair vasodilation and sweating.[242] Extensive surgical dressings may preclude the evaporation of sweat in an otherwise normal patient. Heat-stressed persons with poor cardiac reserve may not be able to sustain a skin blood flow high enough to maintain normothermia.[82,277] Intense motor activity may lead to excessive endogenous heat production in patients with Parkinson disease or hyperthyroidism. Patients with an agitated delirium or seizures also have significantly elevated rates of endogenous heat production. Hypothalamic injury caused by cerebrovascular accidents, trauma, or infection may disturb thermoregulation.[81,185] Hypothalamic dysfunction can lead to high, unremitting fevers and insufficient stimulation of heat loss mechanisms such as sweating. Hypothalamic damage may predispose to hypothermia by interference with centrally mediated heat conservation.[81,185,258,259] Fever, the normal response to stimulation of the hypothalamus by pyrogens, results in an elevated physiologic temperature set point and is a disadvantage in the heat-stressed individual.[131]

HYPOTHERMIA

Epidemiology Hypothermia is defined as a lowering of the core body temperature to <95°F (<35°C). Between 1999 and 2002, 4607 people had hypothermia-related diagnoses listed on the death certificate as the underlying cause of death.[51] Most of these, 2622, were due to exposure to excessive cold; in the remainder hypothermia resulted from causes other than exposure, such as medical illness[48,49,135,163] (Table 15–3).

Most hypothermic deaths occur in the winter months; however, mildly cool environments and windy wet conditions are also frequently associated with hypothermia. From 1999 to 2002, Alaska, Montana, Wyoming, and New Mexico had the greatest overall death rates from hypothermia.[13] States with milder climates and rapid fluctuations in temperature, such as North Carolina and South Carolina, and western states, such as Arizona, with high elevations and cold nighttime temperatures, report hypothermia-related deaths.[51]

Response to Cold The normal physiologic response to cold is initiated by stimulation of cold-sensitive neurons in the skin, so that the onset of the response to cold occurs prior to cooling of central blood. Cold-sensitive neurons in the skin send afferent impulses to the hypothalamus, resulting in shivering and piloerection. Shivering is the main thermoregulatory response to cold in humans, except in neonates, where nonshivering thermogenesis prevails. Shivering is initiated in the posterior hypothalamus when impulses from cold-sensitive thermoreceptors are integrated in the anterior hypothalamus and communicated to the posterior hypothalamus, or when cold-sensitive neurons in the posterior hypothalamus are activated directly. Efferent stimuli from the posterior hypothalamus travel through the midbrain tegmentum, pons, and lateral medullary reticular formation to the motor pathways of the tectospinal and rubrospinal tracts, resulting in shivering.[28] A mechanism of stimulation of shivering that usually occurs later when core temperature falls is the local cooling of the spinal cord. This leads to shivering by increasing excitability of motor neurons.

Heat produced without muscle contraction is known as *nonshivering thermogenesis*.[41,131] Nonshivering thermogenesis is mediated by the sympathetic nervous system.[62] Catecholamines activate adenylate

cyclase, increasing cAMP, and resulting in mobilization of fat and glucose stores (β-adrenergic receptors).[191,252] Nonshivering thermogenesis is blocked by α-adrenergic receptor antagonism and increased by administration of norepinephrine. Brown adipose tissue is the most important site of nonshivering thermogenesis. In humans, brown fat is found primarily in neonates, although in cold-acclimatized people there may be small amounts found on autopsy.[41] Brown adipose tissue functions as a thermoregulatory effector organ, producing heat by the oxidation of fatty acids when the tissue is stimulated by norepinephrine.[45]

In addition to shivering and nonshivering thermogenesis, efferent sympathetic fibers from the hypothalamus stimulate peripheral vasoconstriction (α-adrenergic receptors). Piloerection and vasoconstriction result in decreased heat loss from the body. Intense vasoconstriction shunts blood away from the periphery to the core and antidiuretic hormone antagonism results in increased urine output and hemoconcentration.

Disease Processes and Hypothermia Several disease processes commonly result in an inability to maintain a normal body temperature in a cool environment (see Table 15–3). Hypothermia may develop in association with sepsis,[183] hypothyroidism, hypoglycemia, uremia, hepatic failure, or poor nutrition.[73,239] Hypothalamic injury may result in chronic poikilothermia.[189] Thiamine deficiency adversely affects the hypothalamus, perhaps because of inefficient glucose metabolism, and leads to hypothermia.[167] Spinal cord transections above the first thoracic segment interrupt hypothalamic-sympathetic outflow pathways, resulting in hypothermia.[242] The frail elderly are at greater risk of hypothermia because of decreased vasomotor responses and decreased capacity to shiver.[62,64] Mentally and physically compromised patients may be unable to make appropriate behavioral responses to hot or cold environments.

Evaluations to determine the presence of underlying diseases are often difficult in the hypothermic patient.[96,183] The mental status may be markedly altered by hypothermia but is not usually abnormal until the temperature falls below 90°F (32.2°C).

Alteration of Pharmacology in Hypothermia The pharmacology of certain xenobiotics is altered in the setting of hypothermia. In hypothermic piglets, the volume of distribution and the clearance of fentanyl are decreased.[169] Similarly, in piglets given gentamycin, the volume of distribution and clearance rate decreased in direct proportion to the decrease in cardiac output and glomerular filtration rate.[168] Hypothermic puppies given intravenous lidocaine showed slower rates of disappearance of the drug than when normothermic.[210] Humans and animals given propranolol showed a reduced volume of distribution and decreased total body clearance, resulting in higher than expected propranolol concentrations.[196,197,220] Decreased hepatic metabolism of propranolol during hypothermia has been shown in vitro.[197] Hypothermia prolongs neuromuscular blockade with *d*-tubocurarine,[121] and increases neuromuscular blockade with suxamethonium.[305] Phenobarbital metabolism and volume of distribution decreased with hypothermia in children.[147] The lethal dose of digoxin was doubled in hypothermic dogs.[24] Digoxin-like substances are present during hypothermia.[102,134]

Reasons for altered metabolism in hypothermia include delayed distribution of the drug and altered enzyme function with temperature and pH changes. Cardiac output decreases, leading to decreased liver perfusion and decreased delivery of drug to hepatic microsomal enzymes.[121,150–152,229] Plasma volume decreases as free water moves intracellularly, causing hemoconcentration and further decreasing organ perfusion.[122] Biliary excretion of atropine, procaine, and sulfanilamide decreases in vitro.[150–152] The glomerular filtration rate decreases in hypothermia.[37] In vitro, the activity of metabolic pathways, including acetylation and hydrolysis, decreases with cooling.[151,152]

Clinical Findings The clinical effects of hypothermia are related to the membrane depressant effects of cold, which result in ionic and electrical conduction disturbances in the brain, heart, peripheral nerves, and other major organs (Table 15–4).[136] Cold tissues are protected by decreases in tissue oxygen requirements. As body temperature decreases, metabolic activity declines at a rate of approximately 7% per 1.8°F (1°C).[307] This effect provides significant protection to

vital organs despite the potentially deleterious effects of membrane suppression.

Effects on the CNS are temperature dependent and predictable. Mild hypothermia (90°F–95°F; 32.2°C–35°C) usually results in relatively benign clinical manifestations. Ataxia, clumsiness, slowed response to stimuli, and dysarthria are common.[96] As cooling continues, the mental status slowly deteriorates. In moderate hypothermia (80°F–90°F; 27°C–32.2°C), the patient is usually lethargic but still likely to respond verbally. In severe hypothermia (68°F–80°F; 20°C–26.6°C) the patient is unlikely to respond verbally, but will react purposefully to noxious stimuli.[96,127] In profound hypothermia (<68°F; <20°C), the patient is unresponsive to stimuli. Pupils may be fixed and dilated and the patient

may appear dead.[127] However, standard criteria of brain death do not apply to hypothermic patients. The hypothermia itself protects against cerebral hypoxic damage.[136] Temperature drop inhibits the release of the excitatory neurotransmitter glutamate and attenuates the release of dopamine in brain ischemia animal models, suggesting a protective effect of hypothermia in brain injury.[44] Ventricular cerebrospinal fluid glutamate concentrations were lower in patients with induced mild hypothermia after brain injury when compared to brain-injured patients kept normothermic.[193] Induced mild hypothermia improves neurological outcomes and survival after return of spontaneous circulation in cardiac arrest.[11,22]

Under controlled circumstances patients have survived with body temperatures as low as 48.2°F (9°C).[99] Vigorous resuscitation is required for these patients. In particular, cardiac resuscitation should not be terminated in the field, where temperatures are seldom taken. The adage that a patient cannot be considered dead until the patient is warm and dead is critical to providing appropriate management. This approach may lead to hours of cardiopulmonary resuscitation of hypothermic patients with ventricular fibrillation, ventricular tachycardia, or asystole, but may be ultimately successful in resuscitating patients initially presumed to be dead.[275]

The cardiac and hemodynamic effects of cold correlate closely with body temperature. As cooling begins there is a transient increase in cardiac output. Tachycardia develops secondary to shivering and sympathetic stimulation. At about 81°F (27.2°C) shivering ceases. Bradycardia develops with maintenance of a normal cardiac stroke volume.[43] This bradycardia is responsible for the decreased myocardial oxygen demand that may be protective in the setting of hypothermia.[43] In profound hypothermia, bradycardia may progress to asystole and death.

Unlike cerebral circulation, where autoregulation is preserved during cooling, coronary autoregulation is disturbed during hypothermia, and myocardial injury may ensue.[43] Attempts to maximize myocardial oxygenation through administration of oxygen and volume replacement to increase diastolic filling pressure are appropriate. Pharmacologic or electrical attempts to increase heart rate may dangerously increase myocardial oxygen demand.

The initial response to cold is hyperventilation; however, as temperature continues to decrease, hypoventilation develops, which may progress to apnea and death. In animal models, this has been attributed to cold-induced failure of phrenic nerve conduction.[159]

The Electrocardiogram The most common ECG abnormality in hypothermia is generalized, progressive depression of myocardial conduction. PR, QRS, and QT intervals are all prolonged, and increasingly profound hypothermia may lead to gradual progression to asystole.[79,289] Ventricular fibrillation occurs in an irritable myocardium most commonly at temperatures less than 86°F (30°C) resulting in a high O_2 consumption dysrhythmia. Atrial fibrillation is the most common dysrhythmia occurring in the presence of hypothermia.[97,230] Shivering may not be clinically evident, but the characteristic fine muscular tremor frequently produces a mechanical artifact in the baseline of the electrocardiogram.[84] A deflection occurring at the junction of the QRS and ST segment is invariably present in patients with temperatures 86°F (<30°C) (Fig. 15–2). First described in a single patient in 1938, the J-point deflection is commonly known as the *Osborn wave*.[85,234,285] The J-point deflection, thought to be a "current of injury" associated with CO_2 retention under hypothermic conditions, was believed to be a poor prognostic sign.[234] Subsequent study does not support any prognostic significance, as the J-point deflection is invariably found in the hypothermic patient when multiple electrocardiographic leads are obtained.[84,85,287,294] The size of the J-point deflection increases as body temperature decreases.[230,294] Atrial dysrhythmias that occur in the
FIGURE 15–2. A characteristic electrocardiographic finding in the patient with profound hypothermia. The arrows (↑) indicate the Osborn wave which appears at terminal phase of the QRS complex.

absence of underlying heart disease invariably disappear solely with rewarming.

Management After blood specimens are drawn, the hypothermic patient in whom hypoglycemia is present should be given 0.5–1.0 g dextrose/kg of body weight as $D_{50}W$ (50% dextrose in water) and 100 mg of thiamine IV. If hypoglycemia is the cause of the hypothermia, the response to dextrose may be dramatic, heralded by the onset of shivering and rapid return to normal body temperature. Wernicke encephalopathy is uncommon, but may be associated with mild hypothermia; thermoregulation and normal ocular motion may return after the initiation of thiamine therapy.[167]

If normal mental status is not regained when the temperature reaches 90°F (32.2°C) during rewarming, underlying CNS structural, toxic, or metabolic problems must be considered.[96,183,239] Failure of the patient to rewarm quickly suggests the presence of underlying disease.[73] (Fig. 15–3). In one study, hypothermic patients without underlying disease are reported to rewarm at a rate of 1.0–3.7°F/h (0.6–2.1°C/h) (average, 2.1°F/h; 1.2°C/h), whereas patients with significant underlying disease (sepsis, gastrointestinal hemorrhage, diabetic ketoacidosis, pulmonary embolus, myocardial infarction) warmed at a rate of 0.25–1.8°F/h (0.1–1.0°C/h) (average, 1°F/h; 0.6°C/h).[300]

Hypothermia shifts the oxygen dissociation curve to the left (Chap. 21), resulting in decreased oxygen unloading to tissues; therefore, oxygen administration may be of benefit.[71] If clinically indicated for airway protection or inadequate ventilation or oxygenation, endotracheal

intubation should be performed and can usually be done without complication.[68,176,207] However, there are case reports of ventricular fibrillation occurring during endotracheal intubation.[20,105,127,235,302] Every effort should be made to limit patient activity and stimulation during the acute rewarming period, as activity may increase myocardial oxygen demand or alter myocardial temperature gradients, increasing the risk of iatrogenic ventricular fibrillation. Although pulmonary artery catheters and central venous lines have been inserted without complications, they should be avoided unless absolutely essential, so as not to precipitate ventricular dysrhythmias.[125,177,286] If a central venous catheter is considered necessary, it should not be allowed to touch the endocardium.[288] Patients who develop ventricular fibrillation or asystole are difficult to manage because they require complex and prolonged resuscitation efforts. In these instances, cardiopulmonary resuscitation (CPR) should be initiated, and the patient intubated and ventilated to maintain a pH of 7.40, **uncorrected** for temperature. Active internal rewarming should be instituted in the patient in cardiac arrest because standard therapy for ventricular fibrillation or asystole may be unsuccessful until rewarming is achieved. There is a risk of toxicity if multiple doses of drugs are administered in the hypothermic patient in whom drug metabolism is altered and circulation is arrested; however, based on current research discussed below, it is reasonable to incorporate pharmacologic agents into the management of hypothermic cardiac arrest. A vasopressor, either epinephrine or vasopressin, may be given to increase the coronary perfusion pressure.[303,304] Amiodarone or lidocaine may then be administered if ventricular fibrillation is present. Defibrillation may not be successful until the temperature exceeds 86°F (30°C); however, it can be successfully accomplished in animals and patients with temperatures of less than 86°F (30°C).[6,20,69,213,303] A reasonable approach is that if defibrillation is unsuccessful, it should not be attempted again until the patient has been warmed several degrees centigrade. Individuals presenting with cardiac arrest and hypothermia may appear dead yet respond to rewarming and resuscitative efforts. The pneumatically powered "thumper" and other devices capable of mechanical chest compression, and cardiopulmonary bypass are used successfully during prolonged hypothermic cardiopulmonary arrests.[20,60,180,276,286]

Arterial Blood Gas Physiochemistry Assessment of the adequacy of ventilation and oxygenation in the hypothermic patient often poses a dilemma to clinicians, as chemical effects of cold on arterial pH and blood gases lead to confusion in the interpretation of arterial blood gas values. Cold inhibits the dissociation of water molecules, causing pH to increase as cooling occurs. In vitro, the pH change of blood as it is cooled increases parallel to the pH change of neutral water. The partial
FIGURE 15–3. Relation of rewarming rate to underlying illness.[73]

pressures of CO_2 and O_2 decrease as cooling occurs, even as the blood content of those gases remains unchanged. Blood in a syringe taken from a patient whose body temperature is 98.6°F (37°C) yields a pH of 7.40 and a PCO_2 of 40 mm Hg in the blood gas machine at 98.6°F (37°C), but yields a pH of 7.72 and a PCO_2 of 14 mm Hg if the blood is cooled to 61°F (16°C) and the values are measured at that temperature. Specially calibrated laboratory equipment, not routinely available, is required to measure blood gas values directly at other than normal body temperature. A patient whose body temperature is 61°F (16°C) and whose actual in vivo blood gas values are pH 7.72 and PCO_2 14 mm Hg will have values of pH 7.40 and PCO_2 40 mm Hg when the blood is warmed to 98.6°F (37°C) and measured in the standard laboratory blood gas machine. Because the machine measures pH and blood gas pressures only in blood warmed to 98.6°F (37°C) (the uncorrected values), the actual in vivo values in hypothermic patients are approximated using mathematically derived corrected values. Because the pH of neutrality has also increased, it is unclear what clinical meanings these corrected values have. The uncorrected values indicate what the pH and PCO_2 would be if the patient were normothermic. At first glance, the clinician might be content to learn that a hypothermic patient at 61°F (16°C) has a corrected pH of 7.47 and PCO_2 of 40 mm Hg. However, the uncorrected values of pH 7.18 and PCO_2 111 mm Hg indicate that the patient has a significant respiratory acidosis. Attempts to maintain a corrected pH of 7.40 may lead to hypoventilation and risk alveolar collapse and impairment of oxygenation. The preponderance of evidence in the anesthesia and cardiovascular surgery literature suggests that maintenance of ventilation is associated with a decreased incidence of myocardial injury and a decreased incidence of ventricular fibrillation.[71] pH and PCO_2 blood gas values should be left uncorrected after the blood sample is warmed in the blood gas machine and interpreted in the same way as in the normothermic patient.

Hypotension When hypotension occurs in the patient with hypothermia, it may be a result of the presence of bradycardia and volume depletion. However, hypotension may be a predictor of infection, particularly when associated with a slow rewarming rate.[73] Fluid depletion in hypothermia occurs as a result of a variety of mechanisms, including central shunting of blood by vasoconstriction and cold-induced diuresis. Cold diuresis occurs when increases in central blood volume result in inhibition of the release of antidiuretic hormone. Impairment of renal enzyme activity and decreased renal tubular reabsorption contribute to the large quantities of dilute urine known as cold diuresis.[122,126,177,307] Normal saline should be given to expand intravascular volume. Urine output is an important indicator of organ perfusion and the adequacy of intravascular volume in the hypothermic patient, although the initial cold diuresis may lead to underestimation of fluid needs.[307]

Pharmacologic Interventions The best means to affect resuscitation of the hypothermic victim in ventricular fibrillation is controversial. The most recent recommendations of the American Heart Association for the treatment of cardiac arrest when the core body temperature is <86°F (<30°C) do not include the administration of a vasopressor or antidysrhythmic.[1] However, a recent metanalysis of animal studies of antidysrhythmic and vasopressor therapy for ventricular fibrillation in the setting of hypothermia found there was significant improvement in the return of spontaneous circulation (ROSC) in animals that received epinephrine or vasopressin.[304] In this report, the authors could not identify a benefit to the use of amiodarone or bretylium administered without a vasopressor. They postulated that this is most likely due to the improvement in coronary perfusion pressure caused by vasopressors during cardiac arrest.[304]

Epinephrine and Vasopressin The administration of vasopressin to pigs in hypothermic cardiac arrest increased coronary perfusion pressure

and improved defibrillation success.[265] However, because of defibrillation, there was no difference in the 1-hour ROSC.[265] In a pig model, when warmed thoracic lavage was utilized, vasopressin increased coronary perfusion pressure and increased the 1-hour survival.[264] In this study the administration of saline resulted in zero episodes of successful defibrillation whereas 8 of 8 vasopressin-treated pigs had restoration of spontaneous circulation after electrical defibrillation and improved short-term survival. The whole body temperature was not increased, but the authors postulated that myocardial warming may have occurred.[264] In another study in which epinephrine was given to one group of pigs and vasopressin to another, increased coronary perfusion pressure and ROSC resulted in both groups.[171,172] In contrast, body temperature significantly increased during CPR with thoracic lavage, and epinephrine increased coronary perfusion pressure, but no improvement in ROSC occurred.[170] The length of time of cardiac arrest, the doses of drug, and the efforts to rewarm differed in these studies. A 19-year-old patient who had a prolonged hypothermic cardiopulmonary arrest showed no improvement following 2 mg of epinephrine but following the administration of vasopressin had immediate restoration of spontaneous circulation.[281] Interactions with epinephrine, vasopressin, and ischemia during CPR are complex and incompletely understood.[173]

Amiodarone Amiodarone is recommended in the current AHA algorithim for ventricular fibrillation in normothermia. In one study comparing the use of amiodarone, bretylium, and placebo in a hypothermic dog model, amiodarone showed no statistical improvement in causing ROSC. There was no significant difference between the groups; only 1 of 10 amiodarone-treated dogs demonstrated ROSC, versus 3 of 10 in the placebo group and 4 of 10 in the bretylium-treated dogs.[280] However, in a study in which hypothermic dogs in ventricular fibrillation were treated with epinephrine before administration of amiodarone 10 mg/kg, there was a significantly higher rate of ROSC.[303]

Bretylium Bretylium tosylate is a benzyl quaternary ammonium compound with a biphasic action, initially causing release of norepinephrine and then blocking its release. This may cause transient hypertension, but hypotension is the most common result.[213,233] Hypothermic dogs given bretylium had significantly lower mean arterial pressures and systemic and pulmonary vascular resistance as compared to controls.[233] The mechanism of the antidysrhythmic effect of bretylium in normothermia may be related to its ability to increase the myocardial refractory period.[233] Bretylium is no longer part of the AHA recommendations and is no longer available in the USA. A single case of successful chemical defibrillation with bretylium is reported in an environmentally exposed patient with a core temperature of 85.1°F (29.5°C).[67]

Dopamine Dopamine increases cardiac output, mean arterial pressure, heart rate, and stroke volume in dogs cooled to 77°F (25°C), and stabilizes pulmonary arterial wedge pressure.[219] In a canine hypothermia model, dopamine infusions provided some protection from ventricular fibrillation. Dopamine lowered the temperature at which ventricular fibrillation occurred and reduced the incidence of ventricular fibrillation, as did infusion of norepinephrine.[10] The added benefit of dopamine in hypothermia may be a result of its renal and splanchnic vasodilating properties, increasing renal perfusion and supporting urine output.[109] Dopamine increases myocardial oxygen demand and decreases peripheral perfusion, potentially detrimental effects in the hypothermic patient.[10] Nevertheless, after the administration of intravenous fluids, dopamine infusion during hypothermia is indicated in the patient requiring blood pressure support.

Rewarming Three types of rewarming modalities are used in the management of hypothermic patients.[63,85] *Passive external rewarming*

involves covering the patient with blankets and protecting the patient from further heat loss. Passive external rewarming uses the patient's own endogenous heat production for rewarming and is most successful in healthy patients with mild to moderate hypothermia whose capacity for endogenous heat production is intact.[126] Passive external rewarming is reported to be successful in hypothermic patients with temperatures as low as 69°F (20.6°C).[284,294,301] Advocates of passive external rewarming argue that it allows vasoconstriction to persist and it decreases the afterdrop and shock from vasodilation associated with active skin rewarming.[126,207,284]

Active external rewarming involves the external application of heat to the patient. There is disagreement about the possible detrimental effects of active external rewarming. For example, skin warming may lead to a physiologically detrimental suppression of shivering.[126] Acute vasodilation of peripheral vessels could cause hypotension and an increased peripheral demand on the persistently cold myocardium. The return of cold blood from the extremities to the heart is suggested to exacerbate intramyocardial temperature gradients, which could cause ventricular irritability during hypothermia.[186] However, in pigs, blood returning to the heart was found to be warm before warming of central organs occurred.[110] A new warming method that circulates temperature- controlled water through pads adherent to the skin requires care to prevent skin damage.[115]

Afterdrop is the continuing decrease in temperature once active rewarming begins. The American Heart Association (AHA) Advanced Cardiac Life Support (ACLS) guidelines[1] recommend not in the extremities application of heat to the trunk only, in an attempt to avoid the complications of afterdrop and intramyocardial temperature gradients.[174] In one study of 33 patients with core temperature <82.4⁰F (< 28⁰C), no patient experienced afterdrop during peripheral rewarming.[248] There is no scientific evidence to suggest that afterdrop, should it occur, is more dangerous than the very temperature that had existed originally.[187] In addition, there is no evidence of pooling of blood in the periphery, nor of increased flow during surface rewarming.[187,260] Flow studies in the hand, arm, calf, and foot demonstrate that afterdrop has already occurred and is completed before any increase in blood flow occurs in the limbs.[187,298] Initial experiments demonstrating afterdrop were done in inanimate objects and reflected continued cooling of central structures before heat from external sources reached the core.[110,187,298]

Treatment including complete submersion is available in some institutions. Eighteen patients with temperatures of 78.8°F–91.4°F (26°C–33°C) were successfully warmed in a Hubbard tank, although one fatality not associated with rewarming occurred.[309] Submersion must be used with caution, however, because of the inherent difficulties of controlling agitated patients and monitoring and resuscitating patients in water.

Mortality rates for active external rewarming are frequently reported to be higher than for passive external rewarming,[242] but case selection is not controlled in these series. Sicker patients with stable cardiac rhythms who fail to rewarm passively and are then actively rewarmed have a higher mortality rate directly correlated with their underlying disease, rather than the method of therapy.[73] Selection of either passive or active external rewarming in treatment of mild to moderate hypothermic patients with perfusing cardiac rhythms does not appear to influence the prognosis as much as the presence or absence of underlying disease.[73,139,207,300] In our experience, active external rewarming has not resulted in mortality, except in those patients with severe underlying disease.[73,294]

Active internal rewarming involves attempts to increase central core temperature directly, by warming the heart prior to the extremities or periphery. Minimally invasive modalities of active internal rewarming include the administration of heated, humidified oxygen delivered by face mask or endotracheal tube,[128] and gastric lavage with warmed fluids. More invasive modalities, those procedures that are fundamental to the rewarming controversy, include peritoneal lavage with warmed dialysate,[145,224] and the rerouting of blood through external blood rewarming equipment via cardiopulmonary or femoral–femoral bypass and hemodialysis.[47,133,215] Heparin-coated bypass systems are available that avoid systemic anticoagulation, thus decreasing the risk of bleeding complications. It is suggested that extracorporeal venovenous rewarming and continuous arteriovenous rewarming show improved rewarming rates when compared to standard techniques such as saline lavage of the bladder, stomach, or peritoneal cavity.[103] Extracorporeal methods of active internal rewarming should be reserved for severely hypothermic patients (<80°F or <27°C) or those with unstable cardiac rhythms (ventricular fibrillation or tachycardia, or asystole) attributed to hypothermia.[6,72,123] The evidence for the benefit of extracorporeal methods in those patients with stable rhythms is not clear. In patients with stable rhythms, studies are essential to resolve the debate over the merits of passive or active external rewarming versus active internal rewarming. Transcutaneous pacing was successful in improving hemodynamic parameters and speeding rewarming in an animal model.[81]

Unfortunately, current ACLS guidelines for the management of hypothermia make several recommendations that are not supported by the literature. The most glaring is the recommendation of extracorporeal rewarming for stable patients based on a temperature of 86°F (30°C) or less. ACLS guidelines assert that passive rewarming is ineffective in the stable patient with severe hypothermia, which is defined as a temperature below 86°F (30°C). However, many patients with temperatures below 86°F (30°C) have been successfully treated with passive external rewarming with, at most, the addition of warm, humidified oxygen.[73,248,273,294,301] Patient temperature correlates poorly with outcome.[6,69,176,286,289] Treatment recommendations should not be based solely on temperature. Stability of the vital signs and cardiac rhythm and the underlying cause of hypothermia are much more critical considerations in management. It is hard to imagine a patient with a stable cardiac rhythm and core temperature of 80°F–86°F (26.6°C–30°C) in whom extracorporeal rewarming with cardiopulmonary bypass is indicated.

Additionally, ACLS guidelines state that significant hyperkalemia may develop during rewarming, suggesting that this is a complication of rewarming. Hyperkalemia is not described as a consequence of rewarming.[68] In all of the evidence collected with regard to hyperkalemia, this abnormality was present as a consequence of the hypothermia and not the rewarming.[127,191,261]

Prognosis in Hypothermia   Except in cases of profound hypothermia,[127] the prognosis is most closely correlated with the presence or absence of underlying disease.[139,207,227,300,301] In patients with hypothermia alone, in the absence of underlying disease, mortality is 0% to 10%. In the presence of a severe underlying disease such as sepsis, mortality is much greater.[73] Morbidity results from associated frostbite and trauma.

Prolonged cardiopulmonary arrest and absolute temperature are not predictive of poor outcome.[6,69,176,286,289] In severely hypothermic patients, profound hyperkalemia (K⁺ > 10 mEq/L) is associated with unsuccessful resuscitation.[127,191,261]

Frostbite   Hypothermia may be accompanied by frostbite when patients are exposed to environmental temperatures that are less than 20°F (6.7°C).[208] Frostbite should be managed by rapid rewarming. The extremity involved may be placed in a large, soft basin of warm water (100°F–108°F; 38°C–43°C) for 30 minutes. The water temperature must be frequently adjusted, as the frozen extremity will cool the water in the basin. Parenteral analgesics may be necessary, as the rewarming process is often painful. Frostbitten areas should never be rubbed, as the tissue is particularly sensitive to trauma. Dextran, alcohol, vasodilators, and anticoagulants have not proven

useful. Sympathectomy in this situation is also of unproven benefit and remains highly controversial.[160,175,199]

Prevention Because many patients may not wear (and may not possess) adequate clothing, it is essential that they be assessed for social services support after the acute episode is resolved. In addition, many of these patients live in substandard, inadequately heated (often unheated) housing. Patients should be advised to wear comfortable, warm clothing to prevent future episodes of hypothermia. Adequate clothing is particularly important for patients traveling by automobile during inclement weather conditions. The importance of adequate nutrition should also be stressed.

HYPERTHERMIA

Definition of Heatstroke Heatstroke is defined by a rectal temperature greater than 106°F (41.1°C) in the setting of a neurologic disturbance manifested by mental status changes including confusion, delirium, stupor, coma, and/or convulsions.[164] Temperature criteria cannot be absolute, as information regarding the patient's temperature is rarely available at the time of onset of heatstroke. In some instances the temperature may not be measured for several hours, during which time cooling may have been instituted or occurred spontaneously.[155,156] When appropriate environmental conditions prevail, the diagnosis of heatstroke should be made liberally. Although the absence of sweating was once thought to be an essential component of the definition of heatstroke,[58,226] many patients with heatstroke maintain the ability to sweat.[66,192,270,295]

Epidemiology of Heatstroke Hundreds of people die annually of heatstroke in the United States, and 80% of the victims are older than 50 years of age. When counting heat-related fatalities, the number is underestimated if only death certificates are included in which hyperthermia is listed as the underlying cause of death. Including hyperthermia as a contributing factor to death increased the total number of heat-related deaths by 54% from 1993 to 2003.[12] Several studies show mortality rates from heatstroke to be 5.6% to 80%. Thousands of other victims survive with significant heat-related morbidity.[9,15,33,80,146,157,277] The high morbidity and mortality of heatstroke markedly contrast with those of profound hypothermia, in which the prognosis is related not to the temperature itself, but to the underlying etiology. The overall prognosis in heatstroke depends primarily on how long the temperature has been elevated prior to cooling, the maximum temperature reached, and the affected individual's premorbid health.

Heat-related deaths are preventable, and the public health preparedness of cities, healthcare workers, and the community is essential.[21,50] Mortality during heat waves is increased in urban areas where a heat wave has not occurred for several years.[57,83,146,263] Mortality is decreased when public health interventions improve preparedness. The city of Milwaukee experienced a heat wave in 1995 that resulted in numerous public health and preparedness responses. These efforts may have resulted in a diminution by 49% of the number of heat-related deaths and emergency medical service runs in the heat wave of 1999.[299] After the Chicago heat wave of 1995, public policies targeting the elderly of Chicago may have contributed to a change in the demographics of those who succumbed during a subsequent heat wave in Chicago in 1999. The dead in 1999 were younger; more that 50% of those who died were younger than age 65 years. More than half of the dead were seen or spoken to on either the day of or the day before their death. Psychiatric illness was almost twice as prevalent in the younger victims, compared to those older than 65 years of age.[218]

Heat waves are meteorologic events characterized by air temperatures that are ≥90°F (≥32.2°C) for 3 or more consecutive days.[49] During the summer of 2003, Europe experienced record high temperatures for many consecutive days. The prolonged heat caused extreme increases

in mortality across Europe. In France, there were 14,800 excess deaths caused by heat. This is equivalent to a total mortality increase of 60% between August 1 and August 20, 2003.[178,291] In a followup report of 83 of the survivors, the subsequent mortality at 2 years was 71%.[15] Survivors had dramatic decreases in their ability to function.[15] Italy reported 1094 excess deaths from June to August 2003, a 23% increase compared with the average annual number of deaths from 1995 to 2002.[50] Increased mortality was associated with risk factors previously reported, including old age, limited access to care, poor living conditions, and social isolation.[34,266,292]

Socially isolated individuals or those with pre-existing illness, as well as the physically compromised and frail elderly, are at greatest risk of death during heat waves. Confinement to bed was the strongest predictor of death in the Chicago heat wave of 1995, and living alone doubled the risk of death. There were fewer deaths among people with working air conditioners or who had access to an air-conditioned environment.[249,266] Although fans may seem to improve comfort, they do not prevent heat-related illness and may contribute to heat stress when temperatures and humidity exceed approximately 100°F (37.8°C).[153,157,158,218,266,306] In times of heat waves, preventive public health programs should encourage visiting nurses, housekeepers, and community service programs to increase the awareness of the danger of heat and identify those individuals most at risk.[266] A decreased risk of death was found among people with contacts from these agencies during the Chicago heat wave.[266] The media must alert the public and provide information on avoiding heat illness, as well as encourage individuals to help others to stay cool by assuring access to cooling measures.

The number of deaths from exposure-related illness has increased 3-fold in foreign transients attempting to enter the United States from Mexico. Because urban areas are more tightly patrolled, individuals attempting to cross into the United States illegally have turned to the harsh deserts and mountain ranges of the southwestern United States, increasing prolonged exposure and resulting in death from heat, cold, and dehydration. Although many more bodies may remain undiscovered, 99 individuals' deaths were attributed to environmental causes in the year 2000, many of these due to heat.[88]

From 1995 to 2002, 233 children died from heatstroke when left unattended in cars, 75% of whom were either forgotten or left by caretakers who did not expect the temperature to rise dangerously within the automobile. In 25% of the incidents, children were trapped inadvertently while playing. Most of these deaths occurred during the summer months.[117]

Infants may suffer heatstroke under environmental conditions that would not be expected to place the child in danger. Well-meaning parents sometimes overinsulate children with clothing and blankets, inhibiting their cutaneous heat loss and placing them at risk.[19,142,143]

During 2002, the United States military reported 1816 heat-related injuries of active duty soldiers.[7] During Operation Iraqi Freedom, 6 soldiers died from heat-related causes. There were 30 other cases of heatstroke and many other heat-related casualties. During the period 1997–2002, 8084 soldiers were treated as outpatients for heat injuries.[7] The United States military actively promotes heat illness prevention and exhorts its personnel to not repeat history. In comparison, in 1917, 425 British soldiers on active duty in the area on the Persian Gulf formerly known as Mesopotamia, presently known as Iraq, died of heatstroke during 1 month, and 524 died in 1 year.[302] There were 114 heatstroke deaths among football players from 1960 to 2007. From 1995 to 2007, 33 football players died of heatstroke: 25 high school, 5 college, 2 professional, and 1 sandlot.[211,290]

High ambient temperature is associated with an increase in mortality from cocaine overdose. The mean daily number of deaths from cocaine overdose was 33% higher when the ambient temperature

exceeded 88°F (31°C).[194]

Thermoregulation and Heat Stress The normal thermoregulatory response to heat stress is mediated primarily by heat-sensitive neurons in the hypothalamus. Increased body core temperature results in active dilation of cutaneous vessels and skin blood flow increases.[131,252] Because increased skin blood flow is attained primarily by an increase in heart rate and stroke volume, the capacity to increase cardiac output is critical to cooling. Compensatory shifting of blood flow from the splanchnic and renal vessels to the skin further increases skin blood flow.[138,252] The combination of vasodilation, increased skin blood flow, and increased sweating results in heat loss through convection and evaporation. Dehydration after profuse sweating increases plasma osmolarity. Heat-sensitive neurons in the preoptic anterior hypothalamus are inhibited by locally increased osmolarity and by input from distal hepatoportal osmoreceptors. The inhibition of heat sensitive neurons results in decreased heat dissipation response.[56,228]

Types of Heatstroke Heatstroke is commonly divided into 2 types: *exertional* and *nonexertional*. Nonexertional, or classic, heatstroke describes heatstroke occurring in the absence of extreme exertion. Nonexertional heatstroke is most commonly described during heat waves, and the victims are predominantly those persons least able to tolerate heat: infants,[19] the aged,[61] those with psychiatric disorders, and the chronically ill.

Exertional heatstroke occurs as a result of increased motor activity. It may occur in young, healthy individuals who are exercising, or in individuals whose increased motor activity results from other causes, such as seizures or agitation. Often a period of significant heat stress in exercising individuals precedes the development of heatstroke. Military recruits who develop heatstroke may sometimes present to the camp infirmary with vague complaints prior to collapse.[270] Published studies of heatstroke in miners, athletes, and military recruits describe several precipitating factors in heatstroke: fatigue associated with a recent deficit in sleep; poor physical conditioning; a recent febrile illness; recent heat-related symptoms such as thirst or weakness; relative volume depletion; failure to allow for acclimatization; and obesity. Symptoms of nausea, weakness, headache, diarrhea, or irritability often precede the development of heatstroke. Although rapid onset of symptoms and acute loss of consciousness are frequently reported in exertional heatstroke, the preceding period of heat stress and insidious symptoms may go unrecognized. Although exertional heatstroke is more likely to occur during intense exertion in a hot, humid environment, it may also occur with moderately intense exercise early in the morning, when environmental conditions do not usually represent a thermoregulatory stress.[16]

Differential Diagnosis of Hyperthermia In addition to exposure and exertion, conditions that predispose to severe hyperthermia include primary hypothalamic lesions; intracranial hemorrhage; agitation; alcohol and sedative-hypnotic withdrawal; seizures; and the use of therapeutic and illicit xenobiotics (Table 15–5).[107,112–114,171,195,282] Included in the differential diagnosis of severe hyperthermia are the serotonin syndrome, malignant hyperthermia, and the neuroleptic malignant syndrome, all of which may result in high temperature, altered mental status, and increased muscle tone.

Serotonin Syndrome The serotonin syndrome results from excess stimulation of the serotonin receptor, primarily the 5-HT$_{1A}$ subtype.[279] Drug interactions are most commonly the cause of the syndrome. Monoamine oxidase inhibitors used in conjunction with tricyclic antidepressants,[21] selective serotonin reuptake inhibitors,[91] L-tryptophan,[91,283] meperidine,[124] dextromethorphan,[246] amphetamines,[171] and sumatriptan are reported to lead to serotonergic hyperstimulation and severe symptoms.[108,279] The clinical condition

    Xenobiotics

resulting from excess serotonin includes alterations in consciousness, restlessness, increased muscle tone, tremor, gastrointestinal disturbances, and hyperthermia. Treatment of the syndrome focuses on control of hyperthermia by using aggressive cooling, muscle relaxation primarily by using benzodiazepines, or, in severe cases, endotracheal intubation and paralysis (Chap. 72).

Malignant Hyperthermia Malignant hyperthermia is a very rare disorder that is associated with a congenital disturbance of calcium regulation in striated muscle. Malignant hyperthermia was first reported in 1960. Ten deaths occurred in a single family following general anesthesia.[77] Exposure to anesthetics, depolarizing muscle relaxants, or, rarely, severe exertion precipitates uncontrolled calcium influx into the sarcoplasmic reticulum, leading to severe muscle rigidity and hyperthermia.[116,144] The clinical setting of severe muscle rigidity and hyperthermia following general anesthesia usually is adequate to define the syndrome (Chap. 68).

Neuroleptic Malignant Syndrome Neuroleptic malignant syndrome, a severe extrapyramidal syndrome associated with muscle rigidity, autonomic dysfunction, and altered mental status, was first described in 1968.[74] This disorder develops during the administration of antipsychotics or the withdrawal of dopaminergic xenobiotics. Increased muscle tone, due to dopaminergic blockade of the striatum, as well as central altered hypothalamic thermoregulation lead to hyperthermia.[129] Temperature elevation and alteration of mental status occur after the onset of "lead pipe" muscle rigidity.[27,120] Laboratory findings are not specific and include marked elevation of creatine phosphokinase (CPK) in some patients and leukocytosis with a left shift. Neuroleptic malignant syndrome must be distinguished from the much more common cases of heatstroke in psychiatric patients that are caused by heat intolerance resulting from the anticholinergic effects of antipsychotics or antihistamines prescribed to control extrapyramidal symptoms (Chap. 69).[257,310]

Inflammatory Mediators in Heatstroke The response to heat stress is a coordinated interplay between the mediators of inflammation, including endothelial cells, leukocytes, inflammatory cytokines, and endotoxins. These are important mediators of the systemic immune response. However, in heatstroke they are responsible for systemic inflammation and activation of the coagulation cascade, similar to the sepsis syndrome. Many proinflammatory cytokines are identified in heatstroke, including tumor necrosis factor; interleukin-2, -6, -8, -10, and -12; interferon-α and -β; and granulocyte colony–stimulating factors.[33] In a study of 18 heatstroke patients, circulating cytokine levels correlated with clinical indices of heatstroke severity.[140] Cooling delays the release of interleukin-1B, interleukin-6, and tumor necrosis factor in vitro.[161] Studies in hyperthermic animals focus on the modulation of the mediators of inflammation as possible future adjuncts to cooling. For example, in one report, an interleukin-1 receptor antagonist improved survival.[269] In another, recombinant human activated protein C provided cytoprotection by decreasing release of inflammatory cytokines, but did not improve survival.[35] Whole body cooling restored appropriate levels of cardiac tissue protein associated with loss of structural integrity of the cardiac myocytes, and reversed cardiac dysfunction.[53]

Heat stress causes increased gene transcription of heat shock proteins which render the organism more resistant to heat injury, protecting cells from injury and increasing cell survival. Heat shock protein 72 is protective against injury from heat stress, and the extent of protection correlates with the level of heat shock protein.[188]

During exercise, splanchnic hypoperfusion increases the translocation of bacteria from the gut into the bloodstream, establishing the cascade of inflammation and injury that perpetuate tissue injury after normothermia is established.[89]

Pathophysiologic Characteristics of Heatstroke Hypotension and tachycardia in heatstroke are caused by a number of factors. The patient with heatstroke may have a reduced plasma volume secondary to dehydration. There is peripheral pooling of blood associated with an increase in cutaneous blood flow from 0.5 L/min to 7–8 L/min.[138,252] In addition, patients may manifest primary myocardial insufficiency.[162]

Clinically, patients exhibit either a hypodynamic or hyperdynamic circulatory response. The observed circulatory response to heat stress is a function of the patient's cardiac reserve, volume status, and degree of myocardial heat injury. The hyperdynamic condition is characterized by increased cardiac index and decreased systemic vascular resistance.[225] These hemodynamic characteristics occur in patients who are able to maintain a significantly increased cardiac output in response to the circulatory demand of heat stress.

Salt and water depleted patients, or those patients with primary myocardial insufficiency, may exhibit a hypodynamic response. These patients have a decreased cardiac index and increased systemic vascular resistance.[225,278] Whether pulmonary vascular resistance is affected is unclear. High central venous pressures (CVPs) have been found in some patients, with evidence of right heart failure and right heart dilation on autopsy.[192] These findings have led to the suggestion that pulmonary vascular resistance may be elevated.[225] In 22 of 34 patients with heatstroke, CVPs were greater than 3 cm H_2O. Twelve patients had a CVP of 0, and 10 had a CVP that exceeded 10 cm H_2O. These authors cautioned against injudicious infusion of large quantities of intravenous fluids that can result in complications of congestive heart failure and fluid overload. In the study, only 3 patients required more than 2 L of 0.9% sodium chloride solution during cooling. Crystalloid infusion ranged from 500 to 2500 mL, and none of the patients developed problems associated with fluid overload.[267]

A study of compromised elderly patients with heatstroke, using pulmonary artery catheters, showed that pulmonary vascular resistance was low or normal. Pulmonary capillary wedge pressures were not elevated.[277] A study of 13 cases of heatstroke in pilgrims to Mecca, Saudia Arabia, monitored with pulmonary artery catheters, demonstrated a good correlation of CVP with pulmonary capillary wedge pressures.[3] Serial electrocardiograms in 51 of these pilgrims suffering from heatstroke showed normal sinus rhythm in 25%, sinus tachycardia in 52%, atrial fibrillation in 16%, and sinus bradycardia in 6%. ST segment depression and other ST-T wave changes were reported. The QT interval showed no abnormality.[4] ST changes suggestive of acute coronary syndrome may occur and normal coronary arteries are noted upon coronary catherization.[212] In some patients, echocardiography showed pericardial effusions and regional wall motion abnormalities, asymmetric septal hypertrophy, right ventricular dilation, and left ventricular dilation with impaired function.[4]

Autopsy studies of the heart demonstrate right heart dilation, pericardial effusions, interstitial edema, degeneration and necrosis of myocardial fibers, and subendocardial hemorrhages.[156,192] Postmortem examination of the lungs revealed vascular congestion, pleural effusions, and parenchymal hemorrhages.[192,225]

Gastrointestinal hemorrhage, vomiting, and diarrhea occur frequently.[270] At autopsy, edema and hemorrhage of the bowel wall are demonstrated.[52] These changes may be partly a result of the regional ischemia of splanchnic blood vessels and resultant hypoperfusion and hypoxia. Increased bowel wall edema and bleeding predispose to the release of bacteria into the bloodstream from the gut, causing focal microvascular changes in the intestinal villi, leading to bowel wall anoxia and further injury.[86] Liver injury occurs commonly and is not clinically manifest until the second or third day following the temperature increase.[155,270] Centrilobular changes, such as widening of central veins and adjacent sinusoids and pooling of blood, and varying degrees of hepatocellular degeneration are demonstrated on liver biopsy. Repeat biopsies demonstrated that these changes resolve as the patient recovers.[155] In other cases, only congestion and fatty infiltration are reported.[52]

Neuropsychiatric impairment is, by definition, present in all cases of heatstroke. Duration of altered consciousness correlates significantly with mortality.[18,270] Autopsy studies demonstrate a variety of structural

and microscopic CNS injuries. Edema and venous congestion are evident. The number of cortical neurons is reduced, with concomitant glial proliferation. Cerebellar Purkinje cell deterioration is marked. The hypothalamus appears to be relatively spared, with limited edema of the neuronal nuclei. Hemorrhages occur throughout the brain.[52,192,270] Carotid artery vasoconstriction occurs in response to heating, in an in vitro model using the carotid arteries of rabbits as a possible mechanism of ischemia and injury in heatstroke.[216] Heatstroke-induced cerebral ischemia is associated with increased glutamate release, activation of cerebral dopaminergic neurons causing dopamine overload, and gliosis. These changes are attenuated by induction of hypothermia in an animal model.[55]

Reports of brain MRIs of patients recovering from heatstroke describe radiographic findings, including hemorrhagic and ischemic abnormalities of the cerebrum and cerebellum, delayed cerebellar atrophy, central pontine myelinolysis, vascular infarcts, and medial thalamic lesions, which correspond anatomically to the paraventricular nucleus.[26,200,201] The paraventricular nucleus is involved with core temperature regulation via the hypothalamic—pituitary—adrenal axis.[25] The clinical symptoms of dysphagia, quadriparesis, wasting extrapyramidal syndrome, and pancerebellar syndrome have corresponding MRI findings.[5] Persistent cerebellar dysfunction occurs, as does lower motor neuron damage, manifested by areflexia and muscle wasting.[75,179] Abnormal nerve conduction studies are documented.[149] Higher cortical functions may be spared in survivors, or may be reversible when they occur.[89,182,203] Permanent neurologic sequelae are correlated with the degree and duration of hyperthermia.

Acute renal failure was the major cause of death in heatstroke victims before the advent of hemodialysis.[262,295] In addition to the direct effects of heat, volume depletion, and hypotension, myoglobinuria secondary to rhabdomyolysis results in further renal tubular injury. This is especially common in the agitated or exercising patient.[59,107,237] The mechanism by which myoglobin contributes to renal failure remains controversial. At autopsy the kidneys are enlarged, with extensive petechial hemorrhage.[192] Acute tubular necrosis is seen on biopsy. In exertional heatstroke with acute renal failure, renal hemodynamics are compromised because of increased vasoconstrictive hormones, such as catecholamines, renin, aldosterone, and endothelin-1, and decreased vasodilatory hormones, such as prostaglandin E_2.[184]

Bleeding is associated with significant morbidity and mortality in many cases of heatstroke. Coagulation disturbances seen in patients with heatstroke appear to be multifactorial. Elevation of the prothrombin time may occur within 30 minutes of temperature elevation and is attributed to direct heat injury of clotting factors.[21] Liver damage may significantly contribute to the coagulation disturbances, although this does not manifest as rapidly.[21,40,217] Two patients with severe liver failure secondary to heatstroke received liver transplantation; both died after chronic rejection.[254] A third patient with extensive liver cell necrosis as a consequence of heatstroke was referred for consideration of liver transplantation, but recovered completely with supportive therapy.[104] Evidence of diffuse capillary basement membrane injury has been demonstrated by electron microscopy and is thought to precipitate consumptive coagulopathy in severe cases of heatstroke.[52,274] Thrombocytopenia is very common and occurs within 30 minutes of onset of heatstroke, frequently in the absence of other evidence of disseminated intravascular coagulation. Direct thermal injury leading to decreased platelet survival and megakaryocyte damage may play a role (Table 15–6).[192,217]

Clinical Evolution in Heatstroke Clinical evaluation of the hyperthermic patient begins with careful assessment of the vital signs. Vital sign abnormalities commonly include tachycardia with heart rates greater than 130 beats per minute, hypotension, and tachypnea with the respiratory

---

TABLE 15–6. Physiologic and Clinical Manifestations of Heatstroke

Cardiovascular
Hypodynamic states in elderly
Hyperdynamic states in young healthy individuals
Electrocardiogram
  Nonspecific
  Widening of QRS because of an underlying abnormality (cocaine toxicity, hyperkalemia associated with rhabdomyolysis)

Central nervous system
Altered mental status
  Irritability, confusion, ataxia, seizures, coma
  Weakness, dizziness, headache
  Plantar extension, pupillary abnormalities, decorticate posturing
EEG
  Normal or diffuse slowing
CSF
  Normal or increased protein
  Lymphocytosis

Gastrointestinal
Vomiting, diarrhea, hematemesis

Hematologic
Bleeding diathesis
  Prolonged PT and PTT
  Disseminated intravascular coagulation
  Thrombocytopenia
  Petechiae
  Purpura
Leukocytosis

Hepatic
Hepatic insufficiency at 12–36 h
Elevated AST, ALT, LDH

Metabolic
Metabolic acidosis and respiratory alkalosis
Electrolyte disturbance
  Hypernatremia
  Hyponatremia
  Hypokalemia
  Hypocalcemia
  Hypophosphatemia

Muscle
Rhabdomyolysis
Elevated CPK

Renal
Decreased renal perfusion
Myoglobinuria
Proteinuria
Oliguria
Acute tubular necrosis
Interstitial necrosis

rates often above 30 breaths per minute. Most importantly, temperature is elevated. After cooling, there is often a secondary rise in temperature that suggests persistent disturbances of thermoregulation.[192]

Neurologic examination reveals a delirious, comatose, or seizing patient. Pupils may be normal, fixed and dilated, or pinpoint. Decerebrate or decorticate posturing may be evident. Muscle tone is increased, normal, or flaccid. The skin may be hot and dry or diaphoretic. Nasal and oropharyngeal bleeding may be present as a consequence of the acute coagulopathy. Examination of the lungs is often nonspecific, although heatstroke victims are at risk of pulmonary edema as a primary event associated with capillary endothelial damage or following overly aggressive fluid resuscitation. Cardiac auscultation may reveal a flow murmur secondary to high cardiac output or a right ventricular gallop. Neck vein distension indicates increased CVP. Jaundice suggests hepatic injury and occurs on the second or third day following the onset of heatstroke.[54] Nasogastric aspiration or rectal examination may demonstrate gross bleeding. A petechial rash develops, probably secondary to capillary endothelial damage.

Laboratory Findings of Heatstroke Lactic acid dehydrogenase (LDH) rises as a consequence of diffuse tissue injury. Early rises in alanine aminotransferase (ALT) and aspartate aminotransferase (AST), which peak at 48 hours, are indicators of the liver damage that occurs during heatstroke.[155] Muscle enzymes were elevated in all patients in a study of exertional heatstroke,[270] and in 86% of patients in one study of nonexertional heatstroke.[108] Nonspecific ST-wave and T-wave changes on ECG are common. Myocardial enzyme elevation occurs and correlates with ECG changes.[156] Results of lumbar puncture are nonspecific, are often normal, or may demonstrate elevated cerebrospinal fluid (CSF) protein and lymphocytosis.[270]

Other laboratory parameters are affected by heatstroke. Salt and water depletion leads to hemoconcentration in patients exposed to elevated temperatures for a period of time. Hypokalemia is common, with potassium deficits as great as 500 mEq occurring during the early period of heat exposure. Arterial blood gas analysis may show a respiratory alkalosis secondary to direct stimulation of the respiratory center by heat, or a metabolic acidosis with elevated lactate.[66,278] Metabolic acidosis is the most frequent acid–base disturbance, either alone or part of a mixed picture. The prevalence of metabolic acidosis correlates with the degree of hyperthermia; 95% of patients demonstrated metabolic acidosis when the body temperature exceeded 107.6°F (42°C).[33]

Hypophosphatemia is common and is attributed to respiratory alkalosis, which causes intracellular shifts of phosphate. However, 8 of 10 heatstroke patients developed hypophosphatemia and none were alkalemic.[31] The hypophosphatemia in these cases was associated with increased phosphaturia and decreased tubular reabsorption of phosphorus, a finding that reversed after cooling.[165] Renal tubular damage may also lead to phosphate depletion.[118] Phosphate and potassium are elevated when significant muscle injury has occurred. Calcium is normal or low, the latter secondary to binding to damaged muscle tissue. Later, hypercalcemia occurs, possibly as a result of release of this bound calcium.[100,186]

Significant alterations occur in lymphocyte subsets in heatstroke victims. One study reported an increased ratio of T-suppressor to T-cytotoxic cells, as well as increased natural killer cells. There was a significant decrease in the percentages of T and B cells and T-helper cells. These changes correlate with the degree of hyperthermia.[32,35,247] Catecholamines are increased in heatstroke,[2] and may affect the distribution of the lymphocyte subsets.[32] It is possible that the increased susceptibility to infection described in heatstroke and the alterations in lymphocyte populations are related.[32]

Effects of Xenobiotics in Heatstroke Xenobiotics predispose the individual to heatstroke by 2 primary mechanisms: increased production

of heat as a result of xenobiotic action and interference with the body's ability to dissipate heat because of pharmacologic or toxicologic effects on thermoregulatory centers (see Table 15–5). Xenobiotic interactions may cause life-threatening increases in temperature, such as the combination of monoamine oxidase inhibitors with meperidine or dextromethorphan resulting in the serotonin syndrome. The uncoupling of oxidative phosphorylation by salicylate, pentachlorophenol, or dinitrophenol leads to the release of metabolic energy as heat, rather than trapping that energy in the form of high energy phosphate bonds in ATP. Sympathomimetics may increase heat production by increasing physical activity.

During heat stress, vasodilation leads to increased cutaneous blood flow, resulting in an increased cardiac output. Parasympathetic stimulation results in increased sweating. Xenobiotics that impair these physiologic mechanisms for heat dissipation predispose the individual to heatstroke. Xenobiotics with anticholinergic effects, such as antihistamines, cyclic antidepressants, and antipsychotics interfere with sweating. Heatstroke as a result of oligohydrosis is reported for zonisamide[166,232] and topiramate.[14,221] The mechanism is postulated to concern the inhibition of carbonic anhydrase, an enzyme associated with eccrine sweat gland function.[38,78] Sympathomimetics stimulate β-adrenergic receptors, impairing vasodilation. Antihypertensives and antianginals (most notably calcium channel blockers and β-adrenergic antagonists) with negative inotropic and chronotropic effects impair the ability of the heart to meet the output requirements of increased skin blood flow. Diuretic-induced volume depletion also limits cardiac output. Antipsychotics cause hypothalamic depression, altering the normal CNS response to heat stress. Finally, xenobiotics such as ethanol, opioids, and sedative-hypnotics impair normal behavioral responses, and heat-related discomfort may go unnoticed.[292]

Heatstroke and Subsequent Heat Intolerance Whether heatstroke victims are subsequently unable to adapt to exercise in a hot environment remains unclear. Is the heatstroke victim genetically predisposed to heat intolerance, or does heatstroke occur as a result of environmental and host factors? Several studies suggest that heatstroke leads to persistent heat intolerance. These studies often use a single heat intolerance test.[87,268,271,272] A study of 10 previous heatstroke victims showed no difference in acclimatization responses, thermoregulation, whole body sodium and potassium balance, sweat gland function, and blood values when compared with controls.[16] The rate of recovery from exertional heatstroke probably differs among individuals. In this study, 1 of 10 patients was found to have recurrent heat intolerance 12 months after the study.[16] Resolution of heat intolerance was delayed for 5 months in an individual who had experienced heatstroke twice.[154]

Treatment of Heatstroke Management must focus on the early recognition of hyperthermia. Body temperatures >106°F (>41.1°C) place the patient at great risk for end organ injury. Rapid cooling is the first priority, and is associated with improved outcomes. Cooling that is delayed allowing body temperatures to remain above 102.2°F (38.9°C) for more than 30 minutes is associated with a high morbidity and mortality. In one report of the Chicago heat wave of 1995, only 1 patient of 58 victims was cooled within 30 minutes, resulting in an in-hospital mortality of 21% and an additional 28% mortality within 1 year.[76] Cooling by covering in ice water was twice as rapid in lowering the core temperature as was cooling by using evaporative spray.[17] Ice water immersion results in faster cooling when compared with all of the evaporative cooling methods in some studies.[65,94,101] A recent report of endovascular cooling using a heat exchange balloon catheter demonstrated dangerously lengthy cooling times and inadequate cooling measures.[202]

Successful treatment requires adequate preparation. Equipment needed for rapid cooling should always be readily available in the emergency department, and includes fans, ice, and tubs for submersion. En route to the hospital, the patient's clothes should be removed and the patient should be covered with ice, if available, and water-soaked sheets. Respiration and cardiovascular status should be stabilized and monitored. Oxygen should be administered. The cause of the heatstroke should be determined and appropriate measures initiated immediately. Xenobiotics, such as antihistamines, butyrophenones, and phenothiazines, and physical restraints that interfere with heat dissipation, such as camisoles and strait jackets, should not be used.[114] Light hand and foot restraints should be used to protect the patient from self-harm. If light restraints are used, the patient should be monitored continuously. The patient who is hyperthermic in the setting of ethanol or sedative-hypnotic withdrawal should be treated with a benzodiazepine.[113] The patient should never be confined to a small, unventilated seclusion room. Adequate cooling, hydration, sedation, and electrolytes and substrate repletion should be ensured.[111]

In the emergency department, appropriate laboratory studies should be performed and an IV line inserted. Administration of 100 mg of thiamine should be considered. A rectal probe should be placed for continuous temperature monitoring. The patient should be immersed in an ice bath with a fan blowing over the patient if possible. In addition to the ice bath, iced gastric lavage may be effective.

Agitation, seizures, and cardiac dysrhythmias must be managed while cooling is accomplished. Benzodiazepines are the treatment of choice for agitation and seizures. Heatstroke patients may have significant volume needs, depending on the amount of fluid lost prior to the onset of heatstroke. Hypotension should be treated with fluids and cooling. Volume repletion should be monitored carefully by parameters such as blood pressure, pulse, CVP, pulmonary wedge pressure, and urine output. As the temperature returns to normal, the hypotension may resolve if significant volume deficits are not present.[58,162,163] In patients with myoglobinuria, an attempt should be made to increase renal blood flow and urine output. The use of sodium bicarbonate and mannitol in the prevention of acute tubular necrosis in these cases is controversial.[29,86,100,251]

Phenothiazines and butyrophenones should not be used as they may depress an already altered mental status, may produce hepatotoxicity in a compromised liver, lower the seizure threshold,[29,113,114] cause acute dystonic reactions, exacerbate hypotension, and interfere with thermoregulation and cooling by affecting the hypothalamus. However, although phenothiazines and butyrophenones may theoretically reduce shivering and the possibility of rebound hyperthermia, their onset of action is slow.[226] When shivering occurs during cooling, we recommend the judicious use of a benzodiazepine. In addition, benzodiazepines treat ethanol and sedative-hypnotic withdrawal and cocaine intoxication, common causes of hyperthermia.

There is no role for antipyretics in the management of heatstroke. Aspirin and acetaminophen lower temperature by reducing the hypothalamic set point, which is only altered in a patient febrile from inflammation or endogenous pyrogens.[77,131] Heatstroke, however, occurs when cooling mechanisms are overwhelmed, and the hypothalamic thermoregulatory set point is not disturbed.[23]

Dantrolene sodium is the preferred drug in the treatment of malignant hyperthermia (see Antidotes in Depth A22: Dantrolene Sodium).[144,297] It acts directly on skeletal muscle and either inhibits the release of calcium or increases calcium uptake through the sarcoplasmic reticulum.[39] Its usefulness has not been demonstrated in other conditions associated with hyperthermia, and there is no evidence to support its administration for other conditions.[8] In a prospective, randomized, double-blind, placebo-controlled study of 52 patients with heatstroke, IV dantrolene sodium at 2 mg/kg of body weight did not alter cooling

time.[30] There was no significant difference in the mean number of hospital days necessitated by heatstroke victims who received dantrolene and cooling versus those who received cooling alone. Dantrolene may influence central dopaminergic metabolism in patients with neuroleptic malignant syndrome by affecting calcium-triggered neurotransmitter release in the CNS; however, further study is required.[223] Anecdotal reports of the efficacy of dopamine agonists such as bromocriptine and amantadine have appeared in descriptions of neuroleptic malignant syndrome.[198] No drug therapy should delay the institution of aggressive external cooling (Table 15–7).

SUMMARY

The thermoregulatory processes responsible for the maintenance of normothermia are complex. Xenobiotics may disturb normal thermoregulation and result in the abnormal conditions of hyperthermia or hypothermia. These disturbances of homeostasis present significant clinical management challenges. Although greater understanding is gained through research and thoughtful analysis, hypothermia and heatstroke are largely preventable conditions and emphasis must be placed on prevention. During heat waves, many socioeconomically disadvantaged and elderly individuals are affected, and it is essential that cities be prepared and that the public be aware of the dangers of heat waves. Similarly, hypothermia is preventable by prudent preparation for harsh environmental conditions, and by policies that provide for shelter for those at greatest risk—the poor, the homeless, and those with underlying medical and psychiatric illnesses.

TABLE 15–7. Management of Heatstroke

Preparation
Ice and cooling fans available in emergency department
Monitor weather reports
Alert media

On Arrival
Rapid cooling
    Clear airway and administer oxygen
    Cover with ice and water-soaked sheets
    Stabilize respiratory and cardiovascular status
    Cool as rapidly as possible
Intravenous access
    0.9% NaCl based on CVP or pulmonary artery catheter
    Dextrose 0.5–1.0 g/kg, and thiamine 100 mg if indicated
    Benzodiazepines for agitation, shivering, seizures
Continuous monitoring
    Remove from ice bath at 101°F (38.3°C)
    Watch for rebound hyperthermia
Cautions
    Antipsychotics may have serious adverse effects
    Antipyretics do not work
    Cooling blankets alone are inadequate

CHAPTER 16
FLUID, ELECTROLYTE, AND ACID–BASE PRINCIPLES

Alan N. Charney and Robert S. Hoffman

A meaningful analysis of fluid, electrolyte, and acid–base abnormalities must be based on the clinical characteristics of each patient. Although a rigorous appraisal of laboratory parameters often yields the correct differential diagnosis, it is the history and physical examination that provides an understanding of the extracellular fluid volume (ECFV) and pathophysiology, and as well as development of the appropriate treatment strategy. Thus, the evaluation always begins with an overall assessment of the patient's status.

INITIAL PATIENT ASSESSMENT

■ HISTORY

The history should be directed toward clinical questions associated with fluid and electrolyte abnormalities. Xenobiotic exposure commonly results in fluid losses through the respiratory system (hyperpnea and tachypnea), gastrointestinal tract (vomiting and diarrhea), skin (diaphoresis), and kidneys (polyuria). Patients with ECFV depletion may complain of dizziness, thirst, and weakness. Usually the patients can identify the source of fluid loss.

A history of exposures to nonprescription and prescription medications, alternative or complementary therapies, and other xenobiotics may suggest the most likely electrolyte or acid–base abnormality. In addition, premorbid conditions and the ambient temperature and humidity should always be considered.

■ PHYSICAL EXAMINATION

The vital signs are invariably affected by significant alterations in ECFV. Whereas hypotension and tachycardia may characterize life-threatening ECFV depletion, an initial finding may be an increase of the heart rate and a narrowing of the pulse pressure. Abnormalities may be recognized through an ongoing dynamic evaluation, realizing that the measurement of a single set of supine vital signs offers useful information only when markedly abnormal. Orthostatic pulse and blood pressure measurements provide a more meaningful determination of functional ECFV status (Chaps. 3 and 23).

The respiratory rate and pattern can give clues to the patient's metabolic status. Hyperventilation (manifested by tachypnea, hyperpnea, or both) may be caused by a primary respiratory stimulus (respiratory alkalosis) or may be a response to the presence of metabolic acidosis. Although hypoventilation (bradypnea or hypopnea or both) is present in patients with metabolic alkalosis, it is rarely clinically significant except in the presence of chronic lung disease. More commonly, hypoventilation is associated with a primary depression of consciousness and respiration, and respiratory acidosis. Unless the clinical scenario (ie, nature of the overdose or poisoning, presence of renal or pulmonary disease, findings on physical examination or laboratory testing) is diagnostic, arterial blood gas analysis is required to determine the acid–base disorder associated with a change in ventilation.

The skin should be evaluated for turgor, moisture, and the presence or absence of edema. The moisture of the mucous membranes can also provide valuable information. These are nonspecific parameters and may not correlate directly with the status of hydration. This dissociation is especially true with xenobiotic exposure, as many xenobiotics alter skin and mucous membrane moisture without necessarily altering ECFV status. For example, antimuscarinics and anticholinergics commonly result in dry mucous membranes and skin without producing ECFV depletion. Conversely, patients exposed to sympathomimetics (eg, cocaine) or cholinergics (eg, organic phosphorus insecticides) may have moist skin and mucous membranes even in the presence of significant fluid losses. This dissociation of ECFV and cutaneous characteristics reinforces the need to assess patients meticulously.

The physical findings associated with electrolyte abnormalities also are nonspecific. Hyponatremia, hypernatremia, hypercalcemia, and hypermagnesemia all may produce a depressed mental status. Neuromuscular excitability such as tremor and hyperreflexia may occur with hypocalcemia, hypomagnesemia, hyponatremia, and hyperkalemia. Weakness may be caused by either hyperkalemia or hypokalemia. Also, multiple, concurrent electrolyte disorders can produce confusing clinical presentations, or patients may appear normal. Rarer diagnostic findings, such as Chvostek and Trousseau signs (primarily found in hypocalcemia), may be useful in assessing patients with potential xenobiotic exposures.

■ RAPID DIAGNOSTIC TOOLS

The electrocardiogram (ECG) is a useful tool for screening of several common electrolyte abnormalities (Chap. 22). It is easy to perform, rapid, inexpensive, and routinely available. Unfortunately, because poor sensitivity (0.43) and moderate specificity (0.86) were demonstrated when ECGs were used to diagnose hyperkalemia, in actuality, the test is of limited diagnostic value.[168] However, the ECG is valuable for the evaluation of changes in serum potassium and calcium concentrations ($[K^+]$ and $[Ca^{2+}]$) in a single patient.

In many patients, bedside assessment of urine specific gravity by dipstick analysis may provide valuable information about ECFV status. A high urine specific gravity (>1.015) signifies concentrated urine and is often associated with ECFV depletion. However, urine specific gravity may be similarly elevated in states of ECFV excess, such as congestive heart failure or third spacing. Furthermore, when renal impairment is the source of the volume loss, the specific gravity is usually approximately 1.010 (known as isosthenuria). Patients with lithium-induced diabetes insipidus excrete dilute urine (specific gravity <1.010) despite ongoing water losses, and patients with methylenedioxymethamphetamine (MDMA)-induced antidiuretic hormone secretion excrete concentrated urine (specific gravity >1.015) in the presence of a normal to expanded ECFV.

The urine dipstick is particularly useful for rapidly determining the presence of ketones, which are often associated with common causes of metabolic acidosis (eg, diabetic ketoacidosis, salicylate poisoning, alcoholic ketoacidosis). The urine ferric chloride test rapidly detects exposure to salicylates with a high sensitivity and specificity (Chap. 35).

■ LABORATORY STUDIES

A simultaneous determination of the venous serum electrolytes, blood urea nitrogen (BUN), and glucose, and arterial or venous blood gases is adequate to determine the nature of the most common acid–base, fluid, and electrolyte abnormalities. More complex clinical problems may require determinations of urine and serum osmolalities, urine electrolytes, serum ketones, serum lactate, and other tests. A systematic approach to common problems is discussed in the following sections.

ACID–BASE ABNORMALITIES

■ DEFINITIONS

The terminology of acid–base disorders often leads to confusion and error. The following definitions provide the appropriate frame of reference for the remainder of the chapter.

The terms *acidosis* and *alkalosis* refer to processes that tend to change pH in a given direction. By definition a patient is said to have:

• A *metabolic acidosis* if the arterial pH is <7.40 and serum bicarbonate concentration ($[HCO_3^-]$) is <24 mEq/L. Because acidemia stimulates ventilation (respiratory compensation), metabolic acidosis is usually accompanied by a PCO_2 <40 mm Hg.

• A *metabolic alkalosis* if the arterial pH is >7.40 and serum $[HCO_3^-]$ is >24 mEq/L. Because alkalemia inhibits ventilation (respiratory compensation), metabolic alkalosis is usually accompanied by a PCO_2 >40 mm Hg.

• A *respiratory acidosis* if the arterial pH is <7.40 and partial pressure of carbon dioxide (PCO_2) is >40 mm Hg. Because an elevated PCO_2 stimulates renal acid excretion and the generation of HCO_3^- (renal compensation), respiratory acidosis is usually accompanied by a serum $[HCO_3^-]$ >24 mEq/L.

• A *respiratory alkalosis* if the arterial pH is >7.40 and PCO_2 is <40 mm Hg. Because a decreased PCO_2 decreases renal net acid excretion and increases the excretion of HCO_3^- (renal compensation), respiratory alkalosis is usually accompanied by a serum $[HCO_3^-]$ <24 mEq/L.

It is important to note that under most circumstances a venous pH permits an approximation of arterial pH (see Chap. 21 for a further discussion of the relationship between arterial and venous pH). Any combination of acidoses and alkaloses can be present in any one patient at any given time. The terms *acidemia* and *alkalemia* refer only to the resultant arterial pH of blood (acidemia referring to a pH <7.40 and alkalemia referring to a pH >7.40). These terms do not describe the processes that led to the alteration in pH. Thus, a patient with acidemia must have a primary metabolic and/or respiratory acidosis, but may have an alkalosis present at the same time. Clues to the presence of more than one acid–base abnormality include the clinical presentation, an apparent excess or insufficient "compensation" for the primary acid–base abnormality, a delta (Δ) anion gap-to-Δ $[HCO_3^-]$ ratio that significantly deviates from 1, and/or an electrolyte abnormality that is uncharacteristic of the primary acid–base disorder.

■ DETERMINING THE PRIMARY ACID–BASE ABNORMALITY

It is helpful to begin by determining whether the patient is acidemic or alkalemic. This is followed by an assessment of the pH, PCO_2, and the $[HCO_3^-]$. With these three parameters defined, the patient's primary acid–base disorder can be classified using the aforementioned definitions. Next it is important to determine whether the compensation of the primary acid–base disorder is appropriate. It is generally assumed that overcompensation cannot occur.[118] That is, if the primary process is metabolic acidosis, respiratory compensation tends to raise the pH toward normal, but never to >7.40. If the primary process is respiratory alkalosis, compensatory renal excretion of HCO_3^- tends to lower the pH toward normal, but not to <7.40. The same is true for primary metabolic alkalosis and primary respiratory acidosis. As a rule, compensation for a primary acid–base disorder that is inadequate or excessive suggests the presence of a second primary acid–base disorder.

Based on patient data, the Winters equation[7] predicts the degree of the respiratory compensation (the decrease in PCO_2) in metabolic acidosis as follows:

$$PCO_2 = (1.5 \times [HCO_3^-]) + 8 \pm 2 \qquad \text{(Eq. 16–1)}$$

Thus, in a patient with an arterial $[HCO_3^-]$ of 12 mEq/L, the predicted PCO_2 may be calculated as:

$$(1.5 \times 12) + 8 \pm 2$$

or

$$26 \pm 2 \text{ mm Hg}$$

If the actual PCO_2 is substantially lower than is predicted by the Winters equation, it can be concluded that both a primary metabolic acidosis and a primary respiratory alkalosis are present. If the PCO_2 is substantially higher than the predicted value, then both a primary metabolic acidosis and a primary respiratory acidosis are present.

An alternative to the Winters equation is the observation by Narins and Emmett that in compensated metabolic acidosis, the arterial PCO_2 is usually the same as the last two digits of the arterial pH.[117] For example, a pH of 7.26 predicts a PCO_2 of 26 mm Hg.

Guidelines are also available to predict the compensation for metabolic alkalosis,[67] respiratory acidosis, and respiratory alkalosis.[88] Patients with a metabolic alkalosis compensate by hypoventilating, resulting in an increase of their PCO_2 above 40 mm Hg. However, the concomitant development of hypoxemia limits this compensation so that respiratory compensation in the presence of a metabolic alkalosis usually results in a $PCO_2 \leq 55$ mm Hg. It is difficult to be more precise about the expected respiratory compensation for a metabolic alkalosis although the compensation, as in the case of metabolic acidosis, is nearly complete within hours of onset.

By contrast, the degree of compensation in primary respiratory disorders depends on the length of time the disorder has been present. In a matter of minutes, primary respiratory acidosis results in an increase in the serum $[HCO_3^-]$ of 0.1 times the increase (Δ) in the PCO_2. This increase is a result of the production and dissociation of H_2CO_3. Over a period of days, respiratory acidosis causes the compensatory renal excretion of acid. This compensation increases the serum $[HCO_3^-]$ by 0.3 times the ΔPCO_2. Primary respiratory alkalosis acutely decreases the serum $[HCO_3^-]$ by 0.2 times the ΔPCO_2. If a respiratory alkalosis persists for several days, renal compensation, by the urinary excretion of HCO_3, decreases the serum $[HCO_3^-]$ by 0.4 times the ΔPCO_2.

■ CALCULATING THE ANION GAP

The concept of the anion gap is said to have arisen from the "Gamblegram" originally described in 1939;[50] however, its use was not popularized until the determination of serum electrolytes became routinely available. The law of electroneutrality states that the net positive and negative charges of all fluids must be equal. Thus, all of the negative charges present in the serum must equal all of the positive charges, and the sum of the positive charges minus the sum of the negative charges must equal zero. The problem that immediately arose (and produced an "anion gap") was that all charged species were not routinely measured.

Normally present but not routinely measured cations consist of calcium and magnesium, whereas normally present but not routinely measured anions consist of phosphate, sulfate, albumin, and organic anions (such as lactate or pyruvate).[39,48,120] Sodium and K^+ normally

account for 95% of extracellular cations, whereas Cl^- and HCO_3^- account for 85% of extracellular anions.[39] Thus, because more cations than anions are among the electrolytes usually measured, subtracting the anions from the cations normally yields a positive number, known as the anion gap. The anion gap is therefore derived as shown in Equation 16–2:

$$[Na^+] + [K^+] + [Unmeasured\ Cations\ (U_c)] = [Cl^-] + [HCO_3^-]$$
$$+ [Unmeasured\ Anions\ (U_a)]$$
$$Anion\ Gap = [U_a] - [U_c]$$

or

$$Anion\ Gap = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-])\ \ (Eq.\ 16–2)$$

Because the serum $[K^+]$ varies over a limited range of perhaps 1–2 mEq/L above and below normal and therefore rarely significantly alters the anion gap, it is often deleted from the equation for simplicity. Most prefer this approach, yielding Equation 16–3:

$$Anion\ Gap = ([Na^+]) - ([Cl^-] + [HCO_3^-])\ \ \ \ \ (Eq.\ 16–3)$$

Using Equation 16–3, the normal anion gap was initially determined to be 12 ± 4 mEq/L.[39,166] However, because the normal serum $[Cl^-]$ is higher on modern laboratory instrumentation, the current range for a normal anion gap is 7 ± 4 mEq/L.[165]

A variety of pathologic conditions may result in a rise or fall of the anion gap. High anion gaps result from increased presence of unmeasured anions or decreased presence of unmeasured cations (Table 16–1).[39,48,99,141] Conversely, a low anion gap results from an increase in unmeasured cations or a decrease in unmeasured anions (Table 16–2).[39,48,62,140,150]

■ ANION GAP RELIABILITY

Several authors have considered the usefulness of the anion gap determination.[20,49,77] When 57 hospitalized patients were studied to determine the cause of elevated anion gaps, in those patients whose anion gap was greater than 30 mEq/L the cause was always lactic

TABLE 16–1. Xenobiotic and Other Causes of a High Anion Gap

Increase in Unmeasured Anions	Decrease in Unmeasured Cations
Metabolic acidosis (see Table 16–3)	Simultaneous hypomagnesemia,
Dehydration	hypocalcemia, and hypokalemia
Therapy with sodium salts of	
unmeasured anions	
Sodium citrate	
Sodium lactate	
Sodium acetate	
Therapy with certain antibiotics	
Carbenicillin	
Sodium penicillin	
Alkalosis	

TABLE 16–2. Xenobiotic and Other Causes of a Low Anion Gap

Increase in Unmeasured Cations	Decrease in Unmeasured Anions	Overestimation of Chloride
Hypercalcemia	Hypoalbuminemia	Bromism
Hypermagnesemia	Dilution	Iodism
Hyperkalemia		Nitrate excess
Lithium poisoning		
Multiple myeloma		

acidosis or ketoacidosis.[49] In patients with smaller elevations of the anion gap, the ability to define the cause of the elevation diminished; in only 14% of patients with anion gaps of 17–19 mEq/L could the etiology be determined. Another study determined that although the anion gap is often used as a screening test for hyper-lactatemia (as a sign of poor perfusion), only those patients with the highest serum lactate concentrations had elevated anion gaps.[77] Finally, in a sample of 571 patients, those with higher anion gaps tended to have increased severity of illness. This resulted in higher admission rates, a greater percentage of admissions to intensive care units, and a higher mortality.[20] Thus, although the absence of an increased anion gap does not exclude significant illness, a very elevated anion gap can generally be attributed to a specific cause (typically lactate or ketones) and usually indicates a relatively severe illness.

■ METABOLIC ACIDOSIS

Once the diagnosis of metabolic acidosis has been made by finding an arterial pH <7.40, a $[HCO_3^-]$ <24 mEq/L, and a PCO_2 <40 mm Hg, the serum anion gap should be analyzed. Indeed, the popularity of the anion gap is primarily based on its usefulness in categorizing metabolic acidosis as being of the high anion gap or normal anion gap type. This determination should be made after correcting the anion gap for the effect of hypoalbuminemia, a common and important confounding factor in such patients. The anion gap decreases approximately 3 mEq/L per 1 g/dL decrease in the serum [albumin].[45] In general the electrolyte abnormalities that frequently accompany metabolic acidosis usually have only small and insignificant effects on the anion gap.

It should be noted that although many clinicians rely on the mnemonic **MUDPILES** to help remember this differential diagnosis (M, methanol; U, uremia; D, diabetic ketoacidosis; P, paraldehyde; I, iron; L, lactic acidosis; E, ethylene glycol; and S, salicylates), this mnemonic includes rarely used drugs (phenfomin, paraldehyde) and omits important others (such as metformin).

A high anion gap metabolic acidosis results from the absorption or generation of an acid that dissociates into an anion other than Cl^- that is neither excreted nor metabolized. The retention of this "unmeasured" anion (eg, lactate in lactic acidosis) increases the anion gap. Normal anion gap metabolic acidosis results from the absorption or generation of an acid that dissociates into H^+ and Cl^-. In this case, the "measured" Cl^- is retained as HCO_3^- is titrated and reduced during the acidosis, and no increased anion gap is produced. Normal anion gap acidosis, also referred to as hyperchloremic metabolic acidosis, may be caused by intestinal or renal bicarbonate losses as in diarrhea or renal tubular acidosis, respectively. Other causes of high and normal anion gap metabolic acidoses are described elsewhere[1] and shown in Tables 16–3 and 16–4.

TABLE 16–3. Xenobiotic and Other Causes of a High Anion Gap Metabolic Acidosis

Carbon monoxide	Metformin
Cyanide	Methanol
Ethylene glycol	Paraldehyde
Hydrogen sulfide	Phenformin
Isoniazid	Propylene glycol
Iron	Salicylates
Ketoacidoses (diabetic,	Sulfur (inorganic)
alcoholic, and starvation)	Theophylline
Lactate	Toluene
	Uremia (acute or chronic renal failure)

■ NARROWING THE DIFFERENTIAL DIAGNOSIS OF A HIGH ANION GAP METABOLIC ACIDOSIS

The ability to diagnose the etiology of a high anion gap metabolic acidosis is an essential skill in clinical medicine. The following discussion provides a rapid and cost-effective approach to the problem. As always, the clinical history and physical examination may provide essential clues to the diagnosis. For example, iron poisoning is virtually always associated with significant gastrointestinal symptoms, the absence of which essentially excludes the diagnosis of this poisoning (Chap. 40). Furthermore, when iron overdose is suspected, an abdominal radiograph may show the presence of tablets. The acidosis associated with isoniazid (INH) toxicity results from seizures, the absence of which excludes INH as the cause of a metabolic acidosis (Chap. 57). Methanol toxicity may be associated with visual complaints or an abnormal funduscopic examination (Chap. 107). Methyl salicylate has a characteristic odor (Chap. 20). When these findings are absent, the laboratory analysis must be relied on, as follows:

1. *Begin with the serum electrolytes and glucose:* A rapid blood glucose reagent test should be performed to help confirm or exclude hyperglycemia. While hyperglycemia should raise the possibility of diabetic ketoacidosis, the absence of an elevated serum glucose does not exclude the possibility of euglycemic diabetic ketoacidosis,[79] or alcoholic or starvation ketoacidosis, which are often associated

with normal or even low serum glucose concentrations. An elevated BUN and creatinine are essential to diagnose acute or chronic renal failure.

2. *Proceed to the urinalysis:* Do not wait for the laboratory results, as all of these urinary studies are easily performed. In addition, if there is a suspicion of a high anion gap metabolic acidosis, and only the arterial or venous blood gas analysis is completed, the evaluation may begin here, while the electrolyte determination is pending. A urine dipstick for glucose and ketones helps with the diagnosis of diabetic ketoacidosis and other ketoacidoses. However, the absence of urinary ketones does not exclude a diagnosis of alcoholic ketoacidosis (Chap. 77), and ketones are often present in severe salicylism (Chap. 35) and biguanide-associated metabolic acidosis (Chap. 48). The urine of a patient who has ingested fluorescein-containing antifreeze (ethylene glycol) may not fluoresce when exposed to a Wood lamp. Also, because ethylene glycol is metabolized to oxalate, calcium oxalate crystals may be present in the urine of a poisoned patient. Although the presence of a fluorescent urine and calcium oxalate crystals are useful findings, their absence does not exclude ethylene glycol poisoning (Chap. 107). When clinically available, a urine ferric chloride test should be performed. Although highly sensitive and specific for the presence of salicylate, this test is not specific for the diagnosis of salicylism, as small amounts of salicylate will be detected in the urine even days after its last use (Chap. 35). Thus, a serum salicylate concentration must be obtained to quantify the findings of a positive ferric chloride test. A negative ferric chloride test essentially excludes a diagnosis of salicylism.

3. An arterial or venous blood lactate concentration can be helpful. In theory, if the lactate (measured in milliequivalents per liter) can entirely account for the fall in serum $[HCO_3^-]$, then the cause of the increased anion gap can be attributed to lactic acidosis. However, it is important to remember that glycolate (a metabolite of ethylene glycol) can produce a significant false positive elevation of the lactate concentration with many current laboratory techniques.[111,127,167]

When the above analysis of a high anion gap metabolic acidosis is unproductive, the diagnosis is usually toxic alcohol ingestion, starvation, alcoholic ketoacidosis (with minimal urine ketones), or a multifactorial process involving small amounts of lactate and other anions. One approach is to provide the patient with 1–2 hours of intravenous hydration, dextrose, and thiamine. If the acidosis improves, the etiology is either ketoacidosis or lactic acidosis. Alternatively, a more detailed search for the toxic alcohols, involving either the osmol gap or actual methanol and ethylene glycol concentrations, should be initiated (discussed later).

■ THE Δ ANION GAP-TO-Δ$[HCO_3^-]$ RATIO

Many patients have mixed acid–base disorders such as metabolic acidosis and respiratory alkalosis. Depending on the relative effects of the acid-base disorders, the patient may have significant acidemia or alkalemia, minor alterations in pH, or even a normal pH. Although the clinical presentation, degree of compensation for the primary acid–base disorder, and the presence of unexpected electrolyte abnormalities may suggest whether more than one primary acid–base disorder is present, comparing the Δ anion gap (ΔAG) with the Δ$[HCO_3^-]$ gap may be useful.

In the patient with a simple high anion gap metabolic acidosis, each 1 mEq/L decrease in the serum $[HCO_3^-]$ should (at least initially) be associated with a 1 mEq/L rise in the anion gap.[117] This occurs because the unmeasured anion is paired with the acid that is titrating the HCO_3^-. Any deviation from this direct relationship may be an indication of a

mixed acid–base disorder.[63,117,123] Thus, the ratio of the change in the anion gap (ΔAG) to the deviation of the serum [HCO_3^-] from normal (Equation 16–4) evolved:

$$\text{Anion Gap Ratio} = \Delta AG/\Delta[HCO_3^-] \qquad \text{(Eq. 16–4)}$$

A ratio close to 1 would suggest a pure high anion gap metabolic acidosis. When the ratio is <1, there is a relative increase in [HCO_3^-] that can result only from a concomitant metabolic alkalosis or renal compensation such as renal generation of HCO_3^- for a respiratory acidosis. Alternatively, when the ratio is >1, the additional presence of either hyperchloremic (normal anion gap) metabolic acidosis or compensated respiratory alkalosis is suggested. Although the usefulness of this relationship has been supported strongly by some authors,[121,123] others suggest that it is often flawed and frequently misleading.[32,136]

After reviewing the arguments, the statements of one author[32] appear to be correct in concluding that "the exact relationship between the ΔAG and $\Delta[HCO_3^-]$ in a high anion gap metabolic acidosis is not readily predictable and deviation of the $\Delta AG/\Delta[HCO_3^-]$ ratio from unity does not necessarily imply the diagnosis of a second acid–base disorder." That being said, very large deviations from a value of 1 usually are associated with the presence of a second acid–base disorder.

■ THE OSMOL GAP

The osmol gap which is sometimes used to screen for toxic alcohol ingestion, is defined as the difference between the values for the measured osmolality and the calculated osmolarity.[150] Osmolarity is a measure of the total number of particles in 1 L of solution. Osmolality differs from osmolarity in that the number of particles is expressed per kilogram of solution. Thus, osmolarity and osmolality represent molar and molal concentrations of solutes, respectively.[55] In clinical medicine, osmolarity is usually calculated, whereas osmolality is usually measured.

Calculating osmolarity requires a summing of the known particles in solution. Because molarity and milliequivalents are particle-based measurements, unlike weight or concentration, the known constituents of serum have to be converted to molar values. Assumptions are required based on the extent of dissociation of polar compounds (such as NaCl), the water content of serum, and the contributions of various other solutes such as Ca^{2+} and Mg^{2+}. The nature and limitations of these assumptions are beyond the scope of this chapter. The reader is referred to several reviews for more details.[58,71,122] Many equations have been used and evaluated for calculating osmolarity. One investigation that used 13 different methods to evaluate sera from 715 hospitalized patients[34] concluded that Equation 16–5 provided the most accurate calculation:

$$1.86([Na^+] \text{ in mEq/L}) + ([\text{glucose}] \text{ in mg/dL/18})$$
$$+ ([BUN] \text{ in mg/dL/2.8}) \qquad \text{(Eq. 16–5)}$$

Obvious sources of potential error in this calculation include laboratory error in determining the measured parameters and the failure to account for a number of osmotically active particles.

The measurement of serum osmolality has the potential for error stemming from the use of different laboratory techniques.[38] It is essential to assure that the freezing point depression technique is used, because when the boiling point elevation method is used xenobiotics with low boiling points (ethanol, isopropanol, methanol) will not be detected.

Conceptual errors may also result. In methanol poisoning, the methanol molecule has osmotic activity that is measured but not calculated, and no increase in the anion gap is present until it is metabolized to

formate. Although the metabolite also has osmotic activity, its activity is accounted for by Na^+ in the osmolarity calculation because it is largely dissociated, existing as Na^+ formate. Thus, shortly after a methanol ingestion there will be an elevated osmol gap and a normal anion gap, whereas later, the anion gap will increase and the osmol gap will decrease. This effect is highlighted by several case reports.[9,28,153]

Using Equation 16–5 to calculate osmolarity, it is often stated that the "normal" osmol gap is 10 ± 6 mOsm/L.[34] However, when more than 300 adult samples were studied with a more commonly used equation (Eq. 16–6),

$$2([Na^+] \text{ in mEq/L}) + ([\text{glucose}] \text{ in mg/dL/18})$$
$$+ ([BUN] \text{ in mg/dL/2.8}) \qquad \text{(Eq. 16–6)}$$

normal values were -2 ± 6 mOsm.[71] Almost identical results are reported in children.[106]

The largest limitation of the osmol gap calculation is due to the documented large standard deviation around a small "normal" number.[34,71,78,139] An error of 1 mEq/L (<1.0%) in the determination of the serum [Na^+] may result in an error of 2 mOsm in the calculation of the osmol gap. Considering this variability, the molecular weights and relatively modest serum concentrations of the xenobiotics in question (eg, ethylene glycol, MW 62 daltons, at a concentration of 50 mg/dL contributes only 8.1 mOsm/L), and the predicted fall in the osmol gap as metabolism occurs, small or even negative osmol gaps can never be used to exclude toxic alcohol ingestion.[57,71] This overall concept is illustrated by the case of a patient with an osmol gap of 7.2 mOsm (well within the normal range) who ultimately required hemodialysis for severe ethylene glycol poisoning.[153]

Finally, although large osmol gaps may be suggestive of toxic alcohol ingestions, common conditions such as alcoholic ketoacidosis, lactic acidosis, renal failure, and shock are all associated with elevated osmol gaps.[78,139,147] This is surprising because lactate, acetoacetate, and β-hydroxybutyrate should not account for any increase in the osmol gap because they are charged (and accounted for in the osmolarity calculation). Apparently, these conditions are associated with the accumulation of small uncharged molecules in the serum.

Thus although the negative and positive predictive values of the osmol gap are too poor to recommend this test to screen for xenobiotic ingestion, the presence of very high osmol gaps (>50–70 mOsm/L) usually indicate a diagnosis of toxic alcohol ingestion (Chap. 107).

■ DIFFERENTIAL DIAGNOSIS OF A NORMAL ANION GAP METABOLIC ACIDOSIS

Although the differential diagnosis of a normal anion gap metabolic acidosis is extensive (Table 16–4), most cases result from either urinary or gastrointestinal HCO_3^- losses: renal tubular acidosis (RTA) or diarrhea, respectively. A number of xenobiotics also can cause this disorder, including toluene,[24] which also may cause a high anion gap metabolic acidosis. When the findings of the history and physical examination cannot be used to narrow the differential diagnosis, the use of a urinary anion gap is suggested.[14,131]

The urinary anion gap can be calculated as shown in Equation 16–7:

$$([Na^+] + [K^+]) - [Cl^-] \qquad \text{(Eq. 16–7)}$$

The size of this gap is inversely related to the urinary ammonium (NH_4^+) excretion.[61] As NH_4^+ elimination increases, the urinary anion gap narrows and may become negative, because NH_4^+ serves as an unmeasured urinary cation and is accompanied predominantly by Cl^-.

The normal anion gap metabolic acidosis associated with diarrhea results from HCO_3^- loss. During this process, the kidney's ability to eliminate NH_4^+ is undisturbed; in fact, it increases as a normal response to the acidemia. Thus, with gastrointestinal HCO_3^- losses the urinary anion gap should decrease and may become negative. Alternatively, the patient with RTA has lost the ability to either reabsorb HCO_3^- (type 2 RTA) or increase NH_4^+ excretion (types 1 and 4 RTA) in response to metabolic acidosis, and the urinary anion gap should become more positive. Indeed, when the urinary anion gap was calculated in patients with diarrhea or RTA, it was found that those patients with diarrhea had a mean negative gap (-20 ± 5.7 mEq/L), as compared to a positive gap (23 ± 4.1 mEq/L) in those with RTA.[61] Therefore, when evaluating the patient with a normal anion gap metabolic acidosis, the determination of a urinary anion gap may help to determine the source of the disorder.

■ ADVERSE EFFECTS OF METABOLIC ACIDOSIS

The acuity of onset and severity of metabolic acidosis determine the consequences of this disorder. Acute metabolic acidosis is usually characterized by obvious hyperventilation (due to respiratory compensation). At arterial pH values <7.20, cardiac and CNS abnormalities also become evident. These may include decreases in blood pressure and cardiac output, cardiac dysrhythmias, and progressive obtundation.[1] Chronic metabolic acidosis is often asymptomatic. The symptoms of anorexia and fatigue may be the only manifestations of chronic acidosis, and compensatory hyperventilation may be undetectable. Because the consequences of even severe metabolic acidosis are not specific, the presence of metabolic acidosis is most often suggested by the clinical evaluation.

■ MANAGEMENT PRINCIPLES IN PATIENTS WITH METABOLIC ACIDOSIS

The treatment of metabolic acidosis depends on its severity and cause. Most cases of severe poisoning, with a serum $[HCO_3^-]$ concentration <8 mEq/L and an arterial pH value <7.20 should probably be treated with HCO_3^- to increase the pH to >7.20, as described in detail elsewhere.[1] As an example, to raise the serum $[HCO_3^-]$ by 4 mEq/L in a 70-kg person with an estimated HCO_3^- distribution space of 50% of body weight, approximately 140 mEq must be administered. When ECFV overload (caused by heart failure, renal failure, or the sodium bicarbonate therapy itself) cannot be prevented or managed by administering loop diuretics, hemofiltration or hemodialysis may be necessary.

In patients with arterial pH values >7.20, the cause of the acidosis should guide therapy. Metabolic acidosis primarily caused by the overproduction of acid, as in the case of ketoacidosis and lactic acidosis,

will require very large quantities of HCO_3^- and may not respond well to sodium bicarbonate therapy. Treatment in these patients should be directed at the cause of acidosis (eg, insulin in diabetic ketoacidosis; fomepizole in methanol and ethylene glycol poisonings [see Antidotes in Depth: Fomepizole]; fluids, glucose, and thiamine in alcoholic ketoacidosis; fluid resuscitation, antibiotics, and vasopressors in sepsis-induced lactic acidosis). Metabolic acidosis primarily caused by underexcretion of acid (eg, acute or chronic renal failure, RTA), should be treated with a low protein diet (if feasible) and oral sodium bicarbonate or substances that generate HCO_3^- during metabolism. Such patients can usually be managed with an oral sodium citrate solution (eg, Shohl's solution yields 1 mEq base/mL). The goal of therapy is to increase the serum $[HCO_3^-]$ to 20 mEq/L, and the pH to 7.30.

METABOLIC ALKALOSIS

■ ADVERSE EFFECTS OF METABOLIC ALKALOSIS

Life-threatening metabolic alkalosis is rare but can result in tetany (from decreased ionized $[Ca^{2+}]$),[96] weakness (from decreased serum $[K^+]$),[107] or altered mental status leading to coma,[91] seizures,[59] and cardiac dysrhythmias.[84] In addition, metabolic alkalosis shifts the oxyhemoglobin dissociation curve to the left, impairing tissue oxygenation (Chap. 21). The expected compensation for a metabolic alkalosis is hypoventilation and increased PCO_2. As discussed before, respiratory compensation is irregular and inadequate at best, invoking the teleologic argument that hypoxia is more undesirable than alkalemia.[117] Several authors, however, have reported that severe hypoventilation and respiratory failure can occur in response to metabolic alkalosis, suggesting an actual, although uncommon, risk.[107,124]

■ APPROACH TO THE PATIENT WITH METABOLIC ALKALOSIS

Metabolic alkalosis results from gastrointestinal or urinary loss of acid, administration of exogenous base, and/or renal HCO_3^- retention (ie, impaired renal HCO_3^- excretion). Table 16–5 lists the causes of metabolic alkalosis. As compared to metabolic acidosis, metabolic alkalosis is less common and less frequently a consequence of xenobiotic exposure.

The etiologies of metabolic alkalosis can be characterized from a therapeutic standpoint as chloride responsive or chloride resistant. Chloride-responsive etiologies such as diuretic use, vomiting, nasogastric suction, and Cl^- diarrhea are usually associated with a urinary $[Cl^-]$ <10 mEq/L.[67,84] These disorders respond rapidly to infusion of

TABLE 16–5. Xenobiotic and Other Causes of Metabolic Alkalosis

Gastrointestinal acid loss	Urinary acid loss	Base administration	Renal bicarbonate retention
Nasogastric suction (protracted)	Common	Acetate (dialysis or hyperalimentation)	Hypercapnia (chronic)
Vomiting (protracted)	Diuretics	Bicarbonate	Hypochloremia
	Glucocorticoids	Carbonate (antacids)	Hypokalemia
	Rare	Citrate (posttransfusion)	Volume contraction
	Hypercalcemia	Milk alkali syndrome	
	Licorice (containing glycyrrhizic acid)		
	Magnesium deficiency		

0.9% NaCl solution when concomitant therapy addresses the underlying problem.[2] Chloride-resistant disorders exemplified by hyperaldosteronism and severe K[+] depletion are characterized by urinary [Cl[−]] >10 mEq/L and tend to be resistant to 0.9% NaCl solution therapy.[52,67] These disorders often require K[+] repletion or drugs that reduce mineralocorticoid effects, such as spironolactone, before correction can occur.[52] When 0.9% NaCl solution repletion is ineffective, or emergent correction of the alkalosis is required, some authors have suggested infusions of lysine or arginine HCl, or dilute HCl.[3,108] However, this technique is rarely necessary.

XENOBIOTIC-INDUCED AND OTHER ALTERATIONS OF WATER BALANCE

Significant fluid abnormalities commonly occur in the setting of xenobiotic exposure. Gastrointestinal losses in the form of vomiting, diarrhea, gastrointestinal hemorrhage, and third spacing such as from gastrointestinal burns result from a variety of xenobiotic toxicities and their management with emetics and cathartics. Renal fluid losses result from the ability of many xenobiotics to increase the glomerular filtration rate (inotropes), impair Na[+] reabsorption (diuretics), or enhance urine volume in response to an obligate solute load (salicylates). Fluid losses also may occur through the skin as a result of sweating (sympathomimetics, cholinergics, and uncouplers of oxidative phosphorylation) or the lung as a result of increased minute ventilation (salicylates and sympathomimetics) or bronchorrhea (cholinergics). To the extent that these lost fluids contain Na[+], various signs, symptoms, and laboratory evidence of ECFV depletion may be present.

The diagnosis and treatment of abnormal serum electrolyte concentrations are usually addressed after repletion of the ECFV deficit with isotonic, Na[+]-containing fluids (eg, blood products, 0.9% NaCl solution, lactated Ringer solution). Other fluid balance issues are discussed in Chaps. 25 and 27 and in chapters relating to individual xenobiotics. This section focuses on body water balance (abnormalities of which manifest as hypernatremia and hyponatremia) and specifically on the toxicologically relevant syndromes of diabetes insipidus (DI) and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Sodium concentration in the extracellular space is intrinsically related to and directly reflects total body water balance. This occurs because the sodium cation is largely restricted to the extracellular space, and its serum concentration is primarily, if indirectly, controlled by factors that control water balance. Thus, both the serum [Na[+]] and plasma osmolality vary inversely with changes in the quantity of body water.

Plasma osmolality is maintained through a complex interaction between dietary water intake; the hypothalamus, pituitary gland, and kidney; and the effects of hormones such as antidiuretic hormone (ADH) and adrenal mineralocorticoids.[16,19,119,161] Briefly, changes in osmolality are caused by changes in water intake and insensible (dermal, respiratory, and stool) and sensible (urinary, sweat) water losses. Urinary water losses are controlled by the hormone arginine vasopressin (ADH). Increases in the osmolality of the extracellular fluid stimulate anterior hypothalamic osmoreceptors, thereby stimulating thirst and ADH synthesis and release by the posterior pituitary gland. ADH release reaches its maximum level at a plasma osmolality of about 295 mOsm/kg. Antidiuretic hormone is transported to the kidney via the bloodstream, where it stimulates the synthesis of cyclic adenosine monophosphate (cAMP). cAMP increases the water permeability of the distal convoluted tubule and collecting duct (by stimulating the insertion of aquaporin channels in the apical membrane), increasing water reabsorption and urine concentration and minimizing urinary water losses. Conversely, as plasma osmolality falls, thirst and ADH release are diminished. This results in decreased renal cAMP generation, decreased water permeability of the distal convoluted tubule and collecting duct, and the excretion of a relatively dilute urine that ultimately corrects the body water excess. Marked alterations in water intake combined with perturbations of these various processes often lead to hypernatremia or hyponatremia.

■ HYPERNATREMIA

Table 16–6 summarizes the xenobiotics that cause hypernatremia. Hypernatremia may be caused by the parenteral administration of sodium-containing drugs or rapid and excessive oral Na[+] intake.[3] Oral NaCl and oral sodium citrate have been used as emetics and antiemetics, respectively. As might be expected, both have produced severe hypernatremia.[19] One case of fatal hypernatremia resulted from gargling with a supersaturated salt solution.[110] Similarly, massive ingestion of sodium hypochlorite bleach was associated with hypernatremia.[69,134]

More commonly, hypernatremia results from relatively electrolyte-free (hypotonic) water losses due to xenobiotics or conditions that cause urinary, gastrointestinal, and dermal fluid losses.[3] Indeed, all fluid losses from the body, except hemorrhage and those from fistulas, are hypotonic (and have the potential to cause hypernatremia). The lack of adequate fluid replacement is a key element in the development of hypernatremia because even the large losses caused by DI or cholera-induced diarrhea will not cause hypernatremia if they are adequately replaced. Thus, in patients with hypernatremia caused by fluid losses, the reason why the losses were not replaced by the patient should always be sought.

Xenobiotics that produce significant diarrhea, such as lactulose or cholestyramine, can cause hypernatremia through unreplaced stool water losses. A similar pathogenesis accounts for the hypernatremia caused by the polyethylene-containing solution used for bowel preparation for colonoscopy.[13] Of particular concern is the use of cathartics

TABLE 16–6. Xenobiotic Causes of Hypernatremia

Sodium gain	Water loss	Water loss due to diabetes insipidus
Antacids (baking soda)	Cholestyramine	α-Adrenergic antagonists
Sodium salts (acetate, bicarbonate, chloride, citrate, hypochlorite)	Diuretics	Amphotericin
	Glycerol	Colchicine
Seawater	Lactulose	Demeclocycline
	Mannitol	Ethanol
	Povidone-iodine	Foscarnet
	Sorbitol	Glufosinate
	Urea	Lithium
		Lobenzarit disodium
		Methoxyflurane
		Mesalazine
		Minocycline
		Opioid antagonists
		Propoxyphene
		Rifampin
		Streptozotocin
		Conivaptan and other vasopressin V_2-receptor antagonists

in the management of poisonings, especially when fluid losses are not anticipated. For example, multiple doses of sorbitol can produce severe hypernatremic dehydration and death in both children and adults.[22,41,54,162]

Significant water loss also can occur through the skin. Although diffuse diaphoresis resulting from cocaine or organic phosphorus insecticide toxicity has the potential to produce hypernatremia, this rarely, if ever, occurs. However, application of a remedy containing hyperosmolar povidone-iodine to the skin of burned patients produces significant water losses and hypernatremia.[142]

Diagnosis and Treatment The symptoms of significant hypernatremia consist largely of altered mental status ranging from confusion to coma, and neuromuscular weakness that occasionally results in respiratory paralysis. If hypernatremia is associated with Na^+ losses and marked ECFV depletion, cardiovascular symptoms, tachycardia, and orthostatic hypotension may be present. Treatment consists of first replacing the Na^+ deficit (with isotonic fluids such as 0.9% NaCl solution) if present, and then replacing the water deficit. The water deficit may be estimated by assuming that the fractional increase in serum $[Na^+]$ is equal to the fractional decrease in total body water. Thus, a serum $[Na^+]$ that has increased by 10% (from 144 mEq/L to 158 mEq/L) indicates that the water deficit is 10% (3.6 L in a 60-kg person with 36 L of body water).

When the hypernatremia develops over several hours, for example as occurs after ingestion or administration of a sodium salt, rapid correction is indicated. However, when hypernatremia develops over several days or when the duration is unknown, slow correction of hypernatremia (over several days) is recommended.[3] The adaptation of brain cells to the water deficit (including the gain of intracellular solute) makes cerebral edema a frequent complication of rapid water replacement. Although some sources suggest that 0.9% NaCl solution is an appropriate replacement fluid regardless of the magnitude of the water deficit, recent emphasis has been on the use of hypotonic fluids to correct hypernatremia in the absence of a significant sodium deficit.[3]

■ DIABETES INSIPIDUS

The greatest water losses and, therefore, the potentially most severe cases of hypernatremia occur during DI, which is always characterized by greater or lesser degrees of hypotonic polyuria. DI may be neurogenic resulting from failure to sense a rising osmolality, or from a failure to release ADH, or nephrogenic resulting from failure of the kidney to respond appropriately to ADH. Although there are many nontoxicologic causes of DI (eg, trauma, tumor, sarcoidosis, vascular and congenital), drug-induced DI is also common, and may be mediated through either central or peripheral mechanisms.

Ethanol, opioid antagonists, and α-adrenergic agonists all suppress ADH release.[9,114] Lithium,[98,146] demeclocycline,[145] methoxyflurane,[102] propoxyphene, foscarnet,[118] mesalazine,[100] streptozotocin, amphotericin,[73] glufosinate,[156] lobenzarit,[135] rifampin,[128] and colchicine[161] are associated with nephrogenic DI (see Table 16-6). In addition, nephrogenic DI may be caused by severe hypokalemia from diuretic use, and hypercalcemia from vitamin D poisoning.[161] Of all these xenobiotics, lithium has been the most extensively evaluated. Although polyuria is a common finding with lithium therapy (occurring in 20%–70% of patients on maintenance therapy), the exact incidence of DI and hypernatremia is unknown. Estimates range from 10%–20% to as high as 80%.

Diagnosis Patients with DI complain of polyuria and polydipsia. Urine volumes typically exceed 30 mL/kg/d[161] and may be as high as 9 L/d with nephrogenic DI[98] and 12–14 L/d with neurogenic (central) DI.[115] Nocturia, fatigue, and decreased work performance are often noted.[161]

Neurogenic DI resulting from hypothalamic or pituitary damage is typically associated with other signs of neuroendocrine dysfunction.[115]

Once polyuria is confirmed (eg, in adults, by measuring a urine output >200 mL over 1 hour), the urine osmolality or specific gravity should be measured. The diagnosis of DI is established by the occurrence of dilute urine (urine osmolality <300 mOsm/kg, urine specific gravity <1.010) in the presence of increased serum $[Na^+]$ and an serum osmolality >295 mOsm/kg.[161] Following this determination, a trial of desmopressin (DDAVP), an arginine vasopressin analog, helps to differentiate between neurogenic and nephrogenic DI. If the etiology of the DI is neurogenic, the patient will promptly respond to DDAVP with a decrease in urine output and increase in urine osmolality. In nephrogenic DI, DDAVP will have no significant effect.

Treatment The initial approach to the hypernatremic patient with DI involves the repletion of the water deficit (as described above) and the restoration of electrolyte depletion, if necessary. If a reversible cause for the DI can be established, it should be corrected. Specifically, xenobiotics implicated as the cause of DI should be discontinued or their dose reduced. Patients with neurogenic DI should be maintained on either vasopressin or DDAVP. The latter is preferred because of the lack of vasopressor effects and ease of administration. In the past, patients were occasionally treated with oral medications known to produce SIADH (see later). Patients with nephrogenic DI can be treated with thiazide diuretics,[35] prostaglandin inhibitors,[31,74,93] and/or amiloride, all of which reduce the urine flow rate.[15]

■ HYPONATREMIA

Hyponatremia may be associated with a high, normal, or low serum osmolality. Patients with myeloma or severe hyperlipidemia may exhibit artifactual hyponatremia whenever the measurement technique requires dilution of the serum sample rather than direct measurement by a sodium electrode. These patients have a normal serum osmolality, no symptoms related to their artifactual hyponatremia, and require no therapy.

Hyperglycemic patients develop hyponatremia because the increase in plasma osmolality caused by hyperglycemia results in a water shift from the intracellular to the extracellular space. The reduction in serum $[Na^+]$, which may cause symptoms, is approximately 1.6 mEq/L for every 100 mg/dL increase in serum glucose concentration. The contribution of hyperglycemia to the hyponatremia should be calculated to determine if other causes of hyponatremia should also be sought. All other causes of hyponatremia are associated with a low plasma osmolality. In fact, in the absence of myeloma, hyperlipidemia, and hyperglycemia, the serum osmolality need not be measured in hyponatremic patients and may be assumed to be low.

Hyponatremia associated with a low plasma osmolality usually results from water intake in excess of the renal capacity to excrete it. When renal water excretion is normal, very large intake is required to cause hyponatremia. Usually such large quantities of water are ingested over a short period of time by people with psychiatric or neurologic disorders such as psychogenic polydipsia.[60,132] Xenobiotic-induced water excess comparable to psychogenic polydipsia is quite uncommon. An example occurs during urologic procedures, such as transurethral resection of the prostate (TURP), where large volumes of irrigation solution are required. Because the wounds are electrically cauterized, these fluids cannot contain conductive electrolytes such as sodium. Sorbitol, dextrose, and mannitol were tried in an attempt to maintain a normal osmolality in these irrigating solutions, but their optical characteristics were undesirable during the surgery. Thus, irrigation during TURP is performed with glycine-containing solutions. When 1.5% glycine (osmolality 220 mOsm/kg) is absorbed through

the prostatic venous plexus, a rapid reduction in serum [Na⁺] results and will persist until the glycine is metabolized.[70,109] Symptoms in these patients are probably a result of several factors: hyponatremia, the glycine itself, and NH₃, a glycine metabolite. A similar complication has also been described during hysteroscopy.[125,143]

Rarely, hyponatremia results from the loss of a body fluid with a [Na⁺] greater than the extracellular fluid (ECF) [Na⁺] (of 154 mEq/L). This may occur in patients with adrenal insufficiency through hypertonic urinary losses (although increased ADH secretion as a consequence of ECF sodium depletion is probably a more important mechanism; see later). In burn patients, Na⁺ may be lost directly from the ECF. When treated with the topical applications of silver nitrate cream, hyponatremia may develop from the diffusion of sodium through permeable skin into the hypotonic dressing.[26] Ingestion of licorice that contains glycyrrhizic acid produces a syndrome of hyponatremia, hypokalemia, and hypertension that resembles mineralocorticoid excess. Although the exact mechanism of hyponatremia is debated, one report suggested that a glycyrrhizic acid–induced reduction in 11-β-hydroxysteroid dehydrogenase activity could account for the findings.[37,40] Lithium, which is usually associated with DI and hypernatremia, has been reported to cause renal sodium-wasting and hyponatremia that seems to be unrelated to ADH effects.[108]

Most cases of hyponatremia are caused by water intake in excess of a reduced renal excretory capacity. This reduction in urinary water excretion may be physiologic (as during ECF sodium depletion) or pathologic (in association with renal failure, heart failure, or cirrhosis of the liver).[4,13] Because these conditions are accompanied by alterations in renal sodium handling, signs and symptoms of ECFV depletion, such as postural hypotension, or excess, such as edema, usually accompany the hyponatremia. Other patients cannot excrete water normally because malignancy or various brain or pulmonary diseases cause ADH secretion.[4] In fact, in some cases the tumors are associated with paraneoplastic disease and directly secrete ADH. Xenobiotics, such as diuretics, may cause ECFV depletion but most directly stimulate ADH secretion or augment the renal effects of ADH. Drugs such as the thiazide diuretics cause hyponatremia by several mechanisms, including interference with maximal urinary dilution, and by ADH-induced water retention in response to decreased ECFV.[4,44] Patients with excess secretion and/or action of ADH who have near-normal ECFV are said to have SIADH. Table 16–7 summarizes these and other causes of hyponatremia.

■ SIADH

SIADH is characterized by hyponatremia and plasma hypotonicity in the absence of abnormalities of ECFV, adrenal, thyroid, or renal function. Early reviews claimed that SIADH was a disorder of volume overload, based largely on evidence of weight gain.[114] The consistent absence of edema, however, and the fact that the decrease in serum [Na⁺] cannot be accounted for by the fluid gain (weight gain) suggest that water retention is only part of the mechanism.[87] Urinary Na⁺ loss and Na⁺ redistribution from the extracellular to the intracellular space are apparently important as well.

There are many nontoxicologic etiologies of SIADH, most of which result from altered pulmonary or intracranial pathophysiology. These causes include infections, malignancies, and surgery.[4,87,114,115] Table 16–7 summarizes xenobiotics known to produce SIADH. The oral hypoglycemics, including drugs from both the sulfonylurea (eg, chlorpropamide) and biguanide (eg, metformin) classes, produce hyponatremia more commonly than other drugs.[113] Their actions are multifactorial and can include both the potentiation of endogenous ADH and the stimulation of ADH release.[113] Many psychiatric medications, including

   Tramadol
   Tranylcypromine
   Valproate
   Vasopressin
   Vincristine and vinblastine

the selective serotonin reuptake inhibitors, cyclic antidepressants, and antipsychotics, are implicated in causing SIADH.[25,85,95,152,159] The effects of these drugs may be mediated by the complex interactions between the dopaminergic and noradrenergic systems that control ADH release.[152] Additional evidence supports a role of serotonin in drug-induced SIADH. Serotonin (specifically 5-HT₂ and/or 5-HT₁C) directly stimulates ADH release[10] and water intake.[76] An important role of serotonin is supported by the occurrence of SIADH with methylenedioxymethamphetamine (MDMA) use.[75,164]

Diagnosis The clinical presentation of patients with hyponatremia depends on the cause, the absolute serum [Na⁺], and the rate of decline in serum [Na⁺]. Patients with associated ECFV excess or depletion will present with evidence of altered ECFV, as well as signs and symptoms of the disease that caused the abnormality in ECFV, such as adrenal insufficiency and heart failure.[5] Rarely, will these patients exhibit symptoms of hyponatremia and hyposmolality of body fluids per se. This may be because of the moderate degree of hyponatremia (>130 mEq/L),

the moderate rate of decline in [Na$^+$], and/or because the loss of Na$^+$ and water limits the development of cerebral edema.[90] It is important to note that patients with hyponatremia and a low plasma osmolality (excluding those with primary polydipsia) all have a urinary osmolality that is relatively high, regardless of whether they have excess, diminished, or normal ECFV. Consequently, these disorders can only be differentiated by the history, physical examination, and other laboratory tests.

Patients with SIADH, if symptomatic, usually present with signs and symptoms of hyponatremia. As noted above, the clinical manifestations of hyponatremia are dependent on both the absolute serum [Na$^+$] and its rate of decline.[11,90,115] Chronic, slow depression of the [Na$^+$] is usually well tolerated, whereas rapid decreases may be associated with symptoms and sometimes catastrophic events. Symptoms include headache, nausea, vomiting, restlessness, disorientation, depression, apathy, irritability, lethargy, weakness, and muscle cramps. In more severe cases, respiratory depression, coma, and seizures may develop.

The diagnosis of SIADH is based on establishing the presence of hyponatremia, a low serum osmolality, and impaired urinary dilution in the absence of edema, hypotension, hypovolemia, and renal, adrenal, or thyroid dysfunction.[87] As discussed above, the presence of any of these clinical findings suggests that another cause of hyponatremia may be present. A serum uric acid concentration may be helpful in differentiating SIADH from other causes of hyponatremia. In the presence of hyponatremia and impaired urinary dilution, patients with SIADH have hypouricemia, whereas patients exhibiting ECFV excess or depletion characteristically have hyperuricemia.[29,151]

Treatment   Treatment of patients with demonstrable ECFV excess or depletion should be directed at the abnormal ECFV and its cause, rather than the hyponatremia. In almost all cases, the hyponatremia will improve with correction of the ECFV.[4,90] In a similar way, correction of the serum glucose in hyperglycemic patients and the removal of glycine by hemodialysis in patients with the TURP syndrome will correct the serum [Na$^+$]. The rate of correction of the serum [Na$^+$] in these patients is generally not of concern.

In patients with SIADH, treatment begins with fluid restriction. Because the goal of this therapy is to establish a negative fluid balance, careful attention to intake and output is required. If an offending xenobiotic can be identified, it should be discontinued. Although most cases resolve in 1–2 weeks,[87,115] SIADH caused by chronic cerebral or pulmonary conditions or by malignancy often persists. If this occurs, therapy with demeclocycline or lithium may be helpful, because severe fluid restriction is often intolerable. One author suggested that demeclocycline was more efficacious than lithium when the two drugs were compared in a small series of patients with SIADH.[47]

In all asymptomatic or mildly symptomatic patients (usually patients with chronic hyponatremia of more than 2 days duration), correction should proceed slowly, and certainly at a rate less than 0.5 mEq/L/h during the first 24 hours. This is because too rapid correction of hyponatremia may increase the risk of irreversible CNS damage known as central pontine myelinolysis.[4,12,154] Water restriction is usually sufficient, but occasionally demeclocycline may be appropriate in patients in whom a rapid rate of correction represents a greater risk for brain damage than the absolute serum [Na$^+$]. The use of a vasopressin (V$_2$) receptor antagonists may make the management of these patients easier.[4,66]

When hyponatremia is associated with life-threatening clinical presentations including respiratory depression, altered mental status, seizures or coma, careful infusion of hypertonic (3%) saline (eg, 1–2 mL/kg/h), with or without furosemide, is indicated.[4,87] Alternatively, conivaptan (a V$_2$ receptor antagonist) may be administered intravenously as an initial bolus of 20 mg followed by a continuous infusion of

40 mg/d for no more than 4 days.[65,68] In these symptomatic patients, the goal is to increase the serum [Na$^+$] by 1–2 mEq/L/h, or by 10% over 12–24 hours, or until the symptoms abate.[4,90] After this initial correction and amelioration of symptoms, the serum [Na$^+$] should be increased at a rate <0.5 mEq/L/h, preferably by water restriction alone. Formulae are available to help calculate the rate of correction of hyponatremia.[4] Equation 16–8 may be helpful.

When 1 L of fluid is infused:

$$\text{Change in serum } [Na^+] = \frac{\text{infusate } [Na^+] - \text{serum } [Na^+]}{\text{Total body water} + 1 \text{ L}}$$

$$\text{(Eq. 16–8)}$$

where the infusate [Na$^+$] in mEq/L equals:

3% sodium chloride	513
0.9% sodium chloride	154
Lactated Ringer solution	130
0.45% sodium chloride	77
0.33% sodium chloride	51

XENOBIOTIC-INDUCED ELECTROLYTE ABNORMALITIES

◼ POTASSIUM

Xenobiotic-induced alterations in serum [K$^+$] are potentially more serious than alterations in other electrolyte concentrations because of the critical role of potassium in a variety of homeostatic processes. Potassium balance is complex.[21,126,138] The total body potassium content of an average adult is about 54 mEq/kg, of which only 2% is located in the intravascular space. The large intracellular store of potassium is maintained by a variety of systems, the most important of which is membrane Na$^+$-K$^+$-adenosine triphosphatase (ATPase). The relationship between total body stores and serum [K$^+$] is not linear, and small changes in the total body potassium may result in dramatic alterations in serum concentrations, and, more importantly, in the ratio of extracellular to intracellular [K$^+$].

People eating a western diet ingest 50–150 mEq/d of potassium, approximately 90% of which is subsequently eliminated in the urine. The body has two major defenses against a potassium load: acutely, potassium is transferred into cells; chronically, potassium is excreted in the urine by decreased proximal tubular reabsorption and increased distal tubular secretion (to a maximum of 600–700 mEq/d).[21] Following a meal, K$^+$ transfers into intracellular space through insulin and catecholamine-mediated uptake of potassium in liver and muscle cells.[97,133] Renal potassium excretion is primarily modulated by the renin–angiotensin–aldosterone system. In addition, the gastrointestinal absorption of potassium decreases as the serum [K$^+$] increases.

Hypokalemia results from decreased oral intake, gastrointestinal losses caused by repeated vomiting or diarrhea, urinary losses through increased K$^+$ secretion or decreased reabsorption, and processes that shift potassium into the intracellular compartment.[19,21,144,163] Table 16–8 summarizes the xenobiotics commonly associated with hypokalemia.

The neuromuscular manifestations of hypokalemia are reviewed elsewhere.[86] Patients with hypokalemia are often asymptomatic when the decrease in serum [K$^+$] is mild (serum concentrations of 3.0–3.5 mEq/L). Occasionally, hypokalemia interferes with renal concentrating mechanisms and polyuria is noted. More significant potassium deficits (serum concentrations of 2.0–3.0 mEq/L) cause generalized malaise and weakness. As the [K$^+$] falls to less than 2 mEq/L, weakness becomes prominent and areflexic paralysis and respiratory failure may occur, often necessitating intubation and mechanical ventilation.[86]

TABLE 16–8. Xenobiotic Causes of Altered Serum Potassium

Hypokalemia	Hyperkalemia
Aminoglycosides	α-Adrenergic agonists (phenylephrine)
Amphotericin	β-Adrenergic antagonists
Barium (soluble salts)	Amiloride
β-Adrenergic agonists	Angiotensin-converting enzyme
Bicarbonate	inhibitors
Caffeine	Angiotensin receptor blockers
Carbonic anhydrase	Arginine hydrochloride
inhibitors	Cardioactive steroids
Cathartics	Fluoride
Chloroquine	Heparin
Cisplatin	Nonsteroidal antiinflammatory drugs
Dextrose	Penicillin (potassium)
Hydroxychloroquine	Potassium salts
Infliximab	Spironolactone
Insulin	Succinylcholine
Licorice (containing	Triamterene
glycyrrhizic acid)	Trimethoprim
Loop diuretics	
Metabolic alkalosis	
Osmotic diuretics	
Quinine	
Salicylates	
Sodium penicillin and its analogs	
Sodium polystyrene sulfate	
Sulfonylureas	
Sympathomimetics	
Tenofovir	
Theophylline	
Thiazide diuretics	
Toluene	

Rhabdomyolysis is also likely. These neuromuscular manifestations are so prominent that they may be erroneously attributed to a neuromuscular syndrome such as Guillain-Barré. Other clinical findings associated with hypokalemia include gastrointestinal hypoperistalsis (ileus), manifestations of cardioactive steroid toxicity, worsening hyperglycemia in diabetic patients, and the symptoms and signs of the metabolic abnormalities that often accompany hypokalemia such as hyponatremia, metabolic acidosis, or alkalosis.[163]

Electrocardiographic changes also are common, even with mild potassium depletion, although the absence of ECG changes should never be used to exclude significant hypokalemia. Common ECG findings of hypokalemia include depression of the ST segment, decreased T-wave amplitude, and increased U-wave amplitude (Chap. 22). These findings may herald life-threatening rhythm disturbances.[74,94,163]

Treatment of hypokalemia involves discontinuing or removing the offending xenobiotic and correcting the potassium deficit. Potassium supplementation may be given orally or intravenously. The choice of potassium salt should be based on the associated acid–base abnormality, if present. Thus, potassium chloride should be administered when metabolic alkalosis is present, and another salt of potassium (eg, potassium citrate or potassium bicarbonate[spell out for parallel construction?]) should be administered when metabolic acidosis is present.[163] Potassium phosphate should be part of the K^+ supplement when hypophosphatemia is present, as occurs in diabetic ketoacidosis. Hypomagnesemia, which may cause or accompany hypokalemia (eg, in diuretic-induced hypokalemia), must be corrected because this abnormality may prevent successful potassium replacement.

The debate over the maximum safe infusion rate for intravenous potassium is summarized elsewhere.[89,163] Based on experience with more than 1300 infusions, one group concluded that under intensive care monitoring, intravenous administrations of 20 mEq/h (by central or peripheral vein) were well tolerated. They also found that each 20 mEq of potassium administered resulted in an average increase in serum $[K^+]$ of 0.25 mEq/L. Others have used significantly larger doses (up to 100 mEq/h) in life-threatening circumstances.[30]

Hyperkalemia results from decreased urinary elimination (renal insufficiency, potassium-sparing diuretics, hypoaldosteronism), increased intake (either orally or intravenously), or redistribution from tissue stores.[19,21] The last mechanism is of major toxicologic importance. Overdoses of both cardioactive steroids (Chap. 64) and β-adrenergic antagonists (Chap. 61) cause hyperkalemia by promoting net potassium release from intracellular reservoirs. Presumably because of other protective mechanisms, overdose with a β-adrenergic antagonist produces only a moderate rise in serum $[K^+]$ (usually to 5.0–5.5 mEq/L). By contrast, a similar rise in serum $[K^+]$ as a consequence of blockade of the Na^+-K^+-ATPase pump during cardioactive steroid toxicity may be lethal. This suggests that hyperkalemia per se is not the cause of the lethality of cardioactive steroid toxicity. Thus, the focus of therapy should involve efforts to neutralize or eliminate the cardioactive steroid rather than reduce the serum $[K^+]$.[17] Table 16–8 lists xenobiotics that cause hyperkalemia.

After oral overdoses of potassium salts, patients usually complain of nausea and vomiting. Ileus, and intestinal irritation, bleeding, and perforation may complicate the clinical course.[138] In the absence of potassium ingestion, gastrointestinal symptoms of hyperkalemia are usually very mild. Neuromuscular manifestations include weakness with an ascending flaccid paralysis and respiratory compromise, with intact sensation and cognition.[86,104,126] The similarity of these signs and symptoms to those associated with hypokalemia is striking, suggesting that hyperkalemia may be diagnosed with certainty only by laboratory measurement.

The cardiac manifestations of hyperkalemia are distinct, prominent, and life threatening. Electrocardiographic patterns progress through characteristic changes.[137,138] Although the progression of ECG changes is very reproducible, there is great individual variation with respect to the serum $[K^+]$ at which these ECG findings occur. Initially, the only ECG finding may be the presence of tall, peaked T waves. As the serum $[K^+]$ concentration increases, the QRS complex tends to blend into the T waves, the P-wave amplitude decreases, and the PR interval becomes prolonged. Next, the P wave is lost and ST-segment depression occurs. Finally, the distinction between the S and T waves becomes blurred and the ECG takes on a sine wave configuration (Chap. 22). Hemodynamic instability and cardiac arrest can result. As the patient's serum $[K^+]$ falls with therapy, these ECG changes resolve in a reverse fashion.

The treatment of severe hyperkalemia includes standard airway management and methods to (1) reverse the ECG effects; (2) transfer K^+ to the intracellular space; and (3) enhance K^+ elimination. Pharmacologic interventions, extensively discussed elsewhere,[148] are summarized here. Calcium (eg, $CaCl_2$ 10–20 mEq administered intravenously) works

almost immediately to protect the myocardium against the effects of hyperkalemia although it does not reduce the serum [K$^+$]. However, a potentially life-threatening interaction occurs when the patient with cardioactive steroid toxicity is given calcium salts (Chap. 64); thus, this therapeutic modality is relatively contraindicated in such circumstances.

The administration of insulin (and dextrose to prevent hypoglycemia), sodium bicarbonate, and/or inhalation of a β-adrenergic agonist all stimulate potassium entry into cells.[8] They reduce the serum [K$^+$] over approximately 30 minutes, but potassium begins to reenter the extracellular space over the next several hours. Cationic exchange resins, such as Na$^+$ polystyrene sulfonate, take somewhat longer to reduce the serum [K$^+$] (about 45 minutes), as they enhance gastrointestinal potassium loss. Hemodialysis or peritoneal dialysis may be useful, especially when significant renal impairment is present.

Calcium Calcium is the most abundant mineral in the body and 98%–99% is located in bone. Approximately half of the remaining 1%–2% of calcium in the body is bound to plasma proteins (mostly albumin) and most of the rest is complexed to various anions, with free, ionized calcium representing a very small fraction of extraosseous stores. The serum [Ca^{2+}] is maintained through interactions between dietary intake and renal elimination, modulated by vitamin D activity, parathyroid hormone, and calcitonin. More extensive discussions of calcium physiology are found elsewhere.[6,116]

Xenobiotic-induced hypercalcemia is uncommon and usually caused by an increased dietary calcium as a result of milk or antacid usage, calcium supplements, or a decrease in its renal excretion such as occurs with thiazide use.[6,19] Cholecalciferol, available as a rodenticide, can increase the serum [Ca^{2+}] by increasing its release from bone, increasing gastrointestinal absorption, and decreasing renal elimination (Chap. 108). Vitamin D toxicity from excessive vitamin intake or supplementation of milk also can cause hypercalcemia.[46,81] Table 16–9 lists other causes of hypercalcemia.

Symptoms of hypercalcemia consist of lethargy, muscle weakness, nausea, vomiting, and constipation. Life-threatening manifestations include complications from altered mental status such as aspiration pneumonia and cardiac dysrhythmias (Chap. 22). Treatment of clinically significant hypercalcemia focuses on removing the offending xenobiotic when possible, decreasing gastrointestinal absorption by administering a binding agent, increasing distribution into bone with a bisphosphonate, and enhancing renal excretion through forced diuresis with intravenous 0.9% NaCl solution and furosemide.[6,155] Hemodialysis may be required when significant renal impairment is present.

Xenobiotics more commonly cause hypocalcemia than hypercalcemia. Minor, usually clinically insignificant decreases in serum [Ca^{2+}] can occur in association with anticonvulsant[92] and aminoglycoside therapy.[19] Severe, life-threatening hypocalcemia can occur, however, from ethylene glycol poisoning (Chap. 107) or as a manifestation of fluoride toxicity from either fluoride salts or hydrofluoric acid (Chap. 105).[36,157] Calcium complex formation with fluoride or oxalate ions is responsible for the rapid development of hypocalcemia in these settings. Similar effects occur with excess phosphate[160] or citrate[103,158] intake. This mechanism (calcium complex formation) decreases the ionized [Ca^{2+}], but may or may not reduce the measured total serum [Ca^{2+}]. Other xenobiotics that produce hypocalcemia decrease absorption, enhance renal loss, and/or stimulate calcium entry into cells (Table 16–9).

Symptoms of hypocalcemia consist largely of neuromuscular findings, including paresthesias, cramps, carpopedal spasm, tetany, and seizures. Although ECG abnormalities are common (Chap. 22), life-threatening dysrhythmias are rare. Treatment strategies focus on calcium replacement. When hypomagnesemia or hyperphosphatemia is present, these abnormalities should be corrected or calcium replacement may fail.

■ MAGNESIUM

Magnesium is the fourth most abundant cation in the body (after Ca^{2+}, Na$^+$, and K$^+$), with a normal total body store of about 2000 mEq in a 70-kg person.[129] Approximately 50% of magnesium is stored in bone, with most of the remainder distributed in the soft tissues. Because only approximately 1%–2% of magnesium is located in the extracellular fluid, serum concentrations correlate poorly with total body stores.[130] Magnesium homeostasis is maintained through dietary intake, and renal and gastrointestinal excretion modulated by hormonal effects.[6]

Clinically significant hypermagnesemia is uncommon in the absence of renal failure, except when massive parenteral infusions of magnesium salts overwhelm renal excretory mechanisms. This has been reported with inadvertent intravenous infusion,[18,23,72,112] urologic procedures involving irrigation with magnesium salts,[42,82] and ingestion of large quantities of magnesium-containing antacids[105] and cathartics.[43,51,56] Of concern is iatrogenic overdose from the use of magnesium-containing cathartics used in poison management.[53,83,148] In a series of poisoned patients, a single dose of a magnesium-containing cathartic failed to produce any demonstrable rise in serum [Mg^{2+}].[149] However, patients who received three doses of magnesium sulfate over 8 hours had a significant increase in their serum [Mg^{2+}].[149] Thus the potential for iatrogenic toxicity exists, mandating cautious use of magnesium-containing cathartics, especially in patients with renal insufficiency. Table 16–10 lists xenobiotic causes of hypermagnesemia.

The symptoms of hypermagnesemia correlate with serum concentrations, but depend somewhat on the rate of increase and host factors. At serum [Mg^{2+}] of about 3–10 mEq/L, patients feel weak, nauseated, flushed, and thirsty. Bradycardia, a widened QRS complex on ECG, hypotension, and decreased deep tendon reflexes may be noted. As concentration increases, hypoventilation, muscle paralysis, and

Thiazide diuretics	

ventricular dysrhythmias occur. Serum $[Mg^{2+}]$ greater than 10 mEq/L, and especially those concentrations greater than 15 mEq/L, often cause death.

Hypermagnesemia should be considered a life-threatening disorder. When significant neuromuscular or ECG manifestations are noted, administration of $CaCl_2$ 5–20 mEq intravenously will reverse some of the toxicity.[6,64] Further therapy should focus on enhancing renal excretion by administering fluids and loop diuretics such as furosemide.[64] In the presence of renal failure or inadequate renal excretion, hemodialysis will rapidly correct hypermagnesemia.

Xenobiotic-induced hypomagnesemia is common, but rarely life threatening. Renal losses (caused by diuretics), gastrointestinal losses (caused by ethanol), intracellular shifts due to insulin[101] or β-adrenergic agonists, and complex formation (by fluoride or phosphate) are common.[6] Table 16–10 lists these and other xenobiotic causes of hypomagnesemia. Of note, many causes of hypomagnesemia also cause hypokalemia and hypocalcemia.[5] Therefore, when hypomagnesemia is suspected or discovered, the presence of other electrolyte abnormalities should be sought.

The symptoms of hypomagnesemia are lethargy, weakness, fatigue, neuromuscular excitation (tremor and hyperreflexia), nausea, and vomiting.[27,33] Dysrhythmias may occur, especially in patients treated with cardioactive steroids. Signs and symptoms consistent with hypocalcemia and hypokalemia also may be present.

Treatment involves removing the offending xenobiotic (if it can be identified) and restoring magnesium balance. Although either oral or parenteral supplementation is usually acceptable for mild hypomagnesemia, parenteral therapy is required when significant clinical manifestation is present. When oral therapy is indicated, a normal diet or magnesium oxide, magnesium chloride, or magnesium lactate in divided doses (magnesium 20–100 mEq/d) will often correct the hypomagnesemia.[5,6] When hypomagnesemia is severe or symptomatic,

and renal function is normal, magnesium sulfate 16 mEq (2 g) can be given intravenously over several minutes to a maximum of 1 mEq/kg of magnesium in a 24-hour period.[6,27,80] During any substantial magnesium infusion, frequent serum $[Mg^{2+}]$ determinations should be obtained and the presence of reflexes documented. If hyporeflexia occurs, the magnesium infusion should be discontinued.

SUMMARY

The management of poisoned or overdosed patients must include an evaluation of their fluid, electrolyte, and acid–base status. Abnormalities in acid–base and water balance, and alterations in potassium, calcium, and magnesium concentrations are common in such patients, and often are life threatening. Conversely, the possibility of xenobiotic ingestion or administration must always be considered when patients present with abnormalities of water, electrolyte, or acid–base balance. This is because these abnormalities are frequently caused by therapeutic doses of many drugs. Clearly, an appreciation of the pathophysiology of these abnormalities and a rational approach to their correction are essential for reducing morbidity and mortality. Finally, fluid and electrolyte abnormalities may result from the therapy of poisoned or overdosed patients. Thus, these patients must be monitored and reevaluated as treatment progresses to ensure that iatrogenic fluid, electrolyte, or acid–base disorders do not complicate the clinical course.

CHAPTER 17
PSYCHIATRIC PRINCIPLES

Kishor Malavade and Mark R. Serper

Psychiatric problems may be the cause or the effect of many toxicologic presentations. Suicide attempts and aggressive behaviors are commonly associated with toxicity and can be uniquely difficult to assess and manage. Patient behaviors are often viewed as either totally intentional and deliberate or totally "out of control" and irrational. The truth is usually more complex, with some aspects occurring within the awareness and control of the patient and other aspects either unknown or overwhelming to the patient. This chapter addresses suicide and violence to enable the physician to adopt the appropriate role of both diagnostician and medical decision maker.

SUICIDE AND SELF-INJURIOUS BEHAVIOR

Although suicide may be attempted or accomplished in a variety of settings and by a variety of means it is most typically associated with psychiatric disorders and/or substance abuse, especially ethanol, and is typically accomplished with psychoactive xenobiotics alone or in combination.[37,39]

Suicide is a leading cause of death and injury in the United States and throughout the world. Suicide was the 11th leading cause of death in 2005, with the 32,637 known cases representing 1.3% of the total deaths in the United States that year. The age-adjusted death rate in 2005 was 10.9 deaths by suicide for every 100,000 persons, or 0.0109%.[13] Suicidal ideation and attempts are far more frequent than actual suicide. Recent studies published since 1999 have demonstrated that among individuals age 18 and above, lifetime prevalence rates for suicidal ideation are 5.6%–14.3%. The lifetime prevalence rate for suicidal plans is 3.9% and the lifetime prevalence rates for suicide attempts are 1.9%–8.7%.[13,14]

Although the prevalence of suicide and suicidal behaviors shows significant overlap, one notable area of difference is the consistent pattern of higher rates of suicide attempts among women and of completed suicides among men.[13,14] For adolescents aged 12–17, lifetime prevalence rates for suicidal ideation are 19.8%–24.0%. Lifetime prevalence rates for suicide attempts are 3.1%–8.8%. Twelve-month prevalence rates for suicidal ideation are 15.0%–29.0%. Twelve-month prevalence rates for suicide attempts are 7.3%–10.6%. Twelve-month prevalence rates for suicide plans are 12.6%–19.0%. There are no lifetime data on suicide plans.[14,15,46]

Given that the act of suicide is a statistically rare event in the overall population, it is virtually impossible to predict who will actually commit suicide. It is therefore critical to identify risk factors that increase the likelihood that any individual might attempt suicide, and to identify risk factors that are modifiable. The identification of modifiable risk factors provides opportunities for interventions that may decrease suicide risk. Additionally, there are protective factors that mitigate the risk for suicide, and it is important to assess for the presence or absence of these factors in determining the overall risk for suicide in a patient.

■ TERMINOLOGY OF SUICIDE

The terms and definitions of suicide and suicidal behaviors used in this chapter have been outlined in several reports on the subject.[24,32,54]

The term *suicide* refers to self-inflicted death with evidence (either explicit or implicit) that the person intended to die. The term *suicidal ideation* refers to thoughts of serving as the agent of one's own death. Suicidal ideation may vary in seriousness depending on the specificity of suicide plans and the degree of suicidal intent. The term *suicidal intent* refers to the subjective expectation and desire for a self-destructive act to end in death. The term suicidal plan refers to the formulation of a specific method through which one intends to die. The term *suicide attempt* refers to self-injurious behavior with a nonfatal outcome accompanied by evidence (either explicit or implicit) that the person intended to die. The term *self-harm* refers to self-inflicting of painful, destructive, or injurious acts without intent to die. Lethality of suicidal behavior is the objective danger to life associated with a suicide method or action. Note that lethality is distinct from and may not always coincide with an individual's expectation of what is medically dangerous.

PSYCHIATRIC MANAGEMENT OF SELF-POISONING

Table 17–1 depicts a case of suspected self-poisoning from the starting point of prehospital care through the completion of a comprehensive assessment and treatment planning.

■ FOCUSED PSYCHIATRIC ASSESSMENT

At a relatively early point in the patient's course, when the patient can be cooperative, a focused psychiatric assessment is critical to address specific clinical concerns. A thorough psychiatric consultation is warranted, once the patient is medically stable. The determination that the patient is stable is not solely established on the basis of blood concentrations of a xenobiotic or ancillary medical tests, but rather when the emergency physician or medical toxicologist with an understanding of pharmacokinetics deems it appropriate.[36] Psychiatric examination is not warranted until an altered mental status has cleared. There are several reasons for this approach.

The physician should not unequivocally attribute altered mental status to poisoning or toxicity until the signs of altered consciousness have resolved and cognitive functions have returned to normal. Until that time, other toxic metabolic and structural conditions that might coexist with, or masquerade as, toxicity cannot be excluded. If the patient's cognitive functioning is impaired by xenobiotics critical historical details may be unreliable.[19] It should be understood that much of what the patient reports may be ephemeral, caused by the predictable temporary and reversible effects on mood of these xenobiotics.[9]

A focused assessment is necessary to ascertain elopement risk or decisional capacity. Subacute residual CNS effects of ingestions such as confusion, fatigue, and fear can dispose patients to wander or elope. Additionally, the patient's intentions remain unclear at this point, and the question of unintentional versus intentional exposure to a xenobiotic cannot be completely resolved. For these reasons, a high level of supervision should be maintained, and a patient should not be allowed to leave until an adequate assessment of the patient's mental status is completed. Depending on the architecture and organization of the emergency department (ED) and personnel, it may be sufficient to place the patient in an open area in the direct line of sight of the medical staff. If such an arrangement is not possible, or if the patient is agitated and disruptive, it may be necessary to separate the patient from the general population. Under these circumstances, an individual aide should be assigned to observe the patient on a one-to-one basis. Safe physical and/or chemical restraints may be necessary to prevent further injury to both the patient and the staff.

TABLE 17–1. Case Presentation: Suspected Self-Poisoning

	Case	Evolution			Disposition
Patient course	Patient found in the community unresponsive	Patient monitored in the ED; vital signs stable; still unresponsive	Patient lethargic but cooperative; answers simple questions	Patient fully awake and alert	Evaluation complete
Treatment course	Prehospital	Triage medical assessment	Observation and monitoring	Formal psychiatric evaluation	Treatment planning
Physician course	Patient identification Search for prescription drugs, drug paraphernalia Assessment of cardiac and respiratory function	Orogastric lavage(?) Activated charcoal(?) Diagnostic testing (blood studies, ECG, urine toxicology) Contact collateral sources for history Prior records	Focused psychiatric assessment: elopement, aggressive behavior, decisional capacity, addressing confidentiality, and immediate suicide risk	Comprehensive psychiatric assessment: diagnostic interviewing, risk factors, future risk	Treatments: medication, hospitalization, substance abuse, crisis intervention or family therapy

In general, patients are presumed competent and must consent to treatment, but the issue of decisional capacity frequently arises. Patients may request their discharge, refuse care, or become aggressive. Aggression may arise from lingering effects of ingestion or a xenobiotic-withdrawal, severe anxiety, fear, anger at the loss of autonomy, or the discomfort associated with unpleasant procedures.[52] Although patients may respond to verbal limit setting and repeated explanations of their care, they may also require pharmacologic or physical restraint and involuntary treatment. Patients are not allowed to make poor health-care decisions if their ability to weigh the risks and benefits of the proposed care is limited by cognitive deficits or mental illness. In the setting of toxicity, appropriate care may be provided under the doctrine of implied consent.

The emergency exception to the doctrine of informed consent may also apply in circumstances where self-injury is suspected. The emergency exception permits forcible detention, restraint, medication over objection, and necessary medical care until psychiatric assessment can be accomplished. After the management of the immediate medical emergency and resolution of toxicity, suspected self-injury is sufficient evidence of impaired decisional capacity for the emergency physician to hold a patient for further psychiatric assessment. The emergency physician should document the patient's objections in the patient's medical record and indicate the basis for the determination of diminished capacity.

After the intentionally self-poisoned patient is stabilized, there may be a need for a more thorough assessment of decisional capacity. Psychiatric consultation is appropriate at this stage to help document the degree of impairment, determine the etiology, and predict the likely course.

Immediate Risk After these safety considerations are addressed, the aim of the focused psychiatric assessment moves toward a determination of immediate suicide risk. This examination should answer the following questions: What is the patient's attitude toward lifesaving care? What are the patient's current wishes with regard to living or dying? What are the patient's thoughts about his or her rescue and likely recovery?

These questions can only be answered in the course of a frank discussion between the patient and the emergency physician. The physician should not be concerned about "provoking" further self-injurious impulses by having this vital discussion; many patients will be relieved that the healthcare provider is speaking directly about their distress.

Reliability and Confidentiality Mention should be made here about the difficult issues of reliability and confidentiality with regard to gathering history. Evasiveness, lack of detail, inconsistency, and improbability may lead to an unreliable history. It is appropriate to confront the patient with the implausible aspects of this history and offer an opportunity for the patient to rethink his or her history. This is often successful, although subsequent reports are, of course, equally suspect.

The most important step from the standpoint of both clinical care and risk management is to locate other sources of information to clarify the patient's situation. A careful review of any previous medical and psychiatric records is critical. Any pattern to a patient's presentations such as increasing frequency, more aggravated behavior, or disheveled appearance should be noted.

Collateral contacts are another important source of information, although the level of involvement, sophistication, and reliability of the collaterals must also be taken into account. In the interest of providing necessary medical and psychiatric care for a patient, the ED staff may make contacts that are limited to soliciting information without specific consent. An effort should be made to obtain consent for any broader discussion with family, friends, or other physicians. The patient may express concern about the ED staff contacting a family member or counselor. Any information to be imparted to third parties can be discussed in advance with the patient. The patient may restrict consent to receiving information only and may withhold consent to impart certain information. More caution is indicated in contacting an employer. Although disclosing information about the patient without the patient's consent is a breach of confidentiality, a physician may do so in the interest of protecting the patient.[4]

■ COMPREHENSIVE PSYCHIATRIC ASSESSMENT

The comprehensive psychiatric assessment includes a characterization of the suicidal ideation present, exploration of risk factors, and the formulation of a diagnostic impression. These three elements help to determine the attendant risk and guide treatment planning.[70]

Stress Vulnerability Model The best understanding of suicide at this time is that it results from intrinsic vulnerability factors interacting with extrinsic circumstances. Intrinsic vulnerability may be conferred by a variety of traits such as impulsivity or conditions such as depression, anxiety, and hopelessness. Extrinsic factors include stressful life

events, access to lethal means, and a host of other factors, positive and negative.

Characterization of Suicidal Ideation The core of the suicide risk assessment is a detailed discussion of the patient's suicidal thoughts and urges. This must be included in every mental status examination. It is important to establish rapport and introduce the topic in an appropriate context in order to improve the patient's candor. This evaluation requires significant time and skillful interviewing, for which there is no substitute. This approach will enhance the therapeutic quality of the interview as well as its reliability. For example, almost everyone has had some period in life when he or she was discouraged. The clinician may spend a few moments talking with the patient about the point in life when the patient was most disheartened. This is done by asking the patient if he or she has been feeling "down" lately; and if the patient has, by asking if this is the worst the patient has ever felt. If the patient denies recent depression altogether, or indicates that this is not the worst, it is helpful, for several reasons, to ask the patient to describe the point in his or her life when he or she felt worst. Depression may fluctuate markedly, and characterizing the worst period assures that a prior history of major depression will not be overlooked.

At some point, the physician should ask if, during that worst period in the patient's life, he or she ever felt that perhaps things would never get better (hopelessness), that he or she could not go on (helplessness), or perhaps that he or she would be better off dead (passive suicidal ideation). If failing others was involved in the patient's demoralization (guilt), the physician should ask if the patient had ever felt that others would be better off without him or her. These are common thoughts that most people can endorse without much difficulty and lay the groundwork for discussing more troublesome ideas in the suicidal spectrum. Ultimately, the patient must be asked directly if he or she has ever felt like killing himself or herself (active suicidal ideation). Nothing else will do. The more generic form, "hurting" himself or herself, which might seem to cover more, is in fact confusing to patients—even those who wish to die do not usually consciously intend to be hurt in the process. The latter is more typical of multiple suicide attempters than suicide completers.

For those patients who have felt like killing themselves at some point, the next step in this scenario might be to establish how the patient is currently and to compare this to a prior episode(s). One dimension to assess is the progression from passive to active suicidal ideation. Suicidal feelings may take the form of a relatively inchoate wish to die, perhaps from a fatal disease or injury, and then proceed to consideration of various active means of hastening death. Planning might range from fleeting thoughts or images of a variety of methods from which the patient recoils, to a more detailed consideration of a particular, realistic method of choice, to serious planning concerning acquisition of the means, and so-called last acts. At some point the patient goes beyond thinking to acting by hoarding pills or completing his or her will. An astute family member may observe a series of odd conversations including phone calls to distant friends and family members as the suicidal individual begins to implement the plan with a series of vague farewells. In psychological autopsy studies, approximately 50%–70% of those who completed suicides gave some warning of their intention, and 30%–40% of individuals who completed suicides disclosed a direct and specific intent to kill themselves.[6,57]

Other dimensions of suicidal ideation to assess include frequency, urgency, chronicity, reactivity to positive and negative external events, and subjective distress. Table 17–2 presents a schema for the detailed characterization of suicidal ideation.

The communication of suicidal ideas either directly or indirectly should not be misconstrued as a "cry for help" and hence evidence of lower risk. Communication is probably related to the degree of preoccupation with morbid thoughts and to personality characteristics that dispose individuals to revealing their thoughts to various degrees.[40]

■ RISK FACTORS FOR SUICIDE

The goal of the suicide risk assessment is to identify factors that may increase or decrease the level of suicide risk in a particular patient and develop a plan that addresses the modifiable factors that contribute to suicide risk and the overall safety of the patient. The clinical determination of suicide risk, at the culmination of the suicide assessment, ultimately is a clinical judgment, since no study has identified one specific risk factor or set of risk factors as specifically predictive of suicide or other suicidal behavior. Despite the lack of such predictive factors for suicide, there is a large body of evidence on the multiple risk factors that contribute to suicide risk, and a growing body of evidence on protective factors. Knowledge of this evidence is critical to informing the clinical determination of suicide risk.

TABLE 17–2. Characterization of Suicidal Ideation

Dimension	Benign	Intermediate	Malignant
Onset	None, acute	Chronic, stable	New or fluctuating
Frequency	Occasional	Daily	Constant
Persistence	Fleeting thoughts	Persistent thoughts	Preoccupation
Urgency	Disinterested	Engaged	Intense
Complexity	Simple	Some detail	Elaborate
Activity	Passive ideas	Plans without action	Action
Emotional response	Death repellent	Ambivalent	Death desirable
Circumstances	Victim identifies one clear precipitant	Several complex contributory stressors	Either noncontributory or overwhelming stressors
Alternatives	Some, realistic	Few, problematic	Seems hopeless
Insight	Recognizes remediable psychological problem	Overvalued ideas present, temporarily reassured	Morbid delusions present, reassurance impossible
Intent	Opposed to suicide	Suicide acceptable but prefers to live	Resolutely suicidal

The risk of suicide increases 50 to 100 times within the first 12 months after an episode of self-harm compared to the general population risk. About half of all people who commit suicide have a history of self-harm, and this ratio increases by 60% in juveniles.[5]

While much is known about the risk of suicide for various groups over time, little can be said with certainty about an individual patient at a particular point in time. There is no one type of "typical" suicidal patient or clinically useful test or rating scale at this time. Albeit, while one investigator was able to prospectively identify almost all of those who ultimately died by suicide (97% sensitivity), the investigator over-predicted suicide by almost half (56% specificity).[54] However, there is also no patient in distress for whom the risk of suicide is so remote that it need not be considered. Assessment of the potentially suicidal patient begins with a screen for psychiatric illness, substance abuse, and history of self-harm.

Psychiatric Illness and Suicide   One major consideration in suicide risk assessment is the occurrence of severe mental illness. Suicide risk for individuals with severe mental illness is 20–40 times higher than it is for the general population.[41] Psychological autopsy studies in the United States and Europe over the years have consistently revealed major psychiatric illness to be a factor in suicide, present in 93% of adult suicides.[38,41,55,58] This is also true of those who make medically serious suicide attempts.[8,38] In particular, prospective cohort studies and retrospective case control investigations have revealed clinical depression and bipolar disorder to dramatically increase suicide risk.[33,40,69] For mood disorders, factors correlated with acute suicidality include current depression, severe anxiety, anhedonia, panic, insomnia, ambivalence, and acute alcohol abuse.[40] After mood disorders, chronic alcoholism is the most commonly reported disorder; it is present in approximately 20% of cases. Moreover, alcoholic patients who also suffer from periodic episodes of depression are at more risk for suicide than patients who present with either disorder separately. As a result, any assessment conducted on a patient with a substance abuse history must include an examination of symptoms of major depression or bipolar illness.[25,71]

Schizophrenic patients are at risk for suicide at rates comparable to major depression and are 20 times more likely to attempt suicide than the general population.[68] Approximately 50% of schizophrenic patients will attempt suicide and 13% of schizophrenic patients will complete suicide.[10,68] Additionally, between 5% and 18% of patients with severe borderline personality disorder (especially those patients with comorbid depression) ultimately kill themselves.[27,38,63]

The ability to treat psychiatric disorders such as mood disorders, schizophrenia, and alcoholism suggests that most suicides are preventable. Indeed, a suicide prevention program directed at general practitioners in Sweden was able to demonstrate prevention based on the detection and treatment of depression.[56] The Centers for Disease Control and Prevention (CDC) reported that psychiatric problems in US emergency departments represented approximately 3% of the visits, which is significantly lower than the national psychiatric rate of 20%–28%.[12] This suggests significant psychiatric underdiagnosis is occurring in the ED. Emergency physicians, consequently, must enhance the comprehensive nature of their psychiatric screening in order to identify suicidality and concomitant mental disorders in presenting self-injurious patients.

Demographic Risk Factors   Factors have been identified empirically that place groups of individuals at high risk for suicide; although this level of prediction is actuarial and reflective of groups rather than individuals, knowledge of these risk factors is important.

Table 17–3 presents risk factors that are associated with increased suicide risk. Table 17–4 presents protective factors that are associated

with mitigating suicide risk. Risk factors are additive, with suicide risk increasing with the number of risk factors that are present, but certain risk factors interact synergistically to increase suicide risk. The combined risk of concomitant depression and alcohol intoxication may be greater than the sum of the risk associated with each in isolation. Certain risk factors, such as a recent suicide attempt associated with a high degree of lethality, or the presence of a suicide note, should be considered serious on its own, regardless of whether other risk factors are present.[20]

Although not specifically predictive, suicide is statistically more common in men than women and in whites than in nonwhites. Younger black men, however, have approximately the same suicide rate as white men of the same age. Suicide rates for both black and white adolescents (15 to 19 years of age) are increasing. In contrast, suicide rates in the those over 65 years of age have decreased 3-fold since 1940, but still occur in disproportionately high numbers.[41,69]

Previous suicide attempts are a significant risk factor. However, those who attempt suicide appear to be a somewhat different group demographically and diagnostically. Parasuicidal behavior is more common in 25- to 44-year-olds than in the elderly, and more common in women than men. Existing data also indicate that those who unsuccessfully attempt suicide are equally prevalent across racial and ethnic groups.[24,49] Many individuals who kill themselves seem to do so on the first attempt. Although that suicide attempt is still the strongest predictor of suicidal outcome, only about 1 in 10 attempters is ultimately successful.[34,54] Multiple attempters also appear to have higher risk than those who make a single attempt.[32,64] Medically serious attempts may be a better marker of risk. Those who make serious attempts tend to share with completers a higher rate of serious mental illness.[7]

A number of avenues of inquiry suggest that violent suicide attempts are associated with a persistent deficiency in brain serotonin levels. Impulsive types of aggression and impulsive suicidal behavior have been linked to serotonergic dysfunction in prefrontal cortical regions of the brain.[21] This deficiency has been measured in postmortem brains and spinal fluid of suicide victims and survivors of violent attempts compared to nonviolent attempts and to other patients. Hopelessness has also received a significant amount of study as a potential predictor of suicide. However, hopelessness appears to have high sensitivity but low specificity.[8] Identifying hopelessness as a problem also suggests possible interventions.

Ultimately, most persons belonging to a high-risk group do not commit suicide, and some individuals with no apparent risk factors do. Many risk factors are not modifiable. This type of information, then, weighs most heavily in the assessment in the absence of other more specific data, early in the hospital course, or in the case of the uncooperative or hostile patient. The best foundation for treatment planning and clinical decision making is direct examination and clinical diagnosis.[30]

■ TREATMENT

Following the comprehensive psychiatric assessment, the next step is deciding on treatment alternatives. Any patient who has made a suicide attempt must be considered to be at risk, and some further intervention is warranted. The risk of a subsequent lethal attempt is approximately 1% per year over the first 10 years. The risk is highest in the first month to 1 year.

The treatment alternatives available will depend on the psychiatric sophistication of the staff available to the ED at any given time. This section describes the commonly used interventions in the ED; they can be used singly or in combination.

TABLE 17–3. Factors Associated with an Increased Risk for Suicide

Psychiatric Risk Factors	Neurological and Medical Factors	Sociodemographic Factors	Genetic and Familial Factors
Major depressive disorder	Diseases of the nervous system	Male gender (suicide)	Family history of suicide (particularly in first-degree relatives)
Bipolar disorder	Multiple sclerosis	Female gender (suicide attempts)	Family history of mental illness, including substance use disorders
Schizophrenia	Huntington disease	Widowed, divorced, or single marital status, particularly for men	
Alcohol use disorder	Brain and spinal cord injury	Elderly age group	
Other substance use disorders	Seizure disorders	Adolescent and young adult age groups	
Alcohol intoxication	Malignant neoplasms	White race	
Personality disorders	HIV/AIDS	Gay, lesbian, or bisexual orientation	
Concomitant disorders	Pain syndromes	Recent lack of social support (including living alone)	
Helplessness	Functional impairment	Unemployment	
Hopelessness		Drop in socioeconomic status	
Impulsiveness		Domestic partner violence	
Aggression, including violence against others		Recent stressful life event	
Agitation		Childhood sexual abuse	
Factors related to current or past suicidal behavior		Childhood physical abuse	
Suicide attempts		Access to firearms	
Suicidal ideation			
Suicidal plans			
Suicidal intent and lethality			

Medications can be used acutely in the treatment of severe anxiety or psychosis; however, in the case of antidepressants, a period of weeks is required for therapeutic effect, so their immediate use is not indicated in the ED. In fact, there are concerns about prescribing medications with relatively high potential for lethality in overdose, such as the cyclic antidepressants and nonselective monoamine oxidase inhibitors, to persons who have recently attempted suicide. However, newer antidepressants, particularly the selective serotonin reuptake inhibitors (SSRIs), can be used as first-line drugs for treatment of most depressions and are relatively safe in overdose. Nonetheless, the initiation of antidepressant therapy by the nonpsychiatric physician is not recommended unless a tight linkage can be made between discharge and immediate (within days) aftercare by either a community outreach team or a crisis clinic.

Patients with depressive disorders may suffer from significant anxiety, as may patients with overwhelming situational stressors such as job loss, new financial hardship, bereavement, or divorce. The prescription of a short course of a benzodiazepine may provide significant relief to the patient in crisis.

After the patient's immediate symptoms have been treated in the ED, the next treatment decision is determining the setting in which further treatment may safely be provided. Not all patients with suicidal ideation or even significant attempts necessarily require hospitalization, and there is still a substantial stigma attached to psychiatric hospitalization. In general, hospitalization should be used if less restrictive measures cannot insure the patient's safety. If significant doubt exists about the safety of outpatient treatment, the patient should be held in the ED for further evaluation, admitted to a general hospital with close nursing supervision, or admitted to a psychiatric unit. "Holding beds" now available in some larger psychiatric EDs are ideal for this purpose. Some localities may also have crisis outreach services that follow the patient after discharge from the ED and improve appropriate monitoring and continuity of care.

Patients most likely to respond to interventions in the ED are individuals who, until recently have been stable but who, as a result of some external event, find their way of life threatened. This acute change results in a painful state of anxiety and the mobilization of some combination of adaptive and maladaptive coping strategies. Finally, a second event, the precipitant, intensifies the anxiety to the point that the patient cannot tolerate the instability and is thrown into crisis.

TABLE 17–4. Factors Associated with Protective Effects for Suicide

Children in the home
Effective clinical care for mental, physical, and substance abuse disorders
Pregnancy
Family and community support (connectedness)
Religious beliefs and cultural practices
Positive social support
Skills in problem solving and conflict resolution

The patient then feels desperate and may be completely immobilized or vulnerable to various strong impulses including the impulse to run away, strike out at someone else, or kill himself or herself. Reality testing is preserved, and no major psychiatric syndrome is present. The patient accurately perceives his or her situation, understands that the current reaction is a psychological problem, and is highly motivated to obtain help. The crisis may last for a matter of hours or weeks prior to the ED presentation and will ultimately resolve. Such patients respond well to crisis intervention and may actually undergo some positive development in the course of treatment.

By contrast, patients whose condition has been deteriorating for some time in the absence of significant stressors, and who appear on examination to be suffering from severe depressive symptoms, are unlikely to benefit rapidly from supportive techniques. If such patients present with suicidal ideation or attempts, it will be difficult, though not impossible, to manage them outside the hospital.

Outpatient settings have the advantage of maintaining the patient's functioning as much as possible. Work and childcare responsibilities, financial obligations, and social relationships are not disrupted. Unnecessary regression is halted. The patient is able to assume more responsibility for his or her outcome, and independence helps preserve self-esteem. These individuals remain closer to and more engaged with the people and situations with whom and with which they must learn to cope. Their morale may be rapidly improved by the combination of support, planning, and modest early treatment successes.

In some cases, though, these same factors may be disadvantageous. Routine tasks may seem overwhelming. High levels of conflict may render major relationships at least temporarily unworkable. Inpatient settings offer the advantage of respite, high levels of structure, more intensive professional and peer support, constant supervision, and, usually, more rapid pharmacologic and psychosocial intervention.

The choice of inpatient or outpatient setting will depend on the balance of strengths and weaknesses of the patient, the involvement and competence of family or friends, the availability of a therapist in the community, and the ongoing stresses in the patient's life, and this decision is best made by a psychiatrist. Because a psychiatrist is not always present in many facilities, a trained mental health professional should be on call to every ED. This may be a psychiatric social worker, nurse clinician, or psychologist. When such services are not available, it is appropriate to detain patients in the ED until a practitioner with specific competence is available or to transfer the patient to another facility for evaluation. Every state has laws that provide for the involuntary commitment of the mentally ill under circumstances that vary from state to state. Any acute, deliberately self-injurious behavior would generally qualify. Chronic, repetitive dangerous behavior that is not deliberate, such as frequent unintentional opioid, alcohol, sedative-hypnotic, or illicit "recreational" psychoactive drug overdoses, warrants careful evaluation. In the absence of psychiatric illness, involuntary treatment is usually not necessary. The practitioner should be familiar with the criteria for commitment and the classes of healthcare providers so empowered under state law.

There are other treatment interventions that can be provided in the emergency setting, including crisis intervention, substance abuse counseling, and family therapy. A single session in the ED may be sufficient to defuse a crisis or to spur the drug-abusing patient to seek help. Alternatively, the intervention may be initiated in the ED and continued as an outpatient.

Crisis intervention is a brief, highly focused therapy that seeks to deconstruct how a crisis occurred, with the intent of examining the patient's role. Often, patients have distorted perceptions of the crisis, and a gentle "correction" of catastrophic thinking can be extremely helpful.

The crisis is presented to the patient as an unfortunate and perhaps tragic experience that the patient can overcome. Ideally, the patient should have a relief of symptoms and learn how crises may be avoided in the future. This insight intervention will likely fail for patients with severe depression because of the presence of profound hopelessness. It is most successful for patients who give a history of high functioning just prior to the crisis.

Substance abuse treatment is ultimately an intermediate (weeks to months) to long-term (months to years) intervention. However, there are powerful initial steps that the emergency physician can take. Central among these is confronting the patient about the medical consequences of substance use. This can take the form of discussion only, or the physician can invite the patient to examine clinical laboratory results or view remarkable clinician/diagnostic findings (hepatomegaly, repeated fractures from falls, increased liver enzymes, or evidence of "silent" past myocardial infarction). There is little to be lost from a respectful but blunt confrontation of the patient's deterioration, and he or she may listen to a physician rather than family or friends. Peer counseling is particularly useful in addictive disorders; if possible, patients should be referred to community 12-step programs such as Narcotics Anonymous and Alcoholics Anonymous. Family therapy can occur as a series of sessions over the long term or can be useful in the emergency setting to defuse a crisis, reinstate social supports for the patient, or educate families about mental illness. It is most important to respect a patient's request as to the level of family involvement, because in the emergency setting a patient may be either too angry or ashamed to confront his or her family. It is prudent to defer to the patient's wishes, and to assure the family that the patient is safe and that you will keep them as informed as confidentiality and discretion allow at a later date.

VIOLENCE

Aggression also presents unique challenges to the emergency physician. Moreover, aggression is intimately related to suicidal behavior. Chronic aggression and impulsivity are risk factors for suicidal behavior. Like suicidal patients, aggressive patients are difficult to treat and they tend to elicit strong negative reactions in ED personnel.[60] In one study of violence in the ED, directors of emergency medicine residency programs were surveyed as to the frequency of verbal threats, physical attacks, and the presence of weaponry in the area. Of the 127 institutions surveyed, 74.7% of the residency directors responded; 41 (32%) reported receiving at least one verbal threat each day; moreover, 23 (18%) reported that weapons were displayed as a threat at least once each month. Fifty-five program directors (43%) noted that a physical attack on medical staff occurred at least once a month.[43] Another study involved a retrospective review of university police log records and ED staff incident reports to examine the problem of violence in the ED setting. Almost 75% of the incidents occurred during the evening or night. Of the 686 episodes of violence in this study, more than 25% required physical restraint or removal from the premises. In addition, it was found that the police responded to the ED nearly twice daily.[53] These studies underscore the need for timely identification of the violent patient, as well as appropriate management for this diagnostically heterogeneous group.[22] The assessment and management of the violent patient should include provisions for patient and staff safety as well as a thorough search for the cause of violent behavior.[60] This section addresses the differential diagnosis of violent behavior, the pharmacotherapy of aggressive and/or agitated behavior, and the use of seclusion and restraint. It also provides an overview of potential risk factors for violent behavior.

STRESS-VULNERABILITY MODEL OF AGGRESSION

As in the case of suicide, there are many and varied causes of violent behavior, some more social and some more medical in nature. The stress-vulnerability model suggests that violence should be considered as the outcome of a dynamic interaction among numerous factors both intrinsic and extrinsic to the individual, some of which promote and some of which ameliorate the potential for violent behavior at any given moment. This is the stress-vulnerability model. Education may provide alternatives to violence, but xenobiotic-induced delirium may cause an otherwise nonviolent person to misinterpret healthcare efforts, in which case education is of no benefit at that time. Hence, the individual becomes violent under circumstances that would not normally be sufficient to provoke a violent outburst. Some patients, on the other hand, come from cultures in which aggressive behavior is more acceptable, and these patients require little stress or provocation before responding in what can be perceived as aggression by western cultural standards.

In the ED, likely medical sources of vulnerability include metabolic derangements, exposure to xenobiotics—both licit and illicit, withdrawal syndromes, seizure disorders, head trauma, psychotic states, and personality disorders. Additionally, patients with severe pain, delirium, or extreme anxiety can respond to the efforts of emergency personnel with resistance, hostility, or frank aggression.

PREDICTION

Research on risk factors for community violence may not apply to the prediction of inpatient violence. Some researchers have postulated that violence committed outside the hospital may not be predictive of inpatient violence and that hospital violence may result from the interaction of patients with specific factors found in the hospital environment.[35,60] Other studies are contradictory.[62] Consequently, prior violence is not a perfect predictor of future violence. Other factors, such as mental illness and substance abuse, need to be examined in order to make meaningful predictions of inpatient violence for each individual case.[60] One study found that the most common types of hospital violence were incidents of aggression against objects in the hospital (56.7%), violence directed against the hospital staff (27.8%), and violence directed against other patients (14.4%).[61] In this study, men were not found to be committing significantly greater incidents of violence than women. Other studies concur that men are not necessarily more of a risk for inpatient violence than women inpatients. For example, researchers examining inpatient violence found that close to half of the violent incidents were committed by women patients,[42,55] and the number of violence-related injuries committed by men and women inpatients were almost proportional to the ratio of men and women inpatients on the unit. The conclusion was that gender should not be considered a risk factor for inpatient violence. Long hospitalization was not considered a factor predictive of violence for the majority of inpatients. As with outpatient violence, the correlation of violence with younger age appears to hold true in the inpatient setting.[48,55,56]

SUBSTANCE USE

The association between substance use and violence is well established. Alcohol is found in the offender, the victim, or both in one-half to two-thirds of homicides and serious assaults.[16,55] Substance abuse is seldom the sole cause, but it may contribute to violence in a number of ways. The direct pharmacologic effects include disinhibition and misinterpretation, suspiciousness, or paranoia. Psychological effects of substance use include cultural expectations of appropriate behavior under the influence and the ability to excuse or disavow inappropriate

behavior that occurs while intoxicated. Substance use then interacts with other physiologic, cognitive, psychological, situational, and cultural factors including any underlying mental illness. A tripartite model has been described: (1) systemic violence related to drug distribution, (2) economic compulsive violence associated with the criminal activity necessary to sustain a drug habit, and (3) psychopharmacologic violence resulting from the direct effects of the particular xenobiotic.[29,31]

MENTAL ILLNESS

The relationship between mental illness and violence is also complex. Efforts made to destigmatize mental illness have confused the issue, but it seems clear that mental illness is associated with an increased risk for violence.[55] In one large epidemiologic study, the prevalence of violence for those with no disorder was 2%. Schizophrenia was associated with an 8% rate of violent behavior, and other mental disorders all had similar prevalences of approximately 12%. But of all respondents reporting violent behaviors, 42% had a substance use disorder. Substance use more than tripled the rate of violence for individuals with schizophrenia. Mental illness appears to reduce the threshold for aggression, and the more comorbid conditions present, the greater the risk.[51,65,66]

Researchers consistently find a greater prevalence of personality disorders among violent inpatients than among nonviolent inpatients.[50,52] However, antisocial personality is the condition most strongly associated with both substance use and aggression. In one study, when the history of juvenile deviance was controlled for alcohol, the drug most commonly associated with violence, accounted for only 2% of the violent behavior.

In conclusion, some aggressive behavior is attributable to the direct pharmacologic effects of xenobiotics, but probably represents only a modest fraction. Substance use is also a part of the setting of violent behavior in the community, a coincidental part of the lifestyle of violent individuals, and both substance use and violence are related to common underlying characteristics such as a character disorder.

MEDICATION NONCOMPLIANCE

Many research studies currently list medication noncompliance as a risk factor for violence that is as serious as substance use or mental illness. One such study associated medication noncompliance and substance use with increased violence risk in the mentally ill.[67] It suggested that medication noncompliance may lead to self-medicating through the use of illicit xenobiotics, and substance use may lead to further medication noncompliance. These two factors together may then have the effect of increasing violence for the mentally ill. This study also suggested that low insight into their illness can be associated with greater violence. However, they found that poor insight was correlated with substance use and medication noncompliance, so it is unclear if poor insight is truly predictive. These findings have been replicated.[66]

Patients entering the ED who did not adhere to their medications as outpatients may be more of a risk for inpatient violence. Furthermore, inpatients who refuse to adhere to medication prescribed in the hospital also are more of a risk for violence, especially when comorbid with substance abuse disorders.

ADDITIONAL FACTORS IN AGGRESSIVE BEHAVIOR

Many of the factors correlated with aggression are easy to observe and monitor in the hospital. However, some additional factors that influence violent behavior may not be as easy to detect. For example, one study examining violent behavior found that most violent incidents in the hospital occur on Mondays and Fridays, with very few incidents on weekends. These violence research investigators suggested that the

analysis was comparable in the general population as Mondays and Fridays have special significance in that the work-week and weekends are usually less stressful. This finding illustrates the point that seemingly minor social stressors can be as conducive to violent behavior as any other factor.

Furthermore, researchers have postulated a seasonal variation of violence.[18] There is an increase in the frequency of assaults by inpatients during the winter months, and it has been hypothesized that increased population density, cold temperature, and less sunlight during the day could account for the increased violence. This finding is in contrast to the literature on outpatient violence, which has reported greater incidence of violence during the warmer months.[5] However, this same review conceded that any extreme temperature could evoke aggressive feelings and frustration. Yet another study examined the relationship between temperature and violence and found that more aggressive acts occur during the summer months, both in the hospital and in the community.[26] They cited several explanations, one of which was that the high rate of staff turnover, as vacations are taken, disrupts the social networks that the patients have established, evoking aggressive feelings.

Although it is unclear whether the cold can provoke aggression as much as it has been established that heat can, it does seem clear that overcrowding and social stressors can lead to violent behavior. If the effects of temperature and social stressors (eg, holidays) correlate so drastically with violence in the community, it is likely that such effects would have even more impact when comorbid with severe mental illness, substance use, or any of the other risk factors of aggression.

■ ASSESSMENT

The comprehensive evaluation of the violent patient should include a complete physical examination. The examination may reveal the underlying cause of the violent behavior as well as insuring the treatment of any secondary patient injuries. Laboratory analysis may include blood chemistries (thyroid-stimulating hormone, glucose, electrolytes including calcium and liver enzymes), a complete blood count, lumbar puncture, and neuroimaging as guided by the examination and clinical history.

Illicit xenobiotic and alcohol use often present with symptoms of violence. Acute cocaine toxicity can produce extreme psychomotor agitation, delirium, and transient psychosis characterized by paranoia and hallucinations; a clinically indistinguishable syndrome can occur following the use of amphetamines. Phencyclidine toxicity is manifested by assaultiveness, muscle rigidity, dysarthria, nystagmus, autonomic instability, and ataxia. Alcohol intoxication is characterized by typical signs of cerebellar dysfunction such as slurred speech, gait ataxia, and incoordination; however, patients who are intoxicated are also at risk for violent behavior. Cannabis does not typically produce violent or aggressive behavior but paranoia can occur with intoxication and can secondarily promote reactions of extreme fear associated with distorted perception, as can occur with lysergic acid diethylamide (LSD) and psilocybin, particularly in the naive user (see Chaps. 77–85)

Withdrawal syndromes from specific xenobiotics can also promote aggressive behavior as a consequence of physical discomfort or anticipatory anxiety. Opioid withdrawal is characterized by myalgias, rhinorrhea, and piloerection with a clear sensorium, whereas alcohol, benzodiazepines, and barbiturates share a common syndrome of autonomic hyperreactivity, seizures, and subsequent delirium. Patients suffering from any of these signs and symptoms may become aggressive, verbally abusive, or threatening. Prompt recognition of these syndromes and immediate treatment can prevent some aggressive outbursts. Because drug use is often concealed, is difficult to ascertain on clinical grounds, and frequently contributes to violent behavior, urine and blood toxicologic studies may be useful to enhance the understanding and long-range treatment of some patients[55] (see Chaps. 14, 28, and 78).

Delirium can be a cause of aggression. Patients are often suddenly confused, frightened, or frankly psychotic as a result of impaired perception. Patients may require sedation or physical restraint in order to prevent injury to themselves as well as staff.

Although persons suffering from psychotic disorders are not generally aggressive, there are aspects of the psychosis state that place patients at risk for aggressive behavior. Paranoid ideation can serve to promote misperceptions of impending bodily harm ("They're trying to kill me"), sexual victimization ("Men and women are raping me"), and humiliation ("Everyone is laughing at me"). It follows that these fearful perceptions might provoke violent reactions in a patient. Hallucinations can cause aggression, either as a result of command hallucinations or in reaction to the anxiety and irritation that patients experience with loud or persistent auditory hallucinations ("hearing voices"). Patients with either borderline or antisocial personality disorder are at risk for violent acting out as a result of poor impulse control.

Violence risk is also associated with cognitive dysfunction. Both acute mental illness and chronic substance use can result in neurologic impairment. Psychiatric patients with compromised cognitive abilities such as impaired attention, memory, or executive functioning such as reasoning and planning are found to be at increased risk for violence.[55] Patients presenting with cognitive impairment may also be at increased risk for committing acts of violence in the ED.

■ TREATMENT

The acute pharmacotherapy of violent behavior is directed simply at reducing the level of arousal. A recent review of this issue proposed a model for the efficient use of medication for the control of episodic, as opposed to chronic, agitation and aggression.[2] In this model, agitation and violent outbursts are viewed as transient disturbances of the usual treatment relationship between the physician and patient. Pharmacotherapy and seclusion or restraint are to be used only as needed to restore that relationship, for the benefit of the patient as well as other members in the environment. The restoration of the treatment relationship is necessary in order to take measures to understand and address the cause of the agitation, with the input and consent of the patient, thus preventing future incidents. For this reason, sleep is considered an undesirable use of medication. Sleep delays, rather than promotes, assessment, may further frighten or anger the patient, and does not even guarantee elimination of the agitated state on awakening.

As aggression derives from varied and multiple etiologies, it follows that there is much debate about the specific sedative that should be used, the route of administration, and the dosing interval. Studies examining the treatment of aggression and/or agitation have included such diverse populations as schizophrenics, acutely intoxicated patients (alcohol), trauma patients, postoperative patients, patients in alcohol withdrawal, and patients with presumed personality disorders. Treatment settings for these studies included psychiatric inpatient units and intensive care units, and the ED found that both benzodiazepines and antipsychotics resulted in rapid control of agitation and aggression.[11,23,40,42]

It seems, however, that there are specific clinical situations when benzodiazepines and antipsychotics might be preferentially used. Haloperidol has been safely used in the treatment of agitation and aggression in patients with psychoses, acute alcohol intoxication, and delirium.[1,11,40,42] The drug can be administered orally, intravenously, or intramuscularly. Dosing intervals range from 30 minutes to 2 hours, with a usual regimen of haloperidol 5 mg given every 30–60 minutes; most patients respond after 1–3 doses. The dose of haloperidol needed to achieve sedation rarely exceeds a total of 50 mg in acute management.[44,45]

Benzodiazepines are also quite effective for sedation; their use has been examined in patients with psychoses, stimulant intoxication, sedative-hypnotic and alcohol withdrawal, and postoperative agitation.[28,47]

Diazepam may be given as 5 to 10 mg IV, with rapid repeat dosing titrated to desired effect. Because diazepam is poorly absorbed from intramuscular sites, its route of administration is either intravenous or oral. Lorazepam 1 to 2 mg may be given orally or parenterally and repeated at 15- or 30-minute intervals, respectively, until the patient is calm (see Antidotes in Depth A24: Benzodiazepines). Benzodiazepines may have a unique role in the treatment of agitation secondary to cocaine intoxication (Chap. 76). Antipsychotics, particularly low-potency antipsychotics, are known to lower the seizure threshold in animals, so their use for patients with cocaine or amphetamine toxicity, or alcohol or sedative hypnotic withdrawal should be avoided. Although some studies suggest that the combined use of lorazepam with antipsychotics in patients with known psychiatric illness and delirium afforded relief of psychotic symptoms while allowing for a reduced dose of antipsychotic medications,[1,17,59] the authors generally discourage the combined use of these drugs in cases of unclear etiology and favor the predictable pharmacodynamics of intravenous diazepam or midazolam. Concerns regarding respiratory depression mandate careful observation of patients receiving sedation with any xenobiotic.

■ PHYSICAL RESTRAINT

Isolation and restraint are also used in the treatment of violent behavior. Isolation or seclusion can help to diminish environmental stimuli and thereby reduce hyperreactivity. However, a few aspects are worth mentioning: Because seclusion is defined by a condition of very limited interactive and environmental cues, it is not indicated for patients with unstable medical conditions, delirium, dementia, self-injurious behavior (cutting, head banging), or who are suffering extrapyramidal reactions as a consequence of antipsychotic medication.[3] Restraint is used to prevent patient and staff injury. All facilities should have clear, written policy guidelines for restraint that address monitoring, provisions for patient comfort, and documentation.

■ TRAINING

Finally, training in the management of aggression helps to reduce violence and injuries through the early identification of impending episodes of violence, use of verbal techniques to defuse incidents, and appropriate physical techniques to minimize injuries in those that occur. It is necessary for healthcare providers to maintain their skills through training and to advocate for continuing medical education on this topic at the workplace.[10]

SUMMARY

Both violent and suicidal behavior in the ED may be the cause or the effect of many toxicologic presentations. Patients presenting with suicidal or aggressive behavior pose unique problems for the clinician who must make appropriate assessment and management decisions. It is incumbent on all emergency physicians to screen patients for psychiatric emergency presentations as part of a comprehensive screening for self-harm.

Identifying risk factors for suicide and aggression can aid the clinician in employing preventive or early intervention strategies in the ED. Important risk factors for both suicidal and violent behavior include past history of the behavior, comorbid mental illness, drug and alcohol intoxication, and young age. Mental status examination for suicidality should focus on extrinsic factors such as current ideation, intent, lethality of plan, current life stressors, as well as intrinsic vulnerability factors such as comorbid mental illness, feelings of hopelessness, and impulsivity. In terms of violence risk assessment, drug and alcohol intoxication, mental illness, and psychiatric medication noncompliance (alone or in combination) are robust predictors of aggressive behavior in the ED and other inpatient settings. Early detection and rapid intervention for patients at risk for suicide or violence is, to date, the best means for preventing injury or death.

CHAPTER 18
NEUROLOGIC PRINCIPLES

Rama B. Rao

INTRODUCTION

The central nervous system (CNS) coordinates responses to the fluctuating metabolic requirements of the body and modulates behavior, memory, and higher levels of thinking. These functions require a diversity of cells: astrocytes, neurons, ependymal cells, and vascular endothelial cells. Disruption or death of any one cell type can cause critical changes in the function or viability of another. This cellular interdependence, along with the high metabolic demands of the CNS, make neurons especially vulnerable to injury from both endogenous neurotoxins and xenobiotics. Endogenous neurotoxins like the metals iron, copper, and manganese, are substances that may be critical to CNS function, but are harmful when their penetration into the CNS is poorly controlled.

The understanding of the normal chemical and molecular functions of the CNS is limited at best. Interestingly, cellular mechanisms have sometimes been revealed by investigating xenobiotic-induced neuronal injuries.[38,66] For example, the pathophysiology of Parkinson disease, which affects movement and motor tone, was elucidated by the inadvertent exposure of individuals to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). The mechanisms of axonal transport were elucidated by investigations of the effects of acrylamide exposures in human and animal models.[57] The neurodegenerative changes of amyotrophic lateral sclerosis have a promising xenobiotic model in β-methylamino-L-alanine (BMAA), a neurotoxin found in the cyanobacteria associated with cycad plants ingested by the Chamorro people of Guam.[67]

There are few minimally invasive methods available to investigate xenobiotic-induced CNS injury. Biomarkers are usually nonspecific and not readily available. Xenobiotic concentrations of blood and urine rarely reflect tissue concentrations of the CNS.[58] Cerebrospinal fluid may be useful in excluding CNS injury from infection, hemorrhage and inflammatory processes, but is, with few exceptions, poorly reflective of the mechanisms of neuronal injuries.[88] Similarly, electroencephalograms and electromyelograms are useful in only a few types of xenobiotic exposures, and neuroimaging, while progressively evolving,[54] is a poor substitute for neuroanatomical evaluations which are usually only available on autopsy. Much of the current study to elucidate the mechanisms of CNS injury uses animal models, cultured astrocytes, and other tissue, or postmortem investigations. Less commonly, occupational evaluations, such as the enzyme activity of cholinesterases in pesticide workers, are employed.

This chapter reviews some basic anatomic and physiological principles of the nervous system and the common mechanisms by which xenobiotics exploit the functional and protective components of the CNS with a few relevant examples. The multiple factors determining the clinical expression of neurotoxicity are reviewed.

CELLS OF THE NERVOUS SYSTEM: AN OVERVIEW

NEURONS

Neurons are the major route of cellular communication in the CNS. Having one of the highest metabolic rates in the body, these cells are especially sensitive to changes in the microenvironment and are dependent on astrocytes, choroidal epithelium, and capillary endothelium to confer protection and deliver glucose and other sources of energy.

While each neuron is capable of receiving information through different neurotransmitters and receptor subtypes at the dendrite, neurons typically produce and release a single type of neurotransmitter at the axonal terminal. This specificity allows for cellular classification of neurons based on the neurotransmitter released, for example, serotonergic, cholinergic, and dopaminergic neurons (see Chap. 13). Other substances such as adenosine may be produced and released that are less specific to the neuron type.

The anatomic structure of neurons facilitates their function. Dendrites located on the cell body are lined with receptors that bind neurotransmitters and affect cellular changes via several mechanisms (see Chap. 13). The soma, or cell body is responsible for coordination and production of multiple proteins required to carry out normal physiological functions. This synthesis occurs at a rate several times greater than the liver or kidney. These proteins, organelles, and substrates must then be transported across long distances to the terminal axon. This energy-dependent function is supported by a cytoskeleton comprised of neurofilaments, microfilaments, microtubules, and complex transport proteins. Fast anterograde transport of membrane-bound organelles occurs through *kinesin,* a transport protein, at a rate of 200–400 mm/d. Channel proteins, synaptic vesicles, mitochondria, Na^+, K^+-ATPase, glycolipids, and other substances are transported by kinesin. Slow anterograde transport also occurs at a substantially slower rate (0.5–4 mm/d). The retrograde transport protein, *dyenin,* is produced in the soma and delivered to the nerve terminal for the movement of larger vesicles and reusable proteins back to the cell body.

In the CNS, groups of neurons are organized into complex functional pathways, with a single class of neuron regulating different functions and clinical effects depending on the brain region affected. As an example, dopaminergic neurons regulate cravings, movement, and resting muscle tone, each of which is determined not only by dopaminergic neurons and receptor subtype, but the part of the cortex or basal ganglia specifically affected (see Chap. 13).

Neurons must be able to respond to changes in the local environment and alter the expression of different receptors in response to signaling from neurotrophic factors, variations in metabolic requirements, and xenobiotic interactions. This "neuroplasticity" accounts for the diversity of clinical responses to substances that induce tolerance to xenobiotics like ethanol (see Chap. 14).

GLIAL CELLS

Glial cells are comprised of *astrocytes, oligodendrocytes, Schwann cells,* and *microglia.* These cells serve to support the neurons both structurally and functionally.

Astrocytes comprise between 25% and 50% of the brain volume.[1-3,11] In addition to the anatomic contribution to the blood–brain barrier (BBB), astrocytes play a critical role in maintaining neuronal function.[3,4,91] They contribute to three major areas: homeostasis of the extraneuronal environment, provision of energy substrates, and limitation of oxidative stress. In addition astrocytes contribute to the "plasticity" of cells and receptor expression in the CNS (see later).

In order for cells of all types to function in the CNS, membrane potentials must be adequately maintained. Astrocytes contribute to this by closely regulating the extracellular pH, free water, and, like brain capillaries, the extracellular potassium concentration. Metallothioneins, which control the entry of heavy metals necessary for CNS function, are produced by astrocytes.[28,91] Astrocytes also release energy substrates such as lactate, citrate, alanine, glutathione, and α-ketoglutarate for utilization by neurons.[11]

Astrocytes metabolize glutamate, the main excitatory amino acid (EAA) neurotransmitter in the CNS, as well as ammonia. These cells also produce superoxide dismutase and gluthathione peroxidase to reduce free radical propagation. Glutathione, the major antioxidant for the brain, is predominantly located in the astrocytes. It can be released into the extracellular space or cleaved for neuronal uptake and intracellular reformulation.[11]

Through the release of complex trophic factors, astrocytes control the expression of endothelial transporters of the BBB and the production of tight junctions in both the blood–cerebrospinal fluid barrier (B-CSFB) and BBB. Angiogenesis is similarly astrocyte regulated, as is detection of neuronal injury, immune mediation, and neurotransmitter production. The growth of neurites, the branches of neuronal cell bodies that eventually become dendrites or axons, are similarly modulated by astrocytes.

Oligodendrocytes are a type of glial cell that provide anatomical support, protective insulation, and facilitate rapid neuronal depolarization by the production of myelin. Myelin is the primary constituent of white matter in the CNS. The production of myelin in the peripheral nervous system (PNS) is performed by the Schwann cells. While oligodendrocytes support several axons, each Schwann cell is anatomically dedicated to a single axon.

Finally, microglial cells modulate immune response, inflammation, and tissue repair from a variety of CNS injuries. Like neurons, microglia are dependent on signaling from astrocytes.

MECHANISMS OF NEUROPROTECTION

The nervous system has multiple protective mechanisms. Xenobiotics are prevented from accessing the CNS by the blood–brain and blood–CSF barriers. For xenobiotics that enter the CNS, there are multiple cellular specializations to limit oxidant stress. These protective mechanisms are reviewed.

■ BLOOD–BRAIN BARRIER

The BBB confers an anatomic and enzymatic barrier to xenobiotic entry into the CNS. Brain capillaries are surrounded by the foot processes of adjacent astrocytes. The potential spaces between endothelial cells are limited by tight junctions, or zonulae occludentes, which are between 50 and 100 times tighter than those found on peripheral capillaries.[2-4,52,61] This anatomic barrier prevents movement of substances between cells, also known as the paracellular aqueous pathway, due to osmotic and oncotic forces.[2-4,52,61]

Transendothelial movement of critical substrates and, potentially, xenobiotics occurs through three major mechanisms: diffusion, transport proteins, and endocytosis.[2,3] These routes allow carefully controlled entry of critical substrates and cofactors while limiting the potential for injury from either endogenous or exogenous neurotoxins.

Lipophilic substances may move directly across the luminal and abluminal endothelial membranes abutting the CNS. Other substances may enter the endothelium through bidirectional transport proteins on the luminal surface. These proteins may be specific, such as the GLUT-1 protein for uptake of glucose, or less specific large neutral amino acid transporters (LNAA) that move amino acids and xenobiotics, such as baclofen, intracellularly. These transporters also line the abluminal surface of the endothelial cell for movement of substrates and xenobiotics into the CNS. The third line of entry for larger proteins is via endocytosis. This can be adsorptive, or mediated through specific receptors such as insulin or transferrin.[2-4,52,61,91]

Endothelial cells have other protective properties, including intracellular enzymes, to metabolize xenobiotics and efflux proteins to transport certain xenobiotics back into the capillary lumen. These efflux proteins include energy-dependent P-glycoproteins which are ATP-binding cassette transporters and are sometimes referred to as multidrug-resistant (MDR) proteins. Several hydrophobic xenobiotics are prevented from accumulating in the CNS through these transporters including vinca alkaloids, digoxin, cyclosporine A, and protease inhibitors. Nonsedating antihistamines may have limited sedative properties due, in part, to efflux through P-glyproteins.[25] Another type of saturable transporter, known as organic acid transport (OAT) protein, facilitates the efflux of hydrophilic xenobiotics such as valproic acid or baclofen. The expression of each of these transporters may be upregulated under certain conditions such as intermittent disruptions in the BBB from seizures. This expression upregulation is theorized to account for the resistance of anticonvulsant medications in patients with epilepsy. Comprehensive lists of xenobiotics that are substrates for these transporters are available elsewhere.[2,52,53]

■ BLOOD–CSF BARRIER

The ventricles of the brain are lined by the epithelial cells of the choroid. These cells also have tight junctions, but not as extensive as those of the BBB. They are, however, rich in glutathione peroxidase and other xenobiotic-metabolizing enzymes in concentrations approximating those of the liver. Similar to brain capillary cells, the choroid contains efflux transporters for organic anions and cations, as well as MDR efflux proteins (P-glycoproteins) to limit entry of xenobiotics into the CSF.[2,3,52,91]

NEUROTOXIC PRINICPLES

■ EXCITOTOXICITY

Neuronal function is strictly dependent on aerobic metabolism with the adequate supply of substrates and functioning mitochondria for the production of ATP. When energy expenditure exceeds production, cellular dysfunction and ultimately cell death, or apoptosis, results. The specific cascade of molecular events relating to this process is termed *excitoxicity*.[10,71]

The initial event is traced to an oxidant stress and excessive stimulation of NMDA receptors by glutamate, an EAA neurotransmitter. An influx of intracellular calcium changes membrane potentials across the cellular and mitochondrial membranes. The mitochondria become progressively more inefficient at ATP production and handling the resulting reactive oxygen species. As membrane damage is propagated, calcium further depolarizes the mitochondria, activating a permeability transition pore across the mitochondrial membrane. Gradients are further disrupted, precipitating more injury, energy failure, and ultimately cell death.

Excitotoxicity is considered a common mechanism of cell death due to xenobiotic, ischemic, traumatic, infectious, neoplastic, or neurodegenerative injury. It is the subject of study for many therapeutic interventions in CNS injury.

■ DETERMINANTS OF NEUROTOXICITY

The clinical expression of neurotoxicity is related to many factors. These include the chemical properties of the xenobiotic, the dose and route of administration, xenobiotic interactions, and underlying patient characteristics including age, gender, and comorbid conditions.

■ CHEMICAL PROPERTIES OF XENOBIOTICS

One of the most important determinants of neurotoxicity is the ability of a xenobiotic to penetrate the BBB. Water-soluble molecules larger than M_r 200 to 400 (molecular weight ratio, or mass of a molecule

relative to the mass of an atom) are unable to bypass the tight junctions.[2] Xenobiotics with a high octanol/water partition coefficient are more likely to passively penetrate the capillary endothelium, and potentially the BBB, while those with a low partition coefficient may require energy-dependent facilitated transport.[61] Xenobiotics that are substrates for capillary endothelial efflux mechanisms will have limited penetration regardless of the coefficient.[2,3,52,61]

■ ROUTE OF ADMINISTRATION

The route of xenobiotic administration may also be consequential. While most xenobiotics gain access to the nervous system through the circulatory system, aerosolized solvent and heavy metals in industrial and occupational exposures gain CNS access through inhalation, traveling via olfactory and circulatory routes. Alternatively, some agents may move from the PNS via retrograde axonal transport to the CNS. Naturally occurring proteins such as tetanospasmin, and rabies, polio, and herpes use this mechanism to access the PNS and CNS.[13,16,47] The toxalbumins ricin and abrin as well as bismuth salts may also use this mechanism to a limited extent.[83,89] This understanding may prove beneficial from a therapeutic perspective. For example, in one small series of patients experiencing severe pain, doxorubicin was injected into the involved peripheral nerves. Therapeutically, a chemical ganglionectomy occurred through retrograde "suicide" transport of doxorubicin, providing substantial relief in these patients in this experimental therapy.[50]

Some xenobiotics may be delivered directly into the CSF (intrathecally), the consequences of which are variable (see Special Considerations SC-2: Intrathecal Xenobiotic Administration).

■ XENOBIOTIC INTERACTIONS

Coadministration of xenobiotics may precipitate neurotoxicity by several mechanisms.[45] Extra-axially (outside of the CNS), xenobiotic interactions that increase the blood concentration of one or both agents may overwhelm the protective mechanisms of the BBB.[20] Similar effects may occur in the PNS where elevated blood concentrations may have enhanced clinical effects resulting in peripheral neuropathies.[91]

Xenobiotic interactions can be synergistic, acting on the same neuroreceptor with additive effects. Benzodiazepines and ethanol, for example, both stimulate the $GABA_A$ receptor.[14] The excessive neuroinhibition can result in deep coma and even respiratory depression when these agents are administered together.

In some circumstances, xenobiotic interactions result in excessive neurotransmitter availability.[9] This is demonstrated in patients with the serotonin syndrome, the result, for example, of coadministration of a monoamine oxidase inhibitor and a serotonin reuptake inhibitor or other serotonergics (see Chap. 72).

Access to the CNS may be altered by one of the xenobiotics, allowing the other to bypass the BBB. For example, mannitol causes transient opening of the BBB; as a result, therapeutic use of mannitol is under investigation for the delivery of antineoplastic agents which might otherwise be unable to access the nervous system.[53] Similarly, some xenobiotics, such as verapamil, cyclosporine, and probenicid, are blockers of capillary endothelium efflux.[2,91] These theoretically limit efflux of other substrates of P-glycoprotein or OAT. The clinical utility of employing such efflux blockers is under investigation as was done in a study in which primates received intrathecal methotrexate. The CSF clearance of methotrexate was reduced in animals administered intrathecal probenecid.[12,74]

■ PATIENT CHARACTERISTICS

Patient-specific variables may affect the ability of a xenobiotic to penetrate the BBB and/or the clinical effects of a given exposure. For

example, age of the patient at the time of exposure is critical, especially in the fetus and neonates.[76] The structural and enzymatic development of the BBB is incomplete, and synaptogenesis, or formation of intercellular relationships, is especially sensitive to impaired protein synthesis or other excitotoxic events. This is demonstrated classically by maternal exposure to methylmercury. The mother may be minimally affected, but the developing fetus suffers profound neurological and developmental consequences (see Chaps. 30 and 96).

In neonates, immature liver function may lead to the accumulation of circulating bilirubin. Due to incomplete formation of the BBB, the bilirubin may access the CNS and produce a form of encephalopathy known as *kernicterus.*

Elderly patients may also have increased susceptibility to neurotoxins as a result of relatively impaired circulation or age-related changes in mitochondrial function that predispose to excitotoxicity.[79] Xenobiotic-induced parkinsonism, or the unmasking of subclinical idiopathic Parkinson disease, may occur more readily than in younger patients. Animal models also suggest age-related sensitivity with one study noting increased manganese toxicity with advanced age.[36]

The role of gender in expression of xenobiotic-induced neurological injury is potentially contributory. In animal models, the presence of estrogen-related and progesterone-related compounds may be neuroprotective for some xenobiotic injuries.[62,69] In humans women are more susceptible to some movement disorders such as xenobiotic-induced parkinsonism and tardive dyskinesia, whereas dystonias and bruxism are more prevalent in young male patients.[72] The etiologies of these gender-related differences are incompletely understood.

■ NEUROLOGIC COMORBIDITIES

Conditions affecting the integrity of the BBB can affect CNS penetration of xenobiotics and endogenous neurotoxins. For example, glutamate concentrations are normally higher in the circulatory system than the CNS.[56] Patients with trauma, ischemia, or lupus vasculitis[1] may experience neuropsychiatric disorders as a result of increased penetration of glutamate or sensitivity to additional xenobiotics. Similarly, meningitis and encephalitis cause openings in the BBB and this may be exploited therapeutically. Intravenous penicillin achieves a higher CSF concentration in animals with meningeal inflammation than in those without meningitis.[75]

In some patients previously undiagnosed diseases become evident on exposure to xenobiotics. This is especially true in patients with peripheral neuropathies. For example, patients being treated with therapeutic doses of vincristine suffered a severe polyneuropathy due to unmasking of a previously undiagnosed Charcot-Marie-Tooth disease.[9,22] Similarly, patients with diabetes mellitus, which is the most common cause of peripheral neuropathy, or HIV disease may have exacerbation of symptoms in the presence antiretroviral agents.[24,70] Patients with myasthenia gravis may have exacerbation of weakness with aminoglycoside administration which can affect transmission at the neuromuscular junction (NMJ).[90]

Chronic exposures to some neuroinhibitory xenobiotics such as ethanol may alter neuronal receptor expression and upregulate or increase the amount of receptors for EAAs. In addition to receptor augmentation, neurotransmitter concentrations of the excitatory neurotransmitters glutamate and aspartate are increased, as is homocysteine. These changes induce a tolerance to neuroinhibitory xenobiotics acting on the same receptor, and patients require escalating doses to achieve the same clinical effect. In such patients cessation of ethanol intake results in a relative deficiency of exogenous inhibitory tone. The patient experiences neuroexcitability and the clinical syndrome of withdrawal[17,18] (see Chap. 14).

Adequate nutritional status is important for the maintenance of normal neurological function. The BBB may not be adequately maintained in patients with malnutrition. Deficiencies of heavy metal cofactors such as manganese, copper, zinc, and iron can affect neurological function. In some cases the deficiencies enhance absorption of other xenobiotics. For example, iron deficiency enhances lead and manganese absorption in the gastrointestinal tract which can ultimately overwhelm neuroprotective mechanisms. Vitamins serve as enzymatic cofactors in modulating the production of glutamate, homocysteine, and other amino acids. Specific vitamin deficiencies can precipitate neurological syndromes such as Wernicke encephalopathy in thiamine-depleted patients (see Antidotes in Depth A25: Thiamine Hydrochloride, and Chap. 41). The toxicity of xenobiotics may also be enhanced. For example, a relative pyridoxine deficiency in patients with acute isoniazid overdose may result in seizures as a result of a relative excess of EAAs (see Antidote in Depth: Pyridoxine, and Chap. 57). Glucose is a critical energy substrate that can cause profound neurological impairment when delivery is inadequate (see Antidotes in Depth A10: Dextrose, and Chap. 48).

Interestingly, certain conditions such as temperature may affect the toxicity of xenobiotics. For example, cooling may limit the impedance of ACh neurotransmission caused by botulinum toxin.[41]

EXTRA-AXIAL ORGAN DYSFUNCTION

Renal failure may impair metabolism of xenobiotics or endogenous neurotoxins such as urea rendering it more available to the CNS. Hyperglycemia in patients with diabetes mellitus may also increase formation of CNS reactive oxygen species. Similarly, patients with liver failure may have elevations in CNS manganese. These patients may suffer Parkinson syndrome[51,77] (see Parkinson Syndrome later).

Hepatic encephalopathy illustrates the concept of excitotoxicity from endogenous neurotoxins. Hyperammonemia increases oxidative stress and free radical formation in astrocytes. Ammonia potentially decreases critical metabolic enzymes such as catalases, superoxide dismutase, and glutathione peroxidase. Nitric oxide production is increased due to elevations in NO synthetase. Under these conditions, astrocytes upregulate the expression of the peripheral benzodiazepine receptor (PBR) on the outer mitochondrial membrane. The PBR modulates the production of neurosteroids and, in turn, the $GABA_A$ receptor. Continued CNS exposure to ammonia and other endogenous solutes propagates this oxidative and nitrosative stress to the mitochondrial membrane, potentially opening a channel named the mitochondrial permeability transition pore. Osmotic swelling of the mitochondrial membrane followed by excitotoxicity results in cerebral edema and hepatic encephalopathy.[63,64]

SPECIFIC MECHANISMS OF NEUROTOXICTY

ALTERATION OF ENDOGENOUS NEUROTRANSMISSION

Xenobiotics can induce neurotoxicity by triggering changes in neurotransmission in either the CNS or PNS. In some cases xenobiotics enhance neurotransmission through a specific receptor subtype. This enhanced transmission can occur through inhibition of presynaptic metabolism (monoamine oxidase inhibitors), stimulation of neurotransmitter release (amphetamines), impairment of neurotransmitter reuptake (cocaine), or inhibition of synaptic degradation (acetylcholinesterase inhibitors).

Alternatively, synaptic neurotransmission may be impaired.[78] Xenobiotics may inhibit the presynaptic release of neurotransmitters (botulinum toxin), block receptors (antimuscarinics), or alter membrane potentials at the postsynaptic membrane (tetrodotoxin).[32,33] Patients may present with a clinical syndrome of toxicity associated with altered neurotransmission of the specific receptor (see Chap. 3).

DIRECT RECEPTOR INTERACTION

Some xenobiotics are able to directly stimulate receptors. Both kainate and α-amino-3-hydroxy-5methyl-4-isoxazole propionate (AMPA) are subclasses of the glutamate receptor, which are targeted by some naturally occurring xenobiotics.[42] An example is β-N-oxalylamino-L-alanine (BOAA) found in the grass pea, *Lathyrus sativus*. BOAA stimulates the AMPA and inhibits specific mitochondrial enzymes resulting in the spastic paraparesis of lathyrism.[67] Domoic acid stimulates the kainate receptor and causes the neuroexcitation associated with neurotoxic shellfish poisoning.

Direct inhibition is also possible, as exemplified by phencyclidine, an NMDA (N-methyl-D-aspartate) receptor antagonist.

ENZYME AND TRANSPORTER EXPLOITATION

The classic example of xenobiotics that exploit endogenous enzymes and/or transporters is MPTP.[38] Once MPTP crosses the BBB, it is converted by monoamine oxidase to the neurotoxic compound MPP^+ (1-methyl-4-phenylpyridine) in astrocytes. MPP^+ is taken up by dopamine transporters into the neurons of the substantia nigra pars compacta. MPP^+ inhibits complex I of the mitochondrial electron transport chain resulting in dopaminergic excitotoxicity and the clinical syndrome similar to Parkinson disease (see Disorders of Movement and Tone, and Chap. 38*).

ALTERED CONDUCTION ALONG MEMBRANES: DEMYELINATING NEUROTOXINS

Aside from xenobiotics that affect neurotransmission at the postsynaptic membrane, some affect the production or maintenance of myelin by oligodendrocytes and Schwann cells.[23,34,37,48] In the CNS these are often associated with white matter abnormalities and a leukoencephalopathy.[34] Agents such as hexachlorophene, arsenic, inhibitors of tumor necrosis factor α, neural tissue–derived rabies vaccine, and the act of "chasing the dragon" or inhaling volatilized heroin are associated with a demyelinating neurotoxicity.[23] In the PNS, nitrous oxide, suramin, and tacrolimus are associated with peripheral demyelination.[46]

INHIBITION OF INTRACELLULAR FUNCTIONS

Some xenobiotics are nonspecific inhibitors of cellular function.[29] The neurotoxicity of substances such as carbon monoxide (CO) or cyanide can result in diffuse dysfunction or, depending on the dose and specific vulnerabilities of an exposed patient, be more focal. For example, patients surviving CO exposure may experience delayed neurological sequelae that is a diffuse impairment of neuropsychiatric function, or more focally, present with a xenobiotic-induced Parkinson syndrome (see later and Chap. 125).

Antineoplastics can affect the production of critical proteins required for cellular maintenance. These can be very specific such as the ability of vincristine to impair cytoskeletal transport in the peripheral nervous system (see Chap. 37).

CLINICALLY RELEVANT XENOBIOTIC-MEDIATED CONDITIONS

ALTERATIONS IN CONSCIOUSNESS

The toxicological differential of xenobiotics that induce alterations in mental status or consciousness is expansive. These xenobiotics can be

broadly divided into those agents that produce some form of neuroexcitation, and those that produce neuroinhibition. While some agents such as phencyclidine have elements of both depending on dose, this categorization facilitates a general clinical understanding of neurotoxic alterations in mental status.

Xenobiotics resulting in neuroexcitation are agents that enhance neurotransmission of EAA, or diminish inhibitory input from GABAergic neurons. The clinical presentation of the patient can vary; some patients may be alert and confused, or suffering from an agitated delirium, hallucinations, or a seizure.

Neuroinhibitory xenobiotics typically enhance GABA-mediated neurotransmission. These patients may be somnolent or in deep coma. Benzodiazepines hyperpolarize cells by increasing inward movement of Cl⁻ ions through the chloride channel of the GABA$_A$ receptor. This hyperpolarization limits subsequent neurotransmission (see Chap. 13). Less commonly, neuroinhibition is a result of diminution of EAA. Patients presenting the day after binging on cocaine may be sleepy but arousable and oriented in what is termed cocaine "washout," theoretically related to depletion of EAA and dopamine. Xenobiotics that cause diffuse cortical dysfunction through impairment in the delivery or utilization of oxygen or glucose can also present with depressed or altered consciousness.

Clinical evaluation of patients with altered consciousness includes obtaining complete history including medications, comorbid conditions, occupation, and suicidal intent when relevant or available. Patients should have a complete physical examination, with particular attention paid to vital sign abnormalities or findings that may indicate a toxic syndrome. Assessment and correction of hypoxia or hypoglycemia should be performed. An electrocardiogram may be useful in some circumstances (see Chaps. 22 and 23).

◼ XENOBIOTIC-INDUCED SEIZURES

Seizures are the most extreme form of neuroexcitation. As with alterations of consciousness, this may be due to enhanced EAA neurotransmission (domoic acid, sympathomimetics) or inhibition of GABAergic tone (isoniazid). Unlike patients with traumatic or idiopathic seizure disorders who have an identifiable seizure focus, the initiation and propagation of xenobiotic-induced seizures is diffuse. It is for this reason that most non-sedative-hypnotic anticonvulsants such as phenytoin are unlikely to be effective in terminating seizures.

Seizures may be idiopathic as described with tramadol and bupropion, or they may be concentration-dependent events as described with theophylline and isoniazid toxicity. Alternatively, seizures may be a result of withdrawal from GABAergic substances.

Status epilepticus is variably defined, but involves two or more seizures without a lucid interval, or continuous seizure activity for greater than 15 minutes. True xenobiotic-induced status epilepticus is rare. Cicutoxin, the toxin in water hemlock, *Cicuta maculata*, is a potent inhibitor of GABA$_A$ neurotransmission and may cause status epilepticus.

Theophylline toxicity precipitates seizures and status epilepticus through a different mechanism. Normally, endogenous termination of seizures is mediated through presynaptic release of adenosine during the release of the primary neurotransmitter at the terminal axon. Adenosine functions as a feedback inhibitor of the presynaptic neuron, disrupting propagation of excitatory neurotransmission. Theophylline is an adenosine antagonist. However, adenosine administration is not a useful therapy for theophylline-induced seizures as adenosine is unable to cross the BBB. Generally high-dose sedative-hypnotics, affecting GABA$_A$ receptors are required for seizure control.

Some clinical conditions appear to be centrally mediated tonic–clonic movements, but are due to glycine inhibition in the spinal cord.

TABLE 18–1. Xenobiotics that Commonly Induce Seizures			
Concentration-Related	Idiosyncratic	Withdrawal Related	Tonic-Clonic Seizure-like
Antihistamines			
Baclofen	Bupropion	Baclofen	Strychnine
Camphor*	Carbamazepine	Barbiturates	Tetanus toxin
Carbon monoxide	Ergotamines	Benzodiazepines	
Chloroquine*	GHB	Ethanol	
Cicutoxin*	Mefenamic acid	GHB	
CNS stimulants	Phenylbutazone		
Cyanide	Tramadol		
Diphenhydramine			
Domoic acid			
Isoniazid*			
Hypoglycemics			
Gyromitrin*			
Lidocaine			
Meperidine			
Organic chlorines			
Organic phosphorous compounds			
Propoxyphene			
Strychnine			
Tetramethylenedisulfotetramine (TETS)*			
Thallium			
Theophylline*			
Zinc phosphide			

* High concentrations may result in status epilepticus.

Glycine is the major inhibitory neurotransmitter of motor neurons of the spinal cord. Under normal conditions glycine contributes to termination of reflex arcs. Glycine inhibition results in myoclonus, hyperreflexia, and opisthotonos often without alteration in consciousness. Presynaptic glycine release inhibition is caused by tetanospasmin, the major neurotoxin from *Clostridium tetani*. Postsynaptic glycine inhibition is caused by strychnine, the toxin in *Strychnos nux-vomica*. Patients with exposures to these agents are often treated in quiet environments where the stimuli to initiate hyperreflexia are minimized (see Chap. 112 and Table 18–1.)

◼ XENOBIOTIC-INDUCED MOOD DISORDERS

Certain xenobiotics are inconsistently associated with alterations in mood.[5,19] What predisposes individuals to xenobiotic-induced mood alterations is unclear. In some circumstances patients with previously undiagnosed bipolar disorder are given a xenobiotic that unmasks their disease. Interestingly antibiotic-induced mania is found in some patients without a previous psychiatric history. The symptoms of mania are usually evident within the first week of therapy and, unlike the mania of purely psychiatric origin, readily abate within 48–72 hours of the last antibiotic dose. Some patients with clarithomycin-induced mania have documented recurrence on rechallenge of the antibiotic.[5] In general xenobiotic-induced manias are idiopathic and very rare.

TABLE 18–2. Xenobiotics Commonly Inducing Mood and Neuropsychiatric Disorders

Mania	Depression	Psychosis
Acyclovir	β-adrenergic	Amantadine
Amantadine	antagonists	Corticosteroids
Caffeine	Amiodarone	CNS stimulants
Chloroquine	Interferon	
Clarithromycin	Isoretinoic acid	
CNS stimulants	Ribavirin	
Corticosteroids		
Dextromethorphan		
Dehydroepiandrosterone		
Efavirenz		
Flenfluramine		
Floroquinolones		
Gabapentin		
Ginseng		
Interferon-α		
Isophosphamide		
Isoniazid		
L-dopa		
Mefloquine		
Phentermine		
Phenylpropanolamine		
Pseudoephedrine		
Quetiapine		
St. John's wort		
Testosterone		
Tramadol		

More common are either psychosis from chronic CNS stimulant use or depression from ethanol or the agents listed in Table 18–2.

■ DISORDERS OF MOVEMENT AND TONE

CNS-Mediated Disorders   Most movement disorders, including akathisia, bradykinesia, tics, chorea, and dystonias are mediated by the complex dopaminergic pathways of the basal ganglia. Different dopamine receptor subtypes, modulated by GABAergic, glutaminergic, and cholinergic neurons are involved (see Chap. 13). Chorea occurs in some cases of carbamazepine overdose, therapeutic oral contraceptive use,[31] and after cocaine use when the stimulant effects have subsided.[72]

Dopamine receptor antagonists can precipitate acute dystonic reactions. The D_2 receptor antagonists, in conjunction with alterations in muscarinic cholinergic tone, are usually implicated. Animal models suggest possible mediation through σ receptors, the craniofacial distribution of which corresponds to the common clinical manifestations of acute dystonias.[49]

Diffusely increased motor tone may be seen with glycine antagonists such as tetanospasmin and strychnine, and in adrenergic states such as acute intoxication with CNS stimulants, or withdrawal from sedative-hypnotics.

Other centrally mediated disorders of tone include serotonin syndrome and neuroleptic malignant syndrome (NMS). Both of these potentially life-threatening syndromes consist of altered consciousness, hyperthermia, rigidity, and autonomic insufficiency. NMS may occur in patients on dopamine receptor antagonists such as antipsychotic medications, or in patients with idiopathic Parkinson disease who abruptly stop their dopaminergic therapy. Dopamine receptor agonists such as bromocriptine or restoration of antiparkinson medications are used therapeutically in these circumstances (see Chaps. 15 and 69).

Parkinsonism   Xenobiotic-induced parkinsonism is a syndrome of unstable posture, rigidity, gait disturbance, loss of facial expression, hypokinesis, and variable presence of tremor.[7] The common neuroanatomic target involves the dopaminergic neurons of the basal ganglia, specifically the substantia nigra.[26,84] In some circumstances the toxicity is transient and the mechanism inadequately understood.

Some xenobiotics such as carbon monoxide and heroin produce tissue hypoxia and ischemia in the basal ganglia which occasionally results in xenobiotic-induced Parkinson syndrome.

Other xenobiotics such as MPTP, carbon disulfide, manganese, and the endogenous neurotoxin copper in patients with Wilson disease produce predictable mitochondrial impairment of the basal ganglia neurons. Viscose rayon workers exposed to carbon disulfide may present with a Parkinson syndrome refractory to L-dopa administration[43,44] (see Enzyme and Transporter Exploitation later).

Manganese is a critical substrate for production and metabolism of several neurotransmitters including glutamate. Excessive manganese interferes with normal uptake of glutamate and is critical to the function of superoxide dismutase and glutamine synthetase.[30,35] In patients with liver failure who accumulate manganese from occupational exposure, reversal or treatment of liver disease may result in resolution of parkinsonism.[36,77]

A recent review of patients who intravenously injected the illicit agent metcathinone described a Parkinson syndrome thought to be secondary to contamination with manganese from a precursor, potassium permanganate, which is used in metcathinone production. Unlike patients with idiopathic parkinsonism, these patients did not suffer from a resting tremor, and they had a specific gait abnormality in which they walked on the balls of their feet.[82] Like those with occupational manganese exposures and normal liver function, these patients did not respond to L-dopa (see Table 18–3).

Tremors   Tremors may be observed in adrenergic states, with specific xenobiotics such as lithium, or as a result of sedative-hypnotic withdrawal. These are well reviewed elsewhere.[60]

The Neuromuscular Junction   Flaccid paralysis usually occurs as a result of impaired transmission at the NMJ[14,15,78] or from xenobiotics causing demyelination. Mechanisms of NMJ transmission impairment include

TABLE 18–3. Xenobiotics Commonly Inducing Parkinsonism

Reversible*	Irreversible
Amlodipine	Carbon disulfide
Antineoplastics	Carbon monoxide
Cyclosporine	Copper
Calcium channel blockers	Cyanide
Dopaminergic agents (withdrawal)	Heroin
Kava Kava	Manganese

Trazadone	

* May improve with removal of xenobiotic, sometimes requiring persistent administration of dopaminergic therapy.

impeded propagation of the action potential on the terminal neuron, impaired release of acetylcholine, depression of motor end-plate potential with failure of depolarization, and impedance of myofibril excitation[78] (see also Chap. 68).

Rarely toxins can enhance transmission at the NMJ. Latrotoxin, the toxic compound in the black widow spider (*Latrodectus* spp), causes enhanced release of acetylcholine at the NMJ with severe, painful muscle contractions (see Chap. 119).

NEUROPATHIES AND MYOPATHIES

■ CRANIAL NERVES

Xenobiotics are a relatively rare cause of cranial nerve impairment. Some neuropathies are a result of direct delivery of the xenobiotic to the affected cranial nerve. For example, some patients may have optic nerve impairment from intraorbital installation of silicone

TABLE 18–4. Cranial Neuropathies

Cranial Nerve	Sign	Symptom	Toxin
I[a]		Failure to detect odor	Hydrogen sulfide: olfactory fatigue
II	Pupil unresponsive to light	Blindness	Amiodarone, ammonia, cisplatin, clioquinol, deferoxamine, diethylene glycol (DEG), dimethyl mercury, α_2-interferon, holocyclotoxin, methanol, methotrexate, methyl iodide, oxaliplatin, quinine, solvents
III	In paralysis : Ptosis, pupil unresponsive to light In excess: stimulation	Photophobia Dim vision Muscarinic cholinergics	Amiodarone, antimuscarinics, botulinum toxin, DEG, holocyclotoxin, hypoglycemics, α_2-interferon, methyl iodide, thallium, Venoms: Elapidae, scorpion
IV	Paralysis of the superior oblique muscle of eye with weakness of downward gaze, slight upward gaze of affected eye	Vertical and torsional diplopia which worsens on adduction, and may improve with tilt of head	Barbiturates, botulinum toxin, DEG, holocyclotoxin, thallium, venoms
V	Diminished facial sensation, weakness in chewing and swallowing Excessive contraction: trismus	Parasthesias face, weakness in chewing Difficulty opening mouth/jaw Tetanus and strychnine[b]	Botulinum toxin, ethylene glycol, holocylotoxin, oxaliplatin, vincristine. Tetanus toxin and strychnine[b]
VI	Failure to abduct eye on lateral gaze	Diplopia	DEG, holocyclotoxin, intrathecal water soluble contrast agents, lithium, local anesthetics, MDMA, nitroglycerin, ornithine-ketoacid transaminase, oxaliplatin, thallium, thiamine deficiency, Elapid venom, vitamin A
VII[a]	Weakness of facial muscles, impaired expression	Facial droop, impaired taste	DEG, ethylene glycol, holocyclotoxin
VIII[a]	Impaired hearing on auditory testing, nystagmus	Alterations in hearing, potential alterations in balance	Cisplatin, DEG, ethylene glycol, oxalosis, quinine, salicylates, solvents
IX[c]	Impaired gag reflex	Impaired taste	Botulinum toxin, ethylene glycol, stibanate, cholinergic compounds[c]
X[c,d]	Decreased gag reflex when paralyzed May be enhanced with cholinergic or impaired with anticholinergic: Autonomic instability, altered bowel sounds	Choking, change in voice	Botulinum toxin, ethyleme glycol, stibanate, cholinergic compounds[c]
XI[c]	Weakness shoulder shrug	Weakness neck/shoulders	Botulinum toxin, cholinergic compounds[c]
XII[c]	Impaired speech, tongue deviation	Dysarthria	Botulinum toxin, cholinergic compounds[c]

[a] See also Chap. 20.

[b] Tetanus causes indirect effects on masseter muscles; see section on xenobiotic-induced seizures or Chap. 111.

[c] Weakness of cranial nerves IX–XII is often referred to as bulbar palsy and can be seen in the intermediate syndrome after acute cholinesterase poisoning. This syndrome is often accompanied by paralysis of extraocular muscles (see Chap. 112).

[d] See Chap. 3.

oil,[6] or inadvertent deep space injection of a local anesthetic during dental anesthesia with a resultant abducens palsy.[59] In some cases, a xenobiotic is converted into a toxic substance such as formic acid in the retina.

The neuromuscular junction of the cranial nerves is sensitive to disruptions in neurotransmission. In xenobiotics affecting the occulomotor nerves (CN III, IV, VI) patients may describe diplopia or have gaze palsies on examination. Botulinum toxin, diethylene glycol toxicity, elapid snake venom, and the cranial neuropathy associated with the organic phosphorus insecticide-induced intermediate syndrome are some examples.

Absence of critical substrates such as glucose or thiamine can result in an ophthalmoplegia. In most cases, however, the mechanisms underlying the cranial neuropathy are poorly understood, such as is the case with chemotherapeutic agents. Similarly, some patients who survive ethylene glycol poisoning experience transient ophthalmoplegia days after the initial exposure[55,81] (see Table 18–4 and Chap. 19).

■ PERIPHERAL NERVES

Complaints of pain, paresthesias, numbness, or weakness of extremities are clinically termed *neuropathies*. The mechanisms of evolution are variable. Common to most xenobiotic-induced neuropathies is early bilateral involvement of the lower extremities. This may be due in part to the patient's rapid recognition of impairment during an attempt to ambulate. Additionally, the axons serving the lower extremities are longer. Maintenance and transportation of substrates is more energy dependent and sensitive to xenobiotic-induced disruptions.

In some cases the anatomic structure of the nerve is maintained, but the xenobiotic affects neurotransmission. This may be due to direct impairment of specific enzymes at the NMJ, such as cholinesterase inhibitors.[27] Tri-ortho-cresyl phosphate (TOCP) is an inhibitor of neuropathic target esterase. Contamination of food and the beverage Ginger Jake with TOCP resulted in irreversible lower extremity paralysis in several epidemic exposures.[68,86] Indirectly, the extracellular environment may be altered as in the case of hypermagnesemia, or hypokalemia which can be induced by multiple agents (see Chap. 16) Ciguatoxin, a sodium channel opener, affects neurotransmission causing paresthesias and the unusual symptom of sensory reversal in which the perception of temperature is reversed to the stimulus.

Xenobiotics such as amiodarone and tacrolimus induce peripheral demyelination. Patients present with weakness and flaccidity. Nitrous oxide impairs the production of *S*-adenosyl methionine essential to the production of myelin and is additive to the nitrous oxide disruptions of vitamin B_{12} which further impair axonal function.[87]

Other xenobiotics affect the structure or intracellular function of the peripheral nerves. Those that induce death of the cell body are termed *neuronopathies* and they may be clinically indistinguishable from those that affect the axon, or *axonopathies*.

Peripheral nerve cell death is usually linked to injury at the spinal cord as was described above by the doxorubicin injection of the peripheral nerves.[50] Pyridoxine overdose is another cause of neuronopathy. However, neuronopathies are an unusual mechanism of peripheral nerve toxicity.

Unlike neuronopathies, axonopathies are potentially reversible and are the most common mechanism of xenobiotic-induced peripheral neuropathy. Xenobiotic-induced axonal injuries to the peripheral nerves are usually diffuse and bilateral, with preservation of the proximal cell body. These often target the cytoskeleton and impair the capacity for the microtubule system to deliver functional substrates.[21,40] Patients with occupational exposure to 2,5-hexanedione, a γ-diketone

TABLE 18–5. Xenobiotics Associated with Muscle Toxicity

Amiodarone	HMG-CoA reductase inhibitors
Azidothymine	Hydroxychloroquine
Bothrops spp, and Agkistrodon spp venoms	Ipecac
	Loxosceles spp venom
Chloroquine	Niacin
Cimetidine	Organic phosphorous compounds
Clofibrate	D-Penicillamine
Clostridium toxins	Phencyclidine
Cocaine	Procainamide
Colchine	Propylthiouracil
Crotaline and other tissue-toxic snake venoms	Rifampin
	Sulfonamides
Cyclosporine	Suxamethonium
Doxylamine	Toxic oil syndrome
Epsilon aminocaproic acid	L-Tryptophan
Ethanol	Vincristine
Ethchlorvynol	Zidovudine
Glucocorticoids	
Heroin	

---

metabolite of n-hexane present in certain glues, suffer from a sensorimotor axonopathy due to cross-linking of neurofilaments and impaired substrate transport.[65] Progressive neuropathy may occur long after the initial exposure. Vincristine similarly effects axonal transport. Acrylamide impairs fast anterograde and retrograde transport with animal models suggesting effects on both kinesin and dyenin.

Nucleoside reverse transcriptase inhibitors cause peripheral neuropathy by decreasing the production of mitochondrial DNA.

■ MYOPATHIES

Some patients experience local muscle damage as a result of direct injury from extravasation of tissue toxic substances or enzymatic degradation associated with crotalid snake envenomations.

Most xenobiotic-induced muscle injuries or myopathies are more diffuse.[39,73,80,85] HMG Co-A reductase inhibitors can cause myalgias, cramping, myositis, or rhabdomyolysis. The incidence appears to be higher in patients taking other medications which share the same liver metabolic enzymes. The mechanism underlying the myopathy may be related to impaired cholesterol synthesis in myocytes, or diminished production of regulatory proteins such as ubiquinone and GTP-binding proteins required for mitochondrial function.

Another myopathy that presents predominantly with weakness is the acute quadriplegic myopathy of intensive care patients. This syndrome was originally described in ventilated patients with asthma who received glucocorticoids and nondepolarizing neuromuscular blockers, but is also reported in other critically ill patients[8] (see Chap. 68). The mechanisms underlying quadriplegic myopathy, eosinophilia myalgia syndrome, and toxic oil syndrome are poorly described. Xenobiotics associated with muscle injury can be found in Table 18–5.

CONCLUSIONS

The principles involving xenobiotic-induced neurological injury are an area of intensive and evolving investigation. With improved understanding of these neurotoxic principles, therapeutic medications can be better

delivered to the CNS while limiting the entry of potentially toxic substances. Toxicological models for the investigation of neurodegenerative disorders can be further developed as can new and creative therapies for mood disorders, hepatic encephalopathy, and injuries from infections, trauma, and ischemia. Elucidation of neurotoxicologic principles shows promise for the treatment of many nervous system disorders. The chemical properties of the xenobiotic and the characteristics of the patient exposed are critical to the clinical expression of neurotoxicity.

CHAPTER 19
OPHTHALMIC PRINCIPLES

Adhi Sharma

While it is arguable that the eyes are the mirror to the soul, it is certain that the eyes can reveal a great deal of information with regard to toxicology. In addition to exhibiting findings of systemic toxicity, they are also subject to the direct effects of xenobiotics and can serve as a portal of entry for systemic absorption. An understanding of ophthalmic principles will allow the clinician to make timely and more accurate diagnoses that can be sight-saving or lifesaving and is essential to efficient, organized patient care.

OPHTHALMIC EXAMINATION

As a matter of convention, the routine eye examination is performed in the following sequence: visual acuity, pupillary response, extraocular muscle function, funduscopy, and, when indicated, a slit-lamp examination. Examination of the pupillary size and response to light can help determine the presence of a toxic syndrome. For example, opioids and cholinergics may produce miosis, whereas anticholinergics and sympathomimetics may produce mydriasis. Assessment of the extraocular muscles can reveal xenobiotic-induced nystagmus. Funduscopy can reveal pink discs characteristic of poisoning by methanol or carbon monoxide. The slit-lamp examination allows for evaluation of toxic exposure to the lids, lacrimal systems, conjunctiva, sclera, cornea, and anterior chamber. However, before considering specific xenobiotic exposures in detail, it is important to review the anatomy and physiology of the visual pathways and how alteration of the normal physiology and anatomy correlate with clinical signs and symptoms.

OCULAR ANATOMY AND PHYSIOLOGY

The eye is a roughly spherical structure referred to as a globe. The globe is divided into anterior and posterior structures (Fig. 19–1). The most anterior structures are the cornea, conjunctiva, and sclera. Posterior to the cornea are the iris, the lens, and the ciliary body. The space between the cornea and the iris is the anterior chamber, and the space between the iris and the retina is the posterior chamber. The anterior chamber contains *aqueous humor,* which is produced by the ciliary processes; this fluid nourishes the cornea, iris, and lens. The iris, the ciliary processes, and the choroid compose the uvea. The posterior chamber is filled with a transparent gelatinous mass termed the *vitreous humor.* The vitreous humor is an important body fluid in forensic toxicology as it is less susceptible to postmortem redistribution (Chap. 33). The fundus is the most posterior structure and includes the retina, retinal vessels, and the head of the optic nerve or disc.

■ VISUAL ACUITY AND COLOR PERCEPTION

Normal vision is dependent on light transmission to intact neural elements. Appropriate light transmission requires a clear cornea and aqueous humor, proper pupil size, an unclouded lens, and clear vitreous. The neural elements include the retina, optic nerve, and the optic cortex; all of these structures require intact blood circulation for proper function. Decreased acuity can result from abnormalities anywhere in the visual system that affect either light transmission or neural elements.[4,12,21] Corneal injury or edema may result in blurring of vision, characteristically described as "halos" around lights. Toxicologic causes of corneal abnormalities include direct exposure to chemicals, failure of corneal protective reflexes because of local anesthetic effects or a profoundly decreased level of consciousness, and incomplete eyelid closure during coma. Mydriasis, secondary to various xenobiotics (Table 19–1), may interfere with the pupillary constriction necessary for accommodation, thereby resulting in decreased acuity for near objects. Lens clouding or cataract formation causes blurred vision and decreased light perception, as does blood (hyphema) or other deposits in the aqueous humor or vitreous humors. Xenobiotic-induced lens abnormalities caused by chronic exposures are well described (Table 19–2),[17,21,27] but are unimportant in the evaluation of an acute toxicologic emergency. Even if light reaches the retina without distortion, abnormal reception or transmission can result from ischemia or injury to any neural element from the retina to the optic cortex. Direct, acute, visual neurotoxic injury is rare and is caused almost exclusively by methanol or quinine. Indirect injury following xenobiotic-induced CNS ischemia or hypoxia is far more common. Alterations in color perception generally result from abnormalities in retinal or optic nerve function. Color-vision abnormalities are attributed to hundreds of xenobiotics, but unlike those caused by chronic xenobiotic exposure such abnormalities are rare and inconsistent features of acute toxicity.[17,21]

■ PUPIL SIZE AND REACTIVITY

Generally, pupils are round and symmetric with an average diameter of 3–4 mm under typical light conditions. Physiologic anisocoria (unequal pupils) is a normal variant and is defined as a difference in pupil size of 1 mm or less. However, in the absence of a history of physiologic anisocoria, any asymmetry in pupil size should be considered an abnormal finding. Pupils react directly and consensually to light intensity by either constricting or dilating. Constriction is also a component of the near reflex (accommodation) that occurs when the eye focuses on near objects. The iris controls pupil size through a balance of cholinergic innervation of the sphincter (constrictor) muscle by cranial nerve III and sympathetic innervation of the radial (dilator) muscle.[12]

Pupillary dilation (mydriasis) can result from increased sympathetic stimulation of the radial muscle by endogenous catecholamines, or from xenobiotics such as cocaine, amphetamines, and other sympathomimetics as well as ophthalmic instillation of sympathomimetic agents such as phenylephrine. Mydriasis can also result from inhibition of muscarinic cholinergic-mediated innervation of the sphincter secondary to systemic or ophthalmic exposure to anticholinergic agents (Chap. 50). Because pupillary constriction in response to light is a major determinant of normal pupil size, blindness from ocular, retinal, or optic nerve disorders also leads to mydriasis as exemplified by methanol and quinine toxicity. As such, the reactivity of mydriatic pupils to light varies with the etiology of the mydriasis.[21] Although often difficult to appreciate, constriction to light can usually be elicited after sympathomimetic exposures because constrictor function is preserved, whereas this is often not the case when mydriasis results from anticholinergic excess since constrictor function is potently antagonized. Light reactivity is absent in cases of complete blindness, but may be preserved if there is some remaining light perception.

Miosis can result from increased cholinergic stimulation such as opioids, pilocarpine, and cholinesterase inhibitors such as organic phosphorus compounds, or inhibition of sympathetic dilation caused by clonidine. Miosis was the most common finding in victims of the Tokyo subway sarin attack of 1995 and was used to distinguish between mild and moderate exposure.[33]

There are conflicting reports regarding the pupillary reactions to many xenobiotics. Depending on the stage and severity of toxicity,

the presence of co-ingestants or coexistent hypoxemia, and numerous other factors, many individual xenobiotics (eg, phencyclidine and barbiturates) are reported to cause either mydriasis, miosis, or hippus, the fluctuation between miosis and mydriasis.[21,28] For some xenobiotics, the pupillary examination provides consistent information (Table 19–1), but many factors are involved and the significance of the pupil size and reactivity must always be considered in the context of the remainder of the patient evaluation.

■ EXTRAOCULAR MOVEMENT, DIPLOPIA, AND NYSTAGMUS

Maintenance of normal eye position and movement requires a coordinated function of a complex circuit involving bilateral frontal and occipital cortices, multiple brainstem nuclei, cranial nerves, and extraocular muscles.[2,12] Because of the many elements necessary for normal function, abnormalities of eye movement can result from several

causes and are extremely common.[21] Probably the most common abnormality is reversible nystagmus or rhythmic oscillations of the globes (Table 19–1). Nystagmus is divided into two types: jerk nystagmus has a slow phase and a fast phase, while pendular nystagmus is a rhythmic oscillation. Either type can be torsional (rotary) or in a horizontal or vertical direction. Xenobiotic-induced nystagmus can take many forms, but is most commonly jerk nystagmus, as opposed to pendular. The nystagmus may be evident at rest but is accentuated by visual pursuit and extreme lateral gaze. Although nystagmus with extreme lateral gaze is a normal finding, it extinguishes within 2–5 beats; if nystagmus

[d] Mostly of historical interest; associated with patterns of use that are no longer common.

persists, it is evidence of underlying pathology. Vertical nystagmus in other settings is usually associated with a structural lesion of the CNS. However, xenobiotic-induced vertical nystagmus occurs with phencyclidine, ketamine, dextromethorphan, or phenytoin toxicity.

Loss of conjugate gaze commonly results from CNS depression of any etiology, typically after sedative-hypnotic or ethanol poisoning. Except after extremely rare exposures to neurotoxins (Table 19–1), diplopia without a decreased level of consciousness should not be attributed to an acute toxicologic etiology. In addition to the transient effects of some xenobiotics, thallium, carbon disulfide, and carbon monoxide may cause sustained gaze disorders as a consequence of residual cranial nerve and CNS injury.[21] Nystagmus and ophthalmoplegia caused by thiamine deficiency (Wernicke) usually improves after therapy, but the nystagmus may not completely resolve.[43]

DIRECT OCULAR TOXINS

■ CAUSTICS

The initial approach to all patients with ocular caustic exposures should be immediate decontamination by irrigating with copious amounts of fluids.[9,44] Water, normal saline, lactated Ringer solution, and balanced salt solution (BSS) are all appropriate choices.[37] In theory, BSS is ideal, because it is both isotonic and buffered to physiologic pH. Lactated Ringer solution (pH 6–7.5) and 0.9% sodium chloride solution (pH 4.5–7) are also isotonic and therefore theoretically preferable to water.[22] The use of an ocular anesthetic is usually required to perform irrigation properly. Irrigation is intended to accomplish at least four objectives: immediate dilution of the offending agent; removal of the agent; removal of any foreign body; and, in some cases, normalization of anterior chamber pH. As delays of even seconds can dramatically affect outcome,[21] there is no justification for waiting for any specific solution if water is the first available agent. Irrigation must include the external and internal palpebral surfaces, as well as the cornea and bulbar conjunctiva and its recesses. Effective irrigation includes lid retraction and eversion or use of a scleral shell or other irrigating device. After irrigation, visual acuity testing, inspection of the eye, and slit-lamp examination should be performed. The immediacy with which an ophthalmologic consultation must be obtained will depend on the degree of injury.

■ SULFUR MUSTARD

The alkylating agent reacts with ocular tissues resulting in early and late toxic effects. Of note, there is a latency of 30 minutes to 8 hours during which time victims are asymptomatic. Immediate effects include pain, foreign body sensation (grittiness), lacrimation, photophobia, blepharospasm, corneal ulceration, and blindness.[24] Generally, injury is limited to the anterior chamber. More than 90% of exposed victims will experience late complications associated with conjunctival sensitivity to irritants with resultant recurrent blepharoconjunctivitis. Less than 1% of severely intoxicated victims will suffer delayed keratopathy, resulting in thinning, neovascularization, and epithelial defects of the cornea.[24]

Management is directed at removal from the exposure and aggressive decontamination of the skin and eyes. Any of the irrigation solutions mentioned above will suffice. The goal is to provide irrigation as soon as possible; to this end, even tap water is an acceptable solution. Animal studies have suggested that topical anti-inflammatory agents are helpful; as such, a short course of ocular steroids may be beneficial.[5] Steroid treatment should only be rendered in consultation with an ophthalmologist. Late complications are best managed by referral to an ophthalmologist.

■ EXPOSURE-SPECIFIC IRRIGATING SOLUTIONS

Despite theoretical concern, there is probably no toxic exposure for which standard aqueous solutions are contraindicated. Of greatest concern are

TABLE 19–3. Irrigation Solutions for Various Xenobiotics

Xenobiotic	Irrigation Solution	Duration of Irrigation[a]
Caustics (acids/alkalis)	NS, LR, BSS	1–2 h
HF (hydrofluoric acid)	NS	1–2 h[a]
Phenol	NS, LR, BSS	15–20 min
Cyanoacrylate adhesives	Typically none needed	N/A
Capsaicin (pepper spray)	NS, LR, BSS	15–20 min

NS = 0.9% sodium chloride (pH ~5.5), LR = lactated Ringer's solution (pH ~6.5), BSS = balanced saline solution (pH ~7.0).

[a] Duration of irrigation can also be determined by other endpoints, including symptoms or conjunctival pH. See text for further discussion.

agents such as white or yellow phosphorus, metallic sodium, metallic potassium, and calcium oxide (cement) that may react violently in the presence of water, leading to heat or mechanical injury, or resulting in the generation of sodium hydroxide, potassium hydroxide, and calcium hydroxide.[21] Although not well studied, irrigation with large amounts of water probably dissipates the heat of the initial hydration reaction with conjunctival moisture more than it initiates a thermochemical reaction. In addition to removing the offending material, irrigation serves to dilute and remove the alkaline by-products formed by reaction with conjunctival water. Table 19–3 summarizes irrigation solutions for various xenobiotics.

The use of special irrigating solutions for more uncommon exposures, including hydrofluoric acid and phenols, is also debated. Recent animal models of alkaline injury suggest irrigation with amphoteric or buffered solutions rapidly restores anterior chamber pH.[38] The authors have gone further to conclude that normal saline should be avoided as an irrigation solution.[35] These were all ex vivo models, and the majority of the published human data have been case reports. Therefore, at this time these solutions are probably best suited for first aid treatment at worksite eyewash stations and are neither practical nor proven in the emergency department setting for prolonged irrigation.

Hydrofluoric Acid For hydrofluoric acid exposures (Chap. 105), experimental irrigation with calcium salt solutions was too irritating to the eye, but isotonic magnesium chloride solutions appear effective and not irritating.[29,30] From a practical standpoint, however, 0.9% sodium chloride solution remains readily available, well studied, and effective. In one animal model, it was suggested that irrigation beyond the initial liter yielded worse outcomes; however, this has not been demonstrated in a human model.[29]

Phenol For phenol exposure, topical low-molecular-weight polyethylene glycol (PEG) solutions are effective for treatment of experimental skin exposure; for eyes, copious water irrigation appears to be as effective as PEG.[7] There is, however, a report of superior efficacy of PEG-400 over water in treatment of actual phenol eye burns.[26] Although PEG-400 may be readily available at worksites where phenols are used, it is not a realistic option in the emergency department, and there should be no hesitation to use water, 0.9% sodium chloride solution, lactated Ringer solution, or BSS as lavage solutions.

Cyanoacrylate Adhesives Ocular exposures to cyanoacrylate adhesives such as Dermabond and Krazy Glue occasionally result in rapid adherence between upper and lower eyelids that may persist for days. Such occurrences may be associated with corneal abrasions,[13] but are otherwise relatively harmless. In fact, cyanoacrylate has been safely used for decades to treat corneal perforations.[46] Solvents, such as acetone or ethanol, which are often effective treatment for dermal-to-dermal adhesions caused by cyanoacrylates, should never be used in or around the eyes as they can result in a severe keratitis. Expectant management is the safest approach as spontaneous rejection of the glue will occur over time. Application of gauze pads coated with antibiotic ophthalmic ointment may speed recovery.[25] A thorough eye examination should be performed once the eyelids can be fully opened.

Other xenobiotic-specific treatments have been tried experimentally or clinically,[22] but none should be considered prior to or instead of copious irrigation, most are not advocated, and consideration of such agents should be vanishingly rare.

Duration of Irrigation To accomplish the desired goals of irrigation, the appropriate duration varies with the exposure. Most solvents, for example, do not penetrate deeper than the superficial cornea, and brief (10–20 minutes) irrigation is generally sufficient.[21] After exposure to acids or alkalis, normalization of the conjunctival pH is often suggested as a useful end point. Testing of pH should be done in every case of acid or alkali exposure, but the limitations of testing must be understood. When measured by sensitive experimental methods, normal pH of the conjunctival surface is 6.5–7.6.[1] This is highly method dependent, however, and normal values in the literature range from 5.2 to 8.6.[10] When measured by touching pH-sensitive paper to the moist surface of the conjunctival cul-de-sac, normal pH is most often near 8.[3] Therefore, after irrigation following alkali burns, pH should not be expected to reach 7 and is more likely to stabilize near 8.[21] In this setting, lower pH values may indicate the pH of the irrigant rather than of the ocular surface. Waiting for an interval of several minutes between irrigation and pH testing allows washout of any residual irrigant.[11] Choice of testing paper is important, as some are intended for use at extremes of pH and lack sensitivity in the clinically useful range.

Despite these limitations, a logical role for pH assessment can be described: Probably a minimum of 500–1000 mL of irrigant should be used for each affected eye before any assessment of pH, and after 7–10 minutes, the pH of the lower fornix conjunctiva should be checked. Thereafter, cycles of 10–15 minutes of irrigation followed by rechecks should be continued until the pH is 7.5–8. This is certainly adequate for exposures to weak acids, which do not penetrate well, and for alkaline exposures where the pH is less than 12.

For strong or concentrated acid or alkali exposures normal surface pH is not an adequate end point (see Alkalis later). After these burns, irrigation should be continued for at least 2–3 hours, regardless of surface pH, in an attempt to correct anterior chamber pH;[21,36,44] in addition, immediate ophthalmologic consultation is mandatory. Following this lengthy irrigation, it is important to verify that conjunctival pH has normalized. If not, irrigation must be continued, sometimes for 24–48 hours.

■ OTHERS

Most solvents cause immediate pain and superficial injury because of dissolution of corneal epithelial lipid membranes, but do not penetrate or react significantly with deeper tissue.[21] The epithelial defect may be large or complete, but the limited depth of injury usually allows rapid regeneration of normal epithelium. Detergents and surfactants cause variable injury, ranging from minor irritation from soaps to extensive injury from cationic agents such as concentrated benzalkonium chloride.[21] Ocular exposure to A-200 Pyrinate pediculicide shampoo causes typical detergent-surfactant injury, leading to extensive loss of corneal epithelium but with normal underlying stroma, and therefore complete healing within days. Lacrimators (tear gases), such as chloroacetophenone,

stimulate corneal nerve endings and cause pain, burning, and tearing, but produce no structural injury at low concentrations. At high concentrations, these agents can produce significant corneal injury.

Pepper spray, often used for self-protection by civilians or law enforcement agents, contains the active ingredient oleoresin capsicum (OC). OC results in rapid depolarization of nociceptors containing substance P, resulting in immediate pain, blepharospasm, tearing, and blurred vision. In general, ocular injury is uncommon, although corneal erosions can occur. The solvent used for the spray can be more injurious to the eye than the OC itself. Although most sprays use a water-based or oil-based solvent, some use alcohol, which can result in significant corneal damage.[47] Management of pepper spray exposure consists of rapid irrigation and pain control. Corneal erosions can be treated with artificial tears but corneal abrasions should be treated with topical antistaphylococcal antibiotics. Specific information on thousands of agents is readily available if needed.[21]

■ GENERAL MEASURES

There is a wide array of options for adjunctive therapy of chemical burns of the eye. In all cases in which serious injury is evident, the treatment plan must include consultation with an ophthalmologist. Generally, patients with corneal injury should be treated with an ocular topical antibiotic providing antistaphylococcal and antipseudomonal coverage. Cycloplegics not only reduce pain from ciliary spasm, but also decrease the likelihood of posterior synechiae (scar) formation. Topical NSAIDs and systemic analgesics also improve patient comfort. It is never appropriate to dispense topical ophthalmic anesthetics, because repeated use leads to further corneal disruption both by direct chemical effects and by eliminating corneal protective reflex sensation.

DISPOSITION

Disposition of patients with chemical burns of the cornea can be challenging. Patients with extensive burns to other parts of the body should be evaluated for transfer to a burn center. Grading the degree of injury in patients with isolated ocular injury can guide disposition. The most commonly used grading system is the Roper-Hall modification of the Ballen classification system. Injury is graded on a four-tier scale: Patients with mild conjunctival injection with corneal epithelial loss and minimal corneal haziness are classified as grades 1 and 2 (mild to moderate). These patients can be safely discharged from the emergency department with ophthalmology followup within 24–48 hours. Patients with severe corneal haziness or opacification with significant limbal ischemia are classified as grades 3 or 4 (moderate to severe) and should receive immediate consultation with an ophthalmologist; transfer to a burn unit should be considered.

SYSTEMIC ABSORPTION AND TOXICITY FROM OCULAR EXPOSURES

Systemic absorption from ocular exposure has caused serious toxicity, morbidity, and even death.[14,23] Although the patterns of toxicity are characteristic of the xenobiotics involved, recognition may be delayed as a result of a failure to appreciate the eye as a significant route of absorption. Although transcorneal diffusion of xenobiotics is limited, there is substantial nasal mucosal absorption after nasolacrimal drainage, and absorption via conjunctival capillaries and lymphatics, which is markedly increased during conjunctival inflammation. Unlike the gastrointestinal route of absorption, there is no significant first-pass hepatic removal after ocular absorption; consequently, bioavailability

is much greater.[20,23,39] If nasolacrimal outflow is normal, up to 80% of instilled drug may be absorbed systemically.[14] Unfortunately, by the time toxicity is apparent, there is no role for ocular decontamination to prevent further absorption. After instillation of eye drops, absorption is generally complete within 7 minutes.

Children appear to be at greatest risk, possibly because of the higher relative drug dose they experience when systemic absorption does occur.[14,34,39] Diligent attempts to comply with prescribed dosing in a struggling, crying infant may also result in excessive dosing. As eyedrop size (40–50 µL) exceeds ocular cul-de-sac capacity (30 µL), overflow often occurs and is assumed to represent a failed instillation, which leads to unnecessary reinstillation. Also, as doses of ocular medications are typically not adjusted based on patient weight, the consequences of equivalent degrees of systemic absorption are much greater for an infant than for an adult. Toxicity from eye drops is also a problem among the immunocompromised, probably because of the combination of greater use of potentially toxic ophthalmic medications and the presence of comorbid conditions.

Prevention of systemic toxicity from topical ophthalmic medications requires recognition of the risk, a careful history, use of the lowest effective concentration and dose, and patient education including proper administration instructions. To minimize inadvertent absorption, no more than one drop of any eyedrop solution should be instilled at one time in the superolateral corner of the eye while using gentle finger compression of the medial canthus to limit nasolacrimal drainage.[14,23]

■ MYDRIATICS

Mydriatics are used almost exclusively to dilate the pupils prior to diagnostic evaluation of the eyes. This common practice is not generally considered to be potentially dangerous; however, the risk may be substantial if the precautions outlined are not considered. Anticholinergic poisoning (Chap. 50), including substantial morbidity and mortality, is well described after ocular use of atropine, cyclopentolate, or scopolamine eyedrops, especially in infants.

The use of the α-adrenergic agonist phenylephrine eyedrops in a 10% solution may cause severe hypertension, subarachnoid hemorrhage, ventricular dysrhythmias, and myocardial infarction.[16] Fortunately, these effects are rare if the 2.5% ocular phenylephrine is used. Mydriatics can also precipitate acute angle closure glaucoma in susceptible individuals.

■ MIOTICS AND OTHER ANTIGLAUCOMA DRUGS

Miosis can be induced by the cholinesterase inhibitor echothiphate (sometimes used to treat glaucoma or accommodative esotropia) which can exacerbate asthma, parkinsonism, cardiac disease, and prolong the metabolism of certain medications such as succinylcholine.[23] Miosis can also be produced by use of direct cholinergic agonists, such as pilocarpine. Although absorption is limited, nausea and abdominal cramps can occur at recommended doses. After excessive dosing, salivation, diaphoresis, bradycardia, and hypotension may occur.

β-Adrenergic antagonists, such as timolol, levobunolol, metipranolol, carteolol, and betaxolol, are used to lower intraocular pressure but may cause a variety of adverse effects, including bradycardia, hypotension, myocardial infarction, syncope, transient ischemic attacks, congestive heart failure, exacerbation of asthma, and respiratory arrest. Timolol has exacerbated symptoms in patients with myasthenia gravis and is implicated in both causing and masking symptoms of hypoglycemia in diabetics.[41,42] Nonspecific complaints of anorexia, anxiety, depression, fatigue, hallucinations, headache, and nausea are also described after use of timolol eye drops. Despite the cardioselectivity of betaxolol, respiratory toxicity has occurred.[14]

Dipivefrin, an esterified epinephrine derivative sometimes used to treat glaucoma, can cause adrenergic systemic effects, although much fewer than those caused by epinephrine. Ophthalmic formulations of highly selective α_2-adrenergic agonists, brimonidine (Alphagan) and apraclonidine (Iopidine), were introduced to treat glaucoma.[14,45] Apraclonidine is expected to have a lower potential for toxicity because of limited CNS penetration. Systemic absorption of brimonidine eye drops in a child has led to bradycardia, hypotension, and a decreased level of consciousness, similar to the central effects of other α_2-adrenoceptor agonists (eg, clonidine),[6] apparently mediated through both α_2-adrenoceptors and imidazoline receptors[8] (see Chap. 62).

■ ANTIMICROBIALS

Life-threatening reactions to ophthalmic antimicrobials are unusual. Aplastic anemia has occurred after prolonged use of chloramphenicol eye preparations,[15] and Stevens-Johnson syndrome was reported after short-term use of ophthalmic sulfacetamide in a patient with a history of allergy to sulfa drugs.[20]

TOXICITY TO OCULAR STRUCTURES FROM NONOCULAR EXPOSURES

Ocular toxicity from systemic xenobiotics is almost always the result of chronic exposure, and the manifestations develop over a prolonged period of time. Thousands of xenobiotics are implicated, affecting every element of the visual system from the cornea to the optic cortex. Thorough discussion of this topic is beyond the scope of this text, but Table 19–2 lists examples of causative xenobiotics.[17,21] Many topical and systemic medications are associated with inflammation of the eye, ie, uveitis (inflammation of the iris, ciliary process, or choroids membrane).[18] Unlike many other ocular abnormalities caused by xenobiotics, uveitis should prompt immediate ophthalmologic consultation. Because in many cases the etiology is related to commonly prescribed medications, adverse drug effects should always be considered when patients present with visual abnormalities or unusual ocular findings.

In the setting of emergency care, xenobiotic-induced disturbances of normal vision from systemic exposures take many forms. Impaired near-vision from mydriasis, and diplopia or nystagmus from interference with normal control of extraocular movements, are examples of common, usually harmless visual effects. Serious effects generally result from injury or dysfunction of the neural elements from the retina to the cortex. Such toxicity can be direct (neurotoxic) or indirect (hypoxia, ischemia). Many xenobiotics historically reported to cause acute visual loss directly are no longer available.[21] Methanol and quinine are currently the most important xenobiotics that cause direct visual toxicity after acute oral poisoning. Many xenobiotics capable of causing vasospasm, hypotension, or embolization also cause acute visual loss (Table 19–4).[40] Blindness and other visual defects are described following recovery from severe toxicity with barbiturates and other sedative-hypnotics, opioids, carbon monoxide, and many others.[21]

OCULAR COMPLICATIONS OF DRUG ABUSE

In addition to the well-known ocular pupillary signs of opioid, cocaine, amphetamine, and phencyclidine toxicity, a number of complications may result from short-term or long-term use of these and other agents.[31] Quinine amblyopia (see Quinine earlier) caused by intravenous use of quinine-containing heroin is one of many ocular complications caused by injection of contaminants. Talc contaminants have resulted in talc retinopathy, which was first described after prolonged intravenous use

TABLE 19–4. Xenobiotics Reported to Cause Visual Loss After Acute Exposures

Direct causes	Indirect causes[b]
Caustics	Vasoactive agents
Methanol	Amphetamines
Quinine	Cocaine
Lead[a]	Ergot alkaloids
Mercuric chloride[a]	Hypotension (eg, calcium channel blockers)
	Cisplatin
	Combined endocrine agents (thyrotropin-releasing hormone with gonadotropin-releasing hormone and glucagon)
	Embolization of foreign material (intravenous injection)

[a] Distinctly rare with these poisonings.

[b] Distinctly rare with use of these agents; visual loss often instantaneous, secondary to sudden hypotension, vascular spasm, or embolization.

of adulterated methylphenidate,[19] but was also noted after intravenous use of heroin, methadone,[32] codeine, meperidine, and pentazocine. Talc retinopathy develops only after extensive intravenous drug use. In one study of intravenous methadone abusers, only patients who had injected more than 9000 tablets developed this complication.[32] Infectious complications, such as fungal (*Candida, Aspergillus*) or bacterial (*Staphylococcus* spp, *Bacillus cereus*) endophthalmitis, are well known as both direct effects of intravenous drug use and secondary complications of AIDS. In addition to AIDS-related ophthalmic infections such as cytomegalovirus, cryptococcus, toxoplasmosis retinitis, and choroidal *Mycobacterium avium-intracellulare* complex (MAC), other disorders include retinal cotton-wool spots, conjunctival Kaposi sarcoma, and ocular motility disorders caused by infectious or neoplastic meningitis. Corneal defects have been noted after smoking cocaine alkaloid ("crack eye").[37] Cocaine that is either volatilized or inadvertently introduced by direct contact probably results in corneal anesthesia and loss of corneal protective reflex sensation. Minor trauma, such as eye rubbing, then leads to corneal epithelial defects. In addition, there appears to be an increased incidence of infectious keratitis and corneal ulceration in these patients. The ability of local anesthetics to interfere with corneal epithelial adhesion may also play a role.

SUMMARY

Both systemic and local toxicologic emergencies occur in the ophthalmic system. This discussion has focused on research in the treatment of damage to the eye caused by xenobiotics. Although the obvious physical injuries are apparent to the clinician, the more subtle clues to toxicologic mechanisms that involve the ophthalmic and neurologic systems are made only by a meticulous examination of the eye. A careful ophthalmic examination often leads to early recognition of a toxicologic emergency.

CHAPTER 20
OTOLARYNGOLOGIC PRINCIPLES

William K. Chiang

Many xenobiotics adversely affect the senses of olfaction, gustation, and cochlear-vestibular functions. These toxic effects are not life threatening and frequently considered less important than they actually are to the patient. Because of the lack of standardized diagnostic techniques and normal parameters, such adverse effects may be overlooked and dismissed by healthcare providers, despite significant patient distress and dysfunction. This is particularly true for disorders of olfaction and gustation. This chapter reviews the anatomy and physiology of these senses; describes the effects of xenobiotics on these senses and examines the significant diagnostic information these senses contribute to identifying the presence of xenobiotics. Understanding the effects of xenobiotics on the senses may allow for early detection, which occasionally can be lifesaving.

OLFACTION

■ ANATOMY AND PHYSIOLOGY

Olfactory receptors are bipolar neurons located in the superior nasal turbinates and the adjacent septum. There are 10 to 20 million receptor cells per nasal chamber, and the receptor portion of the cell undergoes continuous renewal from the olfactory epithelium.[106,110] Renewed olfactory receptors regenerate neural connections to the olfactory bulb. These olfactory receptor neurons are distinctive in their ability to regenerate.[22] The axons of these cells form small bundles that traverse the fenestrations of the cribriform plate of the ethmoid bone to the dura. Within the dura, these bundles form connections with the olfactory bulb from which neural projections then connect to the olfactory cortex. There are extensive interconnections to other parts of the brain, such as the hippocampus, thalamus, hypothalamus, and frontal lobe, suggesting effects on other biologic functions.[106] Although primary odor detection is a function of the olfactory nerve (I), some irritant odors, such as ammonia and acetone, are transmitted through the trigeminal nerve (V) and its receptors.[40,144]

The actual olfactory receptor sites are structurally similar to the taste receptors of the mouth and the photoreceptors of the retina. The receptor is a single polypeptide chain consisting of approximately 350 amino acids, which folds back and forth on itself to traverse the cellular membrane seven times. The outer end of the polypeptide contains an amine group (N-terminal) and the cytosol end contains a carboxyl group (C-terminal). The transmembranous portions determine the receptor shape and characteristics of the binding site. When a molecule binds to a specific receptor site, the resultant conformational change leads to the activation of the G protein system and calcium and/or sodium channel activation and neurotransmission.[72]

Smelling is an extremely sensitive mechanism of detecting xenobiotics. Olfactory receptors can detect the presence of a few molecules of certain xenobiotics with a sensitivity that is superior to some of the most sophisticated laboratory detection instruments.[65]

■ LIMITATIONS OF THE OLFACTORY SENSES

The sense of smell can be extremely useful as a toxicologic warning system. Human olfaction is a variable trait.[5,117,174] For example, 40%–45% of people have specific anosmia (inability or loss of smell) for the bitter almond odor of cyanide.[41,86,117] There are limited data on the inheritance characteristics or genetic basis of these specific forms of anosmia. While some studies suggest that the ability to detect the odor of cyanide is a sex-linked recessive trait,[55] other studies yield conflicting results.[5,17,88] Women have a greater ability to detect androsterone, which is prominent in human underarm secretion.[65] Human olfaction usually can distinguish a mixture of no more than four xenobiotics,[92] and therefore specific odors may be masked by other stimuli.

Olfactory fatigue is the process of olfactory adaptation following exposure to a stimulus for a variable period of time. This leads to a temporal diminution of the smell. Unfortunately, this adaptation may lead to a false sense of security with continued exposure to a xenobiotic. For example, hydrogen sulfide, which inhibits cytochrome oxidase, is readily detectable as distinct and offensive at the very low concentration of 0.025 ppm. At the higher and potentially toxic concentration of 50 ppm, the odor is less offensive, and recognition may disappear after 2–15 minutes of exposure.[8,149] At higher concentration still when toxicity is likely, the onset of olfactory fatigue is even more rapid. The combination of the rapid onset of olfactory fatigue and systemic toxicity at high concentrations of hydrogen sulfide exposure has contributed to numerous fatalities (Chap. 126).[1,23,161]

In industrial settings, it is important to be aware of impaired olfactory function in any worker who may be exposed to chemical vapors or gases.[70,154] Such workers are at increased risk for toxic injury. The National Institute for Occupational Safety and Health (NIOSH) requires that an individual using an air-purifying respirator be capable of detecting the odor of a xenobiotic at concentrations below those producing toxicity.[6,154] Sensory perception at this concentration ensures that the individual can detect filter cartridge "breakthrough" or failure at a safe concentration.[154] The odor safety factor refers to the ratio of the time-weighted average (TWA) threshold limit value (TLV) to the odor threshold for a given xenobiotic. A xenobiotic with a high odor safety factor can be detected despite prolonged exposure.[6] Nontoxic xenobiotics, such as ethyl mercaptan, with a very high odor safety factor, can be added to xenobiotics that are odorless with lower safety factors, so that olfactory detection is predictable. This enhanced sensory awareness is the basis for the addition of mercaptans to the odorless natural gases used in the home so as to limit the potential for unrecognized hazardous exposure.

■ CLINICAL USE OF ODOR RECOGNITION

The recognition of odors has traditionally been considered an important diagnostic skill in clinical medicine. Some diseases can be diagnosed accurately by recognizable associated odors of various affected parts of the body such as the breath, sweat, urine, and wounds: diabetic ketoacidosis as a characteristically fruity odor; diphtheria as sweet; scurvy as putrid; typhoid fever as fresh-baked brown bread; and scrofula as stale beer.[35] Odors are also described for disorders of amino acid and fatty acid metabolism, such as phenylketonuria, maple syrup urine disease, hypermethioninemia, and isovaleric acidemia.[35]

The recognition of odors continues to be an important diagnostic skill for the rapid detection of some xenobiotics (Table 20–1). To increase awareness of odors of toxic xenobiotics, a "sniffing bar" of commonly available odors may be prepared.[60] Nontoxic xenobiotics that simulate the odors of toxic xenobiotics are placed in test tubes, numbered, and inserted in a test tube rack for circulation among staff. The sniffing bar, brief descriptions of clinical presentations, and a table of diagnostic odors (Table 20–1) may be used to teach the recognition of odors in medical toxicology.[60]

TABLE 20–1. Odors Suggestive of a Xenobiotic

Odor	Xenobiotic
Bitter almond	Cyanide
Carrots	Cicutoxin (water hemlock)
Disinfectants	Creosote, phenol
Eggs (rotten)	Carbon disulfide, disulfiram, hydrogen sulfide, mercaptans, N-acetylcysteine
Fish or raw liver (musty)	Aluminum phosphide, zinc phosphide
Fruit	Nitrites (amyl, butyl)
Garlic	Arsenic, dimethyl sulfoxide (DMSO), organic phosphorus compounds, phosphorus, selenium, tellurium, thallium,
Hay	Phosgene
Mothballs	Camphor, naphthalene, p-dichlorobenzene,
Pepper	O-chlorobenzylidene malonitrile
Rope (burnt)	Marijuana, opium
Shoe polish	Nitrobenzene
Sweet fruity	Acetone, chloral hydrate, chloroform, ethanol, isopropanol, lacquer, methylbromide, paraldehyde, trichloroethane
Tobacco	Nicotine
Vinegar	Acetic acid
Violets	Turpentine (metabolites excreted in urine)
Wintergreen	Methyl salicylate

TABLE 20–2. Xenobiotics Responsible for Disorders of Smell

Hyposmia/Anosmia	Dysosmia/Cacosmia/Phantosmia
Acrylic acid	Amebicides/antihelminthics: metronidazole
Antihyperlipidemics: cholestyramine, clofibrate, gemfibrozil, HMG-CoA reductase inhibitors	Anesthetics, local
	Anticonvulsants: carbamazepine, phenytoin
	Antihistamines
Cadmium	Antihypertensives: ACE inhibitors, diazoxide
Chlorhexidine	Antimicrobials
Cocaine	Antiinflammatory
Formaldehyde	Antirheumatics: allopurinol, colchicine, gold, D-penicillamine
Gentamicin nose drops	Antiparkinson drugs: levodopa, bromocriptine
Hydrocyanic acid	
Hydrocarbons (volatile)	Antithyroid drugs: methimazole, methylthiouracil, propylthiouracil
Hydrogen sulfide	
Methylbromide	β-Adrenergic antagonists
Nutritional	Calcium channel blockers
Vitamin B_{12} deficiency	DMSO (dimethylsulfoxide)
Zinc deficiency	Ethacrynic acid
Pentamidine	Insecticides
Sulfur dioxide	Lithium
	Nicotine
	Opioids
	Sympathomimetics
	Toothpastes
	Vitamin D

Anosmia = the loss of smell; cacosmia = sensation of a foul smell; dysosmia = a distorted perception of smell; hyposmia = a decreased perception of smell; phantosmia = sensation of smell without stimulus.

CLASSIFICATION OF OLFACTORY IMPAIRMENT

There are different types of olfactory dysfunction. Anosmia, the inability to detect odors, and hyposmia, a decrease in the perception of certain odors, are the most common forms of olfactory impairment. The etiology of olfactory impairment may be classified as conductive, from anatomic obstruction of inspired air, or perceptive, from dysfunction of the olfactory receptors or signal transmission. Most conductive olfactory dysfunction results in hyposmia, because the obstruction is usually incomplete.[106,141]

The most common causes of anosmia and hyposmia are viral infections, trauma, xenobiotics, tumors, and congenital and psychiatric disorders (Table 20–2).[40,127,133,141,144] Viral infections may result in olfactory impairment either by obstructing nasal airflow or by causing damage to the olfactory epithelium.[73] Trauma to the head or nose can shear fragile olfactory nerves crossing the cribriform plate.[144,163]

Chronic exposures to numerous xenobiotics are associated with olfactory dysfunction (Table 20–2). The most common toxic mechanism related is perceptive olfactory dysfunction. This may be a result of a direct injury, or of a structural alteration of the receptor or its components such as G proteins, adenylate cyclase, or receptor kinase.[71,72] Anosmia or hyposmia from hydrocarbons, formaldehyde, cadmium, and antineoplastics such as cytarabine results from direct effects on the receptor sites.[44,72,77] Local effects on the epithelium and the receptors from antibiotic nose drops may lead to temporary anosmia and hyposmia.[83,173] Inhaled corticosteroids may have local effects on the epithelium, as well as direct effects on both G proteins and adenylate cyclase.[74] Cocaine insufflation causes direct local effects, as well as effects on receptor functions.[61,63,69] Because of local effects of most xenobiotics and the regenerative ability of the olfactory receptor neurons, most xenobiotic-induced olfactory dysfunction is reversible.

Many individuals determined to have anosmia actually have congenital anosmia for select molecules, such as hydrogen cyanide, N-butyl mercaptan, trimethylamine, and isovaleric acid.[7,40] Some extreme forms of congenital anosmia are associated with other abnormalities, such as Kallmann syndrome, a hereditary form of anosmia associated with hypogonadotropic hypogonadism where agenesis of the olfactory bulbs and incomplete development of the hypothalamus are responsible for the anosmia.[40,144]

Dysosmia or parosmia is the distorted perception of smell (Table 20–2). Subclassifications of dysosmia include the perception of foul smell or cacosmia, the sensation of smell without a stimulus, or phantosmia, and the sensation of the smell of a burnt or metallic material, torqosmia.[141] The etiologies are classified as peripheral or central. Peripheral etiologies include abnormalities of the nose, sinuses, and upper respiratory tract. Central etiologies may be related to disorders such as Addison disease, hypothyroidism, temporal lobe epilepsy, psychosis, or pregnancy.[40,106,142] How these conditions actually alter the perception of smell is unclear. A number of xenobiotics with similar effects are listed in Table 20–2. Bromocriptine alters dopaminergic transmission and inhibits adenylate cyclase. Levodopa affects the dopaminergic transmission as well as chelating zinc, which is important in the maintenance of normal receptor functions.[72,74]

EVALUATION OF OLFACTORY IMPAIRMENT

General evaluation of olfactory function should include a detailed history, focusing on types, duration, and progression of symptoms,

recent illnesses, head and nose trauma, sinus problems, family history, occupational history, hobbies, and xenobiotic history.[36,64] A physical examination with a detailed examination of the nasopharynx and sinuses should be performed to assess the potential for inflammation or structural abnormality. A simple set of olfactory stimulants, such as ground coffee, almond extract, peppermint extract, and musk, should be used to test each nostril individually with the patient's eyes closed.[64,144] Standardized smell tests such as the UPSIT (University of Pennsylvania Smell Identification Test) and the CCCRC (Connecticut Chemosensory Clinical Research Center) tests are commercially available, and a composite score based on a panel of tests can determine the degree of olfactory dysfunction.[98] Pungent odors or stimulation associated with ammonia, capsaicin, acetone, and menthol are dependent on the trigeminal nerve (V) olfactory function, which is mainly responsible for tactile pressure, pain, and temperature sensation in the mouth and nasal cavity. A patient who has olfactory nerve damage should be able to detect these substances; conversely, a person with hysteria may deny detection of these substances that should physiologically be recognized.[64,144,173] If a xenobiotic-mediated mechanism is suspected, the offending xenobiotic should be discontinued. A coronal CT of the sinuses and nose or an MRI of the brain should be obtained if structural abnormalities are suspected.[144,173] Gas chromatographic analysis of the urine may be useful in patients with fish odor syndrome associated with trimethylaminuria.[93,151] Complicated cases and patients with significant impairment should be referred to an otolaryngologist or neurologist.

GUSTATION

■ ANATOMY AND PHYSIOLOGY

Taste, the sensory interpretation of orally ingested materials, is determined by taste buds on the tongue, palate, throat, and upper third of the esophagus. The cells in the taste buds have a life span of 10 days and are constantly renewed.[11,141] The taste buds on the anterior two-thirds of the tongue and the palate are innervated by the facial (VII) nerve, those on the posterior one-third of the tongue by the glossopharyngeal (IX) nerve, and those on the laryngeal and epiglottal regions by the vagus (X) nerve. There are at least 13 known chemical taste receptors responsible for the five primary taste sensations—sweet, sour, bitter, brothy, and salty: two sodium receptor types; two potassium receptor types; one chloride receptor; one adenosine receptor; two inosine receptor; two sweet receptor types; two bitter receptor types; one glutamate receptor; and one hydrogen ion receptor.[66] One substrate will typically activate multiple taste receptors; the combined effects of these stimulated receptors determine the taste of the substance.[53]

The structure of the taste receptors is similar to that of the olfactory receptors, in that they are coupled to G proteins and sodium and calcium channels permitting neural stimulation. Each receptor is capable of interacting with various classes of xenobiotics, of varying sizes. The pH of the xenobiotic determines sour or acid taste, whereas sodium or potassium concentrations determine salty taste. Many xenobiotics such as sugars, glycols, aldehydes, ketones, amides, amino acids, inorganic salts of lead, and bretylium activate the sweet receptors. Bitter taste may be the result of long-chain organic substances containing nitrogen, or alkaloids, including quinine, strychnine, caffeine, and nicotine.[66] Umami taste is a more recently accepted primary taste, associated with a brothy flavor. The primary xenobiotic that stimulates umami receptor is glutamate, such as monosodium-L-glutamate. Umami receptor stimulation can be enhanced by such 5′-ribonucleotide monophosphates

as IMP and GMP.[177] Salivary proteins, such as zinc-containing gustin and ebnerin, are important in the regulation of taste sensation.[72,76,95,150] These molecules may serve as binding proteins and growth factors for the regeneration of taste receptors. Taste is also affected significantly by the appreciation of aromas or odors and, to a lesser extent, by visual perception.[142]

■ CLASSIFICATION OF GUSTATORY DYSFUNCTION

Types of gustatory dysfunction include ageusia, the inability to perceive taste; hypogeusia, the diminished sensitivity of taste; and dysgeusia, the distortion of normal taste. There are several variations of dysgeusia, such as cacogeusia, which is a perceived foul, perverted, or metallic taste.[64,103] Taste impairment is commonly related to direct damage to the taste receptors, adverse effects on their regeneration, or effects on receptor mechanisms.[73] These effects can result from a xenobiotic, disease, aging, and nutritional disorder (Table 20–3).[59,66,132,159] Any abnormality that interferes with either the direct contact of a xenobiotic with the gustatory cells of the tongue or cranial nerves VII, IX, or X dramatically affects taste.[141] Most common forms of xenobiotic-induced dysgeusia are related to direct effects on the

TABLE 20–3. Xenobiotics Responsible for Alterations of Taste

Hypogeusia/Ageusia	Dysgeusia	Metallic Taste
Local	*Local*	ACE inhibitors
Chemical and thermal burns	Chemical burn	Acetaldehyde
	Radiation therapy	Allopurinol
Radiation therapy	*Systemic*	Arsenicals
Systemic	ACE inhibitors	Cadmium
ACE inhibitors	Adriamycin	Ciguatoxin
Amiloride	Amphotericin B	Copper
Amrinone	Botulism (in recovery)	*Coprinus* spp
Carbon monoxide	Bretylium	Dipyridamole
Cocaine	Carbamazepine	Disulfiram
DMSO (dimethylsulfoxide)	DMSO (dimethylsulfoxide)	Ethambutol
	5-Fluorouracil	Ferrous salts
Gasoline	Griseofulvin	Flurazepam
Hydrochlorothiazide	Isotretinoin	Iodine
Methylthiouracil	Levodopa	Lead
Nitroglycerin	NSAIDs	Levamisole
NSAIDs	Nicotine	Lithium
Penicillamine	Nifedipine	Mercury
Propranolol	Phenylthiourea (hereditary)	Methotrexate
Pyrethrins	Quinine	Metformin
Smoking	Zinc deficiency	*Metoclopramide*
Spironolactone		Metronidazole
Triazolam		Pentamidine
		Procaine penicillin
		Propafenone
		Snake envenomation
		Tetracycline

taste receptor site or effects related to receptor mechanisms such as G proteins, adenylate cyclase, and calcium channels.[91] Other forms of dysgeusia may result from direct stimulation of chemical receptors by xenobiotics.[66,72]

Angiotensin-converting enzyme (ACE) inhibitors commonly cause gustatory impairment, usually hypogeusia and dysgeusia.[16,61,105,175] ACE inhibitors work by inhibiting zinc-dependent ACE, and chelating zinc from taste receptors and salivary proteins results in gustatory dysfunction. Calcium channel blockers act by inhibiting calcium channels of the taste receptor mechanisms.[66] Many diuretics cause zinc depletion by enhancing zinc elimination in the urine,[72] whereas furosemide and spironolactone may also chelate zinc. Numerous xenobiotics also cause gustatory dysfunction through variable degrees of zinc chelation, among them amrinone, ethambutol, hydralazine, methyldopa, the nonsteroidal antiinflammatory drugs (NSAIDs), the antithyroid agents, penicillamine, and phenytoin.[66,72,176] Metals such as arsenic, mercury, chromium, and lead may either chelate zinc or replace zinc in salivary proteins because of a higher level of affinity. Antineoplastics and the antimicrotubular colchicine inhibit cellular division and taste-receptor regeneration. The oral antiseptic chlorhexidine directly alters taste-receptor function.[52] Acetazolamide causes cacogeusia when carbonated beverages are consumed. The exact mechanism is unclear, but is postulated to be a result of the inhibition of carbonic anhydrase causing carbon dioxide accumulation and an increased tissue bicarbonate.[72,84,107]

HEARING

ANATOMY AND PHYSIOLOGY

Normal hearing begins when sound waves are captured by the external auricle, traverse the external auditory canal, and are conducted to the tympanic membrane, the three auditory ossicles of the middle ear, and through the oval window to the perilymph in the scala vestibuli of the cochlea (Figs. 20–1 and 20–2). The sound wave is then transferred through the Reissner membrane at the roof of the cochlear duct, to the endolymph and the organ of Corti.[48,155] The specialized hair cells of the organ of Corti convert mechanical waves into neurologic signals. The hair cells contain cross-linked stereocilia projections that detect transmitted shear forces, which lead to the influx of potassium from the endolymph through opened potassium channels.[38,96] Depolarization of the hair cells results in calcium influx and neurotransmitter release to the cochlear nerve. Neurologic signals from the cochlear nerve are conducted to the cochlear nucleus of the pons; bilateral projections are then sent to the superior olivary nucleus of the midbrain, nuclei of lateral lemnisci, inferior colliculus, medial geniculate body of the thalamus, and then to the auditory cortex of the temporal lobe.[155] Interruption or damage to any part of the hearing mechanism may lead to auditory impairment.

The anatomy and physiology of the cochlea and its importance in the biomechanics of hearing are reviewed in order to better understand the potential for xenobiotic injury. The word *cochlea* is derived from the Greek word *kochlias*, meaning snail, and describes its general structure—a 2.5-turn, spirally wound tube. The cochlea is further divided into three inner tubular structures: the upper tube or scala vestibuli, the middle tube or cochlear duct, and the lower tube or scala tympani. The scala vestibuli and the scala tympani contain the perilymph fluid. The cochlear duct contains endolymph fluid, the Reissner membrane at the roof, and the organ of Corti.[155] The cochlear fluids serve multiple functions: to conduct sound waves to the hair cells; to provide nutrients for and remove waste from the cells lining the cochlear duct; to control
FIGURE 20–1. Pathways of sound conduction in the ear.

pressure distribution in the cochlea; and to maintain an electrochemical gradient for the function of the hair cells. The sodium concentration of the perilymph is similar to that of the extracellular fluid, and the potassium concentration of the endolymph is similar to that of the
FIGURE 20–2. Cross-section of the organ of Corti.

intracellular fluid.[50] Any significant alterations of the sodium or potassium concentrations will depress the cochlear potential and function. The stria vascularis controls the production of the cochlear fluids and the repolarization of the hair cells, and maintains the electrochemical gradient between the endolymph and the perilymph. The stria vascularis contains a high concentration of the oxidative enzymes, Na^+-K^+-adenosine triphosphatase (ATPase), adenylate cyclase, and carbonic anhydrase, which are all highly susceptible to xenobiotics.[18,77,139]

Although human speech is composed of sounds in the frequency of 250–3000 Hz, humans can normally detect sounds in the frequency range of 20–20,000 Hz.[116] The cochlea is a "tuned" structure with varying width and stiffness, such that different regions can receive different sound waves. The stiffer and wider base of the cochlea serves as a receptacle for higher-frequency sounds, whereas the apex is responsible for receiving the lower-frequency sounds.[48] Because various regions of the cochlea are susceptible to different forms of injury, appropriate audiologic testing should be tailored specifically to each patient.[25]

■ XENOBIOTIC-INDUCED OTOTOXICITY

Ototoxicity includes effects on the cochlear and vestibular system. This chapter focuses on cochlear toxicity. Quinine and salicylates were widely recognized in the 1800s and streptomycin in the 1940s as causes of ototoxicity.[78,134] Several hundred xenobiotics have been implicated as causes of other reversible or irreversible ototoxicity (Table 20–4).[21,82,89,113] Ototoxic xenobiotics primarily affect two different sites in the cochlea: the organ of Corti—specifically the outer hair cells—and the stria vascularis. Because of the limited regenerative capacity of the sensory hair cells and other supporting cells, when significant cellular damage occurs, the loss is often permanent.[42,48,78,153] Although cell death of the outer hair cells from inflammation and necrosis is expected when sufficient insults occur, apoptotic cell death is now postulated to be a major mechanism of ototoxicity from certain xenobiotics such as cisplatin and aminoglycosides.[18,21,39,78,82,131] Inhibition of caspases and calpain associated with apoptosis of the hair cells is demonstrated to decrease ototoxicity from cisplatin and aminoglycosides in animals.[131,152] Evidence supports the concept that otic injury can be potentiated by loud noises. Although the actual cellular mechanisms for many forms of ototoxicity remain unclear,[172] some of the mechanisms are known.[56] Loop diuretics, such as furosemide, bumetanide, and ethacrynic acid, cause physiologic dysfunction and edema at the stria vascularis, resulting in reversible hearing loss.[78,101,168] The underlying mechanisms appear

to be the inhibition of potassium pumps and G proteins associated with adenyl cyclase.[9] Studies of loop diuretics demonstrate decreased potassium activity in the endolymph and a decreased endocochlear potential.[136] Permanent hearing loss associated with furosemide and ethacrynic acid is also reported, and may be related to direct interference with oxidative metabolism in the outer hair cells.[90,101,136]

Salicylates are a well-known cause of ototoxicity. Aspirin (acetylsalicylic acid)-induced hearing impairment was first reported in 1877.[85] Salicylate-induced hearing loss is generally mild to moderate (a 20–40 dB loss) and reversible.[15,80] Animal studies demonstrate immediate hearing impairment with the use of high doses of salicylates.[14,102,103,123] The mechanism of salicylate-induced ototoxicity is unclear, although multiple factors are postulated. Salicylates and other NSAIDs inhibit cyclooxygenase, which converts arachidonic acid to prostaglandin G_2 and prostaglandin H_2. These effects may interfere with Na^+-K^+-ATPase pump function at the stria vascularis, and also decrease cochlear blood flow.[27,45,85] A reversible decrease in outer hair cell turgor secondary to membrane permeability changes may impair otoacoustic emissions.[122,126] In support of these theories, pretreatment of animals with leukotriene antagonists and α-adrenergic receptor antagonists attenuates or prevents salicylate-induced ototoxicity.[85]

NSAIDs and quinine also cause reversible hearing loss, particularly at the higher frequencies.[29,78] Occasionally, quinine-induced hearing loss may be permanent.[78,140] The primary mechanism is related to prostaglandin inhibition.[85] Quinine inhibits phospholipase A_2 enzyme, which converts phospholipids to arachidonic acid. Quinine also inhibits calcium channels that interact with prostaglandins.[85]

Certain antineoplastics, such as cisplatin, vinblastine, and vincristine, can cause permanent ototoxicity.[78] Cisplatin is the most toxic of the group, with clinically apparent hearing loss noted in 30%–70% of the patients receiving doses of 50–100 mg/m^2. These antineoplastics typically damage the outer hair cells but may also affect the stria vascularis.[78] The underlying mechanisms may be related to the inhibition of adenyl cyclase in the stria vascularis, the inhibition of protein synthesis, and the formation of oxygen free radicals.[9,78,145] The generation of oxygen free radicals and the depletion of antioxidants result in the irreversible damage to the hair cells.[47] Furthermore, cranial radiation will cause synergistic toxicity if radiation precedes cisplatin therapy. Various antioxidants and free radical scavengers prevent cisplatin-induced ototoxicity in animals.[94,108,111,128,135,157,171] Newer xenobiotics also prevent cisplatin-induced toxicity in animals, perhaps preventing oxidative injury–induced apoptosis to hair cells.[131] Amifostine, a precursor to a thiol free radical scavenger, is available to prevent cisplatin-induced nephrotoxicity. However, amifostine does not appear to prevent cisplatin-induced ototoxicity.[138]

The aminoglycosides are best known for their association with irreversible ototoxicity,[121] but they are not concentrated in the cochlea. It is postulated that toxicity is related to the metabolites of aminoglycosides and not the parent compounds because toxicity can be reproduced in vivo, but not in vitro.[139] The endolymph concentration of gentamicin is approximately 10% of that in the serum. Neomycin and kanamycin are the most ototoxic, although all aminoglycosides are potentially toxic.[90] With the development of the newer aminoglycosides and therapeutic drug monitoring, the incidence of aminoglycoside-related ototoxicity appears to be decreasing. The reported rates of ototoxicity for the more commonly used aminoglycosides gentamicin and tobramycin are between 5% and 8%.[100] In China, where aminoglycosides are readily available as nonprescription medications, as much as 66% of deaf-mutism may be directly related to aminoglycoside toxicity.[54,97] A genetic predisposition to aminoglycoside-induced ototoxicity has been identified.[68] The genetic transmission appears to be maternal via mitochondrial DNA.[51] Chinese patients with this genetic defect may

TABLE 20–4. Etiologies of Xenobiotic-Induced Hearing Loss

Reversible	Irreversible
Antimicrobials: chloroquine, erythromycin, quinine	Aminoglycosides
Carbon monoxide	Antineoplastics: bleomycin, cisplatin, nitrogen mustard, vincristine, vinblastine
Diuretics: acetazolamide, bumetanide, ethacrynic acid, furosemide, mannitol	Bromates
NSAIDs	Hydrocarbons: styrene, toluene, xylene
Salicylates	Metals: arsenic, lead, mercury

suffer rapid and severe hearing loss compared to whites with a similar aminoglycoside exposure.[131]

Several mechanisms of ototoxicity have been postulated including antagonism of calcium channels of the outer hair cells of the cochlea, blocking transduction of the hair cells and resulting in acute, reversible hearing deficits as well as binding to polyphosphoinositides of cell membranes to alter their functions. Polyphosphoinositides are essential for the generation of the second messengers diacylglycerol and inositol triphosphate and their ultimate cellular function, for the maintenance of lipid membrane structure and permeability, and as a source for arachidonic acid.[165] Aminoglycosides interact with iron and copper to generate free radicals, damaging the hair cells. Aminoglycosides also inhibit ornithine decarboxylase which is important for cellular recovery following an injury and makes the cell more susceptible to toxicity.[139] The outer hair cells of the cochlea are increasingly susceptible to aminoglycosides and damage progresses from the inner row of the outer hair cells to the basal turn of the cochlea, and, ultimately, to the apex.[4,7,90,130]

The risks of ototoxicity are increased with a duration of therapy of greater than 10 days, concomitant use of other ototoxic xenobiotics, and the development of elevated serum concentrations.[7,49,137] There is no evidence that single daily dosing of aminoglycosides alters the risk of ototoxicity.[118,166] Loop diuretics increase aminoglycoside toxicity by increasing aminoglycoside penetration into the endolymph. In animal models, certain free radical scavengers, such as glutathione, amifostine, and deferoxamine, decrease aminoglycoside-induced ototoxicity.[57,140,158,164,167] Fosfomycin, a phosphonic antibiotic, has limited efficacy in reducing aminoglycoside-induced ototoxicity, and salicylates are also suggested to reduce ototoxicity.[115,149] Salicylates may act as free radical scavengers in low doses. Leupeptin and Z-DEVD-FNK, a calpain and caspase inhibitor, respectively, that affects the apoptotic pathway, is demonstrated in animal models to decrease ototoxicity.[30,56,148,152] Further studies are required to determine their applicability to humans.

Erythromycin, vancomycin, and their respective analogs are ototoxic. There are a number of reports of hearing loss following erythromycin therapy in humans and an animal study supporting the ototoxic potential. Most deficits in humans are transient, although several cases of permanent hearing loss are reported.[19,20] The mechanisms of toxicity remain unclear, although the proposed effects are on the central auditory pathways. Erythromycin-induced hearing loss occurs at both lower and higher frequencies for speech, allowing for recognition in the early stages of ototoxicity.[19] Ototoxicity from the newer macrolide antibiotics clarithromycin and azithromycin is also reported.

The evidence for vancomycin-induced ototoxicity is less convincing. Although numerous cases of presumed vancomycin-related ototoxicity are reported, concomitant use of other ototoxic antibiotics was common or audiometric studies were not performed. In limited animal studies, vancomycin alone does not induce ototoxicity, but the xenobiotic increases ototoxicity when administered concomitantly with an aminoglycoside. Vancomycin analogs such as teicoplanin and daptomycin probably have similar ototoxic potentials.

Bromates are among the most extensively studied ototoxic xenobiotics.[31,33,99,124] Bromates are used in hair "neutralizers," bread preservatives, and as fuses in explosive devices.[79,124,160] The stria vascularis and hair cells of the organ of Corti are irreversibly damaged.[124] Substantial exposure to bromates may also cause renal failure which in turn increases its ototoxic potential.[79,124]

It is intriguing that xenobiotics such as the bromates, loop diuretics, and aminoglycosides primarily affect both the cochlea and the kidneys. One possible explanation is that the stria vascularis and the renal tubules have similar functions in maintaining electrochemical

gradients.[124,125] However, renal tubules may regenerate while damage to the hair cells and the stria vascularis of the cochlea is more likely to be permanent.

Other xenobiotics implicated as ototoxins are carbon monoxide, lead, arsenic, mercury, toluene, xylene, and styrene.[75,154] However, both human and animal data are quite limited. Carbon disulfide, carbon tetrachloride, and trichloroethylene are also suspected of being ototoxic, but toxicity has not been demonstrated in humans.[75,154] Because exposures to xenobiotics are frequently occupational, they are of great concern as they may potentiate or be additive to other types of occupational hearing impairments.[87,129]

High-frequency hearing is most vulnerable, and early or limited impairment may not be noticeable unless audiometry, especially at 8000 kHz and above, is performed.[165] These hearing tests can be performed in infants using the measurement of auditory brainstem response.[12]

■ NOISE-INDUCED HEARING IMPAIRMENT

Noise-induced hearing impairment has been recognized for hundreds of years, but became a great concern and increasingly prevalent with the industrial revolution and the discovery of gunpowder.[48] Some of the anatomic changes in the organ of Corti and the audiometric features of noise-induced hearing impairment were well described by 1900.[2,3,104] Unfortunately, few longitudinal studies on noise-induced hearing impairment have been performed.

Although noises of sufficient magnitude may cause hearing impairment with limited exposure, most noise-induced hearing losses result from preventable prolonged cumulative occupational exposure. NIOSH has estimated that up to 1.7 million workers in the United States between 50 and 59 years of age have significant occupation-related hearing loss.[116] Noise can be defined as any unwanted sound, which can be further characterized by duration, time pattern (continuous, intermittent, or impulsive), frequency, and intensity. The intensity is measured in sound pressure levels (SPLs) and expressed in a logarithmic scale in decibels (dB). The intensity of a normal conversation is approximately 65 dB (Table 20–5).[116] The risk of noise-induced hearing loss

TABLE 20–5. Typical Sound Levels on the Decibel Scale

Sound	Decibels
Weakest sound that humans can detect	10
Quiet bedroom, soft whisper	20
Broadcast studio	25–30
Insulated lounge	50
Normal conversation	65
Television-audio	70
Vacuum cleaner	80
Machine press, subway car (35 mph)	95
Spray painting, snowmobile	105
Power saw	110
Car horn	115
Armored personnel carrier; ear pain begins	120
Jet plane engine, gunshot	145
Highest sound level that can occur	194

is related to cumulative duration of exposure, intensity, and individual susceptibility.[114,119,170] Much of the risk assessment of noise-induced hearing loss is inexact. Most authorities agree that sounds with maximal intensity below 75–80 dB will not cause hearing impairment, regardless of the duration of exposure.[114] At higher intensity, the risk of hearing impairment increases with increased duration of exposure. Continued occupational exposure at 90–94 dB typically causes some high-frequency hearing loss in approximately 10 years.[2,119] Further exposure results in hearing loss in the lower-frequency range. The Occupational Safety and Health Administration (OSHA) established guidelines for permissible occupational noise exposure based on an analysis of the average intensity and duration of exposure (Table 20–6).[2,170]

The pathophysiology of noise-induced hearing impairment is related to an excessive energy impact on the cochlea, but the exact biochemical changes are unclear. Apoptotic death of the hair cells has now been demonstrated and inhibition of apoptosis pathways mitigates noise-induced toxicity in animal models. A limited exposure to excessive noise results in a temporary hearing impairment or temporary threshold shift with a duration of hours to weeks. However, prolonged exposure results in a permanent threshold shift or hearing impairment.[3,48,170] Initially, outer hair cells are lost, but more significant exposures result in damage to both inner and outer hair cells and all supporting structures in the organ of Corti. Cochlear nerve fibers degenerate after hair cell damage.[48,170] The section of the cochlea most at risk from loud noises is at the 9–13 mm region (the total length is 32 mm).[104] This region is responsible for hearing at the 3000–6000 kHz range, corresponding to the typical noise-induced hearing loss pattern.

Much of the clinical assessment and monitoring of noise-induced hearing loss is based on pure tone hearing loss, demonstrating an audiometric deficit at 3000–6000 kHz.[116,119,170] Although human speech is composed mainly of low frequency sounds, the ability to perceive the higher frequency sounds is extremely important in speech recognition. For this reason, the major impairment in patients with noise-induced hearing loss is an inability to discriminate speech, particularly from background noise.[2,37] Currently, the science of the investigation of speech discrimination is limited with extensive areas for research.

Blast injury to the ear results from exposure of extremely short duration, but very high-intensity sound waves, usually greater than 140 dB. Military personnel are particularly at risk.[28,120,162,165] Hearing loss from blast injury may be related to rupture of the tympanic membrane,

disruption of the ossicles, temporary cochlear dysfunction, and permanent cochlear dysfunction from labyrinthine fistulae and basilar membrane rupture.[26] When a large tympanic membrane rupture or disruption of the ossicles occurs, surgical intervention may be required to treat hearing impairment.[26]

Prevention of any type of noise-induced hearing loss remains the best solution. Various hearing-protection devices are available if the noise exposure cannot be reduced. Better monitoring and more longitudinal studies are required on noise-induced hearing loss. Exposure to xenobiotics that can impair hearing may have synergistic effects with noise-induced hearing loss.[87,89] These factors should be considered when noise exposure is evaluated. Furthermore, noise exposure is not limited to the workplace. Significant noise exposure may occur at home or from leisure activities, such as power tools, stereo, and ambient exposure.[13,34,67,119] The impact of noise exposure outside of the workplace has only recently attracted the attention of investigators.

■ TINNITUS

Tinnitus is the sensation of sound not resulting from mechano-acoustic or electric signals. Virtually all humans experience tinnitus during their lives. The exact mechanism or mechanisms resulting in tinnitus are largely unknown.[143] Tinnitus may or may not be associated with hearing loss. Several theories are proposed, but none is completely satisfactory. Tinnitus may result from spontaneous neurologic discharges when the hair cells or cochlear nerve is injured. Altered sound perception may result from local or central effects when feedback mechanisms are interrupted.[43,46,81,103] Severing the cochlear nerve terminates tinnitus in less than half of affected patients, suggesting important central mechanisms.[10] Furthermore, certain etiologies of tinnitus, such as migraine headache and temporal lobe seizures, do not affect hearing directly. N-methyl-D-aspartate (NMDA) glutamate receptor activation (and enhanced cochlear signal transmission) has been implicated as a mechanism for tinnitus in animal models; NMDA receptor activation may result from cyclooxygenase inhibition or neurologic injuries.[69] Xenobiotics, including salicylate, may cause hair cell dysfunction and may modify neurotransmission centrally in both the cochlear nucleus and the inferior colliculis.[58,169] Although the probable sites involved in tinnitus may be classified as peripheral (external ear, middle ear, or cochlear [VIII]), central, or extra-auditory (vascular, nasopharyngeal), some etiologies may affect peripheral and central sites, and many etiologies remain unknown.[32,46,103]

Numerous xenobiotics are associated with tinnitus (Table 20–7), but the incidence is probably low and the implied relationships have usually been supported only by case reports.[31,146,147] Tinnitus may or may not be associated with transient or permanent hearing loss. It is probable that the xenobiotics associated with hearing loss affect cochlear function, while those that produce tinnitus without hearing loss probably act on signal transmission at the cochlear and the CNS. Xenobiotics that frequently produce tinnitus are streptomycin, neomycin, indomethacin, doxycycline, ethacrynic acid, furosemide, heavy metals, and high doses of caffeine.[62,146,147] Only a few xenobiotics, such as quinine and salicylates, consistently cause tinnitus at toxic doses.[14,46] These two xenobiotics also serve as examples of how the presence of tinnitus may be an indicator of drug toxicity.

Tinnitus associated with salicylates usually begins when serum concentrations are in the high therapeutic or low toxic range of approximately 20–40 mg/dL.[109] Membrane permeability changes cause a loss of outer hair cell turgor in the organ of Corti which may impair acoustic emissions, explaining tinnitus to some extent[122,123,126] (see Xenobiotic-Induced Ototoxicity earlier). Before the wide availability of serum salicylate measurements , physicians treating gout or rheumatoid arthritis often titrated the salicylate dosage until tinnitus developed.[34] Tinnitus

TABLE 20–7. Xenobiotics That Cause Tinnitus

β-Adrenergic antagonists

Anticonvulsants: carbamazepine

Antidepressants: cyclic antidepressants, amoxapine, lithium, trancylcypromine

Antifungals: amphotericin B

Antihistamines

Antimicrobials: Aminoglycosides, vancomycin, dapsone, tetracyclines, sulpha drugs, metronidazole, thiabendazole, clindamycin

Antineoplastics: cisplatin, nitrogen mustard, 6-aminonicotinamide, methotrexate, vinblastine

Antiparasitics: chloroquine, hydroxychloroquine

Antipsychotics: haloperidol, molindone

Bromates

Cinchona alkaloids: quinine, quinidine

Diuretics: furosemide, ethacrynic acid, bumetanide

Hydrocarbons: benzene

Local anesthetics: mepivacaine, bupivacaine, lidocaine

Nonsteroidal antiinflammatory drugs

Oral contraceptives

Salicylates

Sympathomimetics: caffeine, theophylline, metaproterenol, albuterol, methylphenidate

and other signs and symptoms of salicylism (Chap. 35) should be sufficient for physicians to diagnose salicylate toxicity before serum salicylate concentrations are available. However, tinnitus may not be evident in patients with hearing impairment despite significantly elevated salicylate concentrations.[109] The classic constellation of symptoms of quinine and salicylate toxicity, called cinchonism, includes nausea, vomiting, tinnitus, and visual disturbances.[4,24,112] Because serum quinine concentrations are not readily available, symptoms of quinine toxicity define the clinical diagnosis (Chap. 58).[156]

SUMMARY

Numerous xenobiotics commonly affect the sense of smell, taste, and hearing. They may cause significant patient morbidity. Some of the events may be predictable, whereas others will require monitoring and appropriate testing. Significant patient risk and discomfort may be avoided by an understanding of the basic pathophysiology of the otolaryngologic organs and by a heightened suspicion on the part of healthcare providers. Current knowledge about the pathophysiology of xenobiotics and these special organs at the molecular level is expanding rapidly. It is particularly encouraging and exciting to understand and witness the development of potential therapeutic xenobiotics.

CHAPTER 21
RESPIRATORY PRINCIPLES

Andrew Stolbach and Robert S. Hoffman

The primary function of the lungs is to exchange gases. Specifically, this involves the transport of oxygen (O_2) into the blood, and the elimination of carbon dioxide (CO_2) from the blood. In addition, the lungs serve as minor organs of metabolism and elimination for a number of xenobiotics, a source of insensible water loss, and a means of temperature regulation.

Cellular oxygen use is dependent on many factors, including respiratory drive; percent of oxygen in inspired air; airway patency; chest wall and pulmonary compliance; diffusing capacity; ventilation–perfusion mismatch; hemoglobin content; hemoglobin oxygen loading and unloading; cellular oxygen uptake; and cardiac output. Xenobiotics have the unique ability to inhibit or impair each of these factors necessary for oxygen use and result in respiratory dysfunction. This chapter illustrates how xenobiotics interact acutely with the mechanisms of gas exchange and oxygen use. Discussion of chronic occupational lung injury is beyond the scope of this text; the reader is referred to a number of reviews for further information.[5,14,18,91]

PULMONARY MANIFESTATIONS OF XENOBIOTIC EXPOSURES

■ RESPIRATORY DRIVE

Respiratory rate and depth are regulated by the need to maintain a normal Pco_2 and pH. Most of the control for ventilation occurs at the level of the medulla, although it is modulated both by involuntary input from the pons and voluntary input from the higher cortices. Changes in Pco_2 are measured primarily by a central chemoreceptor which measures cerebral spinal fluid (CSF) pH, and secondarily by peripheral chemoreceptors in the carotid and aortic bodies, which measure Pco_2. Input with regard to Po_2 is obtained from carotid and aortic chemoreceptors. Stretch receptors in the chest relay information about pulmonary dynamics, such as the volume and pressure.

Xenobiotics can affect respiratory drive in one of several ways: direct suppression of the respiratory center; alteration in the response of chemoreceptors to changes in Pco_2; direct stimulation of the respiratory center; increase in metabolic demands such as result from agitation or fever, which, in turn, increases total body oxygen consumption; or indirectly, as a result of the creation of acid–base disorders. For example, opioids (Chap. 38) depress respiration by decreasing the responsiveness of chemoreceptors to CO_2 and by direct suppression of the pontine and medullary respiratory centers.[34,78,104] Any xenobiotic that causes a decreased respiratory drive or a decreased level of consciousness can produce bradypnea (a decreased respiratory rate), hypopnea (a decreased tidal volume), or both, resulting in hypoventilation (Chap. 3).

Methylxanthines, cocaine, and other sympathomimetics may cause an increase in respiratory drive as well as an increase in oxygen consumption. Salicylates produce hyperventilation by both central and peripheral effects via respiratory alkalosis and metabolic acidosis. The net consequence of increased respiratory drive, increased oxygen consumption, or metabolic acidosis is the generation of either tachypnea (an elevated respiratory rate), hyperpnea (an increased tidal volume), or both. Either alone or in combination, tachypnea and hyperpnea produce hyperventilation. Tables 21–1 and 21–2 list xenobiotics that commonly produce hypo- and hyperventilation.

■ DECREASED INSPIRED Fio_2

Barometric pressure at sea level ranges near 760 mm Hg. At this pressure, 21% of ambient air is comprised of oxygen (Fio_2 21%), and after subtracting for the water vapor normally present in the lungs, Pao_2 (the alveolar partial pressure of oxygen) is about 150 mm Hg. Any reduction in Fio_2 decreases the Pao_2, thereby producing signs and symptoms of hypoxemia (a low Pao_2 [the arterial partial pressure of oxygen]). At an Fio_2 of 12%–16%, patients experience tachypnea, tachycardia, headache, mild confusion, and impaired coordination. A further decrease to an Fio_2 of 10%–14% produces severe fatigue and cognitive impairment and when the Fio_2 decreases to between 6% and 10%, nausea, vomiting, and lethargy develop. An $Fio_2 < 6\%$ is incompatible with life.[63]

This effect on Pao_2 is typically observed as elevation increases above sea level, because while Fio_2 remains 21%, barometric pressure falls. At 18,000 feet, barometric pressure is only 380 mm Hg, and the Pao_2 falls to below 70 mm Hg. At 63,000 feet, the barometric pressure falls to 47 mm Hg, a level where the Pao_2 equals 0 mm Hg. Although it is important to remember this relationship, altitude-induced decreases in Pao_2 are rarely important in clinical medicine, even in commercial airline flights, where the cabins are pressurized to a maximum of several thousand feet above sea level. However, in closed or low-lying spaces, oxygen may be replaced or displaced by other gases that have no intrinsic toxicity. Common examples of these gases, referred to as simple asphyxiants (Table 21–3), are found alone or in combination with more toxic gases. Because they have little or no toxicity other than their ability to replace oxygen, removal of the victim from exposure and administration of supplemental oxygen are curative if permanent injury as a consequence of hypoxia has not already developed (Chap. 124).

The potential magnitude of toxicity from simple asphyxiants was best exemplified by the disasters in Cameroon near the Lakes of Monoun and Nyos, in 1984 and 1986, respectively. For unclear reasons, Lake Nyos, a volcanic lake, released a cloud of carbon dioxide (CO_2) gas of approximately a quarter million tons. Because CO_2 is 1.5 times heavier than air, the gas cloud flowed into the surrounding low-lying valleys, killing by asphyxia more than 1700 people, and affecting countless more people because of hypoxia. Most survivors recovered without complications.[9,38] Smaller scale, but equally serious, toxicity from CO_2 results from improper handling of dry ice or release into a closed space.[39,44]

■ CHEST WALL

Hypoventilation can result from a decrease in either respiratory rate or tidal volume. Thus, even when the stimulus to breathe is normal, adequate ventilation is dependent on the coordination and function of the muscles of the diaphragm and chest wall. Changes in this function can result in hypoventilation by two separate mechanisms; both muscle weakness and muscle rigidity may impair the patient's ability to expand the chest wall. Toxicologic causes of muscle weakness include botulinum toxin,[86] electrolyte abnormalities such as hypokalemia,[57,105] or hypermagnesemia,[232] organic phosphorus compounds,[68,87] and neuromuscular blockers.[13,50] Patients with hypoventilation caused by muscle weakness respond well to assisted ventilation and correction of the underlying problem (Chaps. 16, 46, 68, and 113). Chest-wall rigidity impairing ventilation can occur in strychnine poisoning,[15,55,62] tetanus,[23,55,93] and fentanyl use[22,24] (Chaps. 38 and 112). Often these patients are difficult to ventilate despite tracheal intubation and may require muscle relaxants, neuromuscular blocking agents, or naloxone (for fentanyl).

TABLE 21–1. Xenobiotics that Produce Hypoventilation

Baclofen	γ-Hydroxybutyrate and analogs
Barbiturates	Isopropanol
Botulinum toxin	Methanol
Carbamates	Neuromuscular blockers
Clonidine	Nicotine
Conium maculatum (Poison Hemlock)	Opioids

■ AIRWAY PATENCY

The airway may be compromised in several ways. As a patient's mental status becomes impaired, the airway is often obstructed by the tongue.[41] Alternatively, vomitus, or aspiration of activated charcoal or a foreign body, can directly obstruct the trachea or major bronchi with resultant hypoxia[41,52,65,69,81,97] Obstruction may also result from increased secretions produced during organic phosphorus compound poisoning. Laryngospasm may occur either as a manifestation of systemic reactions, such as anaphylaxis, as a result of edema from thermal or caustic injury (Chaps. 104 and 128), or as a direct response to an irritant gas (Chap. 124). Similarly, the tongue can become swollen in response to thermal or caustic injury or toxic exposure to plants such as *Dieffenbachia* spp, or as a result of angioedema from drugs such as angiotensin-converting enzyme inhibitors (Chaps. 62, 104, 118, and 128).[34] Regardless of the mechanism, upper airway obstruction results in hypoventilation, hypoxemia, and hypercapnia (hypercarbia) with the persistence of a normal A-a gradient (see discussion of A-a

gradients). Upper airway obstruction is often acute and severe and requires immediate therapy to prevent further clinical compromise. Bronchospasm may be a manifestation of anaphylaxis, as well as exposure to pyrolyzed cocaine,[84,95,96] smoke, irritant gases[43,48, 76] (Table 21–4), or dust (eg, cotton in byssinosis), or as a result of work-related asthma[61,91] and hypersensitivity pneumonitis[96,109] (Chaps. 124 and 128).

Airway collapse may result from pneumothorax caused by barotrauma, which more commonly results from the manner of administration of illicit xenobiotics than from actual drug overdose. Barotrauma may also result from nasal insufflation or inhalation of drugs. This form of barotrauma occurs most often in cocaine (particularly in the form of "crack") and marijuana users, who either smoke or insufflate these xenobiotics and then perform prolonged Valsalva maneuvers in an attempt to enhance the effects of these xenobiotics. (Chaps. 76 and 83).[11,20,74,89,106] The increased airway pressure leads to rupture of an alveolar bleb, and free air dissects along the peribronchial paths into the mediastinum and pleural cavities. Nitrous oxide abuse also causes barotrauma.[53] Siphoning of nitrous oxide from low-pressure tanks meant for inhalation is not typically associated with barotrauma. In contrast, inhalation of nitrous oxide, used as a propellant in whipped cream cans, generates tremendous pressure that sometimes results in severe barotrauma (Chap. 81).

■ VENTILATION–PERFUSION MISMATCH

Ventilation–perfusion (V/Q) mismatch is manifested at the extremes by aeration of the lung without arterial blood supply (as in pulmonary embolism from injected contaminants), and by a normal blood supply to the lung without any ventilation. Impaired blood supply to a normal lung and normal blood supply to an inadequately ventilated lung constitute an infinite number of gradations that exist between the extremes. The normal response to regional variations in ventilation is to shunt blood away from an area of lung that is poorly ventilated, thereby preferentially delivering blood to an area of the lung where gas exchange is more efficient. An hypoxia-induced reduction in local nitric oxide pro-

duction appears to be responsible for the regional vasoconstriction that occurs.[1] This effect, commonly known as hypoxic pulmonary vasoconstriction, is best described in patients with chronic obstructive lung disease and facilitates compensation for the V/Q mismatch associated with that disorder. It is unclear whether xenobiotic-induced alterations in pulmonary nitric oxide production are significant determinants in the V/Q mismatch that occurs in poisoning.

In toxicology, V/Q mismatch most commonly results from perfusion of an abnormally ventilated lung, as may occur following aspiration of gastric contents, a frequent complication of many types of poisoning.[52,69] Although alterations in consciousness and loss of protective airway reflexes are predisposing factors, certain xenobiotics, such as hydrocarbons, directly result in aspiration pneumonitis because of their specific characteristics of high volatility, low viscosity, and low surface tension (Chap. 106).

The diagnosis of aspiration pneumonitis often relies on the chest radiograph for confirmation. The location of the infiltrate depends significantly on the patient's position when the aspiration occurred. Most commonly, aspiration occurs in the right mainstem bronchus, because the angle with the carina is not as acute as it is for entry into the left mainstem bronchus. When aspiration occurs in the supine position, the subsequent infiltrate is usually manifest in the posterior segments of the upper lobe and superior segments of the lower lobe. Aspiration typically involves vomitus; but secretions, activated charcoal, teeth, dentures, food, and other foreign bodies are also frequently aspirated.

■ DIFFUSING CAPACITY ABNORMALITIES

Severe impairment in diffusing capacity commonly results from local injury to the lungs in disorders such as interstitial pneumonia, aspiration, toxic inhalations, and near drowning, and from systemic effects of sepsis, trauma, and various other medical disorders.[8] When this process is acute and associated with clinical criteria including crackles, hypoxemia, and bilateral infiltrates on a chest radiograph demonstrating a normal heart size, it has been traditionally referred to as *noncardiogenic pulmonary edema*; throughout this chapter and text, however, the term *acute lung injury* (ALI) is used, which reflects current nomenclature.[8] ALI is the presence of increased intraalveolar fluid in the lungs with a normal cardiac output. More rigid criteria, such as a Pao_2/Fio_2 ratio < 300 mm Hg (regardless of positive end-expiratory pressure [PEEP]), bilateral infiltrates on the chest radiograph, and either a pulmonary artery wedge pressure that is ≤ 18 mm Hg or no clinical evidence of left atrial hypertension, are used to further define the ALI.[8] When these same criteria are met, but the patient's Pao_2/Fio_2 ratio is < 200 mm Hg (regardless of PEEP), the term *acute respiratory distress syndrome* (ARDS) is used.[8,59] Approximately 150,000 Americans develop ARDS annually, many as a result of xenobiotics; ARDS has a fatality rate near 50%.[4]

Commonly, patients are chronically exposed to xenobiotics associated with reduced diffusing capacity by smoking tobacco and other xenobiotics or working with asbestos, silica, and coal, which slowly causes pulmonary fibrosis or promotes emphysema. More recent work also emphasizes the ability of chronically smoked cocaine to alter pulmonary function.[96] Acutely, ALI from opioids, salicylates, or phosgene and delayed severe fibrosis from paraquat can cause profound alterations in diffusion (Chaps. 35, 38, 115, and 124).[72,82,111] Associated parenchymal damage is almost always present and causes both reduction in lung volumes and V/Q mismatch. Intravenous injection of talc, a common contaminant found in drugs of abuse,[75] and septic emboli from right-sided endocarditis[73,92] may result in isolated vascular defects with reduction in diffusion capacity. Similarly, cocaine-induced pulmonary spasm can obstruct vascular channels and alter pulmonary function, creating V/Q mismatch.[27]

Acute lung injury with or without progression to ARDS is a common occurrence from poisoning. The edema fluid (and the resulting hypoxia, pulmonary crackles, and radiographic abnormalities) may develop in part because of increased permeability of the alveolar and capillary basement membrane.[21,25,64,82] Proteinaceous fluid leaks from the capillaries into the alveoli and interstitium of the lung. Several mechanisms are proposed as the cause for ALI, although there is no single unifying mechanism for all of the xenobiotics that have been implicated. Acute lung injury may result from exposure to xenobiotics that produce hypoventilation by at least three different mechanisms: hypoxia may injure the vascular endothelial cells; autoregulatory vascular redistribution may cause localized capillary hypertension; or alveolar microtrauma may occur as alveolar units collapse, only to be reopened suddenly during reventilation.[82] These and other events may activate neutrophils and release inflammatory cytokines.[3,103] Other xenobiotics may be directly toxic to the capillary epithelial cells or may be partly responsible for the release of vasoactive substances.[3] The effects of salicylates and other NSAIDs may be mediated via effects on prostaglandin synthesis. Finally, sympathomimetic stimulants may cause "neurogenic" pulmonary edema, which is thought to be mediated by massive catecholamine discharge. Elevated catecholamine concentrations are also noted in experimental opioid overdose, possibly representing support for a link between hypoxia, hypercarbia, and the catecholamine hypothesis of ALI.[67]

In the 1880s, William Osler described "oedema of left lung" in a morphine user. The opioids are still among the most common causes of ALI (Chap. 38), but it is now recognized that there are many types of xenobiotics that can cause or are associated with ALI, such as the sedative-hypnotics, salicylates, cocaine, carbon monoxide, diuretics, and calcium channel blockers (Table 21–5).[29,31,33,36,37,42,45,49,56,77,79,90,92,111] The route of xenobiotic administration is not usually the determining factor; ALI can result from oral, intravenous, and inhalational exposure. Because the source of the problem is increased pulmonary capillary permeability, patients with ALI have a normal pulmonary-capillary wedge pressure, unlike patients with cardiogenic pulmonary edema.

Cardiogenic pulmonary edema may also occur as the result of poisoning. Etiologies for this phenomenon include the ingestion of large amounts of a xenobiotic with negative inotropy (eg, β-adrenergic antagonists, type IA antidysrhythmics) or myocardial infarction (from cocaine). Because many overdoses are mixed overdoses, the distinction between cardiogenic pulmonary edema and ALI is often difficult to establish by physical examination and requires invasive monitoring techniques.

Although the treatments for cardiogenic pulmonary edema and ALI have many similarities, critical aspects of the therapy differ, and therefore

TABLE 21–5. Common Xenobiotic Causes of Acute Lung Injury

an accurate diagnosis must be established. Most diagnostic tests are not helpful in differentiating between the two diseases. Physical examination reveals the presence of crackles with both entities. An S_3 gallop, if present, suggests a cardiac cause of pulmonary edema, but its absence does not establish the diagnosis of ALI. In both entities, the arterial blood-gas analysis demonstrates hypoxia and the chest radiograph shows perihilar, basilar, or diffuse alveolar infiltrates. The presence of "vascular redistribution" on the chest radiograph, however, is suggestive of a cardiogenic etiology; a normal-sized heart is more commonly associated with ALI, whereas an enlarged heart is more typical of cardiogenic pulmonary edema. The diagnostic tests that may be useful in establishing the correct diagnosis include echocardiography, transcutaneous bioimpedance, pulmonary artery catheter pressure measurements, and radionuclide ventriculography ("gated-pool" scan). Although the radionuclide scan accurately measures cardiac output, it is not routinely available in the emergency department (ED) or ICU and usually requires the transport of a critically ill patient to the nuclear medicine suite. Although echocardiography can be performed as a portable "bedside" technique, it is less sensitive and less specific for determinations of cardiac output. Therefore, the most definitive diagnostic procedure in the emergency setting is the insertion of a pulmonary artery catheter for hemodynamic monitoring. Cardiogenic pulmonary edema results from an elevated left-atrial filling pressure (elevated pulmonary-capillary wedge pressure) and a decreased cardiac output. In patients with ALI, the pulmonary artery wedge pressure and the cardiac output are normal. Although not specifically well-investigated in poisoning, recent experiences with transcutaneous bioimpedance measurements of cardiac output show promise for this portable non-invasive technique.[8,26,70]

The basic treatment for ALI and ARDS is supportive care while the xenobiotic is eliminated and healing occurs in the pulmonary capillaries.[3,59] The most important specific therapeutic maneuver in patients with ALI/ARDS involves the use of low tidal-volume ventilation (≤ 6 mL/kg predicted body weight).[1,40,103]

This results in reduced airway pressures which seem to "rest" the lung and allow healing to occur. The efficacy of jet ventilators or membrane oxygenators is inadequately studied. Some studies suggested a potential role for extracorporeal membrane oxygenation in the treatment of ALI and ARDS.[54] PEEP, which may derive its benefit from keeping alveoli open, has traditionally been considered an essential component in the management of ARDS.[30,40]

The PEEP should be maintained in the range of 5–12 cm H_2O, to maintain a Po_2 of at least 55 mm Hg, or an oxygen saturation of 88%, with an inspired oxygen concentration of ≤ 40%. Higher PEEP settings are not always beneficial and can cause an increased incidence of pneumothorax or hypotension. An increase in PEEP may result in a modest increase in Po_2, but a larger decrease in venous return and decreased cardiac output. Therefore, with each change in PEEP, the resulting increase (or perhaps decrease) in oxygen delivery to the body should be determined.[4]

A conservative fluid strategy has been shown to improve oxygenation and decrease ICU stay without increasing the incidence of shock or the need for dialysis. A conservative fluid management strategy is recommended for patients with ARDS who are not in shock, have not been in shock for at least 12 hours and do not have other reasons to require liberal fluid administration.[71]

HEMOGLOBIN AND THE CHEMICAL ASPHYXIANTS

Disorders of hemoglobin oxygen content, as well as of hemoglobin loading and unloading, result in cellular hypoxia, which, in turn, results in hyperventilation. Anemia is a common complication of the

infectious diseases associated with injection drug use. In addition, many xenobiotics result in hemolysis or direct bone marrow suppression. Among the latter group are the heavy metals, lead, benzene, and ethanol. Hemolysis may occur in individuals exposed to lead, copper, or arsine gas, and in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency exposed to oxidants (Chap. 24).

The oxygen-carrying capacity of blood declines in almost direct proportion to hemoglobin content,[97] as seen in Figure 21–1. As shown in Figure 21–1A, under most normal conditions the dissolved oxygen content of the blood contributes little, and thus the last portion of the equation can be eliminated. Anemia resulting in a decrease of the hemoglobin content to 7.5 g/dL (a hematocrit of ~ 22%) decreases the oxygen content of the blood to about 10.2 mL O_2/dL (Fig. 21–1B). Because central cyanosis is only visible with a concentration of reduced deoxyhemoglobin of at least 5 g/dL, unless an abnormal hemoglobin is present, anemia can significantly impair oxygen-carrying capacity without the development of this common physical manifestation (Chap. 127).

In contrast, as the Po_2 reaches higher values (as in hyperbaric oxygen [HBO] chambers), the dissolved oxygen content becomes significant and may be of therapeutic value, particularly when the oxygen-carrying content of hemoglobin is compromised. The Po_2 corresponding to an Fio_2 of 100% is approximately 575 mm Hg. In HBO at 3 atm and 100% oxygen, Po_2 values in excess of 1500 mm Hg can be achieved.[63] Under these conditions, the dissolved oxygen content of the blood rises dramatically (to as much as 4.5 mL O_2/dL) and may be adequate to sustain life, even in the absence of any contribution from hemoglobin (Fig. 21–1C).

The chemical asphyxiants that produce methemoglobin, carboxyhemoglobin, and sulfhemoglobin interfere with oxygen loading and/or unloading to various degrees. Methemoglobin inhibits oxygen loading, producing cyanosis that is unresponsive to supplemental oxygen

---

Oxygen content (O_2 content) = hemoglobin bound oxygen + dissolved oxygen

A. <u>Normal conditions:</u> hemoglobin (Hb) = 15 g/dL; PO_2 = 100 mm Hg, oxygen saturation (O_2 Sat) = 95%

O_2 content = [(Hb)(O_2 sat) (constant) + (another constant)(PO_2)]
= [(Hb)(O_2 sat)(1.39 mL O_2/g%) + (0.003 mL O_2 /dL/mm Hg)(PO_2)]
= [(15 g/dL)(95%)(1.39 mL O_2/g%) + (0.003 mL O_2/dL/mm Hg)(100 mm Hg)]
= [(19.8 mL O_2/dL) + (0.3 mL O_2/dL)]
= 20.1 mL O_2/dL = 20.1 vol%

B. <u>Anemia:</u> Hb = 7.5 g/dL; PO_2 = 100 mm Hg, O_2 Sat = 95%

O_2 content = [(Hb)(O_2 sat)(1.39 mL O_2/g%) + (0.003 mL O_2/dL/mm Hg)(PO_2)]
= [(7.5 g/dL)(95%)(1.39 mL O_2/g%) + (0.003 mL O_2/dL/mm Hg)(100 mm Hg)]
= [(9.9 mL O_2/dL) + (0.3 mL O_2/dL)]
= 10.2 mL O_2/dL = 10.2 vol%

C. <u>Hyperbaric oxygen:</u> Hb = 15 g/dL; PO_2 = 1500 mm Hg, O_2 Sat = 100%

O_2 content = [(Hb)(O_2 sat)(1.39 mL O_2/g%) + (0.003 mL O_2dL/mm Hg)(PO_2)]
= [(15 g/dL)(100%)(1.39 mL O_2/g%) + (0.003 mL O_2/dL/mm Hg)(1500 mm Hg)]
= [(20.9 mL O_2/dL) + (4.5 mL O_2/dL)]
= 25.4 mL O_2/dL = 25.4 vol%

FIGURE 21–1. Examples of calculations of the oxygen content of the blood under various conditions.
FIGURE 21–2. Oxyhemoglobin dissociation curve at 98.6°F (37°C) and pH 7.40. Hematocrit does not alter this relationship.

(Chaps. 125, and A37). In addition, the oxyhemoglobin saturation curve is shifted to the left, interfering with unloading (Fig. 21–2). Carboxyhemoglobin has similar effects on oxygen loading and unloading, but carboxyhemoglobin is not associated with cyanosis (Chap. 125). Sulfhemoglobin has similar effects on oxygen loading, but shifts the oxyhemoglobin saturation curve to the right, favoring unloading. Cyanide, hydrogen sulfide, and sodium azide primarily affect oxygen use by interfering with the cytochrome oxidase system (Chap. 126).

■ CARDIAC OUTPUT

Any xenobiotic that causes a decreased cardiac output or hypotension may result in tissue hypoxia and tachypnea. This occurs most frequently with overdoses of β-adrenergic antagonists and calcium channel blockers, antidysrhythmics, cyclic antidepressants, and phenothiazines (Chap. 23).

■ ASTHMA AND OCCUPATIONAL EXPOSURES

Usually considered a cause of morbidity more than mortality, work-related asthma is frequently encountered by the practitioner. The pathophysiology of these illnesses is still being elucidated, and appears to result from both IgE and non–IgE-related mechanisms.[14]

Work-related asthma can be divided into three distinct clinical entities:

1. Work-aggravated asthma: Preexisting asthma worsened by allergens in the workplace.

2. Occupational asthma: Asthma caused by workplace exposure and not factors outside the workplace. There is a latency period between the symptoms and the first exposure, possibly as long as several years.

3. Reactive airway dysfunction syndrome (RADS): Asthma caused by nonimmunogenic stimuli in the workplace, occurring for the first time within 24 hours of exposure to an inhaled irritant xenobiotic.[5,19,102]

Occupational exposures are thought to be responsible for a substantial proportion of adult-onset asthma, estimated at 10%–25% in one international prospective study.[18]

A large number of xenobiotics and occupations are associated with the development of work-aggravated and work-related asthma. Because researchers rely on surveys and interviews, the latency period between exposure and symptoms makes identification of these associations a challenge.

Many high molecular weight xenobiotics, usually plant or animal derived, have been identified, such as arthropod and mite related materials, latex, flour, molds, endotoxins, and biological enzymes. Lower molecular weight xenobiotics associated with work-related asthma include isocyanates (used in spray paints and foam manufacturing), cleaning agents, anhydrides, amines, dyes and glues. For more information on specific xenobiotics see Chapters 124 and 127.

In one study, the following occupations were found, in decreasing order, to be associated with the development of occupational asthma: printing, woodworking, nursing, agriculture and forestry, cleaning and caretaking and electrical processors.[58]

In contrast to the occupational asthma and work-related asthma, the latency period between exposure and symptoms in RADS is short or absent, so the clinician may more easily identify the precipitant from history. Xenobiotics frequently associated with RADS include cleaning materials (including chlorine, hypochlorite, ammonia, and chloramines), solvents, toluene diiosocyanate, acids, alkali, nitrogen oxides, smoke, and diesel exhaust.[46,88]

APPROACH TO THE POISONED PATIENT

The initial assessment of each patient must involve the evaluation of upper airway patency. Adequacy of ventilation should then be determined. If concomitant injury is suspected, care must be taken to protect the cervical spine. When airway patency is in question, maneuvers to establish and protect the airway are of prime importance. Often this may simply involve repositioning the chin, jaw, or head, or suctioning secretions or vomitus from the airway. However, insertion of an oral or nasopharyngeal airway, or nasopharyngeal or endotracheal intubation, or surgical cricothyroidotomy may be required as clinically indicated. After the airway is secured, high-flow supplemental oxygen should be provided and the depth, rate, and rhythm of respirations evaluated. An acceptable tidal breath is one that transports 10–15 mL of air/kg of body weight.[4]

Hypoventilation that results from an inadequate respiratory rate or tidal volume is arbitrarily defined as $P_{CO_2} > 44$ mm Hg and leads to hypoxia and ventilatory failure if uncorrected.[107] The symptoms of hypoxia and or hypercarbia are nonspecific and resemble toxicity from many xenobiotics. Initially, patients appear restless and confused. Signs of sympathetic discharge, such as tachycardia and diaphoresis, may be noted. Later, patients may complain of headache, only to become sedated and subsequently comatose, as further deterioration occurs. Because these signs and symptoms are nonspecific, arterial blood-gas analysis must be used early in the assessment of patients who present with xenobiotic overdose and possible ventilatory failure.

A trial of naloxone, hypertonic dextrose, and thiamine may be indicated for the patient with an altered mental status and or respiratory compromise (Chap. 4). Because opioid overdose and hypoglycemia are rapidly reversible, potential causes of respiratory failure, these diagnoses should be addressed before most other interventions are considered. Failure to identify and reverse these conditions may result in unnecessary diagnostic and therapeutic interventions in addition to irreversible neurologic sequelae.

Having assured an acceptable airway, the remainder of the evaluation can proceed. A rapid assessment of the remainder of the vital signs (Chap. 3) should then occur. Obtaining a history and physical examination, pulse oximetry, arterial blood-gas analysis, measured oxygen saturation, and a chest radiograph are sufficient to determine the diagnosis of pulmonary pathology in most cases. However, adjuncts, such as measurement of negative inspiratory force (NIF), invasive hemodynamic monitoring, evaluation of the arterial–venous

oxygen difference, xenon ventilation and technetium scanning, and CT scanning may be required.

■ HISTORY

A directed history must include questions on the nature, onset, and duration of symptoms; substance use and abuse; home and occupational exposures; and underlying pulmonary pathology. If the patient is suffering from a significant degree of respiratory compromise, most or all of the history may have to be obtained from friends, relatives, paramedics, coworkers, or others.

■ PHYSICAL EXAMINATION

The physical evaluation must include a detailed assessment of depth, rate, and rhythm of respirations, use of accessory muscles, direct evaluation of the oropharynx, position of the trachea, and presence and quality of breath sounds. Skin, nail bed, and conjunctival color must be observed for pallor or cyanosis. Funduscopic examination is a useful adjunct to the examination. Papilledema may be noted in the presence of acute hypercapnia. Additionally, because cyanide poisoning interferes with oxygen delivery to tissue, the venous oxygen saturation remains high. During the funduscopic examination, this may appear as arteriolization of the retinal veins, where the veins take on a color more characteristic of arteries (Chap. 126). A general assessment of muscle tone, with a specific emphasis on ocular and neck muscles may give clues to flaccidity or rigidity syndromes that interfere with respiration. When in doubt, a determination of the NIF will provide a rapid, objective, quantifiable bedside assessment of respiratory strength.

■ PULSE OXIMETRY

Pulse oximeters have gained widespread acceptance as rapid, noninvasive indicators of hemoglobin oxygen saturation. As defined, hemoglobin oxygen saturation is the ratio of oxyhemoglobin to total hemoglobin. By using two light-emitting diodes, the pulse oximeter is able to measure absorbance at the peak wavelengths for oxy- and deoxyhemoglobin (typically at 940 and 660 nm). Thus, the ratio of oxyhemoglobin to oxyhemoglobin plus deoxyhemoglobin (total hemoglobin) can be calculated. The clinician may then estimate the Po_2 from the oxygen saturation.

Limitations of this approach require elaboration. Because the oxyhemoglobin saturation curve becomes quite flat above 90% saturation (see Fig. 21–2), small changes in saturation greater than 90% may represent very large changes in Po_2. Thus, a decrease from 97% saturation to 95% saturation may represent a substantial decrease in Po_2. Although a low saturation is an early indicator of hypoxic hypoxia, this is only one of many causes of tissue hypoxia. If total hemoglobin is low, oxygen-carrying capacity is inadequate even with excellent saturation (see Fig. 21–1). Dyshemoglobinemias, such as carboxyhemoglobin, methemoglobin, and possibly sulfhemoglobin, interfere with the accuracy of pulse oximeter determinations and are of particular concern in the poisoned patient. Specifically, using a standard pulse oximeter, the presence of elevated concentrations of methemoglobin will tend to make the saturation approach 84%–86% (Chap. 127).[7,73] Carboxyhemoglobin is falsely interpreted by the pulse oximeter as mostly oxyhemoglobin, thus readings tend to appear normal even with significant carbon monoxide poisoning,[98] as Table 21–6 illustrates.

Accurate response by the pulse oximeter also requires adequate blood pressure, lack of strong venous pulsations (as might occur in a patient with tricuspid regurgitation), translucent nails (some shades of nail polish may interfere), absence of circulating dyes (methylene blue), and a near-normal temperature. Finally, we are often more interested

TABLE 21–6. Sample Interpretations of Oxygen Saturations Reported by Various Sources of Measurement

Condition	Po_2 (mm Hg)	Percent Oxygen Saturation		
		ABG	Pulse Oximeter	Cooximeter
Normal	95	95	95	95
Anemia	95	95	95	95*
Methemoglobinemia (30%)	95	95	85	70
Carboxyhemoglobinemia (30%)	95	95	95	70
Hypoxemia	60	90	90	90

The table demonstrates limitations of the various methods for determining oxygen saturation (O_2 saturation). The arterial blood gas (ABG) calculates the O_2 saturation from the dissolved oxygen content (Po_2) and becomes abnormal only when the Po_2 falls. The pulse oximeter uses only two wavelengths of light and produces substantial errors in the presence of a dyshemoglobinemia. Because the cooximeter uses more wavelengths of light than the pulse oximeter, it can correctly identify the presence of carboxyhemoglobin and methemoglobin. The cooximeter has the additional advantage (*) of calculating the total hemoglobin and oxygen content, so that it is useful in the setting of anemia. All techniques are acceptable for the assessment of hypoxemia.

in Pco_2 than Po_2 because it is a better measure of ventilation. The pulse oximeter gives no information with regard to Pco_2. Although the pulse oximeter may give early clues to the presence of hypoxic hypoxia, extrapolation of oxygen saturation to standard arterial blood-gas values may be difficult because of the many possible sources of error. Pulse oximetry is therefore best used as an initial screening tool for hypoxic hypoxia and later in combination with the initial arterial blood-gas measurement, as a determination of the patient's response to therapy. Although not widely used in clinical practice, a new pulse-cooximeter (noninvasive spectral analysis cooximeter), designed to measure carboxyhemoglobin and methemoglobin in addition to hemoglobin oxygen saturation, is available.

Use of this device could potentially facilitate early, noninvasive diagnosis of carbon monoxide poisoning and methemoglobinemia, as well as minimize erroneous interpretations of standard pulse oximetry caused by the presence of these abnormal hemoglobins. A volunteer study, sponsored by the manufacturer of the device, demonstrated the ability to measure carboxyhemoglobin with an uncertainty of ± 2% within the range of 0%–15% and methemoglobin with an uncertainty of 0.5% within the range of 0%–12%.[6]

The device has already been used to identify carbon monoxide poisoning at emergency department triage, although another author found the device to have a large number of false positives for carboxyhemoglobin when used for this purpose.[51,94]

■ BLOOD-GAS ANALYSIS

Arterial blood-gas analysis is an easy and rapid means of evaluating both acid–base status and gas exchange. Attention must be paid to the method for determining oxygen saturation, specifically whether it is measured or calculated from Po_2. If the measured O_2 saturation is lower than would be predicted from the Po_2 (the calculated O_2 saturation), the presence of an abnormal hemoglobin (such as carboxyhemoglobin or methemoglobin) must be suspected. A normal calculated O_2 saturation does not exclude these disorders ("Use of the Cooximeter").

Because it is easier to obtain, venous blood-gas analysis is often used as a substitute for arterial blood-gas analysis.[16] In comparison with arterial values, venous pH and P_{O_2} are lower, whereas P_{CO_2} is higher. Errors can be introduced by increased muscle activity of the extremity being tested (eg, seizures) or the prolonged placement of a tourniquet while attempting phlebotomy. Although a venous blood gas is generally acceptable for assessment of the blood pH, it cannot provide a good evaluation of gas exchange.

Mixed venous blood (defined as right-heart blood), however, is required for accurate determination of the arterial–venous oxygen extraction and is an excellent indicator of acid–base status, cardiovascular function, and oxygen use. Unfortunately, a central venous catheter is required for sampling. When performing a peripheral venous blood-gas analysis, it is usually assumed that this is only an approximation of mixed venous blood.

The arterial P_{O_2} is generally considered adequate only if it lies within the flat portion at the upper right of the sigmoidal-shaped oxyhemoglobin dissociation curve (see Fig. 21–2). That portion of the curve includes the P_{O_2} range from 60 to 100 mm Hg, which corresponds to oxygen saturations > 90%. As mentioned earlier, within this flat portion there can be discernible changes in P_{O_2} with little change in oxygen saturation. For instance, an arterial P_{O_2} of 80 mm Hg corresponds roughly to an oxygen saturation of 95%. If the P_{O_2} falls to 60 mm Hg, the oxygen saturation falls to 90%. This insignificant decrease in the oxygen-carrying capacity of the blood is of minimal clinical concern. If the P_{O_2} falls another 20 mm Hg, however, there is a more significant reduction in oxygen saturation, to ∼ 70%. Thus, changes in P_{O_2} > 60 mm Hg are usually not of acute therapeutic significance, because the O_2 saturation is > 90%. These changes are, however, frequently of diagnostic significance.

An exception to this concept applies to the patient who is under metabolic stress, as might result from low cardiac output, impaired vascular flow, anemia, or dyshemoglobinemia. Under these circumstances even the modest gain achieved by increasing both dissolved oxygen content and hemoglobin saturation > 90% may be desirable, as discussed earlier ("Hemoglobin and Chemical Asphyxiants"). Also, even if a P_{O_2} > 60 mm Hg or an O_2 saturation > 90% is considered acceptable in most acute settings, it is still desirable to achieve greater values, when feasible, to create a safety zone in case of clinical deterioration.

■ SIGNIFICANCE OF A DECREASED P_{O_2}

In a patient with a diminished P_{O_2}, five clinically relevant mechanisms for the hypoxemia should be considered: (a) alveolar hypoventilation; (b) V/Q mismatch; (c) shunting; (d) diffusion abnormality; and, rarely, (e) a decrease in F_{IO_2}. In most clinical circumstances, diffusion defects cannot be distinguished from V/Q mismatch. Usually, the responsible mechanism can be identified by calculating the alveolar-arterial (A-a) oxygen gradient. In patients with alveolar hypoventilation, the A-a gradient is completely normal (≤ 15 mm Hg when breathing room air). Patients with V/Q mismatch have an A-a gradient that is increased but which normalizes when 100% oxygen is administered for at least 20 minutes. A normal A-a gradient is defined as < 100 mm Hg on 100% oxygen. The arterial P_{O_2} on 100% oxygen reaches approximately 575 mm Hg. In contrast, a patient with a shunt will also have an increased A-a gradient while breathing room air, but when 100% oxygen is administered, the arterial P_{O_2} falls to substantially less than 575 mm Hg and the A-a gradient does not normalize. Finally, in the case of a patient with hypoxia resulting from breathing in an environment in which the F_{IO_2} is < 21%, the P_{O_2} should correct rapidly when the patient is removed from the environment or supplemental oxygen is delivered.

In general, a low P_{O_2} can be improved by supplying supplemental oxygen. Although in this instance the patient's laboratory values may be corrected, the underlying process persists. It is important to remember that the laboratory correlate of hypoventilation is hypercapnia on the arterial blood-gas analysis. If hypercapnia is associated with a low arterial pH (< 7.35), assisted ventilation should be considered, regardless of whether the P_{O_2} corrects with supplemental oxygen.

■ USE OF THE COOXIMETER

Routine analysis of an arterial blood-gas yields a measured pH, measured P_{O_2}, and measured P_{CO_2}. Ordinarily, the serum bicarbonate, base excess, and percent oxygen saturation of hemoglobin are all calculated values. The oxygen saturation is of clinical significance because it usually correlates with the oxygen content of the blood, and thus the oxygen available to the tissues. However, implied in this relationship is a normal amount of functional hemoglobin. Because the oxygen saturation is calculated from the measured P_{O_2} using the oxyhemoglobin dissociation curve, it represents only the saturation of normal hemoglobin. Thus, in the presence of even a small percentage of abnormal hemoglobin, the calculated oxygen saturation overestimates the total oxygen content of the blood. For example, a patient with P_{O_2} of 95 mm Hg has a calculated oxygen saturation of 95%. If the patient also has a 30% methemoglobinemia, only 70% of the total hemoglobin is saturated to 95% and the actual saturation is only 67%. This gap is clinically important because hemoglobin saturations of < 90% do not provide adequate oxygen delivery to the tissues.

Despite the development of bedside noninvasive pulse-cooximetry, most clinicians still depend on laboratory cooximeters for measurement of carboxyhemoglobin and methemoglobin. Most cooximeters spectrophotometrically measure total hemoglobin, oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, and methemoglobin (Fig. 21–3). The resultant saturation is a measured oxygen saturation of the total hemoglobin by including four common hemoglobin variants, and thus correlates with the total oxygen content of the blood.

The difference between measured and calculated oxygen saturation represents the percentage of abnormal hemoglobin present. This gap is helpful in the diagnosis of methemoglobin and carboxyhemoglobin, and is useful in assessing the adequacy of therapy for these disorders.
FIGURE 21–3. Cooximetry curves for normal and abnormal hemoglobin variants. Transmitted light absorbance spectra are shown for four hemoglobin species: oxyhemoglobin, reduced (deoxy) hemoglobin, carboxyhemoglobin, and methemoglobin.

Common indications for cooximetry include cyanosis that is unresponsive to oxygen (methemoglobin and sulfhemoglobin), known use of methemoglobin-forming xenobiotics (such as dapsone), smoke inhalation (carboxyhemoglobin and possibly methemoglobin), and evaluation of therapy for cyanide toxicity (methemoglobin).

Like so many other tools, the cooximeter is not perfect. Its biggest limitation occurs when dealing with uncommon hemoglobins. Because only four wavelengths of light are used by most cooximeters, they have the ability to define only four hemoglobin variants. Consequently, rare dyshemoglobinemias, such as sulfhemoglobin, are interpreted as one or a combination of the four common hemoglobin variants, giving erroneous results. This phenomenon is commonly noted in neonates, where fetal hemoglobin may be interpreted as carboxyhemoglobin.[100,108] Although this error rarely adds greater than 10% to the true carboxyhemoglobin value, this amount can be significant because of the difficulties in assessing the neuropsychiatric status of infants possibly exposed to carbon monoxide. Some newer cooximeters are unaffected by fetal hemoglobin, and should be used in neonatal cases of suspected carbon monoxide poisoning.[101,112] Similarly, these newer models are now beginning to provide measurements of sulfhemoglobin as well.[28,110,112] Additionally, cooximeters tend to interpret low levels (< 2.5%) of carboxyhemoglobin inconsistently.[66] Fortunately, this rarely has clinical implications.

■ CHEST RADIOGRAPHY

Radiographic detection of a pneumothorax or pneumomediastinum, cardiogenic pulmonary edema, ALI and ARDS, aspiration pneumonitis, or the presence of a foreign body is crucial, but can usually be delayed until the initial evaluation is completed. Confirmation of endotracheal tube placement is necessary but initially can be ascertained by auscultating bilateral breath sounds following compression of a bag valve mask, or using a variety of marketed devices such as end tidal CO_2 detectors designed to help confirm tube placement. For patients with occupational disorders, the chest radiograph is essential to confirm and stage exposures to asbestos, silica, coal, and other causes of pneumoconiosis.

THERAPEUTIC OPTIONS

■ SUPPLEMENTAL OXYGEN

Supplemental oxygen is indicated for all patients with suspected or confirmed respiratory insufficiency. Although it is generally advisable to begin with high flow (12 L/min) via a nonrebreather mask, lower concentrations of oxygen can be used in more stable patients. It is important to remember that a normal saturation on pulse oximetry does not imply that there is no need for supplemental oxygen. This can be determined only after a more complete assessment. Initially, there should be limited concern over worsening hypercapnia in patients with chronic obstructive pulmonary disease (COPD) and respiratory failure. This concern should not deter one from providing needed oxygen as many of these patients will require intubation for their hypoventilation. If time and the patient's clinical condition permit, an arterial blood-gas analysis should be obtained prior to administering supplemental oxygen or mechanical ventilation so that the patient's intrinsic respiratory status can be adequately defined. In many situations, the patient's condition will not permit delay, and subsequent arterial blood-gas analyses will be needed to determine the ability to decrease the FiO_2 or the need for intubation. Hyperbaric oxygen is indicated for carbon monoxide poisoning and rarely other exposures (Antidotes in Depth A37: Hyperbaric Oxygen).

Additional respiratory support can be offered from bilevel positive airway pressure (BiPAP). Some experimental evidence supports the use of BiPAP for patients with acute respiratory dysfunction in the emergency department.[80] Although this technique may be useful in overdosed patients, it should be considered only as a temporizing measure for patients who are expected to recover rapidly, or while preparing for intubation.

■ INTUBATION

After the decision for mechanical ventilation has been made, the route needs to be selected. The editors of this text prefer oral intubation because it permits the use of a larger endotracheal tube—usually 8 mm or larger in adults—than does nasal intubation. If the patient later needs bronchoscopy, it can be done through the endotracheal tube. Some data suggest that bronchoscopy with bronchoalveolar lavage may be of both diagnostic[99] and therapeutic[60] benefit for selected poisoned patients. However, in an awake patient, nasotracheal intubation done blindly or with the aid of a flexible fiberoptic laryngoscope may be more easily performed. An advantage of nasotracheal intubation over oral intubation is that orogastric lavage can be performed more easily when the oral cavity is unimpeded. After the trachea is intubated, the tube should be checked to ensure that it is correctly positioned.

All patients who sustain overdoses and show signs or symptoms of respiratory insufficiency should have chest radiographs performed. Unfortunately, intubated patients usually have portable radiographs performed and the carina may be difficult to visualize because of the poor quality of the study. When seen, the carina is visualized between T-5 and T-7 in most patients. Thus, the tip of the endotracheal tube should be above T-5 for proper (safe) placement. When a portable chest radiograph is obtained, the patient's neck may be extended or flexed, altering the location of the endotracheal tube tip. For this reason it is essential to note the position of the neck during the radiograph, because the tip of the endotracheal tube may move up (with flexion) or down (with extension) by almost 2 cm.[12]

■ MECHANICAL VENTILATION

After a patient is intubated for ventilatory support, the respirator mode—assist, control, or intermittent mandatory ventilation (IMV)—is selected. Patients with pure hypoventilation usually require a controlled fixed rate that can be easily adjusted based on serial arterial blood-gas analyses. Patients with pulmonary parenchymal processes, such as ALI, ARDS, or pneumonia, usually do well when placed on either assist or IMV mode. With the IMV mode, a given number of mandatory breaths is administered at the set tidal volume. The patient may take additional breaths without assistance, permitting lower mean airway pressure, which theoretically may reduce the risk of barotrauma and hemodynamic compromise. Although the lower airway pressures associated with IMV are desirable, many authorities recommend the use of the assist mode because it eliminates the patient's work of breathing.[59]

The next step is to determine the appropriate FiO_2 to be delivered to the patient. A number of formulas have been devised. One simple approach is to intubate a patient, control breathing, administer 100% oxygen, and decrease to an FiO_2 of < 50% as quickly as possible in an attempt to prevent oxygen toxicity.[3] Although the toxic effects of oxygen are well known for paraquat (Chap. 115), evidence suggests that oxygen may be an important mediator of other xenobiotic-induced pulmonary injuries such as with iron.[47] A PO_2 of 55 mm Hg or a measured oxygen saturation > 88% is generally acceptable; thus, there is little reason to expose patients to much higher concentrations of oxygen once these conditions are met.[1,103] Many clinicians feel more comfortable establishing a "buffer" against deterioration by increasing the PO_2 to somewhat greater than 55 mm Hg, but prolonged exposure to higher values is rarely indicated. In patients with pure alveolar hypoventilation, the tidal volume should be set at 10–15 mL/kg/breath. If oxygenation

Two 30-year-old patients who overdosed were brought to the ED. Each had ingested substantial amounts of barbiturates and diazepam. An arterial blood gas drawn from patient 1 while he was breathing room air revealed a pH of 7.18, PCO$_2$ of 70 mm Hg, PO$_2$ of 50 mm Hg, and a calculated bicarbonate of 24 mEq/L. An arterial blood gas drawn from patient 2, also breathing room air, revealed a pH of 7.31, PCO$_2$ of 50 mm Hg, PO$_2$ of 50 mm Hg, and a calculated bicarbonate of 25 mEq/L. Quick analysis showed that patient 1 was hypercapnic with a significant respiratory acidosis. Patient 2 did not appear as ill; his PCO$_2$ was not very elevated and his pH was not significantly reduced. The A-a gradients were calculated to be 12.5 mm Hg for patient 1 and 37.5 mm Hg for patient 2 (Fig. 21–4A and B).

A. Arterial PCO$_2$ approximates alveolar PCO$_2$ and is substituted as:

$$PAO_2 = PiO_2 - \frac{PCO_2}{R}$$

$$PiO_2 = (FiO_2)(PB - PH_2O)$$

where PAO$_2$ is alveolar PO$_2$, PiO$_2$ is partial pressure of inspired O$_2$, PaCO$_2$ is arterial PCO$_2$, and R is the respiratory exchange ratio. Therefore:

$$PAO_2 = [(FiO_2)(PB - PH_2O)] - \frac{PCO_2}{R}$$

where FiO$_2$ is the inspired O$_2$ fraction, PH$_2$O is water vapor pressure, and PB is barometric pressure. On room air at sea level, FiO$_2$ – 21%. At steady state, R = 0.8. At sea level, PB = 760 mm Hg, and PH$_2$O = 47 mm Hg. Therefore:

$$PAO_2 = [(FiO_2)(PB - PH_2O)] - \frac{PCO_2}{R}$$

$$= [(0.21)(760 - 47)] - \frac{PCO_2}{R}$$

$$= 150 - [(1.25)(PCO_2)]$$

Because the A-a gradient is equal to PAO$_2$ – PaO$_2$ it can be expressed as:

$150 - [(1.25)(PCO_2)] - PaO_2$ or $150 - [(1.25)(PCO_2) + PaO_2]$

A normal A-a gradient is 10–15 mm Hg, but this increases with age. A rough estimate of the normal A-a gradient is one-third the patient's age.

B. Referring to the two overdosed patients above, the A-a gradient for patient 1 is:

$$150 - [(1.25)(70) + 50] = 12.5 \text{ mm Hg}$$

This calculation reveals a normal gradient, indicating that the etiology for hypoxemia and hypoventilation is extrinsic to the lung itself. In patient 2 the A-a gradient is:

$$150 - [(1.25)(50) + 50] = 37.5 \text{ mm Hg}$$

This abnormally high A-a gradient is consistent with the aspiration which was pneumonia seen on the patient's chest radiograph.

FIGURE 21–4. (A) Derivation of the definition of alveolar-arterial (A-a) oxygen gradients. (B) Using the A-a gradients.

cannot be maintained with Fio$_2$ ≤ 50%, PEEP may be used, with careful reassessment of serial arterial blood-gas analyses, changes in effective compliance, and hemodynamic data with each increment in PEEP. In patients with ALI or ARDS, however, lower tidal volumes (on the order of 6 mL/kg/breath) decrease both mortality and the total number of days on the ventilator.[1]

■ PHARMACOLOGIC ADJUNCTS

Only a few pharmacologic agents have a significant role in reversing xenobiotic-induced respiratory dysfunction. Naloxone may have the greatest role. Atropine and pralidoxime may be useful for respiratory dysfunction from cholinesterase inhibitors (Antidotes in Depth A33: Pralidoxime and Chap. 113). Elapid antivenom and botulinum antitoxin are rarely used but may be lifesaving. Neostigmine can reverse muscle weakness from nondepolarizing neuromuscular blockers (Chap. 68). More commonly, clinicians are required to treat bronchospasm from exposure to pulmonary irritants. The use of β$_2$-selective adrenergic-agonist bronchodilators is effective in these patients.[35] The role of corticosteroids remains controversial.[3]

When treating patients with bronchospasm from one of the work-related asthma syndromes, it is reasonable that management should be similar to that of any patient with pulmonary bronchospasm: emphasizing inhaled bronchodilators and corticosteroids (Fig. 21–4).

An inhaled solution of 2% sodium bicarbonate may provide symptomatic relief for patients with pulmonary exposure to hydrogen chloride or to chlorine (Antidotes in Depth A5: Sodium Bicarbonate).

Exogenous nitric oxide has been considered for a variety of pulmonary conditions. Specifically, nitric oxide may be useful as a bronchodilator,[17] a means to reverse hypoxic pulmonary vasoconstriction,[3] and as a treatment for ARDS.[2] Unfortunately, controlled studies fail to demonstrate a benefit for nitric oxide in ALI/ARDS patients.[3,103] Similarly, the results are disappointing for glucocorticoids, surfactants, and a variety of antiinflammatory agents.[4,103]

SUMMARY

Xenobiotics affect tissue oxygenation adversely at every step required for oxygen delivery. This process begins with lowering the partial pressure of inspired oxygen (simple asphyxiants) and ends with inhibition or blockade of cytochrome oxidase (carbon monoxide, cyanide, hydrogen sulfide). Although the clinical manifestations of hypoxia are constant regardless of the etiology, the history, physical examination, and some simple laboratory testing will often allow the clinician to determine the specific mechanism of hypoxia. Once the specific mechanism for hypoxia is identified, potential etiologies can be appreciated, and specific treatments begun. While the diagnosis is being determined, the first responses to tissue hypoxia always involve administration of supplemental oxygen, assisted ventilation if necessary, and assuring the adequacy of circulation.

CHAPTER 22

ELECTROPHYSIOLOGIC AND ELECTROCARDIOGRAPHIC PRINCIPLES

Cathleen Clancy

ELECTROPHYSIOLOGIC PRINCIPLES

The clinical tool most commonly used to assess cardiac function is the surface electrocardiogram (ECG). The ECG records the sum of the electrical changes occurring within the myocardium. The electrophysiologic basis of cardiac function and of the ECG, are complex and are subject to functional alternation by numerous xenobiotics. Ion currents flowing through various ion channels are responsible for cardiac function. Electrophysiologic studies have identified the functional types of membrane receptors and ion channels. Molecular genetic studies have identified the gene coding for the key cardiac ion channels and have elucidated the structural and physiologic relationships that lead to the toxic effects of many xenobiotics. These channels are critical for maintenance of the intracellular ion concentrations necessary for action potential development, impulse conduction throughout the heart, and myocyte contraction. This chapter will first review the individual ion channels and their currents, and then review them in summary through the perspective of their contribution and effects on the ECG.

ION CHANNELS OF THE MYOCARDIAL CELL MEMBRANE

■ SODIUM CHANNELS

The voltage-sensitive sodium channels are responsible for the initiation of depolarization of the myocardial membrane. All currently identified voltage-sensitive channels, including the sodium and calcium channel, have structures similar to the functional potassium channel assembly. The sodium channel gene encodes a single protein that contains four functional domains (D I—D IV). Each of these domains has the 6 membrane-spanning regions characteristic of the voltage-gated potassium channel and is structurally similar to an α subunit of the potassium channel (Fig. 22–1A). The single, large α subunit of the sodium channel assembles with regulatory β subunits to form the functional unit of the sodium channel. The best characterized of the sodium channels, the SCN5A gene-encoded α channel, is inactivated by xenobiotic interactions between the D III and the D IV domains to physically block the inner mouth of the sodium channel pore.[26]

■ POTASSIUM CHANNELS

Ion channels that change their conductance of current with changes in the transmembrane voltage potential are called *rectifying channels*. The voltage sensitive potassium channels are categorized based upon their speed of activation and their voltage response. They include the "delayed rectifier" potassium currents, particularly the I_{Kr} (rapidly activating) and the I_{Ks} (slowly activating) channels.[40]

The various voltage gated potassium channels share an underlying structural similarity. The α subunit is a protein molecule with 6 membrane-spanning α-helical domains, termed S1–S6 (Fig. 22–1B). The pore domain is located between the S5 and S6 regions of the α subunit, and the S4 region is the voltage sensor region.[26,49] Four of the α subunits encoded by the KvLQT1 gene assemble with β units encoded by the minK gene (originally thought to be the minimal potassium channel subunit) to form the I_{Ks} potassium channel.[26] Human ether a-go-go related gene (HERG) encodes the α subunit that assembles with β subunit proteins encoded by the minK related protein 1 (MiRPI) gene to form the I_{Kr} potassium channel. The C-terminus region of the α subunit encoded by HERG has a cyclic nucleotide binding domain and an N-terminus region similar to domains involved in signal transduction in cells.[26]

Many xenobiotics interact with the HERG-encoded subunit of the potassium channel to reduce the current through the I_{Kr} channel and prolong the action potential duration. The HERG α subunit of the channel is particularly susceptible to xenobiotic-induced interactions due to two important differences from the other channels. First, the S6 domain of the HERG channel has aromatic domains on the inner cavity pore that can bind to aromatic xenobiotics. Additionally, the inner cavity and entrance of the HERG channel is larger than the other voltage-gated potassium channels.[26] This larger pore can accommodate larger xenobiotics that are then trapped within the pore when the channel closes.[26,48,49,54]

■ CALCIUM CHANNELS

Calcium channel conductivity across the myocardial cell membrane is critical for maintaining the appropriate duration of cell membrane depolarization and for initiation of cellular contraction. The best characterized of the calcium channels are the slow (L-type), the fast (T-type), and the ryanodine receptor calcium channel. They are more prominently involved in cardiac contractility and discussed in Chap. 23.

ION CHANNELS AND THE MYOCARDIAL CELL ACTION POTENTIAL

An understanding of the basic electrophysiology of the myocardial cell is essential to understand the toxicity of xenobiotics and to plan appropriate therapy. Figure 22–2 shows the typical action potential of myocardial cell depolarization, the electrolyte fluxes responsible for the action potential, and the resulting ECG complex. The action potentials of the contractile and the conductive cells are depicted.

The action potential is divided into 5 phases: phase 0, depolarization; phase 1, overshoot; phase 2, plateau; phase 3, repolarization; and phase 4, resting. Phase 0 begins when the cell is excited either by a stimulus from an adjoining cell or by spontaneous depolarization of a pacemaker cell. Selective voltage-gated fast sodium channels (I_{Na^+}) open, resulting in rapid depolarization of the membrane. At the end of phase 0, the voltage-sensitive sodium channels close and a transient outward potassium current (I_{To}) occurs, resulting in a partial repolarization of the membrane—this constitutes phase 1.

During phase 2 (plateau phase), the inward depolarizing calcium currents are largely balanced by the outward repolarizing potassium currents. Voltage-sensitive calcium channels open that allow Ca^{2+} movement down the concentration gradient into the cell. The intracellular Ca^{2+} concentration is 5000–10,000 times lower than the extracellular concentration. The voltage-gated calcium channels that allow movement of Ca^{2+} down its concentration gradient into the cell are categorized based on their conductance (fast or slow) and their
FIGURE 22–1. Structure of the potassium and sodium ion channels. (**A**) The structure of the α subunit of the sodium channel. The protein molecule has 4 domains (D I–D IV) each analogous to one of the potassium channel α subunits. One of these molecules assembles with β subunits to form the membrane sodium channel. (**B**) The structure of the α subunit of the voltage gated potassium channel. The protein molecule has 6 membrane spanning regions (S1–S6); the voltage sensitive region is S4 and the actual ion channel is located between S5 and S6. Four of these α subunits assemble with 4 β subunits to form the potassium channel complex.
FIGURE 22–2. Relationship of electrolyte movement across the cell membrane to the action potential and the surface ECG recording.

sensitivity to voltage changes.[14,45] The calcium currents (mostly the "long-lasting" current) gradually decrease as the channels inactivate. Simultaneously, the outward potassium "delayed rectifier" currents, particularly the I_{Kr} (rapidly activating) and the I_{Ks} (slowly activating) currents, increase terminating the plateau phase of the action potential and initiating cellular repolarization (phase 3). Other, smaller, outward potassium currents (not shown in Fig. 22–2) play a lesser role in the duration of the action potential and development of phase 3, including I_{Kur} (ultrarapid), I_{Kp} (plateau), I_{K-Ach} (acetylcholine-dependent), and I_{K-ATP} (adenosine triphosphate-dependent) currents.

Phase 4 is the resting state for much of the myocardium, except the pacemaker cells, and corresponds to diastole in the cardiac cycle. During phases 3 and 4, active transport of Na^+, K^+, and Ca^{2+} against their electrochemical gradients return the myocyte to the baseline resting state. The transmembrane electrochemical gradient is maintained during the resting state by a Ca^{2+}-Na^+ exchange mechanism and by ATP-dependent pumps in the membrane that together move Ca^{2+} out of the cells.[45] In the pacemaker cells, during phase 4 of the action potential, gradual electrical depolarization of the membrane occurs due to potassium currents (called the I_f for "funny" or the I_h for "hyperpolarization-activated" current).[16] The membrane potential gradually increases in these pacemaker cells until the threshold potential is reached, the fast inward sodium channels open, and the I_{Na} current initiates the next phase 0. This electrical impulse is then propagated via the His-Purkinje conducting system of the heart.

During phases 0–2, the cell cannot be depolarized again with another stimulus; the cell is absolutely refractory. During the latter half of

phase 3, as the calcium channels convert from their inactivated to their resting state, an electrical stimulus of sufficient magnitude may cause another depolarization; the cell is relatively refractory. During phase 4, the cell is no longer refractory and any appropriate stimulus that reaches the threshold level may cause depolarization.

In addition to its role in myocardial contractility, Ca^{2+} influx is also important in pacemaker function. Although spontaneous pacemaker cell depolarization has traditionally been ascribed to inward cation current through "pacemaker channels"[1,16] recent research suggests that it may actually be driven by rhythmic release of calcium from the sarcoplasmic reticulum.[33,34] Regardless, Ca^{2+} fluxes play an important role in the spontaneous depolarization (phase 4) of the action potential in the sinoatrial (SA) node.[35] The rate of pacemaker cell depolarization is enhanced by β-adrenergic stimulation through phosphorylation of proteins on the sarcoplasmic reticulum and by a phosphorylation-independent action of cAMP at the pacemaker channels.[1,33] Depolarization of cells in the SA node spreads to surrounding atrial cells where it triggers the opening of fast sodium channels and impulse propagation. Calcium flux also allows normal propagation of electrical impulses via the specialized myocardial conduction tissues in the atrioventricular (AV) node.

ELECTROCARDIOGRAPHY

The ECG measures the sum of all electrical activity in the heart. It is used extensively in medicine and its interpretation is widely understood by physicians of nearly all disciplines. It is an invaluable diagnostic tool for patients with cardiovascular complaints. However, it is also a valuable source of information in poisoned patients and has the potential to enhance and direct their care. Although it seems obvious that an ECG would be required following exposure to a medication used for cardiovascular indications, many medications with no overt cardiovascular effects at therapeutic doses, are cardiotoxic in overdose. Furthermore, in patients with unknown exposures, the ECG can suggest specific xenobiotics or demonstrate electrolyte abnormalities, long before blood is drawn. For example, oropharyngeal or dermal burns in a patient whose ECG has evidence of hyperkalemia or hypocalcemia suggests exposure to hydrofluoric acid[58] (Chap. 105). Alternatively, a patient manifesting signs of the opioid toxidrome with runs of torsades de pointes might have been exposed to methadone(Chap. 38).[20] QT prolongation may be a clue to the etiology of an overdose with an atypical antipsychotic such as quetiapine (Chap. 69). The ECG can also be used to predict complications of poisoning, such as seizures following a cyclic antidepressant overdose (Chap. 73). Therefore, an ECG should be examined early in the initial evaluation of most poisoned patients.

■ HISTORY OF THE ECG

In the 1900s, Willem Einthoven graphically displayed the electrical activity of the heart and named the different waves—P, QRS, and T. He called this tracing an "elektrokardiogramme," and was awarded a Nobel Prize in 1924 for his efforts. The acronym *EKG*, still employed by some authors, was derived from Einthoven's spelling. The acronym *ECG*, which is consistent with our current spelling of electrocardiogram, is used throughout this text.

Since this initial description, both the normal electrophysiology of the heart and the pharmacologic effects of various xenobiotics on the ECG have been described. Despite the large number, diversity, and complexity of the various cardiac toxins, there are only a limited number of electrocardiographic manifestations.

■ BASIC ELECTROPHYSIOLOGY OF AN ELECTROCARDIOGRAM

Simplistically, a positive or upward deflection on the oscilloscope is generated when an electrical force moves toward an electrical sensor or electrode, and a downward deflection occurs if the force moves away. An ECG represents the sum of movement of all electrical forces in the heart in relation to the surface electrode, and the height above baseline represents the magnitude of the force (Fig. 22–3). Only during depolarization or repolarization does the ECG tracing leave the isoelectric baseline, because it is only during these periods that measurable currents are flowing in the heart. During the other periods, mechanical effects are occurring in the myocardium, but large amounts of current are not flowing.

■ LEADS

Although the reading from a single ECG lead provides an immense amount of information, to visualize the heart in a nearly three-dimensional perspective, multiple leads must be assessed simultaneously. Given the cylindrical nature of both the heart and thorax, at any given moment some of these leads will record positive voltage and others negative. The lead placement that was described and refined in the early 1900s by Einthoven forms the basis for the bipolar or limb leads, described as I, II, and III (Fig. 22–4). The Einthoven triangle is an equilateral triangle formed by the sum of these leads. Unipolar limb leads and precordial leads were subsequently added to the standard ECG. Unipolar leads were created when the limb leads were connected to a common point where the sum of the potentials from leads I, II, and III was zero. The currently used unipolar augmented (a) leads (aV$_R$, aV$_L$, and aV$_F$) are based on these unipolar leads (see Fig. 22–3). The voltage potential of these unipolar, "augmented leads" is small, thus it is amplified by incorporating the voltage change of the other two augmented leads. Together, leads I, II, III, aV$_R$, aV$_F$, and aV$_L$ form the hexaxial reference system that is used to calculate the electrical axis of
FIGURE 22–3. The hexaxial reference system derived from the Einthoven equilateral triangle defining the electrical potential vectors of electrocardiography showing the relationship between cardiac anatomy and electrocardiographic leads.
FIGURE 22–4. The hexaxial reference system derived from the Einthoven equilateral triangle defining the electrical potential vectors of electrocardiography. The relationships of the original three limb leads are illustrated. The equiangular (60°) Einthoven triangle formed by leads I, II, and III is shown (*dotted lines*) with positive and negative poles of each of the leads indicated. Leads I, II, and III are also presented as a triaxial reference system that intersects in the center of the ventricles.

the heart in the frontal plane. The precordial leads, called V_1 through V_6, are also unipolar measurements of the change in electric potential measured from a central point to the 6 anterior and left lateral chest positions (Fig. 22–5). If V_2 is placed over the right ventricle, part of the initial positive ventricular deflection (QRS complex) reflects right ventricular activation, with electrical forces moving toward the electrode.
FIGURE 22–5. Visualized as a cross-section, each of the chest leads is oriented through the atrioventricular (AV) node and exits through the patient's back, which is negative.

The majority of the subsequent terminal negative deflection reflects activation of other muscle tissue (septum, left ventricular wall) when the electrical forces are moving away from the electrode. Recordings from each of these 12 leads (I, II, III, aV_R, aV_L, aV_F, V_{1-6}) evaluate the heart from two different planes in 12 different positions, yielding a three-dimensional electrical "picture" of the heart, with respect to time and voltage.

A continuous cardiac monitor often relies on recordings from one of two bipolar leads: a modified left chest lead (MCL_1) or a lead II. The recording from an MCL_1, in which the positive electrode is in the V_1 position, is similar in appearance to a V_1 recording on a 12-lead ECG. This lead visualizes ventricular activity well; however, lead II shows atrial activity (ie, the P wave) much more clearly.

■ THE VARIOUS INTERVALS AND WAVES

The ECG tracing has specific nomenclature to define the characteristic patterns. Waves refer to positive or negative deflections from baseline, such as the P, T, or U wave. A segment is defined as the distance between two waves, such as the ST segment, and an interval measures the duration of a wave plus a segment, such as QT or PR interval. Complexes are a group of waves without intervals or segments between them (QRS). Electrophysiologically, the P wave and PR interval on the ECG tracing represent the depolarization of the atria. The QRS complex represents the depolarization of the ventricles. The plateau is depicted by the ST segment and repolarization is visualized as the T wave and the QT interval (QT). The U wave, when present, generally represents an afterdepolarization (Fig. 22–6).

■ THE P WAVE

The P wave is the initial deflection on the ECG that occurs with the initiation of each new cardiac cycle.

Electrophysiology The early, middle, and late portions of the P wave are represented sequentially by the electrical potential initiated by the sinus node. The impulse is propagated directly through the right atrial muscle, producing contraction. The impulse is also propagated by specialized conduction tissue across the interatrial septum, to produce contraction of the left atrium. Additionally, internodal pathways rapidly conduct the impulse to the AV node. The electrical excitation of the sinus node differs from that of the ventricular myocardium in that current is mediated primarily by calcium ion influx via slow T-type calcium channels, not by Na^+ entering through fast sodium channels. Furthermore, the vagus nerve exerts a profound suppressive influence on the nodal tissues.
FIGURE 22–6. The normal ECG: P wave, atrial depolarization; QRS, ventricular depolarization; ST segment, T wave, QT interval, and U wave, ventricular repolarization. The U wave is the small, positive deflection following the T wave.
FIGURE 22–7. A notched p wave (arrow) suggests delayed conduction across the atrial septum and is characteristic of quinidine poisoning.

The Abnormal P Wave Clinically, abnormalities of the P wave occur with xenobiotics that depress automaticity of the sinus node, causing sinus arrest and nodal or ventricular escape rhythms (β-adrenergic antagonists, calcium channel blockers). The P wave is absent in rhythms with sinus arrest, such as occurs with xenobiotics that produce vagotonia such as cardioactive steroids and cholinergics. A notched P wave suggests delayed conduction across the atrial septum and is characteristic of quinidine poisoning or atrial enlargement (Fig. 22–7). P waves decrease in amplitude as hyperkalemia becomes more severe until they become indistinguishable from the baseline (Chap. 16).

■ THE PR INTERVAL

The PR interval is measured from the beginning of the P wave to the beginning of the QRS complex (normal is 120–200 msec).

Electrophysiology Despite rapid conduction by specialized conduction tissue from the SA to the AV node, the AV node delays transmission of the impulse into the ventricles, ostensibly to allow for complete atrial emptying. Thus, the PR interval represents the interval between the onset of atrial depolarization and the onset of ventricular depolarization. Children usually have more rapid conduction and a shorter PR interval, and older adults generally have a longer PR interval. The segment between the end of the P wave and the beginning of the QRS complex (the PQ segment) reflects atrial contraction and is usually isoelectric. Atrial repolarization coincides with the Q wave, but its ECG findings, or atrial T waves, are obscured by the QRS complex.
