CHAPTER 90
CADMIUM

Stephen J. Traub and Robert S. Hoffman

Cadmium (Cd)		
Atomic number	=	48
Atomic weight	=	112.40 daltons
Normal concentrations		
Whole blood	<	5 µg/L (<44.5 nmol/L)
Urine (24 hour)	<	3 µg/g creatinine
	<	26.7 nmol/g creatinine)

Cadmium, which is currently used for a variety of industrial purposes, may cause both acute and chronic toxicological injury. After acute inhalation, patients may develop life-threatening pneumonitis; after acute ingestion, they may develop gastrointestinal (GI) necrosis. Chronic toxicity usually presents with renal impairment (proteinuria), although effects on bone and lung are also reported.

HISTORY AND EPIDEMIOLOGY

Cadmium, atomic number 48, is a transition metal in group IIB of the periodic table. In its pure atomic form, it is a bluish solid at room temperature. It is readily oxidized to a divalent ion, Cd^{2+}. Naturally occurring cadmium commonly exists as cadmium sulfide (CdS), a trace contaminant of zinc-containing ores.[36]

Cadmium sulfide, cadmium oxide, and other cadmium-containing compounds are refined to produce elemental cadmium, which is used for industrial purposes. When combined with other metals, cadmium forms alloys of relatively low melting points, which accounts for its extensive use in solders and brazing rods. Today, cadmium is principally used as a reagent in electroplating and in the production of nickel-cadmium batteries. Other uses of cadmium include as a pigment, as part of the phosphorescent system in black-and-white televisions, and as a neutron absorber in nuclear reactors. Cadmium salts have also been used as veterinary antihelminthics.[12]

As cadmium processing has increased, so has the incidence of cadmium toxicity. Cadmium exposure with resultant toxicity usually occurs in the environment, occupations, or hobby work.

■ ENVIRONMENTAL EXPOSURE

Environmental exposure to cadmium generally occurs by the consumption of foods grown in cadmium-contaminated areas. Because cadmium is fairly common as an impurity in ores, areas where mining or refining of ores takes place are the most likely to contain cadmium contamination.

In the 1950s, a mine near the Jinzu River basin discharged large amounts of cadmium into the environment, contaminating the rice that was a staple of the local food supply. An epidemic of painful osteomalacia followed, affecting hundreds of people, with postmenopausal multiparous women being most affected.[67] The afflicted were prone to develop pathologic fractures, and were reported to call out "itai-itai" (translated literally as "ouch-ouch") as they walked, because of the severity of their pain.[28] These symptoms were ultimately linked

to the cadmium. Less consequential environmental cadmium exposures have also occurred in Sweden,[46] Belgium,[10] and China.[48] Environmental exposure also occurs in smokers, who have higher blood cadmium concentrations than nonsmokers,[88] probably as a result of soil contamination. This is noteworthy, in that cadmium and tobacco may be synergistic causes of chronic pulmonary disease.[62]

■ OCCUPATIONAL AND HOBBY EXPOSURE

Welders, solderers, and jewelry workers who use cadmium-containing alloys are at risk for developing acute cadmium toxicity due to inhalation of cadmium oxide fumes. Other workers who do not work with metals per se may develop significant chronic cadmium toxicity through exposure to cadmium-containing dust.

Hobbyists who work with cadmium solders have exposures similar to occupational metalworkers. Significant cadmium toxicity in this population invariably results from metalworking in a closed space with inadequate ventilation and/or improper respiratory precautions.

TOXICOKINETICS

There is no known biologic role for cadmium. The bioavailability of elemental cadmium is unknown. Orally ingested cadmium salts are poorly bioavailable (5%–20%). However, inhaled cadmium fumes (cadmium oxide) are readily bioavailable (up to 90%).[96] As the only data on cadmium toxicokinetics are derived from work with cadmium salts and oxides, "cadmium" in the following discussion refers to these species unless otherwise noted.

After exposure, cadmium is absorbed into the bloodstream, where it is bound to α_2-macroglobulin and albumin.[97] It is then quickly and preferentially redistributed to the liver and kidney. Although other organs, such as the pancreas, spleen, heart, lung, and testes, can take up part of an acute cadmium load, they do so much less avidly.[25] Cadmium enters target organs by three mechanisms: zinc and calcium transporters; uptake of cadmium–glutathione or cadmium–cysteine complexes by transport proteins; and endocytosis of cadmium–protein complexes.[102]

After incorporation into the liver and kidney, cadmium is complexed with metallothionein, an endogenous thiol-rich protein that is produced in both organs. Metallothionein binds and sequesters cadmium. Slowly, hepatic stores of the cadmium–metallothionein complex (Cd-MT) are released. Circulating Cd-MT is then filtered by the glomerulus. A significant amount is reabsorbed and concentrated in proximal tubular cells.[19,83,84] This in part explains why the kidney is the principal target organ in cadmium toxicity.

There is no evidence that cadmium ions are oxidized, reduced, methylated, or otherwise biotransformed in vivo. The volume of distribution (Vd) of cadmium is unknown, but is presumably quite large as a consequence of significant hepatic sequestration. Cadmium distribution and elimination are complex, and an eight-compartment kinetic model was proposed.[54] The slow release of cadmium from metallothionein-complexed hepatic stores accounts for its very long biologic half-life of 10 or more years.

PATHOPHYSIOLOGY

■ CELLULAR PATHOPHYSIOLOGY

Cadmium toxicity results from interaction of the free cation with target cells.[25,35,60,65,84] Complexation with metallothionein is cytoprotective,[22,60] and metallothionein functions as a natural chelator with a strong affinity for cadmium.[18,55] Although metallothionein may play a role in proximal tubular concentration of cadmium, renal damage is actually

TABLE 90–1. Chronic and Acute Organ System Effects of Cadmium		
Organ	Acute	Chronic
Kidney		Proteinuria
		Nephrolithiasis
Bone		Osteomalacia
Lung	Pneumonitis	Cancer
Gastrointestinal system	Caustic injury	

attenuated by metallothionein, as metallothionein-deficient mice demonstrate more toxicity after cadmium exposure than controls.[60]

There are several mechanisms by which cadmium interferes with cellular function. Cadmium binds to sulfhydryl groups, denaturing proteins and/or inactivating enzymes. The mitochondria are severely affected by this process,[1] which may result in an increased susceptibility to oxidative stress.[47] Cadmium also interferes with E-cadherin, N-cadherin, and β-catenin–mediated cell–cell adhesion.[71–73] Finally, the demonstrated interference of cadmium with calcium transport mechanisms[93,94] might lead to intracellular hypercalcemia and, ultimately, apoptosis (Table 90–1).

■ SPECIFIC ORGAN SYSTEM INJURY

Kidney The renal damage caused by cadmium develops over years. Proteinuria is the most common clinical finding, and correlates with proximal tubular dysfunction, which manifests as urinary loss of low-molecular-weight proteins such as β_2-microglobulin and retinol-binding protein. Cadmium also produces hypercalciuria,[80] possibly also via damage to the proximal tubule.

Bone Cadmium-induced osteomalacia is a result of abnormalities in calcium and phosphate homeostasis, which, in turn, result from renal proximal tubular dysfunction. In one autopsy study, the severity of osteomalacia in cadmium-exposed subjects correlated with a decline in the serum calcium-phosphate product.[87]

Lung Acute cadmium pneumonitis is characterized by infiltrates on chest radiograph and hypoxia. Human autopsy studies[32,70,81,98] generally show degeneration and/or loss of bronchial and bronchiolar epithelial cells.

Gastrointestinal Tract Based on case reports,[11,99] ingested cadmium salts are caustic with the potential to induce significant nausea, vomiting, and abdominal pain, and result in GI hemorrhage, necrosis, and perforation. With respect to their effect on the GI mucosa, cadmium salts act similar to mercuric salts (Chap. 96).

CLINICAL MANIFESTATIONS

■ ACUTE POISONING

Pulmonary/Cadmium Fumes Cadmium pneumonitis results from inhalation of cadmium oxide fumes. The acute phase of cadmium pneumonitis may mimic metal fume fever (Chap. 124), but in fact, the two entities are distinctly different, with regard to both mechanism and clinical consequences. Whereas metal fume fever is benign and self-limited, acute cadmium pneumonitis can progress to hypoxia, respiratory insufficiency, and death.

Published case reports of patients who develop acute cadmium pneumonitis[4,5,32,70,81,90,98,101] are strikingly similar in their presentation.

Within 6 to 12 hours of soldering or brazing with cadmium alloys in a closed space, patients typically develop constitutional symptoms, such as fever and chills, as well as a cough and respiratory distress.

On initial presentation these patients, rather than appear seriously ill, instead may have a normal physical examination, oxygenation, and chest radiograph. However, this relatively benign presentation may lead both to the misdiagnosis of metal fume fever and the underestimation of the severity of the patient's illness. As the pneumonitis progresses to acute lung injury (ALI) (Chap. 124), crackles and rhonchi develop, oxygenation becomes impaired, and the chest radiograph develops a pattern consistent with alveolar filling. Despite aggressive supportive care, death may occur, usually within 3 to 5 days.[32,70,81,98]

Patients who survive an episode of acute cadmium pneumonitis may develop chronic pulmonary ailments, including restrictive lung disease,[4,5] diffusion abnormalities,[4] and pulmonary fibrosis.[90] Recovery without sequelae is also reported.[101]

Oral/Cadmium Salts Most acute cadmium exposures are inhalational, and acute ingestions are rare. Based on case report data, GI injury is likely to be the most significant clinical finding after acute ingestion.

In one case,[11] a 17-year-old woman ingested approximately 150 g of cadmium chloride and presented to the emergency department with hypotension and edema of the face, pharynx, and neck. Her condition quickly deteriorated, and she suffered a respiratory arrest. She was intubated and underwent orogastric lavage, chelation with an unspecified agent, and charcoal hemoperfusion. Multisystem organ failure ensued, and she died within 30 hours of presentation. At autopsy, the most significant finding was hemorrhagic necrosis of the upper GI tract. Her blood cadmium concentration was more than 2000 times normal.

In a second reported case of oral ingestion a 23-year-old man ingested approximately 5 g of cadmium iodide in a suicide attempt and presented with acute hemorrhagic gastroenteritis.[99] His condition deteriorated, and despite treatment with ethylenediaminetetraacetic acid (EDTA) and supportive measures, he died on hospital day 7. Autopsy did not reveal a specific cause of death.

■ CHRONIC POISONING

Chronic cadmium poisoning generally occurs to individuals through occupational exposures, although instances of mass environmental exposure, such as occurred in Japan,[28,66] are reported. All studies of chronic cadmium poisoning in humans are retrospective; conclusions about clinical course and treatment are therefore neither randomized nor controlled. In addition, and especially in the industrial setting, cadmium exposure may serve simply as a marker for other exposures, such as toxic vapors, other metals, or solvents. These other xenobiotics may contribute to, or cause, the pathologic condition described.

Nephrotoxicity The most common finding in chronic cadmium poisoning is proteinuria. Low-molecular-weight proteinuria is usually more significant than, and generally precedes, glomerular dysfunction, although some cadmium-exposed workers manifest predominantly glomerular proteinuria.[7] There is a dose–response relationship between total body cadmium burden and renal dysfunction,[10,44,46,67,92] although this relationship may not be as strong at low doses.[39] Patients with diabetes mellitus may be particularly susceptible to the nephrotoxic effects of cadmium.[37] In most cases, proteinuria is generally considered to be irreversible even after removal from exposure,[38,52,76] but improvement is sometimes reported.[91] Less clear is the question of whether renal dysfunction progresses after removal from exposure, with studies showing both stable[38] and deteriorating[42,75,76] renal function in cadmium-exposed workers who are removed from exposure. The routes and duration of exposure, as well as blood and urine cadmium concentrations, differ markedly among these studies, limiting wider applicability of any analysis.

Occupational cadmium exposure is also associated with nephrolithiasis,[45,79] likely as a result of hypercalciuria.[80]

Pulmonary Toxicity Large studies of workers chronically exposed to cadmium fail to demonstrate consistent effects on the lung. In one study of 57 workers with sufficient exposure to cadmium oxide to produce renal dysfunction, there was no evidence of pulmonary dysfunction, even in those with the greatest cumulative cadmium exposure.[27] In contrast, other studies demonstrate both restrictive[17] and obstructive[21,78] changes on pulmonary function tests. Interestingly, a follow-up study of the group with restrictive lung disease showed improvements after cadmium exposure was reduced.[16] The discrepancies in these results may be partly a result of markedly different doses and durations of exposure among the various groups.

Cadmium is associated with pulmonary neoplasia; the carcinogenicity of cadmium is discussed separately (see Cancer section below).

Musculoskeletal Toxicity Cadmium-induced osteomalacia usually occurs in the setting of environmental exposure, as was true in Japan and Sweden.[43] Although mentioned in case reports,[8,52] osteomalacia is generally not a prominent feature of occupational exposure to cadmium. One possible reason for this apparent difference is, whereas victims of the original Itai-Itai epidemic were mostly women, occupational cadmium exposures typically occur in men. In addition, differences in cumulative dosing and in route of exposure (oral versus pulmonary) may partly account for the unique prominence of osteomalacia in environmental exposures.

Hepatotoxicity Although the liver stores as much cadmium as any other organ, hepatotoxicity is not a prominent feature in humans with cadmium exposure, probably because hepatic cadmium is usually complexed to metallothionein.[40] The liver can potentially be a target organ, however, and hepatotoxicity is easily inducible in animals.[1,25,26,74]

Neurologic Toxicity Cadmium exposure is linked to olfactory disturbances,[63,77,86] impaired higher cortical function,[95] and Parkinson syndrome.[68,95]

Other Organ Systems Cadmium induces hypertension in rats,[59] but human studies have only yielded unconvincing and conflicting results.[31,58,69,89] Although there is evidence that cadmium may cause immunosuppression affecting both humoral and cell-mediated immunity in animals,[24] a single human study showed no overt immunopathology in an occupationally exposed cohort.[51] The testes are clearly a target organ in animal exposures,[57] but they are not considered a major target organ in humans.

Cancer Cadmium induces tumors in multiple animal organs, an effect that is exacerbated by zinc deficiency.[96] In humans, cadmium exposure is associated with lung cancer, although the strength of this association has been questioned because most studies have methodologic problems, such as coexposure to arsenic, a known pulmonary carcinogen.[9,53] Despite these confounding coexposures, cadmium is officially designated as a human carcinogen by the International Agency for Research on Cancer.[41]

DIAGNOSTIC TESTING

Cadmium concentrations have limited usefulness in the management of the acutely exposed patient, other than to confirm exposure. Diagnosis and treatment are based on the patient's history, physical examination, and symptoms. In a patient exposed to cadmium oxide fumes, ancillary tests, such as pulse oximetry and chest radiography, are more useful than actual cadmium concentrations.

In the patient chronically exposed to cadmium, both cadmium concentrations and ancillary testing may prove helpful. Urinary cadmium concentrations, which reflect the slow, steady-state turnover and release of metallothionein-bound cadmium from the liver, are a better reflection of the total-body cadmium burden than are whole blood concentrations.

Workers at high risk for cadmium toxicity should routinely have blood and urine cadmium testing and urinary protein testing. Workers with a urinary cadmium concentration greater than 7 μg/g urinary creatinine or a blood cadium concentration greater than 10 μg Cd/L require immediate reassignment to a cadmium-free area. Workers with significant proteinuria (β_2-microglobulin concentrations of 750 μg/g urinary creatinine) should also be reassigned if additional testing confirms cadmium exposure (as defined by a urinary cadmium concentration greater than 3 μg/g urinary creatinine or a blood cadium concentration greater than 5 μg/L). These numbers are reasonable in light of the fact that renal dysfunction can occur at cadmium concentrations as low as 5 μg/g urinary creatinine,[20,44] a concentration significantly higher than that of the general US population, 95% of whom have concentrations that are less than 2 μg/g urinary creatinine.[15]

MANAGEMENT

◼ ACUTE EXPOSURE

Oral Exposure/Cadmium Salts After the status of the patient's airway, breathing, and circulation are addressed, attention can be given to GI decontamination. Although large ingestions of soluble cadmium salts are rare, they frequently prove fatal.[11,99] The lowest reported human lethal dose is 5 g. In light of this, if a significant ingestion occurs but emesis has not occurred, gastric lavage is appropriate. In this situation, a small nasogastric tube should suffice, as inorganic cadmium salts are powders, not pills.

Given the relative lack of experience with acute oral cadmium poisoning, all patients with known exposures and/or abnormal findings consistent with cadmium toxicity or exposure should be admitted to the hospital for supportive care, monitoring of renal and hepatic function, and possibly evaluation of the GI tract for injury.

Although it seems logical to use chelation therapy in any patient with an acute life-threatening ingestion of a metal compound, the benefit of chelation in acute cadmium exposure is unproven. Multiple chelators have been used, all in animal models, with inconsistent results.

The ideal chelator for treatment of oral cadmium toxicity would be well tolerated, and would decrease GI absorption of cadmium and decrease the concentration of cadmium in organs such as the kidney and liver, while not increasing cadmium concentrations in other critical organs such as the brain. Of the chelators currently studied for cadmium toxicity, succimer comes closest to fulfilling these criteria. In models of acute oral cadmium toxicity, succimer decreases the GI absorption of cadmium,[3,6] without increasing cadmium burdens in target organs, and improves survival.[2,6,50]

In a patient thought to have ingested potentially lethal amounts of cadmium, treatment with succimer is reasonable. Succimer should be given as soon as possible after the ingestion, as the effectiveness of chelators decreases dramatically over time in experimental models of cadmium poisoning.[14]

It must be stressed, however, that supporting data for chelation are promising, but not definitive, and are only derived from animal models. Succimer dosing in human cadmium poisoning is unstudied. Doses that are well tolerated (10 mg/kg/dose tid) are appropriate (see Antidotes in Depth A27–Succimer [2,3-Dimercaptosuccinic Acid]).

Other chelators that may be beneficial, but for which further investigation is needed, include diethylenetriaminepentaacetic acid (DTPA)[6,13] and 2,3-dimercaptopropane sulfonate (DMPS),[13,50] both of which reduce tissue burdens and increase survival.

Most other chelators are either ineffective or detrimental, including 2,3-dimercaptopropanol (British anti-Lewisite, BAL),[13,19,49] penicillamine,[13,61] cyclic tetramines (such as cyclam and tACPD),[85] detergent formula chelators such as sodium tripolyphosphate (STPP) and nitrilotriacetic acid (NTA),[29,30] EDTA,[64] and dithiocarbamates.[3,33]

Pulmonary/Cadmium Fumes The patient who is ill after exposure to cadmium fumes (generally cadmium oxide) invariably presents with respiratory complaints and possibly also with constitutional symptoms. The airway should be assessed and appropriate oxygenation ensured, although hypoxia may not be a problem acutely. Steroids are used in most reported cases, but there are no studies to support their efficacy. Because cadmium inhalation injuries are neither benign nor self-limited, all patients with acute inhalational exposures to cadmium should be admitted to the hospital for observation and supportive care until respiratory symptoms have resolved. All such patients should have long-term follow-up arranged with a pulmonologist to assess the possibility of chronic lung injury, even following a single exposure.

Chelation should not be entertained as an option for patients with single acute exposures to cadmium fumes, as these patients do not appear to develop extrapulmonary injury.[4,5,90,101]

■ CHRONIC EXPOSURE

Patients chronically exposed to cadmium frequently come to attention during routine screening, as those who work with cadmium are under close medical surveillance. These patients may have developed proteinuria or, less commonly, chronic pulmonary complaints.

Management is challenging. Cessation of cadmium exposure is the first intervention. However, as mentioned earlier, chronic cadmium-induced renal and pulmonary changes are largely irreversible.

Chelation for chronic cadmium toxicity is not currently recommended. There is no evidence that chelation of chronically poisoned animals improves long-term outcomes, and one study in humans found no improvement in cadmium-induced renal dysfunction with periodic EDTA chelation.[100] Furthermore, in a chronically exposed patient, the majority of cadmium is bound to intracellular metallothionein, which greatly reduces its toxicity. Any attempt to remove cadmium from these deposits risks redistributing cadmium to other organs, possibly exacerbating toxicity, as is known to occur with BAL therapy.[23]

Of all the chelators tested thus far in animal models of chronic cadmium toxicity, the dithiocarbamates have shown the most success in reducing total body cadmium burdens. Unfortunately, these chelators tend to cause redistribution of cadmium to the brain as their lipophilicity not only allows them to cross cell membranes into hepatocytes (to access stored cadmium), but also promotes their uptake into the lipid-rich central nervous system (CNS).[34] Numerous dithiocarbamates have been synthesized and studied with regard to cadmium decorporation, however, and several species effectively reduce whole-body, renal, and hepatic cadmium concentrations without an increase in CNS cadmium.[56,82]

Further research into the subject of chelation for chronic cadmium poisoning is ongoing, and may produce an agent that is both safe and effective without exacerbating end organ toxicity. At present, there is insufficient evidence to justify the use of any chelator in the treatment of chronic cadmium toxicity.

SUMMARY

Cadmium is a toxic element that causes acute and chronic effects dependent on the total dose and route of exposure. After acute oral exposure, GI injury predominates. After acute inhalation, a severe chemical pneumonitis may ensue. With chronic environmental or occupational exposure, nephrotoxicity (usually manifested by proteinuria) is the most significant finding, although other organ systems, such as the lungs, can be affected. Treatment for all patients with suspected cadmium poisoning consists of removal from the source, decontamination if possible, and supportive care. In the rare instance of exposure from acute cadmium salt ingestion, treatment with succimer may be warranted. At this time there is insufficient evidence to recommend chelation in the patient who is chronically poisoned by cadmium.

CHAPTER 91
CHROMIUM

Steven B. Bird

Chromium (Cr)		
Atomic number	=	24
Atomic weight	=	51.99 daltons
Normal concentrations		
Whole blood	=	20–30 μg/L (380–580 nmol/L)
Serum	=	0.05–2.86 μg/L (1–56 nmol/L)
Urine	<	1 μg/g creatinine (<19.2 nmol/g creatinine)

Chromium toxicity may result from occupational exposure, environmental exposure, or a combination of both routes. Similar to the case with many metals, the clinical manifestations of chromium toxicity depend on whether the exposure is acute or chronic and on the chemical form of chromium. Whereas acute toxicity is more likely to involve multiple organ failure, chronic exposure may lead to cancer.

HISTORY AND EPIDEMIOLOGY

Chromium (from the Greek word for color, *chroma*) is a naturally occurring element that may be found in oxidation states of –2 to +6 but primarily exists in the trivalent (Cr^{3+}) and hexavalent (Cr^{6+}) forms. It was first discovered in 1797 in the form of Siberian red lead (crocoite: $PbCrO_4$) and occurs only in combination with other elements, primarily as halides, oxides, or sulfides (Table 91–1). Chromium is found most abundantly in chromite ore ($FeCr_2O_4$).[9] Elemental chromium (Cr^0) does not occur naturally but is extracted commercially from ore.

Elemental chromium is a blue-white metal that is hard and brittle. It can be polished to a fine, shiny surface; affords significant protection against corrosion; and can be added to steel to form stainless steel (an alloy of chromium, nickel, and iron). One of the most important uses of chrome plating is to apply a hard, smooth surface to machine parts such as crankshafts, printing rollers, ball bearings, and cutting tools. This is known as "hard" chrome plating. Elemental chromium is also used in armor plating safes and is used in forming brick molds because of its high melting point and moderate thermal expansion.

The carcinogenic potential of hexavalent chromium was first recognized as a cause of nasal tumors in Scottish chrome pigment workers in the late 1800s. In the 1930s, the pulmonary carcinogenicity of hexavalent chromium was first described in German chromate workers.[12]

PHARMACOLOGY

Chromium is an essential element involved in glucose metabolism. This may be through facilitation of insulin binding to insulin receptors or by amplification of the effects of insulin on carbohydrate and lipid metabolism. Chromium deficiency may have a causal link to diabetes mellitus and atherosclerosis.

The chemical properties and health risks of chromium depend mostly on its oxidative state and on the solubility of the chromium compound. Chromium is found naturally in the hexavalent (Cr^{6+}) or in the trivalent (Cr^{3+}) valence states, and these are the species to which most human exposures occur. However, chromium in the Cr^{6+} and Cr^{3+} oxidation states has very different properties. The relationship between these oxidative states is described by the following equation:[14]

$$Cr_2O_7^{2-} + 14\ H^+ + 6\ electrons \rightarrow 2Cr^{3+} + 7H_2O + 1.33\ eV$$

This difference of 1.33 eV in electric potential between the Cr^{6+} (in $Cr_2O_7^{2-}$) and Cr^{3+} states reflects both the significant oxidizing potential of Cr^{6+} and the high energy required for the oxidation of Cr^{3+} to Cr^{6+}. Reduction of Cr^{6+} to Cr^{3+} occurs in vivo by abstraction of electrons from cellular constituents such as proteins, lipids, DNA, RNA, and plasma transferrin which accounts for the toxicity of Cr^{6+}.[34]

The rapidity and completeness of the reduction of Cr^{6+} has been the subject of considerable scientific debate. Hexavalent chromium is reduced to Cr^{3+} in saliva, the gastrointestinal (GI) tract, respiratory tract epithelium and pulmonary macrophages, and blood.[4,31] During this reduction, several other oxidative states transiently occur (namely Cr^{4+} and Cr^{5+}) and contribute to the cytotoxicity, genotoxicity, and carcinogenicity of Cr^{6+} chromium compounds.[43]

Although most Cr^{6+} is rapidly reduced on entering the GI tract, ingestion of Cr^{6+} in drinking water does lead to measurable chromium concentrations in serum, red blood cells (RBCs), and urine. Hexavalent chromium may accumulate in most body tissues, raising concerns that chromium-induced toxicity and carcinogenesis may be more widespread than is currently appreciated.[12]

■ ENVIRONMENTAL EXPOSURE

The processing of chromium ores primarily releases Cr^{3+} into the environment. However, some hexavalent chromium is released from chromate manufacturing and coal-based power plants. The most significant environmental sources of Cr^{6+} are chromate production, ferrochrome pigment manufacturing, chrome plating, and certain types of welding.

The general population may be exposed to chromium via drinking water, food and food supplements (eg, chromium picolinate), joint arthroplasty, coronary artery stents, and cigarettes. Chromium has been used extensively to prevent equipment and piping corrosion in industrial cooling towers and air conditioning (trivalent chromium). Dermal exposure may occur from use of tanned leather products or wood treated with CCA (copper, chromate, and arsenate), which contains hexavalent chromium that is reduced to trivalent chromium by organic compounds after it is inside wood. CCA-treated lumber was voluntarily removed from the U.S. consumer market in December 2003 because of possible health concerns as a result of exposure to the arsenic and chromium. No specific adverse health effects related to CCA-treated lumber were reported by the Environmental Protection Agency before the voluntary withdrawal. A recent reanalysis of cancer mortality and hexavalent chromium-contaminated drinking water from Liaoning Province, China, demonstrated an increase in stomach cancer rate in communities with chromium-contaminated drinking water.[7] Significant exposure from more than 160 chromate production waste sites within Hudson County, New Jersey, was discovered in the late 1980s.[18] A final report published by the Agency for Toxic Substances and Disease Registry in 2008 found an increased risk of lung cancer incidence in populations living in close proximity to historic chromium ore processing residue sites, although the increases were not statistically significant.[3]

■ OCCUPATIONAL EXPOSURE

Workers in industries that use chromium may be exposed to 100 times greater concentrations of chromium than the general population.

TABLE 91–1. Common Forms of Chromium

Name	Chemical Formula	Oxidation State	Uses
Barium chromate	$BaCrH_2O_4$	6^+	Safety matches, anticorrosive, paint pigment
Calcium chromate	$CaCrO_4$	6^+	Batteries, metallurgy
Chromic acid	H_2CrO_4	6^+	Electroplating, oxidizer
Lead chromate	$PbCrO_4$	6^+	Yellow pigment for paints and dyes
Potassium dichromate	$K_2Cr_2O_7$	6^+	Oxidizer of organic compounds, leather tanning, porcelain painting
Chromic chloride	$CrCl_3$	3^+	Supplement in total parenteral nutrition
Chromic fluoride	CrF_3	3^+	Mordant in dye industry, moth-proofing agent for wool
Chromic oxide	Cr_2O_3	3^+	Metal plating, wood treatment
Chromite ore	$FeCr_2O_4$	3^+	Water tower treatment
Chromium picolinate	$C_{18}H_{12}CrN_3O_6$	3^+	Nutritional

Whereas chromium pigmentation production and leather tanning use significantly more Cr^{6+} compounds, metal finishing, wood preservation, and cooling towers use Cr^{3+} compounds (Table 91–2).

Several studies have focused on the risk of chromium exposure in welders.[38,39] Stainless steel welding liberates significantly more hexavalent chromium than do other types of welding. Although the lung cancer rate of stainless steel (containing chromium) welders has not been found to be different than that in regular steel welders, in 2006, the Occupational Safety and Health Administration (OSHA) lowered the permissive exposure limit of hexavalent chromium by 10-fold for welders.

TABLE 91–2. Occupations at Risk for Chromium Exposure

Cement workers	Machinists
Chromite ore workers	Painters
Electroplaters	Photograph developers
Foundry workers	Tanners
Galvanized steel workers	Textile dyers
Glass polishers and glazers	Welders
Lithographers	Wood preservers

PHARMACOKINETICS AND TOXICOKINETICS

Because they possess significantly different properties, Cr^{3+} and Cr^{6+} must be evaluated separately.

■ ABSORPTION

Trivalent Chromium Compounds Oral absorption of Cr^{3+} salts is limited. Approximately 98% is recovered in the feces, just 0.1% is excreted in the bile, and 0.5% to 2.0% is excreted in the urine.[16,30] Human case reports and animal studies also corroborate the generally poor absorption of Cr^{3+} salts by the oral, inhalational, and dermal routes, except through burns and other disrupted mucosal or epithelial surfaces.[26]

Hexavalent Chromium Compounds Cr^{6+} is modestly absorbed after ingestion partly as a result of the structural similarity between hexavalent chromium compounds and phosphate and sulfate.[13] These three chemicals undergo facilitated diffusion through nonspecific anion channels as well as active transport. In human volunteers, approximately 10% of an orally ingested dose of sodium chromate was absorbed; duodenal administration increased this to roughly 50%.[16] This difference likely relates to the reduction of the hexavalent chromium to trivalent chromium in the acidic environment of the stomach. Similarly, 3 hours after a lethal ingestion of potassium dichromate (hexavalent), greater than 80% of the chromium was reduced to the trivalent state in the blood.[20] Hexavalent chromium compounds are generally not well absorbed after dermal exposure. Whatever the route of exposure, Cr^{6+} is absorbed much more readily than Cr^{3+}, but the Cr^{6+} is then rapidly reduced to Cr^{3+} after absorption.

Epidemiologically, inhalational of Cr^{6+} is the most consequential route of exposure. Furthermore, the greatest health consequences from Cr^{6+} exposure are from inhalation. The exact rate of absorption is unknown but is dependent on the solubility of the specific Cr^{6+} compound, the size of the particles, the phagocytic activity of the pulmonary macrophages, and the general health of the lungs. Animal studies suggest that roughly 50% to 85% of small (<5 μm) Cr^{6+} potassium dichromate particles are absorbed.[2]

■ DISTRIBUTION

Because most of the Cr^{6+} is rapidly reduced upon absorption by the GI tract and by RBCs, Cr^{3+} accounts for virtually the entire body burden of chromium. Trivalent chromium accumulates to the greatest extent in the kidneys, bone marrow, lungs, lymph nodes, liver, spleen, and testes. The kidneys and liver alone account for approximately 50% of the total body burden.[13]

■ ELIMINATION

Urinary excretion of trivalent chromium occurs rapidly. Roughly 80% of parenterally administered Cr^{6+} is excreted as Cr^{3+} in the urine and 2% to 20% in the feces.[30] The urinary excretion half-life of Cr^{6+} ranges from 15 to 41 hours.[21] Because Cr^{6+} undergoes reduction to Cr^{3+} after uptake by RBCs, an apparent slow compartment is created, with the elimination half-life dependent on the life span of erythrocytes. Small amounts of chromium are detectable in sweat, breast milk, nails, and hair.

PATHOPHYSIOLOGY

■ TRIVALENT CHROMIUM

Cr^{3+} is an essential trace metal required for the metabolism of glucose and fats. The complex nutritional interactions of trivalent chromium with numerous metabolic pathways are not understood and remain the

subject of much debate among researchers. However, it is clear that dietary chromium deficiency leads to elevated insulin concentrations, hypercholesterolemia, hyperglycemia, increased body fat, and the attendant risks of these metabolic derangements. Cr^{3+} enhances insulin sensitivity and glucose disappearance concomitantly with lower insulin concentrations in a obese rat models, with no difference in lean controls.[11]

Chromium picolinate is a popular Cr^{3+} dietary supplement. There is a dearth of rigorous science concerning its efficacy and safety. However, it appears that organ deposition of Cr^{3+} occurs.[37] There is no strong evidence of any significant end-organ toxicity from exposure to Cr^{3+}, perhaps because Cr^{3+} is so poorly absorbed. There is little or no rigorous evidence that exposure to Cr^{3+} compounds increases cancer risk. Animal work and epidemiologic studies of workers exposed to Cr^{3+} compounds have failed to demonstrate a statistically significant increased incidence of cancer.[5]

■ HEXAVALENT CHROMIUM

Cr^{6+} is a powerful oxidizing agent that has corrosive and irritant effects. The greatest toxicity from Cr^{6+} lies in its ability to produce oxidative DNA damage. DNA strand breaks, DNA–DNA and DNA–protein cross-links, and nucleotide modifications all occur.[14] Although the exact mechanisms of how Cr^{6+} affects this genotoxicity are unknown, transient toxic chromium intermediates such as Cr^{4+} and Cr^{5+} are probably responsible.[36]

Inconsistent data suggest that either immunostimulation or immunosuppression results from chronic chromium exposure. At least one study suggests that chromium-induced immunosuppression may be responsible for implant-associated infections in patients after hip or knee arthroplasty.[44] Although human data are missing, adverse developmental effects, including cleft palate, hydrocephalus, and neural tube defects, have been demonstrated in animals.[15]

CLINICAL MANIFESTATIONS

The clinical manifestations of chromium poisoning depend on the valence, the source and route of exposure, and the duration of exposure. The clinical manifestations of chromium exposure are best divided into acute and chronic (low-level exposure) effects.

■ ACUTE

Manifestations of acute, massive Cr^{6+} ingestions are similar to other corrosive metal ingestions. GI hemorrhage, with or without bowel perforation, may occur acutely.[47] Because of the strong oxidative properties of Cr^{6+}, intravascular hemolysis with disseminated intravascular coagulation may also develop. Renal effects include acute tubular necrosis leading to renal failure.[46] Metabolic abnormalities after acute, massive exposure include metabolic acidosis with elevated lactate concentration, hyperkalemia, and uremia. Acute lung injury may develop up to 3 days after exposure. Although Cr^{6+} is generally not well absorbed after dermal exposure, it is a corrosive that causes skin inflammation and ulceration, which may lead to increased dermal absorption. Dermal chromic acid (H_2CrO_4) burns may lead to severe systemic toxicity with as little as 10% body surface area involvement.

■ CHRONIC

Because most chronic exposures are inhalational, the respiratory tract is the organ most affected after chronic chromium exposure. When inhaled, Cr^{6+} is a respiratory tract irritant that causes inflammation and, with continued exposure, ulceration (including nasal septum perforation).[22] Furthermore, the sensitizing effects of Cr^{6+} may lead to chronic cough, shortness of breath, occupational asthma, bronchospasm, and anaphylactoid-like reactions. Chronic deposition of chromium dust may also lead to pneumoconiosis.[35]

Epidemiologic studies of chromate workers in the 1980s indicated a significantly increased risk of lung cancer in individuals exposed to Cr^{6+} compounds.[23,32] Small cell and poorly differentiated carcinomas are the most common types, although nearly all pathologic types of lung cancer are associated with inhalational Cr^{6+} exposure.[1] The latency between exposure and development of lung cancer ranges from 13 to 30 years, although cases have been reported after as few as 2 years.[8]

Although conclusive evidence is missing, it appears that chronic exposure to Cr^{6+} via all routes may cause mild to moderate elevation in hepatic aminotransferases and abnormal liver architecture visible on histologic specimens.[47] Unlike acute exposures, low-dose chronic chromium exposure occasionally causes only transiently elevated urinary β_2-microglobulin concentrations, with no obvious lasting effects.[46]

Type IV (delayed-type) hypersensitivity reactions may occur after acute exposure to hexavalent chromium compounds. Chronic hexavalent chromium exposures also occur via dermal contact. Up to 24% of cement workers who have frequent contact with wet cement (which contains Cr^{6+}), automobile part handlers, and locksmiths develop skin sensitivity to chromium compounds.[25,27]

Occupational chromium exposure may also lead to contact dermatitis (dermatitis toxicosis) in as many as 10% to 20% of chromium workers.[41] There remains considerable debate over the relative sensitization abilities of Cr^{3+} and Cr^{6+}. Furthermore, what was initially thought to be sensitization to Cr^{3+} exposure may actually have been exposure to Cr^{6+} with subsequent in vivo reduction to Cr^{3+}. It appears, however, the Cr^{6+} is a more potent sensitizer than Cr^{3+} and that there may be limited cross-reactivity between the two forms of chromium.[17] Similarly, chromium-containing gaming table felt has led to hand dermatitis referred to as "blackjack disease," and virtually all occupations that involve exposure to chromium may lead to painless scarring and skin and nasal septum ulcerations referred to as "chrome holes."[24]

DIAGNOSTIC TESTING

Chromium may be detected in the blood, urine, and hair of exposed individuals. Because of the great difficulty in speciation, differentiation between Cr^{3+} and Cr^{6+} is generally not performed; instead, the total chromium concentration is usually reported. Needles used for phlebotomy and plastic containers used for sample storage may contain significant amounts of chromium. Unfortunately, there are no commercially available chromium-free needles. The use of modern, highly sensitive assay equipment, such as graphite furnace atomic absorption spectrometry, neutron activation analysis, and graphite spark atomic emission spectrometry, requires diligence in sample handling to ensure that biologic samples are not contaminated.

Because of the inherent difficulties in quantifying trace elements such as chromium and the lack of standard chromium reference materials, the reported normal serum and urine chromium concentrations in unexposed people have varied by more than 5000-fold over the past 50 years.[2] Consequently, older reference ranges should be interpreted with caution. Lastly, although cigarette smoke contains chromium, no studies have quantified the effect of smoking on serum, blood, or urinary chromium concentrations.

■ BLOOD OR SERUM

Chromium is distributed evenly between the serum and erythrocytes. Serum chromium concentrations are reflective of recent exposure to

both Cr^{3+} and Cr^{6+}. Serum concentrations in people without occupational exposure to chromium have been reported to be from 0.05 µg/L (1 nmol/L)[10] up to more than 2.8 µg/L (56 nmol/L).[2] It is not certain whether concentrations above these values should be considered potentially toxic because no clear correlation has been found between serum or blood concentrations and physiologic effects.

■ URINE

Although urine chromium concentrations reflect the acute absorption of chromium over the previous 1 to 2 days, wide individual variation in metabolism and total body burden limit the value of urinary chromium monitoring. Urine should be collected over a 24-hour period because of diurnal variation in excretion. Data from the third National Health and Nutrition Examination Survey (NHANES III) demonstrated mean and median urinary chromium concentrations in approximately 500 individuals without known exposure to chromium of 0.22 µg/L (4.4 nmol/L) and 0.13 µg/L (2.6 nmol/L). When corrected for creatinine, the values were 0.21 and 0.12 µg/g creatinine, respectively.[29]

■ HAIR AND NAILS

Hair and nail samples are not reliable indicators of exposure to chromium because of the difficulty in distinguishing between chromium contamination of the hair sample from chromium incorporated into the hair during normal hair protein synthesis. Chromium found in hair is not caused by contamination or exposure to shampoo or tap water.[19] Chromium concentrations in hair may be up to 1000 times higher than those found in serum.

■ ANCILLARY TESTS

After confirmed or suspected acute chromium exposure, complete blood count, serum electrolytes, blood urea nitrogen, creatinine, urinalysis, and liver enzymes testing should be performed. If signs of systemic toxicity are evident, serial determination of coagulation function and disseminated intravascular coagulation may be useful to guide therapy.

MANAGEMENT

Acute chromium ingestions are infrequent but often severe, with significant morbidity and mortality. Consequently, after adequate airway, breathing, and circulatory support have been addressed, attention should be given to decontamination.

■ DECONTAMINATION

As a consequence of its serious but very limited toxicity, Cr^{3+} compounds should require limited decontamination measures. However, because coingestants may be present, standard gut decontamination with activated charcoal should be considered if a patient presents soon after exposure. Similar to most other dermal exposures, decontamination with soap and water should be performed after skin contact. No specific pulmonary decontamination is required.

Hexavalent chromium is corrosive, and profuse vomiting and hematemesis usually occur after acute ingestions. Nasogastric lavage may be beneficial after Cr^{6+} ingestions if the patient presents to the emergency department within 1 to 2 hours of exposure and no vomiting has occurred. There are no data regarding the use of activated charcoal in acute chromium ingestions. Endoscopic visualization may be difficult after administration of activated charcoal, and the relative benefits of these two modalities need to be considered. If there is a low

likelihood of a coingestion, it is better to forego activated charcoal in order to obtain adequate endoscopic visualization. Known or suspected perforation is an absolute contraindication to activated charcoal.

Oral N-acetylcysteine increases the renal excretion of chromium in rats,[6] but there are no human data to support this therapy. Years of clinical experience using N-acetylcysteine for other indications and the very low incidence of adverse effects, however, favor the administration of oral N-acetylcysteine in the setting of acute chromium toxicity.

Although ascorbic acid facilitates reduction of Cr^{6+} to Cr^{3+} in vitro, no data are available to substantiate decreased absorption.[41] Some evidence suggests that topical ascorbic acid may reduce dermal Cr^{6+} exposure, but this has not been demonstrated in controlled trials.[36] Therefore, the routine use of ascorbic acid cannot be advocated at this time.

■ CHELATION THERAPY

The currently available chelators do not appear efficacious at either lowering serum or blood chromium concentrations or ameliorating chromium toxicity in experimental models. Specifically, ethylenediaminetetraacetic acid (EDTA) was found to have no effect on urinary chromium excretion in human subjects,[45] and dimercaprol (British anti-Lewsite, BAL) was not beneficial in an animal model of chromium poisoning.[28]

In a single study, dimercaptopropane sulfonate (DMPS) had no effect on urinary chromium excretion in humans.[42] D-penicillamine also failed to increase urinary excretion of chromium.[28] There have been no studies of chromium chelation with 2,3-dimercaptosuccinic acid (succimer). Therefore, at this time, there is no evidence to support the use of chelation therapy after acute Cr^{6+} or Cr^{3+} poisoning.

■ EXTRACORPOREAL ELIMINATION

Hemodialysis, hemofiltration, and peritoneal dialysis (PD) do not efficiently remove chromium. Studies in animals and human case reports indicate that as little as 1% of chromium is removed by hemodialysis or hemofiltration after acute dichromate (a hexavalent compound) exposure.[20,40] Exchange transfusions may rapidly reduce blood chromium concentrations, but no data are available to suggest that clinical outcomes are positively affected. Limited data in dialysis patients have demonstrated some ability of PD and hemodialysis to remove intravenously administered chromium.[33] Therefore, in the setting of normal renal function, extracorporeal means of eliminated chromium are not likely to be of benefit. In the setting of acute or chronic renal failure, PD or hemodialysis may be beneficial in reducing serum chromium concentrations, although no data are available showing that clinical outcomes are affected.

SUMMARY

Whereas hexavalent chromium remains an uncommon but serious cause of acute metal poisoning, trivalent chromium lacks toxicity. The acute exposure to Cr^{6+} salts by ingestion causes GI hemorrhage, hepatic necrosis, and renal failure. Toxicity after chronic Cr^{6+} exposure includes ulcerations of the skin and nasopharynx ("chrome holes") and, more significantly, lung and stomach cancer. Definitive data regarding other types of cancer resulting from chronic Cr^{6+} exposure are unavailable. Regardless of the time course of the poisoning, treatment for chromium exposure includes removal of the patient from the source of exposure, GI decontamination, and supportive care. There is insufficient evidence to support the use of chelating agents in either acute or chronic chromium poisoning.

CHAPTER 92
COBALT

Gar Ming Chan, MD

Cobalt (Co)

Atomic number	=	27
Atomic weight	=	58.9 daltons
Normal concentrations		
Serum	=	0.1–1.2 µg/L (1.7–20.4 nmol/L)
Urine	=	0.1–2.2 µg/L (1.7–37.3 nmol/L)

Cobalt is extensively mined, has numerous industrial uses, and is an essential trace element in vitamin B_{12}. ^{60}Cobalt is remarkably important in radiotherapy, but an epidemic of cardiomyopathy ensued when cobalt was added to beer to improve the esthetics of the "foam." Toxicologic concerns today have diminished because of preventive respiratory measures in the mining industry. The ingestion of cobalt salts is quite uncommon.

HISTORY AND EPIDEMIOLOGY

The name cobalt (Co) originates from *kobold* German for "goblin," and was given to the cobalt-containing ore cobaltite (CoAsS) because it made exposed miners ill. However, the miners' illness was more likely a result from the arsenic exposure rather than exposure to cobalt. Brandt discovered cobalt in 1753 during an attempt to prove that an element other than bismuth gave glass a blue hue.

With an atomic number of 27 and a molecular weight of 58.93 daltons, Co is a light metal that has a melting point of 1768.2°K and a boiling point of 3373°K. These attributes make elemental cobalt a very useful industrial metal. The main industrial use of cobalt use is the formation of hard, high-speed, high-temperature cutting tools. When aluminum and nickel are blended with cobalt, an alloy (Alnico) with magnetic properties is formed. Other uses for cobalt include electroplating because of its resistance to oxidation and as an artist's pigment because of its bright blue color.

A Co^{3+} ion is at the center of cyanocobalamin (vitamin B_{12}), which is synthesized only by microorganisms and is not found in plants. Common dietary sources are fish, eggs, chicken, pork, and seafood. A diet deficient in cyanocobalamin results in pernicious anemia. Hydroxocobalamin, a Co^{3+}-containing precursor to cyanocobalamin, is used as an antidote for cyanide poisoning (see Antidotes in Depth A40: Hydroxocobalamin).

Historically, cobalt chloride was combined with iron salts and marketed in the 1950s as "Roncovite" for the medical treatment of anemia. As recently as 1976, physicians still used cobalt to reduce transfusion requirements in anemic patients despite concomitant adverse effects.[35] The other common medical use of cobalt is as a radioactive isotope, cobalt-60 (^{60}Co). This γ emitter was formerly used in the radiotherapy of cancers but has been largely replaced by linear accelerators in the Western world. It may also be targeted by terrorist groups as a source of radioactive material.

Epidemics of cardiomyopathy and goiter termed "beer drinker's cardiomyopathy"[12] and "cobalt-induced goiter"[59] occurred in the 1960s and 1970s. During this period, cobalt sulfate was added to beer as a foam stabilizer. In the 1970s, these epidemics were halted with the discontinued utilization of cobalt for this purely aesthetic purpose.[92]

Current sources of cobalt exposure include chemistry kits,[64] weather indicators,[64] antiquated anemia therapies,[64] cement,[71] fly ash,[71] mineral wool,[71] asbestos,[71] molds for ceramic tiles,[41] the production of Widiasteel (used in the wood industry),[126] mining,[65] porcelain paint,[110] orthopedic implants,[63] and dental hardware.[5]

The most clinically important source, however, arises through the formation of cemented tungsten carbide, a "hard metal." In tungsten carbide factories, powdered cobalt and tungsten are combined through an intense sintering process that exposes the metals to hydrogen heated to 1000°C. The first published investigation of these factories reported a 10-fold increase in workspace cobalt concentrations compared with atmospheric concentrations.[38] These respiratory exposures have resulted in pulmonary toxicity, known as "hard metal disease." As a result of this historic report, occupational studies and preventive respiratory measures have greatly reduced the acceptable cobalt exposure concentration in the workplace.

CHEMISTRY

Similar to other metals, cobalt occurs in elemental, inorganic, and organic forms. The clinical effects of each form are less well defined than more common metals such as lead, mercury, or arsenic. Elemental cobalt (Co^0) toxicity is reported through both inhalational[139] and oral exposures.[58,59] Inorganic Co salts most commonly occur in one of two oxidation states: cobaltous (Co^{2+}) or cobaltic (Co^{3+}). Inorganic Co salts, such as cobaltous chloride ($CoCl_2$) and cobaltous sulfate ($CoSO_4$), were historically used for the treatment of anemias[13,48,54,109,146] and were implicated in the "beer drinker's cardiomyopathy" case series.[1,88,94]

Organic cobalt exposure results from cyanocobalamin (vitamin B_{12}) ingestion but because of its limited oral absorption and its rapid renal elimination, it is considered of low toxicity.[106] Another organic form of cobalt (stearate) is toxic in rodents.[15] In animal models, the inorganic chloride, sulfate, and nitrate cobalt salts are more toxic than the organic forms such as cobalt stearate.[15]

TOXICOKINETICS

Based on animal studies, oral absorption of cobalt oxides, salts, and metal is highly variable, with a reported bioavailability of 5% to 45%.[72,82] In human studies, both iron deficiency and iron overload (hemochromatosis) enhance radiolabeled $^{57}CoCl_2$ absorption in the small bowel.[100] Inhaled cobalt oxide is about 30% bioavailable,[82] but the volume of distribution and elimination half-life are not well defined.

Most (50% to 88%) absorbed cobalt (organic and inorganic) is eliminated renally, and the remainder is eliminated in the feces.[124] Acutely, an increase in inorganic cobalt concentrations will result in an increased renal elimination.[69] However, this initial increased elimination decreases rapidly despite a large body burden.[2,100]

The elimination of cobalt correlates with the patterns of occupational exposure.[139] For example, a worker with a standard workweek will have much higher urine cobalt concentrations on Friday morning compared with Monday morning.[139] However, Monday afternoon urine cobalt concentrations may be higher than Friday morning concentrations, which is because of the rapid elimination that occurs after an initial exposure.[2,139] Based on these findings, the exposure over time must be considered when interpreting urinary cobalt levels in occupationally exposed individuals.[9]

PATHOPHYSIOLOGY

Similar to other metals, cobalt is a multiorgan toxin. Co^{2+} inhibits several key enzyme systems and interferes with initiation of protein synthesis.[10] First, polynucleotide phosphorylase, an essential enzyme in RNA synthesis, requires Mg^{2+} to function normally. The enzyme functions at 50% that of normal in the presence of Co^{2+}.[10] It is hypothesized that Co^{2+} is capable of displacing Mg^{2+} from this cofactor site of the enzyme.[10]

The second enzyme cobalt salts interfere with is α-ketoglutarate dehydrogenase, a mitochondrial Krebs cycle enzyme. Co^{2+} increases the rate of glycolysis and at the same time decreases oxygen consumption,[22] suggesting that Co^{2+} inhibits aerobic metabolism. In vitro studies demonstrate that other divalent cations, Zn^{2+}, Cd^{2+}, Cu^{2+}, and Ni^{2+}, inhibit α-ketogluturate dehydrogenase (see Chap. 12).[143] Compared with these divalent cations, Co^{2+}, is not as potent an inhibitor.[143] In an vitro model, Co^{2+} is capable of almost entirely inhibiting the reaction when nicotinamide adenine dinucleotide (NADH) is added to the reaction.[143] This model may suggest that NADH abundance, such as in chronic ethanol use, may potentiate the inhibition of α-ketogluturate dehydrogenase.[144]

Moreover, cobalt salts are capable of inhibiting α lipoic acid and dihydrolipoic acid by complexing with its sulfhydryl groups.[25,143] These reactions result in the inability to convert both pyruvate into acetyl-CoA and α-ketoglutarate into succinyl-CoA (see Chapter 12 and Antidotes in Depth A25: Thiamine). These toxic effects may help explain why the combination of chronic ethanol use and cobalt exposure results in cardiomyopathy (see Clinical Effects: Cardiac).[143]

In addition to enzyme inhibition, cobalt chloride induces oxidant-mediated pulmonary toxicity (see Clinical Effects: Pulmonary).[98] Xenobiotics implicated in free radical–mediated pulmonary injury are capable of accepting an electron from a reductant and subsequently transferring the electron to oxygen, forming a superoxide free radical (see Chap. 11). Cobalt is then capable of accepting another electron, which starts the cycle over again, a process known as redox cycling. This results in an accumulation of free radicals in the lung because of the abundance of oxygen ready to receive electrons and results in injury (see Chap. 124).

Within the endocrine system, $CoCl_2$ is capable of inhibiting tyrosine iodinase.[75] This enzyme is responsible for combining iodine (I_2) with tyrosine to form monoiodotyrosine and serves as the first step in the synthesis of thyroid hormone (see Chap. 49). Inhibition of tyrosine iodinase leads to a decrease of circulating triiodothyronine (T_3) and thyroxine (T_4), which may result in hypothyroidism (see Clinical Effects: Endocrine).

The hematopoietic system is also affected by Co salts. Multiple animal models demonstrate that $CoCl_2$ administration results in reticulocytosis, polycythemia, and erythropoesis.[44,73,91,101,102,146] These events occur in both the bone marrow and extramedullary locations.[13,46] Although the pathogenesis remains largely unknown,[25] one theory is that cobalt binds to iron binding sites such as transferrin,[66] resulting in impaired oxygen transport to renal cells, which in turn induces erythropoietin production. A second theory in which cobalt is thought to stimulate erythropoiesis is through improving iron availability. In an animal model of anemia, a greater degree of gastrointestinal (GI) iron uptake occurs in cobalt-treated rats compared with rats with either hypoxia or nephrectomy.[46] A similar study in mice suggested that the increase in iron uptake exceeded that after exogenous erythropoietin.[3]

Finally, within the nervous system, $CoCl_2$ inhibits neuromuscular transmission by competing with Ca^{2+}, another divalent ion. Cobalt is 20 times more potent than magnesium with regard to its ability to compete with calcium for a site on the motor nerve terminal.[142]

TOXICITY

The single acute minimal toxic dose of cobalt salts is not well defined. In fact, varying effects have occurred at variable doses in different patients. Whereas patients with "beer drinker's cardiomyopathy" received an average daily dose of 6 to 8 mg of $CoSO_4$ (over weeks to months) and developed toxic effects of acidemia, cardiomyopathy, shock, and death,[70,94] infants being treated for anemia who received much higher daily cobalt doses of an iron–cobalt preparation (40 mg of $CoCl_2$ and 75 mg of $FeSO_4$) for 3 months did not develop toxicity.[115] The inconsistency of these findings suggests that multiple factors are responsible for the development of the clinical manifestations; in this case, the role of ethanol metabolism may be an important variable.[64]

CLINICAL MANIFESTATIONS

Organ systems affected by acute cobalt poisoning are the endocrine,[58] GI,[35,48] central[48,123] and peripheral nervous,[123] hematologic,[44,73,91,146] cardiovascular,[59] and metabolic[59] systems. Chronic inhalational exposures affect the pulmonary[18,23,38,77,78,112,131] and dermatologic systems.[42,118,145] Radioactive[60] Co used for radiation therapy has been associated with radiation burns (see Chap. 133). Unlike acute toxicity, chronic cobalt exposure is not associated with an increased mortality; a cohort study evaluating more than 1100 persons with pulmonary exposures to cobalt salts and oxides over a 30-year period was unable to show an increased mortality rate.[96]

■ ACUTE EXPOSURE

Cardiovascular *"Beer Drinkers' Cardiomyopathy".* In 1966, a Veterans Affairs Hospital in Nebraska cared for 28 white men with a history of beer drinking who presented with tachycardia, dyspnea, and metabolic acidosis with elevated lactate concentration but without any finding of congestive heart failure.[88] The mortality rate for these cases was 38% and death occurred rapidly within 72 hours of presentation because of severe acute metabolic acidosis and cardiac failure.[88] The survivors were successfully treated with supportive care and thiamine supplementation.[88] Of the survivors, most responded immediately to therapy, and a lack of response was found to be secondary to complications, most commonly, symptomatic pericardial effusions or embolic events.[88] Epidemiologic evaluation of this case series revealed that these men commonly drank large quantities of beer.

Ultimately, 64 cases and 30 fatalities were reported from Nebraska.[138] Of the reported 30 deaths, 26 decedents received autopsies. Common postmortem cardiac findings were dilated cardiomyopathy and cellular degeneration with vacuolization and edema with a lack of inflammation or fibrosis.[88] When cobalt was implicated in the pathogenesis of these deaths, the preserved cardiac tissue of eight decedents revealed cobalt concentrations 10 times greater than those of control subjects.[138]

Within 1 year of the Nebraska cases, reports began to emerge from Quebec.[94] Forty-eight beer drinkers (only two of whom were women) developed unexplained cardiomyopathy, with a mortality rate of 46%.[94] The only association between these patients was the common consumption of a given brand of beer.[94] The producers of this beer had factories in Quebec City and Montreal. The only difference between the two breweries was that the one in Quebec added 10 times the amount of $CoSO_4$ to the beer as a foam stabilizer.[92] Clinical findings in these cases included tachycardia, tachypnea, polycythemia, and low-voltage electrocardiograms (ECGs).[93] Cases began to appear 1 month after the beer with the excessive cobalt was released on the market, and no new cases were reported in Quebec after the beer with the excessive cobalt concentration was removed from the market.[92]

In 1972, 20 additional cases occurred in Minneapolis with similar findings of tachycardia, dyspnea, pericardial effusion, polycythemia, and metabolic acidosis with elevated lactate concentration; there was a mortality rate of 18% acutely and 43% over a 3-year period.[70]

Because the clinical findings resemble the cardiomyopathy associated with chronic alcoholism[40] and infantile malnutrition,[107] a debate persists as to whether cobalt is the sole cause of this syndrome. Cardiomyopathies caused by poor protein intake and vitamin deficiency both have similar histologic findings to cobalt cardiomyopathy. For example, myocardial biopsy of dogs with cobalt-induced cardiac failure revealed diffuse cytosolic vacuolization, loss of cross striations, and interstitial edema,[121] all of which are similar to findings of malnutrition.[40,107] However, some other findings may be specific to cobalt-associated cardiomyopathy. For example, a small retrospective analysis revealed myocyte atrophy and myofibril loss to be present in people with cobalt-associated cardiomyopathy significantly more often than in those with idiopathic dilated cardiomyopathy.[16]

Some animal models of cobalt cardiomyopathy were only able to reproduce pathologic and ECG findings if cobalt was combined with ethanol[7]; others required protein deficiency.[116] Contrary to these studies, several rat and canine models of cobalt poisoning and nutritional supplementation have demonstrated cardiac lesions,[52,120,121] cardiac failure[55,120,121] and ECG abnormalities.[53,120]

Despite the implication that cobalt-induced cardiomyopathy requires malnutrition or alcoholism, a case of cardiac toxicity after acute cobalt poisoning has been reported.[58,59] However, it is difficult to identify other cases reported outside of the aforementioned small epidemics in beer drinkers. In a controlled study of occupationally exposed subjects evaluated with echocardiograms, significantly more cobalt-exposed workers had diastolic dysfunction compared with control subjects.[80] However, none of these subjects under study developed congestive heart failure.[80] There have been rare reports of cardiomyopathy in chronically exposed workers,[11,21,68] which suggests that the cardiomyopathy reported in the "beer drinkers" cohort is multifactorial and not solely caused by cobalt.

Another source of criticism of the role of cobalt in the development of cardiomyopathy is the relatively low dose of cobalt needed to induce heart failure in these patients.[70] In patients receiving 20 to 75 mg/day of $CoCl_2$ for various red blood cell (RBC) dysplasias, there were no reports of heart failure,[70] but the "beer drinker's cardiomyopathy" group reportedly consumed only 6 to 8 mg/day of $CoSO_4$ from drinking 24 pints of cobalt-containing beer.[70,92] All patients who developed cardiomyopathies were malnourished, which supports the theory that a multifactorial nutritional deficiency in the presence of excessive cobalt may be necessary for the development of cardiomyopathy.[70]

Endocrine Both acute and chronic cobalt exposures are associated with thyroid hyperplasia and goiter. A series of patients with severe sickle cell anemia treated with cobalt therapy also developed goiter with varying degrees of thyroid dysfunction[54,74] including clinical hypothyroidism.[75] In one patient, the goiter was so severe that airway obstruction developed.[74]

More recent occupational data suggest that inhalational exposure to cobalt metals, salts, and oxides may result in abnormalities in thyroid function studies.[139] When 82 workers in a cobalt refinery were compared with gender- and age-matched control subjects, exposed workers had significantly lower T_3 concentrations.[139]

Within the previously mentioned beer drinker's cardiomyopathy cohort, 11 of 14 decedents had abnormal thyroid histology.[117] Among them, the most common findings were follicular cell abnormalities and colloid depletion, which did not exist on thyroid analysis from 11 randomly selected autopsies that served as control subjects.[117]

Hematologic Anemias of the newborn,[19,67,109] erythrocyte hypoplasia,[125] RBC aplasia,[141] renal failure,[48] and chronic infection[114] have all been successfully treated with cobalt salts. Patients undergoing $CoCl_2$ therapy for these diseases had increased hemoglobin,[48,109] hematocrit,[48,109] and RBC counts.[48] Furthermore, the effects did not persist after cessation of therapy.[48,109]

A published series of Peruvian cobalt miners working in an open pit at an elevation of 4300 m (2.7 miles) developed clinical effects, including headache, dizziness, weakness, mental fatigue, dyspnea, insomnia, tinnitus, anorexia, cyanosis, polycythemia, and conjunctival hyperemia consistent with acute mountain sickness.[65] When the study group was compared with age-, height-, and weight-matched high-altitude control subjects, the study group was noted to have higher chronic mountain sickness scores.[65] The only difference detected was elevated serum cobalt concentrations in the study group.[65]

In addition to effects on RBCs, recent work demonstrates transient hemolysis, methemoglobinemia, and methemoglobinuria from subcutaneous $CoCl_2$ exposure in mice.[60] These findings may explain reports of dark urine after cobalt exposure in other animal models.[50,133] Human cases have not been reported.

Other GI distress after the ingestion of "therapeutic" doses of cobalt salts[123] as well as elemental cobalt has been reported.[64] Decreased proprioception, impaired cranial nerve VIII function, and nonspecific peripheral nerve findings are reported with acute oral $CoCl_2$ exposures.[123]

■ CHRONIC

Pulmonary Two pulmonary diseases are associated with cobalt exposure: asthma and "hard metal disease." Occupational asthma is reported in hard metal workers with a prevalence of 2% to 5%[18,77,78] at exposure concentrations as low as 50 µg/m³.[78] As is the case with most causes of occupational asthma, cobalt hypersensitivity–induced asthma is most likely immune mediated rather than toxicologic.[20,77,131] Most hard metal workers are exposed to other metals, such as tungsten (W) and nickel (Ni) in addition to Co, and these other metals may account for some cases of occupational asthma that are attributed to cobalt.[128,130] However, in a small but well-performed study in patients with cobalt-associated asthma, intradermal cobalt chloride ($CoCl_2$) resulted in a positive wheal response in all subjects, and 50% of patients had a positive radioallergosorbent test (RAST) scores, which correlated to the wheal size,[129] suggesting that Co salts independent of the other metals may illicit an immune response.

Cobalt-associated pulmonary toxicity was first noted in tungsten–carbide workers[38,56] and was subsequently referred to as "hard metal disease." Exposures result from the process by which tungsten–carbide is sintered with cobalt. Signs and symptoms of hard metal disease may include upper respiratory tract irritation, exertional dyspnea, severe dry cough, wheezing, and interstitial lung disease ranging from alveolitis to progressive fibrosis. The prevalence of hard metal disease is largely unknown. In one study, 11 of 290 (3.8%) exposed workers were diagnosed with interstitial infiltrates on chest radiographs but only two (0.7%) had a decreased predicted total lung capacity.[134]

Certain individuals who are exposed to large doses of hard metal for prolonged periods never develop disease, which suggests that a susceptible population exists. A glutamate substitution for lysine in position 69 of the β unit HLA-DP has a strong association with hard metal disease, similar to chronic beryllium disease.[108] Clinically, hard metal disease is difficult to distinguish from berylliosis, although an occupational history should be helpful.

Common findings of hard metal disease on histopathology are multinucleated giant cells and interstitial pneumonitis with bronchiolitis.[8] Elevated concentrations of cobalt in lung tissue can be detected,[113,132] even as long as 4 years after exposure.[113] Bronchioalveolar lavage (BAL)

commonly reveals multinucleated giant cells, type II alveolar cells, and alveolar macrophages in patients with interstitial lung disease.[23] The finding of multinucleated giant cells from BAL washing is characteristic of hard metal disease.[20,26,27,89,140]

A cross-sectional study of more than 1000 tungsten carbide–exposed workers found an increased odds ratio of 2.1 for having a work-related wheeze when exposed to greater than 50 µg/m³ of Co.[135] In the same study, workers with exposures recorded at greater than 100 µg/m³ had higher odds (odds ratio [OR], 5.0) of having a chest radiograph profusion score of greater than or equal to 1/0.[135] This profusion score, established by the International Labor Organization (ILO) and most recently updated in 2000, is a grading system for pneumoconioses. When used to grade radiographs of asbestosis, this score correlates strongly with mortality risk,[87] reduced diffusing capacity, and decreased ventilatory capacity.[57,97] A score of 0/1 is suggestive but not diagnostic ("negative"), and a score of 1/0 is presumptively diagnostic but not unequivocal ("positive").[6] Additional studies have similarly concluded that pulmonary disease occurs when individuals are exposed to doses cobalt approach 100 µg/m³.[76] Thus, the current threshold limit value (TLV) is <50 µg/m³.

Until 1984, all reported cases of hard metal disease were associated with the combination of cobalt and other metals, such as nickel, cadmium, and tungsten.[8,56,78,135] Diamond polishers started to institute the use of high-speed grinding disks coated with abrasive microdiamonds embedded a matrix of cobalt powder.[79] Several case reports illustrate that cobalt-exposed diamond polishers develop similar clinical[79] and pathologic findings to hard metal disease, strengthening the link to cobalt.[20,26,99] Some authors still contend that the presence of other metals[8,56,78,135] and diamond dust[26,49,99] are confounding factors.[139] Similar to hard metal disease, most reported cases show resolution of symptoms upon removal from the exposure,[26] although this is not always sufficient.[99]

There are very few reports of isolated cobalt exposures. In an age- and gender-matched study of 82 workers with respiratory exposures to cobalt oxides, cobalt salts, cobalt metal, and no other metal, researchers were unable to detect a difference between exposed (mean, 8 years; TWA, 125 µg/m³, 25% >500 µg/m³) and unexposed workers with any objective measured pulmonary tests.[139] Neither group had any abnormality in chest radiography that would suggest pulmonary fibrosis.[139] The only significant pulmonary differences detected were a higher reported rate of dyspnea both on exertion and at rest and the presence of wheezing in the exposed group.[139] These authors concluded that cobalt contributes to the development of pulmonary disease but is not independently responsible for the development of pulmonary fibrosis.[139]

Despite the progressive and debilitating nature of hard metal disease, most signs and symptoms improve with cessation of exposure.[86,90,147] Moreover, the length and dose of exposure do not appear to correlate with the presence or severity of illness, suggesting that individual susceptibility is the most important risk factor for illness.[86,119]

Renal A single report associates reversible renal tubular necrosis with the chronic administration of $CoCl_2$ as treatment for anemia.[123] Some animal models of cobalt cardiomyopathy demonstrate cellular changes in renal tissue.[51] However, when 26 exposed hard metal workers were evaluated for urinary albumin, retinol binding protein (RBP), β_2-microglobulin, and tubular brush border antigens, no detectable difference could be found between the study group and control subjects.[45] Based on these few reports, it appears that acute and chronic exposure to cobalt has little effect on the kidneys.

Dermatologic In a study of 1782 construction workers, 23.6% developed dermatitis and 11.2% developed oil acne while using cobalt containing cement, fly ash, or asbestos.[71] As in hard metal disease, it is difficult to isolate cobalt as the sole contributor to the development of dermatitis. Nickel, the classic toxicant causing dermatitis, is commonly found in some of these preparations and may be implicated in the development of cutaneous sensitivity.[42,118]

Reproductive A pregnant woman with hard metal disease was able to bring the fetus to term and deliver without complications.[111] In pregnant rats, $CoCl_2$ exposure neither results in teratogenicity nor fetotoxicity.[104] Only doses that are toxic to the mother result in fetal toxicity.[34]

In mice, chronic exposure to cobalt results in impaired spermatogenesis and decreased fertility without affecting follicle-stimulating hormone (FSH) or luteinizing hormone (LH), but acute exposures did not demonstrate similar reproductive effects.[105] Additional murine studies discuss the possible interactions between cobalt with iron and zinc, which are both essential elements for spermatogenesis.[4] Despite these findings, there have been no reported human cases that associate cobalt exposure with teratogenicity or impaired fertility.

Carcinogenesis Based solely on animal experiments leading to the development of soft tissue sarcomas after the injection of $CoCl_2$ into soft tissue resulting in soft tissue sarcomas, the International Agency for Research on Cancer (IARC) considers cobalt and cobalt-containing compounds possibly carcinogenic to humans (group 2B).[14,24,36,136] There have been case reports and cohort studies suggesting that pulmonary exposure to Co^{2+} increases the risk for lung cancer. However, these studies were unable to control for other known carcinogens such as arsenic.[24] In the largest cohort study to date, which followed more than 1100 workers for more than 38 years, there was no increase in the prevalence of lung cancer.[95]

DIAGNOSTIC TESTING

Body fluid cobalt concentrations are not readily available and therefore cannot be used to direct emergent clinical care. Some adjunctive testing that may support a clinical diagnosis of cobalt toxicity should include complete blood count (CBC); reticulocyte count; erythropoietin (EPO) concentration; and T_3, T_4, and thyroid-stimulating hormone (TSH) concentrations. The results of these tests may reflect the level of exposure or potential toxicity discussed above.

■ CARDIAC STUDIES

ECG, echocardiography, and radionuclide angiocardiography with $^{99}Tc(RNA)$ are useful screening tests for detecting abnormalities associated with cobalt cardiomyopathy or pulmonary hypertension caused by hard metal disease.[21] It is important to remember that these cardiac tests are neither specific for nor diagnostic of cobalt-induced cardiomyopathy. Biopsy of myocardial tissue may show multinucleated giant cells, but testing of this nature is impractical.

■ PULMONARY TESTING

Patients with hard metal lung disease may demonstrate bilateral upper lobe interstitial lung disease on chest radiography. However, patients may have signs and symptoms of disease without specific radiographic findings.[111] Pulmonary function testing in occupationally exposed workers may show decreased vital capacity[111] and a decrease in diffusion capacity of lung for carbon monoxide (DLCO), both of which may be useful in identifying patients at risk for developing pulmonary fibrosis.[137] Some authors suggest an inversion of CD4/CD8 ratio in BAL washings as a useful tool for diagnosis and evaluation of progression of illness and that normalization is a marker for improvement.[112] Despite these available tests, a definitive diagnosis of hard metal disease requires a tissue sample with findings of multinucleated giant cells in the setting of interstitial pulmonary fibrosis.

■ COBALT TESTING

Cobalt is primarily eliminated in the urine and to a lesser extent in the feces, making urine cobalt evaluation most appropriate.[82] The difficulty lies in the interpretation of the result. Cobalt is detectable in the urine after inhalational exposure and reflects elimination kinetics that are rapid during an initial exposure but that slow after prolonged exposure.[82,122] Because of this variable elimination pattern, it is difficult to interpret both urine and blood concentrations unless the dose and length of exposure are precisely known. Furthermore, the defined patterns may be applicable only to shift workers using soluble forms of cobalt.[82]

Further complicating the interpretation of urinary cobalt concentrations is the abundance of organic cobalt in the form of vitamin B_{12}. A detailed vitamin supplementation history is required before the interpretation of a urine or blood cobalt concentration because a diet regimen high in vitamin B_{12} may increase urine cobalt concentrations. For this reason, speciation of cobalt has been investigated. The ratio of inorganic to organic cobalt is higher in occupationally exposed workers (2.3) compared with control subjects (1.01) independent of the wide variations of urinary cobalt concentrations.[47] This is a promising area of study for the evaluation of a cobalt-exposed worker.

Toxic concentrations of cobalt in serum and urine are poorly defined. Published literature on "normal levels" is fraught with variability, which may reflect differences in the population under study techniques for measurement. Normal serum concentrations of cobalt are frequently reported as 0.1 to 1.2 µg/L.[2,12,58,59,62,127] In comparison, a single acutely poisoned patient had a reported serum concentration of 41 µg/L.[58] Normal reference urine cobalt concentrations are between 0.1-2.2 µg/L.[2,12,58,59,62,103,127] In contrast, an acute elemental cobalt ingestion resulted in a concentration of 1700 µg/L on a spot urinalysis several days after the exposure.[59]

Patients with chronic exposures should be evaluated differently, as discussed above (see Toxicokinetics). Exposed workers without clinical disease have reported spot urine concentrations that range from 10 µg/L to several hundred µg/L.[61]

TREATMENT

■ ACUTE MANAGEMENT

Patients with acute cobalt poisoning require aggressive therapy. It is reasonable to conclude that the same decontamination principles used for other metals apply to cobalt. There have been no studies to date examining the benefits of gastric emptying, activated charcoal, or whole-bowel irrigation (WBI). An attempt at using WBI for radiopaque solid forms of cobalt should be made before endoscopic or surgical removal. Regardless of the decontamination procedure used, chelation therapy should not be initiated until the GI cobalt source has been removed. If there is a large stomach burden in a solid, endoscopic or surgical removal may be of benefit,[59] keeping in mind that the administration of activated charcoal before surgical removal may obscure visualization of the surgical field (see Antidote in Depth A2: Activated Charcoal). After decontamination, reduction of tissue burden and prevention of end-organ toxicity is the next crucial step.

Unfortunately, the data on chelation therapy are limited to animal models[28–34,83–85] and a single human case report.[59] The basis of chelation therapy originates from the mid 1900s when oral protein intake was found to result in a reduction of cobalt toxicity in calves[37] and rats.[52] Certain sulfur-containing proteins serve as good chelators for some metals.

In a series of animal models of acute cobalt toxicity, several treatments—N-acetylcysteine (NAC), succimer, ethylenediaminetetraacetic acid

(EDTA), glutathione, and diethylenetriaminepentaacetic acid (DTPA)—were evaluated for their ability to enhance urinary and fecal elimination of cobalt.[84] Succimer and EDTA were able to enhance fecal elimination.[84] Glutathione and DTPA were able to enhance urinary elimination, and NAC was able to enhance elimination by both routes.[84]

In two separate animal studies, NAC reduced the tissue burden and injury caused by cobalt in the liver and spleen.[33,84] Glutathione, another sulfur-containing protein, also reduced tissue levels of cobalt but only in the spleen.[84]

The sulfur-containing proteins NAC,[29,33] L-cysteine,[29,29] L-methionine,[29] and L-histidine[31] were studied for their ability to reduce mortality in rats that were administered an LD_{50} of $CoCl_2$ orally and intraperitoneally. NAC, L-cysteine, and L-histidine[31] therapy are more effective than L-methionine in protecting against mortality, upwards of 100%. In a similar fashion, Na_2EDTA was effective in reducing mortality.[32] In all of these therapies, the successful reduction in mortality is predicated on its early administration.[28,29,31–33]

In a murine model, L-cysteine, NAC, glutathione, L-histidine, sodium salicylate, D,L-penicillamine, succimer, N-acetylpenicillamine (NAPA), diethyldithiocarbamate (DDC), BAL, 4,5-dihydroxy-1,3-benzene disulfonic acid, $Na_3CaDTPA$, $Na_2CaEDTA$, and deferoxamine mesylate were each evaluated for exposures to an LD_{50} and an LD_{99} of $CoCl_2$.[85] Agents that were ineffective at improving survival after an LD_{50} were sodium salicylate, NAPA, DOC, BAL, 4,5-dihydroxy-1,3-benzene disulfonic acid, and deferoxamine mesylate.[85] Chelators that were seemingly effective at LD_{50} and not at LD_{99} were L-histidine and D,L penicillamine.[83] NAC, L-cysteine, and succimer were able to improve survival by 40% to 50%.[85] The most effective chelators at LD_{99} were EDTA and DTPA.[83,85] An expanded analysis of these data revealed that EDTA and DTPA had a better therapeutic index compared with succimer.[85] In this study, BAL was ineffective as is suggested in an in vitro study in which BAL was unable to chelate Co^{2+} that is already bound to α-ketoglutarate.[143]

Human chelation data are available from a single pediatric case report involving the ingestion of multiple elemental cobalt–containing magnets yielding a serum cobalt concentration of 4.1 µg/dL.[59] Five days of 50 mg/kg/day of intravenous (IV) $CaNa_2EDTA$ enhanced renal elimination of cobalt, and the metabolic acidosis and the cardiac dysfunction also resolved simultaneously.[59]

In conclusion, based on a single human case report, several animal studies and safety profiles, $CaNa_2EDTA$ and NAC can be used as antidotal therapy. Indications for treatment should include patients who demonstrate end-organ manifestations of toxicity, including metabolic acidosis and cardiac failure. Patients with other manifestations of severe cobalt toxicity such as pericardial effusion, clinically significant goiter, and hyperviscosity syndrome should be treated aggressively with pericardiocentesis, airway protection, and phlebotomy, respectively. Based on years of experience with lead, $CaNa_2EDTA$ should be administered as doses of 1000 mg/m²/day by continuous infusion for 5 days. If the diagnosis is confirmed and signs of cardiac failure and metabolic acidosis persist after 5 days, an alternate chelator (ie, succimer or DTPA) can be started. Similarly, NAC dosing should be based on the acetaminophen experience. The 20-hour IV NAC protocol should be initiated and continued as in the case of fulminant hepatic failure (see Antidotes in Depth A4: N-acetylcysteine) for as long as the patient can tolerate therapy or continued if cardiac failure or acidemia persist.

If there are contraindications to IV NAC, oral NAC can be administered using one of the acetaminophen treatment regimens. Thiamine hydrochloride should be administered to all patients presenting with or without overt cardiomyopathy independent of whether the patient is alcoholic or malnourished. The dose of thiamine is not well defined but should be based on its safety and clinical experience with the

treatment of Wernicke's encephalopathy. The daily administration of 100 mg of parenteral thiamine can be initiated with increasing doses to 100 mg every hour for life-threatening manifestations (ie, cardiac failure and metabolic acidosis) (see Antidotes in Depth A25: Thiamine Hydrochloride).

■ OCCUPATIONAL AND CHRONIC EXPOSURE

As is the case for occupational poisonings, prevention is of paramount importance. The use of skin protection and improvement of personal hygiene has reduced exposure and subsequently the amount of urinary cobalt in occupationally exposed workers.[81] Barrier and emollient creams cannot prevent the dermatitis associated with cobalt metal exposures.[43]

Large, statistically significant reductions in urinary cobalt were demonstrated after the implementation of aspirator systems over machines in the production of Widia steel.[17] These aspirators were found to reduce ambient cobalt concentrations by as much as a factor of six.[39]

SUMMARY

Acute cobalt toxicity results in multiorgan system toxicity, including the cardiac, endocrine, hematopoietic, GI, and neurologic systems. In contrast, chronic toxicity, dependent primarily on the route of exposure, mainly involves the pulmonary and dermal areas. The evaluation of the patient is determined by the cobalt source and type (ie, elemental, inorganic, or organic), route of poisoning, and time and duration of exposure. Cobalt measurements in blood and urine are possible, but toxic concentrations are poorly defined. Treatment of patients with chronic exposures is mainly symptomatic and often improved industrial hygiene is the most critical step. Acute poisoning with end-organ manifestations may require aggressive GI decontamination and chelation therapy using $CaNa_2EDTA$ and NAC and at times succimer.

CHAPTER 93
COPPER

Lewis S. Nelson

Copper (Cu)

Atomic number	=	29
Atomic weight	=	63.5 daltons
Normal concentrations		
Whole blood	=	70–140 µg/dL (11–22 µmol/L)
Total serum	=	120–145 µg/dL (18.8–22.8 µmol/L)
Free serum	=	4–7 µg/dL (0.63–1.1 µmol/L)
Ceruloplasmin	=	25–50 µg/dL (3.9–7.8 µmol/L)
Urine	=	5–25 µg/24 h (.078–3.9 nmol/L)

Copper is a widely available metal that is associated with both acute and chronic poisoning. Although essential to life, acute overdose with copper salts produces severe gastrointestinal (GI) and systemic effects that may be life threatening. This clinical syndrome and the underlying mechanism is similar to that noted with iron poisoning. Regardless of the means of exposure, patients with acute copper poisoning require expeditious identification and empiric therapy.

HISTORY AND EPIDEMIOLOGY

Copper is available naturally, either as native copper (elemental copper) or as one of its sulfide or oxide ores. Important ores include malachite ($CuCO_3\cdot(OH)_2$), chalcocite (Cu_2S), cuprite (Cu_2O), and chalcopyrite ($CuFeS_2$ or $Cu_2S\cdot Fe_2S_3$). Chalcopyrite, a yellow sulfide ore, is the source of 80% of the world's copper production. The smelting, or separation, of copper ores began about 7000 years ago; copper gradually assumed its current level of importance at the start of the Bronze Age, around 3000 B.C. Smelting begins with roasting to dry the ore concentrate, which, in more modern times, is further purified by electrolysis to a 99.5% level of purity. The sulfide ores have a naturally high arsenic content, which is released during the extraction process, posing a risk to those who perform copper smelting.

Although acute copper poisoning is uncommon in the United States, the historical role of copper as a therapeutic agent remains noteworthy. Copper sulfate was used in burn wound debridement until cases of systemic copper poisoning were reported.[63] Interestingly, in one report, each wound debridement procedure was associated with an 8% to 10% decrease in the hematocrit. In the 1960s, copper sulfate (250-mg dose containing 100 mg copper ion) ironically was recommended as an emetic agent, typically for use in children after potentially toxic exposures.[70] It was recognized for its rapidity of onset and effectiveness, and it compared favorably with syrup of ipecac. However, copper-induced emesis was rapidly identified to be a highly dangerous practice, and this use was generally discontinued,[64,78,118] although fatal cases from this use still occur.[78] Copper salts are administered in religious rituals as a green-colored "spiritual water" containing 100 to 150 g/L of copper sulfate as an emetic to "expel one's sins."[7,117]

A growing body of knowledge links copper to the promotion of both physiologic and malignant angiogenesis.[59] In this latter case, copper may enable tumor expansion, invasion, and metastasis. Additionally,

copper binding to amyloid fibers in the brain of patients with Alzheimer's disease may lead to local oxidative damage and cause the characteristic neurodegeneration.[25,39] Copper is also similarly implicated in the pathogenesis of both Parkinson's disease and autism.[28,131]

Acute or chronic copper poisoning may occur when the metal is leached from copper pipes or copper containers. This occurs frequently when carbon dioxide gas, used for postmix soft drink carbonation, backflows into the tubing transporting water to the soda dispensers, creating an acidic solution of carbonic acid that leaches copper from the equipment pipes.[127] Similarly, storage of acidic potable substances, such as orange or lemon juice, in copper vessels may cause copper poisoning. A particularly dangerous situation occurs when acidic water is inadvertently used for hemodialysis.[40,82] In this circumstance, the leached copper avoids the normal GI barrier and is delivered parenterally to the patient's circulation. In one reported series, the copper concentration in the dialysis water was 650 µg/L, causing several poisonings and the death of a patient with a whole-blood copper concentration of 2095 µg/L.[406] Similarly, stagnant water or hot water,[107] even if not highly acidic,[111] can accumulate copper ions from pipes and cause poisoning.[9,41]

Although most natural water contains a small quantity of copper (4–10 µg/L), it is tightly bound to organic matter and therefore not orally bioavailable. Copper pipes typically add about 1 mg of copper to the daily intake of an adult. The Environmental Protection Agency guidelines permit up to 1.3 mg/L of copper in drinking water,[34] although in some areas, intermittent concentrations may rise as high as 60 mg/L. Copper in water may be tasted at concentrations of 1 to 5 mg/L, and a blue-green discoloration is imparted when the concentrations are greater than 5 mg/L.[37] Acute GI symptoms occur when drinking water contains more than 25 mg/L,[65] although concentrations as low as 3 mg/L are associated with abdominal pain and vomiting in many, without an increase in the serum copper concentration.[100] In one blinded, randomized study comparing copper-adulterated water with pure water, women appeared more sensitive than men to copper, but both groups were symptomatic when the copper concentration in the water was 6 mg/L.[8]

Metallic copper is ideal for electrical wiring because it is highly malleable and can be drawn into fine wire. Its electrical conductivity is only exceeded by silver. Similarly, its excellent heat conductivity accounts for its widespread use in cookware. Although the metal is reactive with air, it forms a resistant layer of insoluble copper carbonate on its surface. It is this water- and air-resistant compound that accounts for the green coloration of ornamental roofing and statues. Because copper is a soft metal, it must be strengthened before use in structural applications or as a coinage metal. This is most commonly done by the creation of copper alloys. Brass is an alloy of copper compounded with as much as 35% zinc. Similarly, bronze contains copper combined with up to 14% tin. Gun metal is an alloy that contains 88% copper, 10% tin, and 2% zinc. Sterling silver and white gold also contain copper.

CHEMICAL PRINCIPLES

Metallic copper (Cu^0), although not in itself poisonous, may react in acidic environments to release copper ions. The metallic copper contraceptive intrauterine device (IUD) derives its efficacy from the local release of copper ions.[15] Metallic copper bracelets worn by patients with rheumatoid arthritis and other ailments purportedly derive their far-reaching antiinflammatory effect through dermal copper ion absorption and distribution to affected tissues.[125] Local copper ion release is responsible for the occasional case of dermatitis that occurs after skin exposure to copper metal.[64] Ingestion of large amounts of metallic copper—for example, as coins—may rarely produce acute copper

poisoning.[103,130] Poisoning under these circumstances is a result of the release of large amounts of copper ion from copper alloy by the acidic gastric contents. Also, inhalation of finely divided metallic copper dust or bronze powder, which is used in industry and for gilding, may produce life-threatening bronchopulmonary irritation, presumably as a consequence of the local release of ions.[38,56]

The majority of patients with acute copper poisoning have been exposed to ionic copper. In copper sulfate, also known as cupric sulfate, the copper atom is in the +2 oxidation state. Copper sulfate is used as a fungicide and algicide and to eradicate tree roots that invade septic, sewage, and drinking water systems.[101] Copper sulfate is the most readily available form and is the form involved in the majority of nonindustrial copper salt exposures. Copper sulfate was a favorite ingredient in many home chemistry sets because of its brilliant blue color when dissolved in water. Although serious poisoning, particularly in children,[126] led regulatory agencies in the United States to restrict its use, it still accounts for the most consequential chemistry set–related toxic exposures reported in other countries.[88] Similarly, homegrown copper sulfate crystals from kits are occasionally responsible for fatal poisonings.[53]

Cuprous salts, containing copper in the +1 oxidation state, are unstable in water and readily oxidize to the cupric form. There are numerous copper salts with varying oxidation states used in industry and agriculture (Table 93–1), many of which are not poisonous. Because those salts that are water soluble are more likely to be toxic, it is important to determine the nature of the copper product implicated in an exposure. Analogously, when examining the medical literature, it is critical to discern which form of copper is involved in the scientific experiment or case report before applying the results to clinical practice.

PHARMACOLOGY AND PHYSIOLOGY

Copper is an essential metal that our body stores in milligram amounts (100–150 mg). Daily requirements of copper are approximately 50 μg/kg in infants and 30 μg/kg in adults. The average daily intake of copper in the United States noted in the Third National Health and Nutrition Examination Survey (NHANES III) is about 1.2 mg.[43]

The daily requirement of copper is satisfied by nuts, fish, and green vegetables such as legumes, although our largest source is generally from drinking water. Copper deficiency is exceedingly rare even in the poorest communities and is most frequently caused by excessive zinc intake[91] or by a genetic aberration such as Menkes "kinky-hair" syndrome, in which intestinal copper uptake is impaired. Menkes syndrome is characterized by mental retardation, thermoregulatory dysfunction, hypopigmentation, connective tissue abnormalities, and pili torti (kinky hair). Interestingly, with the increased focus on the role of copper in neurodegenerative disorders and cancer, some authors suggest intentionally depleting patients of their copper stores with tetrathiomolybdate, an experimental copper chelator.[50]

Copper is absorbed by an active process involving a copper adenosine triphosphatase (CuATPase) in the small intestinal mucosal cell membrane, also known as the Menkes ATPase (see below). The GI absorption varies with the copper intake and the food source[60] and is as low as 12% in patients with high copper intake. In the presence of damaged mucosa, such as after acute overdose, the fractional absorption is likely to be significantly higher.[79] After it has been absorbed, copper is rapidly bound to high-affinity carriers such as ceruloplasmin and low-affinity carriers such as albumin for transport to the liver and other tissues. The amount of unbound copper in the blood under

TABLE 93–1. Important Copper Products

Chemical Name	Chemical Structure	Common Name	Notes
Chalcopyrite	$CuFeS_2$	Copper iron sulfide	Copper ore; source of 80% of world's copper
Chromated cupric arsenate	35% CuO 20% CrO_3 45% As_2O_5	CCA	Wood preservative[a]
Copper octanoate	$Cu[CH_3(CH_2)_6COO]_2$	Copper soap	Fungicide in home garden products, paint, rot-proof rope and roofing
Copper triethanolamine complex	$Cu\ ((HOCH_2CH_2)_3N)_2$	Chelated copper	Algicide
Cupric acetoarsenite	$Cu(C_2H_3O_2)_2 \cdot 3Cu(AsO_2)_2$	Paris or Vienna green	Insecticide, wood preservative, pigment[a]
Cupric arsenite	$CuHAsO_3$	Swedish or Scheele's green	Wood preservative, insecticide[a]
Cupric hydroxide	$Cu(OH)_2$	Copper hydroxide	Fungicide
Cupric chloride	$CuCl_2$		Catalyst in petrochemical industry
Cupric chloride, basic	$CuCl_2 \cdot 3Cu(OH)_2$	Basic copper chloride; copper oxychloride	Fungicide
Cupric oxide	CuO	Black copper oxide; tenorite	Glass pigment, flux, polishing agent
Cupric sulfate	$CuSO_4$	Roman vitriol, blue vitriol, bluestone, hydrocyanite	Fungicide, plant growth regulator, whitewash, homegrown crystals
Cupric sulfate, basic	$CuSO_4 \cdot 3Cu(OH)_2 \cdot 3CaSO_4$	Bordeaux solution	Fungicide
Cuprous cyanide	$CuCN$	Cupricin	Electroplating solutions
Cuprous oxide	Cu_2O	Red copper oxide, cuprite	Antifouling paint

[a]No longer used in the United States.

normal circumstances is well below 1%. After being released locally in the reduced form from its carrier, copper uptake by the hepatic cells occurs via a specific uptake pump.[104] This process, which is facilitated by the reducing agent ascorbic acid, provides a potential window, however brief, for detoxification of the ion by chelating agents. In acute overdose, a high fraction of the plasma copper remains bound to low-affinity proteins, such as albumin, and thus is biologically active.

In the hepatocyte, complex trafficking systems exist (involving ceruloplasmin, metallothionein, and other metallochaperones within the cytoplasm) to prevent copper toxicity and to aid delivery to the appropriate enzymes.[45,102] A distinct Cu-ATPase located on certain subcellular organelles such as the *trans*-Golgi network or pericanalicular lysosomes assists in the appropriate localization and elimination, respectively, of the metal.[26] By this mechanism, copper is either incorporated into enzymes or released, as a metallothionein–copper complex, directly into the biliary system for fecal elimination.

Some copper released from the liver is bound primarily to ceruloplasmin, an α_2-sialoglycoprotein with a molecular weight of 132,000 Daltons. Ceruloplasmin-bound copper accounts for approximately 90% to 95% of serum copper. Ceruloplasmin is a multifunctional protein that binds six atoms of copper per molecule. Copper bound to this carrier has a plasma half-life of approximately 24 hours. Ceruloplasmin is also involved in the mobilization of iron from its storage sites, and it serves an analogous role as a ferroxidase during the ferrous–ferric conversion. Cu^+ is oxidized directly by ceruloplasmin, thereby avoiding the generation of reactive oxygen species.

There are several important copper-containing enzymes in humans (Table 93–2). The common link among these enzymes is their participation in redox (reduction–oxidation) reactions in which a molecule, typically oxygen, donates or shares its electrons with another compound. In this respect, the physiology, chemistry, and toxicology of copper are most similar to those of iron. In fact, "blue-blooded" animals, such as octopi and spiders, use copper in hemocyanin, a blue pigment, in an analogous manner that "red-blooded" animals use iron in hemoglobin.

The volume of distribution of copper is 2 L/kg, and the half-life of erythrocyte copper is 26 days. The elimination of copper occurs predominantly through biliary excretion after complexation with ceruloplasmin. Biliary excretion approximates GI absorption and averages 2000 µg/24 h.[5,102,123] Renal elimination under normal conditions is trivial, accounting for approximately 5 to 25 µg/24 h.[5]

TABLE 93–2. Important Copper-Containing Enzymes and Proteins and Their Functions

Enzyme or Protein	Function
Alcohol dehydrogenase	Metabolism of alcohols
Catalase	Detoxifies peroxide
Ceruloplasmin enzymes	Copper transport, ferroxidase
Cytochrome C oxidase	Electron transport chain
Dopamine β-hydroxylase	Converts dopamine to norepinephrine
Factor V	Coagulation cascade
Lysyl oxidase	Cross-links collagen and elastin
Monoamine oxidase	Deamination of primary amines
Superoxide dismutase	Detoxifies free radicals
Tyrosinase	Melanin production

TOXICOLOGY AND PATHOPHYSIOLOGY

■ REDOX CHEMISTRY

Because copper is a transition metal, it is capable of assuming one of several different oxidation (or valence) states, and it is an active participant in redox reactions. In particular, participation in the Fenton reaction and Haber-Weiss cycle explains the toxicologic effects of copper as a generator of oxidative stress and inhibitor of several key metabolic enzymes (see Fig. 11-2).[42,47] In the presence of sulfhydryl-rich cell membranes, such as those on erythrocytes, cupric ions are reduced to cuprous ions, which are capable of generating superoxide radicals in the presence of oxygen.[74] This one-electron reduction of oxygen regenerates the cupric ion, allowing redox cycling and continuous generation of reactive oxygen species (Fig. 93–1). In particular, the mitochondrial electron transport chain and lipid membranes serve as ready sources of electrons for copper reduction, establishing a chain of events that ultimately leads to mitochondrial or membrane dysfunction, respectively.[90]

■ ERYTHROCYTES

Cupric ion inhibits sulfhydryl groups on enzymes in important antioxidant systems, including glucose-6-phosphate dehydrogenase and glutathione (GSH) reductase.[108] However, although support for these effects is only indirect, intraerythrocyte concentrations of reduced GSH decrease demonstrably after copper exposure.[86] This effect is presumably part of the protective role that GSH, a nucleophile or reducing agent, normally has on oxidants, such as either cupric ions or the reactive oxygen species they generate.[84,85] Thus, in the setting of copper poisoning, in which excessive quantities of oxidants are produced, the depletion of GSH presumably augments peroxidative membrane damage.

The importance of hemoglobin-derived reactive oxygen species is demonstrated by the lack of hemolysis in the presence of copper under anaerobic conditions or in an environment saturated with carbon monoxide.[12] The in vitro hemolytic activity of copper sulfate is reduced by albumin and several sulfhydryl-containing compounds, including

$$GSH \quad GSSG$$

$$Cu^+ + H_2O_2 + O_2^{\bullet-} \longrightarrow Cu^{2+} + O_2 + OH^- + OH^\bullet$$
$$\text{Haber-Weiss reaction}$$
FIGURE 93–1. Copper in the cupric or Cu^{2+} state is reduced by sulfhydryl containing compounds such as glutathione (GSH) or dimercaptopropane sulfonate (DMPS) to its cuprous form (Cu^+), forming disulfide links in the process. Oxidized glutathione (GSSG) is subsequently enzymatically reduced by glutathione reductase to regenerate GSH. Superoxide anions, formed when molecular oxygen (O_2) acquires an additional electron, are continually generated by mitochondria. Both the Fenton and the Haber-Weiss reactions use the cuprous form of copper as a catalyst to convert hydrogen peroxide or superoxide radical into the more biologically consequential hydroxyl radical ($OH^\bullet$).[14,73]

D-penicillamine and succimer.[3] Interestingly, dimercaptopropane sulfonate (DMPS), another sulfhydryl-containing compound often used as a chelator, exacerbates copper-induced hemolysis. This paradoxic effect is variably attributed to concomitant inhibition of superoxide dismutase, an important antioxidant enzyme, or to the ability of DMPS to efficiently reduce either membrane dithiols or cupric ions, in either case increasing the generation of superoxide.[2]

Hemolysis frequently occurs within the first 24 hours after with acute copper poisoning.[32,117,129] This rapidity of hemolysis differs markedly from most other oxidant stressors, which may take several days, and is likely a result of the differing nature of the erythrocyte insult. That is, the hemolysis that occurs after most oxidant exposures is caused by precipitation of hemoglobin as Heinz bodies and subsequent erythrocyte destruction by the reticuloendothelial system. Hemoglobin precipitation may also occur in the setting of acute copper poisoning, particularly after less substantial exposure. Additionally, and accounting for the early hemolysis, copper also directly oxidizes the erythrocyte membrane, thereby initiating red cell lysis independently of the reticuloendothelial system.[4,106] Oxidant-induced disulfide cross-links in the erythrocyte membrane reduce its stability and flexibility, thereby predisposing to early cell rupture.[4]

Copper-induced oxidation of the heme iron within the erythrocyte produces methemoglobinemia.[89] Given the high incidence of hemolysis, the methemoglobin is commonly released within the plasma. In this situation, methylene blue may not reliably reduce the ferric iron.

LIVER

Although most of the accumulated copper in hepatocytes is rapidly complexed with metallothionein or otherwise used, failure to completely sequester copper ions allows their participation in redox reactions. Hepatic cells are protected from copper toxicity in vitro by induction of metallothionein with zinc or cadmium salts or by the infusion of metallothionein before exposure. These interventions demonstrate the toxicologic significance of free intracellular copper. These findings also explain the therapeutic use of zinc acetate in patients with Wilson disease because copper itself is not a good inducer of metallothionein in humans.

Copper ions also generate hydroxyl radicals, which are potent inducers of both lipid peroxidation, and other reactive oxygen species. The peroxidative effect on biologic membranes is more significant in animals deficient in vitamin E and is prevented by vitamin E replacement, presumably because of the role of vitamin E as a free radical scavenger.[69,116] These effects are most pronounced in mitochondria, perhaps as a consequence of the reduction of cupric to cuprous ion in these organelles.[52,115] Copper also accumulates in the cellular nuclei, where localized production of hydroxyl radicals may form DNA adducts and cause apoptosis.[105] Histologically, liver damage follows a centrilobular pattern of necrosis.

The sequelae of the potent hepatotoxic effects of copper are not isolated to the liver. After liver necrosis occurs, typically at liver copper concentrations greater than 50 mg/g dry weight, massive release of copper into the blood occurs, which may be of sufficient magnitude to cause hemolysis. This sequence of events is common during the crises of Wilson disease and may allow for an understanding of the delayed secondary episode of hemolysis that occurs in some copper-poisoned patients.

KIDNEYS

The kidneys bioaccumulate copper. Although primarily bound to metallothionein when available, copper is otherwise free to participate in oxidant-generating reactions in a manner analogous to that of iron.

Thus, reactive oxygen species are probably also responsible for the nephrotoxic effects of copper. Pathologic analyses of the kidneys of oliguric or anuric patients typically reveal acute tubular necrosis that may demonstrate hemoglobin casts. These findings suggests that renal failure may result indirectly from the hemoglobinuria induced by the massive release of free extracellular hemoglobin. The urinary hemoglobin, similar to myoglobin, may undergo conversion to ferriheme or release its iron, either of which results in oxidative stress on the renal tubular epithelial cell. Additionally, free extracellular hemoglobin may cause renal vasoconstriction through the local scavenging of nitric oxide within the renal arterioles.

CENTRAL NERVOUS SYSTEM

Although charged entities such as copper ions do not readily cross the blood–brain barrier, elevated cerebrospinal fluid copper concentrations are characteristic of chronic copper overload conditions such as Wilson disease.[119] This accumulation is accomplished through carrier-mediated transport of albumin-bound, not ceruloplasmin-bound, copper into the central nervous system.

CLINICAL MANIFESTATIONS

ACUTE COPPER SALT POISONING

The acutely lethal dose of ingested copper sulfate is suggested to be 0.15 to 0.3 g/kg, but this is unverified. GI irritation is the most common initial manifestation of copper salt poisoning. This syndrome includes the rapid onset of emesis and abdominal pain, possibly followed by gastroduodenal hemorrhage, ulceration, or perforation.[8,33] Blue coloration of the vomitus may occur after the ingestion of certain copper salts, particularly copper sulfate.[53,112,126] Blue vomitus is not, however, pathognomonic for copper poisoning and also occurs in patients who ingest boric acid, methylene blue, or food dyes. Other common symptoms include retrosternal chest pain and a metallic taste.

Given its location within the GI tract, the liver receives the initial and most substantial exposure to any ingested copper. In patients with more severe acute copper sulfate poisoning, hepatotoxicity is a frequent, although rarely an isolated,[66] manifestation. Jaundice, although among the most common clinical and biochemical findings after overdose, can be hepatocellular or hemolytic.[10]

Hemolysis is more common than hepatotoxicity and occurs invariably in patients with liver damage.[86,114] As noted, copper-induced hemolysis often occurs rapidly after exposure and may be severe (see Pathophysiology above and Chap. 24). In most reported cases, the discovery of significant methemoglobinemia occurs early in the patient's clinical course and is rapidly followed by hemolysis.[31] Because free methemoglobin is filterable, methemoglobinuria may occur, although it cannot be differentiated from other heme forms in the urine without specialized testing.

Renal and pulmonary toxicity occur occasionally and represent extraerythrocytic manifestations of the oxidative effects of the copper ions. Despite massive intravascular hemolysis, hemoglobinuric renal failure is uncommon in patients who receive adequate volume-replacement therapy.[32]

Hypotension and cardiovascular collapse occur in patients with the most severe poisoning and is likely multifactorial in origin.[112] Undoubtedly, intravascular volume depletion from vomiting and diarrhea is involved. However, the severity and poor patient outcome despite appropriate volume repletion suggests that the direct effects of copper on vascular and cardiac cells are also involved. Sepsis, as a result of transmucosal bacterial invasion, may also be partially responsible.[79]

Depressed mental status, which ranges from lethargy to coma or seizures after acute poisoning, is likely an epiphenomenon related to damage to other organ systems. These findings are particularly common in patients with hepatic failure and are comparable to those of hepatic encephalopathy from other causes. In patients with chronic copper poisoning, such as Wilson disease, neurologic manifestations are prominent and typically involve movement disorders (see Chronic Copper Poisoning below).

Intravenous injection of copper sulfate reportedly produces a clinical syndrome identical to that that occurs after ingestion, although the GI findings may be less pronounced.[14,18,94] Subcutaneous administration of a veterinary copper glycinate solution produced skin necrosis in the area of the injection.[11,95]

Although not strictly a form of copper poisoning, inhalation of copper oxide fumes, generated during welding or other industrial processes, may produce metal fume fever, a syndrome historically called "brass chills" or "foundry workers' ague." Patients with this syndrome present with cough, chills, chest pain, or fever that are most likely immunologic, not toxicologic, in origin (see Chap. 124). However, copper oxide formation, unlike zinc oxide, only occurs at extremely high temperatures, accounting for the relative infrequency of copper-induced metal fume fever.

■ CHRONIC COPPER POISONING

Although hepatolenticular degeneration, known as Wilson disease, is a condition of chronic copper overload, there are qualitative similarities to acute copper poisoning. Wilson disease is an inherited autosomal recessive disorder of copper metabolism affecting approximately one in 40,000 persons. The gene implicated in this disease (*ATP7B*) codes for a hepatocyte membrane–bound, copper-binding protein that is required for the maturation of ceruloplasmin and the biliary excretion of copper. Transgenic replacement models, in which human *ATP7B* is expressed in deficient animals, demonstrate normalization of copper excretion.[83] The absence of this gene and the resultant increase in hepatic copper concentrations produce continuing oxidative stress on the hepatocyte and cellular necrosis with the inevitable development of cirrhosis. Patients undergo periodic fluctuations in the extent of their copper-induced hepatotoxicity, and episodes of severe hepatotoxicity are frequently associated with hemolysis as stored copper is released from dying hepatocytes.

The adverse effects of copper on the lenticular nucleus in the basal ganglia cause movement disorders such as ataxia, tremor, parkinsonism, dysphagia, and dystonia.[92] No other form of copper poisoning is associated with substantial or direct neurotoxicity. Psychiatric manifestations, such as behavioral changes or mood disorders, may also occur.[21] Accumulation of copper within the cornea accounts for the characteristic green-brown Kayser-Fleischer rings. Although patients' serum copper concentrations are decreased, they typically have a reduced ceruloplasmin concentration caused by the failure of copper incorporation into ceruloplasmin and release from the liver and an elevated urinary copper concentration. Treatment involves lifelong therapy with D-penicillamine, trientine (triethylene tetramine), or molybdenum salts if the patient is D-penicillamine sensitive. Zinc acetate, which has been approved by the Food and Drug Administration (FDA) as a maintenance therapy, induces the formation of intestinal metallothionein and thereby blocks copper absorption by enhancing intestinal mucosal cell sequestration.[22] Orthotopic liver transplantation results in improvement in nearly all aspects of the disease, including the central nervous system and ocular manifestations.[48]

Chronic exogenous copper poisoning is uncommon in adults but is reported after the use of copper-containing dietary supplements.[93] However, subacute or chronic exposure is common in children in some parts of the world. This condition, commonly called *childhood cirrhosis* in India or *idiopathic copper toxicosis* elsewhere, generally occurs in the setting of excessive dietary intake of copper because of copper-contaminated water from brass vessels used to store milk. These children may have a genetic predisposition to copper accumulation because signs of chronic liver disease develop by several months of age and progress rapidly.[110,113] Both serum copper and ceruloplasmin concentrations are markedly elevated, which differentiates this disease from Wilson disease. The incidence of the disease has decreased dramatically, probably as a result of improved nutrition and replacement of copper utensils and storage containers with those made of steel. One family of four developed abdominal pain, malaise, tachycardia, and anemia after approximately 1 month of eating homegrown vegetables treated with copper oxychloride pesticide.[54] Each patient had anemia and a slightly elevated (or upper limit of normal) serum copper concentration.

"Vineyard sprayer's lung," first described in 1969, refers to the occupational pulmonary disease that occurred among Portuguese vineyard workers applying Bordeaux solution, a 1% to 2% copper sulfate solution neutralized with hydrated lime (Ca(OH)$_2$).[97] The patients developed interstitial pulmonary fibrosis and histiocytic granulomas containing copper. Many of these workers also developed pulmonary adenocarcinoma, hepatic angiosarcoma, and micronodular cirrhosis, raising the possibility of a carcinogenic effect of chronic copper exposure.[98] There is also a suggestion of an increased incidence of pulmonary adenocarcinoma among smelters, who are, however, exposed to many other xenobiotics, including arsenic, a known carcinogen.[80] Copper is not on the list of suspected carcinogens compiled by the International Agency of Research on Cancer (IARC).

Ophthalmic effects of copper salts, primarily after occupational exposure, include irritation of the corneal, conjunctival, or adnexal structures. Chronic ophthalmic exposure to particulate elemental copper or one of its alloys may result in chalcosis lentis, from the Greek word *chalkos*, or copper. This chronic exposure manifests as a green-brown discoloration of the lens or cornea, similar to Kayser-Fleischer rings.

DIAGNOSTIC TESTING

Real-time testing for copper is impractical, and almost all management decisions must be based on clinical criteria. Copper concentrations are often obtained for confirmatory or investigative purposes. Although never adequately studied, whole-blood copper concentrations may correlate better with clinical findings than do serum copper concentrations.[33] The rapid movement of copper from serum into the erythrocyte presumably explains this finding. However, although there is a statistical relationship between the whole-blood copper concentrations and the severity of poisoning,[33,124] there is little correlation between clinical findings at any given copper concentration, regardless of which biologic tissue is measured. Similarly, other than at extremely high or low concentrations, there is no defined concentration at which the prognosis may be established with certainty. Reported serum copper concentrations in patients with hemolysis range from 96 to 747 μg/dL, and those after severe poisoning have values of 6600[53] to 8267 μg/dL.[31] Serum copper concentrations in 11 patients with copper-induced acute renal failure ranged from 115 to 390 μg/dL.[30] The normal urinary copper excretion per 24 hours is up to approximately 25 μg and is reportedly as high as 628 μg/24 h in patients with copper poisoning.[44]

Occasionally, serum copper concentrations reveal a secondary increase, likely as a consequence of release during hepatocellular necrosis. This secondary rise typically occurs only in patients with life-threatening poisoning, and clinical evaluation is far more important and relevant than serial copper concentrations.[114]

Elevated copper concentrations are also noted in patients with inflammatory conditions, biliary cirrhosis, pregnancy, and estrogenic

oral contraceptive use.[24,62] These conditions are associated with an elevated ceruloplasmin level, and although the serum copper concentrations increase, the fraction of bound copper in the serum remains normal. Copper concentrations in the erythrocyte remain normal. Patients with Wilson disease have elevated hepatocyte copper content, but their serum copper concentrations are generally below normal unless hepatic necrosis is occurring.[81]

Although serum ceruloplasmin concentrations increase in patients with acute copper poisoning,[124] presumably reflecting increased hepatic synthesis, the ceruloplasmin concentration cannot be used to define the patient's prognosis. Tissue metallothionein concentrations may also increase after copper poisoning, but the implication of this finding, which is limited by the inability to rapidly obtain tissue samples, is unknown.[76] Ceruloplasmin concentrations are low in patients with Wilson disease, reflecting aberrant enzymatic activity.

Routine laboratory testing after acute copper salt poisoning should include an assessment for both hemolysis and hepatotoxicity. Differentiation of these causes as a cause for jaundice is made by standard methodology, such as comparison of the bilirubin fractions and an assessment of the hepatic enzymes and hemoglobin, that is, whereas indirect bilirubin is proportionally elevated in patients with hemolysis, the direct fraction increases in patients with hepatocellular necrosis. An assessment of the patient's electrolyte and hydration status is warranted. The prothrombin time may be prolonged in the absence of liver injury or disseminated intravascular coagulopathy and may be the result of a direct effect of free copper ions on the coagulation cascade.[89] In addition, many reports document abnormal glucose 6-phosphate dehydrogenase (G6PD) activity, suggesting for the cause of hemolysis. However, interpretation of this test result is difficult because copper poisoning interferes with the measurement of G6PD.

Although copper metal embedded in the skin is clearly visible, topically applied copper salts are not visualized.[16] The clinical usefulness of radiographs to identify ingested copper solutions has not been studied. Obtaining an abdominal radiograph, although probably of limited benefit, may be justified because it occasionally demonstrates the presence of radiopaque material in the GI tract.

MANAGEMENT

Supportive care is the cornerstone to the effective management of patients with acute copper poisoning, emphasizing antiemetic therapy, fluid and electrolyte correction, and normalization of vital signs before the consideration of chelation therapy. GI decontamination is of limited concern because the onset of emesis generally occurs within minutes of ingestion and is often protracted. In patients who present early after ingestion of a liquid copper solution and who have not yet vomited, aspiration with a nasogastric tube may remove copper ion. In one case, even after extensive vomiting, nasogastric aspiration still removed blue solution, but removing this remaining volume is unlikely to provide significant clinical benefit.[19] Although oral activated charcoal is unlikely to be harmful, it is of unproved benefit, and it may hinder the ability to perform GI endoscopy to evaluate the corrosive effects of a copper salt on the mucosal surface.[19] For this reason, even though activated charcoal may adsorb the remaining copper in the proximal GI tract, it is relatively contraindicated in most situations. Advanced therapy for patients with renal failure may include hemodialysis, and liver transplantation may be needed for patients with life-threatening hepatic failure.

■ CHELATION THERAPY

Chelation therapy should be initiated when hepatic or hematologic complications are present or there are other manifestations of severe

poisoning. Studies on the efficacy of chelation therapy after acute copper salt poisoning are limited. Even when administered early and appropriately, organ damage and death still occur. Application of the data from the existing literature is complex because of the lack of controlled therapeutic studies of human copper poisoning. Although experimental animal models and uncontrolled human data exist, the results are frequently contradictory. Three chelators are clinically available, and most data regarding dosing and efficacy data are derived either from their use in the treatment of patients with Wilson disease or from their effects on copper elimination during chelation of patients manifesting toxicity from other metals.

Most patients with copper poisoning are initially treated with intramuscular British anti-Lewisite (BAL).[120,126] Although BAL may be less effective, its use is appropriate in patients in whom vomiting or GI injury prevents oral D-penicillamine administration. Furthermore, because the BAL–copper complex primarily undergoes biliary elimination, whereas D-penicillamine undergoes renal elimination, BAL proves useful in patients with renal failure. When tolerated, D-penicillamine therapy should be started simultaneously or shortly after the initiation of therapy with BAL (see Antidotes in Depth A26: Dimercaprol).

Calcium disodium ethylenediaminetetraacetate (CaNa$_2$EDTA) reduces the oxidative damage induced by copper ions in experimental models.[128] However, it does not greatly enhance the elimination of copper when used for the chelation of other metals.[109,121] In addition, short-term use of CaNa$_2$EDTA inactivates dopamine β-hydroxylase in humans, presumably by chelating the copper moiety from its active site.[36] However, because the in vivo activity of this enzyme is restored on the addition of exogenous copper, the potential for inhibition of the formation of neuronal norepinephrine during the treatment of acute poisoning is unknown. Successful clinical use of CaNa$_2$EDTA has been reported.[46,94,120] Interestingly, CuCaEDTA is used as a copper supplement in animals, and overdose of this formulation results in copper poisoning, suggesting that its chelating ability is limited[49] (see Antidotes in Depth A28: Edetate Calcium Disodium).

D-Penicillamine (Cuprimine), a structurally distinct metabolite of penicillin, is an orally bioavailable monothiol chelator. It is used in the treatment of lead, mercury, and copper toxicity, as well as in the management of rheumatoid arthritis and scleroderma. It has also recently been investigated for its antiangiogenesis effects in cancer therapy, which occur by chelation of copper that serves as a cofactor for certain growth factors, such as fibroblast growth factor.[55] D-Penicillamine is effective in preventing copper-induced hemolysis in patients with Wilson disease. Its protective mechanism is primarily mediated through chelation of unbound copper ions, rendering them unable to participate in redox reactions.[72] The D-penicillamine–copper complex undergoes rapid renal clearance in patients with competent kidneys. The use of D-penicillamine is not formally studied in the patients with acute copper salt poisoning, but case studies and animal models suggest that copper elimination is enhanced.[20,51,63] The recommended dose is 1.0 to 1.5 g/d given orally in four divided doses. D-Penicillamine is also indicated for the treatment of chronic exogenous copper poisoning, such as Indian childhood cirrhosis. Initiation early in the course of disease and discontinuation of the exposure are associated with hepatic recovery and dramatically improved survival rates.[13]

Although D-penicillamine appears to be effective, it is associated with several significant complications. In nearly 50% of patients treated with D-penicillamine for Wilson disease, there is worsening of the neurologic findings.[23] Subacute toxicities of D-penicillamine include aplastic anemia, agranulocytosis, and renal and pulmonary disease. Long-term use of D-penicillamine is also associated with the development of cutaneous lesions and immunologic dysfunction. However, in the brief treatment necessary for acutely poisoned patients, the major

risk is the potential for hypersensitivity reactions that occur in 25% of patients who are allergic to penicillin. This hypersensitivity reaction is likely related to contamination of the pharmaceutical preparation with penicillin rather than immunologic cross-reactivity.[61,68] The use of D-penicillamine during pregnancy is associated with congenital abnormalities in fetuses, although all of the data are derived from women with Wilson disease who were receiving long-term therapy.[99]

Succimer is sometimes described as an ineffective copper chelator, although it is able to triple the baseline copper elimination in a murine model.[27] Given its ease of use, relative safety, and benefit in experimental models,[1] succimer may be used in lieu of D-penicillamine in patients with mild or moderate poisoning. Under these circumstances, the use of standard lead poisoning dosing regimens is warranted (see Chap. 93 and Antidote in Depth A27: Succimer [2,3-Dimercaptosuccinic Acid])

DMPS, an experimental chelator that is gaining popularity for the treatment of arsenic poisoning, prevents acute tubular necrosis in copper-poisoned mice.[87] DMPS also proved to be the most effective of a panel of chelators in a murine model of copper sulfate poisoning,[67] and it substantially increased urinary copper elimination in nonpoisoned individuals.[122] However, DMPS, unlike D-penicillamine, forms intramolecular disulfide bridges, which, in so doing, liberates an electron. This property, which accounts for its potency as a reducing agent, also probably explains its propensity to worsen copper-induced hemolysis in vitro.[2,3] Because an adequate analysis of risk versus benefit is unavailable, DMPS should not be used to chelate copper-poisoned patients at this time.

Trientine, an orally bioavailable xenobiotic, is the second-line chelator for patients with Wilson disease, but its use in patients with acute copper poisoning is unreported. This, too, is the case with zinc therapy to induce metallothionine synthesis, which is also of proven efficacy in Wilson disease but has an unknown role in the treatment of acute copper poisoning. The need for several weeks of zinc therapy before realizing full efficacy makes its therapeutic use in acutely poisoned patients questionable. Although large oral doses of zinc salts may limit the absorption of copper ion, the concomitant GI irritant effects of zinc ion make this therapy impractical.[58]

Tetrathiomolybdate, an FDA-recognized chelating agent with orphan drug status, although not marketed, may be available through compounding pharmacies, typically as ammonium tetrathiomolybdate. Tetrathiomolybdate is suggested to benefit copper-poisoned animals in uncontrolled studies,[96] but its use in acute copper poisoning in humans is unstudied. Tetrathiomolybdate depleted the copper stores in a patient with cancer who purchased the compound over the Internet as an "alternative" antiangiogenesis therapy.[77]

■ EXTRACORPOREAL ELIMINATION

There are limited data regarding the extent to which copper ion is eliminated by various extracorporeal means. Exchange transfusion is of undefined, but probably limited, benefit in acute copper sulfate poisoning.[31] Hemodialysis membranes undoubtedly allow copper ions to cross, based on the epidemics in which hemodialysis using copper-rich water inadvertently resulted in copper poisoning.[40] Although copper should be similarly cleared by hemodialysis, its relatively large volume of distribution limits the potential clinical usefulness of this technique. Furthermore, copper ions are highly protein bound, and the dialyzable concentration is typically less than 1 pmol/L, suggesting that hemodialysis would have little clinical usefulness. This fact is supported by case reports in which serum, tissue, or dialysate concentrations of copper are assessed.[6,94] Furthermore, given the propensity of hemodialysis to lyse erythrocytes, which may release stored copper and worsen toxicity, hemodialysis is not recommended.[57]

The molecular adsorbents recirculating system (MARS) and single-pass albumin dialysis (SPAD), which are modified forms of hemodialysis in which albumin is included in the dialysate, are reported to rapidly and substantially lower the serum copper concentrations in patients with fulminant Wilson disease, allowing a bridge to hepatic transplantation.[29,35] One patient was treated with albumin dialysis using a 44 g/L albumin-containing dialysate and a slow dialysate flow rate (1–2 L/h) in a manner similar to routine continuous venovenous hemodiafiltration reportedly removed 105 mg of copper and normalized the serum copper concentration.[17,73] The risk associated with hemolysis likely remains, and caution should be used when extrapolating therapy from Wilson disease to exogenous copper poisoning.

Plasma exchange enhanced the elimination of copper in patients with fulminant Wilson disease.[71,73] Copper removal ranged from 3 to 12 mg per treatment, but it is unclear if either of these removal techniques would be beneficial after an ingestion of gram quantities of copper sulfate. The same warning as above about inadvertent red cell lysis applies.

Peritoneal dialysis is not useful in patients with fulminant Wilson disease.[75] Peritoneal dialysis removed less than 700 μg in a copper sulfate-poisoned child whose copper concentration was 207 μg/dL.[57] However, in the same patient, the addition of albumin to the dialysate removed 9 mg of copper at a time when the child's serum copper concentration had already decreased substantially.

Management of hepatic toxicity requires little more than standard supportive care. The potential benefit of N-acetylcysteine has not been studied, although it is useful in many forms of fulminant hepatic failure. Liver transplantation should be considered, but specific criteria for transfer to a specialized liver unit or for transplant, other than those that are applicable for Wilson disease or other more common, noncopper etiologies, are undefined.

There are no controlled data on the treatment of acute copper poisoning in pregnancy. The available data on pregnant women with Wilson disease document that D-penicillamine is teratogenic and that zinc may be the preferred therapy.

SUMMARY

Acute copper poisoning is rare in the United States but is associated with dramatic toxicologic effects, primarily hemolysis and hepatotoxicity. The effects are primarily mediated by oxidative stress on the erythrocyte and hepatocyte, and this similarity to iron salt poisoning adds a framework for the conceptual understanding of the disease. The infrequency of acute copper poisoning severely limits our ability to perform controlled studies on its management. Chelation is most commonly performed with BAL and D-penicillamine. Succimer is more familiar to most clinicians and has fewer associated adverse effects and may therefore be an acceptable alternative. Extracorporeal elimination is unlikely to be of benefit. Fortunately, exhaustive research into diseases of copper metabolism, particularly Wilson disease, which has periodic exacerbations similar to acute copper poisoning, has provided insight into managing patients with acute copper salt poisoning.

CHAPTER 94
LEAD

Fred M. Henretig

Lead (Pb)

Atomic number	=	82
Atomic weight	=	207 daltons
Normal concentration		
Whole blood	<	10 µg/dL (<0.48 mmol/L)

Lead is a ubiquitous element in the earth's crust that has long been used by humans for a variety of purposes. Lead poisoning, or plumbism, has an equally long history, dating back to antiquity. Today, lead poisoning is primarily an important environmental health problem for young children exposed to deteriorated lead paint and an occupational illness of adults exposed via the workplace. There is no known physiologic role for lead, and thus any lead presence in human tissue represents toxic contamination.

PHYSICAL PROPERTIES

Lead is a silvery-gray, soft metal, with an atomic weight of 207.21 daltons and an atomic number of 82 Daltons. It has a low melting point, 621.3°F (327.4°C), and boils at 2948°F (1620°C) at atmospheric pressure.[159] It occurs principally as two isotopes, [206]Pb and [208]Pb. Metallic lead is relatively insoluble in water and dilute acids, but dissolves in nitric, acetic, and hot, concentrated sulfuric acids. In compounds, lead assumes valence states of +2 and +4. Inorganic lead compounds may be brightly colored and vary widely in water solubility; several are used extensively as pigments in paints such as lead chromate (yellow) and lead oxide (red). Lead also forms organic compounds, of which two, tetramethyl and tetraethyl lead (TEL), were used commercially as gasoline additives.[74] These are essentially insoluble in water but readily soluble in organic solvents.[135] Lead complexes with ligands containing sulfur, oxygen, or nitrogen as electron donors. It thus forms stable complexes with several ligands common to biologic molecules, including $-OH$, $-SH$, and $-NH_2$. Complexes with sulfhydryl ($-SH$) groups are thought to be of most toxicologic importance.

HISTORY AND EPIDEMIOLOGY

■ INDUSTRIAL APPLICATIONS

Lead's low melting point and high malleability made it one of the first metals smelted and used by humans. Ancient Egyptians and Hebrews used lead, and the Phoenicians established lead mines in Spain circa 2000 B.C. The Greeks and Romans released lead during the process of extracting silver from ore. Roman society found many uses for lead, including pipes, cooking utensils, and ceramic glazes, and a common practice was to use sapa, a grape syrup simmered down in lead vessels, as a sweetener and preservative.[109] Postindustrial lead use increased dramatically, and today lead is the most widely used nonferrous metal, with global extraction on the order of 9 million tons annually.[74] Lead is used widely for its waterproofing and electrical- and radiation-shielding

properties. Use of both lead-based paint for house paint and leaded gasoline has been essentially eliminated by regulation in the United States since the 1980s, but is still a concern in many nations, and persistence of lead paint in older U.S. homes still constitutes an enormous environmental challenge.[3]

■ HISTORY OF LEAD-RELATED HEALTH EFFECTS

Dioscorides, a Greek physician in the 2nd century B.C., observed adverse cognitive effects, and Pliny cautioned the Romans of the danger of inhaled fumes from lead smelting.[105] Modern authors have suggested that extensive use of sapa in Roman aristocratic society contributed to the downfall of Roman dominance.[109] Lead poisoning was also recognized in American colonial times. Benjamin Franklin observed in 1763 the "dry gripes" (abdominal colic) and "dangles" (wristdrop) that afflicted tinkers, painters, and typesetters, as well as the "gripes" caused by rum distillation in leaden condensing coils.[96] Lead salts, particularly lead acetate (sugar of lead), were used medicinally in the early 19th century for control of bleeding and diarrhea. With the 19th-century Industrial Revolution, lead poisoning became a common occupational disease. The reproductive effects of lead poisoning were also noted by the turn of the 20th century, including the high rate of stillbirths, infertility, and abortions among women in the pottery industry or who were married to pottery workers.

The modern history of childhood plumbism can be traced to the recognition of lead-paint poisoning in Brisbane, Australia, in 1897.[105] Lead poisoning was reported in American children in 1917, and by 1943, it was established that children who recovered from clinical plumbism were frequently left with neurologic sequelae and intellectual impairment. Symptomatic childhood lead poisoning was a frequent occurrence in American pediatric medical centers throughout the 1950s and 1960s, a period during which research established effective chelation therapy protocols with British anti-Lewisite (BAL) and edetate calcium disodium ($CaNa_2EDTA$).[33] From the 1970s to the present, the research thrust in childhood lead poisoning has centered on the recognition and quantification of more subtle neurocognitive impairment caused by subclinical lead poisoning.[16,106] Over this time period, the Centers for Disease Control and Prevention (CDC) has steadily revised downward the definitions of a normal blood lead concentration (BLL) in children. The CDC definition of lead poisoning was 60 µg/dL in the early 1960s, but the current action concentration is 10 µg/dL.[22] Furthermore, considerable research in recent years has strongly suggested adverse cognitive effects in young children at BLLs below 10 µg/dL.[21]

■ SOURCES OF HUMAN EXPOSURE

Numerous sources of lead exposure exist and can be generally classified as environmental, occupational, or additional (somewhat "exotic") sources. *Environmental* exposures affect the entire population, particularly young children. These occur primarily by exposure to some form of lead paint derivative in most cases of childhood lead poisoning in the United States (Table 94–1). Because of its continuing, major impact in the United States today, lead paint exposure is further detailed here.

Lead pigments (typically lead carbonate) account for 50% by weight of many white house paints from the pre–World War II era. Since 1978, paint intended for interior or exterior residential surfaces, toys, or furniture in the United States may contain, by law, no more than 0.06% lead. However, an estimated 3 million tons of lead remain in 57 million U.S. homes built before 1980 and painted with lead-based paint. This aging housing stock has created an enormous environmental hazard of lead exposure to children and to adult homeowners, house painters, and construction workers who become involved in sanding, scraping, and restoration of painted surfaces in these homes. Furthermore, lead-based paint is still allowed for industrial; military; marine; and some outdoor uses, such as structural components of

TABLE 94–1. Environmental Lead Sources

Source	Comment
Paint	Especially pre-1978 homes
Dust	House dust from deteriorated lead paint
Soil	From yards contaminated by deteriorated lead paint, lead industry emissions, roadways with high leaded gasoline usage
Water	Leached from leaded plumbing (pipes, solder), cooking utensils, water coolers
Air	Leaded gasoline (pre-1976 United States; still prevalent worldwide), industrial emissions
Food	Lead solder in cans (pre-1991 United States; still prevalent in imported canned foods); "natural" dietary supplements; "moonshine" whiskey and lead foil–covered wines; contaminated flour, paprika, other imported foods and candy; lead leached from leaded crystal, ceramics, vinyl lunchboxes

TABLE 94–2. Occupational and Recreational Lead Sources

High-risk occupations
Automobile radiator repairers
Crystal glass makers
Firing range instructors, bullet salvagers
Lead smelters, refiners
Metal welders, cutters (includes bridge and highway reconstruction workers)
Painters, construction workers (sanding, scraping, or spraying of lead paint; demolition of lead-painted sites)
Polyvinyl chloride plastic manufacturers
Shipbreakers
Storage battery manufacturers, repairers, recyclers

Moderate-risk occupations
Automobile factory workers and mechanics
Enamelers
Glass blowers
Lead miners
Plumbers
Pottery glazers
Ship repairers
Shot makers
Solderers
Type founders
Varnish makers
Wire and cable workers

Possible increased-risk occupations
Electronics manufacturers
Jewelers
Pipefitters
Printers
Rubber product manufacturers
Traffic police officers, taxi drivers, garage workers, turnpike tollbooth operators, gas station attendants (exposed to leaded gasoline exhaust fumes; unlikely now in the United States but still a hazard in developing countries)

Recreational and hobby sources
Ceramic crafts
Furniture refinishing, restoring
Home remodeling, refinishing
Painting (fine artist's pigments)
Repair of automobiles, boats
Stained glass making
Target shooting, recasting lead for bullets

Additional sources
Complementary and alternative remedies; cosmetics; ingested lead foreign bodies and retained lead bullets; illicit substance abuse (heroin, methamphetamine, leaded gasoline "huffing"); burning batteries, leaded paper, or wood for fuel; use of lead-glazed ceramics; hand–mouth contact with pool cue chalk, glazes, leaded ink; vinyl mini-blinds; children's toys and jewelry (especially imported products)

bridges and highways; occasionally, some of this paint is inadvertently used in homes.[22] Attempts to abate lead-painted outdoor structures can pollute entire communities.[79]

Although paint-derived lead exposure may result from pica in some children, most lead paint exposure in childhood relates to the crumbling, peeling, flaking, or chalking of aging paint.[22] These fine paint particles are incorporated into household dust and yard soil, where ordinary childhood hand–mouth activity results in ingestion.[28] Seasonal variations in house dust contamination occur, with higher house dust lead levels and increased BLLs in exposed preschool children noted during the summer.

Adults with *occupational* exposures to lead constitute another large group of persons at risk. It is estimated that more than 1 million workers in the United States, employed in more than 100 occupations, are exposed to lead.[130] The most important route of absorption in occupational settings is inhalation of lead dust and fumes. In addition, workers may eat, drink, or smoke in lead-dust–contaminated areas, resulting in some ingestion. (Cigarettes use may provide a source of oral exposure.) However, the presence of lead in the workplace, per se, does not imply a significant risk of poisoning. The risk is correlated with several factors that contribute to the occurrence of respirable lead fumes or dust particles in the worksite atmosphere.[135] There are three general categories of such factors. The first relates to the degree of hazard inherent in the work process itself, including high temperatures; significant aerosol, dust, or fume production; and a less-mechanized workplace (with resulting greater "hands-on" employee exposure). Second, the adequacy of dust elimination, such as local and general ventilation, is critical. The third category is that of worksite and personal hygiene, including proper use of protective clothes and equipment, and thorough housekeeping. For example, lead smelting can be categorized as primary (from raw ore) and secondary (reclamation, such as from used car batteries). Secondary lead production workers may be at higher risk of poisoning because this job more typically involves small, sometimes "backyard" operations that are less likely to adhere to industry safety regulations than large, well-regulated primary smelters.[39] Despite the risk factors that may be specific to each worksite, some types of lead-related work are more hazardous than others. This ranking is based on actual surveys of BLLs and reported incidence of clinical poisoning (Table 94–2).[130,134]

For convenience, environmental and occupational or recreational lead exposures are discussed separately, although there is considerable overlap. For example, workers who fail to change lead dust–covered

work clothes or shoes may bring this occupational lead hazard home and secondarily contaminate their children's environment.[130]

Finally, numerous *additional sources* of lead exposure are also reported, including contaminated folk medications or cosmetics[20,80] ingested lead foreign bodies,[93,97,163] and retained bullets.[46,85,139]

Some potential exposures have raised considerable community concern and media coverage in recent years, for example, the discovery of lead contamination of some artificial turfs,[23] and imported toys coated with lead paint.[86] These, too, are highlighted separately in Table 94–2.

■ PREVALENCE

Several recent national and regional surveys have evaluated current U.S. population-based trends in BLLs and sociodemographic correlates. The CDC estimated in 2005 that BLLs are above 9 μg/dL (representing primarily excessive household exposure) in 310,000 children ages 1 to 5 years[18] and that approximately 10,000 adults are reported each year with BLLs above 24 μg/dL (typically reflecting excessive occupational exposure).[17] Although such numbers are impressive, they represent a considerable decrease from prevalence rates done in prior decades (eg, from 8.6% of children with elevated BLLs from 1988 to 1991 to 1.4% from 1999 to 2004)[70], and it is certainly the observed clinical experience that symptomatic pediatric plumbism, in particular, is far less common than it was a generation ago. Nevertheless, for young minority children and poor people who reside in our nation's deteriorating central cities, the battle is far from won. For example, the CDC reported in 2000 that children enrolled in Medicaid had a prevalence of elevated BLLs three times greater than those not enrolled.[25] Refugee, immigrant, and foreign-born adopted children remain at particularly high risk,[19,80] and remarkable cases of extremely elevated BLLs (>100 μg/dL) may still be detected on routine screening.[38]

TOXICOLOGY

■ PHARMACOKINETICS

Inorganic and Metallic Lead *Absorption.* Gastrointestinal (GI) absorption is less efficient than pulmonary absorption. Adults absorb an estimated 10% to 15% of ingested lead in food, and children have a higher GI absorption rate, averaging 40% to 50%,[1,53] although in animal studies, this varies by type of lead compound studied.[8] However, it should be noted that fasting and diets deficient in iron, calcium, and zinc—factors that are frequent among groups of young children—enhance GI absorption of lead.[53,88] The role of essential trace elements in decreasing lead absorption is assumed to be a consequence of competitive absorption processes. Metallic lead is absorbed as well, although less readily than most lead compounds.[8] The rate of absorption of metallic lead appears to be related to particle size, total surface area, and GI tract location (whereas gastric acidity favors dissolution, the small bowel is likely the site of maximal absorption).[93,97,163]

The overall absorption of inhaled lead averages 30% to 40%. Of note, both minute ventilation and the concentration of lead in air determine airborne lead exposure, so a worker engaged in vigorous physical activity will absorb considerably more lead than a person in the same atmosphere at rest. Likewise, children, with relatively greater volume of inhaled air per unit of body size because of higher metabolic rates, are proportionally at greater risk in a given degree of atmospheric lead pollution. It is estimated that children have a 2.7-fold higher lung deposition rate of lead than do adults.[1]

Cutaneous absorption of inorganic lead is low; one study found an average absorption of 0.06% through intact skin.[100] Soft tissue absorption of metallic lead follows exposure to retained bullets, and by

analogy to GI lead foreign bodies, also depends on particle size, total surface area, and location (multiple small shot and location in which particles are bathed by synovial, serosal, or spinal fluid favor more a rapid increase in BLL).[46,85,139]

Transplacental lead transfer is critical in fetal and neonatal lead exposure, which has been under increasing scrutiny in recent years. Lead readily crosses the placental barrier throughout gestation, and lead uptake is cumulative until birth.[121]

Distribution. Absorbed lead enters the bloodstream, where at least 99% is bound to erythrocytes.[54] From blood, lead is distributed into both a relatively labile soft tissue pool and into a more stable bone compartment. This classic three-compartment model may be somewhat of an oversimplification. Currently, at least two bone compartments are recognized: a more labile pool in trabecular bone and a more stable pool in cortical bone. In adults, approximately 95% of the body lead burden is stored in bone versus only 70% for children. The remainder is distributed to the major soft tissue lead-storage sites, including the liver, kidney, bone marrow, and brain. Lead uptake into soft tissues occurs in a complex fashion that depends on numerous factors, including blood lead concentrations, external exposure factors, and specific tissue kinetics. Most of the toxicity associated with lead is a result of soft tissue uptake, so that the relative decrease in bone storage is another comparative disadvantage for lead-poisoned children.

Lead in the central nervous system (CNS) is of particular toxicologic importance, and studies have addressed specific storage sites. Lead preferentially concentrates in gray matter and certain nuclei.[54] Fetal brain uptake is relatively higher than with postnatal exposure in animal models. The highest brain concentrations are found in the hippocampus, cerebellum, cerebral cortex, and medulla.

Unlike soft tissue storage, bone lead accumulates throughout life. Bone storage begins in utero and occurs across all ranges of exposure, so that there is no threshold for bone lead uptake.[1] Total body accumulation of lead may range from 200 to 500 mg in workers with heavy occupational exposure.[54] Bone lead is thought to be relatively metabolically inert, but it can be mobilized from the more labile compartments and contributes as much as 50% of the blood lead content. This may be of particular importance during pregnancy and lactation, in elderly persons with osteoporosis,[147] and in children with immobilization.[94] Lead also accumulates in the teeth, particularly the dentine of children's teeth, a phenomenon that has been used to quantify cumulative lead exposure in young children.[106]

Excretion. Absorbed lead that is not retained is primarily excreted in urine (approximately 65%) and bile (approximately 35%).[1] A miniscule amount is lost via sweat, hair, and nails. Children excrete less of their daily uptake than adults, with an average retention of 33% versus 1% to 4%, respectively.[173] Biologic half-lives for lead are estimated as follows[1,90,122]: blood (adults, short-term experiments), 25 days; blood (children, natural exposure), 10 months; soft tissues (adults, short-term exposure), 40 days; bone (labile, trabecular pool), 90 days; and bone (cortical, stable pool), 10 to 20 years. Trace amounts of lead are also excreted in breast milk.[9]

Organic Lead Alkyl lead compounds are lipid soluble and have unique pharmacokinetics that are less well characterized than those of inorganic lead.[10] Animal studies and human clinical experience with acute ingestions and leaded gasoline sniffing demonstrate TEL absorption through ingestion, inhalation, and intact skin and subsequent distribution to lipophilic tissues, including the brain.[135,155,171] TEL is metabolized to triethyl lead, which is believed to be the major toxic compound. Alkyl leads may slowly release lead as the inorganic form, with subsequent kinetics as noted above.[10]

PATHOPHYSIOLOGY

■ GENERAL MECHANISMS

Similar to many metals, lead is a complex xenobiotic exerting numerous pathophysiologic effects in many organ systems.[54] Furthermore, genetic polymorphism may impact on individual susceptibility to lead.[110] Recently identified examples of such include the genes for apolipoprotein E, the vitamin D receptor, Na+, K+-ATPase, delta-aminolevulinic acid, and protein kinase C.[137] At the biomolecular level, lead functions in three general ways. First, its affinity for biologic electron-donor ligands, especially sulfhydryl groups, allows it to bind and impact numerous enzymatic, receptor, and structural proteins. Second, lead is chemically similar to the divalent cations calcium and zinc and interferes with numerous calcium- (and perhaps zinc-) mediated metabolic pathways, particularly in mitochondria and in second-messenger systems regulating cellular energy metabolism.[81] Lead-induced mitochondrial injury may result in apoptosis, a phenomenon particularly well studied in animal models of retinal cells.[81] Lead may function as an inhibitor or agonist of calcium-dependent processes. For example, lead inhibits neuronal voltage-sensitive calcium channels[8] and membrane-bound Na+-K+-ATPase (adenosine triphosphatase)[149] but activates calcium-dependent protein kinase C.[92] These effects adversely impact neurotransmitter function.[167] Third, lead exhibits mutagenic and mitogenic effects in mammalian cells in vitro and is carcinogenic in rats and mice.[42] There is mechanistic plausibility and some epidemiologic evidence for at least a facilitative role of lead in human carcinogenesis.[146]

■ NEUROTOXICITY

Lead's neurotoxicity involves several basic mechanisms, including apoptosis, excitotoxicity, adverse influence on neurotransmitter and second-messenger function, mitochondrial injury, cerebrovascular endothelial damage, neural cell adhesion molecule dysfunction, and impaired development and function of both oligodendroglia and astroglia, although particularly the former, with resultant abnormal myelin formation.[81,123,167] Lead-induced dysfunction is reported for several neurotransmitter systems and is linked to lead's calcium-mimetic properties. Lead blocks calcium influx through voltage-sensitive calcium channels, inhibiting evoked release of acetylcholine, dopamine, and amino acid neurotransmitters, but enhances spontaneous release.[35,54,81,167] This results in a decreased "signal to noise" ratio.[51] These effects are particularly important during early childhood, a period marked by rapid growth in brain synaptic connections followed by their "pruning." Because synapse persistence is likely modulated by motor and sensory stimulation, lead's adverse impact on neurotransmitter and synaptic function is believed to impair synaptic pruning, with resulting suboptimal cortical microarchitecture and function.[51] The hippocampus, an important locus of learning and memory, is believed to be a major site for this disturbance.[167] Lead also interferes with the 78-kDa chaperone glucose-regulated protein (GRP78) in astrocytes, which may result in adverse protein conformational effects that are thought to be associated with conditions such as Alzheimer's disease.[167] In severe cases, pathologic changes in cerebral microvasculature may result in cerebral edema and increased intracranial pressure, which are associated with the clinical syndrome of acute lead encephalopathy (Fig. 94–1). Peripheral neuropathy is a classic effect of lead poisoning in adults. The neuropathology in humans is poorly characterized. In animal models, it is associated with Schwann cell destruction, segmental demyelination, and axonal degeneration.[54] Sensory nerves are less affected than motor nerves.
FIGURE 94–1. Computed tomography scan of the brain reveals diffuse cerebral edema and loss of gray-white matter differentiation on day 1 of hospitalization of a 3-year-old boy. He had presented with a brief prodrome of vomiting and altered mental status followed by status epilepticus, characteristic of acute lead encephalopathy. His blood lead concentration was 220 μg/dL. *(Image contributed by Department of Radiology, St. Christopher's Hospital for Children, Philadelphia, PA.)*

■ HEMATOLOGIC

Lead is hematotoxic in several ways, including via potent inhibition of several enzymes in the heme biosynthetic pathway (see Chap. 24 and Fig. 24–3). It also induces a defect in erythropoietin function secondary to associated renal damage.[59,129] A shortened erythrocyte life span is believed to be caused by increased membrane fragility. Inhibition of Na+-K+-ATPase and pyrimidine-5'-nucleotidase may impair erythrocyte membrane stability by altering energy metabolism. The inhibition of pyrimidine-5'-nucleotidase is also thought to underlie the appearance of basophilic stippling in erythrocytes, representing clumping of degraded RNA, which is normally eliminated by this enzyme.[111] (See Fig. 94–2.)

■ RENAL

Functional changes associated with acute lead nephropathy include decreased energy-dependent transport, resulting in a Fanconilike syndrome of aminoaciduria, glycosuria, and phosphaturia. These changes are related to disturbed mitochondrial respiration and phosphorylation and are reversible with discontinuation of exposure or treatment.[56] A pathologic finding is characteristic nuclear inclusion bodies in renal tubular cells composed of lead–protein complex. Chronic high-dose exposure may be associated with progressive interstitial fibrosis.[78] Lead is a renal carcinogen in rodent models, but its status in humans is uncertain.[42,54]

The association of plumbism with gout ("saturnine gout") was noted more than 100 years ago. Lead decreases renal uric acid excretion, with resulting elevated blood urate concentrations and urate crystal
FIGURE 94–2. This peripheral smear of blood examined under high-power microscopy demonstrates the classic basophilic stippling associated with lead poisoning. The patient's blood lead concentration was over 100 mcg/dL. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program).*

FIGURE 94–3. (**A**) Radiograph of the wrist reveals increased bands of calcification ("lead lines") in the same patient as in Figure 94-1. (**B**) Similar radiographic findings in another patient at the knee. *(Part A contributed by Department of Radiology, St. Christopher's Hospital for Children, Philadelphia, PA. Part B contributed by Richard Markowitz, MD, Department of Radiology, Children's Hospital of Philadelphia, Philadelphia, PA.)*

deposition in joints. Renal function is virtually always impaired in patients with gout.

CARDIOVASCULAR

The most important manifestation of lead toxicity on the cardiovascular system is hypertension. This is likely caused by altered calcium-activated changes in contractility of vascular smooth muscle cells secondary to decreased Na^+-K^+-ATPase activity and stimulation of the Na^+-Ca^{2+} exchange pump. Lead may also affect vessels by altering neuroendocrine input or sensitivity to such stimuli or by increasing reactive oxygen species that enhance nitric oxide inactivation.[84] Elevated plasma renin activity is found after periods of modest exposure, although activity may decrease to normal or lower in chronic severe exposure.[164] Rarely, direct cardiotoxicity is reported.[105,125,148] Animal models demonstrate increased sensitivity to norepinephrine-induced dysrhythmias and decreased myocardial contractility, protein phosphorylation, and high-energy phosphate generation.[75] Lead-induced impairment of intracellular calcium metabolism may impact on cardiac electrophysiology.

REPRODUCTIVE SYSTEM

Impairment of both male and female reproductive function is associated with overt plumbism. Gametotoxic effects in animals of both sexes and chromosomal abnormalities in workers with BLLs above 60 μg/dL are reported.[54] Testicular endocrine hypofunction occurs in smelter workers with BLLs in the 60-μg/dL range.[127]

ENDOCRINE

Reduced thyroid and adrenopituitary function are found in adult lead workers.[132,133] Children with elevated lead levels have a depressed secretion of human growth hormone and insulinlike growth factor.[66]

SKELETAL SYSTEM

In addition to the skeletal system's importance as the largest repository of lead body burden, studies suggest that bone metabolism also is adversely affected by lead.[54] Hormonal response is altered by reduced

1,25-dihydroxyvitamin D_3 concentrations and by inhibition of osteocalcin. Both new bone formation and coupling of normal osteoblast and osteoclast function may thus be impaired.[54] Bands of increased metaphyseal density on radiographs of long bones ("lead lines") in young children with heavy lead exposure represent increased calcium deposition (not primarily lead) in the zones of provisional calcification (Fig. 94–3). Impaired bone growth and shortened stature are associated with childhood lead poisoning. Impaired calcium or cyclic adenosine monophosphate (cAMP) messenger systems may underlie these cellular effects.

GASTROINTESTINAL

GI effects are partly explained by spasmodic contraction of intestinal wall smooth muscle, analogous to that believed to occur in vascular walls.[135]

CLINICAL PRESENTATION

INORGANIC LEAD

The numerous observed lead-induced pathophysiologic effects accurately predict that the clinical manifestations of lead poisoning are diverse. These manifestations of lead toxicity are often characterized as falling into distinct syndromes of acute and chronic symptomatology. In most cases, these distinctions really describe a continuum of dose- and time-related severity. Rarely, patients with massive acute exposure present with clinical findings that are somewhat unique but overlap considerably with the more severe cases of chronic lead exposure. These syndromes are sufficiently distinct in epidemiology, clinical manifestations, and current recommended management approaches that they are described separately (Tables 94–3 and 94–4). It should be first reemphasized that the occurrence of overt clinical

TABLE 94–3. Clinical Manifestations of Lead Poisoning in Children	
Clinical Severity	Typical Blood Lead Concentrations (µg/dL)
Severe	>70–100
CNS: Encephalopathy (coma, altered sensorium, seizures, bizarre behavior, ataxia, apathy, incoordination, loss of developmental skills; papilledema, cranial nerve palsies, signs of increased ICP)	
GI: Persistent vomiting	
Hematologic: Pallor (anemia)	
Mild to moderate	50–70
CNS: Hyperirritable behavior, intermittent lethargy, decreased interest in play, "difficult" child	
GI: Intermittent vomiting, abdominal pain, anorexia	
Asymptomatic	≤49
CNS: Impaired cognition, behavior, balance, fine-motor coordination	
Miscellaneous: Impaired hearing, growth	

CNS, central nervous system; GI, gastrointestinal; ICP, intracranial pressure.

TABLE 94–4. Clinical Manifestations of Lead Poisoning in Adults	
Clinical Severity	Typical Blood Lead Concentrations (µg/dL)
Severe	>100
CNS: Encephalopathy (coma, seizures, obtundation, delirium, focal motor disturbances, headaches, papilledema, optic neuritis, signs of increased ICP)	
PNS: Footdrop, wristdrop	
GI: Abdominal colic	
Hematologic: Pallor (anemia)	
Renal: Nephropathy	
Moderate	70–100
CNS: Headache, memory loss, decreased libido, insomnia	
PNS: peripheral neuropathy	
GI: Metallic taste, abdominal pain, anorexia, constipation	
Renal: Nephropathy with chronic exposure	
Miscellaneous: Mild anemia, myalgias, muscle weakness, arthralgias	
Mild	20–69 [a]
CNS: Tiredness, somnolence, moodiness, lessened interest in leisure activities	
Miscellaneous: Adverse effects on cognition, reproduction, renal function, or bone density; hypertension and cardiovascular disease; possible increased risk of cancer	

[a] Chronic lead exposure at lower blood lead concentrations may lead to cumulative body burdens of lead associated with these clinical findings.

CNS, central nervous system; GI, gastrointestinal; ICP, intracranial pressure; PNS, peripheral nervous system.

symptoms in lead-exposed persons is, in most cases, the culmination of a long history of lead exposure. As the total dose increases, these symptoms are almost always preceded first by measurable biochemical and physiologic impairment followed, in turn, by subtle prodromal clinical effects that may only become apparent in hindsight. In general, children are considered to be more susceptible than adults to toxicity for a given measured blood lead concentration; however, the data for this primarily concern effects on the CNS.

Symptomatic Children *Acute lead encephalopathy* is the most severe presentation of pediatric plumbism (see Table 94–3). It may be associated with cerebral edema and increased intracranial pressure (see Fig. 94–1). Encephalopathy is characterized by pernicious vomiting and apathy, bizarre behavior, loss of recently acquired developmental skills, ataxia, incoordination, seizures, altered sensorium, or coma. Physical examination may reveal papilledema, oculomotor or facial nerve palsy, diminished deep tendon reflexes, or other evidence of increased intracranial pressure.[20,169] Encephalopathy usually occurs in children ages 15 to 30 months; is associated with BLLs above 100 µg/dL, although it is reported with BLLs as low as 70 µg/dL; and tends to occur more commonly in summer months, when BLLs peak.[115] Milder but ominous symptoms that may portend incipient encephalopathy include anorexia, constipation, intermittent abdominal pain, sporadic vomiting, hyperirritable or aggressive behavior, periods of lethargy interspersed with lucid intervals, and decreased interest in play activities. Many such patients seek medical advice for vomiting and lethargy during the 2 to 7 days before onset of frank encephalopathy.[33,115] Physical examination of such children usually reveals no specific abnormalities.

Mortality caused by encephalopathy was 65% in the prechelation era, decreasing to below 5% with the advent of effective chelation. The incidence of permanent neurologic sequelae, including mental retardation, seizure disorder, blindness, and hemiparesis, is 25% to 30% in patients who develop encephalopathic symptoms before the onset of chelation (Fig. 94–4).[33]

Subencephalopathic symptomatic plumbism usually occurs in children 1 to 5 years old and is associated with BLLs above 70 µg/dL, but it may occur with concentrations as low as 50 µg/dL. Unfortunately, common complaints in well children of this age (eg, the "terrible twos," with functional constipation and who do not eat as much as parents expect) often overlap with the milder range of reported symptoms of lead poisoning. Frequently, parents of children diagnosed by routine blood screening recognize milder symptoms only in hindsight after chelation treatment results in clinical improvement ("it seemed as if the child was going through a phase").[49] This is especially true currently, when symptomatic plumbism is rarely reported.[20,22] Other uncommon clinical presentations are described, including isolated seizures without encephalopathy (indistinguishable from idiopathic epilepsy), chronic hyperactive behavior disorder, isolated developmental delay, progressive loss of cortical function simulating degenerative cerebral disease, peripheral neuropathy (reported particularly in children with sickle-cell hemoglobinopathy), and the occurrence of GI symptoms (colicky abdominal pain, vomiting, constipation) with myalgias of the trunk and proximal girdle muscles.[33,43]
FIGURE 94–4. Magnetic resonance image of the brain reveals cortical atrophy and multiple areas of cerebral infarction in the same patient as in Figure 94–1, done on hospital day 22. At this time, the child's clinical status was notable for choreoathetoid movements and generalized hypotonia, inability to localize visual or auditory stimuli, and nonpurposeful movements of the extremities. *(Image contributed by Eric Faerber, MD, Department of Radiology, St. Christopher's Hospital for Children, Philadelphia, PA.)*

Asymptomatic Children Children with *elevated body lead burdens but without overt symptoms* represent the largest group of persons believed to be at risk for chronic lead toxicity. The subclinical toxicity of lead in this population centers around subtle effects on growth, hearing, and neurocognitive development. This last effect, in particular, is the subject of intense research interest and scrutiny. An effort to rigorously evaluate several modern (since 1979), carefully done studies of the association of low lead and reduced intelligence (cross-sectional studies with blood or tooth lead and prospective studies) and combine their results with a statistical meta-analysis technique have been reported.[117] The overall finding was that even though the majority of individual studies failed to achieve statistical significance when taken together, there was a significant inverse association between lead exposure and Intelligence Quotient (IQ), on the order of 1 to 2 IQ points for chronic BLL increases from 10 to 20 μg/dL. Since that publication, another study evaluated IQ in patients from 6 months to 5 years old and found that BLLs were inversely correlated with IQ at 3 and 5 years of age and that the magnitude of effect for all subjects was an average 4.6-point decrement in IQ for each 10-μg/dL increase in BLL. Of particular concern, this effect was even greater, with an estimated 7.4 point loss, for the subset of children in the 1 to 10 μg/dL BLL range.[16] The CDC recently compiled a number of studies confirming this association of adverse cognition and BLLs below 10 μg/dL.[21]

Adults Adults with occupational lead exposure may manifest numerous signs and symptoms representing disorders of several organ systems. Severity of symptoms correlates roughly with BLLs, although many conditions thought associated with low-dose chronic lead exposure are better correlated with markers of cumulative dose, such as bone lead or the cumulative blood lead index (area under the curve of BLLs versus time)[65,78] (see Table 94–4). True acute poisoning occurs rarely, after very high inhalational,[74] large oral,[107] or intravenous (IV) exposures.[108] Such patients may present with colic, hepatitis, pancreatitis, hemolytic anemia, and encephalopathy over days or weeks. Most adult plumbism is related to chronic respiratory exposure, although some authors have used the term *acute poisoning* to include patients with such exposure whose symptoms are severe and of relatively recent onset (within 6 weeks of presentation) and whose exposure is relatively brief (average, ≤1 year).[37]

The hallmark of severe toxicity is *acute encephalopathy*, which has been rarely reported in adults since the 1920s.[37] The majority of modern cases are actually not associated with occupational exposures but rather with more exotic exposures, such as ingestion of lead-contaminated illicit "moonshine" whiskey and ethnic alternative medications.[73,152] Encephalopathy in adults is usually associated with very high BLLs (typically >150 μg/dL) and is manifested by seizures (75% of cases), obtundation, confusion, focal motor disturbances, papilledema, headaches, and optic neuritis.[95,168] In addition, adult patients with severe plumbism often manifest attacks of abdominal colic, are virtually always anemic, and are at significant risk for severe peripheral nerve palsy such as wristdrop and footdrop and nephropathy. Rarely, cardiac dysfunction and electrocardiographic (ECG) abnormalities are reported.[125]

Moderate plumbism in adults typically involves CNS, peripheral nerve, hematologic, renal, GI, rheumatologic, endocrine or reproductive, and cardiovascular findings.[74,130,135] At BLLs above 70 μg/dL, such symptoms may include headache, memory loss, decreased libido, and insomnia. GI symptoms may include metallic taste, abdominal pain, decreased appetite, weight loss, and constipation. Musculoskeletal and rheumatologic complaints at this stage include muscle pain and joint tenderness. Peripheral neuropathy may occur, primarily motor, manifesting as muscle weakness, numbness of the legs, occasional paresthesias, tremor, and hyperreflexia. Many patients at this stage have mild anemia, and those with chronic exposure are at risk for nephropathy.

Mild plumbism may manifest as minor CNS findings, such as changes in mood and cognition. Subtle neurocognitive abnormalities demonstrable by neuropsychiatric testing are being found in both adults and children with modest elevations in blood lead concentration. Studies have documented abnormal psychometrics and nerve conduction in workers recently exposed to lead as BLLs increased to above 30 μg/dL.[89] Early symptoms, manifesting at BLLs of 40 to 70 μg/dL, may be subtle and include increased tiredness at the end of the day, disinterest in leisure-time pursuits, falling asleep easily, moodiness, and irritability. Effects on reproductive function and blood pressure may also be apparent in this range of exposure. Historically, infertility and stillbirths were common among heavily exposed female lead workers. More recent studies found reduced sperm counts, impaired sperm motility, and abnormal morphology in battery workers with BLLs above 40 μg/dL[6] and increased incidence of menstrual irregularity and spontaneous abortion in lead-exposed female workers in China[69] and Mexico.[11] Prematurity is more common in children of pregnancies associated with elevated maternal lead levels.[104]

Increased blood pressure is probably the most prevalent adverse health effect observed from lead exposure in adults. Epidemiologic studies document significant associations between hypertension and body lead burdens. The association is particularly strong for adult men ages 40 to 59 years, with an approximate 1.5- to 3.0-mm Hg increase in systolic pressure for every doubling of BLL beginning at 7 μg/dL.[116,158] Additional studies have correlated body lead burden with several other disorders of aging, including a decline in cognitive ability,[134,145] essential tremor,[41] cardiovascular and cerebrovascular events,[67,78,99] ECG abnormalities,[29] chronic renal dysfunction,[84,78] osteoporosis,[15] and cataract prevalence.[136]

Physical examination findings vary with the degree of severity. Mild and moderate symptoms usually occur in patients with normal examination findings.[39] In encephalopathic patients, typical changes

of stupor, coma, posturing, and papilledema are noted. Milder abnormal neurologic findings include dominant wrist or hand weakness, paresthesia, and tremor. One author described grayish stippling of the retina circumferential to the optic disk,[151] but other authors dispute this finding.[112] A bluish-purple gingival lead line (Burton line) representing lead sulfide precipitation is described rarely in adult patients with poor oral hygiene. Abdominal guarding and tenderness are occasionally observed. Patients with saturnine gout may have typical joint findings of acute arthritis. Severely anemic patients may exhibit pallor. Careful neuropsychologic testing may reveal abnormalities of memory span, rapid motor tapping, visual motor coordination, and grip strength.[37]

■ ORGANIC LEAD

Clinical symptoms of TEL toxicity are usually nonspecific initially and include insomnia and emotional instability.[10,135] Nausea, vomiting, and anorexia may occur. The patient may exhibit tremor and increased deep tendon reflexes. In more severe cases, these symptoms progress to encephalopathy with delusions, hallucinations, and hyperactivity, which may resolve or deteriorate to coma and, occasionally, death. Severe cases may also develop hepatic and renal injury. Because many reported patients are exposed via intentional abuse of leaded gasoline, much of the literature reporting this syndrome may be confounded by accompanying volatile hydrocarbon toxicity.[155] Of note, in contrast to inorganic lead poisoning, patients with significant TEL toxicity do not consistently manifest hematologic abnormalities or elevations of heme synthesis pathway biomarkers. In addition, significant neurotoxicity may occur at BLLs considerably lower than those typically associated with inorganic lead poisoning.[61] A recent case report details the clinical course of a 13-year-old boy who unintentionally ingested a mouthful of fuel stabilizer containing 80% to 90% TEL. He developed progressive tremor, weakness, hallucinations, myoclonus, and hyperreflexia and required mechanical ventilation for 2 days and prolonged hospitalization for management of persistent hallucinations, weakness, dysphagia, and urinary and fecal incontinence. His peak BLL on the third day after ingestion was 62 μg/dL.[171]

ASSESSMENT

■ CLINICAL DIAGNOSIS IN SYMPTOMATIC PATIENTS

For all patients in whom plumbism is considered based on clinical manifestations, the medical evaluation should first include a comprehensive medical history. Further inquiry should elicit environmental,

occupational, or recreational sources of exposure as detailed earlier (see Tables 94–1 and 94–2). Plumbism is more likely in a child between the ages of 1 and 5 years with prior plumbism or noted elevated BLLs, pica, including acute unintentional ingestions,[60] or aural, nasal, or esophageal foreign bodies[170], history of iron-deficiency anemia, residence in a pre-1960s–built home, especially with deteriorated paint, or one that has undergone recent remodeling; family history of lead poisoning, or foreign-born status.[3,31,172] Affected children may manifest persistent vomiting, lethargy, irritability, clumsiness, or loss of recently acquired developmental skills, afebrile seizures; or evidence of child abuse or neglect.[48,138] In adults, the history should focus on occupational and recreational activities that might involve lead exposure (see Table 94–2), a history of plumbism, and gunshot wounds with retained bullets.

The differential diagnosis of plumbism is broad. Adult patients may be misdiagnosed as having carpal tunnel syndrome, Guillain-Barré syndrome, sickle-cell crisis, acute appendicitis, renal colic, or infectious encephalitis. Children are often initially considered to have viral gastroenteritis or even to have insidious symptoms passed off as a difficult developmental phase.

A patient who presents to the ED with potential lead encephalopathy presents the physician with a dilemma: severe lead toxicity requires urgent diagnosis, but confirmatory blood lead assays are usually unavailable on an immediate basis.[63] For adults, a history of occupational exposure is often available from medical records or family members, and lead encephalopathy can be strongly considered with positive supportive laboratory findings (usually available on urgent basis) such as anemia, basophilic stippling, elevated erythrocyte protoporphyrin (especially >250 μg/dL), and abnormal urinalysis. In this context, it might be appropriate to institute presumptive chelation therapy while awaiting lead concentrations. In children, a similar indication for presumptive treatment would be suggested by a constellation of clinical features and ancillary studies, such as age 1 to 5 years, a prodromal illness of several days to weeks duration (suggestive of milder lead-related symptoms), history of pica and source of lead exposure, the laboratory features noted above, which are equally helpful in young children, radiologic findings of dense metaphyseal "lead lines" at wrists or knees (see Fig. 94–3), or evidence of recent pica for ingested foreign bodies or lead paint particles on abdominal radiographs (Figs. 94–5 and 94–6). Radiographic confirmation of retained bullets or shrapnel may be relevant in patients of any age (Fig. 94–7).[46,85,139,144] In both adults and children, the decision to institute empiric chelation treatment
FIGURE 94–5. An unusual source of lead poisoning. (**A**) Radiograph of the abdomen reveals ingested metallic foreign body. (**B**) The ingested foreign body was a Civil War era musketball from the collection of the patient's father. *(Images contributed by Evaline Alessandrini, MD, Division of Emergency Medicine, Children's Hospital of Philadelphia, Philadelphia, PA.)*
FIGURE 94–6. (**A**) Abdominal radiograph of a child who had massive paint chip ingestion. The dispersed radio dense (white) fragments are noted to follow the outline of the large intestine. (**B**) No remaining lead is seen on follow-up radiograph after whole-bowel irrigation. *(Images contributed by Department of Radiology, St. Christopher's Hospital for Children, Philadelphia, PA.)*

FIGURE 94–7. Abdominal radiograph of an 8-year-old child who sustained a shot-gun wound to the right paraspinal area, with resultant paraplegia and multiple visceral injuries. The blood lead concentration was found to be 60 μg/dL at 11 weeks after injury, and chelation therapy was commenced. *(Reproduced with permission from Selbst SM, Henretig F, Fee MA, et al. Lead poisoning in a child with a gunshot wound.* Pediatrics*. 1986;77:413-416.)*

should not deter additional emergent diagnostic efforts to exclude or to confirm other important entities while blood lead concentrations are pending. An important consideration in this context may be the suspicion of an acute, potentially treatable CNS infection (eg, bacterial meningitis or herpetic encephalitis). Lumbar puncture may be dangerous in patients with severe lead encephalopathy because of the risk of cerebral herniation.[34] If immediate lumbar puncture is thought to be highly desirable, a computed tomography scan would allow determination of severe cerebral edema, midline shift, or other evidence of an especially high risk for herniation. If performed, the minimal amount of fluid necessary for diagnosis (<1 mL) should be removed using a small-gauge needle. Alternatively, empiric treatment for infectious processes can be initiated while the lead concentration is pending, and delayed lumbar puncture can be performed if the blood lead concentration is normal.

■ LABORATORY EVALUATION

In patients suspected of having plumbism, laboratory testing is used to augment the evaluation of both lead exposure and lead toxicity. The *whole BLL* is the principal measure of lead exposure available in clinical practice, reflecting both recent and remote exposure. In any patient suspected of symptomatic plumbism, whole blood should be collected by venipuncture into special lead-free evacuated tubes. The BLL is typically determined by atomic absorption spectrophotometry. For asymptomatic children, BLL screening is often performed by capillary blood testing for convenience; however, venous confirmation of elevated capillary lead concentrations, unless extremely high (eg, >69 μg/dL) or unless the patient is clearly symptomatic, is still considered mandatory before chelation or other significant interventions. Hair and urine lead concentrations have little clinical utility. The *erythrocyte protoporphyrin concentration* reflects lead's inhibition of the heme synthesis pathway (see Chap. 24) and had been used as a screening

tool in the past, but it is no longer considered sufficiently sensitive. The erythrocyte protoporphyrin concentration test may still be useful for tracking response to therapy and in distinguishing acute from chronic lead exposure; as an adjunct to the emergency diagnosis of symptomatic plumbism if emergent BLL determination is not available; and, rarely, in the evaluation of suspected factitious plumbism. Routine serum chemistries, renal function tests, liver function tests, urinalysis, and complete blood count are indicated in patients who are symptomatic or about to undergo chelation therapy. Radiographic studies may suggest retained bullets, as noted above (see Fig. 94–7), recent lead ingestion, or toxicity. Abdominal radiographs may reveal lead paint chips or other ingested lead foreign material (see Figs. 94–5 and 94–6). The finding of "lead lines," metaphyseal densities at the ends of long bones in young children, may substantiate a clinical diagnosis of plumbism before BLLs are available (see Fig. 94–2), although dense metaphyseal bands are rarely caused by other causes, including other heavy metals (arsenic, bismuth, and mercury), healing rickets, and recovery from scurvy.[120,171]

Finally, two measures of cumulative lead exposure are available. *X-ray fluorescence* technology measures bone lead, and thus indirectly estimates total body lead burden. The *cumulative blood lead index,* derived from several BLLs measured over the presumed course of lifetime lead exposure, calculated as an area under the concentration curve, has also been described.[65] Both techniques have been used in research studies of issues concerning past chronic lead exposure and a variety of current health outcomes.[64,77,166]

SCREENING

Although outside the scope of this discussion, screening is an essential public health practice for the prevention of severe plumbism in both children and adults from high-risk settings. Table 94–5 outlines the current CDC[21,26] pediatric recommendations, which also are endorsed by the American Academy of Pediatrics.[3] Likewise, the Occupational Safety and Health Administration (OSHA) maintains a lead standard for U.S. workers formulated to reduce workplace exposure to lead, decrease symptomatic lead poisoning, and provide quality medical care to workers with elevated blood lead levels.[159–161] Table 94–6A summarizes the OSHA-mandated action BLL values for worker notification, removal, and reinstatement.

TABLE 94–5. Pediatric Screening and Follow-up Guidelines[3,21,26]

Screening

1. The AAP and CDC recommend screening all children who are Medicaid eligible at age 1 and 2 years (and those ages 3–6 years who have not been screened previously). Children who may not be Medicaid eligible but whose families participate in any poverty assistance program should also be screened.
2. Certain local health departments (eg, New York, Chicago, and Philadelphia) recommend screening at younger ages or more frequently. Such recommendations include starting at age 6–9 months, testing every 6 months for children younger than 2 years, and provision of additional education and more rapid follow-up testing for children younger than 12 months old whose BLLs are 6–9 μg/dL.
3. In addition, children who are not Medicaid eligible but are designated high-risk by their state or local health departments should be screened as per these local policies.[a]
4. For children who are neither Medicaid eligible nor live in areas with locale-specific health department guidelines, recommendations are less clear. The AAP supports universal screening of such children as well.[b]
5. Recent immigrant, refugee, or international adoptee children should be screened on arrival to the United States.

Follow-up

BPb (μg/dL)	Recommended Action
≤9	Retest in 1 year
10–14	Retest in 3 months; education[20]
15–19	Retest in 2 months; education; if the level is 15–19 twice, refer for case management
20–44	Clinical evaluation; education; environmental investigation and lead hazard control
45–69	Clinical evaluation and case management within 48 hours; education; environmental investigation and lead hazard control; chelation therapy[3,22]
≥70	Hospitalize child; immediate chelation therapy; education; environmental investigation and lead hazard control

[a] Many relevant state and city health department contacts may be located at http://www.cdc.gov/nceh/lead/grants/contacts/CLPPP%20Map.htm.

[b] The 1997 CDC guidance[26] allowed for targeted screening of some children of low-risk geographic and demographic background based on a personal risk questionnaire. Subsequent studies have found that such survey-based targeted screening is not well validated.[3] Nevertheless, a listing of potential risk factors may be instructive and is summarized here. Screening was recommended if a child had any of the following high-risk factors:

Housing: Lives in or regularly visits a home built before 1950; lives in or regularly visits a home built before 1978 undergoing remodeling or renovation (or renovated within 6 months).

Medical history: Pica for paint chips or dirt; iron deficiency.

Personal, family, social history: Personal, family, or playmate history of lead poisoning; parental occupational, industrial, hobby exposures; live in proximity to major roadway; use of hot tap water for consumption; use of complementary remedies, cosmetics, ceramic food containers; trips or residence outside United States; parents are migrant farm workers, receive poverty assistance.

Educational interventions as per Table 94–7.

Chelation therapy as per Table 94–8.

AAP, American Academy of Pediatrics; BLL, blood lead concentration; BPb, venous blood lead; CDC, Centers for Disease Control and Prevention.

TABLE 94–6A. Occupational Safety and Health Administration General Industry[a] Standards for Various Blood Lead Concentrations (BLLs)

Number of Tests	BLL (µg/dL)	Action Required
1	≥40	Notification of worker in writing; medical examination of worker and consultation
3 (average)	≥50	Removal of worker from job with potential lead exposure
1	≥60	Removal of worker from job with potential lead exposure
2	<40	Reinstatement of worker in job with potential lead exposure

[a] The construction industry standard is similar for worker notification (at 40 µg/dL) and reinstatement (<40 µg/dL twice) but requires worker removal for a single value ≥50 µg/dL.

Adapted from U.S. Department of Labor, Occupational Safety and Health Administration. *Medical Surveillance Guidelines–1910.1025 App C.* Retrieved December 29, 2005, from http://www.osha.gov/pls/oshaweb/owadisp.show_document?p_table=STANDARDS &p_id=10033 and U.S. Department of Labor, Occupational Safety and Health Administration. *Medical Surveillance Guidelines. Lead–1926.62.* Retrieved December 29, 2005, from http://www.osha.gov/pls/oshaweb/owadisp.show_document?p_table=STANDARDS &p_id=10641. See also US Department of Labor. [160–162.]

An expert panel convened by the Association of Occupational and Environmental Clinics recently published an alternative set of health-based management recommendations for lead-exposed workers. The authors propose that their recommendations are more reflective of recent research linking adverse health outcomes to chronic, low-dose lead exposure.[78] These guidelines are summarized in Table 94–6B.

TABLE 94–6B. Health-Based Occupational Surveillance Recommendations[a]

BLL (µg/dL)	Recommendation
<10	BLL every month for 3 months and then every 6 months (unless exposure increases); if BLL increases >4 µg/dL, exposure evaluation or reduction effort; exposure evaluation or reduction if BLL 5–9 µg/dL for women who are or may become pregnant
10–19	As for BLL <10 µg/dL and BLL every 3 months; exposure evaluation and reduction effort; consider removal if no improvement with exposure reduction or complicating medical condition[b]; resume BLL q 6 months if 3 BLLs <10 µg/dL
≥19	Remove from exposure if BLL >30 µg/dL or repeat BLL in 4 weeks; BLL every month; consider return to work after BLL <15 µg/dL twice

[a] All potentially lead-exposed workers warrant pre-employment clinical evaluation, baseline blood lead concentration (BLL), and serum creatinine level.

[b] Such conditions include chronic renal disease, hypertension, neurologic disorders, and cognitive dysfunction.

Adapted from Kosnett MJ, Wedeen RP, Rothenberg SJ, et al. Recommendations for medical management of adult lead exposure. *Environ Health Perspect.* 2007;115:463-471.

MANAGEMENT

There are several caveats about the management of patients with lead poisoning. First, the most important aspect of treatment is removal from further exposure to lead. Unfortunately, effective implementation of this therapy is often beyond the control of the clinician but rather depends on a complex interplay of public health, social, and political actions. Currently, the ability to control exposure is generally more applicable to adults with occupational exposures than to children exposed to residential hazards. Second, in children for whom some residual lead exposure potentially continues, optimization of nutritional status is vital in order to minimize absorption. Finally, pharmacologic therapy with chelators, although a mainstay of therapy for symptomatic patients, is an inexact science, with numerous unanswered questions despite almost 50 years of clinical use.[2,5,77] The rationale for chelation therapy of lead-poisoned patients is that chelators complex with lead, forming a chelate that is excreted in urine, feces, or both. Chelation therapy increases lead excretion, reduces blood concentrations, and reverses hematologic markers of toxicity during therapy. Reports from the 1950s found symptomatic improvement in adults chelated for lead colic.[165] The institution of effective combination chelation treatment of childhood lead encephalopathy in the 1960s contributed to the dramatic decline in mortality and morbidity of that devastating degree of plumbism.[33] However, the same era saw major advances in pediatric critical care in general and medical management of increased intracranial pressure in particular. The situation of chelation therapy for asymptomatic patients with mildly to moderately increased body burdens of lead is even less clear, and many questions regarding efficacy and safety remain.[31,55,77,114] To date, long-term reduction of target tissue lead content or reversal of toxicity is not demonstrated in human trials.[40,93,128]

■ DECREASING EXPOSURE

All patients with significantly elevated lead concentrations warrant identification of the lead exposure source and specific environmental and medical interventions or both (Table 94–7). In adults, this usually involves changes in their worksite.[39,78,135] Remedial actions might include improvements in ventilation, modification of personal hygiene habits, and optimal use of respiratory apparatus. It is vital to prohibit smoking, eating, and drinking in a lead-exposed work area. Work clothes should be changed after each shift and should not be lockered together with street clothes. In patients with plumbism caused by retained bullets, surgical removal of this lead source should be considered.[27,85,98] Table 94–7 also summarizes several specific educational guidelines that may be offered to parents of lead-exposed children.[3,14,22,] Overarching principles include home lead paint abatement (done preferably by professionals, with the family out of the home), home dust reduction techniques, decreasing soil lead exposure, and nutritional evaluation and counseling. Patients manifesting iron deficiency should be treated, and for others, a diet sufficient in trace nutrients, particularly iron and calcium (which may decrease lead absorption) and vitamin C (which may enhance renal lead excretion) is likely of value.[3] Clinicians who have primary responsibility for children with elevated lead levels should refer to the CDC's exhaustive monograph, which details such pediatric case mananagement.[22]

Occasionally, children may require urgent GI decontamination to reduce ongoing acute lead exposure. Patients with large burdens of lead paint chips may benefit from prompt institution of whole-bowel irrigation (WBI) (see Fig. 94–6). The presence of ingested lead foreign bodies is a unique situation that requires careful individualization of management. Several case reports document rapid absorption, with significantly elevated BLLs measured within 24 hours of ingestion in some cases. Such patients warrant baseline BLL determination

---

TABLE 94–7. Evaluation and Management of Patients with Lead Exposure

Workplace Efforts

Adults

Implement careful lead exposure monitoring (see Table 94-6B)

Improve ventilation

Use respiratory apparatus

Wear protective clothing; change from work clothes before leaving worksite

Modify personal hygiene habits

Prohibit eating, drinking, and smoking at the worksite

Evaluate possible sources beyond occupational setting (see Tables 94–1 and 94–2)

Children

Notify the local health department to initiate home inspection and abatement as needed

Home lead paint abatement (professional contractors if possible; use plastic sheeting, low dust-generating paint removal; replacement of lead-painted windows, floor treatment; final cleanup with high-efficiency particle air vacuum, wet-mopping)

Avoid most hazardous areas of the home and yard

Dust control: Wet mopping, sponging with high-phosphate detergent; frequent hand, toy, and pacifier washing

Soil lead exposure reduction by planting grass and shrubs around the house

Use only cold, flushed tap water for consumption

Optimize nutrition to reduce lead absorption: avoid fasting; iron, calcium, vitamin C sufficient diet; supplement iron and calcium as necessary

Avoid food storage in open cans

Avoid imported ceramic containers for food and beverage use

Evaluate parental occupations and hobbies and eliminate high-risk activity

Consider possible sources beyond lead paint exposure (see Tables 94–1 and 94–2)

---

and frequent repeat BLLs, with consideration for prompt endoscopic removal, particularly with gastric location and increasing BLLs.[97,103,163] Proton pump inhibitor and prokinetic therapy have also been recommended for gastric foreign bodies in an effort to decrease gastric acidity, retention time, and resultant lead dissolution.[47] WBI may be an adjunct for more distally located foreign bodies but has not been uniformly successful. Colonoscopy or surgery may be required in serious cases.[103,163] The issue of concomitant chelation therapy in patients with significant GI lead burdens is addressed in the following section.

■ CHELATION THERAPY

The indications for and specifics of chelation therapy are determined by the patient's age, blood lead concentration, and clinical symptomatology (Table 94–8). Three chelation agents are currently recommended as drugs of choice for the treatment of lead poisoning: (see Antidotes in Depth A26: Dimercaprol) BAL and CaNa$_2$EDTA (see Antidotes in Depth A28: Edetate Calcium Disodium) are used parenterally for more severe cases, and succimer (see Antidotes in Depth A27: Succimer) is available for oral therapy. Pharmacologic profiles of these three chelators are detailed in the corresponding Antidotes in Depth. A fourth drug, D-penicillamine (see below), has been used orally for patients with mild to moderate excess lead burdens. Unfortunately, D-penicillamine has a toxicity profile that includes serious, life-threatening hematologic disorders and reversible, but serious, dermatologic and renal effects; consequently, since 1991, its role in lead poisoning treatment at most centers has been largely replaced by succimer. Currently, the American Academy of Pediatrics recommends D-penicillamine use only when unacceptable adverse reactions to both succimer and CaNa$_2$EDTA occur, and it remains important to continue chelation.[2,3] Nevertheless, some authors still commend its use for mild lead intoxication, particularly at a reduced dose regimen.[143]

Chelation is not a panacea for lead poisoning. It is a relatively inefficient process, with a typical course of therapy decreasing body content of heavy metal by only 1% to 2%.[77,102] Furthermore, there is little evidence that chelating agents have significant access to critical sites in target organs, particularly in the brain.[36] Assumptions that reducing blood lead level will improve subtle neurocognitive dysfunction or other subclinical organ toxicity are appealing theoretically but are unproven.[40,128]

■ PEDIATRIC THERAPY

Lead encephalopathy is an acute life-threatening emergency and should be treated under the guidance of a multidisciplinary team in the intensive care unit of a hospital experienced in the management of critically ill children. Encephalopathy requires treatment by combination parenteral chelation therapy with maximum-dose BAL and CaNa$_2$EDTA along with meticulous supportive care.[2,22,33] Such combination therapy has a dramatic effect on decreasing BLL—to 50% or less of baseline within 15 hours and to 75% to 80% of baseline by 48 to 72 hours. It is far superior to monotherapy with CaNa$_2$EDTA in this regard.[33]

Chelation is instituted with 75 mg/m^2/d (or 25 mg/kg/d) of intramuscular (IM) BAL in six divided doses.[2,22] The second dose of BAL is given 4 hours later followed immediately by IV CaNa$_2$EDTA, in maximum concentration of 0.5% solution, at 1500 mg/m^2/d (or 50 mg/kg/d) as a continuous infusion over several hours or in divided-dose infusions.[2,22,115] The delay in initiating CaNa$_2$EDTA infusion is based on past observations of clinical deterioration in encephalopathic patients treated with CaNa$_2$EDTA alone.[2,33] Therapy is typically continued with both agents for 5 days, although in milder cases with prompt resolution of encephalopathy and decrease of BLL to below 50 μg/dL, BAL may be discontinued after 3 days, with continuation of CaNa$_2$EDTA alone for 2 more days.

The presence of radiopaque material in the GI tract on radiography has raised concern that parenteral chelation might enhance absorption of residual gut lead. This issue is not settled fully,[31,71] but most experts advocate initiation of parenteral chelation without delay in seriously symptomatic patients. It seems reasonable to simultaneously attempt bowel decontamination,[2] as with a WBI solution. One case report described the successful use of chelation therapy begun with parenteral BAL and CaNa$_2$EDTA and then enteral succimer (initiated after 3 days of WBI) for a child with lead encephalopathy and an extraordinarily high BLL of 550 μg/dL.[52] This issue applies as well to ingested lead foreign bodies, as noted above.[97,103,163] Generally, oral fluids, feedings, and medications are withheld for at least the first several days. Careful provision of adequate IV fluids optimizes renal function while avoiding overhydration and the risk of exacerbating cerebral edema. The occurrence of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) may be associated with lead encephalopathy,[33,154] so urine volume, specific gravity, and serum electrolytes should be closely monitored, especially as fluids are gradually liberalized with clinical improvement. In the context of lead encephalopathy, this approach would need to be tempered by the requirement for maintaining good urine output to optimize chelation efficacy.

Seizure control is usually accomplished with benzodiazepines. Ongoing anticonvulsant therapy is typically continued with phenytoin or phenobarbital. Rarely, continuous infusions of midazolam or high-dose pentobarbital therapy may be necessary.[169]

TABLE 94–8. Chelation Therapy Guidelines [2,3,22,74,115,118] for Initial Course of Treatment[a]

Condition, BLL (μg/dL)	Dose	Regimen/Comments
Adults		
Encephalopathy	BAL 450 mg/m^2/d[a,b] and	75 mg/m^2 IM every 4 h for 5 d
	CaNa$_2$EDTA 1000–1500 mg/m^2/d[a]	Continuous infusion or two to four divided IV doses for 5 d (start 4 h after BAL)
Symptoms suggestive of encephalopathy or >100	BAL 300–450 mg/m^2/d[a,b] and	50–75 mg/m^2 every 4 h for 3–5 d (base dose, duration on BPb, severity of symptoms; see text)
	CaNa$_2$EDTA 1500 mg/m^2/d[a]	Continuous infusion or two to four divided IV doses for 5 d (start 4 h after BAL)
		Lab: Baseline CT scan; CBC, Ca, BLL, BUN, Cr, LFTs, U/A; repeat CBC, Ca, BUN, Cr, LFTs, U/A daily; BLL on days 3 and 5
Mild symptoms or 70–100	Succimer 700–1050 mg/m^2/d	350 mg/m^2 tid for 5 d, then bid for 14 d. Remove from exposure (Table 94–7)
		Lab: CBC, BLL, BUN, Cr, LFTs, U/A; repeat CBC, LFTs, BLL on days 7 and 21
Asymptomatic and <70	Usually not indicated	–
Children		
Encephalopathy	BAL 450 mg/m^2/d[a] and	75 mg/m^2 IM every 4 h for 5 d
	CaNa$_2$EDTA 1500 mg/m^2/d[a]	Continuous infusion or two to four divided IV doses for 5 d (start 4 h after BAL)
		Lab: Baseline AXR, CT scan, CBC, Ca, BLL, BUN, Cr, LFTs, U/A; repeat CBC, Ca, BUN, Cr, LFTs, U/A daily; BLL on days 3 and 5
Symptomatic (without encephalopathy) or >69	BAL 300–450 mg/m^2/d[a] and	50–75 mg/m^2 every 4 h for 3–5 d (base dose, duration on BPb, severity of symptoms; see text)
	CaNa$_2$EDTA 1000–1500 mg/m^2/d[a]	Continuous infusion or two to four divided IV doses for 5 d (start 4 h after BAL)
		Lab: Baseline AXR, CBC, Ca, BLL, BUN, Cr, LFTs, U/A; repeat CBC, Ca, BUN, Cr, LFTs, U/A on days 3 and 5 and BLL day 5
Asymptomatic: 45–69	Succimer 700–1050 mg/m^2/d[a] or	350 mg/m^2 tid for 5 d and then bid for 14 d
		Lab: Baseline AXR, CBC, BLL, LFTs; repeat CBC, LFTs, BLL day 7 and 21
	CaNa$_2$EDTA, 1000 mg/m^2/d[a]	Continuous infusion or two to four divided IV doses for 5 d (see text)
		Lab: Baseline AXR, CBC, Ca, BLL, BUN, Cr, LFTs, U/A; repeat Ca, BUN, Cr, LFTs, U/A on days 3 and 5 and BLL on day 5
	(*or rarely,* d-Penicillamine)	–
20–44	Routine chelation not indicated (see text)	If succimer used, same regimen as per above group
	Attempt exposure reduction	(see Table 94-7)
<20	Chelation not indicated	
	Attempt exposure reduction	(see Table 94-7)

[a] Subsequent treatment regimens should be based on postchelation BPb and clinical symptoms (see text).

Approximately equivalent doses are expressed in mg/kg: BAL 450 mg/m^2/d ($\sim$24 mg/kg/d); 300 mg/m^2/d ($\sim$18 g/kg/d)

CaNa$_2$EDTA 1000 mg/m^2/d ($\sim$25–50 mg/kg/d); 1500 mg/m^2/d ($\sim$50–75 mg/kg/d); Adult maximum dose 2–3 g/d; Succimer 350 mg/m^2 ($\sim$10 mg/kg)

[b] Some clinicians recommend CaNa$_2$EDTA alone in these contexts (see text).

AXR, abdominal radiography; BLL, blood lead level; BPb, venous blood lead; BUN, blood urea nitrogen; Ca, calcium; CaNa$_2$EDTA, edetate calcium disodium; CBC, complete blood count; Cr, creatinine, CT scan, computed tomography scan of the brain; IM, intramuscular; IV, intravenous; Lab = suggested laboratory and radiologic evaluation; LFTs, hepatic aminotransferases; U/A, urinalysis with microscopy (frequent monitoring of urine dipstick analysis for hematuria and proteinuria also advised during CaNa$_2$EDTA therapy).

Modern approaches to the *management of cerebral edema and increased intracranial pressure (ICP)* have not as yet been critically evaluated in the currently rare context of lead encephalopathy. Lumbar puncture should probably be avoided if lead encephalopathy is highly suspected and acute infectious processes are not (of note, repeated lumbar puncture was used as an adjunct to the treatment of lead encephalopathy associated with increased ICP in the 1950s but was complicated by proximate death when signs of impending herniation were present[34]). It seems reasonable that noninvasive measures such as prevention of hypoxia and hypercarbia with tracheal intubation and controlled ventilation, seizure treatment and prophylaxis, maintenance of adequate cerebral perfusion pressure, mild hyperventilation with PCO$_2$ of 30 to 35 mm Hg, and neutral head positioning with elevation

of the head of the bed to 30 degrees might have a salutary effect at minimal risk of increased iatrogenic morbidity.[2,153] Mannitol administration may prove beneficial in deteriorating patients and has been particularly suggested as an adjunctive therapy when cerebral edema is complicated by SIADH or impaired renal function.[33] Whether more aggressive measures, such acute hyperventilation for impending herniation, intracranial pressure monitoring, drainage of ventricular cerebrospinal fluid, induced hypothermia, or barbiturate coma would decrease mortality or morbidity further is unknown.

For children with *milder symptoms or who are asymptomatic with BLL > 70 μg/dL*, chelation with a two-drug regimen similar to that used for encephalopathy is recommended. It is likely that this group of patients will require only 2 to 3 days of BAL in addition to 5 days

of CaNa$_2$EDTA. Some authors have suggested that asymptomatic patients in this group, particularly those with BLLs below 100, might also be adequately treated with CaNa$_2$EDTA alone,[172] succimer plus CaNa$_2$EDTA, or even succimer alone, but these regimens have not been studied in such children. Intensive care monitoring may be prudent for such patients as well, at least during the initiation of chelation therapy.[102]

Chelation therapy is widely recommended for *asymptomatic children with BLLs between 45 and 70 μg/dL.*[2,5,22,102] Children without overt symptoms may be treated with succimer alone, which has documented efficacy in lowering BLLs and short-term safety since its approval by the Food and Drug Administration in 1991.[58,82] Succimer is initiated at 30 mg/kg/d (or 1050 mg/m^2/d) orally in three divided doses; this is continued for 5 days and then decreased to 20 mg/kg/d (or 700 mg/m^2/d) in two divided doses for 14 additional days.[2,57] The original data establishing this empiric dosing regimen were based on surface area rather than body weight.[57] For younger children, the alternative dosing by body weight results in suboptimal dosing.[126] Although the ability to chelate children orally with succimer makes it tempting to prescribe routinely for outpatient therapy and some animal evidence suggests succimer does not enhance enteral lead absorption,[72] clinical reports suggest that children must be protected from continued lead exposure during succimer chelation.[30,32] Home abatement and reinspection should be accomplished before initiation of ambulatory succimer therapy; if this is not feasible, hospitalization is still warranted. Alternative regimens (for rare patients with succimer intolerance or allergy or because of parental noncompliance) include inpatient parenteral chelation with CaNa$_2$EDTA at 25 mg/kg/d for 5 days[2] or an outpatient oral course of D-penicillamine.

After initial chelation therapy, decisions to repeat treatment are based on clinical symptoms and follow-up BLLs. Patients with encephalopathy or any severe symptoms or with an initial BLL above 100 μg/dL often require repeated courses of treatment. It is suggested that at least 2 days elapse before restarting chelation. The precise regimen and dosing of chelating agents are determined by ongoing symptomatology and the repeat BLLs (see Table 94–8). A third course of chelation should rarely be necessary sooner than 5 to 7 days after the second course ends.[115] For patients with milder degrees of plumbism (eg, asymptomatic, initial BLL <70 μg/dL), it is reasonable to allow 10 to 14 days of reequilibration before restarting treatment.[2]

The management of *asymptomatic children with BLLs of 20 to 44 μg/dL* is controversial.[30,91,101,157] The National Institutes of Health–sponsored Treatment of Lead-exposed Children (TLC) trial found only modest efficacy of succimer in reducing BLL. Furthermore, at 3 years postenrollment, no benefit was noted in treated patients on measures of cognition, neuropsychiatric function, or behavior.[128] This large study enrolled 780 children in a multicenter, randomized, placebo-controlled, double-blind trial, but it still has been criticized, particularly for using a single chelating agent and having failed to lower BLL significantly over time between treated and control groups.[141] Of note, small but statistically significant decrements in growth velocity were noted in the treatment group, which might reflect trace mineral depletion.[114] Since its initial publication, the primary findings of the TLC trial on lack of cognitive improvement were confirmed in a 7-year follow-up study.[40] In addition, a reanalysis of the original data found that decreasing blood concentrations did correlate with improved cognitive scores over the initial 36-month trial period (~4 IQ points for each 10-μg/dL decrease in BLL), but only in the placebo group.[87] Nevertheless, there may still be potential indications for occasional chelation treatment in this group, including BLLs at the higher end of the range (eg, 35–44 μg/dL), especially if BLLs remain the same or increase over several months after rigorous environmental controls are instituted, in younger children (eg, younger than 2 years old), in children with evidence of biochemical toxicity (an elevated erythrocyte protoporphyrin concentration, after iron supplementation, if necessary), or any hint of subtle symptoms. Some clinicians suggest that a reduced dose regimen of D-penicillamine be considered for children with BLLs in this range. One retrospective study reviewed medical records for 55 children, with a mean BLL of 24 μg/dL, treated with 15 mg/kg/day of D-penicillamine in addition to lead hazard abatement. The treatment period averaged 77 days and achieved mean BLL of 16 μg/dL at the end of therapy, with few noted adverse effects.[143] Further study of such therapy on long-term BLLs and clinical outcomes is certainly warranted. Currently, the CDC[20] and the American Academy of Pediatrics[2,3] recommend aggressive environmental and nutritional interventions with close monitoring of blood lead concentrations, without routine chelation therapy, for such children.

BLLs of 10 to 19 μg/dL are defined by the CDC as representing excessive exposure to lead but do not require chelation therapy. Close monitoring (for the 10–14 μg/dL range) and careful environmental investigation and interventions as necessary (particularly for the 15–19 μg/dL range) are appropriate and sufficient.[2,3,22] The educational approaches outlined earlier should be included in the case management of all children with even modestly elevated lead levels (see Table 94–7).

■ ADULT THERAPY

General Considerations The first principle in the treatment of adults with lead poisoning is that chelation therapy may not substitute for adherence to OSHA lead standards at the worksite and should never be given prophylactically.[39,74] In addition to the guidelines for decreasing lead exposure noted earlier, chelation therapy is indicated for adults with significant symptoms (encephalopathy, abdominal colic, severe arthralgias, or myalgias), evidence of target organ damage (neuropathy or nephropathy), and possibly in asymptomatic workers with markedly elevated BLLs or evidence of biochemical toxicity or increased chelatable lead.[78,124,135,140] Table 94–8 outlines suggested chelation therapy regimens for adults. For encephalopathic adult patients, our practice is to recommend combined BAL and CaNa$_2$EDTA therapy, just as for children, although some clinicians suggest that adults with severe lead poisoning may be successfully treated with CaNa$_2$EDTA alone in doses of 2 to 4 g/day by continuous IV infusion.[76] Recent reports support the use of succimer in adult patients with mild to moderate plumbism after environmental and occupational remedies have been instituted.[83,118] Chelation therapy should also be considered in the perioperative period for patients undergoing surgical removal of retained bullets or debridement of adjacent lead-contaminated tissue.[85,98,139] Treatment of patients with acute TEL toxicity is largely supportive, with sedation as necessary. For patients seen soon after a large-volume ingestion, nasogastric suction, with airway protection as needed, may be warranted. In general, chelation therapy for TEL toxicity has been associated with enhanced lead excretion[12] but has not been found clinically efficacious.[135,155,171] However, for symptomatic, especially encephalopathic patients with very elevated BLLs (in whom there may be a significant component of metabolically derived inorganic lead toxicity), we strongly consider chelation therapy.

Pregnancy, Neonatal, and Lactation Issues An area of particular concern in the management of adult plumbism involves decisions regarding therapy during pregnancy. As noted previously, lead freely passes the placental barrier and accumulates in the fetus throughout gestation. Chelation therapy during early pregnancy poses theoretical problems of teratogenicity, particularly that caused by enhanced fetal excretion of potentially vital trace elements, or translocation of lead

from mother to fetus (see also the relevant Antidotes in Depth A26, A27, A28). Symptomatic pregnant women with elevated BLLs certainly warrant chelation therapy, regardless of these concerns. Additionally, of some reassurance regarding fetal health, a recent case series and 25-year literature review of lead poisoning during pregnancy found no reports of chelation-associated birth defects in the handful of such published cases.[142] It should be noted that despite decreases in maternal BLL with chelation therapy, newborn BLLs may be considerably higher and, in some cases, may approximate the pretreatment maternal BLL, implying limited efficacy for in utero fetal chelation. However, in these cases, the newborn's hemoglobin level was generally much higher than the mother's, and thus some of the maternal–neonatal difference in lead concentrations may simply reflect this difference in hemoglobin concentration and hence total blood lead content. In general, there currently seems little support for routine chelation therapy in pregnant women who would not otherwise warrant treatment based on their own symptoms or degree of elevated BLL. Calcium carbonate supplementation may be considered because its use is associated with decreased bone resorption during pregnancy and thus possibly lessened fetal lead exposure.[68]

Postnatally, infant BLLs may decline over time without chelation, but this occurs very slowly.[131] In two reported neonates exposed to prenatal maternal chelation who were then monitored for 2 weeks postpartum, the BLL remained stable or increased until chelation therapy was instituted.[113,156] In two additional cases of neonates whose mothers were not treated prepartum, BLLs also remained stable or increased for 17 days to 3 weeks.[50,150] Thus, postpartum chelation therapy is warranted for neonates, depending on BLLs, as per the guidelines described above for older children. Exchange transfusion might be considered for neonates with extremely elevated BLLs.[13] Succimer chelation therapy has also been reported for one neonate whose exposure was presumably caused by organolead via maternal gasoline sniffing.[119]

Lastly, the issue of allowing mothers with elevated BLLs to breastfeed their infants may arise. Breast milk from heavily exposed mothers may be a potential source of lead exposure and may require lead concentration analysis before breastfeeding can be safely recommended.[9,44] One small case series found that breast milk from two women with BLLs of 34 and 29 µg/dL, respectively, had clinically insignificant lead content (<0.01 µg/mL).[9] Breast milk analysis may be warranted in some cases, particularly with BLLs of 35 µg/dL or greater, before safely advising continued nursing. Despite these considerations, the majority of women without excessive lead exposure should still be encouraged to breastfeed. Of note, one study has found that a relatively simple intervention, calcium supplementation (1200 mg/day of elemental calcium as calcium carbonate), reduces breast milk lead content by 5% to 10%.[45]

SUMMARY

Lead is a widely distributed element that has long been used by humans for a variety of purposes, including waterproofing; electrical and radiation shielding; and the production of ammunitions, paints, plastics, ceramics, glass, and explosives. Lead poisoning, or plumbism, has an equally long history, but today it primarily manifests as an important environmental health problem for young children exposed to deteriorated lead paint and as an occupational toxic exposure for adult workers, although numerous other exposure sources are continually reported.

Lead causes multiorgan toxicity, affecting especially the hematologic and neurologic systems in patients of all ages and renal injury with hypertension in adults. This may result in a broad spectrum of clinical effects ranging from subtle neurocognitive effects to vague constitutional symptoms without overt physical signs to acute encephalopathy

with potentially fatal cerebral edema and increased intracranial pressure. Several techniques have been used to estimate increases in body lead burden, but currently, the measurement of whole-blood lead concentration is favored.

The mainstays of treatment are removal from exposure and chelation therapy for patients with symptoms or significantly elevated body lead burdens. Defining a group of asymptomatic patients that will benefit from chelation therapy has been difficult and controversial. Parenteral chelation with CaNa$_2$EDTA and BAL is efficacious in lowering BLLs and reducing mortality and morbidity from severe lead poisoning. Succimer, an oral chelator, also has efficacy in reducing BLLs in asymptomatic children.

SUCCIMER (2,3-DIMERCAPTOSUCCINIC ACID)

Mary Ann Howland

Succimer
2,3-Dimercaptosuccinic acid

DMPS
2,3-Dimercapto-1-propanesulfonic acid
Succimer (meso-2,3-dimercaptosuccinic acid) is an orally active metal chelator that is approved by the Food and Drug Administration (FDA) for the treatment of lead poisoning in children with blood lead concentrations greater than 45 µg/dL. Succimer is also used to treat patients poisoned with arsenic and organic and inorganic mercury. Succimer has a wider therapeutic index and exhibits many advantages over dimercaprol and edetate calcium disodium (CaNa$_2$EDTA), the two other chelators used for the same clinical problems. Animal studies suggest that succimer does not redistribute lead or arsenic to the central nervous system (CNS). The role of succimer alone and in conjunction with other chelators to treat lead encephalopathy continues to be defined.[61,74]

HISTORY

Succimer was initially synthesized in 1949 in England.[72] In 1954, antimony-a,a′-dimercaptopotassium succinate (TWSb) was developed to treat schistosomiasis.[43] TWSb is antimony bound to the potassium salt of succimer in a 2:3 ratio, forming a water-soluble xenobiotic with 50 times less toxicity than the previously used antimony compound, tartar emetic. Several years later, a group from Shanghai demonstrated the ability of the sodium salt of succimer to increase the median lethal dose for 50% of test subjects (LD$_{50}$) of tartar emetic 16-fold in mice.[109] An early review of the Chinese experience with intravenous (IV) succimer in the treatment of occupational lead and mercury poisoning suggested efficacy similar to IV CaNa$_2$EDTA in increasing urinary lead and to intramuscular (IM) DMPS (racemic-2,3-dimercapto-1-propanesulfonic acid, unithiol) for mercury, with little observed toxicity.[105] This experience, the subsequent widespread use in Asia[76,79,90,105,106,111] and Europe,[17,34,41,44,64,99] and the realization that succimer could be used orally,[7,50] led to US-based animal experiments, human trials, and FDA approval in 1991 for the treatment of lead-poisoned children.

PHARMACOLOGY AND PHARMACOKINETICS

Succimer is a white crystalline powder with a molecular weight of 182 daltons and a characteristic sulfur odor and taste.[6] Succimer is the meso form of 2,3-dimercaptosuccinic acid; the racemic form is being investigated.[38] Because it contains four ionizable hydrogen ions, succimer has four different pK$_a$s—2.31, 3.69, 9.68, and 11.14—with the dissociation of the two lower values representing the carboxyl groups and the two higher values the sulfur groups.[4] Lead and cadmium bind to the adjoining sulfur and oxygen atoms, whereas arsenic and mercury bind to the two sulfur moieties, forming pH-dependent water-soluble complexes (see Fig. A27–1).[86] Succimer is highly protein bound to albumin through a disulfide bond. Subhuman primate studies of IV and oral ^{22}C succimer indicate that following an IV dose, radiolabel is eliminated almost exclusively via the kidney, with only trace amounts (less than 1%) excreted via feces or expired air.[72] Following the administration of a single oral dose of 10 mg/kg, succimer is rapidly and extensively metabolized.[69] Approximately 20% of the administered oral dose is recovered in the urine, presumably reflecting the low bioavailability of the drug.[10] Of the total drug eliminated in the urine, 89% is altered and in the form of disulfides of l-cysteine. The majority of the altered succimer is in the form of a mixed disulfide with two molecules of l-cysteine to one molecule of succimer.[8] The remaining 11% is excreted as unaltered free succimer.[69] Maximal excretion of succimer occurs in urine specimens collected between 2 and 4 hours after administration. Surprisingly, the blood only contains albumin-bound succimer and no evidence of the altered disulfide moieties, which suggests that the kidney may be involved in the biotransformation of succimer.

The pharmacokinetics of a single oral dose of succimer were determined in three children and three adults with lead poisoning, and in five healthy adult volunteers.[33] Children received 350 mg/m^2 of succimer, and adults received 10 mg/kg of succimer. The peak concentration and the time to peak blood concentration of total succimer (parent versus altered oxidized metabolites) were similar for all three groups. The half-life of total succimer was 1.5 times longer in the children than in either adult group. The renal clearance of total succimer was greater in healthy adults than in lead-poisoned patients. Distribution of succimer (parent and/or oxidized metabolites) into erythrocytes appeared greater in poisoned patients than in the healthy adults.[33]

The metabolism of succimer was studied in lead-poisoned children and in normal adults.[15] The results indicate that succimer undergoes an enterohepatic circulation facilitated by gastrointestinal (GI) microflora. Similar to the previous pharmacokinetic study, moderate lead exposure impaired the renal elimination of succimer.

USE FOR LEAD EXPOSURE

In addition to precise analysis of metal elimination kinetics, measures of clinical outcome are essential for an understanding of the utility of this chelator. The Treatment of Lead-Exposed Children (TLC) trial was a step in that direction.[102] The TLC trial was a randomized, multicenter, double-blind, placebo-controlled, ongoing study to examine the effects of succimer on cognitive development, behavior, stature, and blood pressure in children 1 to 3 years old with blood lead concentrations between
FIGURE A27–1. The chelation of cadmium, lead, and mercury with succimer.

20 and 44 µg/dL. In 2000 no beneficial effects on neuropsychological tests administered to those children was reported.[101] A follow-up study also demonstrated that although succimer lowered average blood lead concentrations, no beneficial effects on neuropsychological and behavioral development could be demonstrated in those children at 7 years old.[35] A case study showed similar results.[20] Similarly succimer showed no benefit on growth in children aged 12 to 33 months with blood lead concentrations of 20 to 44 µg/dL.[83]

Several groups are studying the efficacy of succimer in reducing blood, brain, and tissue lead by using rat and nonhuman primate models of childhood and adult lead poisoning.[91,92,94] Although monkeys most closely resemble humans in their lead-associated toxicity, using them in studies is costly[78]; the rat model is economical but limited because of species differences in lead and succimer metabolism and efficacy.

The validity of using blood lead concentrations as a marker of brain lead was studied in the adult rhesus monkey. Lead was administered orally for 5 weeks to achieve a target blood lead concentration of 35 to 40 µg/dL.[32] Five days after lead exposure ceased, succimer chelation was initiated in the currently approved dosage regimen. Two IV doses of radioactive lead tracer were administered prior to succimer chelation to study the kinetics of recent versus chronic lead uptake and distribution. Four areas of the brain, as well as blood and bone, were assayed for lead. Merely stopping further lead exposure significantly reduced blood lead concentrations by 63% and brain lead concentrations by 34% compared with pretreatment concentrations, and was not statistically different from succimer administration after halting exposure. However, when an integrated area under the serum lead concentration versus time curve (AUC) blood analysis was used over the 19-day succimer treatment course, instead of a single blood lead concentration, the differences between succimer and control were statistically significant. The clinical significance of these differences is unclear. Succimer-treated animals showed the greatest drop in blood lead concentrations over the first 5 days, while a similar end point was gradually achieved in the control. The lead from both the recent exposure (radioactive tracer lead) and chronic exposure declined to the same extent, independent of treatment with succimer. A better correlation was found between brain prefrontal cortex lead concentrations and an integrated blood lead analysis than with a single blood lead measurement.

Similarly, a study in neonatal rats demonstrated that increasing the duration of succimer chelation from 7 to 21 days decreased brain lead concentrations without a corresponding decrease in blood lead concentrations.[91] The authors proposed that a slow rate of egress of brain lead to the blood was responsible for the demonstrable benefit of prolonging therapy to 21 days. In this study, succimer decreased blood lead concentration by approximately 50% when compared to the vehicle as control, and this difference persisted for the 21 days of treatment. With succimer treatment, brain lead concentration decreased by 38% at 7 days and by 68% at 21 days. This same group also demonstrated that rats exposed to lead from postnatal day 1 to 30, then treated with succimer, demonstrated reductions in blood and brain lead concentrations and an improvement in cognitive deficits.[95]

revious animal studies demonstrated the ability of succimer to enhance urinary lead elimination[42,50,94] and to reduce blood,[16,30,39,40,55,81,92, 94,96,98] brain,[16,30,81,97,98] liver,[94] and kidney lead concentrations,[16,30,39,55,81,98] while either reducing[16,55,81,98] or demonstrating no effect on bone lead concentrations.[30,94] These studies differ in the amounts and duration of lead administration prior to chelation, as well as in route, dose, and duration of chelation, but several months after a course of succimer chelation, tissue lead concentrations had returned to concentrations found in the pretreatment stage.[30] Given the limited absolute amount of lead that is actually eliminated by chelation in comparison to the total body burden, particularly bone, these transient effects are not surprising.

Under a variety of experimental conditions in animals, succimer prevents the deleterious effect of lead on heme synthesis,[16,50,81] blood pressure,[59] and behavior.[96]

Published studies of the use of succimer in both children and adults with chronic lead poisoning demonstrated consistent findings.[18,27,51–53,65,77] During the first 5 days of succimer chelation (1050 mg/m²/d in children, 30 mg/kg/d in adults both in 3 divided doses), the blood lead concentration dropped precipitously by approximately 60% to 70%. This blood lead concentration remained unchanged during the next 14 to 23 days of continued therapy. Increases in urinary lead excretion are concurrent with the drop in blood lead concentration, with maximal excretion occurring on day 1.[27,52] Calculations indicate that urinary lead excretion exceeds estimated blood content. This suggests that some lead is being removed from soft tissues as a concentration gradient is established from tissue to blood to urine.[27,53] Typically, 2 weeks after the completion of succimer, blood lead concentration rebounds to values 20% to 40% lower than pretreatment values. In the one randomized, double-blind, placebo-controlled trial of succimer use in children with pretreatment blood lead concentrations of 30 to 45 µg/dL, follow-up at 1 month and at 6 months showed no differences between succimer-treated children and controls.[77] Succimer restores red blood cell D-aminolevulinic acid dehydratase (ALA-D) activity, decreases erythrocyte protoporphyrin, and decreases urinary excretion of D-aminolevulinic acid and coproporphyrin.[18,27,52,53,77]

There is a large body of evidence reporting on the usage and safety profile of succimer in adults with chronic lead poisoning. [13,17,27,41,44, 45,48,49,60,62,70,84,100,103] The published experience outside the United States with the use of oral succimer for metal poisoning includes nearly 100 adult cases and contributes considerably to the supporting evidence. At least 74 additional individuals have been successfully treated parenterally (IM or IV) with the sodium salt of succimer.[13,17,41,44]

USE FOR LEAD ENCEPHALOPATHY

The experience with the use of succimer in severely lead-poisoned subjects, including those with encephalopathy, is very limited.[41,44,52] Three children with mean blood lead concentrations of greater than 70 µg/dL who were treated with 5 days of succimer achieved comparable declines in blood lead concentration to two similar children who had been treated previously with a combination of British anti-Lewisite (BAL) for 3 days and CaNa₂EDTA for 5 days.[52] Three adult patients with encephalopathy achieved significant improvement following succimer chelation.[41] A 3-year-old child with a massive lead exposure superimposed on chronic lead poisoning and a blood lead concentration of 550 µg/dL was given BAL and CaNa₂EDTA for 5 days, with whole-bowel irrigation (WBI) performed on the first 3 days and succimer following WBI beginning on day 3 and continuing for 19 days. The blood lead concentration dropped from 550 µg/dL to 70 µg/dL on day 5, but rebounded to 99 µg/dL 2 days after BAL and CaNa₂EDTA, but not the succimer, were discontinued.[47]

USE OF SUCCIMER FOR ARSENIC EXPOSURE

Succimer has been used for arsenic toxicity in China and the Soviet Union since 1965.[7,13] Animal studies with sodium arsenite and lewisite demonstrate the ability of succimer to improve the LD_{50} with a good therapeutic index, lack of redistribution of arsenic to the brain as compared to BAL or control, and reduced kidney and liver arsenic concentrations.[7,13,63,82,87] A few case reports attest to the ability of succimer to enhance the urinary excretion of arsenic[31,88] and presumably normalize urinary arsenic concentrations following ingestion of arsenic trioxide ant bait by toddlers.[107] A randomized, placebo-controlled trial of succimer to treat 21 patients with chronic arsenic poisoning in India demonstrated improved clinical results and enhanced urinary excretion in both the treatment and placebo groups, but no statistical differences could be demonstrated.[71] A comparison of BAL, succimer, and DMPS as arsenic antidotes demonstrated higher therapeutic indices for succimer and DMPS over BAL in chronic arsenic poisoning.[75]

USE OF SUCCIMER FOR MERCURY EXPOSURE

Succimer enhances the elimination of mercury and has been used to treat patients poisoned with inorganic, elemental, and methylmercury. It improves survival, decreases renal damage, and enhances elimination of mercury in animals following exposure to inorganic mercury[4,22,55,58,66,85,110] and methylmercury.[1,2,9,67] However, one study in mice subjected to intraperitoneal mercuric chloride demonstrated an enhanced deposition of mercury in motor neurons following chelation with succimer or DMPS.[37] Of 53 construction workers who were exposed to mercury vapor, 11 received succimer and *N*-acetyl-*d,l*-penicillamine in a crossover study.[21] Mercury elimination was increased during the period of succimer administration compared with the period of *N*-acetyl-*d,l*-penicillamine administration. Because the chelators were administered for only 2 weeks and late in the clinical course, therapeutic benefit could not be evaluated. When succimer was given to victims of an extensive Iraqi methylmercury exposure, blood methylmercury half-life decreased from 63 days to 10 days.[7]

ADVERSE EFFECTS AND SAFETY ISSUES

Succimer is generally well tolerated with few serious adverse events reported.[27,28] Common adverse effects are gastrointestinal in nature, including nausea, vomiting, flatus, diarrhea, and a metallic taste in 10% to 20% of patients. Mild elevations in aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are reported.[26,28,53,65,80] A single patient developed severe hyperthermia and hypotension reportedly related to succimer administration.[80] Rarely, chills, fever, urticaria, rash, reversible neutropenia, and eosinophilia are reported.[18,27,28,48] During the latest open-label prospective study in children, apparently unrelated adverse events included an elevation in bone-derived alkaline phosphatase, eosinophils, and elevated serum aminotransferases.[27]

The Chinese have reported a high incidence of more serious adverse effects (including dizziness and weakness) in response to IV or IM succimer.[106,111] This discrepancy is undoubtedly related to the substantially greater dose of succimer delivered from parenteral administration compared with the relatively low (approximately 20%)[72] oral bioavailability of succimer as a result of first-pass metabolism.

Incidental chelation of essential elements is always a concern with the use of chelators. A number of studies using succimer demonstrate no rise in urinary zinc, copper, iron, or calcium.[27,41,44,51–53] Urinary excretion of essential elements was the focus of a study in a primate model of childhood lead exposure.[92] Infant rhesus monkeys were exposed to lead

for the first year of life to achieve blood lead concentrations of 40 to 50 μg/dL. Succimer was administered in the standard dosage regimen and complete urine collections over the first 5 days were analyzed for calcium, cobalt, copper, iron, magnesium, manganese, nickel, and zinc. Only when the data were analyzed collectively for all eight elements on all 5 days was there a statistically significant increased urinary elimination. These results raise concern that children subjected to repeated succimer chelation may also be at risk for enhanced elimination of essential elements.[27,92,94] An obvious concern regarding the safety of succimer is that there is still relatively limited clinical experience with the xenobiotic, particularly with regard to long-term administration.

One concern with administering succimer orally is that outpatient management might permit continued unintentional lead exposure and the possibility for succimer-facilitated lead absorption. Studies with D-penicillamine, dimercaprol,[56] and $CaNa_2EDTA$ demonstrate enhanced lead absorption and elevated blood lead concentrations.

Most blood lead concentrations are measured by graphite furnace atomic absorption spectrophotometry, in which case succimer does not interfere with the measurement. However, if blood lead concentrations were to be measured by anodic stripping voltammetry, succimer would affect the results by chelating the mercury in the electrode.[24] Succimer may cause a false-positive result for urinary ketones when tests using nitroprusside reagents (eg, Ketostix) are used, and a falsely decreased serum uric acid and creatine phosphokinase (CPK) may occur.[24]

Animal studies suggest that succimer does not promote lead retention in the setting of continued exposure unless lead exposure is overwhelming.[50,57,81] A radiolabeled lead tracer administered to adult volunteers suggested that succimer increased the net absorption of lead from the GI tract and may have distributed it to other tissues, as well as having enhanced urinary elimination.[93] Absorption is bimodal and consistent with an initial phase, followed by a delayed increase attributable to an enterohepatic effect. It may be that succimer-enhanced urinary lead elimination often exceeds enhanced lead absorption.[82] One study reported two children with environmental exposure and dramatic rises in blood lead concentration while receiving succimer.[27] In the event of unintentional exposure to a new lead source, decontamination of the GI tract should complement oral succimer.[73]

Although iron supplementation cannot be given concomitantly with BAL, because the BAL–iron complex may be a potent emetic, iron has been given concomitantly to patients receiving oral succimer without any adverse effects.[54] The prevalence of both iron deficiency and elevated blood lead concentrations is highest among poor, inner-city children.[68] Because heme is a constituent of all cells, including those of the brain, it appears clinically prudent to provide iron supplementation during chelation therapy, when the heme pathway is freed of the inhibitory effects of lead. The timing of administration of the iron should be separate from administration of the succimer.[27]

A case report describes a 3-year-old child who reportedly ingested 185 mg/kg of succimer and was asymptomatic.[89]

USE IN PREGNANCY

The use of succimer in pregnancy is restricted to women who warrant therapy based on their symptoms.[27] There was a dose-dependent effect of succimer on early and late fetal resorption and on fetal body weight and length when succimer was administered to pregnant mice during organogenesis. No observed teratogenic effects were noted when 410 mg/kg, or approximately 5% of the acute LD_{50}, of succimer was administered subcutaneously.[36] However, doses of 410 to 1640 mg/kg/d of succimer administered subcutaneously to pregnant mice during organogenesis is teratogenic and fetotoxic, and doses of more than 510 mg/kg/d to pregnant rats also showed problems with reflexes in the

offspring.[24] Succimer 30 to 60 mg/kg/d was administered by gavage to lead-poisoned rats from day 6 to day 21 of gestation.[25] These doses of succimer decreased embryonic and fetal blood lead concentrations and normalized offspring body weight at 13 weeks. Although succimer was able to reverse some lead-induced immunotoxic effects, succimer itself caused problems with the immune system that persisted into adulthood.[25] Female mice exposed to lead in utero and then administered succimer from the fourth day of gestation to parturition demonstrated decreased blood lead concentrations; however, fetal liver and bone concentrations increased and worsened neural development in the offspring.[108]

COMBINED CHELATION THERAPY

Succimer can be combined with $CaNa_2EDTA$ to take advantage of the ability of succimer to remove lead from soft tissues, including the brain, while capitalizing on the ability of $CaNa_2EDTA$ to mobilize lead from bone.[30] A number of rodent models have examined this combination and found it to be superior in enhancing the elimination of lead, in reducing tissue concentrations of lead, and in restoring some lead-induced biochemical abnormalities.[39,40,97] Although the addition of succimer to $CaNa_2EDTA$ prevented the redistribution of lead to the brain caused by $CaNa_2EDTA$ alone, the combination also increased urinary excretion of zinc, calcium, and iron.[97,98] A retrospective review comparing dimercaprol plus $CaNa_2EDTA$ to succimer plus $CaNa_2EDTA$ in children with blood lead concentrations greater than 45 μg/mL, demonstrated a similar reduction in blood lead concentrations at the end of treatment and at 14 and 33 days following the termination of treatment.[19] Blood lead concentration reductions were approximately 75%, 40%, and 37% at the end of therapy, and at 14 and 33 days posttreatment, respectively. The succimer plus $CaNa_2EDTA$ combination was better tolerated.

DMPS

DMPS (racemic-2,3-dimercapto-1-propanesulfonic acid, Na salt) is a chelator that, like succimer, is a water-soluble analog of BAL.[7,9,23] A dose of 15 mg/kg of DMPS is equimolar to 12 mg/kg of succimer. DMPS was used in the Soviet Union since the late 1950s and continues to be used in Russia and other former Soviet countries. DMPS, which is an investigational drug in the United States, is marketed in both oral and parenteral forms in Germany as Dimaval. DMPS seems promising in mercury and arsenic poisoning.[3,5,7,9,11,14,23,46] DMPS is associated with an increase in the urinary excretion of copper and the development of Stevens-Johnson syndrome.[26,104] Like succimer, DMPS does not appear to redistribute mercury or lead to the brain. More research is needed to determine whether DMPS is more advantageous than succimer, given its lower LD_{50} in rodents (5.22 mmol/kg versus 16.5 mmol/kg for succimer).

DOSING AND AVAILABILITY

Succimer (Chemet) is available as 100-mg bead-filled capsules. For patients who cannot swallow the capsule whole, it can be separated immediately prior to use and the contents sprinkled into a small amount of juice or on apple sauce, ice cream, or soft food, or placed on a spoon and followed by a fruit drink. The dosage is 350 mg/m² in children, three times a day for 5 days, followed by 350 mg/m² twice a day for 14 days. In adults, the dosage is 10 mg/kg three times a day for 5 days followed by 10 mg/kg twice a day for 14 days. At approximately 5 years of age, dosing based on body surface area approximates the 10 mg/kg dose, while for children less than 5 years of age dosing by body surface area, as was done during the premarketing trials, gives higher doses and is recommended.[29,74]

Tables A27–1 A and B

>100	>45	500	5

ᵃ To be administered every 8 hours for 5 days, followed by dosing every 12 hours for 14 days.

SUMMARY

Succimer (meso-2,3-dimercaptosuccinic acid) is an orally active metal chelator that is FDA approved for the treatment of lead poisoning in children with blood lead concentrations greater than 45 μg/dL. There is no evidence at this time that succimer improves cognitive tests in patients with blood lead concentrations less than 45 μg/dL.[29]

Succimer is also used to treat patients poisoned with arsenic and organic and inorganic mercury. Succimer has many advantages over dimercaprol and $CaNa_2EDTA$, the two other chelators used for the same clinical problems. The advantages of succimer use include oral administration; limited effects on trace metals such as zinc; enhanced patient tolerance; limited toxicity; the ability to coadminister iron, if needed; and no contraindication in glucose-6-phosphate dehydrogenase–deficient individuals.[27] In contrast to $CaNa_2EDTA$, succimer does not redistribute lead to the brain of poisoned animals.[11,30] The role of succimer alone and in conjunction with other chelators to treat lead encephalopathy continues to be defined.[61,74]

EDETATE CALCIUM DISODIUM (CaNa$_2$EDTA)

Mary Ann Howland
Edetate calcium disodium (CaNa$_2$EDTA) is a chelating agent that is primarily used for the management of severe lead poisoning. Edetate calcium disodium has been replaced by succimer (2,3-dimercaptosuccinic acid) for the treatment of patients with lead concentrations between 45 and 70 µg/dL. Although, in conjunction with dimercaprol, CaNa$_2$EDTA retains a critical role in the management of serious lead poisoning and lead encephalopathy.

CHEMISTRY

Edetate calcium disodium belongs to the family of polyaminocarboxylic acids. Although it is capable of chelating many metals, its current use is almost exclusively in the management of lead poisoning. The term *chelate* has its origin in the Greek word *chele*, which means "claw," implying an ability to tightly grasp the metal.[42] Implicit in chelation is the formation of a ring-structured complex. When CaNa$_2$EDTA chelates lead, the calcium is displaced and the lead takes its place, forming a stable ring compound.[27]

PHARMACOKINETICS

Edetate calcium disodium is an ionic, water-soluble compound with a molecular weight of 374 daltons. The volume of distribution is small (0.05–0.23 L/kg), and due to its polar nature approximates that of the extracellular fluid compartment in normal individuals,[22,27] but is smaller in patients with renal dysfunction.[33] Edetate calcium disodium appears to penetrate erythrocytes poorly,[2,22] and less than 5% of CaNa$_2$EDTA gains access to the spinal fluid.[22,27] Oral administration of CaNa$_2$EDTA is not practical because of an oral bioavailability of less than 5%. The half-life is about 20 to 60 minutes.[4,22,27] Renal elimination approximates the glomerular filtration rate,[32] which correlates with creatinine clearance,[33] and results in the excretion of 50% of CaNa$_2$EDTA in the urine within 1 hour, and more than 95% within 24 hours.[22,27] When CaNa$_2$EDTA combines with lead, it forms a stable, soluble, nonionized compound that is subsequently excreted in the urine. Following CaNa$_2$EDTA administration, urinary lead excretion is increased 20- to 50-fold.[9,34]

LEAD

■ ANIMALS

Animal studies demonstrate a decrease in tissue lead stores, including brain concentrations, when measurements are performed following CaNa$_2$EDTA therapy.[25] A rat study examining the effect of a single dose of CaNa$_2$EDTA on brain lead concentrations demonstrated a significant increase in brain lead concentrations,[17] suggesting that CaNa$_2$EDTA may initially mobilize lead and facilitate redistribution to the brain. Additional doses enhance lead elimination, reduce blood lead concentrations, and subsequently reduce brain lead concentrations. The initial increase in brain lead may explain why some human case reports demonstrate worsening lead encephalopathy when CaNa$_2$EDTA is used without concomitant dimercaprol (British anti-Lewisite [BAL]) therapy.

■ HUMANS

Edetate calcium disodium is capable of reducing blood lead concentrations, enhancing renal excretion of lead, and reversing the effects of lead on hemoglobin synthesis.[14] With chronic exposure, blood lead concentrations rebound considerably in the days to weeks following cessation of CaNa$_2$EDTA.[1,2,24] Although CaNa$_2$EDTA has been used clinically since the 1970s, no rigorous clinical studies have ever been performed to evaluate whether CaNa$_2$EDTA is capable of reversing the neurobehavioral effects of lead.[15,16] Chelators, including CaNa$_2$EDTA, are incapable of dramatically decreasing the body burden of lead, because only several milligrams of lead are eliminated during chelation.[9,11,35] A study of children with blood lead concentrations of 25 to 50 µg/dL who were given CaNa$_2$EDTA for 5 days revealed very little difference in blood lead, bone lead, or erythrocyte protoporphyrin concentrations, when compared to pretreatment values.[28] Another study in children demonstrated no additional benefits of CaNa$_2$EDTA on cognitive performance beyond that which was achieved by limiting further lead exposure and correcting an iron deficiency anemia.[34,36] A follow-up study in children with initial blood lead concentrations between 25 and 55 µg/dL also suggested an interaction between initial iron status, blood lead concentration and an improvement in perceptual motor performance over a 6-month period. Both correction of iron deficiency and a reduction in blood lead concentration (accomplished with limiting further exposure and or CaNa$_2$EDTA chelation) contributed to the improvement, emphasizing the need to correct iron-deficiency anemia as well as limit lead exposure.[37]

CaNa$_2$EDTA MOBILIZATION TEST

The CaNa$_2$EDTA mobilization test was once widely recommended as a diagnostic aid for assessing the potential benefits of chelation therapy.[31,30] Currently,[10] it can only be considered obsolete.[10,14,17] Criticisms of the test include difficulties with administration of the

antidote, unreliability as a predictor of total-body lead burden, expense, and the risk of worsening toxicity through redistribution of lead to either the kidney or brain.[14]

ADVERSE EFFECTS AND SAFETY ISSUES

The principal toxicity of CaNa$_2$EDTA is related to the metal chelates it forms. In mice, the intraperitoneal (IP) LD$_{50}$ (median lethal dose for 50% of test subjects) values of various CaNa$_2$EDTA metal chelates are CaNa$_2$EDTA, 14.3 mmol/kg; lead EDTA, 3.1 mmol/kg; and mercury EDTA, 0.01 mmol/kg.

When CaNa$_2$EDTA is given to patients with lead poisoning, the resultant sites of major renal toxicity are the proximal convoluted tubule, the distal convoluted tubule, and the glomeruli, possibly caused by the release of lead in the kidneys during excretion.[27] Of 130 children who received both dimercaprol and CaNa$_2$EDTA, 13% had biochemical evidence of nephrotoxicity, and 3% developed acute oliguric renal failure, which resolved over time without the need for hemodialysis.[31] Other studies failed to demonstrate any cases of renal failure in more than 1000 patient courses of therapy, when CaNa$_2$EDTA was given in divided daily doses of 1000 mg/m^2 intravenously (IV) over 1 hour, every 6 hours.[29] Because lead toxicity causes renal damage independent of chelation, it is important to monitor renal function closely during CaNa$_2$EDTA administration and to adjust the dose and schedule appropriately.[32,33] Nephrotoxicity may be minimized by limiting the total daily dose of CaNa$_2$EDTA to 1 g in children or to 2 g in adults, although higher doses may be needed to treat lead encephalopathy. Continuous infusion while maintaining good hydration seems to increase efficacy and decrease toxicity.[32] Because the administration of disodium EDTA can lead to life-threatening hypocalcemia and death, CaNa$_2$EDTA has become the preparation of choice and hypocalcemia is no longer a clinical concern.[5] Other adverse clinical effects of CaNa$_2$EDTA, most of which are uncommon, include malaise, fatigue, thirst, chills, fever, myalgias, dermatitis, headache, anorexia, urinary frequency and urgency, sneezing, nasal congestion, lacrimation, glycosuria, anemia, transient hypotension, increased prothrombin times, and inverted T waves.[27] Mild increases in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) (usually reversible), and decreases in alkaline phosphatase are frequently reported. Extravasation may result in the development of painful calcinosis at the injection site.[34,38] Depletion of endogenous metals, particularly zinc, iron, and manganese, can result from chronic therapy.[8,41] A decrease in serum dopamine β-hydroxylase, a copper-dependent enzyme, occurred after a single injection of CaNa$_2$EDTA in three adult lead welders, without any demonstrable decrease in serum copper.[18] Although the clinical relevance of this is unknown, it merits further investigation.[18]

An animal study suggests that gastrointestinal lead absorption may be enhanced by either IP or oral administration of CaNa$_2$EDTA[26]; consequently, removal of lead from the environment should always remain the first strategy in the management of lead toxicity. In the event of unintentional exposure to a new lead source, decontamination of the gastrointestinal tract must complement chelation.[30]

■ USES IN PREGNANCY

The safety of CaNa$_2$EDTA has not been established in pregnancy, and a risk-to-benefit analysis must be made if its use is considered. In a model of lead poisoning in pregnant rats, fetal resorption decreased and the number of live fetuses increased when CaNa$_2$EDTA was used, although the placental concentrations of lead were increased.[20] Zinc concentrations were not affected. Another study, however, found that when CaNa$_2$EDTA was given to pregnant rats not poisoned with lead, increases in submucous clefts, cleft palate, adactyly/syndactyly, curly

tail, and abnormal ribs and vertebrae resulted.[6] These teratogenic effects occurred with doses of CaNa$_2$EDTA comparable to human doses and without causing noticeable changes in the mother except for weight gain. Use of zinc calcium EDTA and zinc EDTA preparations in pregnant rats caused no teratogenic effects at low doses, but resulted in the development of submucous cleft palates in 30% of the offspring receiving the higher dose of zinc calcium EDTA.[6]

DOSING AND ADMINISTRATION

There has never been a clinical trial to identify the best dose of CaNa$_2$EDTA. The most commonly recommended dose is determined by the patient's body surface area or weight (up to a maximum dose), the severity of the poisoning, and renal function (Chap. 94 and Table 94-8).[14,28,34] For patients with lead encephalopathy, the dose of CaNa$_2$EDTA is 1500 mg/m^2/d approximately 50-75 mg/kg/d by continuous IV infusion, *starting 4 hours after the first dose of dimercaprol* and after an adequate urine flow is established.[13] The dose in obese patients has not been studied. A maximum dose of 3 g seems reasonable. Simultaneous dimercaprol and CaNa$_2$EDTA therapy is administered for 5 days, followed by a rest period of at least 2 to 4 days, which permits lead redistribution. For adults with lead nephropathy, the following dosage regimen is recommended: 500 mg/m^2 every 24 hours for 5 days for patients with a serum creatinine of 2 to 3 mg/dL; every 48 hours for three doses for a serum creatinine of 3 to 4 mg/dL; and one dose for a serum creatinine greater than 4 mg/dL.[7] Previous recommendations were to limit the daily dose to 50 mg/kg when CaNa$_2$EDTA is used in patients with renal dysfunction.[22,32,33] There is limited evidence to suggest that folic acid, pyridoxine, and thiamine increase the antidotal properties of CaNa$_2$EDTA.[39] There is inadequate data to recommend routine administration. A blood lead concentration should be measured 1 hour after the CaNa$_2$EDTA infusion is discontinued, to avoid falsely elevated blood lead concentration determinations.

In symptomatic children without manifestations of lead encephalopathy, the dose of CaNa$_2$EDTA is 1000 mg/m^2/d, approximately 25-50 mg/kg/d in addition to dimercaprol at 50 mg/m^2 every 4 hours. However, with Food and Drug Administration (FDA) approval of succimer, and the demonstrated ability to reduce brain lead concentrations in animals, succimer has essentially replaced CaNa$_2$EDTA as the chelator of choice in lead-poisoned children without encephalopathy and lead concentration less than 70 μg/dL.[11,24]

Because of the pain associated with intramuscular (IM) administration, most clinicians recommend that CaNa$_2$EDTA be administered at concentrations of approximately 0.5% by continuous IV infusion over 24 hours in 5% dextrose or 0.9% NaCl. Concentrations greater than 0.5% may lead to thrombophlebitis and should be avoided. Edetate calcium disodium is incompatible with other solutions. Careful attention to total fluid requirements in children and patients who have or who are at risk for, lead encephalopathy is paramount.[27,34] Rapid IV infusions in patients with lead encephalopathy may increase intracranial pressure and cerebral edema. In children with acute lead encephalopathy, starting BAL 4 hours prior to CaNa$_2$EDTA appears to be more effective than starting CaNa$_2$EDTA prior to and simultaneously with BAL.[12,15] In addition, treating with two chelators also reduces the blood lead concentration significantly faster than CaNa$_2$EDTA alone, while maintaining a better molar ratio of chelator to lead.[12]

If CaNa$_2$EDTA is to be administered IM to avoid the use of an IV and fluid overload, then either procaine or lidocaine is added to the CaNa$_2$EDTA in a dose sufficient to produce a final concentration of 0.5% (5 mg/mL). This can be accomplished by mixing 1 mL of a 1% procaine or 1% lidocaine solution with each mL of chelator.[7,27] The procaine or lidocaine minimizes pain at the injection site.

Table A28–1. Calculations for Intravenous Edetate Calcium Disodium Infusion Over 24 hours

	Avg. Height (in.)	Avg. Weight (lbs.)	m^2	1000 mg/m² over 24 h IV	Dilute in D₅W or NS and Infuse over 24 h[a]	1500 mg/m² over 24 h IV	Dilute in D₅W or NS and Infuse over 24 h[a]
Child[b]							
2-year-old boy	36	30.5	0.593	593 mg	200 mL	890 mg	300 mL
2-year-old girl	35	29	0.57	570 mg	200 mL	855 mg	300
4-year-old boy	42	39.75	0.73	730 mg	250	1095 mg	400
4-year-old girl	41.75	38.75	0.72	720 mg	250	1080 mg	400
Adult[c,d]							
50 kg			1.5	1500 mg	500 mL	2250 mg	750 mL
70 kg			1.8	1800 mg	600 mL	2700 mg	1000 mL
90 kg			2.1	2100 mg	700 mL	3150 mg	1000 mL

Edetate calcium disodium comes in 5-mL ampules of 200 mg/mL.

D₅W, 5% dextrose in water; IV, intravenously; NS, 0.9% sodium chloride solution.

[a] Dilute in D₅W or 0.9% NaCl to concentrations of less than 0.5% to avoid thrombophlebitis with IV administration; be mindful of total fluid requirements if encephalopathic to avoid cerebral edema; if fluid is an issue consider intramuscular injection, otherwise infuse IV over 24 hours.

[b] Do not exceed adult dose.

[c] For adults with lead nephropathy, the following dosing regimen has been suggested: 500 mg/m² every 24 hours for 5 days for patients with serum creatinine levels of 2 to 3 mg/dL, every 48 hours for three doses for patients with creatinine concentrations of 3 to 4 mg/dL, and once weekly for patients with creatinine concentrations above 4 mg/dL.

[d] The dose in obese patients has not been studied. A maximum dose of 3 g seems reasonable.

COMBINATION THERAPY WITH SUCCIMER OR DMPS

The possible benefit of combining CaNa₂EDTA with succimer or 2,3-dimercapto-1-propane-sulfonic acid (DMPS) is under investigation in animals.[19,21,40] The combination of CaNa₂EDTA with succimer appears more potent than either individual agent in promoting urine and fecal lead excretion, and decreasing blood and liver lead concentrations. However, this approach might increase zinc depletion.[40]

A retrospective analysis compared the combination of BAL and CaNa₂EDTA with succimer and CaNa₂EDTA in children with blood lead concentrations of about 35 to 70 μg/dL (up to 90 μg/dL for the BAL group). They demonstrated equivalent reductions in blood lead concentrations with fewer side effects in the succimer group.[3] One case report of a child with lead encephalopathy and an extremely high blood concentration of 550 μg/dL used a combination of BAL and CaNa₂EDTA initially followed by succimer, but a rebound increase in the lead concentration led to the addition of CaNa₂EDTA.[23] More data are needed to confirm this approach.

AVAILABILITY

Edetate calcium disodium is available as calcium disodium versenate in 5-mL ampules containing 200 mg of CaNa₂EDTA per milliliter (1 g per ampule).[27] Disodium edetate (sodium EDTA) should not be considered an alternative to CaNa₂EDTA because of the risk of life-threatening hypocalcemia associated with sodium EDTA use.

SUMMARY

Edetate calcium disodium reduces blood lead concentrations, enhances urinary lead excretion, and reverses lead-induced hematologic effects. Studies evaluating long-term effects in reversing lead-induced neurotoxicity have not been performed. Edetate calcium disodium remains the standard of care for patients with lead encephalopathy when used in conjunction with dimercaprol. A CaNa₂EDTA challenge test is no longer recommended as a diagnostic gesture.[14,17] Recommended doses and dosage schedules should not be exceeded and should be reduced when the creatinine clearance is reduced. Patients should be well hydrated to achieve an adequate urine flow prior to and during CaNa₂EDTA therapy.

CHAPTER 95
MANGANESE

Sari Soghoian

Manganese (Mn)

Atomic number	=	25
Atomic weight	=	54.94 daltons
Normal concentrations:		
Whole blood	=	4–15 µg/L (73–273 nmol/L)
Serum	=	0.9–2.9 µg/L (16–52 nmol/L)
Urine (24h)	<	10 µg/L (182 nmol/L)

Manganese is an essential element of the diet and a known cofactor in many enzymatic processes. Most reported cases of manganese toxicity in humans have involved occupational exposure to inhaled manganese dusts and fumes. Toxicity has also occurred in patients receiving parenteral nutrition and recently in intravenous (IV) methcathinone users.

HISTORY AND EPIDEMIOLOGY

Manganese salts are brightly pigmented and were most likely first used to make paint. Manganese dioxide has been found in prehistoric paints and has been used as a decolorant in glass making since at least the Roman Empire. Manganese–iron alloys were found in Spartan weapons, but the combination was most likely fortuitous but unintentional. In the early 19th century, it was discovered that addition of manganese to iron produced a stronger metal alloy, and manganese became an important component of most steel. The largest industrial use of manganese today is in steelmaking, and more than 85% of manganese in production is used to make ferromanganese alloys.

Manganese, primarily in the form of oxides, is released during mining, and inhalational exposure to dusts from grinding manganese ore has been the most important source of manganese toxicity. Inhalation of inorganic manganese compounds may also occur during smelting, welding, or burning coal, oil, or fuel containing manganese compounds. Manganese was linked to the development of a characteristic neuropsychiatric syndrome since the 1800s when it was described in French pyrolusite mill workers.[17] A neuropsychiatric syndrome in welders is also attributed to inhalation of manganese oxide fumes[12,14,56]; however, many of the studies used to support this claim are methodologically flawed.[31,36]

Other industrial uses of manganese include: manganese chloride in dry-cell battery manufacture and as a catalyst for chlorination of organic compounds; manganese dioxide in batteries and glass production; and manganese sulfate to make ceramics, fungicides, and pesticides. Manganese toxicity from these professional applications has not been reported.

Permanganates were first discovered to be strong oxidizing agents in the 18th century. Weak solutions of potassium permanganate 0.01% are still used in medicine as topical drying and antiseptic skin preparations. Potassium, sodium, and barium permanganate also have uses in the pharmaceutical, chemical, and photographic industries. The toxicity of permanganates is mostly related to their oxidizing effects and is not discussed further here.

Manganese chloride and manganese sulfate are used as nutritional supplements.[10] Manganese toxicity is well documented in patients receiving total parenteral nutrition (TPN),[21,43,48] particularly infants and young children. An epidemic of manganese toxicity was recently reported from the use of IV methcathinone prepared using potassium permanganate as an oxidizing agent.[66] Manganese contamination of freebase cocaine may occur if manganese–carbonate is used as a reagent. The addition of methylcyclopentadienyl manganese tricarbonyl (MMT), a lead alternative, to gasoline has been allowed in Canada since 1976 and in the United States since 1995, but more research is needed to understand the contribution of MMT in gasoline to the environmental burden of manganese and to human health.

CHEMISTRY

Manganese is a transition metal atomic number 25, that is located between chromium and iron in the periodic table. It is dark grey, brittle, and paramagnetic. It is the 12th most abundant element in the earth's crust (0.106%) and occurs in several mineral forms. Most manganese in the environment is found complexed to oxygen, carbon, or chloride. The most economically important ore is pyrolusite, or manganese dioxide (MnO_2), from which metallic manganese was first isolated in 1774. Similar to magnetite and magnesium, the name *manganese* derives from *Magnesia*, a prefecture of Thessaly in ancient Greece. Ores from this region are abundant in manganese oxides and carbonates, among other elements.

Manganese can exist in several oxidation states from −3 to +7. Mn^{2+} is the most common, the most bioavailable, and the most physiologically important form.

PHARMACOLOGY AND PHYSIOLOGY

Divalent manganese ion (Mn^{2+}) is stable in aqueous solution at neutral pH and forms complexes with a variety of ligands in the body. Divalent manganese ion can substitute for Mg^{2+}, Ca^{2+}, and Fe^{2+} in complexes with proteins and enzymes.[45] Mn^{3+} is also biologically important and is, for example, the form of manganese in superoxide dismutase. Manganese is a cofactor in many other human enzyme systems, including hexokinase, xanthine oxidase, and glutamine synthase. It is also present in several metalloproteins.[10]

Manganese is considered an essential element in the diet. Although deficiency in humans is not reported, experimental manganese restriction produced a scaling, erythematous, pruritic rash; alterations in calcium homeostasis (eg, hypercalcemia, hyperphosphatemia); and increased alkaline phosphatase in healthy volunteers.[23] Manganese is present in human breast milk in its trivalent form bound to lactoferrin, which is readily absorbed via receptors in the small intestine. Divalent manganese salts—usually manganese sulfate or manganese chloride—that are typically added to infant formulas, processed foods, and dietary supplements are less well absorbed. Important dietary sources of manganese in adults are nuts, grains, legumes, fruits, and vegetables. Manganese salts in well water also contribute to dietary intake.[61] Most people consume 2 to 9 mg of manganese compounds per day, but vegetarians may consume more.

Normally, less than 5% of dietary manganese is absorbed throughout the length of the small intestine. However, enteral manganese absorption depends not only on the chemical form but also on the dietary needs of the host and the presence of similarly charged compounds. For example, because manganese can compete with iron for binding sites on transferrin, the percentage of absorbed manganese is increased in the presence of iron-deficiency anemia. Radioisotope studies

demonstrate that absorption of dietary manganese is doubled in anemic subjects.[10,22] Manganese absorption from the gastrointestinal tract is also inversely proportional to the amount of calcium in the diet, most likely because of competition between divalent cations for transport.[10]

Divalent manganese can take the place of ferrous or ferric iron in hemoglobin. The incorporation of manganese into hemoglobin by substitution for iron accounts for the large difference between whole-blood manganese concentrations and the typically minute free serum manganese concentrations ($<2.9\,\mu g/L$) that are measured in those with normal concentrations. Because about 85% of manganese in blood is bound up with hemoglobin in erythrocytes, normal measured whole-blood concentrations may be as much as five times higher than those measured in serum.[52] The remaining manganese in plasma is mostly bound to transferrin, β_1-globulin, and albumin.[6] Manganese is widely distributed to all tissues and crosses both the placental[10] and the blood–brain barrier.[5] Transport in the body is also facilitated by transport proteins and for Mn^{2+} by the divalent metal transporter (DMT-1).

The elimination half-life of manganese from the body is approximately 40 days[41] but is highly variable among subjects. Elimination of manganese may be prolonged in young women with high ferritin stores[22] or after the initiation of oral iron therapy for anemia.[41] This effect is most likely attributable to increased hepatic sequestration from increased production of iron transport and storage proteins. High concentrations of manganese are also found in patients with hemochromatosis, supporting the idea that increased or abnormal iron storage proteins also lead to increased hepatic manganese stores.[1]

Manganese is primarily eliminated via the bile in feces. It accumulates in bile against a concentration gradient, which suggests an active transport mechanism for its excretion.[33] Renal excretion is negligible; whereas 67% of a radiolabeled manganese dose injected IV is recovered in feces within 48 hours, less than 0.1% appears in the urine within 5 days of its administration.[33]

PATHOPHYSIOLOGY

Although manganese is widely distributed in the body, the most important clinical effects of manganese toxicity are related to its accumulation in brain. Increased brain manganese stores may be caused by overexposure or impaired elimination. Whereas normal liver function may protect against accumulation of manganese in the brain,[62] patients with hepatic disease have impaired manganese elimination and are also at risk for manganese toxicity from normal dietary intake.[53,58,62] Manganese concentrations are increased in the globus pallidum of cirrhotic patients compared with control subjects and in rats with either biliary cirrhosis or portacaval shunts.[58]

Manganese influx, but not efflux, into the central nervous system is tightly regulated by transferrin-dependent transport mechanisms.[5] Transferrin-receptor mediated endocytosis of bound Mn^{3+} is the major route of entry under normal conditions, but for unclear reasons, free manganese appears to cross the blood–brain barrier more quickly than protein-bound manganese.[47,55] Exposure to manganese in excess of blood ligand-binding capacity may therefore promote its distribution to the brain.

The exact mechanisms of manganese uptake into neuronal cells and its transport within the brain are still being elucidated. Transferrin may also play an important part in manganese accumulation in the basal ganglia, specifically because these are efferent to areas of high transferrin-receptor density.[6,19] The divalent-metal transporter is most likely also important, but more research is needed to understand its role.

Because of its low enteral absorption, ingestion of manganese in any form is unlikely to cause toxic manganese concentrations in the blood. This is more likely to occur with parenteral administration of nutrition or drugs containing manganese. Inhalation of manganese dusts or fumes during mining or welding may also cause acutely elevated blood concentrations or may create pulmonary manganese deposits that can prolong exposure even after the patient is removed from the environmental source.[49]

Manganese is cytotoxic, but the specific cellular mechanisms by which manganese leads to cell death are not well established. Similar to other transition metals, manganese probably causes some local damage by generating reactive oxygen species during redox cycling between the divalent and trivalent forms. The participation of manganese in Fenton reactions also occurs and results in oxidative tissue damage (see Chap. 11) Mn^{2+} concentrates in mitochondria and inhibits both mitochondrial F1-ATPase[6] and complex I[24] in the electron transport chain, thereby disrupting oxidative phosphorylation.[15,24,25,60,74,75] It may also impair glutamate synthesis and transport and alter the glycolytic enzyme glyceraldehyde-3-phosphate. Furthermore, the high-affinity binding of manganese-substituted hemoglobin to nitric oxide scavenges this vasodilatory compound.[37,50]

CLINICAL MANIFESTATIONS

The most characteristic clinical features of manganese toxicity are neuropsychiatric (Table 95–1). Early reports of manganism in German manganese workers[10] and Chilean miners[63] described a biphasic illness. The acute phase is characterized by psychiatric symptoms, or "manganese madness," that may also be progressive. Symptoms include visual hallucinations, behavioral changes, anxiety, impotence, and decreased libido.[10] This acute phase is followed by a late-developing movement disorder that includes tremor, impaired speech, loss of facial expression, and gait disturbances. This extrapyramidal movement disorder is similar to idiopathic Parkinson's disease but is more likely to present with only mild cognitive impairment or vestibular–auditory dysfunction rather than severe progressive dementia.[32] In addition, patients may lack tremors at rest, be more likely to have difficulty walking backward, have frequent falls, have a typical "cock walk" on the balls of

TABLE 95–1. Typical Features of Chronic Manganism

System	Early Manifestations	Late Manifestations
Constitutional	Asthenia, lethargy	–
Gastrointestinal	Anorexia	–
Neurologic	Fine intention tremor Headaches	Coarse intention tremor Visual hallucinations Cognitive impairment Loss of facial expression Dysphagia Micrographia Gait instability[a] Low-volume speech
Psychiatric	Apathy Irritability Emotional lability	Decreased libido or impotence Anxiety Additional behavioral changes
Musculoskeletal	Arthralgias	Muscle rigidity

[a] Decreased arm swing, toe walking, inability to turn or walk backward without falling.

the feet, and have low-volume speech. Furthermore, they may be less likely to improve with levodopa therapy compared with patients who have Parkinson's disease.[66]

Acute inhalational exposure to high concentrations of manganese oxides may also cause metal fume fever (see Chap. 124), with characteristic fever, child, nausea, headache, myalgias, and arthralgias.[10] Chronic exposure to manganese oxide fumes by factory workers is also associated with development of a persistent dry cough, bronchitis, chemical pneumonitis, and increased rates of pneumonia in factory workers but does not appear to cause pulmonary fibrosis.[38,57]

DIAGNOSTIC TESTING

Manganese concentrations in the blood are most commonly determined by flame or furnace atomic absorption spectrophotometry. Normal reference values for manganese in the blood and urine are published (see above), but toxic concentrations are not well defined. Elevated blood manganese concentrations are present in patients with acute toxicity, but this test is neither sensitive nor specific for chronic manganese toxicity. This occurs because manganese is rapidly cleared from the blood,[73] and elevated concentrations reflect only recent exposure. Symptoms of manganism are insidious and therefore likely to occur long after concentrations in the urine or blood have normalized. Increased urinary elimination of manganese after chelation challenge with edetate calcium disodium (CaNa$_2$EDTA) have been reported[59,66] but cannot be interpreted. In most situations, it is unclear whether the increased excretion signifies mobilization of physiologic manganese, an increased body burden of manganese, or toxicity.

Whole-blood manganese concentrations are the most reliable values for biomonitoring purposes, although they only correlate with group and not with individual exposure levels.[10] A cross-sectional study of workers from three different areas in a dry-cell battery plant found no significant differences in urinary manganese concentrations between workers with high, low, and no occupational exposure.[8] A large amount of background variation made it difficult to interpret axillary hair concentrations in this study. Whole-blood manganese concentrations revealed the least background variation and were positively correlated with group-based estimations of airborne manganese exposures.

Patients with manganese associated parkinsonism often have a pattern of magnetic resonance imaging (MRI) abnormalities that includes abnormal T1-weighted signal hyperintensity in the basal ganglia, particularly in the globus pallidus, with normal T2-weighted images.[4,31,32,51,66] This pattern is also reported in patients with iatrogenic manganism from long-term parenteral nutrition.[11,21,30,46,69] In patients without neurologic manifestations, manganese concentrations in TPN are positively correlated with the intensity of increased signal in the basal ganglia on T1-weighted MRI images,[11,69] and basal ganglia changes present on MRI during TPN therapy are reversible with its discontinuation.[46,68]

This MRI pattern also occurs in cirrhotic patients[54,65] and presumably represents an abnormal accumulation of dietary manganese caused by impaired hepatic excretion. The globus pallidi of cirrhotic patients who die with hepatic encephalopathy contain high concentrations of manganese compared with control subjects.[53] Increased T1-weighted signal in the basal ganglia occurs in individuals with many other conditions, however, and may also reflect iron, copper, or lipid deposition; hemorrhage; or neurofibromatosis.[10] MRI findings in patients with idiopathic Parkinson's disease more typically include a hypointense signal in the substantia nigra seen on T2-weighted images.[35,71,42] Positron emission tomography scans of patients with chronic manganese exposure and mild parkinsonism have failed to show abnormal nigrostriatal dopaminergic projections, although these are abnormal in patients with idiopathic parkinsonism.[51,72]

TREATMENT

The treatment of patients with acute or chronic manganese toxicity is primarily supportive. Removal from the source of exposure is paramount, although clinical manifestations of toxicity may progress even as body stores of manganese are decreasing.[29] Chelation therapy with CaNa$_2$EDTA (A-28) or calcium diethylenetriamine pentaacetic acid (DTPA) (A-43) improves urinary excretion of manganese without affecting neurologic manifestations of toxicity.[59,66] Chelation of two workers with diemercaptosuccinic acid (DMSA) had no effect on manganese concentrations in the blood and urine or on clinical signs of manganism.[2]

Deferoxamine has not been studied as a potential therapy for manganese toxicity, and some evidence suggests that it might be counterproductive. In vitro studies with rat pheochromocytoma cells have demonstrated increased rates of apoptosis after coincubation with manganese and the iron chelator deferoxamine compared with incubation with manganese alone.[60] Because iron and manganese tend to compete for ligands, the increased cellular uptake of manganese in these experiments may have been caused by iron sequestration by deferoxamine leaving more transporters available to interact with manganese.

Although levodopa has reportedly improved parkinsonian signs in several manganese neurotoxic patients,[16,44,56] it did not improve the clinical course in double-blinded, randomized, placebo-controlled trials of manganese-associated parkinsonism.[34,39]

SUMMARY

Chronic exposure to high concentrations of manganese produces a characteristic neuropsychiatric disorder, manganism, that includes parkinsonian features, mild cognitive impairment, and possibly emotional instability. The clinical syndrome is associated with an increased signal in the globus pallidus on T1-weighted MRI. Elevated whole-blood manganese concentrations may also help differentiate the cause, but rapid clearance of manganese from the blood makes this a less sensitive test in cases in which exposure is remote from the onset of symptoms. Treatment is primarily supportive because no chelation regimen has been demonstrated to alter the clinical course.

CHAPTER 96
MERCURY

Young-Jin Sue

Mercury (Hg)		
Atomic number	=	80
Atomic weight	=	200.59
Normal concentrations		
Whole blood	<	10 μg/L (<50 nmol/L)
Urine	<	20 μg/L (<100 nmol/L)
	<	5 μg/g creatinine (<25 nmol/g creatinine)

Mercury is a naturally occurring metal that is widely toxic to multiple organ systems. Whereas elemental mercury produces pulmonary toxicity, inorganic mercury initially causes gastrointestinal (GI) symptoms followed by nephrotoxicity. A nearly pure neurologic toxicity results from organic (methylmercury) exposure.

HISTORY AND EPIDEMIOLOGY

The toxicologic manifestations of mercury are well known as a result of thousands of years of medicinal applications, industrial use, and environmental disasters.[58,92] Mercury occurs naturally in small amounts as the elemental silver-colored liquid (quicksilver); as inorganic salts such as mercuric sulfide (cinnabar), mercurous chloride (calomel), mercuric chloride (corrosive sublimate), and mercuric oxide; and as organic compounds (methylmercury and dimethylmercury). In recent centuries, mercury preparations were widely used to treat both syphilis and constipation. The musician Paganini was one of several famous persons whose gingivitis, dental decay, ptyalism (excessive salivation), and erethism (pathologic shyness) were attributed to mercury therapy.[67] In the 1800s, the United States witnessed an epidemic of "hatters' shakes" or "Danbury shakes" and "mercurial salivation" in hat industry workers.[103] Danbury, CT, was a U.S. center of felt hat manufacturing where mercuric nitrate was used to mat animal furs to make felt.[92,103]

In the early 1900s, acrodynia, or "pink disease," was described in children who received calomel for ascariasis or teething discomfort.[12] Vividly described in a series of 41 children, the development of acrodynia was more common in younger children, did not seem to correlate with mercury dose, and was not necessarily related to urine concentrations of mercury.[102]

One of the most devastating epidemics of mercury poisoning occurred as the result of a decade of contamination of Minamata Bay in Japan by a nearby vinyl chloride plant during the 1940s. Methylmercury accumulated in the bay's marine life and poisoned the inhabitants of the local fishing community. Although officially only 121 victims were initially counted, thousands more are believed to have been affected by what has subsequently been named Minamata disease.[72,94] The largest outbreak of methylmercury poisoning to date occurred in Iraq in late 1971. Approximately 95,000 tons of seed grain intended for planting and treated with methylmercury as a fungicide were baked into bread for direct consumption, resulting in widespread neurologic symptoms, 6530 hospital admissions, and more than 400 deaths.[4,18,77]

In 1990, the Environmental Protection Agency (EPA) banned mercury-containing compounds from interior paints.[2] However, mercury-containing paints manufactured before that ruling may still be on interior walls, and mercury-containing paint can still be sold for outdoor use. In 1997, a scientist succumbed to delayed, progressive neurologic deterioration after dermal exposure to a minute quantity of dimethylmercury.[64]

Contemporary exposures occur in the form of mercury-tainted seafood and mercury-based preservatives (thimerosal). However, a once widely feared source of potential poisoning, mercury-containing dental amalgam, does not result in clinically important poisoning. Occasionally, exposure to mercury from broken thermometers leads to poisoning in the home.

The recent movement to replace incandescent light bulbs with compact fluorescent bulbs has raised the concern of exposure to mercury in the home and environment. Promoted to reduce greenhouse gas emissions, each bulb contains 5 mg of elemental mercury. Recycling options are not yet widely available.[7] Tables 96–1 and 96–2 show the potential occupational and nonoccupational risks for mercury exposure.

FORMS OF MERCURY AND TOXICOKINETICS

The three important classes of mercury compounds—elemental, inorganic, and organic—differ with respect to their toxicodynamics and toxicokinetics (Table 96–3). Each class produces distinct clinical patterns of poisoning stemming in part from their unique kinetic features (Table 96–4). Within each class, the specific manifestations are determined by the route of exposure, rate of exposure, distribution, and biotransformation of mercury within the body and relative accumulation or elimination of mercury by the target organ systems.

■ ABSORPTION

Elemental Mercury Elemental mercury (Hg^0) is absorbed primarily via inhalation of vapor, although slow absorption after aspiration, subcutaneous deposition, and direct intravenous (IV) embolization occurs.[49,61,100,107] Volatility, moderate at room temperature, increases significantly with heating or aerosalization, both of which occur with vacuuming.[84] When inhaled by human volunteers, 75% to 80% of mercury vapor is absorbed.[35] However, elemental mercury is negligibly absorbed from a normally functioning gut, and it is usually considered nontoxic when ingested. Abnormal GI motility prolongs mucosal exposure to elemental mercury and increases subsequent ionization to more readily absorbed forms. Similarly, anatomic GI abnormalities such as fistulae or perforation may be associated with extravasation of mercury into the peritoneal space, where elemental mercury is oxidized to more readily absorbed inorganic forms.

Inorganic Mercury Salts The principal route of absorption for inorganic mercury salts is the GI tract. Approximately 10% of inorganic mercury salts are absorbed after dissociation of ingested soluble divalent mercuric salts such as mercuric chloride ($HgCl_2$).[55] Absorption of a relatively insoluble monovalent mercurous compound, such as calomel (HgCl), is thought to depend on its oxidation to the divalent form.[65] Inorganic mercury salts are also absorbed across the skin and mucous membranes, as evidenced by urinary excretion of mercury after dermal application of mercurial ointments and powders containing HgCl.[102] The degree of dermal absorption varies by the concentration of mercury, skin integrity, and lipid solubility of the vehicle. With substantial dermal exposures to inorganic mercury salts, skin absorption may be difficult to distinguish from concomitant absorption via other routes, such as ingestion.

TABLE 96–1. Potential Occupational Exposures to Mercury

Elemental	Salts	Organic
Amalgam	Disinfectants	Bactericide makers
Barometers	Dye makers	Drug makers
Bronzers	Explosives	Embalmers
Ceramic workers	Fireworks makers	Farmers

Paint makers		
Paper pulp workers		
Photographers		
Thermometers		

TABLE 96–3. Classes of Mercury Compounds

	Chemical Formula	Example
Elemental mercury	Hg^0	Quicksilver
Inorganic mercury salts	Hg^+	Mercurous ion
	$HgCl$	Calomel, mercurous chlorine
	Hg^{2+}	Mercuric ion
	$HgCl_2$	Mercuric chloride
Organic mercury compounds	Short-chain alkyl–mercury compounds	Methylmercury, ethylmercury, dimethylmercury
	Long-chain aryl–mercury compounds	Methoxyethylmercury, phenylmercury

Organic Mercury Compounds   As in the case of inorganic mercury salts, organic mercury compounds are primarily absorbed from the GI tract. Methylmercury, considered the prototype of the short-chain alkyl compounds, is approximately 90% absorbed from the gut.[65] Aryl and long-chain alkyl compounds have greater than 50% GI absorption.[65] Although both dermal and inhalational absorption of organic mercury compounds are reported, precise quantitation and exclusion of concomitant absorption by ingestion are difficult to determine.[22,28,104,105]

■ DISTRIBUTION AND BIOTRANSFORMATION

After it is absorbed, mercury distributes widely to all tissues, predominantly the kidneys, liver, spleen, and central nervous system (CNS). The initial distributive pattern into nervous tissue of elemental and organic mercury differs from that of the inorganic salts because of their greater lipid solubility.

Elemental Mercury   Although peak concentrations of elemental mercury are delayed in the CNS as compared with other organs (2–3 days versus

1 day),[35] significant accumulation in the CNS may occur after an acute, intense exposure to elemental mercury vapor. Conversion of elemental mercury to the charged mercuric cation within the CNS favors retention and local accumulation of the metal. Because elemental mercury does not covalently bind to other compounds, its toxicity depends on its oxidation initially to the mercurous ion (Hg^+) and then to the mercuric ion (Hg^{2+}) by the enzyme catalase.[55] Because this oxidation–reduction reaction favors the mercuric cation at steady state, the distribution and late manifestations of metallic mercury toxicity eventually resemble those of inorganic mercury salt poisoning. Conversely, and to a lesser extent, inorganic mercuric ions are reduced to the elemental state, although the site and mechanism of this reaction are not well understood.[65]

TABLE 96–2. Nonoccupational Exposures to Mercury

Medicinal	Food	Other
Antiseptics	Fish	Button batteries
Calomel teething powders	Grains and seed, treated	Chemistry sets
Dental amalgam	Livestock fed treated grain	Home amalgam extraction
Diuretics		Lightbulbs (fluorescent)
Laxatives		Self-injection
Sphygmomanometers		Preservatives
Stool fixatives		Ritualistic use
Thermometers		
Weighted nasogastric tubes		

TABLE 96–4. Differential Characteristics of Mercury Exposure

	Elemental	Inorganic (Salt)	Organic (Alkyl)
Primary route of exposure	Inhalation	Oral	Oral
Primary tissue distribution	CNS, kidney	Kidney	CNS, kidney, liver
Clearance	Renal, GI	Renal, GI	Methyl: GI Aryl: Renal, GI
Clinical effects			
CNS	Tremor	Tremor, erethism	Paresthesias, ataxia, tremor, tunnel vision, dysarthria
Pulmonary	+++	–	–
Gastrointestinal	+	+++(caustic)	+
Renal	+	+++(ATN)	+
Acrodynia	+	++	–
Therapy	BAL, succimer	BAL, succimer	Succimer (early)

ATN, acute tubular necrosis; BAL, British anti-Lewisite.

Inorganic Mercury Salts The greatest concentration of mercuric ions is found in the kidneys, particularly within the renal tubules. Very little mercury is found as free mercuric ions. At least in animal studies, administration of mercury induces the renal synthesis of metallothionein, a compound that binds to and detoxifies mercuric ions.[9] In blood, mercuric ions are found within the red blood cells (RBCs) and are bound to plasma proteins in approximately equal proportions. Blood concentrations are greatest immediately after inorganic mercury exposure, with rapid waning as distribution to other tissues occurs. Although penetration of the blood–brain barrier is poor because of low lipid solubility, slow elimination and prolonged exposure contribute to consequential CNS accumulation of mercuric ions. Within the CNS, mercuric ions are concentrated in the cerebral and cerebellar cortices. Although inorganic mercurials undergo organification in marine life, as in the Minamata Bay disaster, the importance of this conversion in humans is unknown.[22] Animal studies demonstrate that the placenta functions as an effective barrier to mercuric ions.[65]

Organic Mercury Compounds Once absorbed, aryl and long-chain alkyl mercury compounds differ from the short-chain organic mercury compounds (ie, methylmercury) in an important way—the former possess a labile carbon-mercury bond, which is subsequently cleaved, releasing the inorganic mercuric ion. Thus, the distribution pattern and toxicologic manifestations produced by the aryl and long-chain alkyl compounds beyond the immediate postabsorptive phase are comparable to those of the inorganic mercury salts, but organification has facilitated absorption and reduced the caustic effects.[66] In contrast, short-chain alkyl mercury compounds possess relatively stable carbon–mercury bonds that survive the absorptive phase, although conversion to the inorganic mercuric cation at a rate of less than 1% per day may occur after absorption.[104] Because it is lipophilic, methylmercury readily distributes across all tissues, including the blood–brain barrier and placenta.[37] An important consequence of this property is the devastating neurologic degeneration that develops in prenatally exposed infants with Minamata disease.

After methylmercury is distributed to brain tissue, its fate is uncertain. Animal evidence indicates that methylmercury is converted to inorganic mercury in brain tissue.[52] Primates fed oral methylmercury daily for periods exceeding 1 year and then killed within a few days of the last exposure demonstrated an average brain inorganic mercury fraction of only 19%. When the postexposure period was extended to between 150 and 650 days, the inorganic mercury fraction increased to 88%. Similarly, long-term survivors of methylmercury poisoning had a higher ratio of inorganic mercury to total mercury in their brains.[25] In one patient who survived 22 years after methylmercury ingestion, autopsy revealed that the brain mercury was nearly completely in the inorganic form.

Methylmercury concentrates in RBCs to a much greater degree than do mercuric ions, with an RBC-to-plasma ratio of about 10:1 (in contrast to 1:1 RBC-to-plasma ratio for inorganic mercury).[46,65,104] However, despite this apparent affinity for nervous tissue and RBCs, the greatest methylmercury concentrations are found in the kidneys and liver. Also, because of the extensive sulfhydryl bonds in hair, methylmercury deposits in hair at concentrations approximately 250 times that found in whole blood.[45,93]

■ ELIMINATION

Elemental Mercury and Inorganic Mercury Salts Mercuric ions are excreted through the kidney by both glomerular filtration and tubular secretion and in the GI tract by transfer across gut mesenteric vessels into feces. Small amounts are reduced to elemental mercury vapor and volatilized from skin and lungs. The total-body half-life of elemental mercury and inorganic mercury salts is estimated at approximately 30 to 60 days.[17,55]

Organic Mercury Compounds In contrast to elemental mercury and inorganic mercury salts, the elimination of short-chain alkyl mercury compounds is predominantly fecal. Enterohepatic recirculation contributes to its somewhat longer half-life of about 70 days. Less than 10% of methylmercury is excreted in urine and feces as the mercuric cation.[104]

PATHOPHYSIOLOGY

The pervasive disruption of normal cell physiology by mercury is believed to arise from its avid covalent binding to sulfur, replacing the hydrogen ion in the body's ubiquitous sulfhydryl groups. Mercury also reacts with phosphoryl, carboxyl, and amide groups, resulting in widespread dysfunction of enzymes, transport mechanisms, membranes, and structural proteins. Mercury is being investigated in a variety of cellular alterations, including oxidant stress, microtubule disruption, protein and DNA synthesis, and cell membrane integrity.

Because mercury deposits in all tissues, the clinical manifestations of mercury toxicity involve multiple organ systems with variable features and intensity. Necrosis of the GI mucosa and proximal renal tubules, which occurs shortly after mercury salt poisoning, is thought to result from direct oxidative effect of mercuric ions. An immune mechanism is attributed to the membranous glomerulonephritis and acrodynia associated with the use of mercurial ointments.[10] Postmortem examination of the kidneys from two women who died after chronic abuse of mercurous chloride–containing laxatives revealed severe proximal tubular atrophy and mercury deposition within the cortical interstitium and renal macrophages.[101]

Neurologic manifestations of methylmercury poisoning correlate with pathologic findings in the brains of both adults and children who were prenatally exposed.[57,94] Grossly, atrophy of the brain is more severe in children who had prenatally or postnatally acquired methylmercury compared with the brains of those exposed as adults. In the adult brain, neuronal necrosis and glial proliferation are most prominent in the calcarine cortex of the cerebrum and in the cerebellar cortex. In fetal Minamata disease, similar lesions are present but in a more diffuse and severe form. Atrophy of the cerebellar hemispheres, postcentral gyri, and calcarine area of the brain demonstrated on magnetic resonance images in organic mercury–poisoned patients correlates with clinical findings of ataxia, sensory neuropathy, and visual field constriction, respectively.[48] Neuropathologic examination of the brain of a scientist who died after unintentional dermal exposure to dimethylmercury revealed lesions in the cerebellum, temporal lobe, and visual cortex.[87]

In rats, neuronal cytotoxicity of methylmercury may result partly from muscarinic receptor–mediated calcium release from smooth endoplasmic reticulum of cerebellar granule cells.[51] There is animal evidence that methylmercury may trigger reactive oxygen species production. In addition, methylmercury inhibits astrocyte uptake of cysteine, the rate-limiting step in the production of glutathione, a major antioxidant in mammalian cell systems.[86] Cultured astrocytes accumulated methylmercury and exhibited increased mitochondrial permeability and oxidative injury.[106]

CLINICAL MANIFESTATIONS

■ ELEMENTAL MERCURY

Symptoms of *acute elemental mercury inhalation* occur within hours of exposure and consist of cough, chills, fever, and shortness of breath.

GI complaints include nausea, vomiting, and diarrhea accompanied by a metallic taste, dysphagia, salivation, weakness, headaches, and visual disturbances. Chest radiography during the acute phase may reveal interstitial pneumonitis and both patchy atelectasis and emphysema. Symptoms may resolve or progress to acute lung injury, respiratory failure, and death. Survivors of severe pulmonary manifestations may develop interstitial fibrosis and residual restrictive pulmonary disease. The acute respiratory symptoms may occur concomitantly with or lead to the development of subacute inorganic mercury poisoning manifested by tremor, renal dysfunction, and gingivostomatitis.[13,44,75] Thrombocytopenia may also occur during the acute phase.[31]

Although acute exposure to elemental mercury vapor occurs most commonly in the occupational setting, poisonings caused by mishandling of the metal in the home are well reported.[16,40,59,89] In fact, attempts at home metallurgy using metallic mercury have resulted in fatalities with ambient air concentrations of mercury as high as 0.9 mg/m³ (National Institute for Occupational Safety and Health recommended exposure level 8-hour time-weighted average 0.05 mg/m³ for mercury vapor).[15] The lethal dose of inhaled elemental mercury has not been determined. As with other inhaled toxins, younger individuals may be more sensitive to the pulmonary toxicity of mercury vapor.[59] Although pulmonary toxicity from elemental mercury usually results from inhalation of vapor, massive endobronchial hemorrhage followed by death has occurred secondary to direct *aspiration of metallic mercury* into the tracheobronchial tree.[109]

Gradual volatilization of elemental mercury results in chronic toxicity from improper handling, such as vacuuming spilled mercury.[84]

The clinical importance of volatilized metallic mercury from dental amalgams for both the dentist and patient has been a point of contention. The preponderance of evidence refutes the idea that dental amalgam causes mercury poisoning. Several comprehensive reviews of the subject conclude that (1) occupational exposure to mercury from dental amalgam is acceptably low, provided that recommended preventive measures such as adequate ventilation are adhered to; (2) the quantity of mercury vaporized from dental amalgam by mechanical forces, such as chewing, is clinically insignificant; and (3) only in very rare cases will immunologic hypersensitivity to mercury amalgam (manifested as cutaneous signs and symptoms and confirmed by patch testing) necessitate removal of the amalgam.[27,29,30,50,88]

Unusual cases of chronic toxicity have resulted from intentional *subcutaneous or IV injection of elemental mercury* (see Figs. 5-6 and 96–1).[39,61] Aside from management of local and systemic mercury toxicity, local wound care and excision of deposits of mercury are additional therapeutic challenges presented by these cases. Serial or repeat radiographs are useful in guiding the removal of the radiopaque deposits.

INORGANIC MERCURY SALTS

Acute *ingestion of mercuric salts* produces a characteristic spectrum from severe irritant to caustic gastroenteritis. Immediately after the ingestion, a grayish discoloration of mucous membranes and metallic taste may accompany local oropharyngeal pain, nausea, vomiting, and diarrhea followed by abdominal pain, hematemesis, and hematochezia. The lethal dose of mercuric chloride is estimated to be 30 to 50 mg/kg.[96] The hallmarks of severe acute mercuric salt ingestion are hemorrhagic gastroenteritis, massive fluid loss resulting in shock, and acute tubular necrosis.[82]

Oropharyngeal injury, nausea, hematemesis, hematochezia, and abdominal pain were the most prominent symptoms in a series of 54 patients who presented after ingesting up to 4 g of mercuric chloride.[96] In this series, a fatal outcome was associated with the early development of oliguria (within 3 days). The development of anuria appeared to be related to the dose of mercuric chloride ingested. The
FIGURE 96–1. Anteroposterior (**A**) and lateral (**B**) views of the elbow after an unsuccessful suicidal gesture involving an attempted intravenous injection of mercury in the antecubital fossa. Note the extensive subcutaneous mercury deposition, which was partially removed by surgical intervention. *(Images contributed by Diane Sauter, MD.)*

histopathologic finding of proximal tubular necrosis after mercuric salt poisoning results from both direct toxicity to renal tubules by mercuric ions and renal hypoperfusion caused by shock. Consequently, aggressive fluid therapy is useful.[83]

Acute ingestion of mercuric salts is usually intentional, but unintentional ingestion occurs sporadically in both children and adults.[41] Although ingestion of button batteries containing mercuric oxide is associated with a greater incidence of fragmentation than with other batteries, clinically significant systemic mercury toxicity by this route has not been reported.[53,56]

Mercuric chloride–containing stool preservatives are another potential source of unintentional inorganic mercury poisoning. Ingestion of 10 to 20 mL of a polyvinyl alcohol preservative that contained 4.5% mercuric chloride resulted in bloody gastroenteritis and proteinuria.[85] Patent[39] and Ayurvedic[80,81] medicines are also associated with unintentional inorganic mercury poisoning.[43] Not subject to Food and Drug Administration (FDA) regulation and available without prescription, these xenobiotics are often inadequately labeled and of variable composition (see Chap. 43).

Subacute or chronic mercury poisoning occurs after inhalation, aspiration, or injection of elemental mercury; ingestion or application of inorganic mercury salts; or ingestion of aryl or long-chain alkyl mercury compounds. Slow in vivo oxidation of elemental mercury and dissociation of the carbon–mercury bond of aryl or long-chain alkyl mercury compounds result in the production of the inorganic mercurous and mercuric ions.

The predominant manifestations of subacute or chronic mercury toxicity include GI symptoms, neurologic abnormalities, and renal dysfunction. GI symptoms consist of a metallic taste and burning sensation in the mouth, loose teeth and gingivostomatitis, hypersalivation (ptyalism), and nausea.[102] The neurologic manifestations of chronic inorganic mercurialism include tremor, as well as the syndromes of

neurasthenia and erethism. Neurasthenia is a symptom complex that includes fatigue, depression, headaches, hypersensitivity to stimuli, psychosomatic complaints, weakness, and loss of concentrating ability. Erethism, derived from the Greek word *red*, describes the easy blushing and extreme shyness of affected individuals. Other symptoms of erethism include anxiety, emotional lability, irritability, insomnia, anorexia, weight loss, and delirium. Mercury produces a characteristic central intention tremor (see Chap. 18) that is abolished during sleep. In the most severe forms of mercury-associated tremor, choreoathetosis and spasmodic ballismus may be present. Other neurologic manifestations of inorganic mercurialism include a mixed sensorimotor neuropathy, ataxia, concentric constriction of visual fields ("tunnel vision"), and anosmia.

Chronic poisoning with mercuric ions is associated with renal dysfunction, which ranges from asymptomatic, reversible proteinuria to nephrotic syndrome with edema and hypoproteinemia. An idiosyncratic hypersensitivity to mercury ions is thought to be responsible for acrodynia, or "pink disease," which is an erythematous, edematous, and hyperkeratotic induration of the palms, soles, and face, and a pink papular rash that was first described in a subset of children exposed to mercurous chloride powders.[102] The rash is described as morbilliform, urticarial, vesicular, and hemorrhagic. This symptom complex also includes excessive sweating, tachycardia, irritability, anorexia, photophobia, insomnia, tremors, paresthesias, decreased deep-tendon reflexes, and weakness. The acral rash may progress to desquamation and ulceration. The prognosis is favorable after withdrawal from mercury exposure. Childhood acrodynia has become uncommon since the abandonment of mercurial teething powders and diaper rinses. Occasional case reports are still noted, however, with fluorescent light bulbs and phenylmercuric acetate–containing paint implicated.[2,97]

Thimerosal is an example of an aryl or long-chain alkyl mercury compound that results in chronic inorganic mercury toxicity. It is a compound that was widely used as a preservative in the pharmaceutical industry (see Chap. 55). Although initial kinetics suggest a stable ethyl–mercury bond, the later elimination phase more closely resembles that of the inorganic mercury compounds. Thimerosal is approximately 50% mercury by weight. Generally considered safe, toxicity and death can nevertheless occur after both intentional overdose and excessive therapeutic application of Merthiolate (0.1% thimerosal or 600 μg/mL mercury).[71,76]

Concern that the cumulative dose of thimerosal in childhood immunizations may exceed federally recommended maximum mercury doses (EPA, 0.1 μg/kg/d; Agency for Toxic Substances and Disease Registry, 0.3 μg/kg/d; FDA, 0.4 μg/kg/d) led to a call by the American Academy of Pediatrics to reduce or eliminate thimerosal from vaccines.[3] In particular, controversy exists whether thimerosal causes autism. Although sensitization after use in vaccinations has been reported in atopic children,[70] clinical mercury toxicity has not been reported in appropriately immunized children. Moreover, a number of studies suggest that the incidence of autism is unrelated to the use of thimerosal-containing vaccines.[6,54,69,90] Similarly, no causal association with early thimerosal exposure and adverse neuropsychological outcomes was shown in children tested at 7 to 10 years of age.[95] At the present time, there is clearly more evidence for risk to child health from the diseases targeted for prevention by the vaccines than from thimerosal. Nevertheless, since 2001, routinely administered childhood vaccines in the United States, with the exception of injectable influenza vaccine, contain only trace amounts of thimerosal.[38]

■ ORGANIC MERCURY COMPOUNDS

In contrast to the inorganic mercurials, methylmercury produces an almost purely neurologic disease that is usually permanent except in the mildest of cases. Although the predominant syndrome associated with methylmercury is that of a delayed neurotoxicity, acute GI symptoms, tremor, respiratory distress, and dermatitis may occur.[22,104] In addition, electrocardiographic (ECG) abnormalities (ST segment changes) and renal tubular dysfunction are associated with this poisoning.[28,36]

The lipophilic property and slower elimination of methylmercury may contribute to its profound neurologic effects.[28] Characteristically, clinical manifestations occur after the initial poisoning by a latent period of weeks to months. Consequently, the lethal dose of methylmercury is difficult to determine. As noted previously, infants exposed prenatally to methylmercury were the most severely affected individuals in Minamata. Often born to mothers with little or no manifestation of methylmercury toxicity themselves, exposed infants exhibited decreased birth weight and muscle tone, profound developmental delay, seizure disorders, deafness, blindness, and severe spasticity. The development of neurologic symptoms in infants exclusively breastfed by women exposed to methylmercury after delivery and the detection of mercury in the milk of lactating women implies a risk for mercury poisoning via breast milk.[47] In one series of lactating women, mercury concentrations in milk were approximately 30% of the concentrations found in blood.[68] The rapid decline of blood mercury concentrations in both suckling rats and breastfeeding human infants is attributed to rapid growth of body volume combined with limited transport of mercury by milk.[63,78,79]

Several weeks after methylmercury-contaminated grain was ingested in Iraq, patients began to appear with paresthesias involving the lips, nose, and distal extremities. Symptomatic patients also noted headaches, fatigue, and tremor. More serious cases progressed to ataxia, dysarthria, visual field constriction, and blindness. Other neurologic deficits included hyperreflexia, hearing disturbances, movement disorders, salivation, and dementia. The most severely affected patients lay in a mute, rigid posture punctuated only by spontaneous crying, primitive reflexive movements, or feeding efforts.[77]

Although the outlook for methylmercury neurotoxicity is generally considered dismal, observations over the subsequent 2 years in 49 Iraqi children poisoned during the 1971 outbreak revealed complete resolution or partial improvement in all but the most severely affected.[4] Of 40 symptomatic children, 33 mildly to severely affected children showed partial to complete resolution of symptoms, but the seven children classified as "very severely poisoned" remained physically and mentally incapacitated.

The extreme toxicity of dimethylmercury was tragically demonstrated by the delayed fatal neurotoxicity that developed in a chemist who inadvertently spilled dimethylmercury on a break in the gloves on her hands. Over a period of several days, she developed progressive difficulty with speech, vision, and gait. Despite chelation and exchange transfusion, she died within several months of the exposure.[64]

An important route of organic mercury exposure is through seafood consumption. The safe level of methylmercury in seafood remains controversial. The FDA action concentration of 1 ppm for methylmercury in fish was set to limit consumption of methylmercury to less than one-tenth of levels found in cases of symptomatic poisoning. The EPA established a reference dose for methylmercury of 0.1 μg/kg/d.[73,98] Although elevated blood concentrations (19–53 μg/L) of mercury were found in one group of self-reported high consumers of seafood, increased incidence of cognitive and GI complaints were not.[42] Even so, concentrations at which fetuses experience adverse effects are unknown. Longitudinal studies of fish-eating populations are conflicting. No effect of a high prenatal fish diet was found on developmental markers in children followed to 11 years of age in the Seychelles Islands.[24] In the Faroe Island and New Zealand studies, however, a subtle but significant effect on neuropsychological development was seen.[21,33,91] In the Faroe Islands, this effect persisted when children were retested at 14 years of age.[26] One reason for the

discrepancy that occurs between the two populations may be the different concentrations of methylmercury in the seafood consumed by each. The mean concentration of methylmercury in the whale meat consumed in the Faroe Islands was 1.6 µg/g, and the mean concentration of mercury found in New Zealand shark was 2.2 µg/g. In contrast, the mean methylmercury content of Seychellois fish was 0.3 µg/g.[62] The threshold concentration for neuropsychological effects may lie between these concentrations. The FDA recommends that at-risk populations (ie, pregnant women and women who may become pregnant, nursing mothers, and young children) avoid the large predator fish (eg, shark, swordfish, tilefish, and king mackerel) that contain concentrations of methylmercury approaching 1 ppm (1 µg/g).[99] The FDA has ruled that consumption advice is not indicated for the top 10 seafood species, which make up 80% of all seafood consumed: canned (nonalbacore) tuna, shrimp, pollock, salmon, cod, catfish, clams, flatfish, crabs, and scallops. These species contain concentrations of mercury less than 0.2 ppm and are rarely consumed in quantities in excess of the recommended weekly limit of 2.2 pounds. The recommendations are not as clear for albacore tuna, which may have concentrations of mercury as high as 0.34 ppm. The FDA-recommended limit of albacore tuna consumption by at-risk populations is less than 6 oz per week, but some consumer advocacy groups believe that the limit should be lower.[20] Others continue to believe that the benefits of modest fish ingestion, excepting a few select species, also outweigh the risks.[60]

DIAGNOSTIC TESTING

The dual findings of unexplained neuropsychiatric and renal abnormalities in an individual should alert the clinician to the possibility of mercurialism, as should an at-risk occupation or access by the patient to a mercurial product (see Tables 96–1 and 96–2).

Occupational or environmental exposure and a consistent clinical scenario may be suggestive of mercury poisoning, but demonstration of mercury in blood, urine, or tissues is necessary for confirmation of exposure. Of the many methods available to measure mercury, cold atomic absorption spectrometry is rapid, sensitive, and accurate but cannot distinguish the various forms of mercury. Thin-layer and gas chromatographic techniques can be used to distinguish organic from inorganic mercury.[22] Whole blood should be collected into a trace element collection tube obtained from the laboratory performing the assay. Urine should be collected for 24 hours into an acid-washed container obtained from a laboratory. Spot collections must be adjusted for creatinine concentration. Attempts to measure or otherwise handle the specimen should be avoided to prevent contamination.

There is considerable overlap among concentrations of mercury found in the normal population, asymptomatic exposed individuals, and patients with clinical evidence of poisoning. There is no definitive correlation between either whole blood or urine mercury concentrations and mercury toxicity. However, mercury serves no useful role in human physiology, and concentrations below 10 and 20 µg/L for whole blood and urine, respectively, are generally considered to reflect background exposure in nonpoisoned individuals. After long-term exposure to elemental mercury vapor, concentrations as low as 35 µg/L for whole blood and 150 µg/L for urine may be associated with nonspecific symptoms of mercury poisoning.[32]

For inorganic mercury poisoning, urine mercury concentrations may correlate roughly with exposure severity and neuropsychiatric symptoms,[74] but the relationship to total-body burden is probably poor. Urine mercury determinations have their greatest usefulness in confirming exposure and monitoring the efficacy of chelation therapy. Whole-blood mercury concentrations may reflect intense, acute inorganic mercury exposure but become less reliable as redistribution to tissues takes place.

Because organic mercury is eliminated via the fecal route, urine mercury concentrations are not useful in methylmercury poisoning. Because methylmercury concentrates in RBCs, the total-body methylmercury burden is best reflected acutely by whole blood concentrations.[22,46] As methylmercury distributes to and accumulates in brain, the severity of clinical manifestations probably more closely reflects the degree of the irreversible neuronal destruction that has taken place rather than the current body burden of mercury. Correlation of increasing whole-blood mercury concentrations with prevalence of paresthesias was suggested in a population of Iraqis studied early in the course of methylmercury poisoning.[19] However, in another group of patients, whole-blood concentrations did not correlate with severity of methylmercury poisoning.[77] This apparent discrepancy may have resulted from the finding that paresthesias are among the earliest reported symptoms of methylmercury poisoning.

Because mercury accumulates in the hair, hair analysis has been used as a tool for measuring mercury burden. However, because metal incorporation reflects past exposure and hair avidly binds mercury from the environment, the reliability of this method is questionable and is not recommended. In addition to mercury assays, neuropsychiatric testing, nerve conduction studies, and urine assays for N-acetyl-β-D-glucosaminidase and β_2-microglobulin are advocated for early detection of subclinical inorganic and organic mercury toxicity.[29,36,74]

GENERAL MANAGEMENT

After the initial assessment and stabilization, the early toxicologic management of a patient with mercury poisoning includes termination of exposure by removal from vapors; washing exposed skin; GI decontamination; supportive measures, such as hydration and humidified oxygen; baseline diagnostic studies, such as complete blood count, serum chemistries, arterial blood gas, radiographs, and ECG; specific analysis of whole blood and urine for mercury; consideration of possible cointoxicants; and meticulous monitoring.

■ ELEMENTAL MERCURY

Inhalation of mercury vapors or aspiration of metallic mercury may result in life-threatening respiratory failure; in this situation, stabilization of cardiorespiratory function is the initial priority. Postural drainage and endotracheal suction may be effective in removing aspirated metallic mercury. Parenteral deposition of subcutaneous or intramuscular (IM) mercury may be amenable to surgical excision, if well localized (see Fig. 96–1).

An adjunct to the initial management of patients with mercury poisoning is consideration for environmental decontamination. Elemental mercury that spills onto solid surfaces should be adsorbed to sand and the resulting mixture then swept into tightly sealed containers. Ideally, a mercury decontamination kit should be used. The kit consists of calcium polysulfide, which contains excess sulfur to convert mercury to water-insoluble mercuric sulfide (cinnabar). Absorbent surfaces, such as carpets, should be removed. Spilled mercury compounds should not be vacuumed because vacuuming could volatilize the mercury.[14] With respect to compact fluorescent bulbs, recommendations for decontamination after breakage include opening windows to release vapor, using adhesive tape to pick up visible fragments, and discarding in double-wrapped bags any remains after vacuuming. Guidance for decontamination of major spills and disposal of materials can be provided by local and federal hazardous materials agencies.

■ INORGANIC MERCURY SALTS

Ingestion of inorganic mercuric salts may lead to cardiovascular collapse caused by severe gastroenteritis and third-space fluid loss. Fluid resuscitation

is a priority. GI decontamination of ingested inorganic salts of mercury is particularly problematic because of their causticity and risk for perforating injury. Nevertheless, one series of patients with mercuric chloride ingestion of up to 4 g reported recovery without long-term GI sequelae in patients who did not succumb to renal failure.[96] Therefore, unless there is high suspicion for penetrating GI mucosal injury, removal of mercury from absorptive surfaces should take priority over endoscopic evaluation. The prominence of vomiting makes gastric lavage unnecessary for most patients with inorganic mercury poisoning.

Metals are among the substances that are often considered to be poorly adsorbed to activated charcoal. Nevertheless, the serious nature of late sequelae after mercury absorption, the typically small quantities of mercury ingested, and evidence that inorganic mercuric salts actually have substantial adsorption to activated charcoal (800 mg mercuric chloride to 1 g activated charcoal in one in vitro study) justify routine administration of activated charcoal.[5] Whole-bowel irrigation with polyethylene glycol solution may also be useful in removing residual mercury and should be considered, with its progress followed with serial radiographs.

■ ORGANIC MERCURY COMPOUNDS

Organic mercury exposures do not typically present as single acute ingestions but rather as chronic or subacute ingestion of contaminated food. Therefore, GI decontamination is generally moot with respect to organic mercury poisoning. Nevertheless, its irreversible toxicity coupled with unsatisfactory treatments calls for aggressive decontamination when acute ingestions do occur.

CHELATION

After initial stabilization and decontamination, early institution of chelators may minimize or prevent the widespread effects of poisoning. A high degree of protein binding and distribution to the brain are responsible for the lack of efficacy of other measures to increase mercury clearance, such as peritoneal dialysis and hemodialysis.[82] In one report of the use of continuous venovenous hemodiafiltration in combination with a chelator in a patient with severe inorganic mercury poisoning, 12.7% of the ingested dose was recovered in the ultrafiltrate.[23] Hemodialysis may nevertheless ultimately be necessary because of the acute renal failure that often occurs after mercuric chloride poisoning.

Chelators have thiol groups that are believed to compete with endogenous sulfhydryl groups for the binding of mercury, thereby preventing inactivation of sulfhydryl-containing enzymes and other essential proteins (see Antidotes in Depth A26: Dimercaprol [British Anti-Lewisite or BAL] and Antidotes in Depth A27: Succimer [2,3-Dimercaptosuccinic Acid] for further discussion). A history of significant mercury exposure combined with the presence of typical symptoms of mercury poisoning is an appropriate indication for the institution of chelation therapy. Elevated whole-blood and urine mercury concentrations may help support the decision to begin chelation therapy in unclear cases and may also be used to guide the duration of therapy. Provocative chelation, in which urinary mercury excretion before and after a chelating dose is compared to determine the degree of mercury poisoning, is of no value.[42] Chelation tends to increase urinary elimination of mercury, regardless of exposure history and baseline excretion.

■ ELEMENTAL MERCURY AND INORGANIC MERCURY SALTS

For clinically significant acute inorganic mercury poisoning, dimercaprol (BAL) should be administered for 10 days in decreasing

dosages of 5 mg/kg/dose every 4 hours IM for 48 hours, then 2.5 mg/kg every 6 hours for 48 hours, followed by 2.5 mg/kg every 12 hours for 7 days. This dosing regimen of BAL, derived from the use of BAL in lead poisoning, may be adjusted according to clinical response and the occurrence of adverse reactions.

When a patient is able to take oral medications, BAL therapy may be replaced with succimer (2,3-dimercaptosuccinic acid) at 10 mg/kg orally three times a day for 5 days, then twice a day for 14 days if the GI tract is clear. Because headache, nausea, vomiting, abdominal pain, and diaphoresis may result from BAL chelation therapy, oral succimer is recommended in patients who are not acutely ill or who have been chronically poisoned.

Either BAL or succimer is considered the treatment of choice for inorganic mercury poisoning in the United States, but a few other chelators deserve mention. DMPS (2,3-dimercapto-1-propanesulphonate) is a water-soluble dimercaprol derivative that is used in Europe. It may be administered both IV and orally. D-Penicillamine is an orally administered monothiol. Its adverse effects—GI distress, rashes, leukopenia, thrombocytopenia, and proteinuria—although uncommon in therapeutic doses, seriously limit the usefulness of the drug. *N*-acetyl-*d,l*-penicillamine (NAP), an investigational analog of D-penicillamine, is thought to be a more effective chelator of mercury than is D-penicillamine, perhaps because of its greater stability.[8,34]

■ ORGANIC MERCURY COMPOUNDS

The neurotoxicity of methylmercury and other organic mercury compounds is resistant to treatment, and therapeutic options are less than satisfactory. In rats, both BAL and D-penicillamine effectively reduced tissue mercury and prevented neurologic toxicity if administered within the first day of a methylmercury injection.[108] Neither treatment reversed neurologic toxicity when administered 12 days after methylmercury injection. DMPS, D-penicillamine, NAP, and a thiolated resin all led to a marked reduction of blood half-life of mercury (ie, 10, 24, 23, and 19 days, respectively, versus 60 days) during the outbreak of methylmercury poisoning in Iraq in 1971.[19] Clinical improvement was not observed in any treatment group, but it is reasonable to postulate that reducing the total-body burden of methylmercury may prevent or limit the progression of disease. When studied in mice poisoned with methylmercury,[1] succimer was superior to NAP, DMPS, and a thiolated resin in decreasing brain mercury and increasing urinary excretion. Brain mercury was decreased to 35% of control, and the total-body burden fell to 19%. Some animal evidence suggests that BAL may increase mercury mobilization into the brain.[11] For this reason and the lack of serious GI symptoms necessitating parenteral chelation, BAL should not be used for the treatment of patients with organic mercury poisoning.

Because the neurologic impairment associated with methylmercury is both profound and essentially irreversible, early recognition of poisoning and prevention of neurotoxicity are essential to a successful outcome. Although further investigation is necessary, succimer may prove to be the treatment of choice for methylmercury poisoning because of its apparently low toxicity and reported efficacy in animal trials.

SUMMARY

Mercury poisoning by any of the three major forms—elemental, inorganic, and organic—presents a complex toxicologic problem associated with a large variety of clinical presentations. An ever-present awareness of the problems coupled with the knowledge of the differing clinical forms is essential for both early recognition and effective treatment. Although some chelators do show promise in the treatment of mercury poisoning, neurologic sequelae, particularly those

resulting from organic mercury exposures, remain largely irreversible. Promotion of public education regarding the dangers of mercury, its avoidance, and proper disposal may aid in the prevention of mercury poisoning.

CHAPTER 97
NICKEL

John A. Curtis and David A. Haggerty

Nickel (Ni)

Atomic number	=	28
Atomic weight	=	58.7 daltons
Normal concentrations		
Serum	<	1 µg/L (<17 nmol/L)
Urine	<	6 µg/L (<100 nmol/L)

Nickel is a ubiquitous metal commonly found in both the home and industry. It exists in a variety of chemical forms, from naturally occurring ores to synthetically produced nickel carbonyl. The toxicity of nickel is often overlooked outside of the occupational setting, yet it remains one of the most common causes of contact dermatitis worldwide. Nickel carbonyl in particular can produce significant morbidity and mortality, although fortunately such incidents are rare.

HISTORY AND EPIDEMIOLOGY

Nickel is a white, lustrous metal whose name is derived from the German word *kupfernickel* or "devil's copper." Swedish chemist Baron Axel Fredrik first identified nickel in 1751 in a mineral known as niccolite. Nickel comprises 0.008% of the earth's crust and is found in diverse locations, ranging from meteorites and soil to bodies of fresh- and saltwater.

First produced by the Chinese, nickel has been used as a component in a variety of metal alloys for more than 1700 years. The first malleable nickel was produced by Joseph Wharton after the American Civil War. Wharton went on to sell bulk quantities of nickel to the U.S. government for the minting of 3 cent coins and later donated the equivalent of 3.3 million of these coins to help fund what is today known as the Wharton School of Business.[90] The modern United States 5 cent piece, the "nickel," is actually only approximately 25% nickel by weight.[103]

Nickel ores typically consist of accumulations of nickel sulfide minerals of relatively low nickel content. Although a variety of technical methods for extracting nickel from ore have been developed, one method of special note was developed in 1890 by Ludwig Mond, who is credited with the discovery of nickel carbonyl. The Mond process for the extraction of nickel involves passing carbon monoxide over smelted ore. This creates nickel carbonyl, which then decomposes at high temperatures to produce purified nickel and carbon monoxide.[90] Nickel mining was stopped in the United States in 1993,[16] and despite an increasing worldwide demand, as of 2006, there were still no active domestic nickel mines.[49] Nickel is imported into the United States from other nickel-rich countries such as Canada, Russia, and Australia; domestic production of nickel in the United States is essentially limited to the recycling of nickel-containing metals.

Nickel is a siderophoric material that forms naturally occurring alloys with iron, a property that has made it useful for many centuries in the production of coins, tools, and weapons. Today, most nickel is used in the production of stainless steel, a highly corrosion-resistant alloy containing 8% to 15% nickel by weight.[114]

Occupational exposure to nickel and nickel-containing compounds occurs in a variety of industries, including nickel mining, refining, reclaiming, and smelting. Chemists, magnet makers, jewelry makers, oil hydrogenator workers, battery manufacturers, petroleum refinery workers, electroplaters, stainless steel and alloy workers, and welders are at increased risk for exposure to nickel and nickel-containing compounds.[61] The vast majority of nonindustrial human exposures to nickel are usually from dietary and environmental sources. Cigarette smoke contains nickel and elevates urinary nickel concentrations.[34,89] In the occupational setting, nickel carbonyl is responsible for the great majority of acute nickel toxicity; in clinical practice, the most common health issue related to nickel is the development of allergic dermatitis from jewelry and clothing. Nickel ranks behind *Toxicodendron* spp. exposure as the second most common cause of allergic contact dermatitis[31]; in a patch-testing study, more than 30% of adolescents demonstrated an allergy to nickel.[26]

TOXICOLOGY AND PHARMACOKINETICS

■ EXPOSURE

Nickel occurs naturally in soil, volcanic dust, and fresh- and saltwater but also enters the environment from the combustion of fuel oil, municipal incineration, nickel refining processes, and the production of steel and other nickel alloys that may allow aerosolized nickel to be disseminated into the environment.

The specific form of nickel emitted to the atmosphere depends on the source. Complex nickel oxides, nickel sulfate, and metallic nickel are associated with combustion and incineration, as well as smelting and refining processes. Consequently, ambient air concentrations of these forms of nickel tend to be higher in urban areas, and concentrations of nickel in urban household dust may be elevated under certain circumstances and thus may pose some variable exposure risk for young children who crawl or sit on floors.

Nickel carbonyl, $Ni(CO)_4$, deserves special mention. This highly volatile, highly useful, and very deadly liquid nickel compound is commonly used in nickel refining and petroleum processing and as a chemical reagent. Its high vapor pressure and high lipid solubility lead to rapid systemic absorption through the lungs. In the air and in the body, it decomposes into metallic nickel and carbon monoxide, and its toxicity has been compared to that of hydrogen cyanide.[50] Employees are commonly screened for low-level exposure to nickel carbonyl, but disasters such as the Gulf Oil Company refinery incident in 1953 and the Toa Gosei Chemical company incident in 1969 resulted in hundreds of inhalational exposures.[90]

Concentrations of metallic nickel in drinking water in the United States are generally below 20 µg/L.[62] Elevated concentrations of nickel in household and other potable and nonpotable water sources may result from corrosion and leaching of nickel alloys present in various plumbing fixtures, including valves and faucets.[3] Although many water suppliers in the United States monitor nickel concentrations in their water, there is currently no U.S. Environmental Protection Agency regulation regarding how much nickel is permissible in drinking water.

Dietary intake is a recognized source of nickel exposure for humans. Foods high in nickel include nuts, legumes, cereals, licorice, and chocolate. Recently, certain homeopathic medications, Ginseng products, Indian herbal teas, Nigerian herbal remedies, and Chinese herbal plants have been shown to have high nickel content, with some Nigerian herbal remedies containing up to 78 mg nickel/g substance.[23] Although evidence exists for uptake and accumulation of nickel in certain plants, nickel does not seem to bioaccumulate along the food chain.[114] Nickel is not considered an essential element

for human health, and dietary recommendations for nickel have not been established. Normal consumption is between 0.3 to 0.6 mg per day, with the majority of this remaining unabsorbed by the gastrointestinal (GI) tract.[58] Although estimates vary widely, one author estimated that a 70-kg reference human contains 0.5 mg of nickel, giving an average body concentration of 7 ppb.[9] No clear biologic function has been determined for nickel in humans. However, it may serve as a cofactor for various enzymes, or it may facilitate iron absorption or metabolism in microorganisms, as in certain nickel-dependent blue-green algae.[109]

■ ABSORPTION

Nickel enters the body through the skin, lungs, and GI tract. The amount of absorption is dependent on the solubility of the nickel compound in water. Once in the body, nickel exists primarily as the divalent cation. Independent of the particular nickel compound available, elemental nickel, which typically exists as Ni^{+2} under normal conditions, is measured in the serum or urine.

After inhalational exposure, nickel accumulates in the lungs, but only 20% to 35% of nickel deposited in the human lung is systemically absorbed.[9,33] The remainder of the inhaled material is swallowed, expectorated, or deposited in the upper respiratory tract. Subsequent systemic absorption from the respiratory tract is dependent on the solubility of the specific nickel compound in question. The soluble nickel salts (nickel sulfate and nickel chloride) are more easily absorbed than the less soluble oxides and sulfides of nickel.

A man who died of adult respiratory distress syndrome 13 days after being exposed to fumes containing high concentrations of metallic nickel ($\sim$380 mg/m^3) had very high concentrations of nickel in his urine (700 μg/L).[73] This case report demonstrates that metallic nickel can be systemically absorbed from the lungs; however, many authorities believe that pulmonary concentrations must be high enough to result in direct pulmonary injury for systemic absorption to occur after inhalational exposure.

Because soluble nickel compounds tend to be more readily absorbed from the respiratory tract compared with nonsoluble or poorly soluble nickel,[102] exposure to the soluble nickel chloride or nickel sulfate results in higher urinary nickel concentrations than does exposure to less soluble nickel oxide or nickel subsulfide. The half-life of nickel in the lungs of rats exposed by inhalation is reported to be 32 hours for nickel sulfate,[37] 4.6 days for nickel subsulfide, and 120 days for green nickel oxide,[10] a fact that probably reflects slow dissolution and absorption from the lungs of less soluble nickel compounds.

After ingestion, approximately 27% of the total nickel in nickel sulfate given to humans in drinking water is absorbed, but only approximately 1% is absorbed when given in food.[95] Serum nickel concentrations peak between 1.5 and 3 hours after ingestion of nickel.[18,70,95] The bioavailability of nickel increased when nickel was administered in a soft drink but decreased when nickel was given with whole milk, coffee, tea, or orange juice.[85] The presence of food in the GI tract appears to reduce the absorption of nickel, and most ingested nickel remains in the gut and is excreted in the feces.

Human studies show that several nickel compounds are capable of penetrating the skin.[30,66] In one study, radioactive nickel sulfate was applied to occluded skin.[66] It was determined that 55% to 77% of the applied nickel was absorbed within 24 hours, with most of the nickel being absorbed in the first few hours. It could not be determined, however, if the nickel had been absorbed into the deep layers of the skin or into the bloodstream. In a study using excised human skin, whereas only 0.23% of an applied dose of nickel chloride permeated the skin after 144 hours when the skin was not occluded, 3.5% permeated occluded skin.[30]

■ DISTRIBUTION

In human serum, the exchangeable pool of primarily divalent nickel is bound to albumin, L-histidine, and α_2-macroglobulin.[65] A nonexchangeable pool of nickel that is tightly bound to a transport protein known as nickeloplasmin also exists in the serum. Nickel crosses the placenta[79] and may accumulate in breast milk, resulting in the potential for nickel exposure to offspring.[25]

Nickel also appears to be concentrated in various solid organs rather than in serum. An autopsy study of individuals not occupationally exposed to nickel reports the highest concentrations of nickel in the lungs followed by the thyroid, adrenal glands, kidneys, heart, liver, brain, spleen, and pancreas.[74] Nickel concentrations in the nasal mucosa are higher in workers exposed to less soluble nickel compounds relative to soluble nickel compounds,[102] indicating that after inhalation exposure, less soluble nickel compounds remain deposited on the nasal mucosa.

■ ELIMINATION

In humans, most ingested nickel is excreted in the feces; however, because more than 90% of ingested nickel does not leave the gut,[93] most of the nickel found in feces represents this unabsorbed fraction rather than the elimination of body nickel.[70,95] Absorbed nickel is primarily excreted in the urine and to a lesser degree in the saliva and sweat.[52]

Regardless of the route of exposure, workers occupationally exposed to nickel have increased urinary concentrations of nickel.[5,28,33,36,102] After inhalational exposure to green nickel oxide, nickel was only excreted in the feces, implying that the removal of nickel oxide from the lungs is macrophage mediated rather than through mechanisms dependent on dissolution and absorption.[10] After exposure to nickel subsulfide, nickel was excreted in both the urine and the feces, with greater amounts in the urine on days 6 to 14 after exposure. These results indicate that dissolution–absorption plays an important role in the removal of nickel subsulfide from the lungs; thus, in contrast to nickel oxide, nickel subsulfide behaves essentially like a soluble compound after inhalation.[10]

The elimination half-life of nickel depends on the source of exposure. It is important to note that prolonged elevation of serum and urine nickel concentrations after inhalational exposure to insoluble nickel represents continued slow absorption rather than delayed excretion.

In nickel workers, urinary excretion increased from the beginning to the end of the shift, indicating that a fraction of absorbed nickel is rapidly eliminated.[33,102] Similarly, urinary excretion increased as the workweek progresses, indicating the presence of a fraction that is excreted more slowly.[33]

Studies with radioactive nickel chloride injected into rats show that 68% of administered nickel is eliminated in the urine during the first day,[69] and the urine nickel concentration is commonly assumed to measure exposure over the past 2 to 3 days.[18]

In workers who unintentionally ingested water contaminated with nickel sulfate and nickel chloride, the mean serum half-life of nickel was 60 hours.[94] This half-life reportedly decreased substantially (to 27 hours) when the workers were treated with intravenous (IV) fluids.

No data exist regarding excretion of nickel in humans or animals after dermal exposure.

CLINICAL MANIFESTATIONS

■ ACUTE

The most important source of acute, nondermatologic nickel toxicity is nickel carbonyl. Exposure to this compound is associated with pulmonary, neurologic, and hepatic dysfunction[90] (Table 97–1.)

TABLE 97–1. Sequelae Associated with Nickel Carbonyl Poisoning

Acute lung injury or interstitial pneumonitis

Myocarditis

Altered mental status

Seizure

Profound weakness (sometimes requiring ventilatory support)

Prolonged neurasthenic syndrome (≤6 months after exposure)

Death (secondary to interstitial pneumonitis or cerebral edema)

The specific clinical manifestations associated with acute exposure to other forms of nickel depend on the specific compound and the route of exposure. Whereas inhalation of nickel-containing aerosolized particles tends to affect the lungs and upper airways directly, ingestion and IV administration may result in systemic toxicity, usually involving the neurologic system. By far the most common disorder associated with exposure to nickel is allergic dermatitis.

Nickel Dermatitis Nickel dermatitis was first reported in the late 1800s in nickel-plating workers and was recognized as an allergic reaction in 1925. Since then, nickel has been recognized as a common cause of allergic contact dermatitis. Nickel(2+) is not antigenic by itself. Instead, it acts as a hapten, binding larger proteins and inducing conformational changes such that these become recognized as non-self antigens.[42] One population survey reported that 3% of men and 15% of women demonstrated evidence of allergy to nickel.[57] The fivefold greater prevalence of nickel allergy in women is presumably a consequence of their higher rates of body piercing and more frequent wearing of jewelry, both of which are risk factors for nickel sensitization.[54,75]

Nickel dermatitis is classified into two types: primary and secondary. The more common primary dermatitis presents as a typical eczematous reaction in the area of skin that is in contact with nickel. It is characterized initially by erythematous papules that may proceed to lichenification because of pruritus and scratching. Areas typically involved are the wrists, as a result of wearing watches and bracelets; pierced ears; and periumbilical eruptions at the site of contact with nickel-containing buttons on jeans or nickel-containing belt buckles. (See Fig. 97–1)Approximately 50% of all belt buckles and 10% of buttons on blue jeans contain nickel.[17]

FIGURE 97–1. Nickel dermatitis from jewelry. *(Image contributed by Brian Wexler)*.

The secondary form involves more widespread dermatitis as a result of other exposures, such as ingestion, transfusion, inhalation, and implantation of metal medical devices, and may be regarded as a systemic contact dermatitis elicited by nickel. Secondary eruptions are typically symmetrically distributed and may localize in the elbow flexure, on the eyelids, or on the sides of the neck and face, and they can become widespread. Nickel in foods, excessive skin contact, and certain orthodontic appliances with high nickel content are all linked to this eczematous eruption. Nonetheless, orthodontic exposure to nickel-containing alloys is unlikely to induce hypersensitivity reactions in patients without prior sensitization, and such reactions are still infrequent even in those sensitized.[32,41,71,72,81] In nickel-sensitive patients, these alloys do not seem to affect oral or gingival health.[8] Although patients wearing nickel-containing orthodontia have detectable nickel in their saliva, this is found in negligible concentrations (4–12 ppb) well below concentrations in the average daily dietary intake. Furthermore, these patients have no detectable difference between pre- and post-orthodontia serum nickel concentrations.[41]

Other types of medical devices containing nickel have the potential to induce either primary or local nickel dermatitis. Occlusion of a biliary stent caused by nickel allergy is reported.[47] Much debate has arisen over the past decade regarding metallic coronary stents and the potential for nickel allergy–induced restenosis. Several studies have suggested that inflammatory fibroproliferative restenosis occurs in nickel-sensitive patients, but others have failed to find such a correlation.[43,48,67] Stents containing immunosuppressant drugs such as sirolimus are currently being investigated as a possible solution to such proposed allergic reactions.[60]

The most common cause of nickel dermatitis in women is direct contact from jewelry, garments, or wristwatches and occupational contact in the metal, hairdressing, tailoring, hotel, and restaurant industries. In men, nickel dermatitis is often occupational but may also be related to jewelry, body piercing, and garments in some individuals. Recent case reports describe nickel dermatitis occurring in musicians through either direct contact with instruments or guitar strings.[84]

It is reported that the bimetallic core structure of the 1 and 2 Euro coins creates an electrical potential that results in the release of nickel when in contact with sweat.[64] Although studies report no increase in the prevalence of nickel sensitivity before and after the switch to the Euro in the general population,[54] positive patch tests to Euro coins[68] and cases of dermatitis in certain high-risk patients have been reported.[78]

Recently, reports have emerged involving cases of contact dermatitis in users of certain types of cellular phones.[11,53,113] Dimethylglyoxime spot testing has confirmed nickel release in such phones.[100] Nickel should be considered a potential cause in cases of facial contact dermatitis of unknown etiology.

One study showed that after skin application, nickel salts are retained in the skin for an extended period of time,[51] which could lead to prolonged antigen processing and consequent immune responses in dermal tissue. Additionally, when in contact with the skin, nickel is oxidized to form soluble, stratum corneum–diffusible compounds that may penetrate intact skin and have the potential to elicit allergic reactions.[39,40] A recent study showed that elicitation of nickel allergy is dependent on both the size and concentration of exposure.[29]

The allergic reaction caused by contact with nickel is a type IV delayed hypersensitivity immune response that typically occurs in two phases. In the first phase, sensitization occurs when nickel enters the body. The second phase occurs when the body is reexposed to nickel, at which time allergy manifests. The diagnosis of nickel allergy is suggested by specific historical findings listed in Table 97–2.

Nickel Carbonyl Nickel carbonyl is the most potentially harmful form of nickel, and the majority of acute occupational nickel exposures involve

TABLE 97–2. Findings Suggestive of Nickel Dermatitis

History of allergic response to jewelry

Multiple body piercings

Eruptions at the site of metal contact or flexural areas if generalized

Seasonal dermatitis in warm months (increased metal–skin contact and increased sweating)

nickel carbonyl. Once dissociated, nickel carbonyl can be oxidized in tissues to Ni^{2+}. Nickel carbonyl is described as having a "musty" or "sooty" odor, although thresholds for detection vary considerably, and potentially harmful exposures cannot be excluded simply by a reported lack of odor. Exposure to concentrations below 100 mg/m³ is fatal in rats after 20 minutes.[91,96]

Nickel carbonyl exposure may cause symptoms rapidly, or symptoms may be delayed. In a series of 179 exposures, approximately 40% of patients reported symptoms within 1 hour of exposure. It is important to note, however, that symptoms were delayed for approximately 1 week in 20% of patients, and even patients with mild initial symptoms could develop severe delayed symptoms, although usually within the next 2 days.[82] In patients who developed symptoms shortly after exposure, the initial manifestations involved nonspecific complaints, including respiratory tract irritation, chest pain, cough, dyspnea, frontal headache, dizziness, weakness, and nausea. Cases manifesting only these initial signs are categorized as mild intoxication.[82]

Symptoms of severe acute nickel carbonyl poisoning generally develop over the course of several hours to days and may be associated with acute lung injury and interstitial pneumonitis. Myocarditis, marked by prolonged ECG changes, including ST- and T-wave changes, as well as QT interval prolongation, are reported.[82] Neurologic symptoms associated with severe poisoning include altered mental status, seizures, and extreme weakness that sometimes necessitates mechanical ventilation. Moderate leukocytosis (10,000–15,000 white blood cells/mm³), nonspecific opacities on chest radiography, and elevation of aminotransferases may occur, but these tend to resolve over the course of several weeks. Deaths from nickel carbonyl are typically caused by interstitial pneumonitis and cerebral edema occurring within 2 weeks of initial exposure.[96] Survivors usually recover completely, although the development of a prolonged neurasthenic syndrome may occur and may last in some cases for up to 6 months.[82]

Parenteral Administration Acute parenteral toxicity from nickel-containing compounds occurred after the use of water for hemodialysis that had been heated in a nickel-plated tank.[111] The concentration of nickel in the delivered water was 0.25 mg/L, and serum concentrations were exceedingly elevated. These patients developed nonspecific symptoms, including headache, nausea, and vomiting, similar to the symptoms of nickel carbonyl poisoning, although no respiratory complaints were reported. The effects resolved after several hours, and the patients recovered without sequelae.[111]

Ingestion Acute ingestions of contaminated water containing 1.63 g Ni^{2+}/L caused nausea, vomiting, diarrhea, weakness, and headache, as well as pulmonary symptoms, including cough and dyspnea, lasting up to 48 hours.[94] Estimated ingested doses of nickel (as Ni^{2+}) were 0.5 to 2.5 g, and serum concentrations as high as 13.4 µg/L were reported. The death of a 2-year-old girl occurred after ingestion of 2.2 to 3.3 g Ni

in the form of nickel sulfate crystals. After ingestion, this child reportedly developed depressed level of consciousness, nuchal rigidity, mydriasis, erythema, tachycardia, and acute lung injury.[27]

Inhalational Exposure A case report described seizure activity in two patients after occupational inhalational exposure to non-carbonyl nickel. Both patients exhibited elevated urinary nickel concentrations, with no recurrence of seizure activity upon removal from exposure.[24] This complication was documented previously in rats with nickel sulfate toxicity.[2,20] Although the mechanism for this is not quite clear, animal studies indicate that inhibition of the glutamate transporter may be involved.[55] Interstitial pneumonia is also associated with inhalational exposure while spray painting high-temperature nickel–chromium alloys.[38] As previously mentioned, inhalational exposure to metallic nickel may induce acute respiratory distress syndrome.[73]

Dermal Absorption Although transdermal absorption is typically of minor clinical significance, disruption of the normal integument may allow for more efficient systemic absorption. A metal refinery worker experienced a 40% body surface area partial-thickness chemical injury resulting from exposure to a chemical mixture that included nickel carbonate and nickel sulfate. Before the incident, this individual's measured serum nickel concentration was 1.33 µg/L (0.023 µmol/L). On the sixth day after the injury, the serum concentration was 28 µg/L (0.490 µmol/L). Two 5-day courses of chelation with edetate calcium disodium (CaNa₂EDTA) were begun for concomitant cobalt poisoning, and the patient's serum and urine nickel concentrations were within normal limits by 21 days after exposure. He subsequently recovered without manifesting signs of nickel toxicity.[63]

■ CHRONIC NICKEL EXPOSURE

Chronic inhalational exposure to nickel is associated with injury as well as specific histologic changes in the nasopharynx and upper respiratory tract, including atrophy of the olfactory epithelium,[35] rhinitis, sinusitis, nasal polyps, and septal damage.[14] Pulmonary effects may include asthma[56] and pulmonary fibrosis.[12,35]

Although evidence of the effects of chronic nickel exposure on reproduction remains limited, a study of Indian welders occupationally exposed to nickel and cadmium showed reduced sperm counts and quality, with a positive correlation between sperm tail defects and serum nickel concentrations.[22] Several epidemiologic studies investigating the effects of nickel exposure in female refinery workers have found no increased risk of spontaneous abortion, newborn genital malformation, or incidence of small-for-gestational-age newborns.[105–107]

The International Agency for Research on Cancer classifies nickel compounds as a group 1 carcinogen (carcinogenic to humans).[44] The potential for and mechanisms of carcinogenesis of nickel depend heavily on the specific compounds studied. Animal studies show a threshold dose–response curve for inflammation with soluble compounds (nickel sulfate), and similar curves describe the risks of pulmonary cancers with the less soluble nickel oxides and nickel subsulfide.[80] Although earlier studies of occupationally exposed workers, primarily electroplaters and refinery workers, also showed increased rates of nasal and pulmonary tumors, more recent studies of refinery workers in more modern environments with lower permissible limits of nickel exposure do not show an increased risk of cancer or any cause of mortality.[83,86,87]

Reactive oxygen species (ROS) formation occurs secondary to depletion of both glutathione and protein-bound sulfhydryl groups by nickel. Accumulation of ROS leads to lipid peroxidation and DNA damage.[88,108] Formation of ROS consequently causes depletion of ascorbic acid (vitamin C) as a free radical scavenger in conjunction with vitamin E. In vitro studies of human airway epithelial cells have shown that depletion of intracellular ascorbate from nickel causes the

induction of hypoxic stress. Such nickel-induced stress leads to the activation of hypoxia-inducible factor (HIF-1) and upregulation of hypoxia-inducible genes.[76] Hypoxia is encountered in tumors as they outgrow their blood supply, thus selecting for cells with altered energy metabolism, changes in growth regulation, or resistance to apoptosis. HIF-1 activation and upregulation of hypoxia-inducible genes therefore mimics intracellular permanent hypoxia and may be related to nickel-induced carcinogenesis.[77]

Soluble compounds such as nickel sulfate cause a threshold-dependent inflammatory response and may act as promoters of malignancies without a directly genotoxic effect. Insoluble nickel oxides and nickel sulfide bind to chromatin and nucleic acids[19] and affect expression of various mRNAs.[110] Thus, under some conditions, these compounds may be carcinogenic through genetic or epigenetic mechanisms. The more potent carcinogenic effects of insoluble nickel compounds may be a consequence of their increased cellular uptake.[21]

DIAGNOSTIC TESTING

Although nickel is widely distributed to many body fluids and tissues, urine and blood are the most commonly analyzed samples. Urine collection should ideally use acid-washed, metal-free containers. Some authors recommend correcting urinary nickel concentration per gram of urine creatinine, but it is not clear that this offers any particular advantage in clinical decision making. The average nickel concentration in serum is 0.3 µg/L, and the value in urine ranges from 1 to 3 µg/L.[99] Concentrations among workers occupationally exposed to nickel may be substantially higher, and serum concentrations of more than 8 µg/L are indicative of excessive exposure.[59]

Nickel concentrations increase in urine, serum, and whole blood after oral administration. In these studies, serum concentrations were slightly higher than but correlated well with whole blood. Urine and blood concentrations primarily reflect exposure occurring within the previous 48 hours.[18]

Urine nickel concentrations are used more commonly than blood for monitoring of workplace exposures and for prognostic and therapeutic decision making in nickel carbonyl exposures (Table 97–3.) An

TABLE 97–3. Regulatory Standards for Nickel Exposure

STANDARD	EXPOSURE LIMITS	
Elemental	1.5 mg/m³	
Soluble inorganic	0.1 mg/m³	
Insoluble inorganic	0.2 mg/m³	
Nickel subsulfide	0.1 mg/m³	
Nickel carbonyl	0.12 mg/m³	0.05 ppm
OSHA PEL-TWA		
Non-carbonyl nickel	1 mg/m³	
Nickel carbonyl	0.007 mg/m³	0.001 ppm
NIOSH REL-TWA		
Non-carbonyl nickel	0.015 mg/m³	
Nickel carbonyl	0.007 mg/m³	0.001 ppm

ACGIH, American Conference of Governmental Industrial Hygienists; NIOSH, National Institute for Occupational Safety and Health; OSHA, Occupational Safety and Health Administration; PEL, permissible exposure limits; REL, recommended exposure limits; TLV, threshold limit values; TWA, time-weighted average.

8-hour collection is typically performed, and the average urinary excretion of nickel (in these nickel workers) is 2 µg/L, with an upper limit of normal of 6 µg/L. In cases of nickel carbonyl poisoning, concentrations of below 100 µg/L in the initial 8-hour specimen may imply mild toxicity. Concentrations of 100 to 500 µg/L are classified as moderate, and concentrations above 500 µg/L are categorized as severe exposures.[96] These guidelines are often used in guiding treatment decisions. Urine nickel concentrations increase before the onset of symptoms in nickel carbonyl poisoning, making this determination a potentially useful screening tool for both workforce surveillance and the management of patients with acute exposures.

Testing metal surfaces for free nickel is possible and sometimes necessary in the evaluation and treatment of patients with nickel dermatitis. Patients with clinically important sensitivity or suspect medical histories can order an inexpensive, commercially packaged dimethylglyoxime spot test, allowing them to test metal objects for the presence of free nickel.[17]

TREATMENT

The first step in treatment of nickel-related medical problems is eliminating the exposure, which includes detection and removal of the source. In the case of acute exposures to nickel carbonyl, removal of clothing to prevent continued exposure and thorough skin decontamination may be necessary.

Symptomatic treatment for pulmonary symptoms associated with hypoxia includes the administration of supplemental oxygen. The use of bronchodilators and corticosteroids may also be necessary for the treatment of concomitant bronchospasm. Mechanical ventilation may be required in the most severe cases.

The administration of IV fluids to promote diuresis reduces the half-life of orally ingested nickel chloride by approximately 50%.[94] It is important to note, however, that hemodialysis does not effectively remove nickel from the serum.[111]

■ CHELATION

Because there have been no controlled human trials, specific recommendations for the use of chelation to treat nickel toxicity are not currently supported by the literature. As a result, extrapolation from animal studies and case reports forms the basis for most treatment regimens. Most studies and reports involving treatment have focused on workers exposed to nickel carbonyl.

Several chelators are proposed as potential treatments for patients with nickel carbonyl exposures. Studies in rats with various chelators show some protection by administration of British anti-Lewisite (BAL) and D-penicillamine[112]; calcium EDTA had no protective effect.[92] Although BAL was been used in the past,[96] the most recent literature has focused on the use of diethyldithiocarbamate (DDC) (see Chaps. 79 and 99 and Antidotes in Depth A-26 and A-28).

DDC is a chelator formerly used as the color reagent for urine nickel measurements. Rats exposed to several times the LD_{50} (median lethal dose for 50% of test subjects) for nickel carbonyl had dramatically reduced mortality when pretreated with DDC; the antidotal efficacy, however, decreased with increasing delay to treatment.[7] A proposed treatment regimen for exposed workers focused on analysis both of the exposure and of the initial 8-hour urine collection.[96] Patients with suspected severe poisonings are typically given the first gram of DDC in divided oral doses. When less severe exposures are suspected, treatment decisions are based on the urinary nickel concentration (Table 97–4.) At concentrations below 100 µg/L, no initial therapy is recommended because delayed symptoms are unlikely to develop. At concentrations between 100–500 µg/L, an oral regimen consisting of

TABLE 97–4. Proposed Diethyldithiocarbamate (DDC) Treatment Regimen After Nickel Carbonyl Exposure[50,96]

Urine nickel	<10 µg/dL	No DDC therapy required
	≥10 mg/dL	1 g PO, then 0.8 g at 4 h, 0.6 g at 8 h, 0.4 g at 16 h, and then 0.4 g q8h
Critically ill		12.5 mg/kg IV (initial dose)
If DDC is unavailable	Disulfiram	750 mg PO q8h for 24 h and then 250 mg PO q8h

PO, orally.

1 g of DDC initially, 0.8 g at 4 hours, 0.6 g at 8 hours, and 0.4 g at 16 hours is used. DDC is continued at a dosage of 0.4 g every 8 hours until there is symptomatic improvement and urine nickel concentration is normal. Patients with severe exposures with urinary nickel concentrations above 500 µg/L may be treated using the same regimen, although they frequently require closer monitoring. Critically ill patients are given parenteral DDC starting at a dose of 12.5 mg/kg; however, given the animal data that the route and timing of administration are important to survival, some authors recommend that parenteral DDC be given as soon as possible after nickel carbonyl poisoning.[15] Although typically well tolerated, DDC is capable of inducing a disulfiram reaction (see Chap. 79) if taken with alcohol, and there are concerns about using DDC when there is concurrent cadmium exposure.[4]

Disulfiram is metabolized into two molecules of DDC. Given that DDC is not pharmaceutically available in the United States, there is some interest in the use of disulfiram as an antidote for nickel carbonyl. Although case reports describe successful treatment of nickel carbonyl toxicity with disulfiram,[50] concern exists because animal studies show that disulfiram increased nickel concentration in brain tissue.[6] One treatment regimen was 750 mg orally every 8 hours for 24 hours followed by 250 mg every 8 hours.[50]

Considering that the majority of the literature and almost all human case reports of nickel carbonyl refer to the use of DDC, it is considered the treatment of choice for nickel toxicity. Although commonly available as a reagent, pharmaceutical-grade DDC may be available commercially through a "complementary medicine pharmacy." It is recommended that the regional poison control center be contacted if necessary to assist with treatment decisions.

Treatments evaluated for divalent nickel exposure are D-penicillamine and N-benzyl-D-glucamine dithiocarbamate (NBG-DTC), which, although not commonly available, more effectively lowers brain nickel concentrations than does DDC, perhaps because of its lower lipid solubility.[97]

Patients with contact dermatitis from nickel are treated using standard measures, including avoidance, topical steroids, and oral antihistamines. Some patients have benefited from dietary alteration to reduce nickel intake. Although sometimes advised, there does not appear to be a role for avoiding stainless steel cookware to reduce the nickel content of food.[1]

SUMMARY

Nickel is an important metal that is ubiquitous in the human environment and vital to the functioning of an industrialized society. This constant exposure to nickel is reflected by high rates of nickel sensitivity and dermatitis in the public. Although systemic toxicity from nickel is rare, it is a potentially important cause of occupational illness. Acute toxicity from nickel carbonyl and the potential cancer risk posed by chronic inhalation of nickel-containing dusts and fumes remain important concerns in many industries.

CHAPTER 98
SELENIUM

Diane P. Calello

Selenium (Se)

Atomic number	=	34
Atomic weight	=	78.96 daltons
Normal concentrations		
Whole blood	=	0.1–0.34 mg/L (1.27–4.32 µmol/L)
Serum	=	0.04–0.6 mg/L (0.51–7.6 µmol/L)
Urine	<	0.03 mg/L (<0.38 µmol/L)
Hair	<	0.4 µg/g (0.01 µmol/L)

Selenium was discovered by Jöns Berzelius in 1817 as a contaminant of sulfuric acid vats that caused illness in Swedish factory workers. He originally believed it to be the element tellurium (from the Latin *tellus*, "earth"), but on finding it to be an entirely new, yet similar, element, he named it from the Greek *selene*, "moon." Selenium has unusual light-sensitive electrical conductive properties, leading to its widespread use in industry. It is both an essential component of the human diet and a deadly poison.

HISTORY AND EPIDEMIOLOGY

Much of what is known about selenium centers around its role as an essential trace element required in the diet of most living things, not around its toxic properties. In the 1970s, it was discovered to be an essential cofactor of the enzyme glutathione peroxidase. Keshan disease, an endemic cardiomyopathy associated with multifocal myonecrosis, periacinar pancreatic fibrosis, and mitochondrial disruption, was described in 1979 in Chinese women and children who chronically consumed a selenium-poor diet.[9] Kashin-Beck disease, a disease causing shortened stature from chondrocyte necrosis, is described in young children in Russia, China, and Korea; although other factors are also likely involved, partial improvement results from with selenium supplementation.[2]

These observations prompted the establishment, in 1980, of the United States' recommended daily allowance (RDA) of selenium. Taking into account the level of supplementation required to achieve optimal glutathione peroxidase activity in selenium-deficient study populations, as well as the amounts required to cause toxicity, the recommendation calls for 55 µg/d. Deficiency occurs when daily intake falls below 20 µg/d.[9]

Chronic selenium toxicity, or selenosis, has occurred throughout history. Described first in animals, the acute syndrome of "blind staggers" and the more chronic "alkali disease" affected livestock eating highly seleniferous plants. Findings included blindness, walking in circles, anorexia, weight loss, ataxia, and dystrophic hooves. Humans in seleniferous areas of China and Venezuela develop similar integumentary symptoms (dermatitis, hair loss, and nail changes) at an intake of approximately 6000 µg/d, which is more than 100 times the RDA.[4,36] In recent years, there have been several outbreaks of chronic selenium toxicity related to improperly packaged dietary supplements.[14,35,42]

Selenium is widely distributed throughout the earth's crust, usually substituting for sulfur in sulfide ores such as marcasite (FeS_2), arsenopyrite (FeAsS), and chalcopyrite ($CuFeS_2$). It is found in the soil where it has leached from bedrock, in groundwater, and in volcanic gas. The highest soil concentrations of selenium in the United States are in the Midwest and West. Dietary selenium is easily obtained through meats, grains, and cereals. Brazil nuts, grown in the foothills of the highly seleniferous Andes Mountains, contain the highest concentration measured in food, but chronic selenium toxicity from Brazil nuts has not been reported.[2]

In industry, selenium is generated primarily as a byproduct of electrolytic copper refining and in the combustion of rubber, paper, municipal waste, and fossil fuels. In general, selenium compounds are used in glass manufacture and coloring, photography and xerography, rubber vulcanization, and as insecticides and fungicides. Selenium sulfide is the active ingredient in many antidandruff shampoos. Gun bluing solution, used in the care of firearms to restore the natural color to the gun barrel, is composed of selenious acid in combination with cupric sulfate in hydrochloric acid, nitric acid, copper nitrate, or methanol. Tables 98–1 and 98–2 list features and regulatory standards of common selenium compounds.

CHEMICAL PRINCIPLES

Selenium is a nonmetal element of group VIA of the periodic table along with oxygen, sulfur, tellurium, and polonium. Selenium exists in elemental, organic, and inorganic forms, with four important oxidation states: selenide (Se^{2-}), elemental (Se^0), selenite (Se^{+4}), and selenate (Se^{+6}). Solubility in water generally increases with oxidation state. Selenium behaves similarly to sulfur in its tendency to form compounds and in biologic systems[2] and is both photovoltaic (able to convert light to electricity) and photoconductive (conducts electricity faster in bright light), which has led to its use in photography, xerography, and solar cells.

At least three solid allotropes of elemental selenium are described: "grey selenium," which predominates at room temperature; red crystalline selenium; and a red amorphous powder.[2] In general, toxicity from elemental selenium is rare and only occurs from long-term exposure. Hydrogen selenide (H_2Se) is formed from the reaction of water or acids with metal selenides or from the reaction of hydrogen with soluble selenium compounds; at room temperature, it exists in gaseous form and results in industrial inhalation exposures. The organic alkyl selenides (dimethylselenide, trimethylselenide) are the least toxic and are byproducts of endogenous selenium detoxification (methylation). Inorganic salts and acids are responsible for all cases of acute toxicity. Selenious acid (H_2SeO_3), generated from the reaction of selenium dioxide with water, is the most toxic form of selenium; ingestion of selenious acid is often fatal.

PHARMACOLOGY AND PATHOPHYSIOLOGY

Selenium exists in one of three forms in the body. First, *selenoproteins* contain selenocysteine residues and play specific selenium-dependent roles primarily in oxidation–reduction reactions. Second, nonspecific plasma proteins bind and may aid in transport of selenium; they may directly bind selenium (albumin, globulins) or contain it as selenocysteine or selenomethionine in place of cysteine and methionine, respectively. Third, there are several inorganic forms of selenium in transit throughout the body, such as selenate, alkyl selenides, and elemental selenium (Se°).

The known specific selenoproteins—glutathione peroxidase, iodothyronine 5-deiodinases, and thioredoxin reductase—each contain a selenocysteine residue at the active site. The most studied of these is glutathione peroxidase, which is responsible for detoxification of reactive oxygen species. Using reduced glutathione (GSH) as a substrate, glutathione

TABLE 98–1. Selenium Compounds

Name	Chemical Formula	Oxidation State	Uses
Selenium (elemental)	Se	0	Photography, catalyst, dietary supplement, xerography
Selenium sulfide	SeS_2	2−	Antidandruff shampoo, fungicide
Hydrogen selenide	H_2Se	2−	–
Dimethylselenide	CH_3SeCH_3	2−	Metabolite, garlic odor
Selenium dioxide	SeO_2	4+	Catalyst, photography, glass decolorizer, vulcanization of rubber, xerography
Selenium oxychloride	$SeOCl_2$	4+	Solvent, plasticizer
Selenious acid	H_2SeO_3	4+	Gun bluing solution
Sodium selenite	Na_2SeO_3	4+	Glass and porcelain manufacture
Selenium hexafluoride	SeF_6	6+	Gaseous electrical insulator
Sodium selenate	Na_2SeO_4	6+	Glass manufacture, insecticide

TABLE 98–2. Selenium Regulations and Advisories

Oral–Recommended Intake and Exposure Limits

RDA (2000)	55 μg/d[a]	(0.8 μg/kg/d)
NAS-TUL	400 μg/d	(5.7 μg/kg/d)
ATSDR-chronic oral MRL[b]	5 μg/kg/d	

Water–Limits

WHO	Drinking water	0.01 mg/L
FDA	Bottled water	0.05 mg/L
EPA	MCL, drinking	0.05 mg/L

Air–Limits[c]

NIOSH	
REL (TWA)	0.2 mg/m³
IDLH	1.0 mg/m³
OSHA	
PEL (TWA)	0.2 mg/m³

[a] Values differ for pregnant and lactating women, children, and neonates.

[b] No acute or intermediate MRL has been established. Chronic ≥365 days.

[c] Ambient background air concentrations are usually in the ng/m³ range.

AHTSDR, American Toxic Surveillance and Disease Registry; EPA, Environmental Protection Agency; FDA, Food and Drug Administration; IDLH, Immediately Dangerous to Life or Health; MCL, maximum contaminant level; MRL, minimal risk level; NAS, National Academy of Sciences; NIOSH, National Institute for Occupational Safety and Health; OSHA, Occupational Safety and Health Administration; PEL, permissible exposure limit; RDA, recommended daily allowance; REL, recommended exposure limit; TUL, tolerable upper limit; TWA, time-weighted average; WHO, World Health Organization.

peroxidase catalyses the reduction of hydrogen peroxide to water and oxidized glutathione (GSSG, or glutathione disulfide); the reaction occurs by concomitant oxidation of the selenocysteine unit on the enzyme.[3,32] Other selenocysteine-containing proteins, such as thioredoxin reductase, also appear to have antioxidant properties. The selenocysteine-containing thyroid hormone deiodinases are responsible for the conversion of thyroxine (T_4) to the active triiodothyronine (T_3) form.

In selenium deficiency, glutathione peroxidase activity is decreased, and GSH and glutathione-S transferases are increased.[32] Consequently, selenium-deficient rats are more resistant to substances detoxified by glutathione-S transferase, such as acetaminophen and aflatoxin B[5], and less resistant to other prooxidants, such as nitrofurantoin, diquat, and paraquat.[5] In animal studies of metal toxicity, selenium also appears to modify the effects of silver, cadmium, arsenic, copper, zinc, mercury, and fluoride; conversely, vanadium, tellurium, and arsenic modify the effects of selenium deficiency or excess.[13,16,18,28,36] Although it is proposed that this is accomplished through the formation of insoluble selenium–metal complexes, these relationships are not entirely understood.[11]

Less is known about the biochemical mechanism of selenium toxicity, and what is known is from in vitro data. Paradoxically, excess selenium causes oxidative stress, presumably as a result of prooxidant selenide (R-Se−) anions. In addition, the replacement of selenium for sulfur in enzymes of cellular respiration may cause mitochondrial disruption, and the substitution of selenomethionine in place of methionine may interfere with protein synthesis. Integumentary effects are also most likely a result of selenium interpolation into disulfide bridges of structural proteins such as keratin.[40]

PHARMACOKINETICS AND TOXICOKINETICS

Gastrointestinal (GI) absorption varies with the species of selenium, and human data are limited. Elemental selenium is the least bioavailable (≤50%), followed by inorganic selenite and selenate salts (75%)[23]; selenious acid is quite well absorbed in the lungs and GI tract (~85% in animal studies[8]). Organic selenium compounds are the best absorbed at approximately 90% as determined by isotope tracers in human studies.[2,21]

Inhalational absorption was documented in a group of workers exposed to selenium dioxide and hydrogen selenide gas,[2,15] but quantitative inhalation studies in humans are not available. Dermal absorption appears to be limited. Selenium disulfide shampoos are not systemically absorbed as measured by urinary selenium levels[8] except in cases of repeated use on excoriated skin.[31]

The toxic dose of selenium varies widely between selenium compounds, as demonstrated by LD$_{50}$ (median lethal dose for 50% of test subjects) animal studies,[36] making milligram per kilogram exposure estimates difficult to interpret. Elemental selenium has no reported adverse effects in acute overdose, although long-term exposure may be harmful. The selenium salts, particularly selenite, are more acutely toxic, as is selenium oxide (SeO_2) through its conversion to selenious acid in the presence of water. Selenious acid may be lethal with as little as a tablespoon of 4% solution in children.

Metabolic conversion of all forms of selenium to the selenide anion occurs through various means (Fig. 98–1), and the selenide ion undergoes one of three fates: (1) incorporation into selenoproteins such as glutathione peroxidase and triiodothyronine; (2) binding by nonspecific plasma proteins such as albumin or globulins; or (3) hepatic methylation into nontoxic, excretable metabolites. Trimethylselenide is the primary metabolite and is excreted by the kidneys, the major elimination pathway for selenium. Fecal elimination also occurs. Dimethylselenide production is usually minor but increases with exposure; this compound is volatilized through exhalation and sweat and is responsible for the garlic

FIGURE 98–1. Metabolism of selenium. The selenide anion is central in selenium metabolism. Organic selenocysteine is converted via the β-lyase enzyme to elemental selenium and then to selenide. Selenomethionine may either undergo transsulfuration to selenocysteine or methylation to excretable metabolites. The selenate and selenite salts are reduced to selenide. Selenide then undergoes one of three processes: methylation, incorporation into selenoproteins, or binding by nonspecific plasma proteins.[1,13]

odor of patients exposed to excess selenium. The remaining selenium in the body is greater than 95% protein bound within 24 hours.[1,36] Toxicokinetic data are limited and vary by compound, and the significance of metabolism in acute selenium salt poisoning is unclear.

CLINICAL MANIFESTATIONS

■ ACUTE

Dermal and Ophthalmic Exposure Dermal exposure to selenious acid or to selenium dioxide (which is converted to selenious acid) and to selenium oxychloride (a vesicant that is hydrolyzed to hydrochloric acid) causes significantly painful caustic burns.[10] Excruciating pain may result from accumulation under fingernails. Corneal injury with severe pain, lacrimation, and conjunctival edema is reported after exposure to selenium dioxide sprayed unintentionally into the face.[24] In chronic exposures, "rose eye," a red discoloration of eyelids with palpebral conjunctivitis, is also described.

Inhalational Exposure When inhaled, all selenium compounds have the potential to be respiratory irritants. In general, inhaled elemental selenium dusts are less injurious than compounds converted to selenious acid. Hydrogen selenide inhalation toxicity is reported throughout the industrial literature.[6] Hydrogen selenide is oxidized to elemental selenium, so acutely, toxic exposures are limited to confined spaces where the hazardous gas may accumulate; however, similar to hydrogen sulfide (H_2S), its ability to cause olfactory fatigue, rendering the exposed persons anosmic to the toxic fumes, may prove very hazardous (see Chap. 20).[6] Acute exposure to high concentrations of hydrogen selenide gas produces throat and eye pain, rhinorrhea, wheezing, and pneumomediastinum, with residual restrictive and obstructive disease that may persist years later.[33]

In contrast, selenium dioxide and selenium oxide fumes form selenious acid in the presence of water in the respiratory tract. Twenty-eight workers in a selenium rectifier plant were inadvertently exposed to smoke and high concentrations of selenium oxide in an enclosed area. Initial symptoms included bronchospasm with upper respiratory irritation and burning. Some acutely developed hypotension, tachycardia, and tachypnea, which resolved over 2 hours. Patients went on to develop chemical pneumonitis, fever, chills, headache, vomiting, and diarrhea. Five patients required hospitalization for respiratory support, with fever, leukocytosis, and bilateral infiltrates. All patients recovered without sequelae.[44]

Selenium hexafluoride is a caustic gas used in industrial settings as an electrical insulator. Its caustic properties are derived from its conversion, in the presence of water, to elemental selenium and hydrofluoric acid. Severe pain and burning of the eyes, skin, and respiratory tract similar to that seen with hydrofluoric acid exposure can occur after inhalation of selenium hexafluoride (see Chap. 105).

Oral Exposure Acute selenium toxicity occurs after ingestion of inorganic selenium compounds, which include sodium selenite, sodium selenate, selenium dioxide, hydrogen selenide, selenic acid, and selenious acid. Selenious acid is the most toxic of these. Elemental selenium and organic selenium compounds do not cause acute toxicity.

Some authors have proposed a "triphasic" course of acute inorganic selenium toxicity, with GI, myopathic, and circulatory symptoms as the overdose progresses.[39] In reality, acute inorganic selenium poisoning is often rapid and fulminant, with onset of symptoms within minutes and, in some cases, death within 1 hour of ingestion. GI symptoms are the most commonly described and the first to occur and include abdominal pain, diarrhea, nausea, and vomiting. This may be partly caused by caustic esophageal and gastric burns but does not occur in all cases. Patients may have a garlic odor. The myopathic phase is characterized by weakness, hyporeflexia, myoclonus, fasciculations, and elevated creatine phosphokinase (CPK) concentrations with normal MB fraction. Renal insufficiency is also reported and presumably results from myoglobinuria and hemolysis. More severely poisoned patients may exhibit lethargy, delirium, and coma.

Circulatory failure is the hallmark of serious inorganic selenium toxicity. Patients present with dyspnea, chest pain, tachycardia, and hypotension. The initial electrocardiogram (ECG) may demonstrate ST elevation, a prolonged QT interval, and T-wave inversions. Refractory hypotension occurs as a combined product of decreased contractility from toxic cardiomyopathy and decreased peripheral vascular resistance. Pulmonary edema, ventricular dysrhythmias, myocardial and mesenteric infarction, and metabolic acidosis all contribute to poor outcome in these patients.[25,29,44] Death results from circulatory collapse in the setting of pump failure, hypotension, and ventricular dysrhythmias, often within 4 hours of ingestion.[7,17,19,30,38]

Other less frequent abnormalities include hypokalemia, hyperkalemia, coagulopathy, leukocytosis, hemolysis, thrombocytopenia, and metabolic acidosis with elevated lactate.[34,39]

The classic scenario of acute fatal inorganic selenium poisoning is in the context of selenious acid ingestion, usually as gun bluing solution. Similar toxicity may result from selenium oxide and dioxide, which are converted to selenious acid as well as sodium selenite and selenate. The underlying mechanism for this fulminant clinical syndrome is not well understood but may stem from a multifocal disruption of cellular oxidative processes and antioxidant defense mechanisms.

■ CHRONIC

Chronic elemental selenium toxicity, or selenosis, has received recent attention because of reports of improperly packaged nutritional supplements. In 2008, at least 200 people were affected by a manufacturing error in a selenium-containing dietary supplement and developed diarrhea, alopecia, fatigue, and nail deformities.[42] The manufacturer voluntarily recalled the product, and a Food and Drug Administration investigation revealed that the liquid supplement contained 800 μg/L

instead of the 7.3 µg/L of selenium claimed on the packaging.[43] A similar outbreak occurred from a super-potent supplement in 1983, affecting at least 13 patients, all of whom recovered after discontinuation of the supplement.[14,35]

Selenosis is similar to arsenic toxicity, with the most consistent manifestations being nail and hair abnormalities. As with arsenic toxicity, nail or hair findings alone are unlikely to be the sole evidence of selenosis, but their absence makes the diagnosis unlikely. The hair becomes very brittle, breaking off easily at the scalp, with regrowth of discolored hair and the development of an intensely pruritic scalp rash. The nails also break easily, with white or red ridges that can be either transverse or longitudinal; the thumb is usually involved first, and paronychia and nail loss may develop.[27] The skin becomes erythematous, swollen, and blistered; slow to heal; and with a persistent red discoloration. Increased dental caries may occur.[12] Neurologic manifestations include hyperreflexia, peripheral paresthesia, anesthesia, and hemiplegia. Although cardiotoxicity is described with both selenium deficiency and acute poisoning, no such cases are reported with human selenosis. Aside from one case described in the Chinese population, in which there were insufficient postmortem data, there have been no reported deaths from intermediate or chronic exposure.

Selenosis is implicated in a number of long-term environmental exposures. Many descriptions come from inhabitants of the Hubei province of China from 1961 to 1964, the majority of whom developed clinical signs after an estimated average consumption of 5000 µg/d of selenium (but as little as 910 µg/d) derived from local crops and vegetation.[45] Inhabitants of a seleniferous area of Venezuela, consuming approximately 300 to 400 µg/d of selenium, also develop symptoms of selenium excess; however, the low socioeconomic and poor dietary status of the subjects may also contribute to their symptoms. In contrast, U.S. residents in a seleniferous area with a high selenium intake (724 µg/d) over 2 years who were compared with a control population and monitored for symptoms and laboratory abnormalities, remained asymptomatic, with only a clinically insignificant elevation of hepatic aminotransferases in the high-selenium group.[22] Average selenium concentrations were serum, 0.215 mg/L; whole blood, 0.322 mg/L; and urine, 0.17 mg/L.

Selenosis is also reported in the industrial setting. Copper refinery workers demonstrate garlic odor and GI and respiratory symptoms coincident with exposure to selenium dust and fumes.[15] Long before workplace biological monitoring took place, intense garlic odor of the breath and secretions was recognized as a reason to remove a worker from selenium until the odor subsided. Neuropsychiatric findings such as fatigue, irritability, and depression are reported throughout the industrial literature and are difficult to quantify. Early reports describe the selenium factory worker who "could not stand his children about him" at the end of the day.[10]

Although carcinogenicity is suggested by a number of animal studies, in humans, the data available suggest, if anything, an inverse correlation between selenium intake and cancer risk. The International Agency for Research on Cancer does not list selenium as a known or suspected carcinogen.[2]. Animal studies also suggest that selenium has embryotoxic and teratogenic properties.[11] A recent large randomized controlled trial of selenium supplementation suggested an increased the risk of diabetes mellitus with the ingestion of 200 µg/day of elemental selenium-fed baker's yeast compared with placebo.[41]

DIAGNOSTIC TESTING

Over time, selenium is incorporated into blood and erythrocyte proteins, making serum the best measure of acute toxicity and whole blood preferable for the assessment of patients with chronic exposure. Patients with acute poisoning generally demonstrate an initial serum concentration

greater than 2 mg/L, which falls below 1 mg/L within 24 hours, reflecting redistribution.[27] Patients with long-term elemental exposures are reported to have serum concentrations of 0.5 to 1.0 mg/L. However, selenium concentrations do not demonstrate a predictable relationship with exposure, toxicity, or time course. Population-based studies suggest an average serum concentration of 0.126 mg/L in the United States.[26]

Urine concentrations reflect very recent exposure because urinary excretion of selenium is maximal within the first 4 hours. In addition, urine concentrations are an imperfect measure because they can be affected by the most recent meal and hydration status. However, in general, a normal urinary concentration is less than 0.03 mg/L. Freezing of urine specimens after collection is recommended to retard the enzymatic formation of difficult-to-detect volatile metabolites.[27]

Hair concentrations of selenium were measured in the Hubai Chinese populations of interest and may be a useful measure of exposure.[37,45] However, the usefulness of hair selenium is limited in countries such as the United States where the use of selenium sulfide shampoos is widespread.

Other ancillary tests to assess selenium toxicity include ECG, thyroid function, platelet counts, hepatic aminotransferases, creatinine, and serum creatine phosphokinase concentrations. These are abnormal in some patients (eg, in patients with selenious acid poisoning) and are not indicated in patients not expected to develop systemic toxicity.

MANAGEMENT

■ PAIN MANAGEMENT

Treating painful skin, nail bed burns, or ocular pain with 10% sodium thiosulfate solution or ointment may provide relief of symptoms as the result of a reduction of selenium dioxide to elemental selenium.[10] In one series, workers exposed to selenium dioxide fumes reported similar relief from inhalation of fumes from ammonium hydroxide–soaked sponges; the mechanism of this is unclear, and further study is required before this practice can be recommended.[44]

Workers exposed to selenium hexafluoride gas may be treated with calcium gluconate gel to the affected areas. This is the same treatment as in hydrofluoric acid exposures, which is discussed in Chapter 105.

■ DECONTAMINATION

As with any toxic exposure, prompt removal from the source is required if possible. Patients with dermal exposure should be irrigated immediately. There are limited data to support the use of aggressive GI decontamination after the ingestion of most elemental selenium–containing xenobiotics because there is little expected acute toxicity. However, in xenobiotics with the potential for producing systemic toxicity, such as the selenite salts, decontamination with gastric lavage or activated charcoal may be warranted. Although no charcoal adsorption data are available to guide this therapy, it should be considered in light of potential benefit until further information is available.

Special mention should be made of the ingestion of selenious acid, which is both a caustic with attendant decontamination difficulties and a serious systemic poison. The judicious use of nasogastric lavage may be indicated based on the time since ingestion, the amount and concentration ingested, the presence or absence of spontaneous emesis, and the clinical condition of the patient.

■ CHELATION AND ANTIDOTAL THERAPY

There are no proven antidotes for selenium toxicity. Animal studies and scant human data suggest that chelation with dimercaprol (BAL),[21] edetate calcium disodium (CaNa$_2$EDTA), or succimer form nephrotoxic

complexes with selenium do not speed clinical recovery and may, in fact, worsen toxicity.[20,21,29] Arsenical compounds appear to ameliorate selenium toxicity through enhanced biliary excretion,[6,11,15,20] but there are no studies to guide this potentially toxic therapy. Vitamin C is hypothesized to limit oxidative damage but has not been studied. Bromobenzene may accelerate urinary excretion of selenium,[6] but its inherent toxicity limits its use, regardless of efficacy.

Extracorporeal removal techniques such as hemodialysis or hemofiltration decrease selenium concentrations in patients undergoing the procedure regularly for renal failure, so theoretically, this could be of use in lowering toxic serum selenium concentrations. However, because of extensive protein binding, this benefit may be only minor and only relevant to patients undergoing frequent dialysis. Although there are reports of using hemodialysis in patients with acute selenium poisoning, further study must occur before this can be recommended.[18,19]

■ SUPPORTIVE CARE

This is the mainstay of therapy in selenium poisoning. In particular, patients with selenious acid toxicity require intensive monitoring and multisystem support to survive.

SUMMARY

Selenium is an essential trace element and is required in the diet of both animals and humans. However, in overdose or with excessive chronic exposure, toxicity may result. In particular, ingestion of selenious acid is often fatal. Other selenium compounds cause variable toxicity, usually in the setting of occupational exposure. Topical and inhalational exposure causes burns and pulmonary irritation, respectively. Acute systemic exposure results in GI, myopathic, and circulatory symptoms. Long-term exposure to elemental selenium may cause selenosis, of which alopecia is the most consistent finding. Although it is possible to obtain blood, urine, and hair selenium concentrations to confirm exposure, there is no clear relationship between levels and clinical outcome. Supportive therapy remains the standard of care.

CHAPTER 99
SILVER

Melisa W. Lai Becker and Michele Burns Ewald

Silver (Ag)		
Atomic number	=	47
Atomic weight	=	107.9 daltons
Normal concentrations		
Serum	<	1 µg/L (<9 nmol/L)
Urine (24 hour)	<	2 µg/L (<18 nmol/L)

Silver, often referred to as a "precious metal," has been used for thousands of years in an impressive array of applications, including as coins and as a financial standard, instrument and tool material, chemical catalyst, electrical conductor, and medicinal ingredient and adjunct. It occurs throughout the earth's crust at an average concentration by weight of 80 ppb and in sea water at 0.1 ppb. Life-threatening toxicity of silver is uncommon, but chronic exposure may lead to permanent disability.

Silver has considerable strength and malleability, as well as excellent thermal and electrical conductivity, due to its weak interaction with oxygen (second only to gold). These properties are responsible for its widespread use throughout the health, science, and engineering industries, where it remains a key component of batteries, mechanical bearings, catalysts, coins, electroplating, mirrors, coatings, photography, medical bactericidal agents, and water purification.

This prevalence of silver notwithstanding, silver poisoning is rare and is often the result of occupational exposure or self-administration of silver-containing products for unproven medicinal purposes. Since the mid-20th century, the use of silver for medicinal purposes has infrequently resulted in iatrogenic overuse and subsequent *argyria*, which is a permanent bluish-gray discoloration of skin that is the primary manifestation of chronic silver overexposure.[5]

HISTORY

Although the symbol of silver, Ag, is derived from the Latin and Greek words for silver—*argentum* and *argyros*—the word we use in English is derived from Slavic and Germanic *Silubr* and *Sirebro* and Old English *Seolfor*. Even the alchemy symbol of silver (a crescent moon) and dalton symbol (a coinlike circumscribed letter S) etch the impression of silver as a valued and precious element.

In Asia Minor and on islands in the Aegean Sea, dumps of slag (scum formed by molten metal surface oxidation) demonstrate that silver may have been separated from lead as early as 4000 B.C. The use of silver as a precious metal with trade value appears to have begun around 600 B.C., when weighed pieces of silver were exchanged for goods. Silver coinage debuted circa 550 B.C. in the Mediterranean and was adopted by various empires, dynasties, and nation-states thereafter. Today, only Mexico uses silver in circulating coinage; the United States incorporates silver purely in commemorative and proof coins.

The Phoenicians and early Greeks knew to store water, wine, and vinegar in silver-lined vessels during long sea voyages, just as later American pioneers added silver coins to water barrels and jugs of milk to keep them fresh.[37] The phrase "born with a silver spoon in his mouth"

referred originally to health rather than wealth because silver pacifiers and baby spoons were used to help ward off childhood illnesses.

A traded commodity on the world's markets, silver had been used as an abstract financial standard for various economies throughout modern banking history until the late 19th century.

Beyond the economic role of silver, the electrical and thermal conductive properties of the element make it an invaluable material for scientific instrument manufacture and engineering. Because silver contacts neither corrode nor overheat, silver is commonly used in electronic devices and appliances. Silver was a key component of early telecommunications—it was the choice for Morse's first telegraph contacts in 1844—and made the jet age possible because only silver-plated bearings have the adequate dry lubricity necessary for safe engine shutdown without volatile oil lubricants. Today, washing machines, cars, personal digital assistants, and consumer electronics all use small amounts of silver in their functional parts.

Silver is also used to "make rain"—silver iodide crystals, whose lattice structure is similar to ice, are released into "supercooled" (between 7° and 25°F) clouds, causing water droplets in clouds to attach and form ice crystals. Ice crystals that become large and heavy enough drop from the cloud and melt into raindrops en route to earth.

The medicinal value of silver has been greatly exaggerated, with the element being touted by some as a "cure-all." In the late nineteenth and early twentieth century claims were made that oral administration of colloidal silver proteins (CSPs) (gelatinous suspensions of finely divided elemental silver) would successfully treat diverse diseases, most without evidence.[16,51] However, in 1960, the United States Dispensary declared that "there is no justification for this internal use, either theoretically or practically," and silver was banned in all nonprescription drugs.[14] In 1999, the U.S. Food and Drug Administration issued a Final Rule declaring that all nonprescription drug products containing colloidal silver or silver salts are "not recognized as safe and effective and are misbranded."[15] However, CSPs and other silver-containing "natural" products have been reintroduced for use as health and dietary supplements.[16] After the anthrax terrorist acts of 2001, the mayor of Tampa, Florida, called for CSPs to be mixed into the town's water supply as a protective "elixir" without scientific justification.[2]

In 2002, the Associated Press reported on the reelection campaign of the Montana legislator known as the "blue" lawmaker who promoted the use of colloidal silver health supplements. Because silver-containing products continue to be marketed and sold online as "natural" health supplements with few warnings as to the possible development of argyria, there has been a small resurgence of case reports of argyria today.[19]

EPIDEMIOLOGY

Humans are exposed to minute but varying amounts of silver on a daily basis depending on the occupation. Silver is released into the environment during silver nitrate manufacture for use in photography (diminishing), mirrors, plating, inks and dyes, and porcelain, as well as for germicides, antiseptics, caustics, and analytical reagents. Silver-salt catalysts, used for oxidation–reduction and polymerization reactions, are another a source of silver exposure, as are silver powder pigments and paints.[27] Workplace exposure is often via transdermal, transmucosal, or inhalational routes as silver particles are liberated during various mining, refining, and manufacturing processes.

Additionally, industrial exposure of workers involved in silver mining and manufacturing increases the workplace risk of generalized argyria, although development of signs of argyria from uninterrupted occupational exposure takes a minimum of 24 years.[11] Employees are susceptible to localized argyria and corneal argyrosis from working

with smaller amounts of silver in specific applications, as in the coating of metallic films on glass and china, manufacture of electroplating solutions and photographic processing, preparation of artificial pearls, and simple cutting and polishing of silver.

Today silver is used in water filtration cartridges and supermarket products for washing vegetables and to sterilize recycled drinking water on the MIR space station and NASA space shuttle.[44]

Both the National Institute for Occupational Safety and Health (NIOSH) and the Occupational and Safety Health Administration (OSHA) have established the safe occupational exposure limit to silver metal and soluble compounds as 10 μg/m^3 air per 8-hour work shift. The estimated oral intake of silver from average environmental exposure for humans not working in silver-related industries ranges from 10 to 88 μg/d.[13]

PHARMACOLOGY

Silver that is absorbed into the body is transported by globulins in blood and stored mainly in the skin and liver, with average daily intake excreted in the bile and eliminated in the feces (≤30–80 μg/d) and urine (≤10 μg/d).[11,12,14] Silver elimination through the feces occurs in two phases: phase one has a relatively short half-life ranging from 1 to 2.4 days, varying with route of administration (apparent oral half-life is 1 day, inhalational is 1.7 days, and intravenous (IV) is 2.4 days).[12,13,14,17,35] Phase two elimination has a half-life of 48–52 days, thought to represent liver deposition and clearance.[30,36]

Although one study on a single human subject showed 18% of a single dose of an orally administered silver acetate salt was retained after 30 weeks, animal studies show little silver absorption along the gastrointestinal (GI) tract, with 90% of ingested silver excreted within 2 days of ingestion.[12,13]

Humans retain only 0% to 10% of their daily silver exposure of 10 to 88 μg/d.[53] Minute amounts of silver can accumulate in humans throughout life, with a possible estimated lifetime accumulation of 230 to 480 mg by 50 years of age.[13]

Silver has a 1$^+$(Ag$^+$) valence when bonding with other elements and compounds to form complex ions and salts. Because of the microcidal effects of silver cations at low concentrations,[44] silver has been used as a simple medicinal and bactericidal agent.

The antibacterial activity of silver is related to both direct binding to biotic molecules and to disruption of hydrogen ions and thus pH balance. Silver ions bind to electron donor groups of proteins (sulfhydryl, amine, carboxyl, phosphate, and imidazole) to inhibit enzymatic activities and provoke protein denaturation and precipitation.[16] Silver also intercalates with DNA without destroying the double helix, thereby inhibiting fungal DNAse.[11,14] Silver ions induce proton leakage through a bacterial (*Vibrio cholerae*) membrane, leading to loss of the proton motive force in oxidative phosphorylation, with subsequent energy loss and cell death.[9] Bacterial resistance to silver was not reported until the mid-1970s followed shortly thereafter by the identification of the genes for silver resistance in bacteria.[44]

Although banned from routine administration via IV, intramuscular, and oral routes in the United States, silver salts are approved for use in topical medications, either as a caustic styptic or as a key component of burn care. Approved medicinal uses for silver in the United States apply only to silver salts and compounds and specifically preclude use of elemental silver (Table 99–1).

Silver sulfadiazine added to burn dressings kills bacteria and increases the rate of reepithelialization across partial-thickness wounds.[8] However, concerns of long-term toxicity may limit use by some clinicians.[7] Central venous catheters impregnated with silver sulfadiazine and silver-impregnated Foley catheters are used to lower rates of infection.[31] Recently, silver-lined endotracheal tubes have been

TABLE 99–1. Medicinal Silver-Containing Products

Product Name	Route of Administration	Applications
Silver nitrate (1% AgNO$_3$)	Ophthalmic	Prevention of gonorrheal ophthalmia neonatorum
Silver nitrate (10% AgNO$_3$)	Cutaneous	Chemical cautery of mucosa and exuberant granulations (Podiatry: corns, calluses; Dermatology: impetigo vulgaris, plantar warts, and papillomatous growths)
Silver sulfadiazine (0.2%, 1% micronized silver sulfadiazine)	Cutaneous	Antimicrobial adjunct for prevention and treatment of wound infection for patients with second- and third-degree burns

shown to reduce the risk of ventilator-assisted pneumonia (VAP) by up to 51%, including specifically drug-resistant pathogens such as methicillin-resistant *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Acinetobacter baumanii*.[43]

PATHOPHYSIOLOGY

In great enough quantities, silver manifests cardiovascular, hepatic, and hematopoietic toxicity. Acutely, administration of 50 mg or more of metallic silver IV in humans is fatal, leading to pulmonary edema; hemorrhage; and necrosis of bone marrow, liver, and kidneys.[1,14] The mechanism for this acute toxicity was studied only in the water flea (*Daphnia magna*) in which silver blocks Na$^+$-K$^+$-adenosine triphosphate (ATPase) activity.[3] Toxicity in animals is listed by system in Table 99–2.

Silver is neither classified as a human carcinogen nor found to be mutagenic, and no data link therapeutic use of silver to human cancer.[13] Although animal studies show that silver implanted subcutaneously may lead to local sarcoma formation, this reaction has been deemed uninterpretable in regard to carcinogenicity as implantation of other insoluble solids, such as plastic and smooth ivory, produce similar results.[13] Colloidal silver injected into rats induces growths at injection sites, but intramuscular injections of silver powder have not induced cancer.[18] Local inflammatory responses notwithstanding, silver is considered an inert substance and not a human carcinogen.

■ ARGYRIA

The most significant effect of silver overexposure in humans is argyria, a permanent bluish-gray discoloration of skin resulting from silver throughout the integument. (See Fig. 99–1)

Cases of argyria have been reported in the medical literature since at least the early 19th century. One of the most famous cases of argyria is that of the Barnum and Bailey Circus' "Blue Man" who died at New York's Bellevue hospital in 1923 and was described on autopsy as follows: "The color of the skin was of an unusually deep blue and from a distance appeared almost black. This deep color was almost uniform throughout the entire body, although it was more intense over the exposed skin areas."[21] An American woman who developed argyria

TABLE 99–2. Silver Toxicity: Systemic Manifestations

Cardiovascular	Rats given 0.1% silver nitrate in drinking water for 218 days developed cardiac ventricular hypertrophy that was not attributable to silver deposition in the heart despite advanced pigmentation in other body organs.[34]
Hepatic	Vitamin E and selenium deficient rats developed hepatic necrosis with ultrastructural changes after administration of silver salts.[7,10,48] Silver can induce selenium deficiency that consequently inhibits synthesis of the seleno-enzyme glutathione peroxidase.
Hematologic	Topical application of silver correlated with bone marrow depression and subsequent development of leukopenia or aplastic anemia.[7]
Renal	Tubular lesions are demonstrated in animals, and acute tubular necrosis is rarely identified in humans.[28]
Neurologic	Silver deposits in peripheral nerves, basal membranes, macrophages, and elastic fibers were found in one reported case of a 55-year-old woman with progressive vertigo, cutaneous hypoesthesia, and weakness after self-administration of silver salts to treat oral mycosis for 9 years.[50]
	Seizures were reported in a schizophrenic patient who ingested >20 mg silver daily for 40 years. Serum silver concentrations were elevated (12 μg/L). Seizures resolved concurrently with discontinuation of silver ingestion and a subsequent decrease in serum silver concentration (12 μg/L).[33]
Dermatologic	Generalized argyria, localized argyria, and argyrosis (silver deposition in the eyes) developed after chronic administration of silver.

as a teenager during the 1950s from use of a nasal CSP for allergies, has described her story on the Internet to warn others of the effects of prolonged contact with or ingestion of silver salts.[23] Her appearance was documented as an Image in Clinical Medicine in the *New England Journal of Medicine*.[5]

Generalized argyria may result from either simple mechanical impregnation of the skin by silver particles or inhalational and oral absorption of particulate silver. Local routes of silver absorption

FIGURE 99–1. Long-term exposure to AgNO$_3$ in the workplace led to this patient's characteristic pigment changes of argyria. A normally pigmented arm is across the patient's chest. *(Image contributed by New York University Department of Dermatology)*.

may be through the conjunctiva or oral mucous membranes after long-term topical treatment with silver salts. In 2002, a 42-year-old European man developed argyria after weekly application for 4 years of a topical nasal vasoconstrictor (Coldargan, manufactured by Siegfried, Sweden) available in Austria. The patient used this product to treat his rhinitis medicamentosa; each drop of medication contained 0.85 mg of silver protein.[46] More directly, colloidal silver protein ingestion for "health supplementation" leads to body burdens of silver that may produce argyria. Argyria was reported in a 33-year-old woman who had ingested 48 mg/d of elemental silver (from silver nitrate capsules) during alternating 2-week periods over 1 year to treat chronic GI symptoms.[4] Her serum silver concentrations remained at 500 μg/L for 3 months after discontinuation of the capsules, indicating significant silver deposition in tissues.

Mechanical impregnation of silver produces localized argyria or argyrosis (deposition into eyes) after repeated contact with metallic silver or silver salts.[25] Localized argyria is reported from both implanted acupuncture needles and short-contact acupuncture, when particle deposition may occur from silver needles used repeatedly during brief therapeutic sessions.[26] Silver sulfadiazine use produces localized argyria in and around wound scars.[17] Localized argyria of the tongue and gingiva is described in patients with silver dental amalgams.[24,39] These patients may also have elevated tissue concentrations of silver, but there are no known cases of significant absorption resulting in generalized argyria.[12] Even long-standing wearing of silver earrings has resulted in local contact argyria.[29,45,47] Corneal argyrosis was frequently reported from prolonged use of colloidal silver disinfectant eyedrops, but because these drops are no longer used, the condition has become an occupational disease caused by both inadequate eye protection and workers rubbing their eyes with hands contaminated by silver particles.[40,42,54]

Histopathology of Argyria There are no pathologic changes or inflammatory reactions visible at a histologic level from silver deposition or impregnation. Rather, the skin discoloration of argyria comes from the silver itself and from the induction of increased melanin production. Silver granules are initially found within fibroblasts and macrophages and then extracellularly along the basement membrane of blood vessels, sweat glands, and dermoepidermal junction and beside erector pili muscles (see Chap. 29). Patients with argyria commonly manifest increased pigmentation over sun-exposed skin. Although the mechanism for this process is not yet fully understood, it has been proposed

that silver-complexed proteins are reduced to their elemental form via photoactivation from sunlight, similar to photographic image development. Silver plus light then further stimulates melanogenesis, increasing melanin in light-exposed areas and enhancing this cycle.

Argyria develops in stages, beginning with an initial gray-brown staining of gingiva, progressing to hyperpigmentation and bluish-gray discoloration in sun-exposed areas. Later, nail beds, sclerae and mucous membranes become hyperpigmented; on autopsy, viscera are noted to be blue. Confirmation of the diagnosis of argyria is through skin biopsy, showing brown-black clusters of silver granules.

Argyria occurs at exposure doses much lower than those associated with acutely toxic effects of silver; the degree of discoloration is directly proportional to the amount of silver absorbed or ingested.[20] The threshold dose for silver accumulation and retention resulting in generalized argyria varies considerably. Discoloration has been reported in some patients from as little as a cumulative 1 g of metallic silver administered IV (from 4 g of silver arsphenamine used to treat syphilis over a 2-year period in the early 1900s), but others have tolerated infusions containing up to 5 g of elemental silver over 9 months before a clinical change was noted.[20]

DIAGNOSTIC TESTING

Urine and serum concentrations of silver can be measured as indices of silver exposure. Hair is also tested for silver, but airborne silver particles may bind to hair and contaminate samples.

In individuals without a history of medicinal silver ingestion or occupational exposure, the normal serum silver concentration is 1 µg/L or below, and the normal urinary silver concentration is 2 µg/L or below (24-hour urine collection).[49] Workers who smelt and refine silver and who prepare silver salts for use in the photographic industry have mean serum concentrations of 11 µg/L and urine silver concentrations of 2.6 µg/L (in single "spot" urine samples).

■ TREATMENT OF ARGYRIA

Chelators are *ineffective* in treating both silver toxicity and argyria.[14] Dermatology conventional wisdom has suggested that topical hydroquinone 5% may reduce the number of silver granules in the upper dermis and around sweat glands, as well as diminish the number of melanocytes.[6] Sunscreens and opaque cosmetics can prevent further pigmentation darkening from sun exposure. Successful treatment of argyria using laser technology has only recently been reported.[38]

Because oxidant deficiencies may enhance silver toxicity, antioxidants, such as selenium and vitamin E, may play a role in reversing the effects of silver exposure. Selenium-dependent glutathione peroxidase synthesis is diminished when silver binds to, and thus reduces, intracellular selenium.[7,48] Supplemental vitamin E and selenium increase tolerance for silver in rats and chickens.[10] Selenium and sulfur are being considered as possible treatments for argyria. Selenium may act to precipitate or chelate silver: silver selenide is insoluble in vivo and should reduce the availability of monovalent silver to interfere with normal enzymatic activities.[1,32,41] Hence, increased selenium intake is theorized to bind silver for excretion rather than skin deposition. Silver–sulfur complexes may be investigated for similar effect, although the silver–sulfur complex is not as stable.[41]

EMERGENCY MANAGEMENT

Although systemic toxicity of silver is predominantly a result of chronic exposure, clinicians rarely encounter a patient who has ingested a colloidal silver product, a silver-containing medicinal product, or a silver

salt. Burns from silver-salt cautery should be managed as chemical burns. Silver ingestion should be managed supportively. Silver-salt ingestion should be treated as a caustic ingestion (see Chap. 104).

SUMMARY

Silver toxicity—primarily argyria and burns—is still occasionally encountered[22,46,51,52]; the workplace environment and health supplementation products are the main sources of exposure. Despite frequent therapeutic use of silver and silver compounds, there is no evidence of silver acting as a mutagen or carcinogen. Significant toxicity is very rare, although argyria from chronic silver use is essentially a permanent manifestation. There are no proven effective means for removing accumulated silver and reversing argyria.

CHAPTER 100
THALLIUM

Maria Mercurio-Zappala and Robert S. Hoffman

Thallium (T1)

Atomic number	=	81
Atomic weight	=	204.37 daltons
Normal concentrations		
Whole blood	<	2 µg/L (<9.78 nmol/L)
Urine (24 hour)	<	5 µg/L (<24.5 nmol/L)

Thallium is a commonly found constituent of granite, shale, volcanic rock, and pyrites used to make sulfuric acid and is also recovered as flue dust from iron, lead, cadmium, and copper smelters.[23] It has been used in alloys as an anticorrosive, in optical lenses to increase the refractive index, in artists' paints, in lamps to improve tungsten filaments, in extreme cold thermometers, in imitation jewelry, as a catalyst, in fireworks, as a rodenticide, and as a medicinal. Diagnostically, small nontoxic amounts of thallium salts are used as radioactive contrast to image tumors and to permit the visualization of cardiac function.[65] Thallium toxicity presents as an uncommon constellation of signs and symptoms that most commonly include gastrointestinal (GI) distress, a painful ascending peripheral neuropathy, and alopecia.

HISTORY AND EPIDEMIOLOGY

Thallium, a metal with atomic number 81, is located between mercury and lead on the periodic table. Thallium is a soft, pliable metal that melts at 572°F (300°C), boils at 2699.6°F (1482°C), and is essentially nontoxic. Thallium forms univalent thallous and trivalent thallic salts, which are highly toxic.

In the early 1900s, thallium salts were used medicinally to treat syphilis, gonorrhea, tuberculosis, and ringworm of the scalp and as a depilatory.[6,65] Although the usual oral dose given for epilation in the treatment of ringworm of the scalp was 7 to 8 mg/kg, fatal doses ranged from 6 to 40 mg/kg.[13,54] Many cases of severe thallium poisoning (thallotoxicosis) resulted from the treatment of ringworm, with one author summarizing nearly 700 cases and 46 deaths.[67]

Because thallium sulfate is odorless and tasteless, it was also successfully used as a rodenticide. Commercially available as Thalgrain, Echol's Roach Powder, Mo-Go, Martin's Rat Stop liquid, and Senco Corn Mix, thallium sulfate was a very efficient rodenticide. As a consequence of numerous case reports of unintentional poisonings,[67,68,79] the use of thallium salts as a household rodenticide was restricted in the United States in 1965. Ultimately, even the commercial use of thallium salts as a rodenticide was banned in the United States in 1972 because of continued reports of human toxicity.

Life-threatening unintentional poisoning continues to occur in other countries where thallium salts are still commonly used as rodenticides.[12,77,85,100] Additional cases of thallium poisoning are reported in the United States and other countries as a result of the use of thallium as a homicidal agent[19,59,63,71,73,82,89] and through contamination of herbal products[86] and illicit drugs such as heroin[76] and cocaine.[41] Although occupational exposures to consequential amounts of thallium salts are uncommon, toxicity is well described in this setting.[35]

The following discussion of thallium toxicity refers to toxicity resulting from exposure to inorganic thallium salts, which represents virtually the entire literature on thallium poisoning. Although exceedingly rare, cases of poisoning with organic thallium compounds have been reported[2] and should be assessed and managed in a fashion similar to that used for patients with inorganic exposures.

TOXICOKINETICS

Exposures usually occur via one of three routes: *inhalation* of dust, *ingestion*, and *absorption* through intact skin. Thallium is rapidly absorbed following all routes of exposure. Bioavailability is greatest after ingestion and exceeds 90%.[37] Distribution follows three-compartment toxicokinetics[78] (see Chap. 8) into a final volume of distribution that is estimated to be about 3.6 L/kg.[17] Thallium can be found in all organs, but it is distributed unevenly, with the highest concentrations found in the large and small intestine, liver, kidney, heart, brain, and muscles.[6,49] In animals, the highest concentrations of thallium are found in the kidneys.[1,49]

The toxicokinetics of thallium can be described in the following three-phase model. The first phase occurs within the 4 hours after exposure during which thallium is distributed to a central compartment and to well-perfused peripheral organs such as the kidney, liver, and muscle. In the second phase, which may last between 4 and 48 hours, thallium is distributed into the central nervous system (CNS).[78] Whereas previous literature suggests that this distribution phase is generally completed within 24 hours of ingestion,[78] one human case suggests slower distribution into the CNS as evidenced by increasing cerebrospinal fluid (CSF) concentrations in the days after exposure when blood concentrations are declining.[89] The third or elimination phase usually begins within 24 hours after ingestion. The primary mechanism of thallium elimination is secretion into the intestine, but enteral reabsorption of thallium that is present in the bile subsequently reduces the fecal elimination.[17,63] Thallium is excreted primarily via the feces (51.4%) and the urine (26.4%).[53] It is filtered by the glomerulus, with approximately 50% being reabsorbed in the tubules. Thallium is also secreted into the tubular lumen in a manner similar to potassium.[3] The duration of the elimination phase depends on the route of exposure, dose, and treatment. Unlike many other metals, thallium does not have a major anatomic reservoir. For this reason, reported elimination half-lives are as short as 1.7 days in humans with thallium poisoning.[39]

PATHOPHYSIOLOGY

The mechanism of thallium toxicity is not well established. Thallium behaves biologically in a manner similar to potassium because both have similar ionic radii (0.147 nm for thallium and 0.133 nm for potassium). Because cell membranes cannot differentiate between thallium and potassium ions, thallous ions accumulate in areas with high potassium concentrations, such as the central and peripheral nervous system and hepatic and muscle tissue.[60,100] This accumulation is the fundamental principle that governs the use of radioactive thallium in cardiac imaging studies. Thallium replaces potassium in the activation of potassium-dependent enzymes.[60] In low concentrations, thallium stimulates these enzyme systems, but in high concentrations, it inhibits them.[7,62] Thallium also inhibits several potassium-dependent systems. Pyruvate kinase, a magnesium-dependent glycolytic enzyme that requires potassium to achieve maximum activity, has 50 times greater affinity for thallous ions than potassium ions.[45] Succinate dehydrogenase, an essential enzyme in the Krebs cycle, is inhibited by small doses of thallium in rats.[34] Sodium-potassium adenosine triphosphatase

(ATPase), which is responsible for active transport of monovalent ions across cell membranes, can use thallous ions at extremely low concentrations because of an affinity that is 10-fold greater than that of potassium ions[8,28] but is inhibited by thallium at higher concentrations.[42]

Thallium also impairs depolarization of muscle fibers.[65] Mitochondrial energy is decreased as a result of the inhibition of pyruvate kinase and succinate dehydrogenase, resulting in a decrease of adenosine triphosphate (ATP) generation via oxidative phosphorylation. Enzymatic destruction results in swelling and vacuolization of the mitochondria after exposure to thallium.[90] At low concentrations, thallium can activate other potassium-dependent enzymes such as phosphatase, homoserine dehydrogenase, vitamin B$_{12}$–dependent diol dehydrogenase, L-threonine dehydrogenase, and adenosine monophosphate (AMP) deaminase.[65] The net result of these processes is a failure of energy production.

Thallous ions have been used to isolate riboflavin from milk in the form of a reversible precipitate. Thallous ions may also form insoluble complexes and cause intracellular sequestration of riboflavin in vivo.[11] Riboflavin is the vitamin precursor of the flavin coenzyme flavin adenine dinucleotide (FAD). Because of a decrease in riboflavin, metabolic reactions dependent on flavoproteins decrease, causing disruption of the electron transport chain and a subsequent further decrease or impairment in the generation of cellular energy.[11] This decrease in cellular energy may lead to a decrease in mitotic activity and cessation of hair follicle formation, resulting in the clinical sign of alopecia. Subsequent hair loss is the result of combined arrested formation and local destruction of hair shaft cells in the hair bulb.[11,79] (see Chap. 29) Unfortunately, riboflavin supplementation was not beneficial in one animal model of thallium poisoning.[4] Data also demonstrate that the dermatologic, neurologic, and cardiovascular effects of thallium toxicity mirror the manifestations of thiamine deficiency (beriberi), highlighting the inhibitory effect of thallium on glycolytic enzymes.[11,65] It is unclear whether thiamine administration has any beneficial effect in patients with thallium poisoning.

Thallium has a high affinity for the sulfhydryl groups present in many other enzymes and other proteins. Keratin, a structural protein, consists of many cysteine residues that cross-link and form disulfide bonds. These disulfide bonds add strength to keratin. Thallium interferes with the formation of disulfide bonds, which may lead to the development of alopecia and defects in nail growth, resulting in Mees lines.[30,65,71,84,85] Additionally, the complexation of sulfhydryl groups with thallium results in a decrease in both the production of glutathione and the reduction of oxidized glutatione.[32,101] This results in oxidative damage[26] and the accumulation of lipid peroxides in the brain (which is most prominent in the cerebellum) and appears as dark, pigmented, lipofuscinlike areas.[33] The complexity and presumable multifactorial nature of thallium poisoning are again highlighted by the inability of N-acetylcysteine (NAC)–induced augmentation of glutathione stores to protect against toxicity in an animal model.[4]

Thallium also adversely affects protein synthesis in animals by damaging ribosomes, particularly the 60S subunit.[40] Although ribosomes are primarily dependent on potassium and magnesium, thallium will be used if present. In an experimental model, low concentrations of thallium are protective against hypokalemia-induced ribosomal inactivation. As thallium concentrations increase, the protective effects diminish, resulting in progressive destabilization and destruction of the ribosomes. Ribosomal destruction may also be produced by exposure to potassium concentrations of 4.5 to 20 times higher than the thallium concentrations necessary to achieve the same effect.[40]

Pathologic studies of the CNS in patients with thallium poisoning reveal localized areas of edema in the cerebral hemispheres and brainstem. Chromatolytic changes are prominent in neurons of the motor cortex, third nerve nuclei, substantia nigra, and pyramidal cells of the globus pallidus. In chronic exposures, there are signs of edema of the pial and arachnoidal membranes and chromatolysis, swelling, and fatty degeneration in the ganglion cells of the ventral and dorsal horns of the spinal cord.[6,79]

The peripheral nervous system, which is usually clinically affected before the CNS, develops a diffuse axonopathy in a classic dying back or Wallerian degeneration pattern.[5,6,15,21,61] (see Chap. 18) Fragmentation and degeneration of associated myelin sheaths are accompanied by activation of Schwann cells.[6,10,11] Because thallium affects the longer peripheral fibers—first sensory, then motor, and finally the shorter fibers—toxic effects occur initially in the lower extremities.[52,70,105]

CLINICAL MANIFESTATIONS

Many of the effects of thallium poisoning are somewhat nonspecific and occur over a variable time course.[50] When combined, however, a clear toxic syndrome can be defined (Table 100–1). Alopecia and a painful ascending peripheral neuropathy are the most characteristic findings.[5,25,63,70] Because of the delayed development of alopecia, the diagnosis of thallotoxicosis is often delayed. In fact, with acute exposures, a dose-dependent latent period of hours to days may precede initial symptoms.[50,65] When death occurs, it is usually the result of coma with loss of airway-protective reflexes, respiratory paralysis, and cardiac arrest.

Unlike most other metal salt poisonings, GI symptoms are usually modest or even absent in thallium toxicity.[13] The most common symptom is abdominal pain, which may be accompanied by vomiting and either diarrhea or constipation.[19,47,50,62,84,102,103] Constipation may be a result of decreased intestinal motility and peristalsis caused by direct involvement of the vagus nerve.[13,65] Rarely, severe symptoms, such as hematemesis, bloody diarrhea, or ulceration of the mucosal lining occur.

Pleuritic chest pain was described in a small series of poisoned patients.[59] Another patient was reported to have developed "chest tightness" shortly after drinking thallium-poisoned tea.[63] There is no known etiology for this finding, although it may also relate to involvement of the vagus nerve.

Tachycardia and hypertension frequently occur in patients with thallotoxicosis and usually develop during the first or second week after acute ingestion. A poor prognosis may be associated with a persistent and pronounced tachycardia. No exact mechanism has been determined for these cardiovascular effects of thallium toxicity. Some authors theorize that they result from autonomic neuropathic dysfunction directly related to involvement of the vagus nerve,[70] but others have noted early electrocardiographic (ECG) changes, such as prolongation of the QT interval, T-wave flattening or inversion, and nonspecific ST-segment abnormalities, which might suggest direct myocardial injury.[6,10,62,65,81] Another theory suggests that the stimulation of ATPase in the chromaffin cells by thallium may lead to increased output of catecholamines, resulting in sinus tachycardia.[3,63]

Neurologic symptoms usually appear 2 to 5 days after exposure. Patients may develop severely painful, rapidly progressive, ascending peripheral neuropathies.[5,6,21,59] Pain and paresthesias are present in the lower extremities (especially the soles of the feet), and although numbness is present in the fingers and toes, there is also decreased sensation to pinprick, touch, temperature, vibration, and proprioception.[5,86] The weight of bedsheets on the lower extremities may be sufficient to cause excruciating pain.[59,61] Motor weakness is always distal in distribution, with the lower limbs more affected than the upper limbs.[10,65]

Symptoms of confusion, delirium, psychosis, hallucinations, seizures, headache, insomnia, anxiety, tremor, ataxia, and choreoathetosis are common. Onset is variable and most likely dependent on dose. Ataxia

TABLE 100–1. Clinical Manifestations of Thallium Poisoning

Organ System	Immediate (<6 h)	Intermediate (Rarely in the First Few Days; within 2 wk)	Late (>2 wk)	Residual Effects
Gastrointestinal

Memory and cognitive deficits			†	‡
Optic neuritis	†	†		‡

† = Typical onset of symptoms. The time course outlined above may be accelerated with extremely large doses. When ª appears in two adjacent columns, the time course is highly variable and may be dose dependent. With small ingestions, many of the effects listed above may not be evident.

‡ = Effects that may persist long after exposure, possibly permanently.

may develop within 48 hours after ingestion. Insomnia occurs in most patients and may progress to total reversal of sleep rhythm. Coma may occur, especially with larger exposures.[10,50,65,84] All cranial nerves can probably be affected by thallium, although abnormalities of cranial nerves I, V, and VIII have not been reported. Cranial nerve III involvement, as evidenced by ptosis, is common and may be asymmetric.[10] Nystagmus, another common finding, demonstrates involvement of cranial nerves IV and VI.[10] Cognitive abnormalities may persist for months after exposure.[56]

Thallium is toxic to both the retinal fibers and the neural retina.[87] In cases of a large, single ingestion of thallium, approximately 25% of patients may develop severe lesions of the optic nerve.[65,84] Optic neuropathy may lead to optic atrophy and a permanent decrease in visual acuity. In the early stages, the optic disk shows signs of neuritis, which is red and poorly defined, and later develops pallor from resultant optic nerve atrophy. In patients exposed to multiple small doses, nearly 100% suffer optic nerve injury.[62] Visual complaints may be delayed in comparison to other neurologic findings[87] and may include decreased acuity and central scotomata. Other described ophthalmic effects are noninflammatory keratitis, cataracts, and the color vision defect of tritanomaly (blue color defect).[93,94]

Renal function may remain normal in mild cases of thallium poisoning, even though the kidney has greater bioaccumulation than any other organ. Changes in renal function in patients with severe thallotoxicosis include oliguria, diminished creatinine clearance, elevated blood urea nitrogen, and albuminuria.[3,59,62,65] These findings correlate with morphologic studies in thallium-poisoned rats, demonstrating abnormalities in the renal medulla, mainly in the thick ascending limb of the loop of Henle, that occur by the second day after exposure and resolve by the tenth day.[3]

Alopecia is the most common and classic manifestation of thallium toxicity.[63,97] Typically occurring as the presenting symptom in patients
FIGURE 100–1. Hair from a patient with severe thallium poisoning (top) compared to a normal (bottom). Note the dark pigmented granules around the root of the poisoned patient. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program)*.

with chronic exposures after an acute exposure, epilation begins in approximately 10 days, and maximal hair loss usually occurs within 1 month.[25,63,67] Facial and axillary hair, especially the inner third of the eyebrows, may be spared, but in some cases, full beards, as well as all scalp hair, are lost.[79] Microscopic inspection of the hair reveals a diagnostic pattern of black pigmentation of the hair roots of the scalp in approximately 95% of poisoned patients,[9,63,84,97] which can be found within 3 to 5 days of initial exposure.[9,62] (See Fig. 100–1) In patients with recurrent exposures, several bands may be noted on the hair shaft, demonstrating multiple exposures. Initial hair regrowth is very fine and unpigmented but usually returns to normal after mild exposure.[62] In patients with severe exposures, alopecia may be permanent. Other dermatologic effects that are observed include acne, palmar erythema, and dry scaly skin that results from sebaceous gland damage.[97] Mees lines appear within 2 to 4 weeks after exposure.[63,71,84] (See Fig. 88–4)

Other less common findings include hepatotoxicity,[41] hypochloremic metabolic acidosis,[84] and anemia and thrombocytopenia.[51,84]

■ TERATOGENICITY

In animal models, thallium is teratogenic.[29,31] In humans, one study evaluated 297 children born in a region in which the population's urine thallium concentrations were higher than normal because of industrial contamination of their environment.[20] Urine thallium concentrations in the exposed children were as high as 76.5 µg/L. Although these children had a slightly higher than expected incidence of congenital abnormalities, no causal relationship could be established with regard to thallium exposure.[20]

There are few human reports of acute thallium poisoning during pregnancy. A comprehensive literature review demonstrated 25 cases, which included acute and chronic exposures that occurred during all trimesters.[36] Thallium slowly traverses the placenta and is able to cause characteristic fetal toxicity,[22,69] which manifests initially as decreased fetal movement, possibly as a consequence of fetal paralysis. The classic clinical signs and symptoms of thallium poisoning have been described both in the fetus after abortion and in neonate after viable delivery.[22,62,69,77] However, the outcome of the pregnancy may be normal despite significant maternal toxicity.[22,43] The only consistent finding is a trend toward prematurity and low birth weight, especially in children exposed during the first trimester.[36] One author recommends continuing the pregnancy as long as the mother is clinically improving.[22] It is

reasonable to conclude that a fetus exposed to thallium during organogenesis has the potential for permanent injury. Those exposed later in pregnancy may recover without deficit if their exposures are limited and the mother recovers. If the exposure occurs closer to term, the child may be born with overt toxicity such as alopecia, dermatitis, nail growth disturbances, and permanent CNS injury.[62]

These few case reports and animal studies provide confusing and sometimes contradictory results. It seems that fetal outcome is determined both by the trimester of pregnancy and the extent of maternal toxicity. However, because there are insufficient data to predict the outcome of pregnancy complicated by maternal thallium poisoning, no specific course of action can be recommended other than extensive fetal monitoring and aggressive treatment for the mother. When a viable child is delivered, it is important to note that thallium is eliminated in breast milk, and a maternal toxicity reevaluation is essential because nursing may result in continued exposure.[34]

ASSESSMENT

Most patients with acute thallium toxicity seek healthcare soon after exposure because of alterations in their GI, cardiovascular, and neurologic function. Establishing the correct diagnosis at this early stage is essential to assure a satisfactory outcome. Unfortunately, many patients with either smaller acute exposures or chronic thallium poisoning first present days to weeks after their initial exposure, and diagnosis is often further delayed. In these instances, many valuable epidemiologic aspects of the exposure history may be difficult to obtain. GI symptoms may not have occurred or their consequence or etiology may have gone unrecognized because of their nonspecific, mild, and transient nature. Many patients with small acute or chronic exposures usually seek care because of alopecia or neuropathy.

The differential diagnosis of the neuropathy includes poisoning by arsenic, colchicine, and vinca alkaloids and disorders such as botulism, thiamine deficiency, and Guillain-Barré syndrome. Both the sensory neuropathy and the preservation of reflexes help differentiate thallium-induced neuropathy from Guillain-Barré syndrome and most other causes of acute neuropathy.[10] When GI symptoms are present in addition to a neuropathy and other end-organ effects, poisoning with metal salts such as arsenic and mercury should be considered (see Chaps. 88 and 96). The differential diagnosis of rapid onset alopecia is more restricted and includes arsenic, selenium, colchicine, and vinca alkaloid poisoning (see Chap. 29). When present, Mees lines indicate past exposure to metals, mitotic inhibitors, or antimetabolites and as such are nonspecific for thallium poisoning (see Chaps. 29, 88, and 96).

■ DIAGNOSTIC TESTING

Radiographs of tampered food products[59] or of the abdomen[30] can document the presence of a heavy metal such as thallium, which is radiopaque. Although abdominal radiography may be useful shortly after a suspected exposure, the sensitivity and specificity of this test is unknown. Similarly, the yield from other routine studies, such as the complete blood count, electrolytes, urinalysis, and ECG, is limited in that these other studies are often normal or at most, merely demonstrate nonspecific abnormalities. Although microscopic inspection of the hair is intriguing, this test is likely to be inconclusive for inexperienced observers.

The definitive clinical diagnosis of thallium poisoning can only be established by demonstrating elevated thallium concentrations in various body fluids or organs. Thallium can be recovered in the hair, nails, feces, saliva, CSF, blood, and urine, and standard assays and normal

concentrations for most of these sources can be found.[65] Qualitative point of care urine spot tests notoriously give false-negative results and require the use of dangerous chemicals that are not routinely available (20% nitric acid) and therefore should be avoided.[84] The standard toxicologic testing method is to assay a 24-hour urine sample for thallium by atomic absorption spectroscopy.[14,104] Normal urine concentrations are below 5 μg/L. Some authors suggest a potassium mobilization test to enhance urinary elimination (similar to the ethylenediaminetetraacetic acid [EDTA] mobilization test) to assist in the diagnosis of thallium exposure.[9,41,84] We advise against this practice because of its lack of proven usefulness and its potential to exacerbate neurologic toxicity (see Potassium below).

MANAGEMENT

The treatment goals for a patient with thallium poisoning are initial stabilization, prevention of absorption, and enhanced elimination. After the initial assessment and stabilization of the patient's airway, breathing, and circulatory status, GI decontamination should be instituted in all patients with suspected thallium ingestions because of the morbidity and mortality associated with a significant exposure.

■ DECONTAMINATION

Patients who present within 1 to 2 hours after ingestion should be considered candidates for orogastric lavage (see Chap. 7). If the patient presents more than 2 hours after ingestion or has had considerable spontaneous emesis, gastric emptying is unnecessary.

Thallium salts are substantially adsorbed to activated charcoal in vitro.[38,47] Additionally, because thallium undergoes enterohepatic recirculation, activated charcoal may be useful both to prevent absorption after a recent ingestion and to enhance elimination of thallium in patients who present in the postabsorptive phase.[95] In fact, a rat model of thallium poisoning demonstrated that multiple-dose activated charcoal (given as 0.5 g/kg twice daily for 5 days) increased the fecal elimination of thallium by 82% and substantially improved survival.[53] Other data demonstrate that activated charcoal alone is superior to either forced diuresis or potassium chloride therapy.[48]

In patients with severe thallium toxicity, constipation is common, so the addition of mannitol[55,91,102] or another cathartic to the first dose of activated charcoal is appropriate. Although no studies address the efficacy of whole-bowel irrigation with polyethylene glycol electrolyte lavage solution, this technique may prove useful, especially when radiopaque material is demonstrated in the GI tract by abdominal radiography.

■ POTASSIUM

The similarities between the cellular handling of potassium ions and thallium ions led to the investigation of a possible role for potassium in the treatment of thallium poisoning. In humans, potassium administration is associated with an increase in urinary thallium elimination.[13,27,72] The magnitude of this increase is reported to be on the order of two- to threefold.[72] This is supported by animal models that demonstrate some benefit in terms of either enhanced thallium elimination or animal survival.[28,48,53] Potassium administration is believed to both block tubular reabsorption of thallium and mobilize thallium from tissue stores, thereby increasing thallium concentrations available for glomerular filtration.[66,84] However, the mobilization of the thallium is of concern. Many authors report either the development of acute neurologic toxicity or the significant exacerbation of neurologic symptoms during potassium administration.[5,27,59,72,81,98] Others cite data demonstrating that the augmentation of thallium elimination by

potassium administration in humans is quite limited.[46] Additionally, animal models demonstrate that potassium loading enhances lethality[58] and permits thallium redistribution into the CNS.[34] For these reasons, the routine use of potassium should be considered potentially dangerous. Some authors recommend forced diuresis, especially in conjunction with potassium chloride.[18,95] However, no convincing experimental or clinical evidence can support the use of forced diuresis with or without potassium at this time.

Likewise, the similarities between thallium and potassium might suggest a role for administration of sodium polystyrene sulfonate (SPS) as a sodium–thallium exchange resin. Although in vitro binding between thallium and SPS is excellent, it is unlikely to be clinically useful because of preferential binding between potassium and SPS.[38] Consequently, neither the use of potassium nor of SPS is recommended.

■ PRUSSIAN BLUE

Prussian blue is a Food and Drug Administration–approved antidote for thallium toxicity (see Antidotes in Depth A29: Prussian Blue).[96] When given orally, Prussian blue acts as an ion exchanger for univalent cations, with its affinity increasing as the ionic radius of the cation increases. As such, Prussian blue interferes with the enterohepatic circulation of thallium by exchanging potassium ions from its lattice for thallium ions in the GI tract. This results in the formation of a concentration gradient, causing an increased movement of thallium into the GI tract.

Humans with thallium poisoning are routinely given Prussian blue, which appears to result in clinical benefits, enhanced fecal elimination, and decreasing thallium concentrations.[14,16,59,75,91,98,99,102,103] One series of 11 thallium-poisoned patients demonstrated both the safety of Prussian blue and its ability to substantially increase fecal thallium elimination.[91] Unfortunately, because there have been no controlled trials in humans that compare Prussian blue with other drugs and because many of the patients reported above received multiple therapies, the actual efficacy of Prussian blue is unknown.

The dose of Prussian blue is 250 mg/kg/d orally via a nasogastric tube in two to four divided doses.[91] For patients who are constipated, the Prussian blue may have greater benefit if dissolved in 50 mL of 15% mannitol.[95] Although any cathartic may be useful, most authors have used mannitol, possibly because of concerns regarding repeated use of magnesium-containing cathartics in patients with neurologic findings and the use of sorbitol in patients with poor GI mobility. (Other dosing regimens are discussed in Antidotes in Depth A29: Prussian Blue.)

■ EXTRACORPOREAL DRUG REMOVAL

Extracorporeal drug removal may have a limited beneficial role in patients with thallium toxicity, especially if it is begun shortly after the initial exposure while serum concentrations remain high before effective tissue distribution. Because a frequently quoted review attests to the benefits of hemodialysis,[62] many patients still receive this therapy.[61] The actual data, however, show that hemodialysis, at various stages of poisoning, is no better than forced diuresis.[16,74] Reported thallium removal rates by hemodialysis are trivial: 143 mg of thallium was removed by 120 hours,[75] 222.8 mg was removed by 121 hours,[16] and 128 mg was removed by 54 hours of hemodialysis.[16] These quantities can be placed in perspective knowing that the minimum lethal adult dose of thallium is estimated to be on the order of 1 g[65] and that many reported cases exceed that by a factor of 10. Data from a more recent hemodialysis experience suggest that by using high blood flow rates (300 mL/min), clearances as high as 90 to 150 mL/min could be obtained.[55] Although these clearances seem encouraging, they should be interpreted with an appreciation of the large volume of distribution of thallium.

TABLE 100–2. Treatment for Thallium Poisoning

Early (patients who present in the first 1–2 hours postexposure)
- Stabilize airway, breathing, and circulation if necessary.
- Consider orogastric lavage if the patient has not vomited.
- Consider whole-bowel irrigation with polyethylene glycol electrolyte lavage solution for patients with large ingestions or the presence of radiopaque material on abdominal radiographs.
- Begin multiple-dose activated charcoal therapy; add a cathartic to the first dose if the patient does not have diarrhea.
- Give 250 mg/kg/d of Prussian blue in two or four divided doses dissolved in water or 50 mL of 15% mannitol if the patient does not have diarrhea.
- Consider simultaneous charcoal hemoperfusion and hemodialysis, especially if the patient has renal insufficiency.

Late (patients who present more than 24 hours after exposure or with chronic toxicity)
- Stabilize airway, breathing, and circulation if necessary.
- Begin multiple-dose activated charcoal therapy; add a cathartic to the first dose if the patient does not have diarrhea.
- Give 250 mg/kg/d of Prussian blue in two or four divided doses dissolved in water or 50 mL of 15% mannitol if the patient does not have diarrhea.

With lower blood flow rates, charcoal hemoperfusion may be two to three times more efficient than hemodialysis, providing clearance rates as high as 139 mL/min.[16] Combined hemoperfusion and hemodialysis were used in several cases[2,16,17] and were reported to remove as much as 93 mg of thallium within 3 hours of therapy.[2] Although extracorporeal therapy alone is probably insufficient for patients with significant poisoning and unnecessary in those with small exposures, it may have some benefit when used in combination with other therapies, especially in patients with renal insufficiency and those with early massive, and presumed lethal, exposures. As is the case with other xenobiotics, thallium is probably not effectively removed by the use of peritoneal dialysis.[46] Table 100–2 summarizes the suggested therapy for thallium-poisoned patients.

■ CHELATION

Patients with thallium toxicity do not respond to traditional chelation therapy. Studies demonstrate that the use of EDTA and diethylenetriamine pentaacetic acid are without benefit.[65,84] Dimercaprol (British anti-Lewisite [BAL]) and D-penicillamine also fail to enhance thallium excretion in experimental models.[65,84] In one model in which D-penicillamine was able to enhance thallium elimination, it did so at the cost of substantial thallium redistribution into vital organs.[80] Similarly, sulfur-containing compounds such as cysteine and NAC have not been demonstrated to be beneficial.[53,57] Another chelator, diphenylthiocarbazone (dithizone), forms a minimally toxic complex with thallium, resulting in a 33% increase in fecal elimination of thallium in rats.[88] Unfortunately, dithizone is goitrogenic and diabetogenic in animal studies.[53,64,95] Dithiocarb (sodium diethyldithiocarbamate), an intermediate metabolite of tetraethylthiuram disulfide (disulfiram, or Antabuse) (see Chap. 79), also increases the urinary excretion of thallium.[88,92] Before thallium elimination, however, the formation of a lipophilic thallium–diethyldithiocarbamate complex may result in the redistribution of

thallium into the CNS.[44,92] After decomposition of the chelate complex, thallium may remain in the CNS, potentially exacerbating neurologic symptoms.[44,82] Because of the significant adverse effects of dithizone and the redistribution of thallium after Dithiocarb use, neither agent is recommended in the treatment of patients with thallium poisoning.

Currently, there is renewed interest in the water-soluble analogs of BAL (DMPS [dimercaptopropane sulfonate] and succimer). However, in an animal model, DMPS failed to decrease tissues concentrations of thallium.[64] Similarly, in another animal model, although succimer improved survival over control subjects, the benefit was less than that achieved for Prussian blue and was at the cost of an increase in brain thallium concentrations.[83] One recent animal investigation demonstrated a significant reduction in serum thallium concentration after repeated administration of deferoxamine.[24] Although worthy of additional study, these results are too preliminary to recommend deferoxamine use in thallium-poisoned patients.

SUMMARY

The elimination of thallium salts from depilatories and rodenticides has substantially reduced the incidence of both intentional and unintentional thallium toxicity in the United States. Despite this, cases of significant poisoning still occur in countries where thallium-containing rodenticides remain in use, as well as in this country, from attempted homicide and by personal injury from contamination of foods and illicit drugs. Early recognition of the characteristic signs and symptoms of thallium poisoning and prompt initiation of safe and appropriate therapy will substantially improve the patient's prognosis. When recognition and subsequent treatment are delayed, morbidity and mortality may be consequential.

PRUSSIAN BLUE

Robert S. Hoffman

Prussian blue, the first artificially synthesized pigment, was discovered unintentionally by Diesbach in 1704 while he was attempting to make cochineal red lake. Although it immediately became popular in art and later in printing, it took approximately 250 years to recognize that Prussian blue was able to attract monovalent alkali metals into its crystal lattice. Subsequently, in 1963, Nigrovic was the first investigator to demonstrate that Prussian blue enhanced cesium elimination from the gut of rats.[33] In 2003, the US Food and Drug Administration (FDA) approved Prussian blue (Radiogardase®) for the treatment of thallium and radioactive cesium poisoning.

The literature associated with Prussian blue is complicated by many confusing chemical and physical terms. The product synthesized by Diesbach, $Fe_4[Fe(CN)_6]_3$, commonly known as insoluble Prussian blue, is assigned the Chemical Abstracts Service (CAS) number 14038-43-8, and is the FDA-approved product Radiogardase® (Fig. A29–1). Synonyms for Prussian blue include Berlin blue, Hamburg blue, mineral blue, Paris blue, and Pigment blue 27, among others.[51] These names are often used interchangeably to refer to both insoluble Prussian blue and a soluble (colloidal) Prussian blue that has the molecular formula either $KFe[Fe(CN)_6]_3$ or $K_3Fe[Fe(CN)_6]_3$. Thus "Prussian blue" also carries two additional CAS numbers: 25869-98-1 and 12240-15-2.[37] Compounds containing the same basic core structure, such as $NH_4Fe[Fe(CN)_6]_3$ (ammonium ferric ferrocyanide or Chinese blue) and sodium ferric ferrocyanide, may have similar efficacy in binding monovalent cations, and are also sometimes incorrectly called Prussian blue. For the purpose of clarity, general statements that follow use the term "Prussian blue." In many instances the terms "insoluble" and "soluble" are chosen to highlight differences between the compounds. Unfortunately, because many studies do not specify which Prussian blue is used, some inherent ambiguity persists.

PHARMACOLOGY

Typically, the crystal lattice of Prussian blue takes up cationic potassium ions from the surrounding environment. However, because its affinity increases as the ionic radius of the monovalent cation increases, Prussian blue preferentially binds cesium (ionic radius: 0.169 nm) and thallium (ionic radius: 0.147 nm) over potassium (ionic radius: 0.133 nm).[6,16] Additionally, binding for rubidium (ionic radius: 0.148 nm) has been demonstrated.[44] Thus, when given orally, Prussian blue binds unabsorbed thallium or cesium in the gastrointestinal tract, preventing absorption as well as reversing the concentration gradient to enhance elimination through gut dialysis. In addition, Prussian blue can interfere with enterohepatic circulation, causing a further reduction in tissue stores.

Insoluble Prussian blue is essentially not absorbed from the gastrointestinal tract and is eliminated in the feces at a rate determined by gastrointestinal transit time. In a radiolabeled study of healthy pigs, 99% of a single ingested dose was recovered unchanged in the stool.[30] In contrast, soluble Prussian blue is absorbed based on the clinical finding of a blue discoloration that develops in the sweat and tears of patients undergoing prolonged therapy.[12] This discoloration appears to be benign and resolves when therapy is stopped. No significant food or drug interactions are known to exist. Animal studies show no adverse effects of therapeutic doses,[39] and oral lethal doses are not known. The only significant adverse effects reported in humans receiving therapeutic doses are constipation and hypokalemia,[50] and the constipation may be related more to the thallium toxicity than to the Prussian blue.

Although there is some concern regarding the potential concentration of cyanide liberated from Prussian blue, this release appears to be quantitatively minimal. Cyanide release from soluble Prussian blue was less than 3 mg/24 h in simulated gastric fluid.[56] When three human volunteers were given 500 mg of radiolabeled soluble Prussian blue, only 2 mg of cyanide were absorbed.[31] Over the physiological range of potential gastrointestinal pH the maximal cyanide release of insoluble Prussian blue was determined to be 135 µg/g at pH 1.[59] When extrapolated, even repeated therapeutic doses would only deliver a trivial amount of cyanide.

IN VITRO ADSORPTION OF THALLIUM

In vitro and, presumably, in vivo binding of thallium to Prussian blue are influenced by its chemical formulation. An early investigation demonstrated that the soluble form more effectively adsorbs thallium than the insoluble form.[8] In a more rigorous study, the in vitro adsorptions of both forms were similar when thallium concentrations remained low.[15] However, as thallium concentrations increased, the colloidal (soluble) form demonstrated far greater adsorptive capacity. Although not proven, this difference may occur because the soluble form contains more potassium and can therefore exchange proportionally more cation. Furthermore, the actual size of the crystal lattice alters its efficacy. Laboratory synthesized Prussian blue (with a crystal size of 17.68 nm) was compared with a commercial preparation (with a crystal size of 31.19 nm). The laboratory synthesized product adsorbed more thallium in vitro, because its smaller size increased its surface area.[16] In vitro analysis of the FDA approved antidote demonstrated that pH and hydration state greatly influence binding with the maximal absorptive capacity (MAC) predicted to be as high as 1400 mg/g at pH 7.5.[60]

THALLIUM POISONING

A thorough analysis of the efficacy of Prussian blue in thallium poisoning is severely hampered by many factors. First, and most importantly, there are no controlled human trials. Second, although multiple patients have received Prussian blue in the setting of thallium poisoning, many were simultaneously treated with a variety of therapies, including forced potassium diuresis, single- or multiple-dose activated charcoal, and either hemodialysis or hemoperfusion. Thus, it is impossible to determine the specific effects of Prussian blue on mortality or other
FIGURE A29–1. The chemical structure of insoluble Prussian blue. The Roman numerals II and III denote the valence state of iron. Although in the most current nomenclature this would be expressed as Fe^{2+} and Fe^{3+}, the figure is drawn this way to be consistent with most available references, which use the older nomenclature.

clinical outcomes, and even toxicokinetic data must be interpreted with caution. Third, many of the in vitro and animal investigations fail to specify the exact type of Prussian blue used. Those investigations that do specify the type of Prussian blue used typically used the soluble form, which is presently unavailable as a pharmaceutical preparation. Discussions of the available data in the following sections are limited by these considerations.

IN VITRO COMPARISON OF PRUSSIAN BLUE WITH ACTIVATED CHARCOAL

In one in vitro study, thallium was well adsorbed to Norit® brand activated charcoal.[15] Although numerical data are not supplied in the body of the paper, the 10% to 20% adsorption to activated charcoal demonstrated in a figure was far less than the results achieved with several different forms of Prussian blue tested simultaneously.[15] Two other binding studies showed different results from the Norit® activated charcoal study. An early investigation determined that the MAC of activated charcoal was 124 mg of thallium/g, whereas the MAC for Prussian blue was only 72 mg of thallium/g.[17] More recently, a MAC of only 59.7 mg of thallium/g was calculated for CharcoAid® activated charcoal, compared with a higher MAC for insoluble Prussian blue of 72.7 mg of thallium/g.[13] Although the MACs for Prussian blue in these two studies are nearly identical, they differ significantly from binding reported above, possibly as a result of different experimental conditions.[60] Similarly, the variable results for activated charcoal may also be a function of the study pH or the different types of activated charcoal used.

ANIMAL DATA: KINETICS, TISSUE CONCENTRATIONS, AND SURVIVAL

Sublethal doses of thallium were used to evaluate the effects of various antidotes in rats over an 8-day period.[17] Although the control group only eliminated 53% of the administered dose of thallium, 93% of the dose was eliminated in the activated charcoal and 82% was eliminated in the insoluble Prussian blue groups. In contrast, other investigators demonstrated only a modest increase in thallium elimination in rats treated with oral activated charcoal while a consistent benefit of Prussian blue was noted.[18]

Multiple studies clearly demonstrate that Prussian blue not only decreases the half-life of thallium in animals but also lowers thallium content in critical organs such as the brain and the heart.[11,27,28,43,45] Half-lives are typically reduced by approximately 50% when Prussian blue is given with or without a cathartic. The rationale for the cathartic is that constipation is invariably present in humans and animals with severe thallium poisoning.

Only a few studies evaluate the effects of Prussian blue on survival. In these studies, a statistically significant survival advantage is shown

in thallium-poisoned rats[16,45] and mice[22] treated with Prussian blue. The experimental benefit is on the order of a 31% increase in the LD_{50} (median lethal dose for 50% of test subjects) in poisoned animals.[46]

RADIOACTIVE THALLIUM

There is no published experience describing human poisoning with radioactive thallium. Prussian blue has demonstrable efficacy in an animal model of radioactive thallium poisoning, as would be expected because the ionic radii of isotopes are generally similar. In one small study, insoluble Prussian blue decreased the biologic half-life of radioactive thallium in rats by approximately 40%.[2]

HUMAN DATA

Three patients, in 1971, were the first to receive Prussian blue as a treatment for thallium poisoning.[15] Although daily fecal thallium concentrations were not determined in two of the three patients because of severe constipation, an approximately sevenfold increase in fecal thallium elimination over baseline was attributed to Prussian blue therapy in the third patient. Subsequently, many humans with thallium poisoning have received Prussian blue, with or without a cathartic, as part of their therapy.[1,3,5,6,10,15,38,41,49,53,54,58] Unfortunately, other components of therapy that may have confounded the effects of Prussian blue in these cases include single- or multiple-dose activated charcoal, and the use of D-penicillamine, dimercaprol, ethylenediaminetetraacetic acid (EDTA), succimer, 2,3-dimercaptopropane-1-sulphate (DMPS), forced potassium diuresis, and either hemodialysis or hemoperfusion. There are no controlled trials of any of these modalities alone or in combination, and most of the data presented are based on single case reports or small case series.

One of the largest series was composed of 11 thallium-poisoned patients who were treated with soluble Prussian blue.[49] This report not only demonstrated the tolerability of Prussian blue, but also was the first to systematically evaluate its fecal elimination. In all individuals studied, fecal elimination remained high, even when urinary elimination fell, suggesting selective redistribution of thallium into the gut.[49] Although the authors commented on clinical improvement in these patients, the lack of controlled data makes these subjective observations difficult to interpret. Similarly, a substantial reduction in thallium half-life was demonstrated when Prussian blue was compared with no therapy at all in patients with thallium poisoning.[6]

DOSAGE AND ADMINISTRATION

The dosage of Prussian blue has never been investigated systematically in either humans or animals. In most of the case reports and series mentioned above, a total dose of 150 to 250 mg/kg/d was administered orally or via a nasogastric tube in two to four divided doses.[49] Because constipation or obstipation is often present or expected, Prussian blue is generally administered dissolved in 50 mL of 15% mannitol.[50] Although any cathartic may be appropriate, mannitol is used most frequently, possibly because of concerns over the risks associated with repeated doses of magnesium or sorbitol (see Antidotes in Depth A3–Whole-Bowel Irrigation and Other Intestinal Evacuants). The manufacturer of Radiogardase® recommends that adults and adolescents with thallium poisoning receive a total dose of 9 g divided daily (3 g every 8 hours) and that children receive a total dose of 3 g divided daily (1 g every 8 hours). Although the manufacturer does not recommend using a cathartic, a high-fiber diet is advocated when constipation is present. Because Prussian blue is well tolerated, the editors continue to favor the 150 to 250 mg/kg/d dosing because it provides more antidote. In addition, because many severely poisoned

patients cannot eat, the use of a cathartic should be considered when constipation is consequential.

The end point of therapy is similarly poorly defined. By convention, Prussian blue is usually continued until urinary thallium concentrations fall below 0.5 mg/d. This end point may not be a meaningful measurement of thallium burden, as fecal elimination may continue, even when urinary elimination has diminished.[49] However, because most laboratories are not equipped to measure fecal thallium concentrations, the use of some urinary end point seems reasonable as the reported residual amounts of fecal elimination are small.

CESIUM POISONING

The radioactive isotope of cesium (^{137}Cs), a common byproduct of nuclear fission reactions, is a strong β and γ emitter with a physical half-life of more than 30 years and a biologic half-life of about 110 days. Another isotope ([134]Cs) is only produced by neutron activation of the stable isotope ([133]Cs) and has a physical half-life of about 2 years and a biologic half-life comparable to [137]Cs. Cesium is absorbed in the small bowel, distributes like potassium, and undergoes enteric recirculation in a manner comparable to thallium.[26] Approximately 80% of a given dose of cesium is eliminated in the urine, with 20% cleared in the feces.

The isotope ^{137}Cs is used clinically as a radiation source in nuclear medicine. Although uncommon, radiologic disasters such as Chernobyl and Goiânia (see Human Clinical Trials section below) have resulted in lethal incorporation exposures. Additionally, concerns over the use of ^{137}Cs in "dirty bombs" have increased the awareness of, and the potential need to treat, patients with radioactive cesium poisoning. Toxicity from nonradioactive cesium is also reported. Many cases of QT interval prolongation and torsades de pointes are reported in patients who take cesium chloride either as a dietary supplement or for its alleged antineoplastic effects.[4,20,36,42,47] To date, there have been no reports of Prussian blue therapy for nonradioactive cesium poisoning, but the following discussion is most likely applicable.

■ IN VITRO ADSORPTION OF CESIUM

Standard binding studies compared the ability of activated charcoal, sodium polystyrene sulfonate (SPS), and both soluble and insoluble Prussian blue to bind ^{137}Cs over a range of gastrointestinal pHs.[55] Unlike thallium, the adsorption of cesium to activated charcoal was negligible. Comparable to thallium, SPS offered no benefit, likely because of preferential effects on potassium. Although both forms of Prussian blue adsorbed cesium, the insoluble form was consistently superior. A pH of 7.5 was selected to represent the pH of the small bowel lumen, the location where most adsorption would occur. At this pH, a MAC of 238 mg of ^{137}Cs/g of insoluble Prussian blue was determined. In an interesting extension, when the same authors bound insoluble Prussian blue to a hemoperfusion column, they demonstrated a clearance of approximately 100 mL/min of ^{137}Cs from plasma, and projected that a 4-hour treatment would adsorb about 0.3 terabecquerel (TBq) of radioactive cesium.[57] When the FDA-approved antidote was analyzed, like thallium, pH and hydration introduced significant variations in binding, with a MAC of 715 mg/g noted at pH 7.5.[9]

■ ANIMAL DATA: KINETICS, TISSUE CONCENTRATIONS, AND SURVIVAL

Small animal investigations with either [134]Cs or ^{137}Cs consistently demonstrate that Prussian blue therapy reverses the urine-to-stool-elimination ratio from 8:1 to 0.3:1, and reduces the biologic half-life and the total body area under the curve by as much as 60%.[29,33,34,44,48] For example, rats given oral [134]Cs retained 84.7% of the ingested dose at 7 days. Treatment with insoluble and soluble Prussian blue, as well as Chinese blue, produced significant reductions in retained cesium (only 6.36%, 2.63%, and 2.43% of the dose was retained at 7 days, respectively).[7]

In addition to human toxicity, concern over radioactive cesium incorporation into cattle milk and meat has resulted in a number of large animal investigations. Daily Prussian blue therapy reduced radioactive cesium concentrations in sheep by as much as 42%.[14,40] Likewise, radioactive cesium transfer to milk was reduced by 85% in cows.[52] When dogs were contaminated with ^{137}Cs, Prussian blue reduced total-body burden by as much as 51%.[24] Similar efficacy in reducing the amount of cesium was demonstrated in meat from pigs fed [134]Cs-contaminated whey, with insoluble Prussian blue reducing activity from 359 Bq/kg to 11 Bq/kg.[7]

■ HUMAN VOLUNTEER STUDIES

Two human volunteers ingested meals contaminated with [134]Cs to compare the efficacy of both the soluble and insoluble forms of Prussian blue with controls.[7] At 14 days after loading and without therapy, the volunteers retained 94.7% of the ingested dose, compared with a retention of only 5.1% following therapy with insoluble Prussian blue and 4.9% following soluble Prussian blue. In another study, two volunteers demonstrated that Prussian blue decreased the biologic half-life of ingested radioactive cesium by approximately 33%.[21] Finally, in two volunteers, the effects of pretreatment were compared with simultaneous posttreatment Prussian blue. When a single dose of Prussian blue was administered 10 minutes before [134]Cs, absorption decreased from 100% (without therapy) to 3% to 10%. However, simultaneous administration of 0.5 or 1 g of Prussian blue with [134]Cs resulted in 38% to 63% absorption. Finally, when Prussian blue was given daily at a dose of 0.5 g every 8 hours in the postabsorptive phase, the biologic half-life of [134]Cs was reduced from 106 to 44 days.[32]

■ HUMAN CLINICAL TRIALS

There are no controlled trials of Prussian blue in radioactive cesium poisoning. Experience is derived exclusively from treating disaster victims. In 1987, a number of people in Goiânia, Brazil, were contaminated with radioactive cesium from a discarded radiotherapy unit.[35] Although the reported total number of individuals treated is uncertain because of multiple reports that probably include overlapping patients, one group describes 37 patients who were given insoluble Prussian blue in doses ranging from 3 g/d in children up to 10 g/d in adults. Untreated, elimination kinetics were first order and half-lives varied extensively from 39 to 106 days in adults (mean: 65.5 days in women and 83 days in men). Half-lives were shorter in children. Therapy with insoluble Prussian blue reduced half-lives by a mean of 32%[19] and reduced the retained cesium dose 51% to 84%.[23]

The nuclear disaster at Chernobyl, Ukraine, resulted in many cases of acute radiation exposure as well as incorporation into the population of radioactive iodine, cesium, and strontium. In one trial, insoluble Prussian blue was given to three victims of radioactive cesium incorporation many weeks after their exposure. The reported reduction in biologic half-life ranged from 12% to 52%.[25] The authors of this paper include data from the Chinese literature describing another six patients who demonstrated a similar reduction in the biologic half-life of cesium following Prussian blue therapy.

■ DOSAGE AND ADMINISTRATION

The manufacturer of Radiogardase® recommends that for radioactive cesium poisoning, adults receive a total daily dose of 9 g divided into

3 g, three times per day. Children should receive a total daily dose of 3 g divided into 1 g, three times per day. Although these are the same doses used for thallium poisoning, therapy for cesium poisoning should be continued for at least 30 days. Even though there are no recommendations of other criteria to determine the end point of therapy, quantitative and radiologic evaluations of cesium elimination should be performed.

PREGNANCY CATEGORY

Insoluble Prussian blue is listed as pregnancy category C. Because of the severe consequences of poisoning from radioactive cesium and thallium and the lack of systemic absorption of insoluble Prussian blue, a risk-to-benefit analysis favors the use of the antidote in all poisoned pregnant patients.

AVAILABILITY

Insoluble Prussian blue (Radiogardase®) is available as a 0.5-g blue powder in gelatin capsules for oral administration manufactured from Haupt Pharma Berlin GmbH for distribution by HEYL Chemisch-pharmazeutische Fabrik GmbH & Co. KG, Berlin.

CHAPTER 101
ZINC

Nima Majlesi

Zinc (Zn)		
Atomic number	=	30
Atomic weight	=	65.37 daltons
Normal concentrations		
Blood	=	800 ± 200 µg/dL (122 ± 30 µmol/L)
Serum	=	109–130 µg/dL (16.7–20 µmol/L)
Urine (24 hour)	<	500 µg/d (<77 µmol/L)

Zinc is a ubiquitous element that is physiologically important to normal human function. However, zinc exposure can result in multiple consequential toxicities that are dependent on the dose and route. The typical systems affected are the respiratory, hematopoietic, and neurologic. Recent medical literature has contributed to the current knowledge of these effects.

HISTORY AND EPIDEMIOLOGY

The Babylonians used zinc alloys more than 5000 years ago,[1] and references to zinc oxide as a lotion to heal lesions around the eye can be found in the Ebers papyrus, written in 1500 B.C.[15] Zinc oxide and zinc sulfate were used in Western Europe during the late 1700s and early 1800s for gleet (urethral discharge), vaginal exudates, and convulsions. In the late 1800s, brass workers who inhaled zinc oxide fumes were noted to develop "zinc fever," "brass founders' ague," and "smelter shakes," all of which are now identified as metal fume fever (Chap. 124).[57]

Throughout history, humans have contaminated the environment with zinc. For example, release of zinc and other metals from mines produces elevated concentrations of zinc in the local water supply and vegetation, which may lead to elevated tissue zinc concentrations and clinical effects in the nearby population.[40,51]

The antiinflammatory effects of zinc sulfate were studied with mixed results in the late 1970s for acne vulgaris. However, a double-blinded controlled study found no difference between zinc and placebo.[63] The more recent use of zinc supplementation as an alternative preventive and treatment strategy is exposing large numbers of patients to undefined risks for unclear benefits.

CHEMISTRY

Zinc, a transition metal, has two common oxidation states, Zn^0 (elemental or metallic) and Zn^{2+}. Like other transition metals iron (Chap. 40) and copper (Chap. 93), zinc participates in reactions that result in the generation of reactive oxygen species. Such as superoxide radicals or hydroxyl radicals which can damage both local and remote tissues (Chapter 11).

The pure element exists as a blue to white shiny metal, but it also combines with other elements to form many compounds: zinc chloride ($ZnCl_2$), zinc oxide (ZnO), zinc sulfate ($ZnSO_4$), and zinc sulfide (ZnS). Once the metal is exposed to moisture, it becomes coated with zinc oxide or carbonate ($ZnCO_3$).[71]

PHARMACOLOGY AND PHYSIOLOGY

Zinc is an essential nutrient and found in more than 200 metalloenzymes, including acid phosphatase, alkaline phosphatase, alcohol dehydrogenase, carbonic anhydrase, superoxide dismutase, and DNA and RNA polymerases.[71] Zinc contributes to gene expression and chelates with either cysteine or histidine in a tetrahedral configuration, forming looped structures known as *zinc fingers*, which bind to specific DNA regions.[8,87] Other functions of zinc include membrane stabilization, vitamin A metabolism, and the development and maintenance of the nervous system. Zinc and copper concentrations generally have an inverse relationship in the serum with elevated zinc concentrations resulting in decreased copper concentrations (Chap. 93). Zinc accumulates in erythrocytes resulting in whole blood concentrations 6- to 7-fold higher than those in the serum.[59]

The average daily intake of zinc in the United States is 5.2–16.2 mg; foods that contain zinc include leafy vegetables (2 ppm), meats, fish, and poultry (29 ppm).[71] The recommended daily allowance is 11 mg/d for men and 8 mg/d for women. Pregnant and nursing women require 12 mg/d.

Zinc is important in maintaining olfactory and gustatory function (see Chap. 20). Serum, urine, and salivary zinc concentrations are lower in patients with dysfunctional senses of smell or taste. This is thought to be related to an abnormality in a salivary growth factor known as gustin/carbonic anhydrase VI.[30] Because this enzyme is zinc dependent, oral zinc may produce subjective improvement in taste and smell in patients with a known decrease in parotid gustin/carbonic anhydrase VI complex.[31] Oral zinc sulfate also improved subjective findings in a group of 25 patients with posttraumatic olfactory disorders.[4]

Zinc is also considered important for fetal growth. When 29 pregnant mothers who were at risk for small-for-gestational-age babies were given zinc citrate, zinc sulfate, or zinc aspartate, no intrauterine growth retardation was observed.[77] Subsequent studies have shown that zinc supplementation in women with low serum zinc concentrations in early pregnancy is associated with greater infant birth weights and head circumferences.[27] No adverse reproductive effects were observed in a rodent model exposed to inhalational zinc oxide.[54]

The role of zinc within the immune system is undefined. Zinc may be effective in the treatment of nonspecific infectious diarrhea, and specifically in the management of *Shigella* by improving the shigellacidal antibody response and increasing circulating B lymphocyte and plasma cells.[69,70]

Zinc – and zinc acetate–containing lozenges are sold as dietary supplements with conflicting evidence that they can shorten the duration of the "common cold."[36,53] One placebo-controlled study found that zinc nasal gel shortened the duration of viral syndromes when applied within 24 hours of the onset of symptoms.[32]

Zinc deficiency, or hypozincemia, is a well-described clinical entity. It can either be inherited as an autosomal recessive pattern known as acrodermatitis enteropathica, or develop due to a defect in zinc absorption in the GI tract.[64] Those patients at risk for acquiring the disorder include patients who receive total parenteral nutrition without adequate zinc supplementation, patients who have undergone intestinal bypass procedures, those with Crohn disease, and premature infants with low zinc storage. Physical findings that suggest the diagnosis of zinc deficiency, regardless of etiology, include the triad of dermatitis (acral and perioral), diarrhea, and alopecia. Zinc salts in initial doses of 5–10 mg/kg/d of elemental zinc followed by maintenance doses of 1–2 mg/kg/d are highly effective; in fact, skin lesions typically heal within 2–4 weeks and hair growth also restarts during this time frame.

The FDA approved zinc acetate in 1997 for maintenance therapy of Wilson disease, a disorder associated with copper overload.[9,49] Its use in

this disorder is related to the ability of zinc to induce the formation of metallothionein, which assists in the elimination of copper from the blood and body tissues (Chap. 93)[5] (see next section for further discussion).

TOXICOKINETICS AND PATHOPHYSIOLOGY

When ingested the main site of zinc absorption is the jejunum, although absorption is reported to occur throughout the intestine by binding to metallothionein as a zinc–protein complex in the luminal cells.[86] Metallothionein is a family of specific metal-binding proteins with diverse and complex functions considered essential to metal homeostasis. Metallothioneins are of low molecular weight (3500–14000 Da) and are rich in thiol ligands; it is these ligands that allow high-affinity binding to metals such as zinc, copper, cadmium, mercury, and silver. Excess zinc absorption leads to upregulation of metallothioneins as a counterregulatory mechanism to prevent zinc overload. However, the affinity of other metals, especially copper, is higher for metallothionein, resulting is copper elimination. The primary route of excretion of the copper–metallothionein complex is fecal. The fecal loss of the zinc–metallothionein complex appears to also be the primary route of excretion with a small percentage excreted in the urine. Very little metallothionein is bound to zinc in the blood as it is primarily an intracellular cytosolic molecule. This appears to play a role in the peripheral utilization of zinc once it has been absorbed.[24] Albumin binds about two-thirds of zinc in the plasma and the remainder is bound to α_2-globulins.[71] Zinc concentrations in the body show a great variability by organ, with the prostate having the highest amount due to its high concentration of the zinc-containing enzyme acid phosphatase.[6]

The possibility of an inherited zinc overload syndrome has been proposed;[67,68,78] researchers believe the pattern of inheritance is either autosomal recessive or autosomal dominant with low penetrance or the development of new mutations. Whether the pathophysiology is analogous to the iron overload of hematochromatosis or to the copper overload with subsequent decreased zinc excretion of Wilson disease remains to be determined.

Zinc salts are used to enhance the solubility of pharmaceuticals such as insulin. Certain salts, such as zinc oxide, are used in baby powder, sun blocks, and topical burn preparations, and may be used on latex and latex-free gloves.

CLINICAL MANIFESTATIONS

The toxicity of zinc is dependent on the route of exposure. Each zinc compound has similar toxic manifestations following oral and dermal exposure; however, they have unique inhalational toxicities. The metallic form of zinc is not toxic per se, and only the salt forms are considered here unless otherwise specifically mentioned.

■ ACUTE

The hallmark of acute oral zinc (Zn^{2+}) toxicity is gastrointestinal (GI) distress, including nausea, vomiting, abdominal pain, and gastrointestinal bleeding.[6] In initial studies that evaluated the oral use of zinc sulfate ($ZnSO_4$) as an acne therapy, epigastric distress was noted in 33% of patients.[20,26] In a separate case report, a patient developed GI bleeding within a week of initiation of zinc sulfate at a therapeutic dose of 220 mg twice a day.[60] Zinc chloride solutions in concentrations greater than 20% are particularly corrosive when ingested. Partial- and full-thickness burns to the oral mucosa, pharynx, esophagus, and stomach, as well as to the laryngotracheal tree, can occur even following small unintentional ingestions of zinc chloride by children.[18,42,58] Delayed gastric stricture may occur

after acute[58] or chronic zinc chloride consumption.[17] Pancreatitis was noted in a piglet model[25] and also in a 24-year-old man who inadvertently ingested liquid zinc chloride.[18] Hyperamylasemia, pulmonary edema, hypotension, vomiting, diarrhea, jaundice, anemia, thrombocytopenia, and subsequent death occurred following an unintentional intravenous infusion of 7.4 grams of zinc sulfate (via total parenteral nutrition) over 60 hours. The patient's serum zinc concentration was 4184 µg/dL.[10]

Inhalational toxicity will often depend on the type of zinc compound involved in the exposure. The water solubility of the various zinc salts plays an important role in the extent and time to onset of pulmonary toxicity. The solubility of zinc chloride in water at 25°C is 432 g/100 mL whereas that of zinc oxide at 29°C is 0.00016 g/100 mL.[71] Acute inhalation of zinc chloride aerosol from smoke bombs produces lacrimation, rhinitis, dyspnea, stridor, and retrosternal chest pain. Upper respiratory tract inflammation, acute lung injury (ALI), and acute respiratory distress syndrome (ARDS) may occur, generally with no manifestations of systemic absorption in the liver or kidneys.[33,35,55] Morbidity and mortality increase when the exposure to a zinc chloride aerosol occurs in an enclosed space.[74] Of 70 individuals exposed to a zinc chloride smoke bomb in a tunnel during World War II, 10 died within 4 days. Ambient zinc concentrations in the tunnel were measured at 33,000 mg/m³.[21] Inhalation of zinc oxide, a far less water-soluble zinc salt, is associated with metal fume fever (see Chap. 124) and not pneumonitis despite similar ambient zinc concentrations[6] (see later for further discussion on metal fume fever).

Animal research suggests that intranasal zinc sulfate use can cause transient or persistent anosmia as a consequence of disruption of functional connections between the main olfactory bulb and the olfactory epithelium.[56] Topical zinc sulfate is used experimentally in both rat and mouse models to eliminate olfactory input.[84] Multiple patients, ages 31–55 years, who developed a burning sensation after intranasal zinc gluconate application to the olfactory epithelium later developed either a long-lasting or permanent anosmia and olfactory dysfunction.[39]

US pennies lodged in the distal esophagus release reactive zinc ions following exposure to gastric acids and can damage the local esophageal tissue.[14] The phenomenon of acid dissolution is demonstrated in animal[2] and in vitro models.[62]

Rare reports of renal complications exist. Hematuria was observed in a 24-year-old man who ingested liquid zinc chloride but whose renal function remained otherwise normal.[18] Intentional intravenous zinc sulfate administration can result in acute tubular necrosis and renal failure.[10]

Certain zinc salts, such as zinc oxide, found in baby powders and calamine lotion, are usually nonirritating for intact skin.[3] Although older studies suggested the possibility of pruritic, pustular rashes in workers who are exposed to zinc oxide, other causative factors, including personal hygiene, were not considered.[82] One case report describes urticaria and angioedema in a 34-year-old welder following contact with zinc oxides fumes at a smelting plant.[22] The patient was asymptomatic once he was removed from the environment and had no further difficulty during the welding process when personal protective equipment was employed.

■ CHRONIC

Chronic zinc toxicity following nutritional supplements and the ingestion of coins can produce a reversible sideroblastic anemia, as well as a reversible myelodysplastic syndrome.[11] Both anemia and granulocytopenia occur with the bone marrow showing vacuolated precursors and ringed sideroblasts; the mechanism appears to be zinc-induced copper deficiency.[23]

A 55-year-old schizophrenic patient with a 15-year history of pica (typically metal objects) presented with pancytopenia, including a hemoglobin of 3 g/dL and a white blood cell count of 1300/mm³.[43]

A serum zinc concentration of 280 µg/mL and low serum copper concentration of <0.05 µg/mL reflected his ingestion of zinc-containing coins over many years. The patient refused surgery to remove the coins which formed a massive bezoar in his GI tract. Meat tenderizer and pancreatin were given in an unsuccessful to attempt to loosen the objects. Throughout his medical therapy the patient continued to ingest coins. Despite treatment efforts, he died of sepsis and multiorgan failure; an autopsy revealed a coin mass weighing 1870 g in his stomach and another bezoar at the site of a sigmoid volvulus. A 17-year-old boy who used megadoses of oral vitamins and mineral supplements containing zinc to treat acne over a 6–7 month period developed copper deficiency and anemia, leukopenia, and neutropenia.[73] A 28-month-old boy developed anemia, neutropenia, and developmental delay after 11 months of oral zinc gluconate. The parents were administering 314 mg/d of oral zinc gluconate (3.6 mg/kg/d of elemental zinc).[80] Hyperzincemia and hypocupremia were present and improved after discontinuation of zinc without copper supplementation.

It is suggested that zinc and other transition metals may be important in the pathogenesis of demyelinating diseases.[45,67] Clusters of cases of multiple sclerosis (MS) were described in northern New York in a factory where zinc was the primary occupational exposure. One hypothesis is that the allele frequency for transferrin (an iron- and zinc-binding protein) may differ in these MS patients.[75,79] Another cluster was found in Canada where excess metals, including zinc, were found in the soil and water.[28,38,37] A conclusive link to MS, however, has not been established.

Since the prostate contains the highest concentration of zinc in the human body, the role of zinc in the development of prostate cancer has been investigated. Specifically, American men participating in the Health Professionals Follow-Up Study were followed for 14 years, from 1986 to 2000. Of the 46,974 in the cohort, 2901 new cases of prostatic cancer were diagnosed, with 434 of them considered to be in an advanced stage.[50] Men who used zinc supplementation at a dose greater than 100 mg/d had a relative risk of 2.29 for advanced prostate cancer, and those using zinc for longer than 10 years had a relative risk of 2.37. To date, neither the International Agency for Research on Cancer (IARC) nor the Environmental Protection Agency (EPA) have classified zinc as a carcinogen.

A syndrome of progressive myeloneuropathy called *swayback* is defined by a spastic gait and a prominent sensory ataxia.[44,45,47,48] This neurologic syndrome may exist without the hematologic manifestations. These cases involve patients with copper deficiency, with a majority having a concomitant elevated serum zinc concentration. Though a history of excess zinc exposure could be obtained in some of the patients, many had no such history. The potential of an inherited zinc overload syndrome has been considered.[29] A 46-year-old man presented with evidence of bone marrow suppression followed by sensory ataxia and a progressive myelopathy. His neuroimaging evaluation was normal. His only remarkable laboratory studies included an elevated serum zinc concentration of 184 µg/dL (28.2 µmol/L) and a low copper concentration of less than 10 µg/dL (<2 µmol/L). There was no known exposure to or supplementation of zinc by history. Although his copper deficit improved with copper therapy, hyperzincemia persisted for more than 3 years that he was followed.

An unusual source of high concentration zinc that has recently been identified is denture creams, which may contain as much as 34 grams of zinc per gram of cream. Four patients with chronic exposure to excess denture cream were described to develop neurological abnormalities in the setting of hyperzincemia with associated hypocupremia.[61]

OCCUPATIONAL EXPOSURES

The United States penny currently contains 97.5% zinc and 2.5% copper.[83] Zinc is widely used in industry because it enhances the durability of iron and steel alloys; it also is commonly used in construction. Galvanization involves coating an iron product with metallic zinc to prevent it from oxidizing (rusting). Zinc is routinely encountered by electroplaters, smelters, jewelers, artists working on stained glass or sculpting metal, as well as aircraft manufacturing workers. Zinc chloride is commonly a component of flux which can be used for soldering galvanized iron.

Zinc is present in drinking water, and beverages stored in metal containers or that flow through pipes coated with zinc. Zinc concentrations in air are typically low; average zinc concentrations in the United States are less than 1 µg/m³. Air concentrations near industrial areas can be higher, and may be substantially greater in certain occupational settings. The currently accepted occupational threshold limit value (TLV) time-weighted average (TWA) is 1 mg/m³.[71]

METAL FUME FEVER

Metal fume fever (MFF) typically occurs within 12 hours after an exposure to zinc fumes. Patients develop fever, chills, cough, chest pain, dyspnea, dry throat, and a metallic taste in the mouth. Although exposure to zinc oxide fume is the most commonly associated exposure with this syndrome, other zinc compounds and other metal oxides may be implicated. The chest radiograph is often normal, but may show an infiltrate. Hypoxia and tachycardia are rare, but may occur. Overall, however, the syndrome is relatively benign, with tolerance developing within days. An immune mechanism is suggested, and chronic exposure is needed for sensitization (Chap. 124).

DIAGNOSTIC TESTING

Because zinc is ubiquitous in the environment and laboratory, great care must be taken to avoid contamination of any samples for investigation.[71] Since elevated zinc concentrations cause copper deficiency, a serum copper and ceruloplasmin concentration should be obtained in patients with zinc poisoning.

Urine zinc concentrations are not well defined. In a cohort of non-occupationally exposed patients, the mean urine concentrations were 450 µg/L, with a maximum concentration up to 1300 µg/L.[59] In the United States, normal urine values are generally accepted as less than 500 µg/day. The National Institute for Occupational Safety and Health states that the detection limits in urine and blood are as low as 0.1 µg per sample and 1 µg/100 g, respectively. Testing requires extraction of the metals from urine with polydithiocarbamate resin prior to digestion with concentrated acids and analysis.[71]

Errors can be caused by incorrect sample collection, equipment malfunction or miscalibration, inadequate reagent purity, and atmospheric deposition. Zinc oxide powder in some gloves can contaminate specimens, as can the rubber stoppers in certain blood collection tubes. Specific tubes are recommended with negligibly low concentrations of trace elements.[16] During sample analysis, laminar flow is recommended to prevent airborne particles from interfering.

Abdominal radiographs may play a role in determining the gastrointestinal burden of zinc, especially with ingestions of pennies. This may guide the decision to continue gastrointestinal decontamination in certain circumstances[13] (see Management).

Neuroimaging in patients with chronic zinc exposure leading to copper deficiency may reveal characteristic findings. MRI typically reveals increased T_2 signal in the dorsal columns of the cervical cord similar to that found in B_{12} deficiency.[46] These lesions are thought to represent Wallerian degeneration and demyelination of white matter. One case showed evidence of bilateral subcortical hyperintense T_2 abnormalities on an MRI of the brain.[61] These findings are likely the result of copper deficiency and not necessarily zinc toxicity.

MANAGEMENT

Treatment for acute oral zinc (Zn^{2+}) toxicity is primarily supportive. Efforts should be focused on hydration, as well as on antiemetic therapy. H_2 receptor antagonists or proton pump inhibitors may relieve abdominal discomfort when given for several days following the zinc salt ingestion.[6]

Gastrointestinal decontamination after zinc salt ingestion may include whole-bowel irrigation (WBI). A radiograph in a 16-year-old boy who ingested 50 zinc sulfate tablets each containing 500 mg noted no change in their position 4 hours after gastric evacuation. Within 1 hour of institution of WBI therapy, zinc tablets were present in the rectal effluent.[13]

Intravenous N-acetylcysteine (NAC) increased the urinary zinc excretion in a patient who had inhaled zinc chloride smoke.[65] Two individuals with inhalational zinc chloride–induced ARDS had simultaneous transient decreases in serum zinc concentrations and increases in urinary zinc excretion with intravenous and nebulized NAC.[33] However, they succumbed at days 25 and 32 after inhalation. Although an increase in urinary zinc excretion was noted in one rat model, ten healthy volunteers who were treated with oral NAC for 2 weeks had no significant change in either their serum or urine zinc concentrations.[34] This therapy requires further study and cannot be recommended at this time.

The data regarding the efficacy of chelation therapy for zinc are limited in humans. Edetate calcium disodium ($CaNa_2EDTA$) was used successfully in several cases, including in a child who was exposed to zinc chloride that was a component of soldering flux[66] and in a 24-year-old man exposed to liquid zinc chloride.[18] The combination of $CaNa_2EDTA$ and British anti-Lewisite (BAL) was used successfully in a 16-month-old toddler 74 hours after ingestion.[58] Both diethylenetriaminepentaacetic acid (DTPA) and ethylenediaminetetraacetic acid (EDTA) were effective in enhancing the urinary excretion of zinc in a rodent model of zinc acetate poisoning.[19] DTPA had its greatest antidotal efficacy when given within 30 minutes of the intraperitoneal injection of zinc acetate.[52] The urinary excretion of zinc increased 1.6- to 44-fold following a 3 mg/kg intravenous dose of sodium 2,3-dimercaptopropane-1-sulfonate (DMPS) in one human study where metal toxicity in patients with dental amalgams was the focus.[81] Two potential zinc-selective chelators, DPESA (4-{[2-(bis-pyridin-2-ylmethylamino)ethylamino]-methyl} phenylmethanesulfonic acid) sodium salt, as well as TPESA (4-{[2-(bis-pyridin-2-ylmethylamino) ethyl]pyridine-2-ylmethylamino}-methyl)phenyl] methanesulfonic acid) sodium salt, rapidly chelate zinc in vitro, but further detailed in vivo studies are needed before its clinical use can be considered.[41] Finally, an iron-chelator, deferiprone, was incidentally noted to cause decreased serum zinc concentrations in a transfusion overload study.[85] A subsequent prospective trial showed enhanced urinary excretion of zinc in children with thalassemia major who had received multiple blood transfusions.[7]

Many of the clinical and systemic manifestations of zinc toxicity are due to its ability to cause copper deficiency. In patients with zinc overload–related copper deficiency, the supplementation of oral copper alone was able to improve the hematopoeitic effects and prevent further neurological deterioration without chelation therapy.[72]

Though treatment with copper sulfate alone may be adequate for patients with neurological sequelae and mild hematopoietic effects, the addition of chelation may be required for patients with hemodynamic compromise or other consequential systemic manifestations. Limited experience exists in regard to treatment of these patients; however, 1000 mg/m²/d IV $CaNa_2EDTA$ divided every 6 hours seems to be a reasonable choice based on case reports of successful use. The role of BAL is unclear; however, its ability to potentially increase copper elimination should deter its use.

Supportive care is used for patients with inhalational zinc exposures, including oxygen therapy and bronchodilators as clinically indicated, but these patients may necessitate ventilatory support in severe cases. Exposure to zinc oxide vapors by rescuers is minimal, although respiratory protective equipment should be worn.[76] In a case series of five soldiers exposed to zinc chloride during military training, the two individuals not wearing gas masks developed ARDS;[33] the others remained clinically well.

Metal fume fever is typically self-limited. Nonsteroidal antiinflammatory drugs should be sufficient to relieve the transient discomfort. Personal protection equipment and/or adequate engineering strategies may allow the individual to continue to work in this setting.

Dermal decontamination is paramount to prevent direct epidermal effects or systemic absorption of zinc salts.[12] However, water should not be used to perform dermal decontamination of patients exposed to metallic zinc because of concerns that zinc metal will ignite when wet. Treatment in these situations includes mechanical removal of any metallic particles with forceps and the application of mineral oil to the affected skin to protect the metal from ambient moisture.

SUMMARY

Zinc is a ubiquitous element. Exposures to humans occur as part of the diet, medicinal uses, nutritional supplements, and in occupational settings. Clinical manifestations include acute, life-threatening gastrointestinal and pulmonary effects, which are generally treated with supportive care. Copper supplementation alone often corrects systemic manifestations, but chelation therapy may be considered in acutely life-threatening circumstances.

CHAPTER 102
ANTISEPTICS, DISINFECTANTS, AND STERILANTS

Paul M. Wax

INTRODUCTION

Antiseptics, disinfectants, and sterilants are a diverse group of antimicrobials used to prevent infection (Table 102–1). Although these terms are sometimes used interchangeably and some of these xenobiotics are used for both antisepsis and disinfection, the distinguishing characteristics between the groups are important to emphasize. An *antiseptic* is a chemical that is applied to living tissue to kill or inhibit microorganisms. Iodophors, chlorhexidine, and the alcohols (ethanol and isopropanol) are commonly used antiseptics. A *disinfectant* is a chemical or physical agent that is applied to inanimate objects to kill microorganisms. Bleach (sodium hypochlorite), phenolic compounds, and formaldehyde are examples of currently used disinfectants. Neither antiseptics nor disinfectants have complete sporicidal activity. A *sterilant* is a chemical or physical process that is applied to inanimate objects to kill all microorganisms as well as spores. Ethylene oxide and glutaraldehyde are examples of sterilants. Not unexpectedly many of the xenobiotics used to kill microorganisms also demonstrate considerable human toxicity.[17,60]

The use of these xenobiotics evolved during the 20th century as their toxicity and the principles of microbiology became better understood. Two of the more toxic antiseptics—iodine and phenol—were gradually replaced by the less toxic iodophors and substituted phenols. The use of mercuric chloride was superseded by the organic mercurials (eg, merbromin, thimerosal), which also proved toxic. In recent years, newer compounds, such as quaternary ammonium compounds, ethylene oxide, and glutaraldehyde, have become more extensively used.

ANTISEPTICS

■ CHLORHEXIDINE

This cationic biguanide has been in use as an antiseptic since the early 1950s. It is found in a variety of skin cleansers, usually as a 4% emulsion (eg, Hibiclens), and may also be found in mouthwash. Chlorhexidine is reported to have low toxicity.

Clinical Effects Few cases of deliberate ingestion of chlorhexidine are reported. Symptoms are usually mild and gastrointestinal irritation is the most likely effect after oral ingestion.[23] Chlorhexidine has poor enteral absorption. In one case, ingestion of 150 mL of a 20% chlorhexidine gluconate solution resulted in oral cavity edema and significant irritant injury of the esophagus.[111] In the same case, liver enzymes concentrations rose to 30 times normal on the fifth day after ingestion. Liver biopsy showed lobular necrosis and fatty degeneration. In another case, the ingestion of 30 mL of a 4% solution by an 89-year-old woman did not result in any GI injury.[44] An 80-year-old woman with dementia ingested 200 mL of a 5% chlorhexidine solution and subsequently aspirated.[70] She rapidly developed hypotension, respiratory distress, coma, and died 12 hours following ingestion.

Intravenous administration of chlorhexidine is associated with hemolysis, although this may be caused by the hypotonicity of the injected solution,[25] and acute respiratory distress syndrome.[80] Inhalation of vaporized chlorhexidine is reported to cause methemoglobinemia as a consequence of the conversion of chlorhexidine to *p*-chloraniline.[183] In one patient, the rectal administration of 4% chlorhexidine resulted in acute colitis with ulcerations.[59]

Topical absorption of chlorhexidine is negligible. Contact dermatitis is reported in up to 8% of patients who received repetitive topical applications of chlorhexidine.[60] More ominously, anaphylactic reactions, including shock, are associated with dermal application.[6,128] Some of these cases of chlorhexidine-related anaphylaxis occurred during surgery, appearing 15–45 minutes after application of the antiseptic.[12] Eye exposure may result in corneal damage.[177]

Management Treatment guidelines for chlorhexidine exposure are similar to those for other potential caustics. Patients with significant symptoms may require endoscopy, but the need for such extensive evaluation is quite uncommon.

■ HYDROGEN PEROXIDE

Hydrogen peroxide, an oxidizer with weak antiseptic properties, has been used for many years as an antiseptic and a disinfectant.[187] This oxidizer is generally available in two strengths: dilute hydrogen peroxide, with a concentration of 3%–9% by weight (usually 3%), sold for home use, and concentrated hydrogen peroxide, with a concentration greater than 10%, used primarily for industrial purposes. Commercial-strength hydrogen peroxide is commonly found in solutions varying from 27.5%–70%. Home uses for dilute hydrogen peroxide include ear cerumen removal, mouth gargle, vaginal douche, enema, and hair bleaching. Dilute hydrogen peroxide is also sometimes used as a veterinary emetic. Commercial uses of the more concentrated solutions include bleaching and cleansing textiles and wool, and producing foam rubber and rocket fuel. A 35% hydrogen peroxide solution is also available to the general public in health food stores and is sold as "hyperoxygenation therapy" and as a health food additive to aerate health food drinks.[76] This potentially dangerous therapy is touted as a treatment for a variety of conditions, including AIDS and cancer.

TABLE 102–1. Antiseptics, Disinfectants, Sterilants, and Related Xenobiotics

Xenobiotic	Commercial Product	Use	Toxic Effects	Therapeutics and Evaluation
Acids				
Boric acid	Borax	Antiseptic	Blue-green emesis and diarrhea	GI decontamination
	Sodium perborate	Mouthwash	Boiled lobster appearance of skin	Hemodialysis (rare)
	Dobell solution	Eyewash	CNS depression; renal failure	
		Roach powder		
Alcohols				
(Chaps. 77 and 107)				
Ethanol	Rubbing alcohol	Antiseptic	CNS depression	Supportive
	(70% ethanol)	Disinfectant	Respiratory depression	
			Dermal irritant	
Isopropanol	Rubbing alcohol	Antiseptic	CNS depression	Supportive
	(70% isopropanol)	Disinfectant	Respiratory depression	Hemodialysis (rare)
			Ketonemia, ketonuria	
			GI irritation/bleeding	
			Hemorrhagic tracheobronchitis	
Aldehydes				
Formaldehyde	Formalin	Disinfectant	Caustic	Gastric lavage
	(37% formaldehyde,	Fixative	CNS depression	Hemodialysis
	12%–15% methanol)	Urea insulation	Carcinogen	Sodium bicarbonate
				Endoscopy
				Folinic acid
Glutaraldehyde	Cidex (2% glutaraldehyde)	Sterilant	Mucosal and dermal irritant	Supportive
Chlorinated Compounds				
Chlorhexidine	Hibiclens	Antiseptic	GI irritation	Supportive
Chlorates	Sodium chlorate	Antiseptic	Hemolytic anemia	Exchange transfusion
	Potassium chlorate	Matches	Methemoglobinemia	Hemodialysis
		Herbicide	Renal failure	
Chlorine		Disinfectant	Irritant	Supportive
Chlorophors	Household bleach	Disinfectant	Mild GI irritation	Endoscopy (rare)
(sodium hypochlorite)	(5% NaOCl)			
	Dakin solution (1 part 5%	Decontaminating		
	NaOCl, 10 parts H$_2$O)	solution		
Ethylene Oxide		Sterilant	Irritant	Supportive
		Plasticizer	CNS depression	
			Peripheral neuropathy	
			Carcinogen?	
Mercurials	Merbromin 2% (Mercurochrome)	Antiseptic (obsolete)	CNS	Gastric lavage, activated charcoal dimercaprol, succimer
(Chaps. 55 and 96)	Thimerosal (Merthiolate)		Renal	
Iodinated Compounds				
Iodine	Tincture of iodine	Antiseptic	Caustic	Milk, starch,
	(2% iodine, 2% sodium iodide			sodium thiosulfate
	and 50% ethanol)			Endoscopy
	Lugol solution (5% iodine)			
Iodophors	Povidone-iodine (Betadine)	Antiseptic	Limited	Same as iodine
	(0.01% iodine)			

TABLE 102–1. Antiseptics, Disinfectants, Sterilants, and Related Xenobiotics (*Continued*)

Xenobiotic	Commercial Product	Use	Toxic Effects	Therapeutics and Evaluation
Oxidants				
Hydrogen peroxide	H_2O_2 3%–household	Disinfectant	Oxygen emboli	Gastric lavage
	H_2O_2 30%–industrial		GI caustic	Radiographic evaluation
				Endoscopy
Potassium permanganate	Crystals, solution	Antiseptic	Oxidizer, caustic, increased serum manganese	Decontamination Endoscopy as needed
Phenols				
Nonsubstituted	Phenol (carbolic acid)	Disinfectant	Caustic	Decontamination:
			Dermal burns	polyethylene glycol or water
			Cutaneous absorption	Endoscopy as needed
			CNS effects	
Substituted	Hexachlorophene	Disinfectant	CNS effects	Supportive
Quaternary Ammonium Compounds				
Benzalkonium chloride	Zephiran	Disinfectant	GI caustic	Consider endoscopy

Toxicity from hydrogen peroxide may occur after ingestion or wound irrigation. Hydrogen peroxide has two main mechanisms of toxicity: local tissue injury and gas formation. The extent of local tissue injury and amount of gas formation is determined by the concentration of the hydrogen peroxide. Dilute hydrogen peroxide is an irritant and concentrated hydrogen peroxide is a caustic. Gas formation results when hydrogen peroxide interacts with tissue catalase, liberating molecular oxygen, and water. At standard temperature and pressure, 1 mL of 3% hydrogen peroxide liberates 10 mL of oxygen, whereas 1 mL of the more concentrated 35% hydrogen peroxide liberates more than 100 mL of oxygen. Gas formation can result in life-threatening embolization. Gas embolization may be a result of dissection of gas under pressure into the tissues or of liberation of gas in the tissue or blood following absorption. The use of hydrogen peroxide in partially closed spaces, such as operative wounds, or its use under pressure during wound irrigation increases the likelihood of embolization.

Clinical Effects Airway compromise manifested by stridor, drooling, apnea, and radiographic evidence of subepiglottic narrowing may occur.[39] The combination of local tissue injury and gas formation from the ingestion of concentrated hydrogen peroxide may cause abdominal bloating, abdominal pain, vomiting, and hematemesis.[77,105] Endoscopy may show esophageal edema and erythema and significant gastric mucosal erosions.[153]

Symptoms consistent with sudden oxygen embolization include rapid deterioration in mental status, cyanosis, respiratory failure, seizures, ischemic ECG changes, and acute paraplegia.[48,102] A 2-year-old boy died after ingesting 120–180 mL of 35% hydrogen peroxide.[27] Antemortem chest radiography showed gas in the right ventricle, mediastinum, and portal venous system. Portal vein gas is also a prominent feature in other cases.[76,105] Arterialization of oxygen gas embolization may result in cerebral infarction.[159] Encephalopathy with cortical visual impairment[21] and bilateral hemispheric infarctions detected by MRI imaging may occur after ingestion of concentrated hydrogen

peroxide.[79] In a case of acute paraplegia after the ingestion of 50% hydrogen peroxide, MRI revealed discrete segmental embolic infacts of the cervical and thoracic spinal cord as well as both cerebral hemispheres and left cerebellar hemisphere.[102]

Death from intravenous injection of 35% hydrogen peroxide is also reported.[95] The use of a concentrated hydrogen peroxide solution as part of a hair highlighting procedure resulted in a severe scalp injury including necrosis of the galea aponeurotica.[154]

Clinical sequelae from the ingestion of dilute hydrogen peroxide are usually much more benign.[39,67] Nausea and vomiting are the most common symptoms.[39] A whitish discoloration may be noted in the oral cavity. Gastrointestinal injury is usually limited to superficial mucosal irritation, but multiple gastric and duodenal ulcers, accompanied by hematemesis, and diffuse hemorrhagic gastritis are reported.[67,117] Portal venous gas embolization may occur as a result of the ingestion of 3% hydrogen peroxide.[28,117,143]

The use of 3% hydrogen peroxide for wound irrigation may result in significant complications. Extensive subcutaneous emphysema occurred after a dog bite to a human's face was irrigated under pressure with 60 mL of 3% hydrogen peroxide.[162] Systemic oxygen embolism, causing hypotension, cardiac ischemia, and coma, resulted from the intraoperative irrigation of an infected herniorrhaphy wound.[11] Gas embolism, resulting in intestinal gangrene, was reported to occur following colonic lavage with 1% hydrogen peroxide during surgical treatment of meconium ileus.[157] Multiple cases of acute colitis are reported as a complication of administering 3% hydrogen peroxide enemas.[113] The use of 3% hydrogen peroxide as a mouth rinse is associated with the development of oral ulcerations.[145] Ophthalmic exposures may result in conjunctival injection, burning pain, and blurry vision.[39,112] Optic neuropathy including transient blindness (ability to visualize shadows only) and subsequent optic atrophy from possible inhalational of hydrogen peroxide has also been described.[40]

Diagnosis A careful examination should be performed to detect any evidence of gas formation. A chest radiograph might reveal gas in

the cardiac chambers, mediastinum, or pleural space. An abdominal radiograph might show gas in the GI tract or portal system and define the extent of bowel distension. MRI and CT scan might be useful for detecting brain and spinal cord lesions secondary to gas embolism.[5,79,102] Endoscopic evaluation might be necessary in patients who ingest concentrated hydrogen peroxide to determine the extent of mucosal injury.

Management The treatment of patients with hydrogen peroxide ingestions depends, to a large degree, on whether the patient has ingested a diluted or concentrated solution. Those with ingestions of concentrated solutions require expeditious evaluation. Dilution with milk or water, although unstudied, is unlikely to be helpful. Nasogastric aspiration of hydrogen peroxide might be helpful if the patient presents immediately after ingestion. Induced emesis is contraindicated and activated charcoal offers no antidotal benefit. Patients with abdominal distension from gas formation should be treated with nasogastric suctioning. Those with clinical or radiographic evidence of gas in the heart should be placed in the Trendelenburg position to prevent gas from blocking the right ventricular outflow tract. Careful aspiration of intracardiac air through a central venous line may be attempted in patients in extremis.[27] Case reports suggest that hyperbaric therapy may be useful in cases of life-threatening gas embolization after hydrogen peroxide ingestion.[76,102,105,119,183] Asymptomatic patients who unintentionally ingest small amounts of 3% hydrogen peroxide can be safely observed at home.

IODINE AND IODOPHORS

Iodine is one of the oldest topical antiseptics.[155] Iodine usually refers to molecular iodine, also known as I_2, free iodine, and elemental iodine which is the active ingredient of iodine-based antiseptics. The use of ethanol as the solvent, such as tincture of iodine, allows substantially more concentrated forms of I_2 to be available. I_2 and tincture of iodine ingestions are much less common than in the past as a result of the change in antiseptic use from iodine to iodophor antiseptics.[41]

Iodophors have molecular iodine compounded to a high-molecular-weight carrier or to a solubilizing agent. Povidone-iodine (Betadine), a commonly used iodophor, consists of iodine linked to polyvinylpyrrolidone (povidone). Iodophors, which limit the release of molecular iodine and are generally less toxic, are the standard iodine-based antiseptic preparations. Iodophor preparations are formulated as solutions, ointments, foams, surgical scrubs, wound-packing gauze, and vaginal preparations. The most common preparation is a 10% povidone-iodine solution that contains 1% "available" iodine (referring to all oxidizing iodine species), but only 0.001% free iodine (referring only to molecular iodine).[17,60]

Iodine is used to disinfect medical equipment and drinking water. Iodine is an effective antiseptic against bacteria, viruses, protozoa, and fungi, and is used both prophylactically and therapeutically.[37] Iodine is cytotoxic and an oxidant. It is thought to work by binding amino and heterocyclic nitrogen groups, oxidizing sulfhydryl groups, and saturating double bonds. Iodine also iodinates tyrosine groups.[60]

There may be significant systemic absorption of iodine from topical iodine or iodophor preparations.[134] Markedly elevated iodine concentrations do occur in patients who receive topical iodophor treatments to areas of dermal breakdown, such as burn injuries.[93] Significant absorption occurs when iodophors are applied to the vagina, perianal fistulas, umbilical cords, and the skin of low-birth-weight neonates.[184] The mucosal application of povidone-iodine during a hysteroscopy procedure resulted in acute renal failure that transiently required hemodialysis.[13] A fatality following intraoperative irrigation of a hip wound with povidone-iodine is also reported.[32] In this latter case, the postmortem serum iodine concentration was 7000 µg/dL (normal: 5–8 µg/dL).

Clinical Effects Problems associated with the use of iodine include unpleasant odor, skin irritation, allergic reactions and clothes staining. Ingestion of iodine may cause abdominal pain, vomiting, diarrhea, GI bleeding, delirium, hypovolemia, anuria, and circulatory collapse. Severe caustic injury of the GI tract may occur. The ingestion of approximately 45 mL of a 10% iodine solution resulted in death from multisystem failure 67 hours after ingestion.[42]

Reports of adverse consequences from iodophor ingestions are rare. In one case report, a 9-week-old infant died within 3 hours of receiving povidone-iodine by mouth.[91] In this unusual case, the child was administered 15 mL of povidone-iodine mixed with 135 mL of polyethylene glycol by nasogastric tube over a 3-hour period for the treatment of infantile colic. Postmortem examination showed an ulcerated and necrotic intestinal tract. A blood iodine concentration of 14,600 µg/dL was recorded. Significant toxicity from intentional ingestions of iodophors in adults is not documented.

Acid–base disturbances are among the most significant abnormalities associated with iodine and iodophors. Metabolic acidosis occurred in several burn patients after receiving multiple applications of povidone-iodine ointment.[93,135] These patients had elevated serum iodine concentrations and normal lactate concentrations. The exact etiology of the acidosis remains unclear. Postulated mechanisms for the acidosis include the povidone-iodine itself (pH 2.43), bicarbonate consumption from the conversions of I_2 to NaI, and decreased renal elimination of H^+ as a consequence of iodine toxicity.[135] Metabolic acidosis associated with a high lactate level after iodine ingestion likely reflects tissue destruction.[37]

Electrolyte abnormalities also may occur following the absorption of iodine. A patient with decubitus ulcers who received prolonged wound care with povidone-iodine–soaked gauze developed hypernatremia, hyperchloremia, metabolic acidosis, and renal failure.[37] The hyperchloremia was thought to be caused by a spurious elevation of measured chloride ions as a consequence of iodine's interference with the chloride assay. This interference occurs on the Technicon STAT/ION autoanalyzer, but does not occur when the silver halide precipitation assay is used.[37] Spurious hyperchloremia from iodine (or iodide) may result in the calculation of a low or negative anion gap (Chap. 16).[22,46]

Other problems associated with topical absorption of iodine-containing preparations are hypothyroidism (particularly in neonates),[22,163] hyperthyroidism,[144,147] elevated liver enzyme concentrations, neutropenia anaphylaxis,[1] and hypoxemia.[37] Because of the lack of consistency between iodine concentrations and symptomatology, and because many of these patients had significant secondary medical problems that may have accounted for their symptoms, the exact relationship between iodine absorption and the development of a specific clinical syndrome remains speculative. However, a clinical controlled trial that compared preterm infants exposed to either topical iodinated antiseptics or to chlorhexidine-containing antiseptics showed that the infants exposed to topical iodine-containing antiseptics were more likely to have higher thyrotropin concentrations and elevated urine iodine concentrations than was the chlorhexidine group.[99]

Contact dermatitis can result from repetitive applications of iodophors.[108] A dermal burn may result from the trapping of an iodophor solution under the body of a patient in a pooled dependent position or under a tourniquet.[101,123]

Management The patient who ingests an iodine preparation requires expeditious evaluation, stabilization, and decontamination. Careful nasogastric aspiration and lavage may be performed to limit the caustic effect of the iodine if signs of perforation are absent. Irrigation with a starch solution will convert iodine to the much less toxic iodide and, in the process, turn the gastric effluent dark blue-purple. This change in color may serve as a useful guide in determining when lavage can

be terminated. If starch is not available, milk may be a useful alternative. Instillation of 100 mL of a solution of 1%–3% sodium thiosulfate can also be used to convert any remaining iodine to iodide. Activated charcoal binds iodine and may be useful.[36] Early endoscopy may help assess the extent of the gastrointestinal injury.

Most patients with iodophor ingestion require only supportive management. The use of starch or sodium thiosulfate may be considered in symptomatic patients. Hemodialysis and continuous venovenous hemodiafiltration was used successfully to enhance elimination of iodine in patient with renal insufficiency who had become iodine toxic after undergoing continuous mediastinal irrigation with povidone-iodine.[87A] The benefit of hemodialysis or continuous venovenous hemodiafiltration is unknown in patients with normal renal function and therefore not recommended.

■ POTASSIUM PERMANGANATE

Potassium permanganate ($KMnO_4$) is a violet water-soluble xenobiotic that is usually sold as crystals or tablets or as a 0.01% dilute solution.[85] Historically, it was used as an abortifacient, urethral irrigant, lavage fluid for alkaloid poisoning, and snakebite remedy. Currently, potassium permanganate is most often used in baths and wet bandages as a dermal antiseptic, particularly for patients with eczema.

Potassium permanganate is a strong oxidizer and poisoning may result in local and systemic toxicity.[165] Upon contact with mucous membranes, potassium permanganate reacts with water to form manganese dioxide, potassium hydroxide, and molecular oxygen. Local tissue injury is the result of contact with the nascent oxygen, as well as the caustic effect of potassium hydroxide. A brown-black staining of the tissues occurs from the manganese dioxide. Systemic toxicity may occur from free radicals generated by absorbed permanganate ions.[193]

Clinical Effects Following ingestion, initial symptoms include nausea and vomiting. Laryngeal edema and ulceration of the mouth, esophagus, and, to a lesser extent, the stomach, may result from the caustic effects. Airway obstruction and fatal gastrointestinal perforation and hemorrhage may occur.[38,114,130] Esophageal strictures and pyloric stenosis are potential late complications.[89]

Although potassium permanganate is not well absorbed from the GI tract, systemic absorption may occur, resulting in life-threatening toxicity. Systemic effects include hepatotoxicity, renal damage, methemoglobinemia, hemolysis, hemorrhagic pancreatitis, airway obstruction, acute respiratory distress syndrome, disseminated intravascular coagulation, and cardiovascular collapse.[97,107,114,130] Elevation in blood or serum manganese concentration may also occur, confirming systemic absorption (normal concentrations blood manganese 3.9–15.0 μg/L; serum manganese 0.9–2.9 μg/L).

Chronic ingestion of potassium permanganate may result in classic manganese poisoning (manganism) characterized by behavioral changes, hallucinations, and delayed onset of parkinsonian-like symptoms. A 66-year-old man who mistakenly ingested 10 g of potassium permanganate over a 4-week period (because of medication mislabeling) developed impaired concentration and autonomic and visual symptoms. He also developed abdominal pain, gastric ulceration, and alopecia. Serum manganese concentration was elevated. Nine months later, the patient's neurologic examination displayed extrapyramidal signs consistent with parkinsonism (Chap. 95).[74]

Management Because the consequential effects of potassium permanganate ingestion are a result of its liberation of strong alkalis, the initial treatment of such a patient should include assessment for evidence of airway compromise. Dilution with milk or water may be useful. Patients with symptoms consistent with caustic injury should undergo early upper GI endoscopy. Corticosteroids along with antibiotics may

be warranted if laryngeal edema is present. Analysis of liver enzymes, BUN, creatinine, lipase, serum manganese, and methemoglobin concentrations should be performed when systemic toxicity is suspected. Methemoglobinemia, if clinically significant, should be treated with methylene blue. Dermal irrigation with dilute oxalic acid may be successful in removing cutaneous staining.[165] The administration of *N*-acetylcysteine (see Antidotes in Depth A4: *N*-Acetylcysteine) to increase reduced glutathione production, thereby limiting free radical–mediated oxidative injury in cases of systemic potassium permanganate poisoning, has been suggested, but clinical trials have not been performed.[193]

OTHER ANTISEPTICS

■ ALCOHOLS

Isopropanol and ethanol are commonly used as skin antiseptics. Sold as rubbing alcohol, the standard concentration for these solutions is usually 70%. Their antiseptic action is thought to be a result of their ability to coagulate proteins. Isopropanol is slightly more germicidal than ethanol.[60] The alcohols have limited efficacy against viruses or spores. Isopropanol tends to be more irritating than ethanol and may cause more pronounced central nervous system depression.[185] The greater toxicity of isopropanol has caused some emergency departments to switch rubbing alcohol formulations from isopropanol to ethanol (Chaps. 77 and 107).

■ CHLORINE AND CHLOROPHORS

Chlorine, one of the first antiseptics, is still used in the treatment of the community water supply and in swimming pools. Chlorine is a potent pulmonary irritant that can cause severe bronchospasm and acute lung injury. Chapter 124 further discusses chlorine.

Sodium hypochlorite, found in household bleaches and in Dakin solution, remains a commonly used disinfectant. First used in the late 1700s to bleach clothes, its usefulness arises from its oxidizing capability, measured as "available chlorine," and its ability to release hypochlorous acid slowly. It is used to clean blood spills and to sterilize certain medical instruments. A 0.5% hypochlorite solution is sometimes recommended for dermal and soft-tissue wound decontamination after exposure to biologic and chemical warfare agents (Chaps. 131 and 132).[78] Toxicity from hypochlorite is mainly a result of its irritant effects. The ingestion of large amounts of household liquid bleach (5% sodium hypochlorite) on rare occasions can result in esophageal burns with subsequent stricture formation.[47] In a cat model of bleach ingestion, a high incidence of mucosal injury and stricture formation was noted.[188] However, the vast majority of household bleach ingestions in humans do not cause significant GI injuries.[136] Accordingly, endoscopic evaluation is usually not warranted when assessing most patients with household liquid bleach ingestions. The ingestion of a more concentrated "industrial strength" bleach preparation (eg, 35% sodium hypochlorite) increases the likelihood of local tissue injury and should be managed accordingly (Chap. 104).

■ MERCURIALS

Both inorganic mercurials, such as mercuric bichloride, and organic mercurials, such as merbromin (mercurochrome) and thimerosal (merthiolate), which both contain 49% mercury, were used in the past as topical antiseptic agents. The usefulness of mercurials is significantly limited because of their relatively weak bacteriostatic properties and the many problems associated with mercury toxicity (Chap. 96).

Repeated application of topical mercurials may result in significant absorption and systemic toxicity.[120,148] The use of high-dose hepatitis B immunoglobulin (HBIg) may cause mercury toxicity because of the use of thimerosal as a preservative in the HBIg preparation.[104] In one case, a 44-year-old male patient received 250 mL of HBIg (containing about 30 mg of thimerosal) over 9 days following liver transplantation.[104] He developed speech difficulties, tremor, and chorea. His whole blood mercury concentration was 104 μg/L (normal <10 μg/L). Increased mercury concentrations in both preterm and term infants, following immunizations with thimerosal-containing hepatitis B vaccine, have also generated much concern and led to the call to reduce or eliminate the mercury content of vaccines (Chap. 96).[57,167]

DISINFECTANTS

■ FORMALDEHYDE

Formaldehyde is a water-soluble, highly reactive gas at room temperature. Formalin consists of an aqueous solution of formaldehyde, usually containing approximately 37% formaldehyde and 12%–15% methanol. Formaldehyde is irritating to the upper airways, and its odor is readily detectable at low concentrations. Lethality in adults may follow ingestion of 30–60 mL of formalin.[43]

Formerly used as a disinfectant and fumigant, its role as a disinfectant is now largely confined to the disinfection of hemodialysis machines. Nonetheless, formaldehyde has many other applications. Healthcare workers are probably most familiar with the use of formaldehyde as a tissue fixative and embalming agent.

Exposure to formaldehyde, a potent caustic, may result in both local and systemic symptoms, causing coagulation necrosis, protein precipitation, and tissue fixation. Ingestions of formalin may result in significant gastric injury, including hemorrhage, diffuse necrosis, perforation, and stricture.[3,10] The most extensive damage appears in the stomach, with only occasional involvement of the small intestine and colon.[192] Chemical fixation of the stomach may occur. Esophageal involvement is not very prominent, and, if present, is usually limited to its distal segment.

The most striking and rapid systemic manifestation of formaldehyde poisoning is metabolic acidosis, resulting both from tissue injury and from the conversion of formaldehyde to formic acid. The patient may present with profound acidemia, accompanied by a large anion gap metabolic acidosis. Although the methanol component of the formalin solution is readily absorbed and has resulted in methanol concentrations as high as 40 mg/dL,[20,43] the rapid metabolism of formaldehyde to formic acid appears to be responsible for much of the acidosis (Chap. 107). Blindness as a consequence of the accumulation of formate, a retinal toxin, is not reported.

Clinical Effects Patients presenting after formaldehyde ingestions complain of the rapid onset of severe abdominal pain, which may be accompanied by vomiting and diarrhea. Altered mental status and coma usually follow rapidly. Physical examination may demonstrate epigastric tenderness, hematemesis, cyanosis, hypotension, and tachypnea. Hypotension may be profound with decreased myocardial contractility, as well as hypovolemic shock, contributing to the cardiovascular instability.[69,176] Early endoscopic findings include ulceration, necrosis, perforation, and hemorrhage of the stomach, with infrequent esophageal involvement. Chemical pneumonitis occurs after significant inhalational exposure.[138] Intravascular hemolysis is described in hemodialysis patients whose dialysis equipment contained residual formaldehyde after undergoing routine cleaning.[131,142]

Occupational and environmental exposure to formaldehyde receives considerable attention. In particular, there is concern over the potential off-gassing of formaldehyde from the widely used urea formaldehyde building insulation and particle boards.[129] Headache, nausea, skin rash, sore throat, nasal congestion, and eye irritation are associated with the use of these polymers.[34] Formaldehyde, at concentrations as low as 1 ppm, may cause significant irritation to mucous membranes of the upper respiratory tract and conjunctivae.[73,103] Formaldehyde is also a potential sensitizer for immune-mediated reversible bronchospasm.[66] The exact immunologic mechanism is not yet elucidated, although it is likely that formaldehyde acts as a hapten. In addition, formaldehyde is thought to be a dermal sensitizer.[164]

Recent concerns about the health effects from the off-gassing of formaldehyde in trailers used by the Federal Emergency Management Agency (FEMA) after Hurricane Katrina illustrates the potential public health issues related to low-level formaldehyde exposure.[106] Preliminary investigations from the Center for Disease Control (CDC) revealed that air formaldehyde concentrations in closed, unventilated trailers are, in fact, high enough to cause acute symptoms in some people.[4]

Both animal and human data suggest that formaldehyde exposure is associated with an increased incidence of nasopharyngeal carcinoma.[2,62,133,149] Although its role in the pathogenesis of cancer in humans is the subject of much debate,[30,109] in 2004 the International Agency for Research on Cancer (IARC) reclassified formaldehyde from a Group 2 *probable* to a Group 1 *known* carcinogen.

Management The immediate management of a patient who has ingested formaldehyde includes dilution with water. Although such an approach may be useful in reducing the caustic effect, strong evidence for a beneficial result is lacking. Gastric aspiration with a small-bore nasogastric tube may limit systemic absorption. The role of activated charcoal is not studied and it probably should not be used if endoscopy is considered likely. Significant acidemia should be treated with sodium bicarbonate and folinic acid (Chap. 107). Immediate hemodialysis may remove the accumulating formic acid as well as the parent molecules, formaldehyde, and methanol.[43] Independent treatment for methanol toxicity may be indicated (see Chap. 107). Early endoscopy is recommended for all patients with significant GI symptoms to assess the degree of burn injury. Surgical intervention may be required for those with suspected severe burns and/or perforation.[192] Emergent gastrectomy, as well as late surgical intervention to relieve formaldehyde-induced gastric outlet obstruction, is infrequently required.[63,90]

■ PHENOL

Phenol, also known as carbolic acid, is one of the oldest antiseptic agents. It is rarely used as an antiseptic today, secondary to its toxicity, and has been replaced by the many phenolic derivatives. Currently, phenol is used as a disinfectant, chemical intermediary, and nail cauterizer. The last application uses a highly concentrated 89% solution. Phenol is also a component (0.1%–4.5%) of various lotions, ointments, gels, gargles, lozenges, and throat sprays.[60] Campho-Phenique and Chloraseptic contain 4.7% and 1.4% phenol, respectively. Although many cases of phenol poisoning were reported in the past, acute oral overdoses of phenol-containing solutions are uncommon today.[53]

Phenol acts as a caustic causing cell wall disruption, protein denaturation, and coagulation necrosis. It also acts a central nervous system (CNS) stimulant. Intentional ingestion of concentrated phenol, ingestion of phenol-containing water, occupational exposure to aerosolized phenol, dermal contact, and parenteral administration may all result in symptomatic phenol poisoning. Phenol demonstrates excellent skin penetrance.[15] Severe dermal burns from phenol have resulted in systemic toxicity, even death within minutes to hours.[15,96] Parenteral administration of phenol has also resulted in death (see Chap. 135). The lethal oral dose may be as little as 1 g.[75]

Clinical Effects Clinical manifestations can be divided into local and systemic symptoms. Systemic symptoms from gastrointestinal (GI) or dermal absorption of phenol are usually more dangerous than the local effects. Manifestations of systemic toxicity include CNS and cardiac symptoms. CNS effects include central stimulation, seizures, lethargy, and coma.[56] In a study of patients who had ingested Creolin (26% phenol), CNS symptoms predominated.[166] Of the 52 patients who were evaluated at the hospital, 9 developed lethargy and 2 developed coma. Seizures were not reported. Cardiac symptoms from phenol include tachycardia, bradycardia, and hypotension.[56] Parenteral absorption of 10 mL concentrated 89% phenol resulted in hypoxemia, acute respiratory distress syndrome, pulmonary nodular opacities, and acute renal failure requiring intubation and hemodialysis.[55] This last case was associated with a phenol concentration of 87 mg/dL (normal <2 mg/dL).

Other systemic symptoms that may develop include hypothermia, metabolic acidosis, methemoglobinemia, and rabbit syndrome.[75,86] Rabbit syndrome is most commonly observed as a distinctive extrapyramidal effect from antipsychotic drugs and is characterized by fine rapid repetitive movements of the perioral musculature resembling a rabbit's chewing movements. Increased acetylcholine release and a relative dopaminergic hypofunction may explain the development of rabbit syndrome after phenol exposure.[86]

Local toxicity to the GI tract from the ingestion of phenol may result in nausea, painful oral lesions, vomiting, bloody diarrhea, dark urine, and severe abdominal pain.[7,84] Serious GI burns are uncommon, and strictures are rare. White patches in the oral cavity may be detected. In the Creolin study cited above, only 1 of 17 patients who underwent endoscopy had a significant esophageal burn.[166] Dermal exposures to phenol usually result in a light-brown staining of the skin. Excessive dermal absorption of phenol during chemical peeling procedures is associated with dysrhythmias and many of the other symptoms.[180,186]

Markedly elevated blood and urine concentrations of phenol may be detected after ingestion, or dermal absorption, of phenol and phenol-containing compounds (eg, Campho-Phenique).[15,75]

Management When phenol is mixed with water, a bilayer with unique properties is created that makes it difficult to remove from tissues. A variety of treatments have been suggested for dermal and gastric decontamination of phenol. A study employing a rat model showed that cutaneous decontamination with a low-molecular-weight polyethylene glycol solution decreased mortality, systemic effects, and dermal burns.[19] Although this study suggested that polyethylene glycol (PEG) was superior to water as a decontamination agent, a subsequent study using a swine model could not demonstrate a difference between these two therapies.[141] In another swine model, PEG 400 and 70% isopropanol were both superior to water washes and equally effective in decreasing dermal burn.[116] Given the lack of definitive efficacy data, either low-molecular-weight PEG, for example, PEG 300 or 400 (not to be confused with high-molecular-weight PEG that is used for whole-bowel irrigation), or high flow water is currently recommended for dermal irrigation and careful gastric decontamination. Isopropanol could also be considered as another treatment for dermal decontamination. Endoscopic evaluation, as needed to determine the extent of GI injury, and good supportive care are also recommended.

■ SUBSTITUTED PHENOLS AND OTHER RELATED COMPOUNDS

Hexachlorophene (pHisoHex), a trichlorinated *bis*-phenol, is one of the best known substituted phenols. Hexachlorophene, considered generally less tissue-toxic than phenol, was formerly used extensively as a disinfectant in hospitals. During the 1970s, an association was observed between repetitive whole-body washing of premature infants with 3% hexachlorophene and the development of vacuolar encephalopathy and cerebral edema.[110] There were also multiple reports of significant neurologic toxicity and death in children who became toxic after ingesting hexachlorophene.[68] In addition, fatalities also occurred after patients absorbed substantial amounts of hexachlorophene during the treatment of burn injuries.[26] The use of hexachlorophene has declined significantly.

Clinical Effects pHisoDerm contains sodium octylphenoxyethoxyethyl ether sulfonate and lanolin, and is a safe antiseptic. Irritative effects (nausea, vomiting, diarrhea) would be the main adverse effects with oral ingestions.

In a study of poisoning admissions to Hong Kong hospitals, the ingestion of Dettol liquid, a household disinfectant that contains 4.8% chloroxylenol, 9% pine oil, and 12% isopropanol, accounted for 10% of admissions.[24] Aspiration (perhaps, in part, because of the pine oil) occurred in 8% of these patients, resulting in upper airway obstruction, pneumonia, and acute respiratory distress syndrome. More common symptoms included nausea, vomiting, sore mouth, sore throat, drowsiness, abdominal pain, and fever. Dermal contact with Dettol may result in full-thickness chemical burns.[35]

Cresol, a mixture of three isomers of methylphenol, has better germicidal activity than phenol and is a commonly used disinfectant. Exposure to concentrated cresol may result in significant local tissue injury, hemolysis, renal injury, hepatic injury, and CNS and respiratory depression.[35,61,87,191] Phenol concentrations, as well as cresol concentrations, serve as markers of exposure.[191]

Management Treatment is mainly supportive.

■ QUATERNARY AMMONIUM COMPOUNDS

Quaternary ammonium compounds are a type of cationic surfactant (surface-active agent); they are used as disinfectants, detergents, and sanitizers. Chemically, the quaternary ammonium compounds are synthetic derivatives of ammonium chloride, and structurally similar to other quaternary ammonium derivatives, such as carbamate cholinesterase inhibitors and neuromuscular blockers. Other cationic surfactants include the pyridinium compounds and the quinolinium compounds. Benzalkonium chloride (Zephiran) was one of the most commonly employed quaternary ammonium compounds in the past. Many newer quaternary ammonium compounds have supplanted its use. However, nebulized solutions used for the treatment of asthma, including albuterol and ipratropium bromide, may contain small amounts of benzalkonium chloride.

Clinical Quaternary ammonium compounds are less toxic than phenol or formaldehyde. Most of the infrequent complications that are described result from ingestions of benzalkonium chloride. Complications of these ingestions include burns to the mouth and esophagus, CNS depression, elevated liver enzyme concentrations metabolic acidosis, and hypotension.[71,182,189] Paralysis is also occasionally described as a complication of these ingestions and is presumably a result of cholinesterase inhibition at the neuromuscular junction.[53] Chronic inhalational exposure is associated with occupational asthma.[16] Topical use of the quaternary ammonium compounds can cause contact dermatitis.[160] Few data are available on the toxicity of the newer quaternary ammonium compounds.

Ingestions of other cationic surfactants, such as the pyridinium agent cetrimonium bromide (Cetrimide), are associated with caustic burns to the mouth, lips, and tongue.[118] Peritoneal irrigation with cetrimonium bromide can produce metabolic abnormalities, hypotension, and methemoglobinemia.[8,115] Intravenous administration of cetrimide produced cardiac arrest, hemolysis, and muscle paralysis.[49]

Management Treatment recommendations following the ingestion of the quaternary ammonium compounds and other cationic surface-active agents are similar to those for other potentially caustic ingestions. Emergency department evaluation should be considered for all patients who ingest more than a taste of a dilute (less than 1%) solution. Therapy is mainly supportive. Endoscopy may be warranted if symptoms suggest the possibility of a burn injury.

STERILANTS

■ ETHYLENE OXIDE

Ethylene oxide is a gas that is commonly used to sterilize heat-sensitive material in healthcare facilities. Unlike antiseptics and disinfectants, which generally do not exhibit full sporicidal activity, sterilants, such as ethylene oxide, inactivate all organisms. Ethylene oxide is also used in the synthesis of many chemicals, including ethylene glycol, surfactants, rocket propellants, and petroleum demulsifiers, and has been used as a fumigant. Ethylene oxide has a cyclic ester structure that acts as an alkylating agent, reacting with most cellular components, including DNA and RNA.

Medical attention regarding ethylene oxide toxicity has centered on its mutagenic and possible carcinogenic effects.[92] Approximately 270,000 workers (including 96,000 hospital workers) in the United States are at risk for occupational exposure to ethylene oxide.[170] Retrospective studies suggest a possible excess incidence of leukemia and gastric cancer in ethylene oxide-exposed workers.[72,170] These studies are inconclusive, and the carcinogenicity of ethylene oxide remains subject to debate. It is also suggested that an increased incidence of spontaneous abortions may be associated with occupational exposure to ethylene oxide.[65]

Clinical Effects The acute toxicity of ethylene oxide is mainly the result of its irritant effects. Conjunctival, upper respiratory tract, GI, and dermal irritation may occur. Dermal burns from acute exposure to ethylene oxide are reported. Acute exposure to a broken ethylene oxide ampule by a 43-year-old recovery room nurse resulted in nausea, lightheadedness, malaise, syncope, and recurrent seizures.[152] There were no long-term complications. In another case of acute exposure, coma was followed by an irreversible parkinsonism.[9]

Chronic exposure to high concentrations of ethylene oxide may cause mild cognitive impairment and motor and sensory neuropathies.[18,54,127] The risk of cancer with occupational exposure is low.[29,169]

Management Treatment for patients with ethylene oxide exposure is supportive.

■ GLUTARALDEHYDE

Glutaraldehyde is a liquid solution used in the cold sterilization of nonautoclavable endoscopic, surgical, and dental equipment. It is also employed as a tissue fixative, embalming fluid, preservative, and tanning agent, in radiographic solutions, and in the treatment of warts.[51] Glutaraldehyde is a dialdehyde with two active carbonyl groups that is less volatile than formaldehyde. It kills all microorganisms, including viruses and spores. The germicidal ability of glutaraldehyde results from the alkylation of sulfhydryl, hydroxyl, carboxyl, and amino groups, within microbes interfering with RNA, DNA, and protein synthesis.[151] It is prepared as a 2% alkaline solution in 70% isopropanol (Cidex). Healthcare workers may be exposed to glutaraldehyde vapors when equipment is processed in poorly ventilated areas, or in open immersion baths or after spills. Under these circumstances, the evaporation of glutaraldehyde may result in the increase in ambient air concentrations that may easily exceed recommended limits. Approximately 35,000 workers are occupationally exposed to glutaraldehyde.[137] Patients

may be exposed when diagnostic instruments are inadequately rinsed following cold sterilization with glutaraldehyde.

Clinical Clinical signs and symptoms are thought to be comparable to those of formaldehyde exposure although human toxicity data are limited. Animal studies show that glutaraldehyde's inhalational and dermal toxicity are comparable to formaldehyde at equivalent doses.[175]

Glutaraldehyde is a mucosal irritant. Coryza, epistaxis, headache, asthma, chest tightness, palpitations, tachycardia, and nausea are all associated with glutaraldehyde vapor exposure.[14,31,124,132] Contact dermatitis and ocular inflammation may also occur.[33,156] Colitis has been reported following the use of endoscopes contaminated with residual glutaraldehyde solution.[158] Patients with glutaraldehyde-induced colitis typically present with fever, chills, severe abdominal pain, bloody diarrhea, and an elevated white blood cell count blood within 48 hours after colonoscopy or sigmoidoscopy.

The IARC has not ranked the carcinogenic potential of glutaraldehyde.

Management Treatment recommendations are similar to those for patients with formaldehyde exposure. Prompt removal from the exposure is essential. Copious irrigation with water provides adequate dermal decontamination. Severe inhalational exposures may require hospital admission for observation, supportive care, and treatment of bronchospasm.

OTHER PRODUCTS

■ BORIC ACID

Boric acid is an odorless, transparent crystal, although it is most commonly available as a finely ground white powder. It is also commonly found as a 2.5%–5% aqueous solution. Boric acid (H_3BO_3), prepared from borax (sodium borate; $Na_2B_4O_7 \cdot 10\ H_2O$), was first used as an antiseptic by Lister in the late 19th century. Although used extensively over the years for antisepsis and irrigation, boric acid is only weakly bacteriostatic. As a result of its germicidal limitations and its inherent toxicity, boric acid is nearly obsolete in modern antiseptic therapy. Nonetheless, it continues to be used as an antimicrobial to treat such conditions as vulvovaginal candidiasis.[140] Boric acid is also employed in the treatment of cockroach infestation and as a soap, contact lens solution, toothpaste, and food preservative.[58]

Boric acid is readily absorbed through the GI tract, wounds, abraded skin, and serous cavities. Absorption does not occur through intact skin. Boric acid is predominantly eliminated unchanged by the kidney. Small amounts are also excreted into sweat, saliva, and feces.[50] Boric acid is concentrated in the brain and liver.

The exact mechanism of action of boric acid's toxicity remains unclear. Although it is an inorganic acid, it does not behave as a caustic. Local effects are limited to tissue irritation.

Over the years, boric acid has developed a reputation as an exceptionally potent toxin. This reputation was derived in great part from a series of reports involving neonatal exposures to boric acid resulting in high morbidity and mortality. Life-threatening toxicity resulted from the repetitive topical application of boric acid for the treatment of diaper rash or the use of infant formulas unintentionally contaminated with boric acid.[50,190] Fatality rates greater than 50% were reported in some series.[190] Although infants appear to be the most sensitive to the toxic effects of boric acid, many cases of significant adult toxicity are also reported. These cases date predominantly from the time when boric acid was widely used as an irrigant. Routes of exposure to boric acid, resulting in fatalities, include wound irrigation, pleural irrigation, rectal washing, bladder irrigation, and vaginal packing.[181]

Clinical Effects Classic boric acid poisoning usually involves multiple exposures over a period of days. Gastrointestinal, dermal, CNS, and renal manifestations predominate. The initial symptoms—nausea, vomiting, diarrhea, and occasionally crampy abdominal pain—may be confused with an acute gastroenteritis. At times, the emesis and diarrhea are greenish blue.[190] Following the onset of GI symptoms, the majority of patients develop a characteristic intense generalized erythroderma.[190] This rash, described as producing a "boiled lobster" appearance, may appear indistinguishable from toxic epidermal necrolysis or staphylococcal scalded skin syndrome in the neonate.[150] The rash may be especially noticeable on the palms, soles, and buttocks.[50] Typically, extensive desquamation takes place within 1–2 days. On occasion, prominent mucous membrane involvement of the oral cavity and conjunctivae is also apparent.[190] At about the time of the development of the erythroderma, patients, particularly young infants, may develop prominent signs of CNS irritability, resembling meningeal irritation. Seizures, delirium, and coma can occur.[50] Renal injury is common, both a result of the renal elimination of this compound and prerenal azotemia from GI losses.[50] Other complications of boric acid poisoning include hepatic injury, hyperthermia, and cardiovascular collapse. The abandonment of boric acid as an irrigant and particularly its removal from the nursery setting have led to a marked decrease in the incidence of significant boric acid poisoning.

Two retrospective studies on boric acid ingestions suggest that a single acute ingestion of boric acid is generally quite benign.[98,100] In these studies, 79–88% of patients remained asymptomatic. Symptoms, when present, primarily consist of GI irritative symptoms, such as nausea and vomiting. None of the 1184 patients in these two studies manifested the generalized erythroderma so commonly described in previous reports. Central nervous system manifestations of acute overdose were infrequent and limited to occasional lethargy and headache. Renal toxicity did not occur following single acute ingestions.

Several reports suggest, however, that significant toxicity from massive acute ingestion of boric acid can occur. Fatality resulted from a single ingestion of 2 cups (280 g) of boric acid crystals by a 45-year-old man.[146] Symptoms on presentation (2 days after ingestion) included nausea, vomiting, green diarrhea, lethargy, hypotension, renal failure, and a prominent "boiled lobster" rash on his trunk and extremities. In another case, the ingestion of 30 g of boric acid by a 77-year-old man resulted in similar symptoms and death 63 hours postingestion, despite hemodialysis.[81] The diagnosis of boric acid poisoning can be confirmed with the measurement of blood or serum boric acid concentrations (normal = 1.4 nmol/mL), but this test is not routinely available.

Long-term chronic exposure to boric acid results in alopecia in adults and seizures in children.[126] A 32-year-old woman who chronically ingested mouthwash containing boric acid over a 7-month period developed progressive hair loss.[174] The chronic application of a borax and honey mixture to pacifiers resulted in the development of recurrent seizures in nine infants, which resolved after the mixture was withheld.[52,126]

Management Treatment of boric acid toxicity is mainly supportive. Activated charcoal is not recommended because of its relatively poor adsorptive capacity for boric acid.[36] Since boric acid has a low molecular weight and relatively small volume of distribution, in cases of massive oral overdose or renal failure. Hemodialysis or perhaps exchange transfusion in infants, may be helpful in shortening the half-life of boric acid.[100,122,178,190] In patients with normal renal function, forced diuresis enhances renal elimination.[179]

■ CHLORATES

Sodium chlorate is a strong oxidizer. At one time, the chlorate salts, sodium chlorate and potassium chlorate, were used as medicinal to treat inflammatory and ulcerative lesions of the oral cavity and could be found in various mouthwash, toothpaste, and gargle preparations.[168] Although their use as local antiseptics is obsolete, chlorates are used as herbicides and in the manufacture of matches, explosives, and dyestuffs.[82] More recent cases of chlorate poisoning resulted from the ingestion of sodium chlorate–containing weed killers, or dispensing errors that confused sodium chlorate with sodium sulfate or sodium chloride.[82] Sodium chlorate in the form of white crystals has also been mistaken for table sugar.[64] A case of significant toxicity from the inhalation of atomized chlorates is also reported.[82]

Sodium chlorate is rapidly absorbed from the GI tract and eliminated predominantly unchanged from the kidneys.[83] Its systemic effects are chiefly hematologic and renal. Chlorate's major mechanism of toxicity is its ability to oxidize hemoglobin and increase red blood cell membrane rigidity.[161] Consequently, significant methemoglobinemia and hemolysis may result. Chlorates may also be directly toxic to the proximal renal tubule.[94] The hemolysis and the resultant hemoglobinuria may secondarily cause disseminated intravascular coagulation and potentiate renal toxicity. The worsening renal function is especially problematic because of its adverse effect on chlorate elimination. The methemoglobinemia may be severe and cause significant hypoxic stress. Methemoglobinemia may occur prior to or after the development of hemolysis.[125,171] Chlorates may also act locally as a GI irritant, and cause mild CNS depression after absorption.[53]

Clinical Clinical signs and symptoms of chlorate poisoning usually begin 1–4 hours after ingestion.[88] The earliest symptoms are GI, including nausea, vomiting, diarrhea, and crampy abdominal pain. Subsequently, the patient may exhibit cyanosis from the methemoglobinemia and black-brown urine from the hemoglobinuria. Obtundation and anuria may ensue. Laboratory studies may show methemoglobinemia, anemia, Heinz bodies, ghost cells, fragmented spherocytes, metabolic acidosis, decreased platelet count, and abnormal coagulation.[45] Hyperkalemia may be particularly problematic if the patient ingests potassium chlorate preparations.[121] In a recent case of chlorate poisoning from the ingestion of 120 potassium chlorate–containing matchsticks, an MRI revealed symmetric abnormal signal intensity within the deep gray matter and medial temporal lobes.[121] This finding can be explained by the basal ganglia's increased vulnerability to oxygen deprivation. Followup MRI two months later was normal.

Management Treatment of a patient with a significant chlorate ingestion should include orogastric lavage and the use of activated charcoal.[64] It has been suggested that administration of sodium thiosulfate may inactivate the chlorate ion by reducing it to the chloride ion,[64] but an in vitro study did not confirm this hypothesis.[173] Although methylene blue is used in the treatment of symptomatic methemoglobinemia, its efficacy in the treatment of chlorate-induced methemoglobinemia may be limited, as compared to its efficacy in the treatment of other oxidant-induced methemoglobinemias.[125,172] This may be a consequence of the inactivation by chlorates of glucose-6-phosphate dehydrogenase, an enzyme that is required for methylene blue to effectively reduce methemoglobin.[161] Exchange transfusion, peritoneal dialysis, and hemodialysis have all been advocated in the treatment of patients with severe chlorate poisoning.[125,172] Because the chlorate ion is easily dialyzable, hemodialysis is capable of removing this xenobiotic as well as treating any concomitant renal failure that may have developed.[82,88,94]

SUMMARY

A chemically diverse group of antiseptics, disinfectants, and sterilants exist. Many of the more toxic xenobiotics, such as iodine, phenol, and chlorates, are no longer commonly used as cleansers but may still be

available in some settings. Formaldehyde exposures, although also uncommon, can also cause significant problems. Frequently employed antiseptics, such as chlorhexidine, pHisoDerm, and many of the currently used quaternary ammonium compounds, have a relatively limited toxicity. Ingestions of the iodophors do not usually cause significant toxicity, but absorption through other routes may produce significant adverse effects. Ingestions of hydrogen peroxide, particularly the more concentrated formulations, may result in life-threatening injuries.

CHAPTER 103

CAMPHOR AND MOTH REPELLENTS

Edwin K. Kuffner

Camphor Naphthalene Paradichlorobenzene
Many different products have historically been used as moth repellents. In the United States, paradichlorobenzene has largely replaced both camphor and naphthalene as the most common active component of moth repellent and moth flakes because of its decreased toxicity. However, because paradichlorobenzene is widely available and because life-threatening camphor and naphthalene toxicity still occur, all of these xenobiotics need to be considered in evaluating possible exposure moth repellent.

CAMPHOR

■ HISTORY AND EPIDEMIOLOGY

Camphor (2-bormanone, 2-camphonone), a cyclic ketone of the terpene group, is an essential oil distilled from the bark of the camphor tree, *Cinnamomum camphora*. Today, most camphor is synthesized from the hydrocarbon pinene, a derivative of turpentine oil. Camphor has been used as an aphrodisiac, contraceptive, abortifacient, suppressor of lactation, analeptic, cardiac stimulant, antiseptic, cold remedy, muscle liniment, and drug of abuse.[27,34,40,45,50,60,71,72]

Camphorated oil and camphorated spirits contain varying concentrations of camphor. Historically, most camphorated oil was 20% weight (of solute) per weight (of solvent) (w/w) camphor with cottonseed oil, and most camphorated spirits contained 10% w/w camphor with isopropyl alcohol. Toxicity and death following ingestion of camphorated oil, which was confused with castor oil and cod liver oil, prompted the FDA to ban the nonprescription sale of camphorated oil in the United States in 1983.[3,21,40,64,81] Today, based on the 1983 FDA ruling, nonprescription camphor-containing products may not have greater than an 11% concentration of camphor. Camphorated oil is still used as an herbal remedy and muscle liniment, and products containing greater than 11% camphor can still be purchased outside of the United States.[78]

Common camphor-containing products include cold sore ointments (usually <1% camphor), muscle liniments, rubefacients (usually 4%–7% camphor), and camphor spirits (usually 10% camphor). Paregoric, camphorated tincture of opium, contains a combination of anhydrous morphine (0.4 mg/mL), alcohol (46%), and benzoic acid (4 mg/mL) but only a small amount of camphor.[43] Camphor for industrial use can be purchased legally in the United States and contains up to 100% camphor. Occupational exposures to camphor occur during the manufacture of plastic, celluloid, lacquer, varnish, explosives, embalming fluids, and numerous pharmaceuticals and cosmetics.[35]

Although products containing lower concentrations of camphor are implicitly safer, life-threatening toxicity and death may still result, usually from misuse or intentional overdose. Most reported cases of acute camphor poisoning are unintentional ingestions of camphor-containing liquids mistaken for other medications.[3,40,63,79] According to data obtained by the American Association of Poison Control Centers (AAPCC), each year there are approximately 10,000 exposures to camphor with very few reports of "major" toxicity. Over the past 20 years, according to the AAPCC, only six reported deaths were attributable to camphor, all in adults, at least two of which occurred in the setting of an intentional suicidal overdose. Chapter 135 contains complete references and discussion of the AAPCC data.

■ PHARMACOLOGY

Camphor is a colorless glassy solid. Camphor's pharmacologic activity is not well studied and its mechanism of action remains unclear. It is unlikely that camphor has therapeutic benefit as an expectorant or an antiinfective. Camphor may provide some local analgesic and antipruritic effects, but much safer xenobiotics are available for these indications. No therapeutic benefit of camphor has been proven in any well-controlled clinical trials.

■ PHARMACOKINETICS AND TOXICOKINETICS

There are limited data on the pharmacokinetics and toxicokinetics of camphor. Toxicity is reported following ingestion, inhalation, intranasal instillation, intraperitoneal administration, and transplacental transfer.[15,65,69,75,76,86] Dermal exposures have been reported to cause systemic toxicity.[30,61] Camphor from liquid preparations is rapidly absorbed from the gastrointestinal tract and camphor can be detected in the blood within 15–20 minutes postingestion.[65] Camphor is highly lipid soluble and is predominantly metabolized in the liver where it undergoes hydroxylation followed by conjugation with glucuronic acid. Inactive metabolites, including campherol, borneol, hydroxycamphor, and camphoglycuronic acid, are excreted by the kidneys.[66]

As with many xenobiotics, the toxic dose of camphor reported in the medical literature is highly variable.[31,40,74] As little as 1 teaspoon (approximately 5 gms) of 20% camphorated oil reportedly caused death in an infant.[74] Workplace standards include the Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL), which is 2 mg/m³, the American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV), which is 12 mg/m³ (2 ppm), and the ACGIH short-term exposure limit (STEL), which is 19 mg/m³ (3 ppm); NIOSH Immediately Dangerous To Life or Health Concentration (IDLH) is 200 mg/m³.[83]

■ PATHOPHYSIOLOGY

The mechanism of toxicity of camphor is unknown. Camphor is an irritant. Pathologic changes following ingestion include cerebral edema, neuronal degeneration, fatty changes, centrilobular congestion of the liver, and hemorrhagic lesions in the skin, gastrointestinal tract, and kidneys.[19,41,74,86]

■ CLINICAL MANIFESTATIONS

Exposure to camphor can often be detected by its characteristic aromatic odor (Chap. 20). Ingestion of camphor typically produces oropharyngeal irritation, nausea, vomiting, and abdominal pain. Generalized tonic–clonic seizures may be the first sign of camphor toxicity, usually

occurring within 1–2 hours postingestion.[5,8] Most seizures are brief and self-limited, although some patients may have a more protracted course.[5,26,47,75] Delayed seizures, up to 9 hours following ingestion and up to 72 hours following dermal exposure, have been reported.[30,67] Central nervous system (CNS) depression is common, but rarely compromises respiratory function.[15,46] Other neurologic effects include headache, lightheadedness, transient visual changes, confusion, myoclonus, and hyperreflexia.[44,65,69] Psychiatric effects include agitation, anxiety, and hallucinations.[31,44,46] Dermal effects include flushing and petechial hemorrhages.[15,34,76] Camphor does not typically cause life-threatening cardiovascular effects although a case of myocarditis is reported.[9,34] Death is reported secondary to respiratory failure or seizures.[15]

Case reports suggest that acute ingestion of camphor can cause transient elevations of the hepatic aminotransferases.[3,41,65,69,74] Chronic administration of camphor to a child caused altered mental status and elevated hepatic aminotransferases concentrations suggestive of Reye syndrome.[41] When hepatotoxicity occurs, however, camphor does not typically produce morphologic changes of the liver characteristic of Reye syndrome. Albuminuria can also occur.[74]

Camphor crosses the placenta. Both fetal demise and delivery of healthy neonates are reported in mothers who develop camphor toxicity within 24 hours of term delivery.[10,65,86] Specific dose-related toxicity could not be determined from these case reports.

Inhalational and dermal exposure from camphor usually produces only mucous membrane and dermal irritation, respectively.[29]

■ DIAGNOSTIC TESTING

When managing most patients with camphor toxicity, no specific toxicologic diagnostic testing is indicated. Although camphor and its metabolites can be identified in blood and urine, concentrations are not useful in most cases of acute toxicity because they are not readily available and have not been proven to correlate with clinical toxicity.[34,45,66]

■ MANAGEMENT

The patients who should be evaluated in a healthcare facility after an acute ingestion include those who have signs or symptoms consistent with camphor toxicity, those who have ingested more than 1 g of camphor (1 teaspoon of 20% camphorated oil or approximately 2 teaspoons of 11% camphorated oil), suicidal patients, and any patient with a significant occupational exposure.

Gastric decontamination is not well studied in patients who have ingested camphor. If lavage is deemed necessary following recent ingestion of a camphor-containing solution, nasogastric suctioning and lavage are preferable to orogastric lavage. Because camphor-containing solutions are so rapidly absorbed, the benefit of gastrointestinal decontamination is expected to rapidly diminish as the time following ingestion increases. Emetics should not be administered because camphor-induced seizures can occur rapidly prior to the onset of emesis, raising the risk of pulmonary aspiration. There is no human evidence in support for or against the use of activated charcoal in camphor ingestions. A consensus panel has recommended against the use of activated charcoal in isolated camphor ingestions.[52] There is no antidote for camphor. Most patients survive with supportive care. Although the management of camphor-induced seizures is not well studied, patients should be treated with benzodiazepines. Repeat doses of benzodiazepines may be needed to control seizures. If benzodiazepines fail to control seizures, other sedative-hypnotic agents, including phenobarbital, pentobarbital, and propofol, should be administered. Case reports suggest that most patients who develop life-threatening camphor toxicity develop symptoms within a few hours postexposure. Based on this, an observation period of at least 2–4 hours following a

potentially toxic ingestion of camphor is reasonable. Delayed seizures, up to 9 hours following ingestion and up to 72 hours following dermal exposure, have been reported.[30,67] In case reports, hemodialysis with a lipid dialysate and either hemoperfusion using an Amberlite resin or charcoal hemoperfusion successfully removed camphor.[3,25,46,47,53] Neither isolated lipid hemodialysis nor lipid dialysis in combination with hemoperfusion is routinely recommended or widely available.

NAPHTHALENE

■ HISTORY AND EPIDEMIOLOGY

Historically, naphthalene toxicity has resulted from its use as an antihelminthic and an antiseptic.[73] Toilet-bowl and diaper-pail deodorizers containing naphthalene have also caused toxicity.[14,91] Naphthalene is the single most abundant component of coal tar and is a component of petroleum. Occupational exposures to naphthalene may occur during the manufacture of dyes, synthetic resins, celluloid, solvents, and fuels. Naphthalene is a component of fuels and is also generated as a by-product of combustion.

Most unintentional exposures to naphthalene-containing moth repellents occur in children and do not cause life-threatening toxicity. According to data from the AAPCC, each year there are between 1500 and 2000 case mentions of naphthalene. Since 1998 there has not been a naphthalene-associated death reported to AAPCC, and reports of "major toxicity" are very unusual (see Chap. 135). Mothball vapors are also intentionally inhaled as a form of inhalant abuse.[49]

■ PHARMACOLOGY, PHARMACOKINETICS, AND TOXICOKINETICS

Naphthalene ($C_{10}H_8$), an aromatic bicyclic hydrocarbon, is a white, flakey crystalline solid with a noxious odor. Synonyms include white tar and tar camphor. Naphthalene toxicity is reported following ingestion, dermal application, and inhalation.[16,18,20,68,85] Although the absorption of naphthalene is not well studied, highly lipid-soluble compounds may increase both oral and dermal absorption. Naphthalene metabolism is complex and varies considerably among species and different anatomical regions.[11] Naphthalene is metabolized in the liver by CYP isoenzymes to naphthalene 1,2-oxide. Naphthalene 1,2-oxide can react with cellular components such as DNA and protein to form covalent adducts, can be spontaneously converted to 1-naphthol and 2-naphthol, the glucuronides and sulfates of which are renally eliminated, further metabolized to 1,4-naphthoquinone or detoxified by glutathione-S-transferase and excreted in the urine as mercaputuric acid metabolites.[11,64] These hepatic metabolites, primarily α-naphthol, but not the parent compound,[64,90] cause the oxidant stress responsible for naphthalene-induced hemolysis and methemoglobinemia. As with most xenobiotics, the toxic amount of naphthalene reported in the medical literature is highly variable. As little as one naphthalene mothball has resulted in toxicity, including hemolysis in an infant.[24,91] Workplace standards include the OSHA PEL, which is 50 mg/m³ (10 ppm), ACGIH TLV, which is 52 mg/m³ (10 ppm), and the ACGIH STEL, which is 79 mg/m³ (15 ppm); NIOSH IDLH is 250 ppm (US Dept of Labor OSHA).[82]

■ PATHOPHYSIOLOGY

To understand naphthalene-induced hemolysis and methemoglobinemia, it is important to understand how oxidant stress affects erythrocytes and the normal mechanisms erythrocytes use to prevent and reverse the effects of oxidant stress.

Oxidant stressors can cause methemoglobinemia and/or hemolysis. When oxidant stress causes an iron atom from any of the four globin chains of hemoglobin to be oxidized from the ferrous state (Fe^{2+}) to the ferric state (Fe^{3+}) state, methemoglobin is formed (see Chap. 127). When oxidant stress causes hemoglobin denaturation, the heme groups and the globin chains dissociate and precipitate in the erythrocyte, forming Heinz bodies. An erythrocyte with denatured hemoglobin is more susceptible to hemolysis and removal by the reticuloendothelial system (see Chap. 24).

Hemolysis and methemoglobinemia can occur independently of each other or simultaneously in patients with either normal or deficient glucose-6-phosphate dehydrogenase (G6PD) activity.[24,39,85,91]

Theoretically, patients with G6PD deficiency are at increased risk for both hemolysis and methemoglobinemia following oxidant stress. In practice, however, patients with glucose-6-phosphate deficiency are at much greater risk of hemolysis than of methemoglobinemia.

Patients with G6PD deficiency are at increased risk for hemolysis because they have decreased glutathione stores.[85,90] Glucose-6-phosphate deficiency affects all races but is most prevalent in patients of African, Mediterranean and Asian descent. The gene that codes for G6PD is X-linked; consequently, men are affected more often than women.

Infants are also at increased risk of methemoglobinemia because fetal hemoglobin is more susceptible to the formation of methemoglobin and also because nicotinamide adenine dinucleotide (NADH) methemoglobin reductase activity is decreased, impairing the reduction of methemoglobin to hemoglobin.[42]

■ CLINICAL MANIFESTATIONS

Both acute and chronic exposures to naphthalene result in similar toxicity.[14,57,90] Ingestion and inhalational exposures to naphthalene commonly cause headache, nausea, vomiting, diarrhea, abdominal pain, fever, and altered mental status.[14,51,58] Dermal exposure results in dermatitis.[27]

Hemolysis or methemoglobinemia usually becomes clinically evident, as early as 24–48 hours postexposure, but more typically on the third day postexposure because of the time necessary for the metabolism of naphthalene.[18] Anemia secondary to hemolysis often does not reach its nadir until 3–5 days postexposure.[80]

Signs and symptoms of hemolysis and methemoglobinemia are nonspecific and include tachycardia, tachypnea, shortness of breath, generalized weakness, decreased exercise tolerance, and altered mental status. Methemoglobinemia may produce cyanosis, whereas hemolysis may produce pallor and jaundice (see Chap. 127). Renal failure as a complication of naphthalene-induced hemolysis and hemoglobinuria is reported. Naphthalene or its metabolites cross the placenta.[4] Naphthalene pica during pregnancy causes both maternal and fetal toxicity. Children born to mothers who were experiencing naphthalene toxicity at the time of delivery have developed hemolytic anemia believed to be related to the maternal naphthalene exposure.[90] Although cataracts have been reported in animals following naphthalene exposure, human data are limited.[55]

Although naphthalene is classified by the International Agency for Cancer Research (IARC) as a Group 2B carcinogen (possibly carcinogenic to humans), and by the EPA as a Group C possible human carcinogen, the data supporting human carcinogenicity of naphthalene are limited.[28,38]

■ DIAGNOSTIC TESTING

No specific diagnostic testing is indicated, although both naphthalene and its metabolites can be identified in blood and urine. Identification of 1-naphthol and 2-naphthol in the urine can confirm exposure to naphthalene;[59] qualitative or quantitative testing for naphthalene or its metabolites is rarely clinically indicated when managing a case of an acute overdose.

The presentation of naphthalene-induced hemolysis is similar to that of hemolysis from other causes. Reticulocytosis occurs as a response to restore a normal hemoglobin concentration. Hyperbilirubinemia from hemolysis is characterized by an elevation of the indirect bilirubin (unconjugated bilirubin) and a relatively normal direct (conjugated) fraction. Serum haptoglobin is usually low because the haptoglobin–hemoglobin complex is cleared by the kidneys. Both the direct and indirect Coombs tests are negative in naphthalene-induced hemolytic anemia. Lactate dehydrogenase is elevated because it is released from hemolyzed red blood cells. Gross or microscopic hemoglobinuria is confirmed by a urine dipstick that reacts strongly positive for hemoglobin with a paucity of red blood cells on microscopic examination of the urine sediment. This should be differentiated from myoglobinemia by measuring the serum creatine phosphokinase, which will be elevated in patients with rhabdomyolysis and myoglobinuria.

Examination of a peripheral blood smear can reveal evidence of hemolysis before a patient develops clinical or laboratory evidence of anemia. The peripheral smear may reveal red blood cell (RBC) fragmentation, anisocytosis, microspherocytosis, reticulocytosis, nucleated RBCs, Blister cells, and Heinz body formation (see Chap. 24). Peripheral smear abnormalities and anemia may occur within the first 24 hours following ingestion.[14,70,90,91] Testing for G6PD activity is not routinely recommended during an acute episode of hemolysis. Reticulocytes have higher G6PD activity than do older RBCs. If G6PD activity is measured during an episode of hemolysis when many of the older RBCs have already been destroyed, the G6PD activity may be falsely normal. It is best to delay testing for G6PD activity for a few months following an episode of hemolysis. Family members of patients with life-threatening G6PD deficiency should also be tested.

Naphthalene-induced methemoglobinemia is similar in presentation to methemoglobinemia from other xenobiotics. The percentage of methemoglobin can rapidly be determined using a cooximeter (see Chap. 127).

■ MANAGEMENT

Most patients with an unintentional exposure to all or part of one naphthalene-containing mothball do not require medical evaluation. Patients who should be evaluated in a healthcare facility following an acute ingestion include those who recently ingested more than one naphthalene-containing mothball equivalent, those with signs or symptoms of toxicity, especially hemolysis and/or methemoglobinemia, those with known or suspected G6PD deficiency, all intentional ingestions, and those patients with large inhalational exposures, especially after exposure occurs in an occupational setting.

Gastrointestinal decontamination is not well studied in patients who have ingested naphthalene. Most patients with unintentional exposures do not require gastrointestinal decontamination. Emesis may be useful following ingestion of multiple naphthalene-containing mothballs in children, provided it can be administered within 30–60 minutes postingestion. Administration of activated charcoal, 1 g/kg, although not of proven efficacy, is also reasonable because it is considered safe. Repeat doses of activated charcoal 0.5 g/kg and/or whole-bowel irrigation with polyethylene glycol electrolyte lavage solution would only be indicated for patients with large ingestions of naphthalene who are expected to have significant ongoing absorption of naphthalene within the gastrointestinal tract.

Diagnostic testing within the first 24–48 hours postexposure may detect the onset of methemoglobinemia and/or hemolysis before a patient becomes symptomatic. Most low-risk patients who are asymptomatic within the first 24–48 hours postexposure and who have no laboratory evidence of hemolysis or methemoglobinemia can be managed as outpatients if reevaluation within 24 hours can be arranged. Patients who are discharged should be instructed to return if they

become symptomatic. High-risk patients, patients with laboratory evidence of hemolysis and/or methemoglobinemia, and patients who cannot reliably be managed as outpatients should be admitted.

Patients with life-threatening hemolysis and anemia should be transfused with packed red blood cells. However, most healthy patients will be able to compensate for the hemolysis and will not require a transfusion. Patients with symptomatic methemoglobinemia should receive methylene blue, 1–2 mg/kg (0.1–0.2 mL/kg of a 1% solution) intravenously. Repeat doses may be necessary (see Antidotes in Depth A41: Methylene Blue).

PARADICHLOROBENZENE

■ HISTORY AND EPIDEMIOLOGY

Paradichlorobenzene is widely used as a deodorizer, disinfectant, repellent, fumigant, insecticide, fungicide, and industrial solvent. Today, paradichlorobenzene is the most common component of moth repellents. Exposure to paradichlorobenzene in the United States is extremely common. A 1995 study suggested that 2,5-dichlorophenol, a metabolite of paradichlorobenzene, was detectable in the urine in 98% of the US population.[36]

Most unintentional exposures to paradichlorobenzene-containing moth repellents occur in children and do not cause toxicity. According to the AAPCC data there were no deaths and no reports of major toxicity associated with paradichlorobenzene between 1998 and 2007.

■ PHARMACOLOGY, PHARMACOKINETICS, TOXICOKINETICS, AND PATHOPHYSIOLOGY

Paradichlorobenzene ($C_6H_4Cl_2$) is a colorless solid with a noxious odor. It is available as pure white crystals, as a solid in combination with other chemicals, or as a liquid dissolved in volatile solvents or oil.[2] The mechanism for the effects and toxicology of paradichlorobenzene has not been studied. Although rare, paradichlorobenzene toxicity has been reported following ingestion and inhalation.[37,54] Inhalation toxicokinetics reveal that in humans there is rapid distribution to tissues, specifically adipose, and that the major route of elimination is urinary excretion followed by metabolism, not exhalation.[7,89] Workplace standards include the OSHA PEL, which is 450 mg/m³ (75 ppm) TWA, ACGIH TLV, which is 60 mg/m³ (10 ppm) TWA, and the ACGIH STEL, which is 675 mg/m³ (110 ppm); NIOSH IDLH is 150 ppm.[84]

■ CLINICAL MANIFESTATIONS

Inhalation of paradichlorobenzene may cause nausea and vomiting, headache, and mucous membrane irritation.[17,37] Only a single case report links acute ingestion of a moth repellent, purportedly containing paradichlorobenzene with hemolysis. The demothing agent itself was not confirmed to be paradichlorobenzene.[32]

Case reports associate chronic exposure to paradichlorobenzene with weight loss, leukoencephalopathy, a spectrum of neuropsychiatric effects including weakness, ataxia and hypotonia, pulmonary granulomatosis, dyspnea, hepatotoxicity, anemia, and fixed drug eruptions.[12,13,17,22,33,36,54,56,77,87]

Paradicholorobenze is classified by IARC as a Group 2B, Possibly Carcinogenic to Humans.

■ DIAGNOSTIC TESTING

Both paradichlorobenzene and its metabolite, 2,5-dichlorophenol, can be identified in blood and urine following exposure.[7] Identification of 2,5-dichlorophenol can confirm exposure to paradichlorobenzene. Quantifying the amount of paradichlorobenzene in the urine of workers may be useful for monitoring occupational exposures.[23] Qualitative or quantitative testing for paradichlorobenzene or its metabolites is not generally indicated when managing a patient with an acute overdose. Structural CNS abnormalities including toxic leukoencephalopathy may be noted on imaging studies.[6]

■ MANAGEMENT

Referral to a Healthcare Facility Most unintentional exposures to paradichlorobenzene do not cause life-threatening toxicity. Thus most asymptomatic patients with unintentional exposures can be managed as outpatients. Patients who should be evaluated in a healthcare facility include those with clinical signs or symptoms, suicidal patients, and patients who have sustained a large exposure.

Gastrointestinal Decontamination Gastrointestinal decontamination has not been studied in patients who ingest paradichlorobenzene. Most patients with unintentional exposures do not require gastrointestinal decontamination. Administration of activated charcoal, 1 g/kg, although not studied, is reasonable for patients with large, intentional ingestions.

TABLE 103–1. Moth Repellents: Laboratory Differentiation[1,48,50,62,88]

Characteristic	Camphor	Naphthalene	Paradichlorobenzene
Water solubility (g/L)	1.2	0.03	0.08
Buoyancy in water	Floats	Sinks	Sinks
Buoyancy in water saturated with table salt	Floats	Floats	Sinks
Radiopacity	Radiolucent	Faintly radiopaque	Densely radiopaque
Melting point	350.6°F (177°C)	176°F (80°C)	127.4°F (53°C)
Placement in covered test tube in 140°F (60°C) water bath	Does not melt	Does not melt	Melts
Boiling point	399.2°F (204°C)	424.4°F (218°C)	345.2°F (174°C)
Addition of chloroform	Untested	Blue color	No reaction
Place on copper wire in a flame	Untested	Flame is yellow-orange	Initially flame is yellow-orange then bright green
Solubility in turpentine	Untested	Fast	Slow.
FIGURE 103–1. Radiograph of mothballs. Paradichlorobenzene (➡) is densely radiopaque, whereas naphthalene (➡) is faintly radiopaque.

MOTH REPELLENT RECOGNITION

Healthcare providers occasionally must determine whether a mothball is made of naphthalene, paradichlorobenzene, or camphor since management and prognosis differ. When the container is unavailable, as is often the case, mothballs are difficult to distinguish based on appearance, odor, texture, or size. Most mothballs are white, crystalline, and have a noxious odor.[88] Camphor moth repellents are more oily than both naphthalene and paradichlorobenzene mothballs. If controls are available, moth repellents can often be differentiated based on their odor and texture.[1] Although most new paradichlorobenzene moth repellents are slightly larger than most new naphthalene moth repellents, all moth repellents shrink over time when exposed to air, making size an unreliable differentiating characteristic. Identifying a moth repellent as paradichlorobenzene can often result in outpatient management, saving both money and undue worry. The tests described in Table 103–1 and shown in Figure 103–1 might allow rapid identification of the component of an unknown moth repellent. When performing these tests it is most helpful to have camphor, naphthalene, and paradichlorobenzene controls available for comparison.

SUMMARY

Historically, the most common components of moth repellents are camphor, naphthalene, and paradichlorobenzene. In the United States, paradichlorobenzene has largely replaced both camphor and naphthalene. If an unknown moth repellent can be identified as paradichlorobenzene, limited toxicity is expected following an acute exposure. It is important for clinicians to understand how to use simple tests to identify the component of an unknown mothball. Because life-threatening camphor and naphthalene toxicity are still reported, it is important for clinicians to understand how to manage patients exposed to both of these xenobiotics.

CHAPTER 104
CAUSTICS

Jessica A. Fulton

Exposure to caustic agents may occur via the dermal, ocular, respiratory, and gastrointestinal routes with the most significant of these, by far, resulting from ingestion.

Morbidity and mortality from exposures to caustics is a worldwide problem. One study from India describing outcomes in patients following acid ingestions found that acute complications occurred in 39.1% of cases with death resulting in 12.2%.[131] In the United States, even though legislation limiting the concentration of caustic agents has existed since the early 20th century, exposures to both acids and alkalis continue to be significant. Data collected by the American Association of Poison Control Centers from 2002 through 2006 revealed 49,531 chemical acid exposures and 24,119 chemical alkali exposures. Of these, 7525 (15.2%) acid exposures and 4297 (17.8%) alkali exposures resulted in moderate to major outcomes and a total of 50 deaths occurred (see Chap. 135).

HISTORY AND EPIDEMIOLOGY

Caustics cause both histologic and clinical damage on contact with tissues. Table 104–1 lists common caustics and the commercial products that contain them. Many are available for home use, in both solid and liquid forms, with variations in viscosity, concentration, and pH.

As early as 1927, regulatory legislation in the United States governing the packaging of lye- and acid-containing products mandated that warning labels be placed on products containing these xenobiotics. In response to the recognition that caustic exposures were more frequent in children, in 1970 the Federal Hazardous Substances Act and Poison Prevention Packaging Act were passed, stating that all caustics with a concentration greater than 10% must be placed in child-resistant containers. By 1973, the household concentration for child-resistant packaging was lowered to 2%. In addition, the subsequent development of poison prevention education dramatically decreased the incidence of unintentional caustic injuries in children in the United States. The positive impact of both regulatory legislation and education is evident when observing the decrease of exposures in the United States compared to the number of exposures in developing nations that lack these policies.

Usually, children are unintentionally exposed to household products. Adults may be exposed to household or industrial products that result from occupational exposure or are suicide attempts.

Although less frequent, intentional exposures by adults are invariably more significant. One study noted that while children comprised 39% of admissions for caustic ingestions, adults comprised 81% of patients requiring treatment.[47] The severity of a caustic injury may not be immediately evident in patients who present shortly after exposure. Predicting which patients will require immediate interventions to prevent morbidity and mortality requires multiple clinical and laboratory parameters. This chapter reviews the pathophysiology and approach to patients with potentially serious exposures.

PATHOPHYSIOLOGY

A caustic is a xenobiotic that causes both functional and histologic damage on contact with tissue surfaces. Although there are many ways to categorize caustics, they are most typically classified as acids or alkalis. An acid is a proton donor[80] and causes significant injury, generally at a pH below 3. An alkali is a proton acceptor[80] and causes significant injury, generally at a pH above 11. Chapter 11 contains a more detailed discussion of the chemistry of acids and bases. The extent of injury is modulated by duration of contact; ability of the caustic to penetrate tissues; volume, pH, and concentration; the presence or absence of food in the stomach; and a property known as *titratable acid/alkaline reserve* (TAR). TAR quantifies the amount of neutralizing xenobiotic needed to bring the pH of a caustic to that of physiologic tissues. Neutralization of caustics takes place at the expense of the tissues, resulting in the release of thermal energy, producing burns. Generally, as the TAR of caustics increases, so does their ability to produce tissue damage.[6,11,30,44,50,95] Some xenobiotics, such as zinc chloride and phenol, have a high TAR and are capable of producing severe burns even though their pH is near physiologic.

◼ ALKALIS

Following exposure to an alkaline xenobiotic, dissociated hydroxide (OH⁻) ions penetrate tissue surfaces producing what is histologically described as liquefactive necrosis (see Figs. 104–1 and 104–2). This process includes protein dissolution, collagen destruction, fat saponification, cell membrane emulsification, transmural thrombosis, and cell death.[6,44] Animal studies following alkali exposure to the eye[49] demonstrate rapid formation of corneal epithelial defects with eventual deep penetration that may lead to perforation. Similarly, animal studies of the esophagus demonstrate that erythema and edema of the mucosa occur within seconds followed by an inflammatory reaction extending to the submucosa and muscular layers. The alkali, such as sodium hydroxide ("liquid lye"), then continues to penetrate until the OH⁻ concentration is sufficiently neutralized by the tissues.[6,63,67,116]

Although federal regulations have lowered the maximal available household concentration of many caustics, there are two industrial strength products that seem to be readily available and therefore warrant special mention: ammonium hydroxide and sodium hypochlorite. Ammonia (ammonium hydroxide) products are weak bases—partially dissociated in water—that can cause significant esophageal burns, depending on the concentration and volume ingested.[47,107,114,116] Household ammonium hydroxide ranges in concentration from 3% to 10%. Strictures have formed in patients who ingested 28% solutions.[89] Sodium hypochlorite is the major component in most industrial and household bleaches. Large case series and reports have found that severe injuries occur only in patients with large-volume ingestions of concentrated products[24] and that most other patients do well with supportive care.[17,47,113] A series of 393 patients with household bleach ingestions demonstrated no stricture formation.[66] Likewise, a canine model found that although vomiting was a common effect of bleach, no esophageal lesions were noted, and perforation occurred only following prolonged contact.[66]

Ingestion of button batteries were once considered a unique caustic exposure. Composed of metal salts and a variety of alkaline xenobiotics, such as sodium and potassium hydroxide, leakage of battery contents was a legitimate concern. In recent years, however, new techniques used in the production of button batteries that effectively prevent leakage have shifted the concern following their ingestion from caustic to foreign-body exposure. For a more in depth review of the management of button battery ingestion, the reader is referred to the previous editions of this text.

Household detergents, such as laundry powders and dishwasher detergents, contain silicates, carbonates, and phosphates, and have the

TABLE 104–1. Sources of Common Caustics

Xenobiotic	Applications
Acetic acid	Permanent wave neutralizers, photographic stop bath
Ammonia (ammonium hydroxide)	Toilet bowl cleaners, metal cleaners and polishes, hair dyes and tints, antirust products, jewelry cleaners, floor strippers, glass cleaners, wax removers
Benzalkonium chloride	Detergents
Boric acid	Roach powders, water softeners, germicide
Formaldehyde, formic acid	Deodorizing tablets, plastic menders, fumigant, embalming agent
Hydrochloric acid (muriatic acid)	Metal and toilet bowl cleaners
Hydrofluoric acid	Antirust products, glass etching, microchip etching
Iodine	Antiseptics
Mercuric chloride ($HgCl_2$)	Preservative
Methylethyl ketone peroxide	Industrial synthetic agent
Oxalic acid	Disinfectants, household bleach, metal polish, antirust products, furniture refinisher
Phenol (creosol, creosote)	Antiseptics, preservatives
Phosphoric acid	Toilet bowl cleaners
Phosphorus	Matches, fireworks, rodenticides, methamphetamine synthesis
Potassium permanganate	Illicit abortifacient, antiseptic solution
Selenious acid	Gun bluing agent
Sodium hydroxide	Detergents, paint removers, drain cleaners and openers, oven cleaners
Sodium borates, carbonates, phosphates, and silicates	Detergents, electric dishwasher preparations, water softeners
Sodium hypochlorite	Bleaches, cleansers
Sulfuric acid	Automobile batteries, drain cleaners
Zinc chloride	Soldering flux

FIGURE 104–1. Photograph demonstrating burns to the lips and tongue of a 20-year-old man following ingestion of sodium hydroxide. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program.)*

resulting in what is histologically referred to as *coagulation necrosis*. This process leads to edema, erythema, mucosal sloughing, ulceration, and necrosis of tissues. Dissociated anions of the acid (Cl^-, SO_4^{2-}, PO_4^{3-}) also act as reducing agents further injuring tissue.

Ophthalmic exposure to acids results in coagulative necrosis that tends to prevent further penetration into deeper layers of the eye.

In most series, following an acid ingestion, both the gastric and esophageal mucosa are equally affected.[25,56,131] On occasion, the esophagus may be spared damage while severe injury is noted in the stomach.[21,41,47,114] (See Fig. 104–3) This tends to be a rarer finding than concomitant injury to both stomach and esophagus, and is probably related to the rapid transit time of liquid acids through the upper gastrointestinal tract. Skip lesions from acid ingestions may be a function of viscosity and contact time.[47] Additionally, acid-induced pylorospasm may lead to gastric outlet obstruction, antral pooling, and perforation.[16,21,24,25,41,56,64,65,76,87,112,113,126,130] A cat model of the effects of sulfuric acid on the esophagus revealed a coagulative necrosis of the mucosa with whitish discoloration of the tissues and underlying smooth muscle spasm.[6] Other animal models demonstrate esophageal motility dysfunction and shortening.[110,111]

potential to induce caustic burns and strictures even when ingested unintentionally.[18,114] Airway compromise also may occur,[18,27,73] but the majority of exposures result in only minor toxicity.

Cationic detergents include quinolinium compounds, pyridinium compounds, and quaternary ammonium salts. These are frequently found in products for industrial use, as well as household fabric softeners. A concentration greater than 7.5% can cause severe burns.[71]

■ ACIDS

In contrast to alkaline exposures, following exposure to an acid, hydrogen (H^+) ions desiccate epithelial cells, producing an eschar and

FIGURE 104–3. Postmortem specimen from a man with an intentional ingestion of a mixture of phosphoric and hydrochloric acid that was used as a brick cleaner. Chapters 96 and 105 contain a more detailed discussion of mercury and hydrofluoric acid, respectively, each a uniquely caustic compound, and the management specific to their exposure.

■ CLASSIFICATION AND PROGRESSION OF CAUSTIC INJURY

Esophageal burns, secondary to both alkali and acid exposures, are classified based on endoscopic visualization that employs a grading system similar to that used with burns of the skin. Grade I burns are generally described as hyperemia or edema of the mucosa without evidence of ulcer formation.[20,62,130] Grade II burns include submucosal lesions, ulcerations, and exudates. Some authors further divide grade II lesions into grade IIa, noncircumferential lesions, and grade IIb, near-circumferential injuries.[17] Grade III burns are defined as deep ulcers and necrosis into the periesophageal tissues.[34,38,46,62]

Human case reports, postmortem studies, histologic inspection of surgical specimens, and experimental animal models reveal a consistent pattern of injury and repair following caustic injury.[1,32,39,74,82,104] As wound healing of gastrointestinal tract tissue occurs, neovascularization and fibroblast proliferation take place, laying down new collagen and replacing the damaged tissue with granulation tissue. A similar pattern of repair occurs following caustic injuries of the eye.

Burns of the esophagus may persist for up to 8 weeks as remodeling takes place, and may be followed by esophageal shortening.[124] If the initial injury penetrates deeply enough, there is progressive narrowing of the esophageal lumen. The dense scar formation presents clinically as a stricture.[22,44] Strictures can evolve over a period of weeks to months, leading to dysphagia and significant nutritional deficits.[100,105,124] Grade I burns carry no risk of stricture formation.[20,62,130] Grade II circumferential burns lead to stricture formation in approximately 75% of cases. Grade III burns invariably progress to stricture formation and are also at a high risk of perforation.[4,47,82]

CLINICAL PRESENTATION

The gastrointestinal tract, respiratory tract, eyes, and skin of a patient can be sites of caustic injury. Caustics may produce severe pain on contact with any of these tissues. By far, the majority of long-term morbidity and mortality from caustic exposure results from ingestion.

In general, patients who have ingested either alkaline or acid agents have similar initial presentations. Depending on the type, amount, and formulation (solid vs. liquid) of the substance, ingestion may lead to the development of severe pain of the lips, mouth, throat, chest, or abdomen. Oropharyngeal edema and burns may lead to drooling and rapid airway compromise. Symptoms of esophageal involvement include dysphagia and odynophagia, whereas epigastric pain and hematemesis may be symptoms of gastric involvement.

Respiratory tract damage may occur through direct inhalation or aspiration of vomitus leading to the clinical manifestations of hoarseness, stridor, and respiratory distress. Injury may result in epiglottitis, laryngeal edema and ulceration, pneumonitis, and impaired gas exchange. Patients may also be tachypneic or hyperpneic as a compensatory response to the metabolic acidosis with elevated lactate concentrations from necrotic tissue or hemodynamic compromise.

■ PREDICTORS OF INJURY

Many attempts have been made to define a method for clinical identification of patients with grade II or III esophageal injuries as these injuries typically progress to severe complications. Various studies, mostly involving alkaline xenobiotics, examine the predictive value of stridor, oropharyngeal burns, drooling, vomiting, and abdominal pain. A retrospective study of 378 children admitted for a caustic injury found that signs or symptoms could not be used to predict significant esophageal injury.[34] However, one prospective study of 79 children evaluated for vomiting, drooling, and stridor found that a combination of two or more of these signs were predictive of significant esophageal injury as visualized on endoscopy.[20] Another study found that drooling, buccal mucosal burns, and white blood cell count were significant independent predictors of severe gastrointestinal tract injury following acid ingestions.[45] Studies evaluating the presence or absence of oropharyngeal burns as a predictor of distal esophagogastric injury have repeatedly found this finding to be poorly predictive.[2,12,20,34,38,97,120] In one study esophageal injury was present 51.5% of the time in the absence of oropharyngeal lesions, and 22.2% of these were second- and third-degree burns.[97] A prospective study of alkali ingestions in both adults and children found that stridor was 100% specific for significant esophageal injury, but this was based on only three patients with this sign.[38]

Based on these findings, endoscopy, a standard diagnostic tool used in the management of caustic ingestions, is recommended in all patients with intentional ingestions. Endoscopy should also be performed in any patient with an unintentional ingestion in the presence of stridor, and in any patient with two or more of the following findings: pain, vomiting, and drooling.[20,99] Children with unintentional caustic ingestions who remain completely asymptomatic and tolerate liquids after a few hours of observation probably require no further medical care.

The abdominal examination is likewise an unreliable indicator of the severity of injury. The presence of abdominal pain suggests tissue injury, but the absence of pain or findings on abdominal examination do not preclude life-threatening gastrointestinal damage.[28,56,100,107,128] Esophageal perforations result in mediastinitis and are commonly associated with fever, dyspnea, chest pain, and subcutaneous emphysema of the neck and chest. Although indicative of viscus perforation, abdominal peritoneal signs are late findings.

In addition to the direct effects that occur with tissue contact, acids are systemically absorbed, resulting in damage to the spleen, liver, biliary tract, pancreas, and kidneys, as well as producing a metabolic acidosis, hemolysis, and, ultimately, death.[52,124]

Significant complications can occur at various stages of wound recovery. Most importantly, these include airway compromise, hemodynamic instability secondary to hemorrhage from vascular erosion or septic shock, perforations of the gastrointestinal tract with the development of mediastinitis or peritonitis, and other overwhelming infections

from bacteria residing in the oropharynx. A patient who survives acute injury with an acid or an alkali may also subsequently develop stricture formation, gastric atony, decreased acid secretion, pseudodiverticula, and gastric outlet obstruction.[13,37,64,112,130]

Other complications include dysmotility of the pharynx and esophagus,[23] formation of aorto- and tracheoesophageal fistulas, delayed massive hemorrhage from erosion into a great vessel, and pulmonary thrombosis.[10,47,62,88,107,109]

Those patients surviving a few weeks after a grade II or III injury may subsequently present with dysphagia and vomiting from stricture formation. One study suggested that involvement of the entire length of the esophagus as well as hematemesis and increased serum lactic dehydrogenase are useful indicators for the development of strictures.[90] Strictures may also present with esophageal motility disorders caused by impaired smooth muscle reactivity.[119] The early assessment and long-term prognosis may be better defined by manometric studies of the esophagus which provide precise information on the severity of the initial injury and aid in long-term prognosis.[36]

Although the risk of carcinoma after caustic ingestions is inadequately studied, three patients developed squamous cell cancer of the stomach following acid ingestion[26] and 15 patients developed squamous cell cancer of the esophagus following lye ingestion many years after their initial injuries.[59] Long-term survivors of moderate and severe injury of the esophagus have a risk of esophageal carcinoma that is estimated to be 1000 times higher than that of the general population and appears to present with a latency of up to 40 years.[5]

DIAGNOSTIC TESTING

■ LABORATORY

All patients with presumed serious caustic exposure should have an evaluation of serum pH, blood type and cross-match, hemoglobin, coagulation parameters, electrolytes, and urinalysis. Elevated prothrombin time (PT) and partial thromboplastin times,[128] as well as an arterial pH lower than 7.22,[14] are associated with severe caustic injury.

Absorption of nonionized acid from the stomach mucosa may result in acidemia. Following ingestion of hydrochloric acid, hydrogen and chloride ions (both of which are accounted for in the measurement of the anion gap) dissociate in the serum resulting in a hyperchloremic normal anion gap metabolic acidosis. Other acids, such as sulfuric acid, result in an elevated anion gap metabolic acidosis because the sulfate anion (SO_4^{2-}) is not measured in the calculation of the anion gap. Although alkalis are not absorbed systemically, necrosis of tissue may result in a metabolic acidosis with an elevated lactate concentration.

A gastric pH greater than 7.30 correlated retrospectively with severe alkaline injury. The prospective usefulness of this information is limited, as obtaining gastric secretions without direct visualization is dangerous. One prospective study in children also found an increase in uric acid and decreases in phosphate and alkaline phosphatase concentrations to be useful in predicting the presence of esophageal injuries.[92]

■ RADIOLOGY

Chest and abdominal radiographs are useful in the initial stages of assessment to detect gross signs of esophageal or gastric perforation. Signs of alimentary tract perforation that may be present on plain radiographs include pneumomediastinum, pneumoperitoneum, and pleural effusion. However, these studies have a limited sensitivity, and an absence of findings does not preclude perforation.[128] Free intraperitoneal air is best visualized on an upright chest radiograph. Occasionally, free air may only be visible on the lateral view.[125] In patients too ill to obtain an upright chest radiograph, an abdominal

radiograph obtained with the patient in a left-side-down position may reveal free intraperitoneal air adjacent to the liver. CT scanning is considerably more sensitive than radiography for detecting viscus perforation and should be obtained in patients with potentially serious caustic ingestions as soon as is feasible.[29,122]

A contrast esophagram is useful for defining the extent of esophageal injury (Fig. 104–4). Late after the ingestion, it can detect stricture formation. In patients for whom there is a high suspicion for esophageal perforation and in whom adequate visualization of the upper gastrointestinal tract by endoscopy is not possible (grade IIb circumferential burns or grade III burns), an enteric contrast study (esophagram and upper GI series) can be obtained 24 hours after the ingestion.[99,132] Extravasation of contrast outside of the gastrointestinal tract is diagnostic of perforation.[130] Water-soluble contrast should be used when perforation is suspected as it is less irritating to mediastinal and peritoneal tissues if extravasated.[32] However, barium contrast agents are more radiopaque than water-soluble agents and offer greater radiographic detail. Consequently, some authors recommend barium swallow if the water-soluble contrast study is nondiagnostic but demonstrates no leak.[42,70,115] In addition, if there is risk of aspiration, barium is preferred because water-soluble contrast material can cause a severe chemical pneumonitis. Significant necrosis with impending perforation may be suspected on enteric contrast studies when there is esophageal dilation, displacement of the pleural reflection, and widening of the pleuroesophageal line.[74] Enteric contrast studies may fail to detect perforation, and therefore must be interpreted within the context of the patient's clinical status.[10,19,43,56,74]

Although promising, a role for CT in caustic ingestions has not been formally investigated. CT has great sensitivity at detecting extraluminal air in the mediastinum or peritoneal cavity as a sign of perforation. In addition, CT can visualize the esophagus and stomach distal to severe caustic burns that cannot be safely seen using endoscopy or an esophagram. CT may therefore replace enteric contrast radiography for detection of perforation in the acute stage (within 24 hours) of a caustic ingestion. Other imaging modalities have been proposed. One study suggested a role for a technetium 99m-labeled sucralfate swallow for assessing esophageal injury after ingestion of caustic substances.[83] In another study, esophageal ultrasonography was helpful in determining the depth of injury.[86]

Another use of radiographic imaging is to noninvasively follow the patient after initial evaluation and stabilization. For example, contrast radiography is routinely used in the weeks or months following a caustic ingestion to detect esophageal narrowing representing stricture formation.[74,117] Chest CT may also be useful to determine the response of strictures to dilation procedures.[65]

■ ENDOSCOPY

Endoscopy should be performed within 12 hours and generally not later than 24 hours postingestion. Numerous case series demonstrate that the procedure is safe during this period. Early endoscopy serves multiple purposes in that it allows patients with minimal or no evidence of gastrointestinal injury to be discharged. It also offers a rapid means of obtaining diagnostic and prognostic information while shortening the period of time that patients forego nutritional support, permitting more precise treatment regimens.[17,22,24,28,44,47,69,81,99,107,108,121,125,130] The use of endoscopic assessment from the 2nd or 3rd day postingestion is discouraged and should be avoided between 5 days and 2 weeks postingestion as it is at this time that wound strength is least and the risk of perforation is greatest.

The choice of rigid versus flexible endoscopy is dependent on the comfort and experience of the endoscopist. The flexible endoscope has a smaller diameter but may require gentle insufflation of air to achieve or enhance visualization. A prospective evaluation of the role of fiberoptic endoscopy in the management of caustic ingestions

A

B
FIGURE 104–4. (A) Barium swallow several days after ingestion of liquid lye shows the esophagus to be atonic. There is poor coating of the esophagus, suggesting edema and intramural penetration. Note that the initial evaluation immediately following a caustic ingestion to assess the extent of injury is esophagoscopy, rather than a contrast esophagram. (B) Four months later, a repeat barium esophagram shows a severe stricture below the middle third of the esophagus. The barium barely passes the stricture, and the remainder of the esophagus is pencil thin. *(Images contributed by Emil J. Balthazar, MD, Professor of Radiology, New York University.)*

recommended the following guidelines: (1) direct visualization of the esophagus prior to advancing the instrument, (2) minimal insufflation of air, (3) passage into the stomach unless there is a severe (particularly circumferential) esophageal burn, and (4) avoidance of retroversion or retroflexion of the instrument within the esophagus. Provided that the patient is hemodynamically stable and endoscopy is indicated, every attempt should be made to visualize the esophagus, stomach, and duodenum after a caustic ingestion.

The absence of burns in the esophagus does not imply that severe necrosis and ulcerations do not exist in the stomach[81,114,120,130] and duodenum. In the case of termination of endoscopy because of grade IIb or grade III esophageal burns, barium studies,[99] CT scan, or consideration of surgical exploration should be undertaken to visualize remaining structures.

Endoscopy permits limited evaluation of gastrointestinal injury. For example, the endoscopist is able to appreciate only the mucosal surface of tissues, and not the serosal side. This is especially evident in stomach ulcerations, which may appear black and necrotic from a true burn through the layers of the stomach, or from the effect of stomach acid on the blood exposed from a shallow lesion. Some studies suggest that the use of endosonography during endoscopy may improve assessment of injury depth.[7,61] Often, though, only direct visualization of serosal and mucosal tissues with laparoscopy or laparotomy allows for definitive evaluation.

Most cases of perforation clearly linked to endoscopy have occurred when the endoscope was advanced through an esophagus with severe circumferential lesions—a violation of current endoscopic standards.[121] In addition, perforations are also more likely to occur when rigid instruments are used in children or in uncooperative patients. The use of the flexible endoscope has decreased the complications from endoscopic evaluation.[99] Some authors advocate the presence of a surgeon during endoscopy to assist in the assessment for potential surgical intervention.[105]

MANAGEMENT

■ ACUTE MANAGEMENT

As in the case of any patient presenting with a toxicologic emergency, the healthcare provider must adhere to universal precautions. Initial stabilization should include airway inspection and protection, basic resuscitation principles, and decontamination. Examination of the oropharynx for signs of injury, drooling, and vomitus, as well as careful auscultation of the neck and chest for stridor, may reveal signs of airway edema that should prompt immediate airway protection. Careful and constant attention to signs and symptoms of respiratory distress and airway edema, such as a change in voice, are essential and should prompt intubation as airway edema may rapidly progress over minutes to hours.

If airway involvement is significant enough to warrant intubation, it is best to mobilize a team of the most skilled physicians early in case of unforeseen complications. A delay in prophylactic airway protection may make subsequent attempts at intubation or bag-valve-mask

ventilation difficult or impossible. Direct visual inspection of the vocal cords with a fiberoptic laryngoscope may also reveal signs of impending airway compromise. Patients necessitating intubation are best served by direct visualization of the airway either via direct laryngoscopy or fiberoptic endoscope, as perforation of edematous tissues of the pharynx and larynx is a grave complication that may occur during blind nasotracheal intubation attempts. Neuromuscular blockers should be avoided for induction of intubation as airway edema and bleeding may distort the ability to successfully ventilate via bag-valve-mask should intubation be unsuccessful.

Nonsurgical airway placement is recommended whenever possible as both cricothyrotomy and tracheostomy may interfere with the surgical field if esophageal repair is required.[128] Some patients with significant ingestions, however, may require emergent surgical airway intervention. The decision to perform the technique of a surgical airway is dependent on the status of the patient, the ability to orotracheally or nasotracheally intubate via a fiberoptic endoscope, and the comfort of the physician performing the procedure.

Following control of the airway, large-bore intravenous access should be secured and volume resuscitation initiated. Although not studied, most clinicians agree that patients with signs of caustic-induced airway edema benefit from dexamethasone 10 mg IV in adults and 0.6 mg/kg up to a total dose of 10 mg in children. Both acid and alkali ingestions cause "third spacing" of intravascular fluid to the interstitial space, which can result in hypotension. Empiric rehydration with clinical assessment of central venous pressures should be used to guide individual fluid requirements.

Serial physical examinations and constant monitoring of the vital signs and urine output may provide information on the severity of the exposure and the progression in clinical status.

■ DECONTAMINATION, DILUTION, AND NEUTRALIZATION

Decontamination should begin with careful, copious irrigation of the patient's skin and eyes when indicated to remove any residual caustic and to prevent contamination of other patients and staff.

Gastrointestinal decontamination is usually limited in patients with a caustic ingestion. Induced emesis is contraindicated, as it may cause reintroduction of the caustic to the upper gastrointestinal tract and airway. Activated charcoal is also contraindicated, as it will interfere with tissue evaluation by endoscopy and preclude a subsequent management plan. Additionally, most caustics are not adsorbed to activated charcoal.

Exceptions, such as cationic detergents, that do bind well to activated charcoal[71] have not been evaluated with a large series. For this reason, therapy with activated charcoal following any caustic ingestion cannot be recommended. Gastric emptying via cautious placement of a narrow nasogastric tube with gentle suction may be attempted to remove the remaining acid in the stomach only in patients with large life-threatening intentional ingestions of acid who present within 30 minutes.[95] Although this technique has never been studied and carries the risk of perforation, the outcome for these patients is often grave and options for treatment are limited. Therefore, preventing absorption of some portion of the ingested acid may have potential benefit in reducing systemic toxicity. Although the procedure has the potential to induce injury, a risk-to-benefit analysis favors gastric emptying following a presumed lethal ingestion.

In contrast, gastric emptying should be avoided with alkaline and unknown caustic ingestions as blind passage of a nasogastric tube carries the risk of perforation of damaged tissues; a risk that outweighs the benefit.

Exceptions to the general rules of gastrointestinal decontamination of caustic agents exist in the management of zinc chloride ($ZnCl_2$)

and mercuric chloride ($HgCl_2$). Both are caustics with severe systemic toxicity.[15,77,78,96] Ingestion of these xenobiotics causes life-threatening illness from cationic metal exposure. The local caustic effects, though of great concern, are less consequential than the manifestations of systemic absorption. Therefore, prevention of systemic absorption should be addressed primarily, followed by the direct assessment and management of the local effects of these xenobiotics. Initial management to prevent systemic absorption includes aggressive decontamination with gentle nasogastric tube aspiration and administration of activated charcoal. In vitro data exist to suggest adequate charcoal adsorption of Hg^{2+} ion.[3]

The use of dilutional therapy has been examined using in vitro, ex vivo, and in vivo models in an attempt to assess its efficacy in caustic ingestions. An early in vitro model demonstrated a dramatic increase in temperature when either water or milk was added to crystal Drano.[106] Another in vitro model found less consequential increases in temperature despite large volumes of diluent. Results of both studies suggested that dilutional therapy was of limited benefit.[75] Dilutional therapy was also attended by an increase in temperature in an ex vivo study of harvested rat esophagi that examined the histopathologic effects of saline dilution after an alkali injury. Additionally, the usefulness of dilution appeared to be inversely related to the length of time from exposure, with minimal efficacy noted in as little as 30 minutes.[52,53] In contrast, an in vivo canine model of alkaline injury demonstrated that water dilution did not cause an increase in either temperature or intraluminal pressures.[55]

The extrapolation of these variable results to humans with caustic ingestions is limited, and suggests that histologic damage can only be attenuated by milk or water when administered within the first seconds to minutes following ingestion.[6,52,53,54,55,67,116] For solid, as opposed to liquid, substances (eg, crystal lye), there may be some value for delayed dilutional therapy, as tissue contact time is increased with solids and their concentration is usually 100% over a small surface area. Milk may be the best diluent to attenuate the heat generated by a caustic.[114]

Caution should be used in advising patients or family members about the use of dilutional agents. A child who refuses to swallow or take oral liquids should never be forced to do so. In general, dilutional therapy should be limited to patients within the first few minutes after ingestion who have no airway compromise, who are not complaining of significant pharyngeal, chest, or abdominal pain, who are not vomiting, and who are alert. Dilutional therapy should be avoided in patients with nausea, drooling, stridor, or abdominal distension as it may stimulate vomiting and result in reintroduction of the caustic into the upper gastrointestinal tract.[106]

Attempts at neutralization of ingested caustics should likewise be avoided. This technique has the potential to worsen tissue damage by forming gas and generating an exothermic reaction. In vitro and ex vivo models demonstrate that neutralization of caustics generates heat, requires a large volume to attain physiologic pH, and may have limited usefulness in preventing histologic damage if delayed beyond the first several minutes following caustic exposure.[51,76,106] In one in vivo canine model, orange juice was used to neutralize sodium hydroxide–induced gastric injury and demonstrated no change in temperature or intraluminal pressure.[55] Despite this study, neutralization is not recommended at this time as there are no other data demonstrating that clinical outcome is improved.

■ SURGICAL MANAGEMENT

The decision to perform surgery in patients with caustic ingestions is obvious in the presence of either endoscopic or diagnostic imaging evidence of perforation,[128] severe abdominal rigidity, or persistent hypotension. Hypotension is a grave finding and often indicates perforation or significant blood loss. Additionally, elevated prothrombin time (PT) and partial thromboplastin times,[128] as well as an arterial pH lower than 7.22,[14] are associated with severe caustic injury.

Many patients will not have an obvious indication for surgical intervention despite impending perforation, necrosis, sepsis, or delayed hemorrhage. Although more challenging to diagnose, all of these sequelae are potentially avoidable if surgery is performed early[91] as morbidity and mortality increase in patients whose surgery is delayed.[28,56,58,103,107] For this reason, some surgeons advocate surgery for all patients with grades II and III esophageal burns identified on endoscopy.[28,81] This aggressive approach allows for direct inspection of serosal surfaces and an opportunity for early surgical repair.

Multiple studies have attempted to codify the signs and symptoms necessary or sufficient to rapidly identify patients who would benefit from surgery, but who lack clear clinical indications. Several retrospective and prospective series of caustic ingestions found that patients with large ingestions (>150 mL), shock, acidemia, or coagulation disorders tended to have severe findings on surgical exploration. These studies also reinforce that the abdominal examination was frequently unreliable in predicting the need for surgery.[107,128,131] It should be noted, again, that patients with severe acid injuries may lack abdominal pain, abdominal tenderness, and have positive findings on diagnostic imaging.[25,56,131] One author used a stepwise approach of bronchoscopy, endoscopy, and abdominal ultrasonography to provide additional information regarding extent of injury prior to surgery. Respiratory distress, ascites, pleural fluid, and a serum pH less than 7.2 were used as indications for surgery.[128] A history of a large-volume caustic ingestion (between 40 and 200 mL) should also prompt consideration of early surgical intervention as delay is associated with increased mortality.[25,56,128]

Surgical intervention may include laparotomy for tissue visualization, resection, and repair of perforations. Laparoscopy may also be used, although it may not allow inspection of the posterior aspect of the stomach.

■ SUBACUTE MANAGEMENT

The extent of tissue injury dictates the subsequent management and disposition of patients with caustic ingestions.

Grade I Esophageal Injuries Patients with isolated grade I injuries of the esophagus do not develop strictures and are not at increased risk of carcinoma. Their diet can be resumed as tolerated. No further therapy is required. These patients can be discharged from the hospital as long as they are able to eat and drink and their psychiatric status is stable.

Grade IIa Esophageal Injuries If endoscopy reveals grade IIa lesions of the esophagus and sparing of the stomach, a soft diet can be resumed as tolerated, or a nasogastric tube can be passed under direct visualization. If oral intake is contraindicated because of the risk of perforation, feeding via gastrostomy, jejunostomy, or total parenteral nutrition should be instituted as rapidly as possible. Providing interim enteral support is imperative as metabolic demands are increased in any patient with a significant burn.

Grades IIb and III Esophageal Injuries Patients with grades IIb and III lesions must be followed for the complications of perforation, infection, and stricture development. Strictures are a debilitating complication of both acid and alkaline ingestions that can evolve over a period of weeks or months. They form as a result of the natural process by which the body repairs injured tissue through the production of collagen with resultant scar formation. Although steroid therapy is theorized to arrest the process of inflammatory repair and potentially prevent stricture formation, there is some evidence that grade III burns, in particular, will progress to stricture formation regardless of therapy.[4,47,82,121] In addition to stricture formation, patients with grade III burns are also at high risk for other complications, including fistula formation, infection, and perforation with associated mediastinitis and peritonitis. The use of corticosteroids in the management of grade III burns may mask infection and make the friable, necrotic

esophageal tissue more prone to perforation.[94] For these reasons, steroid therapy is not a recommended therapy for grade III esophageal burns. When required in these patients for other indications such as caustic-induced airway inflammation, short-term steroids should be administered in conjunction with antibiotics.

Currently, some controversy exists regarding the use of steroid therapy in the management of grade IIb circumferential esophageal burns. A meta-analysis of studies completed from 1956–1991, with a total of 361 patients, evaluated the efficacy of corticosteroid therapy and found that in patients with grades II and III esophageal burns, strictures formed in 19% of the corticosteroid-treated group and in 41% of the untreated group.[57] The usefulness of the results of this study, however, are limited as no distinction was made between grades II and III burns. Another meta-analysis of studies from 1991 to 2003, with a total of 211 patients, was unable to find a benefit in treating patients with steroids with grades II and III esophageal burns.[94] However, no distinction was made between grades II and III burns. A systematic pooled analysis of studies from 1956 to 2006, with a total of 328 patients, attempted to reevaluate the usefulness of steroid therapy in grade II esophageal burns. Although methodologically limited, this study found no benefit in treating patients with steroids with grade II esophageal burns. A major limitation to the clinical usefulness of this study is that no distinction was made between grades IIa and IIb burns.[31] In addition, a multitude of case series also failed to clearly differentiate between grades IIa, IIb, and III lesions, making clinical application of their results difficult.[4,19,82,85,107,121]

Two prospective studies attempted to evaluate the efficacy of steroid therapy for caustic injuries to the esophagus. Both of these studies failed to show a benefit of steroid therapy and one even suggested harm.[3,4,60] It is imperative that the clinician understands that neither study clearly differentiates between grades IIb and III lesions.

Adequate human data demonstrating the efficacy of corticosteroids with or without antibiotics in the treatment of grade IIb circumferential lesions have yet to be generated. Because of the inherent risks involved in this therapy and the paucity of data supporting their use, steroid therapy in the management of grade IIb esophageal burns can no longer be routinely recommended.

No major outcome studies have investigated the use of antibiotics alone as prophylactic treatment for stricture prevention, but most clinicians would agree that it is probably best to reserve antibiotics for an identified source of infection.

A variety of other management strategies have been used in an attempt to prevent strictures and esophageal obstruction. In both animal models[102] and in human case series,[48,84,101] intraluminal stents and nasogastric tubes[84,125] made of silicone rubber tubing can successfully maintain the patency of the esophageal lumen. For nutritional support, the stents are usually attached to a feeding tube secured in the nasopharynx through which the patient can receive feedings without interfering with esophageal repair. These tubes are left in place for 3 weeks[101,102] and are often used with concomitant corticosteroid and antibiotic therapy. In animal models, the use of a stent for 3 weeks is superior in maintaining esophageal patency when compared to corticosteroids and antibiotics alone.[102]

Potential disadvantages of esophageal stents include mechanical trauma at the site and increased reflux, both of which may inhibit healing.[111] A feline model of esophageal exposure to sodium hydroxide used stents but reported deaths from aspiration and mediastinitis.[102] One series of 251 humans exposed to caustics who were managed with silicone rubber stents found that the procedure was successful in preventing stricture formation.[9]

Additionally, multiple therapies have been studied in various animal models in an attempt to identify agents that either inhibit synthesis or stimulate breakdown of collagen and thereby prevent stricture formation. β-Amino propionitrile (BAPN), penicillamine, *N*-acetylcysteine

(NAC), halofuginone, vitamin E, and colchicine are some of these agents.[118] BAPN was examined in a canine model in conjunction with dilation, and there was some suggestion that it was useful.[72] Both penicillamine and NAC were of some benefit in preventing strictures in rats and rabbits.[35,68,118] Halofuginone, a specific inhibitor of collagen type I synthesis, and vitamin E, a known antioxidant, significantly reduced esophageal stricture[93] and collagen synthesis,[40] respectively, in rats. In addition, epidermal growth factor and interferon-γ also decreased collagen synthesis and stenosis following sodium hydroxide burns in rats.[8] Colchicine, which decreases collagen synthesis, was found to delay wound healing and was associated with stricture formation in rabbits with sodium hydroxide-induced esophageal burns. Sphingosylphosphorylcholine, an intracellular second messenger, was shown to be effective in preventing caustic esophageal strictures via diminished collagen deposition in rats.[129] As none of these treatments have been adequately studied in humans, they cannot currently be recommended in the routine management of caustic ingestions.

■ CHRONIC TREATMENT OF STRICTURES

Commonly, the management of esophageal strictures includes early endoscopic dilation for which a variety of types of dilators are available. Contrast CT can be used to determine maximal esophageal wall thickness, which can then be used to predict response,[65] as well as the number of sessions required to achieve adequate dilation. Multiple dilations are often necessary. In one study, patients with a maximal esophageal wall thickness of 9 mm or greater required more than seven sessions to achieve adequate dilation. This was significantly higher than in patients with a lesser maximal wall thickness.[65] Measurement of maximal wall thickness may be also be useful in determining long-term followup, type of nutritional support, and the potential need for surgical repair as an alternative to dilations. It may also provide an indication for those who should undergo dilations under fluoroscopy to limit the risk of perforation.

The risk of perforation from esophageal dilation is decreased if the initial procedure is delayed beyond 4 weeks postingestion, when healing, remodeling, and potential stricture formation in the esophagus have already taken place. Several series report perforation secondary to esophageal dilation.[47,62,65,98,121] Following perforation, patients may complain of dyspnea or chest pain with associated subcutaneous emphysema or pneumomediastinum. Diagnostic imaging may identify the perforation and provide information for emergent surgical repair if the diagnosis is unclear.

Patients with stricture formation require long-term endoscopic followup for the presence of neoplastic changes of the esophagus that may occur with a delay of several decades.[5]

■ MANAGEMENT OF OPHTHALMIC EXPOSURES

Ophthalmic exposures frequently occur from splash injuries, and, more recently, from the alkaline byproducts of sodium azide released in automobile air bag deployment and rupture.[123] The mainstay of therapy for these patients is immediate irrigation of the eye for a minimum of 15 minutes with 0.9% sodium chloride, lactated Ringer solution, or tap water, if it is the only therapy immediately available. Several liters of irrigation fluid are recommended. The normal pH of ophthalmic secretions is close to 7.40. This can be tested colorimetrically by using a urine dipstick, which can test a range of pH from 5 to 9 using a color chart.[79] Litmus paper can be used in the same fashion. Another option is Nitrazine paper, which changes color from yellow to dark blue at a pH above 6.5,[33] and which may be useful in acid exposures. These different test strips can be applied to the ophthalmic secretions to test the baseline pH, and followed with intermittent evaluations after 15 minutes to determine the adequacy of irrigation. If these xenobiotics are not readily available, irrigation should not be delayed, as the depth of penetration of the caustic agent will determine outcome. Anterior chamber irrigation may be required; and should be performed emergently by an ophthalmologist. A thorough eye examination should be completed and followup should be arranged. Chapter 19 contains a more detailed description of the evaluation and management of toxicologic emergencies of the eye.

SUMMARY

Assessing the severity of injuries in patients with caustic exposures can be clinically challenging. For all patients with caustic exposures, the primary consideration is adherence to universal precautions by healthcare professionals in an effort to prevent further exposures. For patients with ingestions, this effort should be immediately followed by airway assessment and stabilization. Basic decontamination, and consideration of multiple bedside, laboratory, and diagnostic imaging factors to decide how best to inspect the affected tissues should then be considered. Ideally, early in the course of management of a caustic ingestion, gastroenterologists and surgeons are involved in the care of the patient, so that any surgical intervention deemed necessary can be performed promptly. Exposures to the skin and eyes require rapid decontamination with simple irrigants such as 0.9% sodium chloride solution.

Household and industrial exposures to caustics constitute a potentially life-threatening global health concern. Public health efforts, such as the successful implementation of child-proofing caustic substance containers and limiting the concentration in household items in the United States should be encouraged in developing nations as well.

CHAPTER 105
HYDROFLUORIC ACID AND FLUORIDES

Mark Su

Hydrofluoric acid (HF) has multiple applications and is widely used throughout industry, especially in organofluorine chemistry. Organofluorine compounds (eg, Teflon, freon, etc.) are synthesized using HF as the source of fluorine. Since this widespread use of HF invariably leads to human exposures, it is essential for clinicians to recognize that HF and fluoride-containing compounds are protoplasmic poisons that may result in deleterious systemic effects.

HISTORY AND EPIDEMIOLOGY

Hydrofluoric acid has been known for centuries for its ability to dissolve silica. The Nuremberg artist Schwanhard is given credit for the first attempt (in 1670) to use HF vapors to etch glass.[42] Since then, HF has been developed for multiple uses in addition to glass etching, such as brick cleaning, etching microchips in the semiconductor industry, electroplating, leather tanning, rust removal, and the cleaning of porcelain.[23,42] From 2005 to 2007, the American Association of Poison Control Centers (AAPCC) reported more than 2500 exposures to HF and 5 deaths. Hands are by far the most common exposure location. Exposures to HF are often unintentional and they can be an occupationally related hazard. The actual number of work-related poisonings from HF appears difficult to quantitate because of limitations in ICD (*International Classification of Diseases*) medical coding and lack of notification of regional poison centers by worksites.[7]

Hydrofluoric acid is also the most common cause of fluoride poisoning, although other forms of fluoride, including sodium fluoride (NaF) and ammonium bifluoride (NH_4HF_2), may also produce significant toxicity. Historically, sodium fluoride has been used as an insecticide, rodenticide, antihelminthic agent in swine, and a delousing powder for poultry and cattle. Ammonium bifluoride is mainly used in industrial inorganic chemistry, especially in the processing of alloys and in glass etching. Other fluoride salts are widely used in, for example, the steel industry, drinking water, toothpaste additives, electroplating, lumber treatment, and the glass and enamel industries.

The widespread use of HF and fluoride-containing compounds has resulted in significant toxicity. In 1988, an oil refinery in Texas released a cloud of hydrogen fluoride gas that resulted in 36 people requiring hospital treatment.[42] The petroleum industry has since been plagued by similar HF incidents.[95] NaF was responsible for the poisoning of 263 people and 47 fatalities when it was mistaken for powdered milk and unintentionally combined with scrambled eggs.[52] These and other forms of fluoride salts can be converted to HF in vivo after ingestion. Consequently, many inorganic fluoride compounds can result in significant fluoride toxicity, especially when large exposures occur.

CHEMISTRY

Hydrofluoric acid has unique properties that can cause life-threatening complications following seemingly trivial exposure. Anhydrous HF is highly concentrated (>70%) and used almost exclusively for industrial purposes. The aqueous form of HF, which generally ranges in concentrations from 3% to 40%, is commonly used in both industrial and household products.

Hydrofluoric acid is synthesized as the product of gaseous sulfuric acid and calcium fluoride, which is subsequently cooled to a liquid.[53] Aqueous HF is a weak acid, with a pK_a of 3.5; as such, it is approximately 1000 times less dissociated than equimolar hydrochloric acid, a strong acid.

Sodium fluoride is commonly synthesized by the reaction of sodium hydroxide (NaOH) with HF, with subsequent purification by recrystallization. NaF is highly soluble and readily dissociates.[2]

To synthesize NH_4HF_2 ammonium fluoride (NH_4F) is first formed by the reaction of ammonium hydroxide (NH_4OH) and HF. Ammonium fluoride is then converted to bifluoride by dehydrating the aqueous solution.

Fluorine is the most electronegative element in the Periodic Table due to its relatively large number of protons in the nucleus compared to its molecular size, and the minimal amount of screening or shielding by inner electrons. Other halides also possess electronegative properties but to a lesser extent. Consequently, the corresponding anion of fluorine, the fluoride ion (F^-), is a weak base because of it is unwillingness to donate its electrons.

PATHOPHYSIOLOGY

Exposures to HF occur via dermal, ocular, inhalation, and oral routes with one reported case of toxicity from an HF enema.[15] A permeability coefficient of 1.4×10^{-4} cm/sec allows HF to penetrate deeply into tissues prior to dissociating into hydrogen ions and highly electronegative fluoride ions.[29] These fluoride ions avidly bind to extracellular and intracellular stores of calcium and magnesium, depleting them, and ultimately leading to cellular dysfunction and cell death.[8,51,60] The alteration in local calcium homeostasis causes neuroexcitation and accounts for the development of neuropathic pain. Furthermore, ischemia related to calcium dysregulation–mediated localized vasospasm is likely an additional contributory factor to the development of pain.[37,88]

Formation of insoluble calcium fluoride (CaF_2) is proposed as the etiology for both the precipitous fall in serum calcium concentration and the severe pain associated with tissue toxicity. There are several theories regarding the actual fate of calcium and fluoride ions in tissues. In vitro evidence suggests that fluorapatite is formed in the presence of phosphate and hydroxyapatite. This may be a more likely pathway for disposition of the fluoride ion.[8] Fluorapatite, like calcium fluoride, is insoluble and its formation may contribute to the clinical findings that occur with HF exposures.

Fluoride also binds magnesium and manganese and there is in vitro evidence that this interferes with many enzyme systems. In the anhydrous form, the high concentration of hydrogen ions in HF also produces a caustic burn similar to that caused by strong acids (see Chap. 104).

The minimal lethal dose in humans is approximated to be 1 mg/kg of fluoride ion.[42]

CLINICAL MANIFESTATIONS

■ LOCAL EFFECTS

Skin The extent of tissue injury following dermal exposures is determined by the volume, concentration, and contact time with the tissues. Following dermal exposure, concentration of HF is inversely related to the rapidity of onset of the excruciating pain at the contact site.[27,53,87] Concentrations of greater than 50% cause immediate pain with

FIGURE 105–1. Severe injury to the fingers resulted from exposure to hydrofluoric acid. Note the arterial line in place for administration of calcium. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program.)*

visible tissue damage.[81] Exposure to household rust-removal products (6% and 12% HF) is often associated with a delay of several hours before pain develops.[27,82,92,93] The initial site of injury may also appear relatively benign despite significant subjective complaints of pain. Over time, the tissue may become hyperemic, with subsequent blanching and coagulative necrosis. As calcium complexes precipitate, a white discoloration of the affected area may appear.[70] (See Fig 105–1) Ulcerations may form at a rate dependent on the concentration and duration of contact.[23,43,54] If more than 2% of the body surface area is burned with high-concentration HF, life-threatening systemic toxicity should be expected.[16,67,69,81,87] Small body surface area exposures to low concentrations typically do not result in life-threatening systemic toxicity, although fatalities have resulted with dermal exposures to concentrated HF covering less than 5% body surface area.[86]

Pulmonary Patients with inhalational exposures can present with a variety of signs and symptoms depending on the HF concentration and exposure time. Thirteen oil refinery workers exposed to a low-concentration HF mist experienced minor upper respiratory tract irritation.[49] In contrast, in a mass inhalational exposure to HF, throat burning and shortness of breath were among the more common chief complaints.[95] Some of these patients had altered pulmonary function tests and hypoxemia, and 16% developed hypocalcemia. Stridor, wheezing, rhonchi, and erythema and ulcers of the upper respiratory tract were described. Eye pain was also noted, reinforcing the fact that ophthalmic injury typically accompanies inhalational or dermal exposures.[49,58,76,95]

Gastrointestinal Intentional ingestion of concentrated HF (or other fluoride salts such as NaF) causes significant gastritis yet often spares the remainder of the gastrointestinal tract. Patients promptly develop vomiting and abdominal pain. Although systemic absorption is rapid and almost invariably fatal, there is at least one report of a patient with an ingestion of a low concentration of HF who suffered multiple episodes of ventricular fibrillation and was successfully resuscitated.[84] Following HF ingestion patients may present with an altered mental status, airway compromise, and dysrhythmias.[10,52,55,84]

Ophthalmic Hydrofluoric acid appears to result in more extensive injury to the eye than most other acids.[61] Ophthalmic exposures from liquid splashes or hydrogen fluoride gas denude the corneal and conjunctival epithelium, and lead to stromal corneal edema, conjunctival ischemia, sloughing, and chemosis.[42] Fluoride ions can penetrate deeply

to affect the anterior chamber structures.[42] The effects are usually noted within one day.[42] Other possible findings include corneal revascularization, recurrent epithelial erosions, and, sometimes, keratoconjunctivitis sicca (dry eye) developing as a long-term complication.[4,61,77]

■ SYSTEMIC EFFECTS

Significant systemic toxicity can occur via any route of exposure because of the ability of HF to penetrate tissues. The potential for systemic toxicity is an important consideration in management as patients should be rapidly decontaminated and treated.[9,13,28,80,81,89,90] Fatal exposures to HF by any route share the similar features of hypocalcemia, hypomagnesemia, and, in many cases, hyperkalemia as preterminal events.[2,10,20,28,48,53,55,62,63,87] In some circumstances, the hypocalcemia severely disrupts the coagulation cascade, resulting in the inability of blood clotting, even on postmortem examination.[55,65,66]

Fatalities from HF may occur as a result of either sudden-onset myocardial conduction failure or ventricular fibrillation. Although the evidence regarding the mechanism of myocardial irritability is inconclusive, electrolyte disturbances that lead to ventricular dysrhythmias and fibrillation are thought to be the primary cause of death in patients with severe systemic fluoride poisoning.[16,67,81,87,98] Some postmortem cases reveal significant structural myocardial injury.[65] However, these findings are inconsistently encountered in humans and in animal cardiac arrest models that fail to demonstrate any histologic abnormalities of the myocardium.[22,59]

Although systemic fluoride toxicity results in systemic hypocalcemia, by mechanisms not fully elucidated, fluoride may induce intracellular hypercalcemia leading to an efflux of potassium ions into the extracellular space.[22,51,65] One in vitro study performed with human erythrocytes suggests that fluoride inhibition of Na^+-K^+ ATPase and Na^+-Ca^{2+} exchange leads to intracellular hypercalcemia.[64] The subsequent hyperkalemia may alter the automaticity and resting potential of the heart, leading to fatal dysrhythmias.[63] Dogs treated with quinidine, a potassium efflux blocker, are protected from lethal doses of intravenous sodium fluoride.[22] Likewise, amiodarone, which also possesses potassium efflux blockade properties, has demonstrable efficacy in both in vitro and in vivo models of fluoride toxicity.[18,85] However, efficacy in humans has not been studied or documented. Furthermore, the mechanism of toxicity may be much more complicated.[100] A child with systemic fluoride toxicity, who was appropriately repleted with calcium, and who had normal electrolytes still experienced nonfatal ventricular fibrillation.[9,100] Perhaps this is because serum potassium, calcium, and magnesium concentrations only partly represent tissue concentrations.[8,9,22,62,63] Furthermore, HF may directly impair myocardial function. Rabbits exposed to topical HF over 2% of their total body surface area developed focal necrosis of myocardial fibers, as well as significant elevations in cardiac enzymes that persisted for almost 5 days after injury.[99]

Assessing Severity of Clinical Exposures. Historical and clinical features of an exposure will determine which HF exposures are life-threatening. All oral and inhalational exposures should be considered potentially fatal, as should burns of the face and neck, regardless of HF concentration. Inhalational exposure should be assumed for all patients with skin burns of greater than 5% body surface area, any exposure to HF concentrations greater than 50%, and head and neck burns.[41] Patients presenting with altered mental status are critically ill and necessitate rapid therapy.

Hydrofluoric acid concentrations of greater than 20% have potential for significant toxicity in a patient even if only a small surface area has been exposed.[57] As a general rule, patients who experience severe pain within minutes of contact are most likely exposed to a very high concentration of HF and their condition can rapidly deteriorate. An

otherwise well-appearing patient may have a precipitous demise without any clinical manifestations of hypocalcemia.

DIAGNOSTIC TESTING

Diagnostic testing for systemic fluoride poisoning is currently based on monitoring of serum electrolytes. Ionized calcium should be serially monitored along with magnesium and potassium.[28] Additional information may be obtained from a venous or arterial blood gas analysis. As systemic toxicity progresses, there is potential for development of metabolic acidosis.[8] Serum fluoride concentrations may be assessed but the results will not return in a clinically relevant timeframe. Although a serum fluoride concentration of 0.3 mg/dL has been reported as fatal, one patient survived with a serum fluoride concentration of 1.4 mg/dL.[87,100]

Electrocardiographic findings of both hypocalcemia (prolonged QT interval) and hyperkalemia (peaked T waves) may be reliable indicators of toxicity.[2,13,28,31,36,66,87] In fact, ECG findings of peaked T waves from hyperkalemia have preceded the onset of ventricular dysrhythmias, thus potentially serving as a marker of severe fluoride toxicity.[9,62]

MANAGEMENT

■ GENERAL

For patients with more than localized exposure to low concentration HF or exposures to high concentration HF, the mainstay of management is to prevent or limit systemic absorption, assess for systemic toxicity, and rapidly correct any electrolyte imbalances. Intravenous access should be obtained. An ECG should be examined for signs of hypocalcemia, hypomagnesemia, and hyperkalemia. The patient should be attached to continuous cardiac monitoring and have a rapid assessment of serum electrolyte concentrations. A Foley catheter should be placed as needed to follow urine output.

Rapid airway assessment and protection should occur early in patients with inhalation or ingestion, respiratory distress, ingestion with vomiting, or burns significant enough to cause a change in mental status or voice.

For patients with less-significant dermal exposures, recent studies have focused on alternatives to irrigation with water or saline as topical decontamination techniques. The compound "hexafluorine" has been promoted for dermal and ocular decontamination of HF splashes.[56,83] Hexafluorine is a proprietary name and not representative of a conventional chemical compound. Despite anecdotal supportive data, in a controlled and blinded experimental study hexafluorine treatment was less effective than irrigation with water followed by the application of topical calcium.[35] In a followup animal study, water irrigation was as effective as hexafluorine in preventing systemic toxicity from HF.[38] At this time, until further objective data are available, it is premature to recommend the routine use of hexafluorine for initial decontamination of HF exposures.

An iodine-containing preparation specifically formulated by the study authors was studied for HF-induced burns in guinea pigs.[96] Iodine has demonstrated protective effects against burns from various alkylating agents, including mustard gas, and is hypothesized to inhibit apoptosis.[96] Because experience with iodine treatment of human HF burns is lacking at this time, it cannot be recommended at this time.

To prevent absorption from dermal exposures, irrigation with copious amounts of water should be done. The most important therapy for skin exposures is rapid removal of clothing and irrigation of the affected area with copious amounts of water or saline, whichever is more readily available.[1,46,50,54]

One report describes a woman who was dying from severe HF toxicity who was treated by amputation of the affected limb, and survived. Although rarely considered, this may be an alternative measure for patients who are critically ill and demonstrating an inadequate response to all other therapeutic modalities.[12,45]

■ DERMAL TOXICITY

Several therapeutic options have been studied and described in animal models for treatment of topical HF burns. Unfortunately, many study designs use histologic or subjective wound inspection as outcome parameters,[14,72] some with unblinded inspection.[11,25,45,46,68] These animal models do not address the clinically important parameters of pain reduction, cosmesis, and functionality.

Topical calcium gel should be applied to the affected area. This is prepared by mixing 3.5 g of calcium gluconate powder in 150 mL of sterile water-soluble lubricant, or 25 mL of 10% calcium gluconate in 75 mL of sterile water-soluble lubricant.[1,14,41] If calcium gluconate is unavailable, calcium chloride or calcium carbonate can be used in a similar formulation.[17] Topical therapy for both severe and non–life-threatening exposures scavenges fluoride ions. An animal study examining the efficacy and mechanism of topical calcium gel therapy found that the fluoride ion concentration of the calcium gel was significantly higher than non–calcium-containing gel controls. Although this was a limited study, these animals also had a decrease in urinary fluoride ion concentration as compared to controls, suggesting less overall absorption of the HF into the tissues.[46] Delivery of calcium transcutaneously may be enhanced by various means. In a rodent study of HF burns, iontophoretic (facilitated transport using an electromotive force) delivery of calcium ions appeared to increase calcium concentrations in vitro and improve pathologic changes in vivo.[97] Significant limitations to this study are time to administration of therapy and feasibility in patients with complex burns.[78] Human data are lacking. Dimethyl sulfoxide (DMSO) mixed with topical calcium salts may also facilitate the transport of calcium ions through the skin to penetrate deeply into the tissues. It also is able to act as a scavenger of free radicals, thus limiting inflammation and ongoing injury.[31] Although one group of authors recently advocated the combined use of DMSO and calcium,[31] concerns remain over reported adverse effects of DMSO.[42] There is currently inadequate data to support the use of DMSO in the treatment of HF burns.

Four therapies have had variable success in human exposures: the application of calcium via topical, intradermal, intravenous, and intraarterial routes. After irrigation, a gel solution of calcium carbonate or gluconate can be applied directly to the affected area or mixed directly into a sterile surgical glove and then placed on the patient's hand for 30 minutes for hand burns. Two case series report limited success with this therapy.[1,17] Some patients describe prompt and dramatic relief of pain. Alternatively or simultaneously, analgesics can be administered orally or intravenously as needed, but preferably not to the point of sedation, because local pain response will guide therapy. Digital blocks with subcutaneous lidocaine or bupivacaine can be used for patients presenting 12–24 hours after the injury from a low concentration of HF and with no systemic signs of toxicity at which time topical calcium salts are unlikely to be effective.[24]

If topical gel therapy fails within the first few minutes of application, consideration should be given to intradermal therapy with dilute calcium gluconate, because the benefit in pain control often occurs immediately. This treatment may have limited usefulness, however, in nondistensible spaces such as fingertips. Histologic studies in animal models demonstrate that 10% calcium chloride solution can be damaging to the tissues and should be avoided.[24,30] The preferable method is to approach the wound from a distal point of injury and inject intradermally no

more than 0.5 mL/cm^2 of 5% calcium gluconate. Although one author recommends a palmar fasciotomy whenever this method of treatment is used in the hand,[1] this practice is not currently recommended unless a compartment syndrome is present. The potential for iatrogenic injury exceeds the potential benefit of injections in the hand. The limits of intradermal injection include the potential to increase soft-tissue damage without adequate relief, infection, and inadequate space to safely inject without causing a compartment syndrome.

Effective pain relief is especially problematic for nail involvement, leading some authors to suggest removal of the nail. This approach has some advantages in accessing the affected area; however, it is a painful procedure that is often cosmetically undesirable and the outcome is not always significantly improved.

If the wound is large or on a section of the fingerpad or an area that is not amenable to intradermal injections, consideration should be given to the use of intraarterial calcium gluconate. This procedure delivers calcium directly to the affected tissue from a proximal artery. Placement should be ipsilateral and proximal to the affected area, usually in the radial or brachial artery. The method of obtaining access is somewhat debated. Because of the potential to damage the endothelial lining of the artery, and because extravasation can have potentially devastating consequences, angiographic confirmation or direct visualization of the vessel was formerly recommended. This practice is still prudent if cannulation of the artery is expected to be difficult because of prior surgery or if an anatomic deformity is suspected. If the arterial line is carefully placed in a single attempt, and a good confirmatory arterial tracing is obtained, the infusion can be started. The recommended protocol consists of 10 mL of 10% calcium gluconate added to either 40 mL of D$_5$W (dextrose 5% in water) or 0.9% sodium chloride solution infused continuously over 4 hours.[1,44,73,82,91,92] This results in a 2% calcium gluconate solution. An animal model examined the effect of undiluted 10% calcium gluconate intraaortically. Although the model did not involve exposure to HF, there was significant tissue injury in the vessel wall as compared to a 2% calcium gluconate solution.[24] Calcium chloride has also been used successfully, although the potential for vessel injury and extravasation are significant and there is no defined benefit over calcium gluconate.[91,101] The complications associated with the use of intraarterial calcium infusion in several case series were relatively benign, and include radial artery spasm, hematoma, inflammation at the puncture site, and a fall in serum magnesium.[79,92] After the infusion is initiated, patients typically experience significant pain relief. Patients requiring an arterial line for treatment should be admitted to the hospital, as the majority will require more than one treatment, and some patients may require as many as five separate infusions of calcium gluconate. Although wounds may require débridement,[1] some suggest that following intraarterial calcium infusion, tissue can be salvaged that initially would not have been considered viable.[93] There have been no reported cases of clinically significant hypercalcemia following infusion as the total dose infused is quite low, although serum calcium concentrations were not always routinely recorded.

Administration of magnesium salts is an alternative or adjunctive therapy to the administration of calcium for dermal HF burns. Magnesium hydroxide and magnesium gluconate gel used in rabbit models show some histologic evidence of efficacy in dermal HF burns.[14] Two other animal models of intravenous magnesium for the management of dermal HF burns also suggest efficacy in terms of wound healing.[21,94] Magnesium is suggested to be an antidote for fluoride poisoning because magnesium fluoride is more soluble than calcium fluoride and magnesium is readily excreted by the kidneys.[95] However, these magnesium models inadequately address the disadvantage of magnesium salt solubility, and both topical and intravenous magnesium therapy are insufficiently evaluated in humans.

Another reported therapy for localized HF poisoning is an intravenous Bier block technique that uses 25 mL of 2.5% calcium gluconate. In one case, the effects lasted 5 hours and there were no adverse events.[34] In two other cases of patients exposed to HF, a 6% calcium gluconate solution administered using this procedure resulted in rapid and complete analgesia and minimal tissue necrosis.[79] Although the intravenous Bier block technique is not reported as being used in a substantial number of patients, it may be particularly useful when intraarterial infusion is problematic.[79] Further data are required before this therapy is routinely recommended.

All patients with digital exposures should be observed over 4–6 hours, as the pain is likely to recur and reapplication of the gel or an alternative therapy may be necessary. Even if successful pain control is achieved, the patient will require specialized followup and wound care.

■ INHALATIONAL TOXICITY

Patients with symptomatic inhalational injuries can be treated with nebulized calcium gluconate. A report of patients exposed to a low concentration of HF and treated with 4 mL of a 2.5% nebulized calcium gluconate solution demonstrated a subjective decrease in irritation with no adverse effects.[49] Another report demonstrated a good outcome following nebulization of a 5% calcium gluconate solution in a patient with an inhalational exposure.[47] Because nebulized calcium gluconate appears to be a relatively benign therapy, a dilute solution should be given to all patients with symptomatic inhalational exposures to any concentration of HF.[26]

■ INGESTIONS

In patients with intentional ingestions of HF, gastrointestinal decontamination poses a dilemma. Induction of emesis is also potentially harmful. Although placement of a nasogastric tube to perform gastric lavage is clearly associated with risks to the patient, insertion of a nasogastric tube may be beneficial if done safely and in a timely manner. Consequently, gastric emptying via a nasogastric tube should be considered because these exposures are almost universally fatal.[2,10,55,66] Healthcare providers should exercise extreme caution during this procedure because dermal or inhalational exposures can occur in the absence of appropriate protection. Because aqueous HF is a weak acid, the risk of perforation by passage of a small nasogastric tube may be lower than the risk of death from systemic absorption.[2,55] In the acidic environment of the stomach, more of the weak acid solution remains unionized, thus penetrating the gastric mucosa and causing rapid systemic poisoning. Moreover, activated charcoal is unlikely to adsorb the relatively small fluoride ions.

If an oral exposure occurs, a solution of calcium or magnesium salt should be delivered to the stomach as soon as possible to prevent HF penetration and to provide an alternative source of cations for the damaging electronegative fluoride ions.

When considering the efficacy of calcium to magnesium salts, calcium may be better than magnesium in reducing the bioavailability of fluoride as described in a murine model.[33] Magnesium citrate in a standard cathartic dose, magnesium sulfate, or any of the calcium solutions can be administered orally to prevent absorption, (see Antidotes in Depth A30: Calcium). Although intuitive, evidence for the benefit of oral calcium or magnesium salts is limited. In a mouse model of oral HF toxicity, administration of calcium- or magnesium-containing solutions did not change average survival time.[32] The study results, however, were limited because the calcium and magnesium salts were premixed together with the HF during administration, thus being an atypical model of HF ingestion. In a more recent study, the survival rate

of mice poisoned with NaF was significantly greater when treated with high doses of oral $CaCl_2$ or $MgSO_4$.[40]

■ OPHTHALMIC TOXICITY

Patients with ophthalmic exposures should have each eye irrigated with 1 L of 0.9% sodium chloride solution, lactated Ringer solution, or water.[61] Although there are limited data, repetitive or prolonged irrigation appears to worsen outcome.[61] A complete ophthalmic examination should be performed after the patient is deemed stable, and an ophthalmology consultation should be obtained (see Chap. 19). One case report demonstrated a good outcome following ocular HF exposure with the use of 1% calcium gluconate eyedrops.[4] Although two recent reviews also recommend the use of 1% calcium gluconate for this purpose,[26,31] calcium salts tend to be irritating to the eye and this therapy has not been adequately studied; consequently, routine use is not indicated at this time. There is no role for gel therapy or intraocular injection in these patients, because most calcium and magnesium salts are potentially toxic to ocular tissues and may actually worsen outcome.[3,61]

■ SYSTEMIC TOXICITY

If there is clinical suspicion of severe toxicity, the immediate intravenous administration of calcium and magnesium salts is recommended. In general, calcium gluconate is preferred over calcium chloride because of the risks associated with extravasation (see Antidotes in Depth A30: Calcium). Patients can require several grams of calcium to treat severe HF toxicity.[28,84] Intravenous magnesium can be administered to adults as 20 mL of a 20% solution (4 g) over 20 minutes. An approach that uses intravenous calcium or magnesium, and local calcium or magnesium gels to limit absorption may protect against life-threatening hypocalcemia and hyperkalemia. Due to the numerous adverse effects of systemic fluoride poisoning, administration of calcium and magnesium salts alone may be insufficient in improving survival from systemic fluoride poisoning.[19] Furthermore, an animal model of hydrogen fluoride toxicity found that maintaining a normal acid–base balance was protective against HF toxicity.[75] Moreover, in a study of patients receiving enflurane anesthesia, urine alkalinization improved the excretion of fluoride.[74] Thus, it may be beneficial to correct any significant acidemia with hydration and IV sodium bicarbonate (calcium salts and sodium bicarbonate cannot be mixed). Standard treatment for systemic fluoride toxicity includes administration of calcium salts and sodium bicarbonate, which may also improve the hyperkalemia.

Treatment with large quantities of calcium and magnesium has not generally resulted in significant hypercalcemia or hypermagnesemia.[26] Several explanations are proposed. First, in systemically HF poisoned patients total-body calcium and magnesium stores are severely decreased so that large doses are required for adequate repletion. Also, most patients who are exposed to HF are young and healthy, with intact renal function.[26] Administration of calcium also results in antidiuretic hormone antagonism on renal tubular reabsorption resulting in polyuria which facilitates the urinary excretion of calcium and magnesium.[26]

Because most of the fluoride ions are eliminated renally,[5,39,46,80] hemodialysis may be considered in patients with severe HF poisoning, particularly if renal function is compromised. There are several reported cases of successful clearance of fluoride ions via hemodialysis with one case also using continuous venovenous hemodialysis.[5,6] Because the reported clearance rate did not differ significantly from normally functioning kidneys, it is unclear whether hemodialysis alters outcome in patients with normal renal function.

Although the use of quinidine, a potassium channel blocker, is protective in dogs,[65] it has not been studied or used in humans, and at this time cannot be routinely recommended.

SUMMARY

Hydrofluoric acid and fluoride salts are extremely potent cellular toxins. Hydrofluoric acid exposure typically results in isolated local tissue damage but may also result in severe systemic toxicity and death especially in large exposures. Fluoride salts cause systemic toxicity only when ingested. Development of fluoride toxicity is dependent on many variables including form, concentration, route(s) of exposure, and immediacy and completeness of decontamination, as well as premorbid health conditions. Treatment consists of immediate decontamination, protection of staff, rapid administration of agents to detoxify fluoride ions, enhancement of elimination of fluoride ions, and, rarely, extracorporeal removal. It is imperative for clinicians to be aware of the potentially deceptive nature of fluoride, as well as the possible therapeutic modalities used to treat fluoride poisoned patients.

ANTIDOTES IN DEPTH (A30)

CALCIUM

Mary Ann Howland

Calcium is essential to maintaining the normal function of the heart, vascular smooth muscle, skeletal system, and nervous system. It is vital in enzymatic reactions, in neurohormonal transmission, and in the maintenance of cellular integrity.[25] The endocrine system maintains calcium homeostasis. Approximately half of the total serum calcium is ionized and active, and the remainder is primarily bound to albumin. Hypercalcemia raises the threshold for nerve and muscle excitation, resulting in muscle weakness, lethargy, cardiac conduction disturbances and coma.[25] Hypocalcemia can result in hyperreflexia, muscle spasms, tetany, and seizures (Chap. 16).[25]

CALCIUM CHANNEL BLOCKERS

Although calcium enters cells in numerous ways, only one of these, the voltage-dependent L-type channels in cardiac and smooth muscles, is inhibited by the calcium channel blockers (CCBs) available in the United States.[5,71] Calcium channel blocker overdoses (Chap. 60) may result in nausea, vomiting, hypotension, bradycardia, myocardial depression, sinus arrest, atrioventricular (AV) block, and metabolic acidosis with hyperglycemia, shock, pulmonary edema, altered mental status, and seizures.[58] Because CCBs do not alter either receptor-operated channels or the release of calcium from intracellular stores,[76] the serum calcium concentration remains normal in CCB overdose.

Intravenous (IV) administration of calcium to dogs poisoned with verapamil or diltiazem improves cardiac output secondary to increased inotropy.[29] The heart rate and cardiac conduction are affected minimally, if at all.[26,29,65] Case reports and reviews of the literature suggest similar findings in humans.[2,3,13,20,24,30,33,38,47,61,62,73]

Calcium should be administered to symptomatic patients with CCB overdoses.[34,43,46] Unfortunately, the most seriously ill patients respond inadequately, and other measures are often required. The dose of calcium needed to treat patients with CCB overdose is unknown. In animal experiments, there appears to be a dose-related improvement.[13,29] Since calcium chloride is extremely irritating to small vessels, subcutaneous tissue and muscle and may cause necrosis following extravasation, it is usually only administered through a central venous line. The customary approach is to administer an initial IV dose of 3 g of calcium gluconate (30 mL of 10% calcium gluconate) or 1 g of calcium chloride (10 mL of 10% calcium chloride) to adults.[58] Based on case reports, this dose may need to be repeated as clinically indicated. The hypothesis is that sufficient calcium must be present to compete with the CCB for binding to the L-type calcium channel. One author used a total of 10 g of calcium gluconate as 1 g boluses over 12 minutes after diltiazem-induced asystole and another 2.5 g of calcium gluconate minutes later for a second asystolic event, with a resultant serum calcium concentration of 3.36 mmol/L (normal: 2.2–2.6 mmol/L) about 1 hour after administration of the calcium gluconate.[36] Several authors have

successfully treated patients with a total of 18 to 30 g of calcium gluconate or 13 g of calcium chloride over 2 to 12 hours, either by intermittent bolus dose or infusion, without apparent adverse effects.[13,34,35,43,46,47] Following the use of large doses of calcium, hypercalcemia can occur and is associated with severe consequences including myocardial depression and intense vasoconstriction leading to multiorgan ischemia.[70] Introduction of hyperinsulinemia euglycemia (see Antidotes in Depth A18: Insulin Euglycemia Therapy and A21: Intravenous Fat Emulsion) in the treatment of CCBs has diminished the need for excessive doses of calcium. This approach should be limited, and if used, meticulous monitoring of ionized calcium and blood glucose is advised to avoid hypercalcemia and hypoglycemia.

The administration of calcium to a patient with toxicity from cardioactive steroids such as digoxin could prove quite harmful.[28,81] In the event of concurrent overdose with both a cardioactive steroid and a CCB, the early use of digoxin-specific antibody fragments (A-20) should enable the subsequent safe use of calcium (see Chap. 64).

Therapy in children is based on even more limited data. The current pediatric guidelines of the American Heart Association[1] suggest an initial dose of 20 mg/kg of 10% calcium chloride (0.2 mL/kg) up to the adult dose. This is infused over 5 to 10 minutes, preferably into a central venous line. If a beneficial effect is observed an infusion of 20 to 50 mg/kg/h should follow. These guidelines preferentially suggest calcium chloride based on one study that compared the chloride to the gluconate salt in critically ill children with hypocalcemia.[12] However, since $CaCl_2$ may be irritating, calcium gluconate may be preferable, especially if central venous access is unavailable. A starting dose in children should be about 60 mg/kg of 10% calcium gluconate (0.6 mL/kg) titrating to the adult dose if needed.

β-ADRENERGIC ANTAGONISTS

In vitro studies suggest that the negative inotropic action of β-adrenergic antagonists are related to interference with both the forward and reverse transport of calcium in the sarcoplasmic reticulum and the inhibition of microsomal and mitochondrial calcium uptake (Chap. 61).[21,44,55] In a canine model of propranolol poisoning, the administration of calcium chloride improved mean arterial pressure, maximal left ventricular pressure change over time, and peripheral vascular resistance, but had no significant effect on bradycardia or QRS complex prolongation.[45] Several case reports attest to the beneficial effects of IV calcium in β-adrenergic antagonist overdose.[11,37,60,67] Because distinguishing an overdose of a CCB from that of a β-adrenergic antagonist may be difficult and the two may be taken simultaneously, a trial of IV calcium is appropriate for a presumed β-adrenergic antagonist overdose if cardioactive steroid toxicity which can produce similar effects can be excluded.

HYPOCALCEMIA SECONDARY TO ETHYLENE GLYCOL

Following ethylene glycol poisoning (Chap. 107) metabolism of the parent molecule generates oxalic acid, which complexes with calcium and subsequently precipitates in the kidneys, brain, and elsewhere,

resulting in hypocalcemia.[2,35,57,71,74] After exposure to ethylene glycol, the ionized calcium concentration should always be monitored along with repeated examinations for such signs of hypocalcemia as prolongation of the QT interval on the electrocardiogram (ECG), hyperreflexia, muscle spasms, tetany, and seizures (Chap. 16). Intravenous calcium should be administered in the customary recommended doses (as above) to patients with these findings.

HYPOCALCEMIA SECONDARY TO HYDROFLUORIC ACID AND FLUORIDE–RELEASING XENOBIOTICS

Deaths from hypocalcemia secondary to dermal, gastrointestinal, and pulmonary hydrofluoric acid (HF) exposures are documented in the literature.[15,27,80] Any body contact with HF (Chap. 105) can result in severe burns and death, depending on concentration, area exposed, and duration of exposure. The pathophysiologic derangements noted result from (1) release of free hydrogen ions; (2) complexation of fluoride with calcium and magnesium to form insoluble salts, which causes cellular necrosis; (3) liberation of potassium ions; and (4) cellular dehydration.[8,9,14,23,48,50,52,77] Soluble salts of fluoride and bifluoride (eg, sodium, potassium, and ammonium) have all of the toxicity associated with HF and should be managed accordingly. Following HF exposure, the gluconate salt of calcium is used topically and subcutaneously to manage minor to moderate cutaneous burns, intravenously to treat systemic hypocalcemia, and intraarterially to manage significant burns.[2,8,9,14–16,19,23,27,48,50,54,59,64,66,69,77–79,84] Experimental studies demonstrate that when concentrated HF burns are immediately flushed with water and then treated with topical calcium there is a significant reduction in burn size.[10,77] A randomized clinical trial comparing the dimethyl sulfoxide (DMSO)/calcium gluconate combination to calcium gluconate alone is currently under way.[31] Although a DMSO preparation is not commercially available, a 2.5% calcium gluconate topical gel is marketed. In the event that the commercial preparation is inaccessible, a topical calcium gel can be prepared from calcium carbonate tablets, calcium gluconate powder or solution, and a water-soluble jelly such as K-Y Jelly® (mix 3.5 g calcium gluconate powder or 25 mL of calcium gluconate 10% solution or 10 g of calcium carbonate tablets with 5 ounces of K-Y Jelly®). An experimental study in rats demonstrated that iontophoretic delivery of calcium chloride appeared to enhance the delivery of calcium and to significantly reduce the burn area if applied within 30 minutes and may be a promising modality in the future.[65,83]

The chloride salt is also acceptable for topical therapy. However, calcium chloride should *never* be injected into tissues (subcutaneously, intramuscularly) since severe tissue necrosis can result.

In patients with severe topical HF exposures, aggressive administration of regional IV calcium using a Bier block technique (10 mL of 10% calcium gluconate plus heparin 5000 units in a total volume of 40 mL) or intraarterial calcium (10 mL of 10% calcium gluconate in 50 mL of 0.9% sodium chloride solution over 4 hours) may be required, along with frequent serum calcium determinations to titrate the dose.[31] One patient who was massively exposed to HF required a total of 267 mEq of calcium infused over a 24 hour period.[27]

In patients with life-threatening poisoning and particularly HF inhalation simultaneous administration of IV, oral, and nebulized 2.5% calcium gluconate can also be given to facilitate the availability of the maximum amount of calcium. To prepare nebulized calcium gluconate, mix 1.5 mL of 10% calcium gluconate solution with 4.5 mL of sterile water or saline to make a 2.5% solution. For moderate to severe burns (generally from HF concentrations greater than 10%) of

the fingers and hands, an intraarterial calcium infusion may be more effective than local or IV therapy, although it is more invasive[59,69,75,78,79] and more hazardous.[69] A calcium gluconate solution (10 mL of 10%) mixed in 40 to 50 mL of 5% dextrose or 0.9% NaCl solution can be infused intraarterially over 4 hours followed by subsequent 40-50 mL infusions after 4 hours when pain persists.[78] Serum calcium, potassium, and serum magnesium concentrations should be carefully monitored in all severely poisoned patients.

HYPOCALCEMIA SECONDARY TO PHOSPHATES

Inappropriate use of oral and rectal phosphates as a laxative can result in hypocalcemia, hyperphosphatemia, and hyperkalemia with resultant morbidity and mortality.[4] Intravenous calcium may be needed for life-threatening hypocalcemia. However, since administration of calcium in the presence of hyperphosphatemia risks precipitation of calcium phosphate throughout the body, hemodialysis and other therapies should be considered in non–life-threatening cases.

HYPERMAGNESEMIA

Hypermagnesemia causes both direct and indirect depression of skeletal muscle, resulting in neuromuscular blockade, loss of reflexes, and profound muscular paralysis (Chap. 16).[42,53] Excess magnesium also causes prolongation of the PR interval and QRS complex on ECG, and depression of the sinoatrial (SA) node, leading to a bradycardic arrest. Intravenous calcium serves as a physiologic antagonist to these effects of magnesium (Table A30–1).

HYPERKALEMIA

Hyperkalemia causes significant myocardial depression. The resultant ECG changes are well defined: the height of the T wave increases and lengthening of the PR interval and QRS complex occur; ultimately, a sine wave pattern leading to cardiac arrest may occur if treatment is not initiated (Chaps. 16 and 22).[25] Calcium makes the membrane threshold potential less negative so that a larger stimulus is required to depolarize the cell. This stabilization antagonizes the hyperexcitability caused by modest hyperkalemia. However, when severe hyperkalemia exists, voltage-gated sodium channels are inactivated and cannot be depolarized, regardless of the strength of the impulse. Calcium may transform the voltage sensor of the sodium channel from inactive to closed, thus allowing the sodium channel to be opened with depolarization.[32] If hyperkalemia is secondary to the toxic effects of cardioactive steroids on the Na+-K+-adenosine triphosphatase (ATPase) pump, IV calcium can potentially exacerbate an already excessive intracellular calcium concentration, making IV calcium potentially harmful (see Chap. 64).[25]

BLACK WIDOW SPIDER ENVENOMATION (HISTORIC INDICATION)

Envenomation by the black widow spider (*Latrodectus* spp) (Chap. 119) leads to local and systemic symptoms. Most commonly, severe abdominal or back pain begins within several hours of envenomation.[17] The venom exerts its effects by opening sodium channels leading to calcium influx; the release of synaptic transmitters, including norepinephrine and acetylcholine, are believed to be involved.[63] Analgesics, benzodiazepines,

TABLE A30–1. Calcium Salts for Intravenous Use

	Calcium Gluconate[a]	Calcium Chloride (CaCl$_2$)[a,b]
10% Solution	10 mL = 1 g of Ca^{2+} gluconate	10 mL = 1 g of CaCl$_2$
	10 mL = 4.5 mEq elemental Ca^{2+}	10 mL = 13.6 mEq elemental Ca^{2+}
Adult dose	3 g (30 mL of 10% solution) over 10 min (unless in extremis–deliver over 30-60 sec)	1 g (10 mL of 10% solution) over 10 min (unless in extremis–deliver over 30-60 sec)[b]
	Repeat every several minutes as necessary[a]	Repeat every several minutes as necessary[a]
Pediatric dose (not to exceed the adult dose)	60 mg/kg (0.6 mL/kg) of 10% solution infused over 5-10 minutes (unless in extremis– deliver over 30-60 sec)[b]	20 mg/kg (0.2 mL/kg) infused over 5-10 minutes (unless in extremis–deliver over 30-60 sec)[b]
	Repeat every several minutes as necessary[b]	Repeat every several minutes as necessary[b]

[a] Monitor calcium after several doses and every 30 minutes during administration.

[b] Use of a central venous line is recommended to avoid extravasation.

and muscle relaxants are used to successfully relieve the pain and muscle spasms.[17,22,39,68] Rarely, antivenom may be indicated.

Intravenous calcium was previously recommended.[17,39] Animal studies suggested that the venom induces changes in the permeability of calcium that may be overcome by increasing the extracellular concentration of calcium.[40,56] In support, one prospective study noted improvement in six of 13 patients treated with calcium gluconate.[39] However, a large retrospective study of 163 patients cast doubt on the effectiveness of calcium.[17] Very few patients had adequate pain relief from calcium, and all but one patient also required opioids.[17] As a result, there is no longer a role for calcium in the management of black widow spider envenomation (see Chap. 119).

SAFETY ISSUES AND CALCIUM PREPARATIONS

Severe hypercalcemia is defined by a serum calcium concentration greater than 3.5 mmol/L (14.0 mg/dL) in a patient with a normal albumin concentration. The adverse effects of hypercalcemia (independent of the rate of administration) include nausea, vomiting, constipation, ileus, hypertension if intravascular volume is adequate, polyuria, polydipsia, cognitive difficulties, hyporeflexia, coma, and enhanced sensitivity to cardioactive steroids.[6] Significant hypercalcemia may lead to myocardial depression. The symptoms exhibited depend on the patient's age, rate of increase in the serum calcium concentration, and duration of the hypercalcemia.[6]

A variety of calcium salts are available for parenteral administration. The two most commonly used are calcium chloride and calcium gluconate (see Table A30-1). Neither salt should be combined and administered intravenously with sodium bicarbonate because calcium carbonate, a precipitate, is formed. Calcium chloride is an acidifying salt and is extremely irritating to tissue. It should *never* be given intramuscularly, subcutaneously, or perivascularly.[25,51] Calcium gluconate is less irritating, but care should also be taken to avoid extravasation. The best reason for choosing calcium gluconate in almost all clinical situations is that the tissue risk is far less. If extravasation should occur, subcutaneous injection of aliquots of hyaluronidase can be injected around the site (see Special Considerations SC3–Extravasation of xenobiotics). Equivalent molar doses of calcium found in calcium chloride (1 g CaCl$_2$ 10%) and calcium gluconate (3 g Ca gluconate 10%) produce similar serum ionized

calcium concentrations, with peaks occurring within 30 seconds and accompanied by hemodynamic improvement.[49] These results support the idea that simple dissociation of calcium from gluconate is responsible for releasing calcium, rather than hepatic metabolism. Earlier evidence has been challenged that suggested that infusions of IV calcium chloride in hypocalcemic children[12] produce slightly larger increases in ionic calcium than infusions of calcium gluconate.[49,82] Intravenous calcium must be administered slowly, at a rate not exceeding 0.7 to 1.8 mEq/min or one 10-mL vial of calcium chloride or three 10 mL vials of calcium gluconate over 10 minutes in adults unless the patient is severely hypocalcemic. More rapid administration may lead to vasodilation, hypotension, bradycardia, dysrhythmias, syncope, and cardiac arrest.[7,18,41,51,72]

In cases of extreme life-threatening hypocalcemia or for a patient in extremis, a slow IV push may be required.

SUMMARY

Intravenous calcium infusion is an effective antidote for the hypocalcemia induced by either ethylene glycol, HF and fluoride–releasing xenobiotics. It serves as a physiologic antagonist to the cardiac and/or neurologic effects of hypermagnesemia and hyperkalemia and counteracts the effects of CCB overdoses. It may have some benefit in the treatment of β-adrenergic antagonist overdoses. Great care must be taken to avoid extravasation as calcium chloride in particular can cause tissue necrosis. Equivalent molar calcium doses found in appropriate volumes of calcium gluconate and calcium chloride deliver equal amounts of ionized calcium. Electrocardiographic monitoring and frequent ionized calcium concentration measurements are required to prevent iatrogenic toxicity. Although most clinical experience involves IV use, advances in intraarterial, topical, inhalational, and intraosseous calcium therapy may offer unique potential advantages.

CHAPTER 106
HYDROCARBONS

David D. Gummin

Our present world could not exist without hydrocarbons. Nearly everything we touch today is either comprised of or coated with hydrocarbon products. In the practice of clinical toxicology, initial efforts usually entail precisely determining the specific xenobiotics that might be involved in a specific exposure, followed by defining the type and extent of the exposure. In this regard, hydrocarbon exposures are always clinically challenging. Despite significant chemical diversity, most classification schemes group hydrocarbons by specific uses or applications, rather than by chemical structure or physiologic properties. Most hydrocarbons in everyday use, such as gasoline, charcoal starter, and lamp oil, are actually mixtures of chemicals obtained from a common distillation fraction. The chemical diversity within a mixture makes it challenging to try to assess individual contribution to toxicity. As a result, generalities are often needed to describe the behavior of these complex mixtures. This chapter focuses primarily on toxicity of hydrocarbons present in such mixtures. Individual hydrocarbons are addressed only when they are commonly available in purified form, or when individual xenobiotics present unique toxicologic concerns.

HISTORY AND EPIDEMIOLOGY

Organic chemistry originated in the industrial revolution and evolved largely because of advances in coal tar technology. Coal liberates hydrocarbons in the coking process, when bituminous (soft) coal is heated to remove coal gas. The gas is then separated into a variety of natural gases. The viscous residue from the heating process forms coal tar, which can be further distilled into kerosene and other hydrocarbon mixtures.

Over the years, crude oil has replaced coal tar as the most common source for distillation of organic compounds. Crude oil distillation involves heating the oil to fixed temperatures in large-scale processors that separate hydrocarbons into fractions by vapor (boiling) point. Because of the relationship between boiling point and molecular weight, distillation roughly divides hydrocarbons into like-sized molecules. The most volatile fractions come off early, as gases. These are used primarily as heating fuels. The least volatile fractions (larger than about 10 carbons) are used chiefly for lubricants or as paraffins, petroleum jelly, or asphalt. The remaining volatile distillation fractions (C_5 to C_{10}) are the ones most commonly used in combustion fuels and as solvents. Petroleum distillates are also used as chemical feedstocks and as precursors or intermediates for production. The many contemporary applications of petroleum distillates in consumer and household products include paints and thinners, furniture polish, lamp oils, and lubricants (Table 106–1).

Mineral oil, castor oil, and glycerine are commonly used as laxatives. Hydrocarbon-based ointments, petroleum jelly, and camphor are used topically on skin and mucous membranes. Volatile oils (or essential oils) are fragrant hydrocarbon plant extracts. Examples include menthol, eucalyptus oil, clove oil, sassafras oil, and pennyroyal, among others. These oils have had a variety of medicinal uses over many centuries and are enjoying a resurgence with recent popularity of herbal products (Chap. 43). Phenol and substituted phenols are common medical

disinfectants (Chap. 102). Diethyl ether and halogenated hydrocarbon compounds, like chloroform, were among the first general anesthetics used more than 150 years ago. Cyclopropane and trichloroethylene (TCE) were also widely used anesthetics.[135]

Three populations appear to be at particular risk for hydrocarbon-related illness, children who have unintentional exposures, often ingestions, workers with occupational exposures, often dermal and inhalational, and adolescents or young adults who intentionally abuse solvents through inhalation. Specific occupations at risk for exposure include petrochemical workers, plastics and rubber workers, printers, laboratory workers, painters, and hazardous waste workers. The Occupational Safety and Health Administration (OSHA) estimates that nearly 238,000 American workers are exposed annually to significant concentrations of benzene alone.[72] But the epidemiology of hydrocarbon exposure and hydrocarbon-related illness is difficult to assess. Most exposures do not involve ingestion, and most do not result in illness. Because a common property of hydrocarbons is high volatility, inhalation is extremely common. Lipid solubility facilitates dermal absorption when skin is exposed.[63] Exposures may range from self-pumping gasoline, to painting a spare bedroom, to applying or removing fingernail polish. Table 106-1 lists frequently encountered hydrocarbon compounds and properties.

During the years 2003 to 2007, American poison centers reported 52,398 average yearly human hydrocarbons exposures to the American Association of Poison Control Centers (AAPCC). These exposures accounted for 2.2% of total human exposures reported. The incidence of exposures has not changed appreciably in the AAPCC database since the first report in 1983. Over the most recent 5-year period, 34% of reported human exposures to hydrocarbons involved unintentional exposures in children younger than 6 years of age. Exposures in young children appear to be declining over the past decade of AAPCC reports, but this may be an artifact of the way in which cases are reported into the database. Within the AAPCC database, many thousands of hydrocarbon exposures are not listed as such, but are ascribed to chemicals, pesticides, personal care products, cleaning substances, paints, automotive products (see Chap. 135). The alarming rate of intentional misuse of volatile solvents by young people and the concomitant rate of death from volatile substance abuse is discussed in Chap. 81.

CHEMISTRY

A *hydrocarbon* is an organic compound made up primarily of carbon and hydrogen atoms, typically ranging from 1 to 60 carbon atoms in length. This definition includes products derived from plants (pine oil, vegetable oil), animal fats (cod liver oil), natural gas, petroleum, or coal tar. There are two basic types of hydrocarbon molecules, *aliphatic* (straight or branched chains) and *cyclic* (closed ring), each with its own subclasses. The aliphatic compounds include the *paraffins* (*alkanes*, with a generic formula C_nH_{2n+2}); the *olefins* (*alkenes* have one double bond and *alkadienes* have two double bonds); *acetylenes* (alkynes) with at least one triple bond; and the *acyclic terpenes* (polymers of isoprene, C_5H_8). Some aliphatic compounds have branches in which the subchain also contains carbon atoms; both the chain and branches are essentially straight.

The cyclic hydrocarbons include *alicyclic* (three or more carbon atoms in a ring structure, with properties similar to the aliphatics), and *aromatic* compounds, as well as the *cyclic terpenes*. The alicyclics are further divided into *cycloparaffins* (*naphthenes*) such as cyclohexane, and the *cycloolefins* (two or more double bonds) such as cyclopentadiene.

Saturated hydrocarbons contain carbon atoms that exist only in their most reduced state. This means that each carbon is bound to either hydrogen or to another carbon, with no double or triple bonds

TABLE 106–1. Classification and Viscosity of Common Hydrocarbons

Compound	Common Uses	Viscosity (SUS)[a]
Aliphatics		
Gasoline	Motor vehicle fuel	30
Naphtha	Charcoal lighter fluid	29
Kerosene	Heating fuel	35
Turpentine	Paint thinner	33
Mineral spirits	Paint and varnish thinner	30–35
Mineral seal oil	Furniture polish	30–35
Heavy fuel oil	Heating oil	>450
Aromatics		
Benzene	Solvent, reagent, gasoline additive	31
Toluene	Solvent, spray paint solvent	28
Xylene	Solvent, paint thinner, reagent	28
Halogenated		
Methylene chloride	Solvent, paint stripper, propellant	27
Carbon tetrachloride	Solvent, propellant, refrigerant	30
Trichloroethylene	Degreaser, spot remover	27
Tetrachloroethylene	Dry cleaning solvent, chemical intermediate	28

[a] Direct values for kinematic viscosity in Saybolt universal seconds (SUS) were not available for the following compounds: naphtha, xylene, methylene chloride, carbon tetrachloride, trichloroethylene, perchloroethylene, and toluene. SUS was calculated by converting from available measurements in centipoise viscosity and/or centistokes viscosity using the following conversions: the value in centistokes is estimated by dividing centipoise by density at 68°F (20°C); SUS is approximated from centistokes using $y = 3.2533x + 26.08$ ($R^2 = 0.9998$). Centipoise viscosity for naphtha was estimated from the value for butylbenzene. Centipoise viscosity for xylene is the average of *o-*, *m-*, and *p-*xlyiene.

present. Conversely, *unsaturated* compounds are those with hydrogens removed, in which double or triple bonds exist.

Solvents are a heterogenous class of xenobiotics used to dissolve and to provide a vehicle for delivery of other xenobiotics. The most common industrial solvent is water. The common solvents most familiar to toxicologists are *organic solvents* (containing one or more carbon atom), and most of these are hydrocarbons. Most are liquids in the conditions under which they are used. Specifically named solvents (Stoddard solvent, white naphtha, ligroin) represent mixtures of hydrocarbons emanating from a common petroleum distillation fraction.

Aromatic hydrocarbons are divided into the *benzene* group (one ring), *naphthalene* group (two rings), and the *anthracene* group (three rings). *Polycyclic aromatic hydrocarbons* (polynuclear aromatic hydrocarbons) have multiple, fused benzene-like rings. Aromatic organic compounds may also be *heterocyclic* (where oxygen or nitrogen substitutes for carbon in the ring). Structurally, all of these molecules are flat, with reactive electron clouds above and below the ring.

The *cyclic terpenes* are the principal components of the variety of plant-derived essential oils, often providing color, odor, and flavor. *Limonene* in lemon oil, *menthol* in mint oil, *pinene* in turpentine, and *camphor* are all terpenes (Chap. 42).[108]

Physical properties of hydrocarbons vary by the number of carbon atoms and by molecular structure. Unsubstituted, aliphatic hydrocarbons that contain up to 4 carbons are gaseous at room temperature, 5 to 19 carbon molecules are liquids, and longer-chain molecules tend to be tars or solids. Branching of chains tends to destabilize intermolecular forces, so that less energy is required to separate the molecules. The result is that, for a given molecular size, highly branched molecules have lower boiling points and tend to be more volatile.[104]

Gasoline is a mixture of alkanes, alkenes, naphthenes, and aromatic hydrocarbons, predominantly 5 to 10 carbon molecules in size. Gasoline is separated from crude oil in a common distillation fraction. However, most commercially available gasolines are actually blends of up to eight component fractions from refinery processors. More than 1500 individual xenobiotics may be present in commercial grades, but most analytical methods are only able to isolate 150 to 180 compounds from gasolines. Notably, *n*-hexane is present at up to 6%, and benzene is present between 1% and 6%, depending on the grade and the place of origin of the product. A number of additives may go into the final formulation: alkyl leads, ethylene dichloride, and ethylene dibromide in leaded gasoline, and oxygenates such as methyl *t*-butyl ether (MTBE), as well as methanol and ethanol.[170]

Organic halides contain one or more halogen atoms (fluorine, chlorine, bromine, iodine) usually substituted for a hydrogen atom in the parent structure. Examples include chloroform, trichloroethylene, and the freons.

Oxygenated hydrocarbons demonstrate toxicity specific to the oxidation state of the carbon, as well as to the atoms adjacent to it (the "R" groups). The *alcohols* are widely used as solvents in industry and in household products. Their toxicity is discussed in Chaps. 77 and 107. *Ethers* contain an oxygen bound on either side by a carbon atom. Acute toxicity from ethers tends to mirror that of the corresponding alcohols. *Aldehydes* and *ketones* contain a single carbon-oxygen double bond (C=O), the former at a terminal carbon, the latter somewhere in the middle. Organic *acids, esters, amides,* and *acyl halides* represent more oxidized states of carbon; human toxicity is agent-specific.

Phenols consist of benzene rings with an attached hydroxyl (alcohol) group. The parent compound, phenol, has only one hydroxyl group attached to benzene. The toxicity of phenol can be dramatically altered by addition of other functional groups to the benzene ring (Chap. 102). Cresols, catechols, and salicylate are examples of substituted phenols.

A variety of amines, amides, nitroso and nitro compounds, as well as phosphates, sulfites, and sulfates are used commercially and industrially. The addition of these functional groups to hydrocarbons dramatically alters the toxicity of the compound.

PHARMACOLOGY

Inhalation of hydrocarbon vapor depresses consciousness. Acute central nervous (CNS) toxicity from occupational overexposure or recreational abuse parallels the effect of administering an inhaled general anesthetic.[140] The concentration of volatile anesthetic that produces loss of nociception in 50% of patients defines the minimum alveolar concentration (MAC) required to induce anesthesia. Inhaled solvent vapor similarly produces unconsciousness in 50% of subjects when the partial pressure in the lung reaches its median effective dose (ED_{50}). The ED_{50} of occupational parlance is effectively the same as the MAC used in anesthesiology parlance (see Chap. 67). Virtually all patients will be anesthetized when the partial pressure is raised 30% above the MAC (MAC × 1.3), and death, if ventilation is not supported, typically occurs when the concentration reaches two to four times the MAC.[87] Dose–response curves suggest that essentially no individual

will be rendered unconscious by an inhaled dose 30% below the MAC. However, impairment of cognitive and motor function may occur with much lower exposures.[18]

Occupational exposure to lipid-soluble solvents, such as aromatic, aliphatic, or chlorinated hydrocarbons, are more likely to cause acute and chronic CNS effects than exposure to water-soluble hydrocarbons such as alcohols, ketones, and esters.[94] The property of an inhaled anesthetic that correlates most closely with its ability to extinguish nociception is its lipid solubility. The Meyer-Overton hypothesis, proposed more than 100 years ago, implies that an anesthetic dissolves into some critical lipid compartment of the CNS, causing inhibition of neuronal transmission. In this construct, the target structure for general anesthetics is the neuronal lipid membrane itself.[64]

Inhaled hydrocarbons and other volatile anesthetic xenobiotics (Chap. 67) exhibit pharmacodynamic properties suggestive of a receptor-ligand interaction. The sigmoidal dose-response curves exhibit a near-linear midrange with a plateau effect at higher inhaled concentrations. Different xenobiotics produce curves whose linear segments parallel one another, implying that each xenobiotic produces the same physiologic effect at a particular concentration related to that xenobiotic's potency.[121] Thus, it has long been tempting to find the single, intangible "receptor" responsible for general anesthesia, and in doing so, to improve upon the Meyer-Overton hypothesis.

Unfortunately, a single mechanism remains elusive. Halothane, isoflurane, sevoflurane, enflurane, and desflurane inhibit fast sodium channels.[117] Toluene, trichloroethylene, perchloroethylene, and others inhibit neuronal calcium currents.[113,136] The halogenated hydrocarbons increase the outward potassium rectifying current.[137] Specific ligand-receptor interactions occur,[43] such as the inhibition of receptor function at nicotinic,[165] and at the glutamate receptors,[42] as well as enhancement of type-A γ-aminobutyric acid ($GABA_A$) and glycine receptor currents.[16] Independent of other mechanisms, halogenated hydrocarbons appear to decrease exocytosis of neuronal synaptic vesicles.[68] This growing body of research suggests that the Meyer-Overton hypothesis is too simplistic to explain the differences in pharmacologic profiles observed with this wide class of xenobiotics.

The effect of hydrocarbons on cardiac conduction remains an active arena of toxicologic research. Nearly all classes of hydrocarbons, to varying degrees, augment the dysrhythmogenic potential by "sensitizing" the myocardium. Sensitization occurs with both xenobiotic and class specificity. Ethylene and aliphatic ethers are very poor sensitizers. Aromatic, and even more so the halogenated hydrocarbons, are often potent sensitizers.[23]

Cardiac sensitization is incompletely understood.[43] Halothane and isoflurane inactivate sodium channels,[141] whereas chloroform and others attenuate potassium efflux through voltage-gated channels.[133] Sensitization may be mediated by slowed conduction velocity through membrane gap junctions. Dephosphorylation of connexin-43 results in a configurational change that increases gap junctional resistance. Halocarbons, in the presence of epinephrine, cause dephosporylation of this gap junction protein, thereby increasing gap junctional resistance and slowing conduction velocity in myocardial tissue.[77]

TOXICOKINETICS

Human toxicokinetic data are lacking for most hydrocarbons, and much of our understanding of the kinetics comes from animal studies. Hydrocarbons are variably absorbed through ingestion, inhalation, or dermal routes of exposure. Partition coefficients, in particular, are useful predictors of the rate and extent of the absorption and distribution of hydrocarbons into tissues as the higher the value the greater

the potential for redistribution. A partition coefficient for a given chemical species is the ratio of concentrations achieved between two different media at equilibrium. The blood-to-air and tissue-to-air or tissue-to-blood coefficients directly relate to the pulmonary uptake and distribution of hydrocarbons. The tissue-to-blood partition coefficient is commonly determined by dividing the tissue-to-air coefficient by the blood-to-air coefficient.[53,120] Table 106–2 lists the partition coefficients for commonly encountered hydrocarbons. Where human data is limited, rat data is presented in the table, because human and rat data often correlate.[120]

Inhalation is a major route of exposure for most volatile hydrocarbons. The absorbed dose is determined by the air concentration, duration of exposure, minute ventilation, and the blood-to-air partition coefficient. Most hydrocarbons cross the alveolus through passive diffusion. The driving force for this is the difference in vapor concentration between the alveolus and the blood. Hydrocarbons that are highly soluble in blood and tissues are readily absorbed through inhalation, and blood concentrations rise rapidly following inhalation exposure. Aromatic hydrocarbons are generally well absorbed through inhalation, absorption of aliphatic hydrocarbons varies by molecular weight: aliphatic hydrocarbons with between 5 and 16 carbons are readily absorbed, through inhalation, whereas those with more than 16 carbons are less readily absorbed.[3]

Absorption of aliphatic hydrocarbons through the digestive tract is inversely related to molecular weight, ranging from complete absorption at lower molecular weights, to approximately 60% for C-14 hydrocarbons, 5% for C-28 hydrocarbons, and essentially no absorption for aliphatic hydrocarbons with more than 32 carbons.[3] Oral absorption of aromatic hydrocarbons with between 5 and 9 carbons ranges from 80% to 97%. Oral absorption data for aromatic hydrocarbons with more than 9 carbons are sparse.

While the skin is a common area of contact with solvents, for most hydrocarbons the dose received from dermal exposure is a small fraction of the dose received through other routes, such as inhalation. The skin is comprised of both hydrophilic (proteinaceous portion of cells) and lipophilic (cell membranes) regions. While many hydrocarbons can remove lipids from the stratum corneum, permeability is not simply the result of lipid removal; permeability also increases with hydration of the skin. When xenobiotics have near equality in the water-to-lipid partition coefficient, their rate of skin absorption is increased. Solvents that contain both hydrophobic and hydrophilic moieties (eg, glycol ethers, dimethylformamide, dimethylsulfoxide) are particularly well absorbed dermally.[94] Other factors, in addition to the partition coefficient and permeability constant, that determine penetration across the skin, include the thickness of the skin layer, the difference in concentration of the solvent on either side of the epithelium, the diffusion constant, and skin integrity (ie, normal versus cut or abraded).

The dose received via skin absorption will also depend on the surface area of the skin exposed and the duration of contact. Though highly volatile compounds may have a short duration of skin contact because of evaporation, skin absorption can also occur from contact with hydrocarbon vapor. In studies with human volunteers exposed to varying concentrations of hydrocarbon vapors, the dermal dose accounted for only 0.1%–2% of the inhalation dose. With massive exposure (eg, whole-body immersion), dermal absorption may contribute significantly to toxicity. Significant dermal absorption with resultant toxicity is described with carbon tetrachloride,[76] tetrachloroethylene,[63] and phenol.[93]

Once absorbed into the central compartment, hydrocarbons are distributed to target and storage organs based on their tissue-to-blood partition coefficients and on the rate of perfusion of the tissue with blood. During the onset of systemic exposure, hydrocarbons accumulate

TABLE 106–2. Kinetic Parameters of Selected Hydrocarbons

	Partition Coefficients		$t_{1/2}$			
	Blood/Air	Fat/Air	α	β	Elimination	Relevant Metabolites
Aliphatics						
n-Hexane	2.29[a]	159[a]	11 min	99 min	10%–20% exhaled; liver metabolism by CYP 2E1	2-Hexanol, 2,5-hexanedione, γ-valerolactone
Paraffin/tar	Not absorbed or metabolized					
Aromatics						
Benzene	8.19	499[a]	8 h	90 h	12% exhaled; liver metabolism to phenol	Phenol, catechol, hydroquinone, and conjugates
Toluene	18.0[a]	1021[a]	4–5 h	15–72 h	Extensive liver extraction and metabolism	80% metabolized to benzyl alcohol; 70% renally excreted as hippuric acid
o-Xylene	34.9	1877[a]	30–60 min	20–30 h	Liver CYP 2E1 oxidation	Toluic acid, methyl hippuric acid
Halogenated						
Methylene chloride	8.94	120[a]	Apparent $t_{1/2}$ of COHb 13 h	40 min	92% exhaled unchanged. Low doses metabolized; high doses exhaled. Two liver metabolic pathways	(a) CYP 2E1 to CO and CO_2 (b) Glutathione transferase to CO_2, formaldehyde, formic acid
Carbon tetrachloride	2.73	359[a]	84–91 min[a]	91–496 min[a]	Liver CYP 2E1, some lung exhalation (dose-dependent)	Trichloromethyl radical, trichloromethyl peroxy radical, phosgene
Trichloroethylene	8.11	554[a]	3 h	30 h	Liver CYP 2E1–epoxide intermediate; trichloroethanol is glucuronidated and excreted	Chloral hydrate, trichloroethanol, trichloroacetic acid
1,1,1- Trichloroethane	2.53	263[a]	44 min	53 h	91% exhaled; liver CYP 2E1	Trichloroacetic acid, trichloroethanol
Tetrachloroethylene	10.3	1638[a]	160 min	33 h	80% exhaled; liver CYP 2E1	Trichloroacetic acid, trichloroethanol

[a] Fat/blood partition coefficient is obtained by dividing the fat/air coefficient by the blood/air coefficient, as determined in rat models. All coefficients are determined at 98.6°F (37°C).

in tissues that have tissue/blood coefficients greater than 1 (eg, for toluene, the fat-to-blood partition coefficient is 60). Table 106-2 lists the distribution half-lives of selected hydrocarbons.

Hydrocarbons can be eliminated from the body unchanged, for example, through expired air, or can be metabolized to more polar compounds, which are then excreted in urine or bile. Table 106-2 lists the blood elimination half-lives (for first-order elimination processes) and metabolites of selected hydrocarbons. Some hydrocarbons are metabolized to toxic compounds (eg, methylene chloride, carbon tetrachloride, *n*-hexane, methyl-*n*-butyl ketone). The specific toxicities of these metabolites are discussed under Special Cases later in the chapter.

PATHOPHYSIOLOGY AND CLINICAL FINDINGS

■ RESPIRATORY

Several factors are classically associated with pulmonary toxicity after hydrocarbon ingestion. These include specific physical properties of the xenobiotics ingested, the volume ingested, and the occurrence of vomiting. Physical properties of viscosity, surface tension, and volatility are primary determinants of aspiration potential.

Dynamic (or absolute) viscosity is the measurement of the ability of a fluid to resist flow. This property is measured with a rheometer and is typically given in units of pascal-seconds. More frequently, engineers

work with *kinematic viscosity*, measured in square millimeters per second, or centistokes. Dynamic viscosity is converted to kinematic viscosity by dividing the dynamic viscosity by the fluid's density. An older system for measuring viscosity was initially popularized by the petroleum industry and expresses kinematic viscosity in units of Saybolt Universal seconds (SUS). Unfortunately, many policy statements were developed in an era when SUS units were popular, so many still describe viscosity in SUS units. Various look-up tables and calculators are available to convert kinematic viscosity to SUS units. Table 106-1 shows kinematic viscosity of common hydrocarbons, measured in SUS. A unit conversion approximation is given in the table's footnote.

Hydrocarbons with low viscosities (less than 60 SUS; eg, turpentine, gasoline, naphtha) have a higher tendency for aspiration in animal models. The US Consumer Products Safety Commission issued a rule requiring child-resistant packaging for products that contain 10% or more hydrocarbon by weight and that have a viscosity less than 100 SUS.[160]

Surface tension is a cohesive force generated by attraction (ie, Van der Waals forces) between molecules.[118] This influences adherence of a liquid along a surface ("its ability to creep"). The lower the surface tension, the less well the liquid will creep and the higher the aspiration risk.[55]

Volatility is the tendency for a liquid to become a gas. Hydrocarbons with high volatility tend to vaporize, displace oxygen, and potentially lead to transient hypoxia.

It is not clear which physical property is most important in predicting toxicity. Early reports conflicted in attempting to relate risk of

pulmonary toxicity to the amount of hydrocarbon ingested, or to the presence or absence of vomiting. One prospective study addressed both of these variables. The cooperative kerosene poisoning (COKP) study was a multicenter study that enrolled 760 cases of hydrocarbon ingestion. Of these, 409 could provide an estimate of the amount ingested. Patients who reportedly ingested more than 30 mL had a 52% chance of developing pulmonary complications, compared with 39% of those who ingested less than 10 mL. Risk of central nervous complications was 41%, compared with 24% using the same criterion. There was a 53% incidence of pulmonary toxicity when vomiting occurred, compared with 37% when there was no history of vomiting.[122] While this knowledge may help modify the index of suspicion regarding possible pulmonary toxicity, none of these parameters is completely predictive. Severe hydrocarbon pneumonitis may occur after ingestion of "low-risk" hydrocarbons.[131] Patients may develop severe lung injury after low-volume (less than 5 mL) ingestions, as well as after ingestions with no history of coughing, gagging, or vomiting.[9]

It is widely held that aspiration is the main route of injury from ingested simple hydrocarbons. The mechanism of pulmonary injury, however, is not fully understood. Intratracheal instillation of 0.2 mL/kg of kerosene causes physiologic abnormalities in lung mechanics (decreased compliance and total lung capacity) and pathologic changes such as interstitial inflammation, polymorphonuclear exudates, intraalveolar edema and hemorrhage, hyperemia, bronchial and bronchiolar necrosis, and vascular thrombosis.[11,61,156] These changes most likely reflect both direct toxicity to pulmonary tissue and disruption of the lipid surfactant layer.[173]

Most patients who go on to develop pulmonary toxicity after hydrocarbon ingestion will have an episode of coughing, gagging, or choking. This usually occurs within 30 minutes after ingestion and is presumptive evidence of aspiration. The majority of patients who have respiratory signs and symptoms beyond the initial history of gagging, choking, and coughing develop radiographic pneumonitis.[9] Absence of tachypnea on initial evaluation has 80% negative predictive value for pneumonitis.[168] Pulmonary toxicity may manifest as crackles, rhonchi, bronchospasm, tachypnea, hypoxemia, hemoptysis, acute lung injury (hemorrhagic or non-hemorrhagic), or respiratory distress.[156] Cyanosis develops in approximately 2% to 3% of patients.[99] This may result from simple asphyxiant effects from volatilized hydrocarbons, from ventilation–perfusion mismatch, or, rarely, from methemoglobinemia (aniline, nitrobenzene, or nitrite-containing hydrocarbons). Clinical findings often worsen over the first several days but typically resolve within a week. Death is rare (less than 2%), and typically occurs after a severe, progressive respiratory insult marked by hypoxia, ventilation–perfusion mismatch, and barotrauma.[14,180]

Intravenous (IV) and subcutaneous injection of hydrocarbons have been reported.[129,162] Severe hydrocarbon pneumonitis may occur following intravenous exposure. Animal experiments show that intravascular hydrocarbons injure the first capillary bed encountered. Intravenous injection thus causes pulmonary toxicity, and portal vein injection leads to direct hepatic injury.[127,175] The clinical course after IV hydrocarbon injection mirrors that of aspiration injury.

Radiographic evidence of pneumonitis develops in 40%–88% of admitted aspiration patients.[15,44,114,125] Findings can develop as early as 15 minutes or as late as 24 hours after exposure (Fig. 106–1).[36,51,122,163] Chest radiographs performed immediately on initial presentation are not useful in predicting infiltrates in either symptomatic or asymptomatic patients.[168] Ninety percent of patients who develop radiographic abnormalities do so by 4 hours postingestion.[36] Clinical signs of pneumonia (eg, crackles, rhonchi) are evident in 40%–50% of patients.[44] A small percentage (less than 5%) are completely asymptomatic after a period of observation, but still have radiographic findings.[9]

Specific radiologic findings include perihilar densities, bronchovascular markings, bibasilar infiltrates, and pneumonic consolidation.[56] Right-sided involvement occurs in 75% of cases and bilateral involvement in approximately 50%. Upper-lobe involvement is uncommon.[25] Pleural effusions develop in 3% of cases, with one-third appearing within 24 hours.[98] Pneumothorax, pneumomediastinum, and pneumatoceles occur uncommonly.[11,17,79] Initial radiographs after ingestion may reveal two liquid densities in the stomach, known as the "double-bubble" sign. This represents an air–fluid (hydrocarbon or water) and a hydrocarbon–water interface, as the hydrocarbon is not miscible with gastric fluids (primarily water) and may have a specific gravity less than that of water.[37]

Radiographic resolution does not correlate with clinical improvement, but rather lags behind by several days to weeks. There are few reports of long-term follow up on patients with hydrocarbon pneumonitis.[25,51,62,125,152] Frequent respiratory tract infections are described in individuals after hydrocarbon pneumonitis, but studies addressing this are poorly controlled.[51,156] Delayed formation of pneumatoceles may occur.[17,79] Bronchiectasis and pulmonary fibrosis are reported but appear to be uncommon.[59,125] In one study, 82% of patients examined 8–14 years after hydrocarbon-induced pneumonitis had asymptomatic minor pulmonary function abnormalities. The abnormalities were consistent with small-airway obstruction and loss of elastic recoil. The authors hypothesized that this group may be predisposed to chronic obstructive pulmonary disease.[62]

■ CARDIAC

The most concerning cardiac effect from hydrocarbon exposure is precipitation of a dysrhythmia by myocardial sensitization (see Pharmacology previously). These events are described with all classes of hydrocarbons, but halogenated compounds are most frequently implicated, followed by aromatic compounds.[13,126] Malignant dysrhythmias occur after exposure to high concentrations of volatile inhalants or inhaled anesthetics. Atrial fibrillation, ventricular tachycardia, junctional rhythm, ventricular fibrillation, and cardiac arrest are reported.[103,111,126] This is termed the "sudden sniffing death syndrome." Myocardial depression occurs by an unclear mechanism. Prolongation of the QT interval raises concern for torsades de pointes.[14,88,133]

Any route of exposure to hydrocarbons may result in cardiotoxicity. Classically, sudden death follows an episode of sudden exertion.[14] Tachydysrhythmias, cardiomegaly, and myocardial infarction are rarely reported after ingestion of hydrocarbons.[74,143] A retrospective followup cohort of exposed methylene chloride workers did not find evidence of excess long-term cardiac disease.[115]

■ CENTRAL NERVOUS SYSTEM

Transient CNS excitation may occur after acute hydrocarbon inhalation or ingestion.[88] More commonly, CNS depression or anesthesia occurs.[44] In cases of aspiration, hypoxemia from pulmonary damage may contribute to the CNS depression.[96,176] Coma and seizures are reported in 1%–3% of cases.[114,125,179] Chronic occupational exposure or volatile substance use may lead to a chronic neurobehavioral syndrome; the painter's syndrome, most notably described after toluene overexposure. The clinical features include ataxia, spasticity, dysarthria, and dementia, consistent with leukoencephalopathy.[49] Autopsy studies of the brains of chronic toluene abusers show atrophy and mottling of the white matter, as though the lipid-based myelin were dissolved away. Microscopic examination shows a consistent pattern of myelin and oligodendrocyte loss with relative preservation of axons.[86] Animal models of toluene poisoning reveal norepinephrine and dopamine depletion. The severity and reversibility of this syndrome depends on the intensity

FIGURE 106–1. Three sequential radiographs of a young girl with severe hydro-carbon aspiration pneumonitis. (**A**) Initial: Patchy densities appear in basilar areas of both lung fields with increased interstitial markings and peribronchial thickening. (**B**) Day 2: More extensive diffuse alveolar infiltrates are apparent. (**C**) Day 6: Dense consolidation and atelectasis are evident in the right lower lobe. (*Images contributed by Nancy Genieser, MD, Professor of Radiology, New York University.*)

and duration of toluene exposure.[132] Infrequent exposure may produce no clinical neurologic signs, whereas heavy (eg, daily) use can lead to significant neurologic impairment after as little as one year, but more commonly after 2–4 years of ongoing exposure. The specific cognitive and neuropsychological findings in toluene-induced dementia are termed a white matter dementia.[46,52]

Initial findings of white matter dementia include behavioral changes, impaired sense of smell, impaired concentration, and mild unsteadiness of hand movements and gait. Further exposure leads to slurred speech, head tremor, poor vision, deafness, stiff-legged and staggering gait, and subsequent dementia. Physical findings may include nystagmus, ataxia, tremor, spasticity with hyperreflexia, abnormal Babinski

reflexes, deafness, impaired vision, and a broad-based, staggering gait. An abnormal brainstem auditory-evoked response appears to be a sensitive indicator of toluene-induced CNS damage. The electroen-cephalogram can show mild, diffuse slowing. Computed tomography in severe cases shows mild-to-moderate cerebellar and cortical atrophy. MRI findings are consistent with white matter disease. Most cases show significant clinical improvement after 6 months of abstinence, although with moderate to severe abuse, improvement may be incomplete. Chronic toluene misuse is addicting and can produce withdrawal.[132]

In the occupational setting, exposures are rarely as extensive as those that occur with volatile substance misuse. Given the significantly lesser exposures, the findings among workers overexposed to solvent

concentrations above permissible exposure limits are often subclinical, and detected primarily through neurobehavioral testing. In rare cases, however, a worker may be acutely overexposed to solvent concentrations that can produce acute CNS depression. Repeated, symptomatic overexposures over long periods of time have the potential to lead to a chronic encephalopathy, as evident from the experience with solvent abusers.[46]

■ PERIPHERAL NERVOUS SYSTEM

Peripheral neuropathy is well described following occupational exposure to *n*-hexane or methyl-*n*-butyl ketone (MnBK).[20] This axonopathy results from a common metabolic intermediate; 2,5-hexanedione. The mechanism by which this intermediate causes peripheral neuropathy probably relates to decreased phosphorylation of neurofilament proteins, with disruption of the axonal cytoskeleton (see Special Cases below). Methyl ethyl ketone (MEK) may exacerbate this neurotoxicity, probably by interfering with metabolic pathways of *n*-hexane and MnBK.[8,130] Other organic solvents, such as carbon disulfide, acrylamide, and ethylene oxide, may cause a similar peripheral axonopathy.[58] Cranial and peripheral neuropathies are reported after acute and chronic exposure to trichloroethylene (TCE).[78,92,149] Pathologically, TCE appears to induce a myelinopathy.[47,58]

Trichloroethylene is also associated with trigeminal neuralgia.[31,45,92] Trigeminal nerve damage was documented by evoked potentials following 15 minutes of TCE inhalation.[92] Some evidence suggests that decomposition products or impurities in TCE may be responsible for cranial neuropathy.[31,45]

Axonopathy from MnBK or *n*-hexane exposure typically begins in the distal extremities and progresses proximally (a classic, "dying-back" neuropathy) (see Chap. 18). Exposure to one of these hydrocarbons should be considered in the differential diagnosis of the patient with Guillain-Barré syndrome (GBS) although sensory findings are present with MnBK and absent in GBS.[139] The longest axons appear to be affected initially, so that the patient manifests a "length-dependent polyneuropathy." With discontinuation of exposure many of the effects reverse over weeks to months.[69,82,123,178] Alternatively, the phenomenon of "coasting" may occur, in which neuropathy progresses for a time (weeks to months) after discontinuation of the toxic insult.[139] A reversible peripheral neuropathy occurred in 40% of chronic toluene abusers and was characterized by severe motor weakness without sensory deficits or areflexia.[148] It is unclear whether the toluene in this series may have been contaminated by *n*-hexane or MnBK.[8,140]

■ GASTROINTESTINAL

Hydrocarbons irritate gastrointestinal mucous membranes. Nausea and vomiting are common after ingestion. As discussed earlier, vomiting may increase risk of pulmonary toxicity.[112,114,131] Hematemesis was reported in 5% of cases in one study.[112] Gastrointestinal ulcerations are seen in animal studies.[83]

■ HEPATIC

The chlorinated hydrocarbons (Table 106–1) and their metabolites are hepatotoxic. In most cases, activation occurs via a phase I reaction to form a reactive intermediate (Chap. 12). In the case of carbon tetrachloride, this intermediate is the trichloromethyl radical. This radical forms covalent bonds with hepatic macromolecules, and may initiate lipid peroxidation.[22] Carbon tetrachloride causes centrilobular necrosis after inhalational, oral ingestion, or dermal exposure.[101] Hepatotoxicity in animals has been ranked for common hydrocarbons as follows: carbon tetrachloride is greater than benzene, trichloroethylene is greater than

pentane.[174] Vinyl chloride is a liver carcinogen, and trichloroethylene, tetrachloroethylene, and 1,1,1-trichloroethane are considered less acutely hepatotoxic than vinyl chloride.[101,154] Hepatotoxicity rarely follows ingestion of petroleum distillates.[75] Hepatic injury, manifested as aminotransferase elevation and hepatomegaly, is usually reversible except in massive overexposures (see Special Cases later in the chapter).

■ RENAL

Halogenated hydrocarbons such as chloroform, carbon tetrachloride, ethylene dichloride, tetrachloroethane, 1,1,1-trichloroethane, and TCE are nephrotoxic. Acute renal failure and distal renal tubular acidosis occur in some painters and volatile-substance abusers.[81] Toluene causes a renal tubular acidosis like syndrome (see Toluene later in the chapter). Human studies of nephrotoxicity are confounded by other exposures, and findings in many animal studies conflict.[2]

■ HEMATOLOGIC

Hemolysis has been sporadically reported to occur after hydrocarbon ingestion.[1,7,146] One retrospective study of 12 patients showed hemolysis in three individuals and disseminated intravascular coagulation in another.[7] Although one patient required transfusion, hemolysis is usually mild and does not require red blood cell transfusion (also see discussion of benzene's effects on bone marrow, under Benzene later in the chapter).

■ IMMUNOLOGIC

Hydrocarbons disturb the integrity of membrane lipid bilayers, causing swelling and increased permeability to protons and other ions. This alters the structural and functional integrity of the membrane. Changes in the lipid composition of the membrane occur, and membrane lipopolysaccharides and proteins are disturbed.[138] Resultant toxicity may directly destroy capillary endothelium.[21] Additionally, there appears to be derangement of basement membranes, and this is postulated to underlie both alveolar and glomerular toxicity of hydrocarbons.[144] Immune mechanisms may account for basement membrane dysfunction in chronic exposures. Hydrocarbon exposure is suggested as one possible cause of the Goodpasture syndrome (immune dysfunction causing both pulmonary damage and glomerulonephritis),[19] though the association is not widely accepted. Measurable changes in immune function occur after hydrocarbon exposure,[12] but our knowledge of any clinical implication is deficient.

■ DERMATOLOGIC

Most hydrocarbon solvents cause nonspecific irritation of skin and mucous membranes. Repeated, prolonged contact can dry and crack the skin. The mechanism of dermal injury appears to be defatting of the lipid layer of the stratum corneum. Up to 9% of workers may develop eczematous lesions from dermal contact.[177] Limonene and turpentine contain sensitizers that can rarely result in contact allergy (Chap. 29).

Contact dermatitis and blistering may progress to partial- and even full-thickness burns.[65] Severity is proportional to duration of exposure. Hydrocarbons are irritating to skin. Acute, prolonged exposure can cause dermatitis and even full-thickness dermal damage.[65] Chronic dermal exposure to kerosene or diesel fuel can cause oil folliculitis.[38,161] A specific skin lesion called chloracne is associated with exposure to chlorinated aromatic hydrocarbons with highly specific stereochemistry (eg, dioxins, polychlorobiphenyls).

Soft-tissue injection of hydrocarbon is locally toxic, leading to necrosis. Secondary cellulitis, abscess formation, and fasciitis can occur.

Infectious complications are treated by meticulous wound care, with surgical debridement as necessary. A particularly destructive injury involves high-pressure injection-gun injury. These injuries typically involve the extremities, with high-pressure injection of grease or paint into the fascial planes and tendon sheaths. Emergent surgical debridement is necessary in most of these cases.[48,106]

HYDROCARBONS WITH SPECIFIC AND UNIQUE TOXICITY

■ *n*-HEXANE

Hexane is a six-carbon simple aliphatic hydrocarbon. It is a constituent of some brake-cleaning fluids, rubber cement, glues, spray paints, coatings, and silicones. Outbreaks of *n*-hexane–related neurotoxicity have occurred in printing plants, sandal shops, furniture factories, and automotive repair shops.[32] Human exposure occurs primarily by inhalation. Both *n*-hexane and MnBK are well-known peripheral neurotoxins that cause a classic "dying-back" peripheral polyneuropathy, beginning in a "stocking-glove" distribution.[20,33] Neurotoxicity does not appear to be directly caused by the parent compounds, but results from a common metabolic intermediate—2,5-hexanedione. Toxicity appears related to the ability of this intermediate to form a ringed pyrrole structure, which causes decreased phosphorylation of neurofilament proteins, disrupting the axonal cytoskeleton.[58] Similar five- and seven-carbon species do not induce similar neurotoxicity, except those that are direct precursor intermediates in the metabolic pathway producing 2,5-hexanedione[58,150] (see Fig. 106–2).

■ METHYLENE CHLORIDE

Methylene chloride is commonly encountered in paint removers, as well as in cleaners and degreasers and in aerosol propellants. Like other halogenated hydrocarbons, it can rapidly induce general anesthesia by inhalation or ingestion. Unlike other hydrocarbon agents, methylene chloride and similar one carbon halomethanes (eg, methylene dibromide) are metabolized by liver P450 2E1 mixed-function oxidase to carbon monoxide. Significant, delayed, and prolonged carboxyhemoglobinemia can occur (Table 106–2 and Chap. 125).[4,124]

■ CARBON TETRACHLORIDE

Carbon tetrachloride (CCl_4), although not actually a hydrocarbon, has been used as an industrial solvent and reagent. Its use in the United States has declined dramatically since recognition of its toxicity caused the

Environmental Protection Agency (EPA) to restrict its commercial use.[3] Absorption occurs by all routes, including dermal. CCl_4 is an irritant to skin and mucous membranes and is a potent gastric irritant when ingested. As with other halogenated hydrocarbons, aspiration can result in pneumonitis, and systemic absorption may result in ventricular dysrhythmias.

More unique to CCl_4 exposures are hepatotoxicity and nephrotoxicity. Both occur more commonly with repetitive exposure (eg, occupational exposures).[34,76,153] Toxicity follows phase-I dehalogenation of the parent compound, which produces free radicals, causes lipid peroxidation and the production of protein adducts.[22] Localization of specific phase-I hepatic enzymes in the centrilobular area of the liver results in regionalized (zone 3) centrilobular injury after CCl_4 exposure (Chap. 26). Hepatotoxicity is typically manifested as reversible aminotransferase concentration elevations with or without hepatomegaly. Cirrhosis is reported in both animal models and in humans with prolonged overexposures. Nephrotoxicity is less-well studied but may result from a similar mechanism. The proximal convoluted tubule and the loop of Henle appear to be specifically targeted.[50] Carbon tetrachloride is a suspected human carcinogen.[3]

■ TRICHLOROETHYLENE

Trichloroethylene is a commonly used industrial solvent, cleanser, and degreaser. TCE was used for years as a general anesthetic agent, and hundreds of disposal sites in the United States. remain sources of ongoing human exposure. Its use as a general anesthetic was abandoned because of acute cardiotoxicity. TCE is also hepatotoxic, neurotoxic, and nephrotoxic in humans and animals. A recent report links TCE exposure to the development of neurodegenerative diseases, such as Parkinsonism.[54] This study has not been repeated or further validated.

An interagency group convened by the National Research Council recently assessed health risks associated with TCE. This group noted that compelling recent information implicates TCE as a human carcinogen. The final report calls upon federal agencies to finalize risk assessments so that informed risk management decisions about TCE can be made expeditiously.[107]

■ BENZENE

Benzene is hematotoxic and associated with acute hemolysis, or the delayed development of aplastic anemia and acute myelogenous leukemia.[5,57,89,100,119] Other aromatic hydrocarbons that are reported to cause similar hematologic effects most likely are contaminated with benzene. An excess risk of hematologic toxicity has not been demonstrated in groups with long-term exposure to toluene, xylene, or other aromatic hydrocarbons.[10,40,128,164,172] Other hematologic malignancies also may be linked to benzene, including chronic myelocytic leukemia, myelodysplastic syndromes, and lymphoma.[155] Chromosomal changes are believed to provide a marker for carcinogenicity.[159] Because of the carcinogenic risk, most benzene-based solvents have been unilaterally removed from the US market, and OSHA has limited the permissible worker exposure level to 1 ppm.[72]

■ TOLUENE

Toluene has essentially replaced benzene as the primary organic solvent in many commercial products. Many oil paints and stains contain primarily toluene as solvent. As such, it is readily available and readily abused as an inhalant. The CNS sequelae of chronic solvent inhalation are most frequently related to chronic toluene exposure.

Chronic toluene abuse can also cause a syndrome that resembles transient distal renal tubular acidosis (RTA).[151,166] Although the mechanism is incompletely understood, the acidosis results in great part from
FIGURE 106–2. The metabolism of both organic solvents *n*-hexane and methyl *n*-butyl ketone produce the same common metabolite, 2,5-hexanedione.

the urinary excretion of hippuric acid (Table 106-2).[30,80] Renal potassium loss may be severe and can result in symptomatic hypokalemia.[80] Clinical findings are a hyperchloremic metabolic acidosis, hypokalemia, and aciduria. Typically an associated transient azotemia occurs, as well as proteinuria and an active urine sediment.[148,166] Some have reported a proximal RTA, or the Fanconi syndrome.[105,166] A metabolic acidosis resulting from the metabolism of toluene to benzyl alcohol through alcohol dehydrogenase to benzoic acid may be an adequate explanation for the serum and urine acid–base disturbances.

■ PINE OIL AND TERPENES

Pine oil is an active ingredient in many household cleaning products. It is a mixture of unsaturated hydrocarbons comprised of terpenes, camphenes, and pinenes. The major components are terpenes, which are found in plants and flowers. Wood distillates are products derived from pine trees and include pine oil and turpentine. Patients who ingest pine oil often emit a strong pine odor. Wood distillates are readily absorbed from the gastrointestinal tract and ingestion may cause CNS and pulmonary toxicity without aspiration.

The clinical features of pine oil ingestion can include CNS depression, respiratory failure, and gastrointestinal dysfunction and are rarely fatal.[85,171] Aspiration pneumonitis remains the primary clinical concern. Acute toxicity is similar to that of petroleum distillate ingestion, and management is similar. Rare reported complications of wood distillate ingestion include turpentine-associated thrombocytopenic purpura, acute renal failure, and hemorrhagic cystitis.[90,167]

■ TAR AND ASPHALT INJURY

Tar and asphalt injuries are common occupational hazards among construction workers. Asphalt workers are at risk for toxic gas exposure of hydrogen sulfide, carbon monoxide, propane, methane, and volatilized hydrocarbons.[70] In addition, cutaneous exposure to these hot hydrocarbon mixtures can cause severe burns. The material quickly hardens and is very difficult to remove. However immediate cooling with cold water is important to limit further thermal injury. Complete removal is essential to ensure proper burn management and to limit infectious complications. Attempts to mechanically remove hardened tar or asphalt often cause further damage. Dissolving the material with mineral oil, petroleum jelly, or antibacterial ointments are met with variable success. Surface-active agents combined with an ointment (De-Solv-it, Tween-80, Polysorbate 80) are more effective.[41,147,158]

DIAGNOSTIC TESTING

Laboratory and ancillary testing for hydrocarbon toxicity should be guided by available information regarding the specific xenobiotic, the route of exposure, and the best attempt at quantifying the exposure. Inhalation or ingestion of hydrocarbons associated with pulmonary aspiration is most likely to result in pulmonary toxicity. The use of pulse oximetry and arterial blood gas testing in this group of patients is warranted when clinically indicated. Early radiography is indicated in patients who are severely symptomatic; however, radiographs performed immediately after hydrocarbon ingestion demonstrate a low predictive value for the occurrence of aspiration pneumonitis. In the asymptomatic patient, early radiography is not cost-effective. Patients observed for 6 hours after an ingestion, who demonstrate no abnormal pulmonary findings, have adequate oxygenation, are not tachypneic, and have a normal chest radiograph after the 6-hour observation period, have a good medical prognosis with very low risk of subsequent deterioration.[9,168]

The choice of specific diagnostic laboratory tests to assess organ system toxicity or function following exposure to a hydrocarbon depends on the type, dose, and route of exposure, and on the assessment of the patient's clinical condition. Useful clinical tests may include pulse oximetry and an electrocardiogram (ECG).[116] Laboratory tests include serum or urine electrolytes, arterial blood gas, complete blood counts, and creatine phosphokinase. If a hydrocarbon has specific target organ toxicities (eg, benzene/bone marrow, carbon tetrachloride/liver, or n-hexane/peripheral nervous system), evaluating and monitoring target organ system function is indicated.

Specific diagnostic testing for hydrocarbon poisoning can include (1) bioassays for the specific hydrocarbon or its metabolites in blood, breath, or urine, or (2) assessment of toxicity. Bioassays for a hydrocarbon are seldom necessary for diagnosis or management of hydrocarbon poisoning in the emergency setting and rarely clinically available. Exceptions might include testing to assist in differential diagnosis (eg, testing for carbon tetrachloride in a comatose patient with unexplained hepatic and renal toxicity or a carboxyhemoglobin determination in a paint stripper with chest pain), testing for worker compensation purposes (eg, testing for urinary trichloroethanol and trichloroacetic acid in a worker exposed to trichloroethylene with unexplained bouts of dizziness), or for forensic purposes (eg, sudden death in a huffer).

When deciding whether to obtain a bioassay for a hydrocarbon, the clinician should determine the following: (1) What is the most informative biologic sample (blood, urine, breath) and how should it be collected, handled, and stored? (2) What are the kinetics of the hydrocarbon and the timing of exposure, and how should the results be interpreted in light of these kinetics? (3) What ranges of concentrations are associated with toxicity? Most hydrocarbon bioassays are performed by only a few, specialized clinical laboratories. The analytic toxicologist can often assist the clinician in determining the appropriate choice and timing of a bioassay. Table 106-2 provides useful information on the elimination kinetics of selected hydrocarbons and on their common metabolites.

Chronic overexposures to hydrocarbons, as occur with volatile substance use, can result in persistent damage to the central nervous system. Damage can be detected and quantified using neuroimaging methods such as magnetic resonance imaging (MRI) or positron emission tomography (PET). Major MRI findings in patients with chronic toluene abuse include atrophy, white matter T2 hyperintensity, and T2 hypointensity involving the basal ganglia and thalamus.[29] Neurobehavioral testing can be used to detect subtle central nervous system effects following chronic occupational overexposures.

MANAGEMENT

Identification of the specific type, route, and amount of hydrocarbon exposure is rarely essential to achieve effective management.

Decontamination is one of the cardinal principles of toxicology, with priority that is second only to stabilization of the cardiopulmonary status. Safe decontamination can avoid further absorption and avoids secondary casualties in those attempting to provide care. Protection of rescuers with appropriate personal protective equipment and rescue protocols is paramount, especially in situations where the victim has lost consciousness. The principle of removing the patient from the exposure (eg, vapor or gaseous hydrocarbon) or the exposure from the patient (eg, hydrocarbon liquid on skin or clothing), while protecting the rescuer, implies that personal protective equipment be considered at each level of the healthcare delivery system.

Exposed clothing should be removed and safely discarded as further absorption or inhalation of hydrocarbons from grossly contaminated clothing can worsen systemic toxicity.[145] Decontamination of the skin

TABLE 106–3. Orogastric Lavage for Hydrocarbon Ingestion

Contraindications
  Occurrence of spontaneous vomiting
  Asymptomatic initally and at initial medical evaluation
Indications
  Hydrocarbons with inherent systemic toxicity (CHAMP)
    C: camphor
    H: halogenated hydrocarbons
    A: aromatic hydrocarbons
    M: hydrocarbons containing metals
    P: hydrocarbons containing pesticides

should have a high priority in massive hydrocarbon exposures, particularly those exposures involving highly toxic hydrocarbons (Table 106–3). Water alone may be ineffective in decontaminating most hydrocarbons, but early decontamination with soap and water may be adequate. The caregiver should remain aware that certain hydrocarbons are highly flammable and pose a fire risk to hospital staff (see Chap. 130).

Several studies have attempted to evaluate the role of gastric decontamination after hydrocarbon ingestion. Results were largely inconclusive and the level of evidence, poor. In the subset of patients who were randomized to receive gastric lavage, 44% had pulmonary complications, compared with 47% of those who were not lavaged. Available studies do not offer a conclusive answer to the question of gastric emptying after hydrocarbon ingestion.[122]

In the absence of a contraindication, gastric emptying is potentially useful only when the hydrocarbon has inherent severe toxicity or is co-ingested with a more potent xenobiotic (Table 106-3). Patients who have no symptoms at home or upon initial medical evaluation are unlikely to need gastric emptying.[9,95] For patients who do undergo gastric emptying, gastric lavage is likely the superior method.[109,110,122] If lavage is performed, a small nasogastric tube (18-French, not a large-bore tube) should be employed. If no gag reflex is present, an endotracheal tube should be placed prior to lavage (Chap. 7).

Activated charcoal (AC) has limited ability to decrease gastrointestinal absorption of hydrocarbons and may distend the stomach and predispose patients to vomiting and aspiration.[90,102,169] The use of AC may be justified in patients with mixed overdoses, but its role in isolated hydrocarbon ingestions appears very limited. The use of cathartics and promotility agents for hydrocarbon ingestions is also of limited importance in current management.

The use of olive oil or mineral oil was previously suggested as management for hydrocarbon ingestions.[15,51,179] Although these hydrocarbon oils have very high viscosities and low aspiration potential, they show no benefit in animal models,[102] can cause hydrocarbon pneumonitis and lipoid pneumonia themselves, and are therefore not indicated.[39]

Antibiotics are frequently administered in the setting of hydrocarbon pneumonitis to treat possible bacterial superinfection.[36,71,88,112,122,163] In experimental models, superinfection occurs as rapidly as 7 hours after aspiration.[71] Using radiolabeled *Staphylococcus aureus,* hydrocarbon-injured lungs were shown to have a decreased ability to clear bacteria by 4 hours after insult.[27]

Despite this, animal models, including guinea pigs, dogs, and baboons, did not demonstrate any efficacy of prophylactic antibiotics.[24,142,175]

One study showed that administered antibiotic altered bacterial lung flora to predominantly Gram-negative organisms, compared to Gram-positive lung cultures in the controls.[24] These studies led to decreased use of prophylactic antibiotics, so that clinical evidence of infection dictated therapy for most clinicians.[44] This approach, however, is not without limitations. Abnormal lung auscultation, fever, leukocytosis, and abnormal radiographic findings are the initial manifestations of both bacterial pneumonia and hydrocarbon pneumonitis. Abnormal temperatures are reported to occur in 50%–90% of patients with hydrocarbon toxicity.[15,36,112,114] An elevated temperature is often initially noted, with the temperature reaching maximum at 8–12 hours, then declining over several days.[36,114] Leukocytosis is frequently reported, present in up to 60% of patients who aspirate hydrocarbons.[112,114,125]

Antibiotic administration may be justified in severely poisoned patients. Ideally, sputum cultures should direct antibiotic use. These, however, are often delayed and are not useful in critically ill patients. Most authorities do not recommend prophylactic antibiotics. Most recommend close observation of temperature and blood leukocyte count, as delayed elevation (24 hours after presentation) of temperature and/or leukocytes may signal bacterial superinfection. No human studies are available to support either approach, and this issue remains controversial.

Corticosteroids, like antibiotics, have been prophylactically administered in the setting of hydrocarbon pulmonary toxicity.[59,122] The rationale for their use is prevention and limitation of the inflammatory response in the lungs after hydrocarbon injury. Animal models do not show any benefit of corticosteroid administration.[6,24,142] In one study, corticosteroids increased the risk for bacterial superinfection with or without concomitant antibiotics.[24] Furthermore, two controlled human trials failed to show a benefit from corticosteroid administration.[66,97] It is clear that corticosteroid use does not improve the acute course of hydrocarbon pulmonary toxicity, although some authors suggest improved outcome with delayed corticosteroid therapy there is little supporting evidence.[79,84] Coupled with the possible increased risk of bacterial superinfection, corticosteroid administration in this setting is not recommended.

Patients with severe hydrocarbon toxicity pose unique problems for management. Respiratory distress requiring mechanical ventilation in this setting may be associated with a large ventilation–perfusion mismatch. The use of positive end-expiratory pressure (PEEP) in this setting is often beneficial. However, very high levels of PEEP may be required with subsequent increased risk of barotrauma.[131,180] High-frequency jet ventilation (HFJV), using very high respiratory rates (220–260) with small tidal volumes, has helped to decrease the need for PEEP.[28] Patients who continue to have severe ventilation–perfusion mismatch despite PEEP and HFJV have benefitted from extracorporeal membrane oxygenation (ECMO).[67,73,180] ECMO appears to be a useful option in severe pulmonary toxicity after other treatments have failed.

Cyanosis is uncommon after hydrocarbon toxicity. Although this is most often caused by severe hypoxia, methemoglobinemia associated with hydrocarbon exposure is reported.[35,91] The potential for methemoglobinemia should be investigated in patients who remain cyanotic following normalization of arterial oxygen tension.

Hypotension in severe hydrocarbon toxicity raises additional concerns. The etiology of hypotension in this setting is often compromise of cardiac output because of high levels of PEEP. Hydrocarbons do not have significant direct cardiovascular effects, and decreasing the PEEP may improve hemodynamics. The use of β-adrenergic agonists such as dopamine, epinephrine, isoproterenol, and norepinephrine should be avoided if possible, as certain hydrocarbons predispose to dysrhythmias.[14,126]

Management of dysrhythmias associated with hydrocarbon toxicity should include consideration of electrolyte and acid–base abnormalities

such as hypokalemia and acidosis result from toluene, hypoxemia, hypotension, and hypothermia. Ventricular fibrillation poses a specific concern, as common resuscitation algorithms recommend epinephrine administration to treat this rhythm. If it is ascertained that the dysrhythmia emanates from myocardial sensitization by a hydrocarbon solvent, catecholamines should be avoided. In this setting, lidocaine has been used successfully, as have β-adrenergic antagonists.[103]

Hyperbaric oxygen (HBO) was studied in a rat model of severe kerosene-induced pneumonitis.[134] HBO at 4 ATA showed some benefit in 24-hour survival rates. No followup studies have been performed. Patients with carbon tetrachloride poisoning, however, may benefit from hyperbaric oxygen (see Antidotes in Depth A37: Hyperbaric Oxygen).[26,157]

In the past, hospital admission was routinely recommended for patients who had ingested hydrocarbons, because of concern over possible delayed symptom onset and progression of toxicity.[36,60] Several reports documented patients with relatively asymptomatic presentations who rapidly decompensated with respiratory compromise. However, progressive symptoms after hydrocarbon ingestion are rare.[9,95] In a retrospective study of 950 patients, only 14 (1.5%) had progression of pulmonary toxicity.[9] Of these 14, seven had persistence of symptoms for less than 24 hours. Eight hundred patients were asymptomatic on initial evaluation with normal chest radiographs, remained asymptomatic after 6–8 hours of observation, and had a normal repeat radiograph. No patient in this group of 800 had progressive symptoms, and all were discharged without clinical deterioration. Seventy-one of the 950 patients had initial respiratory symptoms but were asymptomatic at initial medical evaluation. Of the 71 patients, 36 had radiographic evidence of pneumonitis. Among these 36 patients, 2 (6%) developed progression of pulmonary symptoms during their 6-hour observation period. Of the 35 who had a normal radiograph, 2 (6%) developed pulmonary symptoms and radiographic pneumonitis during the 6-hour observation period. The four patients who were hospitalized for progression of symptoms became asymptomatic over the next 24 hours and had no complications.

A separate poison center-based study evaluated 120 asymptomatic patients for an 18-hour telephone followup period.[95] Sixty-two patients had initial pulmonary symptoms that quickly resolved. One of the 62 patients (1.6%) developed progressive pulmonary toxicity. This patient was hospitalized and had resolution of symptoms within 24 hours without complications.

A number of investigators have suggested protocols for determining which patients can be safely discharged.[9,83,95] None of these protocols has been prospectively validated. However, rational guidelines for hospitalization can be recommended. Those patients who have clinical evidence of toxicity, and most individuals with intentional ingestions, should be hospitalized. Patients who do not have any initial symptoms, have normal chest radiographs obtained at least 6 hours after ingestion, and who do not develop symptoms during the 6-hour observation period can be safely discharged. Care should be individualized for patients who are asymptomatic but who have radiographic evidence of hydrocarbon pneumonitis, and for patients who have initial respiratory symptoms but quickly become asymptomatic during medical evaluation. Reliable patients may be considered for possible discharge with next-day followup.

SUMMARY

Hydrocarbons are a diverse group of xenobiotics that can cause toxicity by inhalation, ingestion, or dermal absorption. Most hydrocarbons occur as mixtures of several to many chemicals. Ubiquitous use of hydrocarbons in our society means that exposures are extremely common. Populations at particular risk for toxicity include children who ingest hydrocarbon compounds, workers who are occupationally exposed by inhalation or dermal absorption, and youths who intentionally inhale volatile hydrocarbons.

Toxicity is largely determined by the route of exposure, and is xenobiotic-specific. Aspiration pneumonitis is the primary concern after hydrocarbon ingestion. Many hydrocarbons are poorly absorbed from the gastrointestinal tract and unlikely to produce systemic poisoning. Acute systemic toxicity is unlikely to occur in the absence of CNS effects such as excitation or sedation. Most hydrocarbons are capable of producing profound CNS depression, even general anesthesia if absorbed systemically.

Specific hydrocarbons may demonstrate specific organ toxicity: halogenated hydrocarbons are cardiotoxic, hepatotoxic, and nephrotoxic. Most are also acutely toxic to the CNS and some are peripheral neurotoxins. Diagnosis is predominantly clinical. Diagnostic studies are rarely specific, and hydrocarbon-specific studies are seldom helpful in the acute setting. Skin decontamination is important in massive dermal exposures. Gastrointestinal decontamination, as well as the use of prophylactic antibiotics or corticosteroids are rarely if ever indicated initially. Management is largely supportive, and no specific antidotes are available.

CHAPTER 107
TOXIC ALCOHOLS

Sage W. Wiener
Ethylene glycol **Isopropanol** **Methanol**

Ethylene Glycol
MW = 62 Daltons
Isopropanol
MW = 60 Daltons
Methanol
MW = 32 Daltons

Toxic alcohols are important components of many household, automotive, and industrial products, and they are frequently implicated in suicidal, unintentional, and even epidemic poisoning. Consideration of toxic alcohols as a cause of illness is also often encountered clinically in the differential diagnosis of a metabolic acidosis with an elevated anion gap. Evaluation of these patients is complex, in part because serum concentrations are not readily available in many institutions. Treatment involves a choice between the antidotes fomepizole and ethanol in addition to multiple other therapeutic modalities including hemodialysis, bicarbonate, thiamine, pyridoxine, and folate. Further complicating matters, the role of hemodialysis remains controversial despite a long history of its effective use in treating patients poisoned by toxic alcohols.

HISTORY AND EPIDEMIOLOGY

Methanol was a component of the embalming fluid used in ancient Egypt. Robert Boyle first isolated the molecule in 1661 by distilling boxwood, calling it *spirit of box*.[23] The molecular composition was determined in 1834 by Dumas and Peligot, who coined the term *methylene* from the Greek roots for "wood wine."[145] Industrial production began in 1923, and today most methanol is used for the synthesis of other chemicals. Methanol-containing consumer products that are commonly encountered include model airplane fuel, windshield washer fluid, solid cooking fuel for camping and chafing dishes, photocopying fluid, perfumes, and gas line antifreeze ("dry gas"). Methanol is also used as a solvent by itself or as an adulterant in "denatured" alcohol.[95] Most reported cases of methanol poisoning in the United States involve ingestions of one of these products, with over 60% involving windshield washer fluid.[38] In a Tunisian series, ingested cologne was the most common etiology.[24] There have also been sporadic epidemics of mass methanol poisoning, most commonly involving tainted fermented beverages.[18,90] These epidemics are a continuing problem in many parts of the world.[12,105,133,173]

Ethylene glycol was first synthesized in 1859 by Charles-Adolphe Wurtz and first widely produced as an engine coolant during the second World War, when its precursor ethylene oxide became readily available.[47] Today its primary use remains as an engine coolant antifreeze used in car radiators. Antifreeze used in gas tanks generally contains methanol. Because of its sweet taste, it is unintentionally consumed by animals and children. Aversive bittering agents have been added to ethylene glycol-containing antifreeze to try to prevent ingestions by making the antifreeze unpalatable, an approach required by law in two states. However, no evidence suggest that this strategy is effective, and comparisons in poison center data between ethylene glycol ingestions where bittering agents were required and where they were not have revealed no significant differences in frequency or volume of ingestion, or any other outcome variable.[170]

Isopropanol is primarily available as rubbing alcohol. Typical household preparations contain 70% isopropanol. It is also a solvent used in many household, cosmetic, and topical pharmaceutical products. Perhaps because it is so ubiquitous, inexpensive, and its common name contains the word alcohol, isopropanol ingestions are the most common toxic alcohol exposure reported to poison centers in the United States,[29] typically in cases where it was used as an ethanol substitute (see Chap. 135).

CHEMISTRY

Alcohols are hydrocarbons that contain a *hydroxyl* (-OH) group. The term *toxic alcohols* traditionally refers to alcohols other than ethanol, those not intended for ingestion. In a sense, this is arbitrary, since all alcohols are toxic, causing inebriation and end-organ effects if taken in excess. The most common clinically relevant toxic alcohols are methanol and ethylene glycol (1,2-ethanediol). Ethylene glycol contains two hydroxyl groups; molecules with this characteristic are termed *diols* or *glycols* because of their sweet taste. Other common toxic alcohols include isopropanol (isopropyl alcohol or 2-propanol), benzyl alcohol (phenylmethanol), and propylene glycol (1,3-propanediol). *Primary* alcohols, such as methanol and ethanol, contain a hydroxyl group on the end of the molecule (the *terminal* carbon), whereas *secondary* alcohols, such as isopropanol, contain hydroxyl groups bound to middle carbons. Glycol ethers are glycols with a hydrocarbon chain bound to one or more of the hydroxyl groups (forming the basic structure $R^1O-CH_2-CH_2-O-R^2$ or $R^1O-CH_2-CH_2-CH_2-OR^2$). Poisoning with these compounds may clinically resemble toxic alcohol poisoning, and will be discussed in detail in Special Considerations: Diethylene Glycol. Glycol ethers commonly encountered include ethylene glycol butyl ether (also known as 2-butoxyethanol, ethylene glycol monobutyl ether, or butyl cellusolve), ethylene glycol methyl ether (2-methoxyethanol), and diethylene glycol (2,2'-dihydroxydiethyl ether).

TOXICOKINETICS/TOXICODYNAMICS

Alcohols are rapidly absorbed after ingestion[51,59] but not completely bioavailable because of metabolism by gastric alcohol dehydrogenase, as well as by first pass hepatic metabolism. Occasionally, delayed or prolonged absorption may occur.[45] Although methanol may also be absorbed in significant amounts by inhalation, poisoning by this route is uncommon. In workers exposed to methanol fumes from industrial processes for up to 6 hours at concentrations of 200 ppm (the Occupational Health and Safety Administration [OSHA] permissible exposure limit), there was no significant accumulation of methanol or its metabolite formate.[102] Another study showed that with methanol use in the semiconductor industry, ambient methanol concentrations generally do not approach this OSHA limit even in an a room with low ventilations rates and with no local exhaust ventilation.[57] Surprisingly, concentrations far in excess of the OSHA concentration limit can be present within the passenger compartment of a car when using the windshield wipers and methanol-containing windshield-washing fluid.[16] No cases of human poisoning have been reported from this

type of exposure, probably because these concentrations are not sustained over a long time. However, cases of inhalational poisoning have been reported with intentional inhalation of methanol as a drug of abuse ("huffing") (see Chap. 81) and with massive exposures of rescue workers responding to the scene of an overturned rail car filled with methanol.[10,52,110,165] Two case series suggest that patients who present after chronic inhalation of methanol do well with folate and ADH blockade alone and without need for hemodialysis.[15,110] Ethylene glycol has low volatility and is not reported to cause poisoning by inhalation. In one study, human volunteers inhaled vaporized ethylene glycol at a concentration of 1340–1610 mM for 4 hours to simulate an industrial exposure. Afterward, the volunteers had detectable but not clinically significant concentrations of ethylene glycol and its metabolites.[164] Most alcohols have some dermal absorption, although isopropanol and methanol are able to penetrate the skin much better than ethylene glycol.[41,106,167] Most reported cases of toxic alcohol poisoning by this route involve infants,[37] because of their greater surface area to volume ratio, and likely also involved simultaneous inhalation. One reported case of transdermal methanol poisoning involved a 51-year-old woman, but details of the exposure were not reported.[156] Another case involved a 52-year-old woman who reportedly frequently massaged with methanol-containing cologne and spirit over the course of 3 days. That patient suffered significant visual and neurologic sequelae despite aggressive treatment with ethanol and hemodialysis.[1] One methanol fatality was deemed to be caused by transdermal absorption (in addition to blunt trauma) when high tissue methanol concentrations were measured in the absence of detectable methanol in the gastrointestinal tract,[11] but inhalational exposure could also conceivably have contributed. When human volunteers were exposed to 100% ethylene glycol applied to a 66 cm^2 area of skin under an occlusive dressing for 6 hours, detectable but not clinically significant amounts were absorbed.[164]

Once absorbed, alcohols are rapidly distributed to total body water. In human volunteers given an oral dose of methanol on an empty stomach, the measured Vd was 0.77 L/kg, with a distribution half-life of about 8 minutes.[59] This is only slightly longer than the absorption half-life, so serum concentrations typically peak soon after ingestion and then begin to fall.

Without intervention, toxic alcohols are metabolized through successive oxidation by alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), each of which is coupled to the reduction of NAD$^+$ to NADH and H$^+$. Methanol is metabolized to formaldehyde, then formic acid (Fig. 107–1). Ethylene glycol has two hydroxyl groups that are serially oxidized by ADH and ALDH, producing, in turn, glycoaldehyde, glycolic acid, glyoxylic acid, and finally oxalic acid (Fig. 107–2). Like ethanol, this metabolism follows zero-order kinetics, with a rate that is reported to be about 10 mg/dL/hr.[35,83,119] Additionally, this rate is apparently unchanged in chronic ethanol users.[65,66]

Alternate minor metabolic pathways such as catalase exist for methanol and ethylene glycol. After methanol ingestion, the formate metabolite is bound by tetrahydrofolate and then undergoes metabolism by 10-formyltetrahydrofolate dehydrogenase to carbon dioxide and water. Ethylene glycol is metabolized to ketoadipate and glycine using thiamine and pyridoxine as co-factors.[126] Because of the low toxicity of these ethylene glycol metabolites, these normally minor metabolic pathways are attractive targets for potential therapy.

Methanol and ethylene glycol may also be eliminated from the body as unchanged parent compounds. When renal function is normal, ethylene glycol is slowly cleared by the kidneys, with a half-life of approximately 11 to 18 hours.[22,33,154] Methanol does not have significant renal elimination and is cleared much more slowly than is ethylene glycol presumably as a vapor in expired air (half-life 30–54 hours).[26,134]

CLINICAL MANIFESTATIONS AND PATHOPHYSIOLOGY

CNS EFFECTS

All alcohols may cause inebriation, depending on the dose. Based on limited animal data, it appears that higher molecular weight alcohols are more intoxicating than lower molecular weight alcohols (therefore, isopropanol ≈ ethylene glycol > ethanol > methanol).[169] However, the absence of apparent inebriation does not exclude toxic alcohol ingestion, particularly if the patient chronically drinks ethanol and is thereby tolerant to its central nervous system (CNS) effects.[160] This is intuitively obvious; serum methanol concentrations of 25 to 50 mg/dL may potentially be associated with toxicity, whereas in most states one may legally drive a car with a blood alcohol concentration of 80 mg/dL.

The CNS manifestations of toxic alcohol poisoning are incompletely understood. It is assumed by analogy that inebriation is similar to that of ethanol, where effects are mediated through increased GABAergic tone both directly and through inhibition of presynaptic GABA, $GABA_A$ receptors as well as inhibition of the N-methyl-D-aspartic acid (NMDA) glutamate receptors.[6,31,60,72,121] Although the CNS effects of other alcohols are clinically similar, there is no direct evidence that they are mechanistically the same.

METABOLIC ACIDOSIS

Metabolic acidosis with an elevated anion gap is a hallmark of toxic alcohol poisoning. This is a consequence of the metabolism of these alcohols to toxic organic acids. The acids have no rapid natural metabolic pathway of elimination unlike acetic acid from ethanol metabolism, which can enter the Krebs cycle, and therefore they accumulate. In methanol poisoning, formic acid and lactic acid in the most seriously ill are responsible for the acidosis, whereas in ethylene glycol poisoning, glycolic acid is the primary acid responsible for the acidosis, with other metabolites making a minor contribution. An exception to the formation of an acid metabolite is isopropanol, which is metabolized to acetone. Acetone is a ketone, not an aldehyde, and therefore cannot be further metabolized by aldehyde dehydrogenase (ALDH) (Fig. 107–3). Thus it has no organic acid metabolite and does not cause metabolic acidosis. In fact, ketosis without acidosis is diagnostic of isopropanol poisoning. Occasionally, a non-anion gap metabolic acidosis may result from ethylene glycol poisoning (almost 18% in one series), often concurrently with anion gap acidosis.[155] The mechanism for this is unclear, but a similar pattern has been observed in the setting of diabetic ketoacidosis, lactic acidosis, alcoholic ketoacidosis, and toluene poisoning.

END-ORGAN MANIFESTATIONS

Additional end-organ effects depend on which alcohol is involved. Methanol causes visual impairment ranging from blurry or hazy vision or defects in color vision, to "snowfield vision" or total blindness in severe poisoning. On physical examination, central scotoma may be present on visual field testing, and both hyperemia and pallor of the optic disc, papilledema, and an afferent papillary defect are described as characteristic findings.[18,131,176] Electroretinography may demonstrate a diminished b-wave,[163] a marker of bipolar cell dysfunction, and optical coherence tomography (similar in principal to ultrasound, but using reflected light waves to image translucent tissues) may demonstrate peripapillary nerve fiber swelling and intraretinal fluid accumulation.[54] The formate metabolite of methanol is a mitochondrial toxin, inhibiting cytochrome oxidase and thereby interferes with oxidative phosphorylation.[46,127,128] Although it is unclear why this results in ocular toxicity while other tissues are relatively spared, retinal
FIGURE 107–3. Isopropanol metabolism.

pigmented epithelial cells and optic nerve cells appear to be uniquely susceptible.[44,116,162,163]

Interestingly, neurons in the basal ganglia appear to be similarly susceptible to this toxicity; bilateral basal ganglia lesions, the putamen, and less commonly, caudate nucleus are characteristically abnormal visualized on cerebral computerized tomography or magnetic resonance imaging after methanol poisoning.[3,8,19,20,40,42,49,55,67,68,136,147,151] While lesions of this type are nonspecific, and may occur in other disease states, such as hypoxia, hypotension, and carbon monoxide exposure, they may occur in the absence of hypotension and hypoxia in methanol poisoning,[117] suggesting a direct toxic mechanism. In one series, typical radiological lesions were present in six of nine cases.[151] Other CNS lesions reported include necrosis of the corpus callosum[93] and intracranial hemorrhage.[9,150] Rarely, injury to other tissues may also occur; both renal failure and pancreatitis are reported after methanol poisoning.[70,96] For unclear reasons, one case series showed a much higher incidence of pancreatitis (50%)[70] and in another, 11 of 15 patients had pancreatitis[166] but this is not typical. Some of the renal failure that results from methanol poisoning may be due to myoglobinuria.[61] In one series of methanol-poisoned patients with renal failure, about half had associated myoglobinuria. Patients with renal failure were also more likely than a control group of patients to have severe poisoning, as manifested by low initial serum pH, high initial osmolality, and high peak formate concentration.[166]

The most prominent end organ effect of ethylene glycol is nephrotoxicity. The oxalic acid metabolite forms a complex with calcium to precipitate as calcium oxalate monohydrate crystals in the renal tubules, leading to acute renal failure.[50,62,64,118,141,159,161] The diagnosis of ethylene glycol poisoning has been made at autopsy by demonstrating this abnormality, including one homicide case;[7,104] in another case, the diagnosis was made by renal biopsy.[92] Although the intermediate products of ethylene glycol metabolism and possibly ethylene glycol itself were shown to be directly toxic to the renal tubules in some studies,[34,50,140,143] this appears not to occur at clinically relevant concentrations.[62] Currently no explanation exists for the presence of necrotic lesions to the glomerular basement membrane on some pathology specimens[50] as oxalic acid generally does not cause glomerular injury.[88]

Ethylene glycol can occasionally affect other organ systems. In severe poisoning, the oxalic acid metabolite may be present in sufficient amounts to cause systemic hypocalcemia by precipitation with calcium. This can result in prolongation of the QT interval on the electrocardiogram and ventricular dysrhythmias.[149] Cerebral edema was present on CT scan in two patients that died of ethylene glycol poisoning.[53,161] Precipitation of calcium oxalate crystals in the brain has also been found on autopsy after severe ethylene glycol poisoning[5,50,53] and may account for the multiple cranial nerve abnormalities that occasionally develop,[39,157] although there is as yet no direct evidence of causation. Peripheral polyradiculoneuropathy has been diagnosed by EMG in a case of ethylene glycol poisoning,[4] and intracranial hemorrhage

involving the globus pallidus has also occurred.[30] A leukemoid reaction may also occur in the setting of severe ethylene glycol poisoning, but the mechanism remains unclear.[112,124] One pediatric case of hemophagocytic syndrome and liver failure in the setting of ethylene glycol poisoning resulted in fatality.[100] Finally, two patients developed parkinsonism after concomitant poisoning by methanol and ethylene glycol.[144]

Hemorrhagic gastritis has been reported in association with isopropyl alcohol intoxication. Although this has previously been assumed to be caused by a local irritant effect, one reported case of hemorrhagic gastritis after percutaneous isopropanol exposure suggests that this is not the only mechanism, and may in fact be a specific end-organ effect.[43] Hemorrhagic tracheobronchitis has occurred in fatal cases of isopropanol aspiration.[2]

DIAGNOSTIC TESTING

■ TOXIC ALCOHOL CONCENTRATIONS

Actual serum methanol, formate, ethylene glycol, oxalate, and isopropanol concentrations would be, in theory, the ideal tests to perform when toxic alcohol poisoning is suspected shortly after exposure. However, these concentrations are most commonly measured by gas chromatography with or without mass-spectrometry confirmation, methodologies that are not available in most hospital laboratories on a 24-hour basis, if at all. In fact, in many hospitals these are only available as "send-out" tests, so results arrive too late for early clinical decision-making.[91] Enzymatic assays for methanol, formic acid, ethylene glycol, and glycolic acid have been developed,[21,158,168] and these may lead to more readily-available clinical tests, but a commercial product is currently approved for veterinary use only. This veterinary test is effective for confirming the qualitative presence of ethylene glycol in human poisoning, although false-positives may occur with propylene glycol.[109] A group in Finland described a point-of-care breath test for methanol, using a portable Fourier transform infrared (FT-IR) analyzer similar to the "breathalyzers" used by law enforcement agents.[101] Although analyzers like this are used to check for methanol as a combustion product in industry, they are not yet approved for medical use in the United States. Once approved, they would be ideal for early clinical decision-making because they are easy to use and provide a rapid result. They also can provide continuous monitoring of concentrations, a feature that would be very helpful during hemodialysis. Unfortunately, this methodology could not be used to detect ethylene glycol because of its low volatility.

Patients presenting late after ingestion may already have metabolized all parent compound to toxic metabolites, and thus may have low or no measurable toxic alcohol concentrations. Fortuitously, the enzymatic assay for ethylene glycol is also capable of detecting glycolic acid, though as mentioned, this assay is only approved for veterinary use. Some authors have actually advocated for routine testing for glycolic acid in addition to testing for the parent compound when ethylene glycol poisoning is suspected.[143] Similarly, a formate concentration may be valuable when a patient presents late after methanol ingestion.[80,132] Formate has been detected in blood samples from 97% of patients who died of methanol poisoning in one series; all of these patients also had detectable blood or vitreous methanol.[89] Clearly, a low or undetectable toxic alcohol concentration must be interpreted within the context of the history and other clinical data, such as the presence of acidosis and end-organ toxicity, with glycolate and formate concentrations as potentially valuable additions.

Samples must be handled correctly for accurate toxic alcohol results. Particularly with the more volatile alcohols methanol and isopropanol, concentrations may be falsely low if the sample tubes are not airtight.

This commonly results in low concentrations if alcohol concentrations are done as "add-on" tests to samples already opened for electrolyte or osmol determinations.

Other alcohols such as benzyl alcohol and propylene glycol are not routinely assessed for by gas chromatography. Thus these xenobiotics present a much greater diagnostic challenge than methanol and ethylene glycol. Enzymatic assays for methanol or ethylene glycol would also fail to detect these, although false-positive ethylene glycol tests may occur if propylene glycol is present. Thus a high index of suspicion is critical to establishing the diagnosis in these cases. If suspected on the basis of history, specific toxic alcohol testing should be performed.

Once alcohol concentrations are obtained, their interpretation represents a further point of controversy. Traditionally, a methanol or ethylene glycol concentration greater than 25 mg/dL has been considered toxic, but the evidence supporting this as a threshold is often questioned. In a case series of methanol-poisoned patients from the 1950s, a methanol concentration of 52 mg/dL was the lowest associated with vision loss.[18] This may have been the origin of the 25 mg/dL threshold, incorporating a 50% reduction as a margin of safety. However, the patient with the 52 mg/dL concentration presented 24 hours after his initial ingestion, and therefore was much more severely poisoned than suggested by his serum concentration at that point. In fact, almost all reported cases of methanol poisoning involve late presenters with metabolic acidosis.[97] The only reported patient who went untreated after presenting early with an elevated methanol concentration (45.6 mg/dL) and no acidosis never developed acidosis or end-organ toxicity.[25,97] A systematic review found that 126 mg/dL was the lowest methanol concentration resulting in an acidosis in a patient who arrived early after ingestion and met the authors' inclusion criteria. The authors concluded that the available data are currently insufficient to apply a 20 mg/dL treatment threshold in a patient presenting early after ingestion without acidosis.[97] However, until better data are available demonstrating the safe application of a higher concentration, it seems prudent to use a conservative concentration such as 25 mg/dL as a threshold for treatment.

Because of the problems with obtaining and interpreting actual serum concentrations, many surrogate markers have been used to assess the patient with suspected toxic alcohol poisoning. The initial laboratory evaluation should include: serum electrolytes including calcium, blood urea nitrogen, serum creatinine concentrations urinalysis, measured serum osmolality, and a serum ethanol concentration. Blood gas analysis with a lactate concentration is also helpful in the initial evaluation of ill-appearing patients.

■ ANION GAP AND OSMOL GAP

For a full discussion of the anion gap concept, refer to Chap. 16. As previously discussed, anion gap elevation is a hallmark of toxic alcohol poisoning. In fact, the possibility of methanol or ethylene glycol poisoning is often first considered when patients present with an anion gap acidosis of unknown etiology, frequently with no history of ingestion. Unless other clinical information suggests otherwise, it is important to exclude metabolic acidosis with elevated lactate concentration and ketoacidosis, which are the most common causes of anion gap acidosis, before pursuing toxic alcohols in these patients. This is because of the extensive evaluation and expensive, potentially invasive course of therapy to which they are otherwise committed. However, elevated lactate concentrations may be present in the setting of both methanol and ethylene glycol poisoning.

The unmeasured anions in toxic alcohol poisoning are the dissociated organic acid metabolites discussed above. The acidosis takes time to develop, sometimes up to 16–24 hours for methanol. Thus the absence of an anion gap elevation early after reported toxic alcohol ingestion

does not exclude the diagnosis. If ethanol is present in the body, the development of acidosis will not begin to occur until the ratio of the ethanol to the toxic alcohol falls below a number that varies by alcohol.

A potential early surrogate marker of toxic alcohol poisoning is an elevated *osmol gap* (the principles and the calculations are discussed in detail in Chap. 16). However, it is important to recognize that osmol gap elevation is neither sensitive nor specific for toxic alcohol poisoning. Since a baseline osmol gap is generally not available when evaluating a patient, and a normal osmol gap ranges from −14 to +10 units, so-called "normal" osmol gaps cannot exclude toxic alcohol poisoning.[75] For example, in a patient with a baseline osmol gap of −10 units, a gap of +5 units represents a methanol concentration of 47 mg/dL or an ethylene glycol concentration of 93 mg/dL, values that might require hemodialysis. Inversely, a moderately elevated osmol gap (+10 to +20) is not necessarily diagnostic of toxic alcohol poisoning because other diseases such as alcoholic ketoacidosis and metabolic acidosis, with elevated lactate concentration, may raise the osmol gap.[148] Furthermore, mean osmol gaps vary within populations over time, further limiting their utility.[98] However, a markedly elevated osmol gap (>50) is difficult to explain by anything other than a toxic alcohol.

Further complicating matters, the anion gap and osmol gap have a reciprocal relationship over time. This is because soon after ingestion, the alcohols present in the serum raise the osmol gap, but do not affect the anion gap because metabolism to the organic acid anion has not yet occurred. As the alcohols are metabolized to organic acid anions, the anion gap rises while the osmol gap falls, because the metabolites are negatively charged particles that have already been accounted for in the calculated osmolarity by doubling of the sodium. Thus patients who present early after ingestion may have a high osmol gap and normal anion gap, while those who present later may have the reverse.[77,82] Figure 107–4 depicts a more intuitive visual representation of this process.

One retrospective and one prospective study have attempted to look at the performance characteristic of the osmol gap as a diagnostic test. Although in both cases, the osmol gap performed fairly well, the studies were small, 20 patients with toxic alcohol poisoning in the retrospective study and 28 patients with methanol poisoning in the prospective study, and the prospective study identified three patients with significant poisoning and acidosis but normal osmol gaps defined in the study as less than 25.[77,113] Therefore, these data do not eliminate the concern that someone with significant poisoning could be missed by relying on the osmol gap to exclude poisoning.
FIGURE 107–4. The reciprocal relationship of anion gap and osmol gap over time (hours). Note that patients presenting early may have a normal anion gap while patients who present late may have a normal osmol gap.

ETHANOL CONCENTRATION

A serum ethanol concentration is an important part of the assessment of the patient with suspected toxic alcohol poisoning. As discussed in Chap. 16, the ethanol concentration is necessary for the calculation of measured osmolarity. In addition, because ethanol is the preferred substrate of alcohol dehydrogenase (4:1 over methanol and 8:1 over ethylene glycol), a significant concentration would be protective if co-ingested with a toxic alcohol. In fact, ethanol concentrations near 100 mg/dL virtually preclude toxic alcohols as the cause of an unknown anion gap metabolic acidosis because the presence of such a concentration should have prevented metabolism to the organic acid. A possible exception would be ingestion of ethanol several hours after ingestion of a toxic alcohol.[73]

LACTATE CONCENTRATION

Both methanol and ethylene glycol can result in elevated lactate concentrations, for very different reasons. Formate, as an inhibitor of oxidative phosphorylation, can lead to anaerobic metabolism and resultant lactate elevation. Additionally, metabolism of all alcohols results in an increased NADH/NAD+ ratio, which favors the conversion of pyruvate to lactate. Furthermore, hypotension and organ failure in severely poisoned patients can also result in elevated lactate concentrations. However, lactate production by these mechanisms tends to result in serum concentrations less than 5 mmol/L.

In ethylene glycol poisoning, the glycolate metabolite may also cause a false-positive lactate elevation when measured by some analyzers, particularly with whole blood arterial blood gas analyzers. Specific models implicated include: ABL 625, Radiometer ABL 700, Beckman LX 20, Chiron 865, Bayer (formerly Chiron) 860, Rapidlab (Bayer) 865, Integra and to a lesser extent, Hitachi 911 analyzers, but not the Vitros 950 or Vitros 250.[28,48,114,123,142,172] In such cases, the degree of lactate elevation directly correlates with the concentration of glycolate present,[114] and the artifact results from the lack of specificity of the lactate oxidase enzyme used in these machines,[123,142,172] although direct oxidation of glycolate at the analyzer anode has also been suggested as a possible mechanism.[152] It has been suggested that the presence of a "lactate gap" might also be used to diagnose ethylene glycol poisoning in hospitals where lactate assays are available with and without sensitivity to glycolate.[152]

OTHER DIAGNOSTICS

The urine may provide information in the assessment of the patient with suspected ethylene glycol poisoning. Calcium oxalate monohydrate (spindle-shaped) and dihydrate (envelope-shaped) crystals may be seen when the urine sediment is examined by microscopy, although this finding is neither sensitive nor specific.[56,83,122] In fact, calcium oxalate crystals were present in the urine of only 63% (12 of 19) of patients with proven ethylene glycol ingestion in one series.[27]

Some brands of antifreeze contain fluorescein to facilitate the detection of radiator leaks. If one of these products is ingested and the urine is examined with a Woods lamp within the first 6 hours, there may be urinary fluorescence.[171] False positive fluorescence may result from examining the urine in glass or plastic containers due to the inherent fluorescence of these materials, so if this test is performed, an aliquot of the urine should be poured onto a piece of white gauze or paper. Recent work has suggested a lack of utility of this test; almost all children had urinary fluorescence, and there was poor interrater agreement in determining fluorescence of specimens.[32,135]

The evaluation of patients with known or suspected ethylene glycol poisoning should also include a serum calcium and creatinine concentrations. Patients with methanol poisoning and abdominal pain also

warrant an assessment of liver function tests and serum lipase and/or amylase because of the possibility of associated hepatitis and pancreatitis.

MANAGEMENT

As always, immediate resuscitation of critically ill patients starts with management of the airway, breathing, and circulation. Because alcohols may cause respiratory depression and coma, intubation and mechanical ventilation are commonly necessary for patients with severe poisoning. Alcohol-induced vasodilation combined with vomiting often lead to hypotension, and many patients will require fluid resuscitation with intravenous crystalloid. Gastrointestinal decontamination is rarely, if ever, indicated for toxic alcohols because of their rapid absorption and limited binding to activated charcoal. However, placement of a nasogastric tube and aspiration of any gastric contents is probably worthwhile in intubated patients, as absorption may sometimes be delayed after a large dose.[45]

■ ALCOHOL DEHYDROGENASE INHIBITION

The most important part of the initial management of patients with known or suspected toxic alcohol poisoning (after initial resuscitation) is blockade of ADH. This allows for the establishment of a definitive diagnosis and arrangement for hemodialysis while preventing the formation of toxic metabolites. Additionally, in some cases ADH blockade may itself serve as definitive therapy.

Teleologically, ADH exists for the purpose of metabolizing ethanol, so it is not surprising that the enzyme has a higher affinity for ethanol than for other alcohols. ADH metabolizes ethanol with a Km that is 15 times smaller in vitro than its Km for methanol metabolism and 67 times smaller than its Km for ethylene glycol metabolism.[137,138] Thus significant concentrations of ethanol prevent metabolism of other alcohols to their toxic products. Ethanol is the traditional method of ADH inhibition and may still be the only option in some institutions. A 10% solution is administered through a central venous catheter and titrated to maintain a serum concentration of 100 mg/dL (see Antidotes in Depth A32: Ethanol). Complications of the infusion, while uncommon,[146] include hypotension, respiratory depression (with supratherapeutic concentrations), flushing, hypoglycemia, hyponatremia, pancreatitis and gastritis, as well as inebriation, so patients getting intravenous ethanol require admission to an intensive care unit. Orally administered ethanol is also effective, and may be considered when intensive monitoring is unavailable, particularly in rural areas where there may be a significant delay in getting the patient to a hospital.

Fomepizole is a competitive antagonist of ADH that has many advantages over ethanol. It reliably inhibits ADH when administered as an intravenous bolus every 12 hours, and concentrations do not need to be monitored as with an ethanol infusion.[26,27] It does not cause inebriation and is associated with fewer adverse effects, so it does not require intensive care unit monitoring.[13,14,26,27] For these reasons, it has become the preferred method of ADH blockade, despite being significantly more expensive then ethanol. In fact, the savings in ICU monitoring and laboratory costs probably compensate for the higher drug cost of fomepizole, unless the patient requires intensive monitoring anyway based on the severity of illness.[22] The dose of fomepizole is 15 mg/kg intravenously as an initial loading dose followed by 10 mg/kg every 12 hours. Bradycardia and hypotension may occur after fomepizole infusion, so vital signs should be monitored closely during and after each dose.[103] After 48 hours of therapy, fomepizole induces its own metabolism, so the dose must be increased to 15 mg/kg every 12 hours. Pharmacokinetic data from a human volunteer study show that there is no significant difference in serum concentrations between oral and intravenous fomepizole.[115] However, there is currently no oral preparation of fomepizole on the market. (see Antidotes in Depth A31: Fomepizole)

Indications for fomepizole or ethanol therapy may be based on the history or on laboratory data. Any patient with a believable history of methanol or ethylene glycol ingestion should be treated until concentrations are available because as previously discussed, early symptoms and laboratory markers other than serum concentrations may be absent. In addition, any patient with an anion gap acidosis without another explanation or a markedly elevated osmol gap should also be treated. Once concentrations are available, therapy should be continued until the serum toxic alcohol concentration is predicted or measured to be below 20 mg/dL, although as discussed above, this value is based more on consensus opinion than on data.

■ HEMODIALYSIS

The definitive therapy for symptomatic patients poisoned by toxic alcohols is hemodialysis. Hemodialysis clears both the alcohols and their toxic metabolites from the blood, and corrects the acid-base disorder. The indications for hemodialysis have become more restricted with the advent of fomepizole because of its effectiveness combined with its low incidence of adverse effects. Particularly for ethylene glycol, which can generally be expected to be cleared within a few days once ADH is blocked if the GFR is normal, some have argued that the risks of an invasive procedure like hemodialysis are not warranted, in minimally symptomatic patients and in those whose symptoms are due to the parent toxic alcohol. However, patients with end-organ toxicity or severe acidosis have significant amounts of toxic metabolites, a problem not addressed by ADH blockade, and acidosis is associated with poor prognosis.[108] Additionally, although formate in normally cleared rapidly once ADH is blocked, the half-life increases with higher serum methanol concentrations and varies from 2.5 to 12.5 hours.[69,76] In one patient with severe poisoning, formate was eliminated at an extremely slow rate with a half-life of 49.5 hours until hemodialysis was initiated,[79] underscoring the importance of hemodialysis in patients with significant metabolic acidosis. In addition, patients with renal failure will not eliminate the parent compound once ADH is blocked, except very slowly in expired air in the case of methanol. Therefore, the consensus is that metabolic acidosis, signs of end-organ toxicity including coma and seizures and renal failure are indications for hemodialysis. A "toxic concentration" and possibly a very high osmol gap[139] are more relative indications for hemodialysis, and decisions must be based on the judgment of the clinician for the specific clinical scenario, considering the available resources. Some authors have advocated using toxic metabolite concentrations if available as additional criteria for hemodialysis. In data from case series, an elevated formate concentration appears to be a better predictor of clinically important toxicity than methanol concentrations.[132] Similarly, glycolate concentrations are a better predictor of death and renal failure than ethylene glycol concentrations.[143] However, although clearance of formate by hemodialysis is substantial,[86,87,94] the overall clearance in one case series did not appear to increase significantly above endogenous clearance in patients also treated with folate and bicarbonate.[94] Some have questioned the data quality in this series, pointing out: (1) that the pre-dialysis clearance in two patients was calculated using only two data points, and in the three others was calculated using three points, generally considered the minimum; (2) that several patients actually had decreased clearance during dialysis, contradicting all previous data; and (3) that two of the patients had variable blood flow during dialysis.[78,174]

The American Academy of Clinical Toxicology (AACT) practice guidelines are ambiguous with respect to a threshold methanol concentration for hemodialysis in the absence of acidosis, renal failure, end-organ effects or worsening clinical status.[13] However, until additional investigations are completed, a methanol concentration of 50 mg/dL remains a reasonable indication for consideration of hemodialysis in the absence of significant acidosis or end-organ effects. The AACT guidelines for ethylene glycol actually advise against hemodialysis for a concentration alone without any of these clinical indications.[14] Clearly, there are still insufficient data to establish threshold concentrations of alcohols or their metabolites where dialysis is absolutely indicated, and the decision is ultimately a subjective one based on the overall clinical scenario.[74]

Although hemodialysis effectively clears isopropanol and acetone from the blood, it is rarely if ever indicated for this purpose. Because isopropanol does not cause a metabolic acidosis and very rarely results in significant end-organ effects, the risks of hemodialysis likely outweigh the benefits.

Many patients will require multiple courses of hemodialysis to clear the toxin. Nephrologists may estimate the dialysis time required using the formula:

$$t = [-V \ln (5/A)/0.06k]$$

where t is the dialysis time required to reach a 5 mmol/L toxin concentration, V is the Watson estimate of total body water (liters), A is the initial toxin concentration (mmol/L) and k is 80% of the manufacturer-specified dialyzer urea clearance (mL/min) at the observed initial blood flow rate.[71,175] Additionally, the normalization of the osmol gap may guide the required duration of dialysis, but this has not been validated.[81] Regardless of how the duration of dialysis is determined, ADH blockade should be continued during and after hemodialysis until a subsequent concentration of the offending alcohol is confirmed to be nontoxic. Ethanol infusion rates must be increased during hemodialysis to maintain a therapeutic serum concentration as the ethanol is cleared (see Antidotes in Depth A32: Ethanol). Fomepizole should be redosed every 4 hours during hemodialysis to maintain therapeutic serum concentrations.[13,14]

■ ADJUNCTIVE THERAPY

There are several therapeutic adjuncts to ADH blockade with or (especially) without hemodialysis that should be considered for these patients. One of the differences that has been invoked to explain the absence of retinal toxicity from methanol in some species is the relative abundance of hepatic folate stores in these species such as the rat. Folate and leucovorin enhance the clearance of formate in animal models.[129,130] Thiamine enhances ethylene glycol's metabolism to ketoadipate, and pyridoxine enhances its metabolism to glycine and ultimately hippuiric acid (Fig. 107–2).[126] While all of these modalities offer theoretical advantages, they have yet to be proven to change outcome in humans. However, there is one human case report showing enhanced formate elimination with folinic acid therapy.[85] Additionally, some have suggested that the apparent lack of an increase in formate clearance by hemodialysis was because it was dwarfed by the effectiveness of folate supplementation in both the study group and the control group.[94] Because of the safety of vitamin supplementation, the potential benefit likely outweighs the risk of therapy (see Antidotes in Depth A25: Thiamine; Antidotes in Depth A13: Leucovorin (Folinic Acid) and Folic Acid; and Antidotes in Depth A15: Pyridoxine).

Formate (dissociated formic acid) is much less toxic than the undissociated formic acid, likely because undissociated formic acid has a much higher affinity for cytochrome oxidase in the mitochondria,

the ultimate target site for toxicity.[107] In addition, the undissociated form is better able to diffuse into target tissues.[87] Alkalinization with a bicarbonate infusion shifts the equilibrium to favor the less toxic, dissociated form, in accordance with the Henderson-Hasselbach equation. This also enhances formate clearance in the urine by ion trapping.[87] Uncontrolled case series data exist showing that patients treated with bicarbonate alone had better than expected outcomes after severe methanol poisoning,[125] but the results are equivocal in patients also treated with ADH blockade and hemodialysis.[26,84,120] Additionally, the severity of the metabolic acidosis after methanol poisoning is a good predictor of severe neurological effects such as coma and seizures,[108] although it is not proven that alkalinization prevents these effects. However, in the absence of contraindications to a bicarbonate infusion (eg, hypokalemia, volume overload), alkalinization should be used in the patient with suspected methanol poisoning and a significant acidosis. A blood pH greater than 7.20 is a reasonable endpoint. Alkalinization should also be considered for patients with ethylene glycol poisoning and significant metabolic acidosis.

Aluminum citrate has potential promise as an adjunctive therapy for ethylene glycol poisoning. It interacts with the surface of calcium oxalate monohydrate crystals and prevents their aggregation. This decreases tissue damage from calcium oxalate monohydrate crystals in an *in vitro* model of human proximal tubule cells.[63] However, there are not yet any *in vivo* human studies or even case reports, so it cannot be recommended for clinical use.

One group has reported possible benefit of corticosteroids for retinal injury following methanol poisoning. This was an uncontrolled case series, but 13 of 15 patients showed improvement in their vision after treatment with 1 gram of methylprednisolone daily for 3 days, with one having worsening vision and one unchanged.[153] A patient in another case report had permanent vision loss despite steroid therapy using the same regimen.[54] Currently insufficient data exists to support the routine use of corticosteroids in methanol poisoning.

SPECIAL POPULATIONS

■ PREGNANT WOMEN AND PERINATAL EXPOSURE

There are very few reported cases of pregnant women with toxic alcohol poisoning, but some conclusions can be drawn from the available data. Toxic alcohols readily cross the placenta, and perinatal maternal methanol ingestion has resulted in death of a newborn.[17] One woman was initially misdiagnosed with eclampsia after ingesting ethylene glycol and presenting with seizures and metabolic acidosis in her 26th week of pregnancy. An emergency Caesarian section was performed, and she was later treated with hemodialysis and ethanol once the correct diagnosis was recognized. The child was severely ill, with an initial pH of 6.63 and an initial serum ethylene glycol concentration of 220 mg/dL. She was treated with exchange transfusion and ultimately survived without sequelae after a long hospital course.[99] In rat but not rabbit models of chronic high-dose ethylene glycol exposure, fetal axial skeletal malformations occur and are thought to be caused by glycolate.[36] No human case has yet been reported.

OTHER ALCOHOLS

■ PROPYLENE GLYCOL

Propylene glycol is commonly used as an alternative to ethylene glycol in "environmentally safe" antifreeze. It is also used as a diluent for many pharmaceuticals (such as phenytoin and lorazepam). This

alcohol is successively metabolized by ADH and ALDH to lactate, so a metabolic acidosis results. This can result in extremely high lactic acid concentrations typically that would be incompatible with life if generated by any disease process. In other disease states associated with lactate accumulation and acidosis, the lactate is a reflection of underlying anaerobic metabolism, a marker of severe illness rather than part of the underlying pathophysiology. Lactic acidosis from propylene glycol is surprisingly well-tolerated because it represents nothing more sinister than its own metabolism, and it is rapidly cleared by oxidation to pyruvate, which then undergoes normal carbohydrate metabolism (see Chap. 55 for further discussion of propylene glycol).

■ BENZYL ALCOHOL

Benzyl alcohol is used as a preservative for intravenous solutions. Although it is no longer used in neonatal medicine, it has been responsible for "neonatal gasping syndrome," involving multiorgan system dysfunction, metabolic acidosis and death because of its metabolism to benzoic acid and hippuric acid[58,111] (see Chap. 55 for further discussion of benzyl alcohol).

SUMMARY

Toxic alcohol poisoning is complex and may result in consequential toxicity. Early symptoms may include inebriation, and subsequent toxicity results from metabolism to organic acid anions that cause metabolic acidosis and end-organ effects. The time required for this metabolism results in a delay before toxicity clinically manifests itself. Until serum concentrations are available, the serum anion gap and osmol gap may help with decision-making but do not exclude toxicity if the history is concerning. Therapy consists of ADH antagonism with fomepizole or ethanol, as well as adjunctive therapy with bicarbonate, folate or folinic acid, pyridoxine and thiamine. Hemodialysis is the definitive therapy for clinically ill patients as it removes the alcohol as well as toxic metabolites while correcting the metabolic acidosis and electrolyte abnormalities. However, hemodialysis may have a more limited role in the future, particularly for ethylene glycol poisoning (when renal function is normal) because of the safety and efficacy of fomepizole.

DIETHYLENE GLYCOL

Joshua G. Schier

$$HO—CH_2-CH_2-O—CH_2-CH_2-OH$$
Diethylene glycol is a common industrial solvent with physical and chemical properties similar to propylene glycol. (Chap. 55) Substitution of diethylene glycol for propylene glycol in oral elixirs has repeatedly caused epidemics of mass poisoning (Chap. 2). Patients develop neurologic symptoms and acute renal injury that often progresses to renal failure.

BRIEF HISTORY AND EPIDEMIOLOGY OF DIETHYLENE GLYCOL POISONING

Diethylene glycol (DEG) is produced by the condensation of two ethylene glycol molecules with an ether bond,[1] yielding a molecular weight of 106 Da. It was first isolated in 1869 and has been used in industry and manufacturing since 1928.[1] Since then it has found use as an antifreeze, as a finishing agent for wool, cotton, silk and other fabrics, and in dye manufacturing. DEG is chemically inert, does not ignite at normal temperatures, and has a higher boiling point than ethylene glycol (EG).[17,43] Its other physical properties are quite similar to EG, including a sweet taste.[17,43] It is often used as an intermediate in the production of polymers, higher glycols, morpholine, and dioxane.[26] Its physical properties enable it to serve as an excellent solvent for water-insoluble substances including drugs. This unfortunate use has accounted for the overwhelming majority of reported cases of illness.[4,6,7,9,11,12,14,15,21,23,29–33,36,38,43] In these recurring events, DEG was substituted for a safe and appropriate diluent such as glycerin or propylene glycol. Other causes of DEG-associated illness have resulted from the intentional addition of DEG to wine as a sweetening agent[40,41] and ingestion of radiator fluid or antifreeze,[27] brake fluid,[5] Sterno,[34] a "fog solution,"[16] cleaning solutions,[1] wallpaper stripper,[25] and as a substitute for ethanol.[44]

■ PHARMACOKINETICS/TOXICOKINETICS

Diethylene glycol is rapidly absorbed after ingestion and distributed primarily based on blood flow, with the kidneys receiving the most DEG, followed by the brain, the spleen, liver, and muscles.[17] The degree of protein binding and the volume of distribution (Vd) in humans is unknown but the Vd in the rat is approximately 1 L/kg.[17] Maximal DEG concentrations likely occur within 1 to 2 hours postingestion.[17,43] In both rats and dogs, as much as 30% of a given dose is converted to 2-(hydroxy) ethoxyacetic acid (HEAA).[10,26] In rats, there does not appear to be other metabolites although it is unclear if humans metabolize DEG by similar mechanisms.[17] Several early rat studies reported that oxaluria or calcium oxalate crystal formation occurred in renal tubules.[18,24,28] This limited evidence suggested that perhaps the ether bond joining the 2 ethylene glycol molecules was cleaved. This could then result in ethylene glycol-associated glycolate, glyoxylate and oxalate formation and the subsequent adverse health effects associated with ethylene glycol toxicity. (Chap. 107). Although this hypothesis for the pathophysiology of DEG induced renal toxicity remained popular for many years, more recent studies either failed to reproduce the oxaluria or found no difference in urinary oxalate concentrations when compared to control specimens.[24] In addition, during this previous work, there was no confirmation that the ingested DEG was the source of the oxalic acid production. In more recent work, rats given DEG with radiolabeled carbon had no subsequent radioactivity appear as ethylene glycol, glycoaldehyde, glycolate, glyxoylate, or exhaled carbon dioxide, indicating that there is no metabolism of DEG to any of these compounds.[42] The previous studies that found oxaluria all administered unlabeled DEG may have had unintentional contamination of their DEG with EG, because DEG is commercially prepared using EG.[42] Currently, it is believed that after ingestion, DEG undergoes oxidation by alcohol dehydrogenase to (2-hydroxyethoxy) acetaldehyde and then by aldehyde dehydrogenase to (2-hydroxyethoxy) acetic acid (HEAA). This was demonstrated when the formation of HEAA was decreased by 91% after administration of pyrazole (an alcohol dehydrogenase inhibitor) and by 66% after administration of diethyldithiocarbamate (an inhibitor of aldehyde dehydrogenase).[42] Further oxidation to diglycolic acid did not occur and is likely due to the subsequent formation of a cyclic compound that is not oxidized by alcohol or aldehyde dehydrogenase.[42] Rats pretreated with pyrazole and then administered the LD_{50} dose of DEG had decreased lethality.[42] However, pyrazole pretreatment did not confer a protective benefit in animals receiving greater than 25% above the LD_{50} dose.[42] This suggests that toxicity may be caused, in part, by another mechanism such as the parent compound, or another as of yet undiscovered metabolite. The possibility that higher doses of pyrazole were needed to protect against higher doses of DEG also exists.

Metabolism is saturable and as the dose increases, urinary elimination of the parent compound increases.[26] Carbon-14-labeled DEG is excreted primarily (~80%) in urine within 24 hours of ingestion.[26] Serum half-lives are dose-dependent with oral doses of 6 mL/kg and 12 mL/kg in rats producing biologic half-lives of 8 and 12 hours, respectively.[43] Another study found that urinary excretion half-lives for DEG in rats were dose dependent and ranged from 6 to 10 hours depending on doses ranging from 1–10 mL/kg.[17] At higher doses ($\geq$5–10 mL/kg), DEG induces an osmotic diuresis, which accelerates elimination. This diuretic effect has a ceiling, as even greater doses of DEG (17.5 mL/kg) do not consistently trigger increased renal fluid losses.[17] At these greater doses, DEG elimination appears to follow first order kinetics with an elimination half-life of 3.6 hours.[17] However, increased doses are associated with lethargy, which limits oral intake and contributes to the development of oliguria and anuria.[17,26] This narcotic effect, triggered at doses of 5 and 10 mL/kg of DEG is strong evidence for DEG's ability to cross the blood brain barrier.[17]

■ TOXIC DOSE

Most available information on the pharmacokinetics and toxicokinetics of DEG is from studies in rats; however, limited data in humans are available. The median estimated toxic dose from the Haiti mass poisoning was determined to be 1.34 mL/kg (range, 0.22–4.42 mL/kg) or approximately 1–1.5 g/kg.[29] In the 1930s outbreak in the United States, the reported toxic doses in adults were similar.[6] Another study, examining postmortem DEG concentrations from a mass poisoning in Argentina in 1992, found a potentially lower lethal dose ranging from 0.014 to 0.170 mg/kg of body weight.[9,11] However, some questions remain concerning the validity and applicability of these calculations.[35] Furthermore, the analytical testing techniques used in this report may be subject to error due to cross-reactivity with other products formed as the result of normal postmortem processes.[13]

■ PATHOPHYSIOLOGY

The pathophysiology of DEG-induced nephrologic and neurologic illnesses are not well characterized. Limited evidence suggests that DEG may cause acute renal failure (ARF) through interruption of renal tubular transport processes.[22] This is consistent with observations made in the recent Panama poisonings.[37] In contrast, DEG-induced cortical necrosis is also reported.[25] The mechanism of DEG-induced neurologic toxicity remains unknown.[37] Furthermore, although HEAA is known to be a toxic metabolite, it is unclear if it is the only toxic compound. Questions remain about the possibility of inherent toxicity in the parent compound (DEG).

■ CLINICAL MANIFESTATIONS

The signs and symptoms of DEG poisoning are dependent on duration of exposure, dose, and other intrinsic host factors such as the presence of comorbidities. The presence of ARF remains the single unifying feature.[4,7,9,11,14,15,21,29–33,36,38] The permanence of DEG-induced ARF is unclear but it is not nearly or as readily reversible with either supportive or antidotal treatments (eg, fomepizole) as ethylene glycol-induced ARF. A spectrum of neurologic signs and symptoms can also occur and include unilateral or bilateral cranial VII (facial nerve) dysfunction, peripheral neuropathy, frank encephalopathy, and coma.[1,16,34,37]

In the Panama experience, the overwhelming majority of patients were adults who ingested small amounts of a product that was approximately 8% DEG concentration by volume.[33] The majority of patients presented with vague gastrointestinal or respiratory signs and symptoms and were found to be in ARF.[37] A significant number of these patients rapidly progressed to develop bilateral VII nerve paralysis and peripheral extremity weakness, often within several days. Finally, many also rapidly developed encephalopathy, coma, and death within 24 to 48 hours.[37] This incident was unique in that patients were mostly adults who received small amounts over an extended period of time in contrast to many other past incidents in which subjects were mostly children receiving relatively large doses of DEG.

DEG poisoning can also produce nausea, vomiting, abdominal pain, diarrhea, headache, metabolic acidosis, and confusion.[5] Some of the nonspecific symptoms may be attributable to ARF. Finally, patients may progress to develop multiple system organ failure and death.[5]

■ DIAGNOSTIC TESTING

Although specialized laboratory assays for DEG in blood and urine have been developed, they are not routinely available at most hospitals. The clinician will likely have to rely on a high index of suspicion and more commonly encountered "routine" testing methodologies including serum electrolytes and renal function tests. Nerve conduction studies may prove helpful in establishing the pattern of neuropathy if present. Use of an osmol gap has limitations[19] but may be helpful in patients with acute ingestions.

■ TREATMENT

Treatment of DEG poisoned individuals is complicated because they may not present until days after the initial exposure. This is especially true in individuals who have consumed small amounts of DEG over time as the first evidence of toxicity (oliguria or anuria) may be a delayed manifestation.[1,25,29,37] Following larger ingestions, symptoms such as confusion and altered mental status may present within hours of the ingestion.[3] Gastrointestinal decontamination including nasogastric lavage and activated charcoal administration should be strongly considered when the time to presentation to healthcare is minimal. Lavage is unlikely to be of any clinical benefit greater than 1 to 2 hours after ingestion as residual intragastric DEG beyond 2 hours is probably minimal or nonexistent. Although evidence supporting a clinical benefit with activated charcoal administration after 1 hour is lacking, little harm will result from giving a dose of activated charcoal when the patient has no contraindications to administration because DEG is potentially so toxic.[39] Unfortunately, however, gastrointestinal decontamination is unlikely to be of any benefit unless the patient presents within a few hours of the ingestion.

Fomepizole or other alcohol dehydrogenase inhibitors may be of some benefit in DEG poisoning.[42] However, the benefit appears to decrease or disappear as the dose increases, at least in animals.[42] This suggests that toxicity either may not be entirely caused by the primary metabolite (HEAA) or that larger doses of an inhibitor may be needed.[42] Fomepizole or ethanol was administered or coingested in at least four reports of DEG-associated illness.[1,3,5,34] In the first instance (and only case series), ethanol was administered to five of seven inmates who reportedly drank a DEG containing cleaning fluid and who presented to a tertiary healthcare facility for evaluation approximately 21 to 30 hours after the ingestion. Three of the 5 ill inmates had a severe metabolic acidosis (serum pH <7.1, or serum bicarbonate concentrations of 2.7 and 4 mEq/L) and elevated serum creatinine concentrations. All three were treated with ethanol and hemodialysis therapy but they either died or became hemodialysis dependent with persistent neurologic deficits. The remaining 2 ill inmates had evidence of milder toxicity including a milder metabolic acidosis (serum pH concentrations of 7.2 and 7.29 and serum bicarbonate concentrations of 16.4 and 12.1 mEq/L) and were treated with ethanol and hemodialysis, after which they had full recoveries.[1] The remaining two non-ill cases claimed a much milder exposure to the DEG containing fluid, were asymptomatic on hospital presentation and remained that way until discharge.[1]

There are limited conclusions that can be drawn from this information. The 2 patients who presented early (<10 hours)[3,5] and were treated aggressively (gastrointestinal decontamination, fomepizole, and hemodialysis) appeared to do much better than those who presented late (>10 hours).[1,16,34] Among the patients in the case series the three who died or had permanent neurologic and renal deficits, all presented late and with clinical manifestations of severe toxicity. Of the remaining four who reportedly drank DEG-containing brake fluid, all presented late but had full recoveries. As mentioned previously, of these four patients, two were asymptomatic on hospital presentation to begin with and remained that way. The remaining two patients had evidence of mild metabolic acidosis on presentation but no evidence of renal impairment. This strongly suggests that all four were exposed to a smaller dose than the first three and probably explains their lack of illness or recovery.[1]

In the Panama mass poisoning, the case-fatality rate was lower among patients who presented after the discovery of DEG as the etiology when compared to patients who presented before the etiology was discovered.[37] The reasons for this are unclear but may reflect a shorter time to critical therapies such as hemodialysis.[37] At least 1 report

documented higher prehemodialysis and lower posthemodialysis concentrations of DEG suggesting that it is cleared by hemodialysis, although the gradient was relatively small (0–1.6 mg/dL).[5] Although the degree of DEG-protein binding is unknown, its molecular weight is 106.14 Da and its Vd is thought to be near 1 L/kg[17] (based on animal data), which suggest that hemodialysis would be effective in removing the compound.

At least one of the toxicants in DEG poisoning is the DEG metabolite HEAA.[42] If fomepizole or ethanol therapy is to be used in suspected or known cases of significant DEG poisoning, it should probably be administered in concert with hemodialysis, as the parent compound is most likely toxic as well.

SUMMARY

Patients with exposure to diethylene glycol present a diagnostic and therapeutic challenge. The repetitive epidemics of the use of this industrial solvent for human consumption has led to mass poisonings and critical nephrologic and neurologic illness. Early recognition of the epidemic and appropriate consideration of the antidotes fomepizole and ethanol as well as hemodialysis are indicated, although prevention of contamination of pharmaceuticals is truly most important.

FOMEPIZOLE

Mary Ann Howland
Fomepizole is a competitive inhibitor of alcohol dehydrogenase (ADH) that prevents the formation of toxic metabolites from ethylene glycol and methanol. It may also have a role in halting the disulfiram–ethanol reaction, and in limiting the toxicity from a variety of xenobiotics that rely on ADH for metabolism to toxic metabolites. In addition, as both an inducer and an inhibitor of certain cytochrome P450 (CYP) isoenzymes, the presence of fomepizole may lead to drug interactions.

HISTORY

In 1963, Theorell and associates described the inhibiting effect of pyrazole on the horse ADH-NAD$^+$ (nicotinamide adenine dinucleotide) enzyme–coenzyme system.[78] They noted that pyrazole blocked ADH by complexation, and that the administration of pyrazole to animals poisoned with methanol and ethylene glycol improved survival.[79] However, pyrazole also inhibited other liver enzymes, including catalase and the microsomal ethanol-oxidizing system.[55] Additional adverse effects of pyrazole administration resulted in bone marrow, liver, and renal toxicity, and these effects increased in the presence of ethanol and methanol.[66] These factors led to the search for less-toxic compounds with comparable mechanisms of action.

In 1969, Li and Theorell found that both pyrazole and 4-methylpyrazole (fomepizole) inhibited ADH in human liver preparations,[54] and studies in rodents found that fomepizole, unlike pyrazole, was relatively nontoxic regardless of the presence or absence of ethanol.[11] Subsequent studies of fomepizole in monkeys and humans poisoned with methanol and ethylene glycol confirmed both the inhibitory effect and relative safety of fomepizole.[16,17,66]

PHARMACOLOGY

Fomepizole has a molecular weight (MW) of 82 daltons, and a pKa of 2.91 at low concentrations and a pKa of 3.0 at high concentrations. The free base is used in the United States, whereas the salts are used in Europe. The free base is chemically equivalent to the chloride and sulfate salts at physiologic pH.[21]

Values for K_m (Michaelis-Menten dissociation constant; substrate concentration where the rate of metabolism is half the maximum) have been estimated for the toxic alcohols, along with the value for K_i (dissociation of enzyme-inhibitor complex inhibition constant) with fomepizole. The smaller the K_m, the higher the affinity of the substrate (alcohol) for the enzyme, and the lower the concentration of the substrate that is needed to half saturate the enzyme. Studies in monkey and human liver tissue demonstrate that fomepizole is a competitive inhibitor of alcohol dehydrogenase.[58,73] In monkey liver, fomepizole demonstrated very similar K_is for both ethanol and methanol at 7.5 and 9.1 μmol/L, respectively.[58] The affinity was 10 times higher when human liver was used.[72] Studies in monkeys demonstrate that a fomepizole concentration of 9 to 10 μmol/L (0.74–0.8 μg/mL) is needed to inhibit the metabolism of methanol to formate.[11,66] In human liver, the concentration needed to achieve inhibition is about 0.9 to 1 μmol/L.[54,72] The most recent trial using intravenous fomepizole attempted to maintain a serum fomepizole concentration above 10 μmol/L. Current dosing calls for a serum fomepizole concentration of 100 to 300 μmol/L to ensure a margin of safety.[1]

The CYP2E1 isoenzyme oxidizes to toxic metabolites ethanol and a number of other xenobiotics, including acetaminophen, carbon tetrachloride, nitrosamines, and benzene. Fomepizole, like ethanol and isoniazid, has the following effects on this isoenzyme: Fomepizole induces CYP2E1 in rat liver and kidney, but not in the lung, through a posttranscriptional mechanism not involving increased mRNA. However, when fomepizole is present, the isoenzyme is inhibited. It is not until after fomepizole is eliminated that the consequences of induction are manifest.[14,83,84] In hepatocyte culture, fomepizole stabilizes and maintains the induced metabolic activity of the isoenzyme for about 1 week.[85]

PHARMACOKINETICS

The volume of distribution of fomepizole is about 0.6 to 1 L/kg; it is metabolized to 4-carboxypyrazole, an inactive metabolite that accounts for 80% to 85% of the administered dose.[63] In healthy human volunteers, oral doses of fomepizole were rapidly absorbed and demonstrated saturation and nonlinear kinetics.[40,60] The K_m was estimated to be 75 μmol/L in two studies and 0.94 μmol/L in the most recent analysis, although the reason for the discrepancy is not known.[40,60,61] First-order kinetics were exhibited at concentrations below the K_m, whereas zero-order elimination occurred at concentrations 100% to 200% of the K_m.[40] Thus, elimination of fomepizole at doses of 10 mg/kg, 20 mg/kg, 50 mg/kg, and 100 mg/kg was 3.66, 5.05, 10.3, and 14.9 μmol/L/h, respectively.[40] Classical Michaelis-Menten kinetics would predict that the elimination rate should be the same at the two higher doses, but this is not the case. The authors speculate that multiple metabolic pathways with different affinities exist and predominate at different fomepizole concentrations. At a dose of 20 mg/kg, the half-life of fomepizole calculated from the linear portion of the curve was 5.2 hours and occurred when serum concentrations were less than 100 μmol/L. Peak concentrations after oral administration were achieved within 2 hours and were 132, 326, 759, and 1425 μmol/L following 10, 20, 50, and 100 mg/kg doses, respectively. Every increase of 10 mg/kg in the oral dose of fomepizole raised the serum concentration 130 to 160 μmol/L.[40] The renal clearance was

low (0.016 mL/min/kg), and only 3% of the administered dose was excreted unchanged in the urine.[40]

In a pharmacokinetic study in healthy volunteers, oral administration produced similar serum concentrations to intravenous (IV) fomepizole.[60] The pharmacokinetics of IV fomepizole were studied in 14 patients being treated for ethylene glycol toxicity.[48] A mean peak concentration of 342 µmol/L (200–400 µmol/L) was achieved following a loading dose of 15 mg/kg (183 µmol/kg).[63,75] A significant weakness of the study involving toxicokinetic data is that the effect of simultaneous serum ethanol concentrations was not analyzed. The lowest serum fomepizole concentration of 105 µmol/L was present at 8 hours after the loading dose. The rate of elimination was determined to be zero order at 16 µmol/L/h compared with a first-order elimination half-life of 3 hours during hemodialysis. Other authors have reported similar fomepizole clearances (12.99 µmol/L/h).[18] A recent pharmacokinetic analysis in patients poisoned with methanol or ethylene glycol demonstrated a mean peak fomepizole concentration of 226 µmol/L (19 µg/mL), an apparent half-life of 14.5 hours (in the presence of methanol or ethylene glycol), and an apparent half-life of 40 hours in the presence of ethanol along with methanol or ethylene glycol. In the sole death, hepatic tissue contained 12 µg/g of fomepizole, even when the serum concentration was less than 1 µg/mL (12 µmol/L).[82]

The hemodialysis clearance of fomepizole ranges from 50 mL/min to 137 mL/min.[27,47] An analysis using determinations of dialysis fluid revealed an extraction ratio of approximately 75% and a dialysance of 117 mL/min, which was very similar to a simultaneous ethylene glycol determination.[27] The dialysance of fomepizole was similar to urea in a pig model and suggests no significant protein binding of fomepizole.[41]

The pharmacokinetic interactions between fomepizole and ethanol were studied in a double-blind crossover design in healthy human volunteers.[45] Fomepizole was given orally in doses of 10, 15, and 20 mg/kg one hour prior to oral ethanol at 0.5 to 0.7 g/kg as a 20% solution in orange juice. Fomepizole decreased the elimination rate of ethanol by approximately 40%, from 12 to 16 mg/dL/h to about 7 to 9.5 mg/dL/h. When IV fomepizole was administered at 5 mg/kg over 30 minutes and ethanol was administered orally at doses to achieve a concentration of 50 to 150 mg/dL for 6 hours beginning at the end of the fomepizole infusion, the elimination of fomepizole was decreased by approximately 50%.[45] This decrease occurred without a change in the amount or fraction of unchanged fomepizole appearing in the urine. The authors suggested that the ethanol probably inhibited the metabolism of fomepizole to 4-carboxypyrazole by the CYP system. A single low dose of fomepizole given to humans had a maximal effect on ethanol metabolism at 1.5 to 2 hours.[10] Thus, ethanol and fomepizole mutually inhibit the elimination of the other, prolonging their respective serum concentrations.[59,64] Methanol also decreases the elimination of fomepizole by approximately 25% in the monkey.[66]

METHANOL

■ IN VITRO AND ANIMAL STUDIES

Studies using human livers demonstrate the inhibitory effect of fomepizole on alcohol dehydrogenase.[72] Studies in monkeys, the animal species that most closely resembles humans in metabolizing methanol, also clearly demonstrate the inhibitory effect of fomepizole in preventing the accumulation of formate.[9,66,67]

■ HUMAN EXPERIENCE

The two largest fomepizole case series to date involved 11 and eight patients, respectively, who were given IV fomepizole in the approved US dosing regimen.[15,17,36] Following administration, formate concentrations

in all patients fell and the arterial pH increased.[17] Case reports demonstrate similar findings.[18,29,32]

■ EFFECT OF FOMEPIZOLE ON METHANOL AND FORMATE CONCENTRATIONS

Methanol exhibits dose-dependent kinetics.[44] At low doses (0.08 g/kg), which achieve serum concentrations of about 10 mg/dL, methanol elimination is first order, with a half-life of about 2.5 to 3 hours.[48,51] In concentrations of about 100 to 200 mg/dL, methanol exhibits zero-order kinetics and is eliminated at about 8.5 to 9 mg/dL/h in untreated humans[46] and 4.4 to 7 mg/dL/h in untreated monkeys.[25,69] When monkeys were given 3 g/kg of methanol with resultant serum concentrations of about 500 mg/dL, the elimination of methanol exhibited apparent first-order kinetics. This alteration is likely caused by the greater contribution of other first-order pathways, such as pulmonary and urinary elimination, which may account for a greater fraction of the total body clearance under these circumstances.[44] Once fomepizole was administered, the elimination of methanol became first order in humans, and the half-life of methanol was about 54 hours.[17,36] When the metabolism of methanol to formate is blocked, formate is eliminated with a half-life dependent on dose and with an uncertain effect of folate and bicarbonate therapies. When formate was administered to monkeys in the absence of methanol, formate half-life was 30 to 50 minutes.[22] In monkeys given methanol followed by fomepizole, the formate concentrations decreased by more than 80% in 2 hours.[9] An analysis of formate concentrations in six patients with methanol poisoning treated with fomepizole, folate, and sodium bicarbonate revealed a formate half-life of 235 +/− 83 minutes.[49] A more recent analysis involving eight patients with methanol poisoning treated with fomepizole and sodium bicarbonate revealed a formate half-life of 156 minutes.[36]

ETHYLENE GLYCOL

■ IN VITRO AND ANIMAL STUDIES

Monkeys given 3 g/kg of ethylene glycol intraperitoneally recovered without treatment, whereas those given 4 g/kg died without therapy. All those given 4 g/kg of ethylene glycol with fomepizole survived.[22]

■ HUMAN EXPERIENCE

The first three patients treated with oral fomepizole improved clinically and tolerated the therapy.[4] Subsequent case reports and case series using fomepizole orally or IV, with or without hemodialysis, have also demonstrated effectiveness of fomepizole in preventing glycolate accumulation.[5,12,16,30,33,35,47,68,71,75]

■ EFFECT OF FOMEPIZOLE ON ETHYLENE GLYCOL AND GLYCOLATE CONCENTRATIONS IN HUMANS

Renal function is essential in the elimination of ethylene glycol. With normal renal function, the half-life of ethylene glycol is about 8.6 hours.[75] Based on pooled human data, the half-life of ethylene glycol after alcohol dehydrogenase is blocked by fomepizole is about 14 to 17 hours in patients with normal renal function, and about 49 hours in patients with impaired renal function.[4,33,75] Based on a limited number of determinations, the renal clearance of ethylene glycol averaged 31.5 mL/min during the first two days; the corresponding creatinine clearance was 112 mL/min, and estimated total body

clearance during fomepizole therapy was 57 mL/min.[5] These calculations suggest that the renal clearance of ethylene glycol accounted for only 55% of estimated total body clearance. In a study where neither renal function was defined nor the amount of glycolate (MW = 76 daltons) excreted unchanged by the kidneys described, glycolate had a mean half-life of 10 ± 8 hours in patients treated with fomepizole before hemodialysis, and a mean half-life of less than three hours during hemodialysis.[42,50,68]

SAFETY AND ADVERSE EFFECTS

Retinol dehydrogenase, which is responsible for converting retinol to retinal in the eye, is an isoenzyme of ADH. As such, it was essential to study whether fomepizole would inhibit this enzyme and subsequently produce retinal damage.[66,67] Studies in several animal species demonstrate that fomepizole is relatively nontoxic, with no demonstrable signs of ophthalmic toxicity.[9] Two of the largest case series, and two recent case reports confirm the lack of retinal toxicity with fomepizole and demonstrate the reversibility of methanol-induced visual toxicity when patients are treated with fomepizole and hemodialysis before permanent ophthalmic toxicity developed.[16,17,26,77]

The LD_{50} (median lethal dose for 50% of test subjects) of fomepizole in mice and rats is 3.8 mmol/kg after IV administration, and 7.9 mmol/kg following oral administration.[57] An oral placebo-controlled, double-blind, single-dose, randomized, sequential, ascending-dose study was performed in healthy volunteers to determine fomepizole tolerance at 10 to 100 mg/kg.[44] There were no adverse effects in the 10 and 20 mg/kg groups, whereas at 50 mg/kg, three of four subjects experienced slight to moderate nausea and dizziness within 2.5 hours of fomepizole administration. All subjects reported comparable symptoms at 100 mg/kg, which lasted for 30 hours in one individual without vital sign or laboratory abnormalities noted. The most common adverse effects of the use of fomepizole reported by the manufacturer (in a total of 78 patients and 63 volunteers) were headache (14%), nausea (11%), and dizziness, increased drowsiness, and bad taste/metallic taste (6%).[1] Other less commonly observed adverse effects include phlebitis, rash, fever, and eosinophilia. A recent case report of a patient severely poisoned with ethylene glycol describes a temporal association between IV fomepizole administration during hemodialysis and the development of bradycardia and hypotension. However, this patient was severely acidotic, and when the patient received the fomepizole postdialysis no such adverse effects were noted.[52] Divided daily doses of fomepizole up to 20 mg/kg for 5 days have been administered without any demonstrable toxicity.[65] The most common laboratory abnormality after fomepizole administration is a transient elevation of aminotransferase levels, which was reported in six of 15 healthy volunteers.[43] In the two largest case series of patients treated with fomepizole for toxic alcohol poisoning, there were no adverse events classified as "definitely" or "probably" related to fomepizole.[16,17] Fomepizole is not approved for use in children, but has been used successfully in children who have ingested ethylene glycol and methanol.[6,13,19,23,24,34,82]

Fomepizole is pregnancy category C and thus should be used appropriately as indicated.

DISULFIRAM AND OTHER XENOBIOTICS

Fomepizole successfully terminated the adverse reactions resulting from the use of disulfiram administered to volunteers pretreated with a small dose of ethanol, and reactions occurring in a chronic alcoholic surreptitiously given disulfiram by his wife.[56] Pretreatment with oral fomepizole was also successful in preventing the facial flushing

and tachycardia typically associated with ethanol administration in ethanol-sensitive Japanese subjects.[38,39]

Limited animal studies and a few case reports suggest that fomepizole may be effective in limiting the toxicity secondary to diethylene glycol, triethylene glycol, and 1,3-difluoro-2-propanol.[12,28,80] The role of fomepizole in overdoses secondary to 2-butoxyethanol (ethylene glycol monobutyl ether, butyl cellosolve) is unclear, but fomepizole may be useful if administered within several hours of ingestion and before rapid metabolism of butoxyethanol to butoxyacetic acid occurs.[62,70] Isopropanol is probably metabolized at least in part by alcohol dehydrogenase, but fomepizole therapy is not indicated, as this intervention would prolong the metabolism of isopropanol to acetone.[1]

COMPARISON TO ETHANOL

Ethanol has been used for many years to inhibit the metabolism of methanol and ethylene glycol to their respective toxic metabolites.[31,81] Although very inexpensive, ethanol has many disadvantages, compared to fomepizole. Ethanol causes central nervous system (CNS) depression that is at least additive to that of the methanol or ethylene glycol; dosing difficulties occur as a result of the rapid and often unpredictable rate of ethanol metabolism, and prolonged ethanol administration causes tolerance to ethanol to develop; an intravenous formulation of ethanol is no longer readily available[7]; the serum concentrations of ethanol must be closely monitored; a 5% or 10% IV preparation of ethanol is hyperosmolar[86]; and there is a great potential for hyponatremia and hypoglycemia or other ethanol-related adverse effects, such as pancreatitis and hepatitis. In contrast to all of these problems associated with ethanol administration, fomepizole has the advantage of being a very potent inhibitor of alcohol dehydrogenase without producing CNS depression. Fomepizole dosing is much easier without a need for serum concentration monitoring, thus allowing for every-12-hour dosing except during hemodialysis, when dosing should occur every 4 hours. Limited adverse effects of fomepizole include local reactions at the site of infusion when concentrations exceeding 25 mg/mL are used, nausea, dizziness, anxiety, headache, rash, transiently elevated aminotransferases, and eosinophilia.

Fomepizole is preferred to ethanol for all of the above reasons. Ethanol should only be used when fomepizole is not readily available. Hospitals should be encouraged to stock fomepizole.[53,76]

DOSING

The loading dose of fomepizole is 15 mg/kg IV, followed in 12 hours by 10 mg/kg every 12 hours for 4 doses. If therapy is necessary beyond 48 hours, the dose is then increased to 15 mg/kg every 12 hours, for as long as necessary. This increase is recommended because fomepizole stimulates its own metabolism. Patients undergoing hemodialysis require additional doses of fomepizole to replace the amount removed during hemodialysis.

The manufacturer recommends dosing fomepizole every 4 hours during hemodialysis.[1] Fomepizole should be administered at the beginning of hemodialysis if the last dose was more than 6 hours earlier. At the completion of hemodialysis, administer the next scheduled dose if more than 3 hours have transpired, or one-half of the dose if 1 to 3 hours have passed. Then continue with every-12-hour dosing.

The fomepizole dose must be diluted in 100 mL of 0.9% sodium chloride solution or dextrose 5% in water (D_5W) prior to IV administration, and then infused over 30 minutes to avoid venous irritation and phlebosclerosis. Once diluted, fomepizole remains stable for 24 hours when stored in the refrigerator or at room temperature.[1]

Fomepizole therapy should be continued until the methanol or ethylene glycol is no longer present in sufficient concentrations to produce toxicity. Although these concentrations are not precisely known, 25 to 50 mg/dL of either ethylene glycol or methanol is a conservative estimate that can be lowered in the presence of acid–base disturbances.[1–3]

The threshold concentrations for hemodialysis of methanol or ethylene glycol can be based on measurements when analyses can be done in a timely fashion. The duration of fomepizole therapy in the absence of hemodialysis can be estimated based on the assumption of half-life of the toxic alcohol when blocked with fomepizole. The half-life of methanol is approximately 54 hours in the presence of fomepizole.[12] The half-life of ethylene glycol in the presence of fomepizole is approximately 14 to 17 hours in patients with normal renal function, and 49 hours in patients with impaired renal function.[4,35,75]

The need for hemodialysis is based on the presence of toxic metabolites inferred by metabolic acidosis and presence of end-organ damage; the ability of the kidney to eliminate ethylene glycol and glycolic acid, and formate; the risk benefit of hemodialysis; and the length of time to remain hospitalized for elimination of the remaining methanol and ethylene glycol.[37,74]

AVAILABILITY

Fomepizole is marketed as Antizol injection by Jazz Pharmaceuticals (originally by Orphan Medical) in a tray pack containing four vials (1.5 mL vials of 1 g/mL). It is now also available generically by X-Gen Pharmaceuticals and Sandoz, both of whom allow the purchase of just one vial. Temperatures of less than 77°F (25°C) cause the contents of the fomepizole vials to solidify. Warming reliquifies the product without adversely affecting its potency.

SUMMARY

Fomepizole is a potent competitive inhibitor of alcohol dehydrogenase that is useful in inhibiting the metabolism of methanol, ethylene glycol, and other xenobiotics that use ADH in the formation of toxic metabolites. Once ADH is blocked, the decision to use hemodialysis depends on how much damage has occurred to the organs of elimination, and how well the body can eliminate both the parent compound and the toxic metabolites formed prior to fomepizole administration. Fomepizole appears to be safe and, although it has been used successfully orally, only an IV dosing regimen is approved and available. Fomepizole is more costly than ethanol, but its many advantages over ethanol, including the ability to often deliver care outside an intensive care unit, make fomepizole the preferred antidote. Hospitals should be encouraged to stock fomepizole.

ANTIDOTES IN DEPTH (A32)

ETHANOL

Mary Ann Howland
Ethanol is used therapeutically as a competitive substrate for xenobiotics metabolized by alcohol dehydrogenase, thus limiting the bioactivation of those xenobiotics to toxic metabolites. Methanol and ethylene glycol are potentially the two most lethal xenobiotics metabolized by this pathway.[8,9] Ethanol may also inhibit the metabolism of short-chain polyethylene glycols, such as di- and triethylene glycol,[50] as well as compete with monofluoroacetate and fluoroacetamide for binding to the tricarboxylic acid cycle via the formation of acetate. Ethanol also affects the cytochrome P450 (CYP) enzyme system, especially CYP2E1, for which it has biphasic properties as an inducer/inhibitor similar to fomepizole and isoniazid. The competitive relationship of ethanol with potentially toxic xenobiotics are used to therapeutic advantage, but the effect of ethanol on the CYP system often leads to unwanted drug interactions and pharmacokinetic tolerance after several days of administration.

AFFINITY FOR ALCOHOL DEHYDROGENASE

The dose of ethanol necessary to achieve competitive inhibition depends on the relative concentrations of the toxic alcohols and their affinity for the enzyme. An affinity constant, K_m, is used to express the degree of affinity: the lower the K_m value, the stronger the affinity. A summary of in vitro experiments using human liver cells demonstrated a K_m of 30 mM for ethylene glycol, 7 mM for methanol, and 0.45 mM for ethanol.[26,39,40] This means that the molar affinity of ethanol for alcohol dehydrogenase is 67 times that of ethylene glycol and 15.5 times that of methanol. Studies in methanol-poisoned monkeys revealed that when ethanol was administered at a molar ethanol-to-methanol ratio (E:M) of 1:4, the metabolism of methanol was reduced by 70%; at a 1:1 E:M ratio, metabolism was reduced by greater than 90%.[29] In these experiments, the dose of methanol was kept constant at about 1 g/kg (31 mmol/kg), whereas the dose of ethanol was varied. Although the serum methanol concentration was not measured, a calculation using this dose and a volume of distribution of 0.6 L/kg would predict a serum concentration of about 166 mg/dL. Even in molar ratios as high as 1:8, methanol did not inhibit ethanol metabolism. When ethylene glycol and methanol are administered together in a 0.5:1 molar ratio, ethylene glycol did not inhibit methanol metabolism.[29] When compared to methanol smaller amounts of ethanol are required to block the metabolism of ethylene glycol, as the affinity of ethylene glycol for alcohol dehydrogenase is less than that of methanol.[19,26,39,40,42,48]

Most authors[1,19,48] recommend either a serum ethanol concentration of 100 mg/dL, or at least a 1:4 molar ratio of ethanol to methanol or ethylene glycol, whichever is greater. Using this ratio, 100 mg/dL (~22 mmol/L) of ethanol protects against 88 mmol/L (286 mg/dL) of methanol or 88 mmol/L (546 mg/dL) of ethylene glycol. Inhibiting the metabolism of methanol and ethylene glycol impedes the formation of toxic metabolites and prevents the development of metabolic acidosis.[10,13,18,48] After this toxic metabolic pathway is blocked with ethanol, renal, pulmonary, and extracorporeal routes of toxic alcohol removal become the sole mechanisms for elimination.

Case reports attest to the efficacy of ethanol in preventing the sequelae of methanol and ethylene glycol poisoning when administered in a timely fashion after the toxic alcohol ingestion and before the accumulation of the toxic metabolites.[5,7,21,47,52] In the presence of sufficient blocking concentrations of ethanol, the half-life of ethylene glycol in two patients with normal kidney function was 17.5 hours, which was comparable to 17 hours in a case series of patients receiving fomepizole alone with normal kidney function.[5,46] A half-life of 46.5 hours for methanol was reported in a patient with methanol poisoning who had received a sufficient quantity of ethanol.[37] Again, this half-life for methanol in the presence of ethanol was quite similar to the 54 hours reported in a case series of methanol-poisoned patients treated only with fomepizole.[3,21]

PHARMACOKINETICS AND DOSING

Ethanol can be given either orally or intravenously (IV) (Tables A32–1 and A32–2). Concentrations of 20% to 30% orally and 5% to 10% IV are well tolerated. Intravenous administration has the advantages of complete absorption[23] and avoidance of most gastrointestinal symptoms, and it is a route that can be used in an unconscious or uncooperative patient. The disadvantages of IV ethanol include difficulty in obtaining and preparing an IV ethanol solution, the hyperosmolarity of a 5% ethanol solution (about 950 mOsm/L), and the possibilities of osmotic dehydration, hyponatremia, and venous irritation. Ethanol administered orally is rapidly absorbed and achieves peak concentrations in about 1 to 1.5 hours.[6,12,27,49] The amount of ethanol absorbed after oral administration is highly variable and dependent on a number of factors, such as ethanol dose, fasting, nutritional status, accelerated gastric emptying, gender, genetics, chronic alcohol use, lean body mass, and increasing age, as well as the presence of certain H_2 receptor antagonists.[4,7,12,22,24,34,51,53] Sufficient concentrations are generally achieved when 0.8 g/kg of ethanol is given orally over 20 minutes.[4,6,7,12,24,49]

Regardless of route, the objective is to rapidly achieve and maintain a serum concentration of at least 100 mg/dL of ethanol, which is adequate for enzyme inhibition in most cases. Inhibition is best achieved by administering a loading dose of ethanol, followed by a maintenance dose. Given that the volume of distribution for ethanol is approximately 0.6 L/kg,[54] the loading dose of ethanol is obtained by the following formula:

$$\text{Loading dose} = C_p \times Vd$$
$$= 1 \text{ g/L (100 mg/dL)} \times 0.6 \text{ L/kg}$$
$$= 0.6 \text{ g/kg}$$
$$C_p = \text{plasma concentration which is comparable}$$
$$\text{to the serum concentration}$$

TABLE A32–1. Intravenous Administration of 10% Ethanol

Loading Dose[a]	Volume (mL)[b] (given over 1 h as tolerated)					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
0.8 g/kg of 10% ethanol (infused over 1 h as tolerated)	80	120	240	400	560	800

Maintenance Dose[c]	Infusion Rate[b] (mL/h for various weights)[d]					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
Ethanol Naive						
80 mg/kg/h	8	12	24	40	56	80
110 mg/kg/h	11	16	33	55	77	110
130 mg/kg/h	13	19	39	65	91	130
Ethanol Tolerant						
150 mg/kg/h	–	–	–	75	105	150
During hemodialysis						
250 mg/kg/h	25	38	75	125	175	250
300 mg/kg/h	30	45	90	150	210	300
350 mg/kg/h	35	53	105	175	245	350

[a] A 10% V/V concentration yields approximately 100 mg/mL.

[b] For a 5% concentration, multiply the amount by 2.

[c] Infusion to be started immediately following the loading dose. Concentrations above 10% are not recommended for IV administration. The dose schedule is based on the premise that the patient initially has a zero ethanol concentration. The aim of therapy is to maintain a serum ethanol concentration of 100 to 150 mg/dL, but constant monitoring of the ethanol concentration is required because of wide variations in endogenous metabolic capacity. Ethanol will be removed by hemodialysis, and the infusion rate of ethanol must be increased during hemodialysis. Prolonged ethanol administration may lead to hypoglycemia.

[d] Rounded to the nearest mL.

Adapted from Roberts JR, Hedges J, eds. *Clinical Procedures in Emergency Medicine*. Philadelphia: WB Saunders; 1985:1073-1074.

For a 70-kg person, the loading dose would be 42 g (70 kg × 0.6 g/kg) of ethanol, or 420 mL of 10% V/V (volume-to-volume) ethanol. However, a 0.8 g/kg or 8 mL/kg loading dose of a 10% ethanol solution is recommended in order to provide a margin of safety because of the inconsistencies in volume of distribution and the ongoing metabolism that occurs during administration.[23,41] The IV loading dose should be administered over 20 to 60 minutes, as tolerated by the patient. The 10% ethanol concentration is preferable to the 5% concentration in order to limit the volume of fluid administered. It is also preferred over the more concentrated solutions in order to limit local venous irritation and avoid postinfusion phlebitis. Because of the free water content and significant hypertonicity of the 10% solution, the patient should be closely observed for the development of hyponatremia.

To maintain an ethanol concentration of 100 mg/dL, enough ethanol has to be administered to replace the ethanol that is undergoing elimination (66–130 mg/kg/h). The average hourly dose for a 70-kg person is 4.6 g, but higher doses are required in ethanol tolerant patients (100–154 mg/kg/h) or others who may have induced enzymes, and in those undergoing hemodialysis (250–350 mg/kg/h) (Chap. 9).[9,19,30,37,38]

Because ethanol elimination varies in each individual, frequent serum ethanol determinations should be made to ensure adequate dosing while also monitoring blood glucose and fluid and electrolyte status. Also, any increase in the anion gap or decrease in bicarbonate concentration implies that the ethanol dose is inadequate to achieve blockade of alcohol dehydrogenase and the ethanol dosing should be increased.

Problems encountered with the administration of ethanol include further risk of central nervous system (CNS) depression;[11,15,31,35,36] behavioral disturbances or ethanol-related toxicities, such as hepatitis and pancreatitis, hypoglycemia, dehydration, and fluctuating serum concentrations, and potential drug interactions resulting in disulfiramlike reactions.[55]

AVAILABILITY

A more practical problem often involves preparing the ethanol to be given since commercial preparations of 5% ethanol in 5% dextrose are no longer available for IV administration.[2] Not having a commercially available preparation increases the delay to administration of IV ethanol and the potential for a medication error in preparation. Sterile ethanol USP (absolute ethanol) can be added to 5% dextrose to make a solution of approximately 10% ethanol concentration; 55 mL of absolute ethanol is then added to 500 mL of 5% dextrose to produce a total end volume of 555 mL (10% = 10 mL in 100 mL, in this case, 55 mL in 555 mL or 55/555). If oral administration is chosen, it is important to remember that in the United States the "proof" number on the label is double the concentration; that is, "100-proof" ethanol is 50% ethanol (50 g/100 mL). If there will be any delay in preparing ethanol for IV use and fomepizole is not available or used, oral therapy with ethanol should be initiated immediately.

TABLE A32–2. Oral Administration of 20% Ethanol

Loading Dose[a]	Volume (mL)					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
0.8 g/kg of 20% ethanol, diluted in juice (may be administered orally or via nasogastric tube)	40	60	120	200	280	400

Maintenance Dose[b]	mL/h for various weights[c,d]					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
Ethanol naive						
80 mg/kg/h	4	6	12	20	28	40
110 mg/kg/h	6	8	17	27	39	55
130 mg/kg/h	7	10	20	33	46	66
Ethanol tolerant						
150 mg/kg/h	8	11	22	38	53	75
During hemodialysis						
250 mg/kg/h	13	19	38	63	88	125
300 mg/kg/h	15	23	46	75	105	150
350 mg/kg/h	18	26	53	88	123	175

[a] A 20% V/V concentration yields approximately 200 mg/mL.

[b] Concentrations above 30% (60 proof) are not recommended for oral administration. The dose schedule is based on the premise that the patient initially has a zero ethanol concentration. The aim of therapy is to maintain a serum ethanol concentration of 100 to 150 mg/dL, but constant monitoring of the ethanol concentration is required because of wide variations in endogenous metabolic capacity. Ethanol will be removed by hemodialysis, and the dose of ethanol must be increased during hemodialysis. Prolonged ethanol administration may lead to hypoglycemia.

[c] Rounded to the nearest mL.

[d] For a 30% concentration, multiply the amount by 0.66.

COMPARISON TO FOMEPIZOLE

Although ethanol has been used as an antidote for toxic alcohols for many years in both adults and children[43] and has the advantages of easy access to oral ethanol and low acquisition cost, fomepizole is a very potent inhibitor of alcohol dehydrogenase with many important advantages.[14,16,20,28,32,33] Fomepizole does not produce CNS depression, is easier to dose, and does not require serum concentration monitoring. Although fomepizole is more costly than ethanol, its many advantages over ethanol make fomepizole the preferable antidote.[25,45] Hospitals should be strongly encouraged to stock fomepizole (see Antidotes in Depth A31: Fomepizole and Chap. 107).

SUMMARY

When administered appropriately, ethanol is an excellent first step in preventing further metabolism of methanol and ethylene glycol to their respective toxic metabolites. However, the disadvantages of ethanol compared with fomepizole (when available) now make ethanol an outmoded antidote. The only advantage that ethanol might have compared with fomepizole would be in a mass casualty situation until sufficient supplies of fomepizole could be procured.[35] It is important to remember, however, that neither fomepizole nor ethanol affect the toxic metabolites that are already present in the body. Once alcohol dehydrogenase is blocked, the decision whether to use hemodialysis depends on how much end-organ damage has occurred, how well the body can eliminate the parent compound without the benefit of hemodialysis, and how much toxic metabolite is already present. With the use of either ethanol or fomepizole alone (without subsequent hemodialysis), the increase in hospital length of stay in an intensive care unit or on a medical floor may be substantial for methanol-poisoned patients, and a risk-benefit analysis should be applied.[17,44]

PESTICIDES

CHAPTER 108

PESTICIDES: AN OVERVIEW OF RODENTICIDES AND A FOCUS ON PRINCIPLES

Neal E. Flomenbaum

Pesticides are defined by the US Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) as "any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest, and any substance or mixture of substances intended for use as a plant regulator, defoliant, or desiccant."[24,109] Pesticides are most commonly categorized into four major and several minor classes based on the intended targets. The four major classes are insecticides, herbicides (weeds), fungicides (fungi and molds), and rodenticides. Minor classes include acaricides and miticides (mites), molluscides (snails etc.), larvicides, pediculocides (lice), nematocides, and scabicides, as well as attractants (pheromones), defoliants, dessicants, plant regulators, and repellants.[23] Currently, the Annual Report of the American Association of Poison Control Centers, National Poison Data System (AAPCC-NPDS) lists six categories of pesticides: fumigants, fungicides, herbicides, insecticides, repellents, and rodenticides. In 2007, the total number of exposures mentioned was 95,657, of which 85,617 were described as unintentional and 43,469 were in children younger than 6 years of age. Remarkably, despite these large numbers, fewer than 20 annual deaths were attributed to all pesticides by AAPCC in 2006 and 2007 (Chap. 135).

REGULATION AND EPIDEMIOLOGY

Since 1947, the production, use, and distribution of pesticides in the United States have been regulated under FIFRA and its subsequent amendments in 1972, 1975, and 1978. In 1970, the Environmental Protection Agency (EPA) was given the authority to administer and enforce FIFRA regulations. Under FIFRA, all pesticides and their manufacturers must be registered with the EPA, and the pesticide must be classified for either general use or restricted use by licensed or certified applicators. Also, a pesticide must be sold exactly as formulated, registered, and labeled. Failure to comply with any of these regulations can result in civil and criminal penalties, and product recall, seizure, or ban from future sales.[109] The EPA and FDA together establish pesticide tolerance concentrations for agricultural products and foods, and the 1978 amendment to FIFRA allows individual states to enact and enforce pesticide regulations, resulting in some states establishing even more stringent requirements and lower acceptable concentrations than EPA itself.[109] However, the EPA retains the authority to act when states are unable or unwilling to do so.

In addition to its authority under FIFRA, the EPA regulates pesticides under several other acts: the Federal Environmental Pesticide Control Act; the Resource Conservation Recovery Act of 1972 (RCRA); the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA, also called the "superfund" Act); the Toxic Substance Control Act (TSCA); the Clean Water Act and the Safe Drinking Water Act.

FIFRA is granted considerable authority to protect the health of the population. When evidence indicates that a pesticide may pose a significant hazard, one or more of the following actions may be taken: permissible workplace exposure limits may be issued, a product may be removed from sale or its registration canceled, restrictions on use or application of a product may be ordered and tolerance concentrations for pesticide residue on food stuffs or water contamination may be set.[109] However, since 1978, demonstration of efficacy may be waived, unless the pesticide actually affects public health. The Food Quality Protection Act of 1996 requires that EPA establish tolerances based in part on the higher vulnerability of children to pesticide residues, and on the aggregate exposures from residues from all sources and from all agents with the same mechanism of toxicity.[89] Table 108–1 summarizes the EPA toxicity classifications; the significance of oral median lethal doses for 50% of test subjects (LD_{50}) is discussed under rodenticides in the next section.

■ NEW RESTRICTIONS ON RODENTICIDES IN THE UNITED STATES

In an effort to reduce the risk of unintentional exposures to children, pets, and non-targeted wild life, in June 2008 the EPA announced significant new restrictions limiting the sale and use of 10 rodenticides. The 10 rodenticides covered by the new rules include the *nonanticoagulants* bromethalin, cholecalciferol, and zinc phosphide; the *"first-generation" anticoagulants* warfarin, chlorphacinone, and diphacinone; and the *"second-generation" anticoagulants* brodifacoum, bromadiolone, difenacoum, and difethialone. Under the new rules, use of all second-generation anticoagulants is restricted to use by professional applicators, and all other rodenticides available directly to consumers can only be sold in pre-loaded, tamper-resistant bait stations. Prohibited from sale are rodenticide baits in the form of meal, treated whole grain, loose pellets, and liquids, as are individual rodenticide "refills" sold without bait stations.

Insecticides are discussed in Chaps. 113 and 114, *herbicides* in Chap. 115, and *fumigants* including methyl bromide are discussed in Chapter 116. The remainder of this chapter explores the clinical problems posed by rodenticide poisoning. The specific rodenticides discussed

TABLE 108–1. EPA Toxicity Classifications

Category and Signal Word	Oral LD$_{50}$ (mg/kg)	Dermal LD$_{50}$ (mg/kg)	Inhalation LC$_{50}$ (mg/L)	Eye Irritation	Skin Irritation
I Danger	0–50	0–200	0–0.05	Corrosive: corneal opacity not reversible within 21 d	Corrosive
II Warning	50–500	200–2000	0.05–0.5	Corneal opacity reversible within 8–21 d; irritation persisting for 7 d	Severe irritation at 72 h
III Caution	500–5000	2000–20,000	0.5–5.0	Corneal opacity; irritation reversible within 7 d	Moderate irritation at 72 h
IV None	>5000	>20,000	>5.0	Irritation cleared within 24 h	Mild or slight irritation at 72 h

here are α-naphthyl thiourea (ANTU), cholecaliciferol, norbormide, bromethalin, tetramethylene disulfotetramine (tetramine), α chloralose and salmonella-based rodenticides. Some of the oldest and most toxic rodenticides—including barium, sodium monofluoroacetate/fluoroacetamide, phosphorous, and strychnine—are individually discussed in Chaps. 109 to 112, and three highly toxic metallic rodenticides—arsenic, thallium and zinc phosphide—are considered in Chaps. 88, 100, and 101.

RODENTICIDES

■ INTRODUCTION

The prevention of rat-borne diseases and bites has been an important public health goal for centuries, and the use of chemical rodenticides—to achieve these goals has always been part of the efforts. Although the rodenticides legally available today in most of the industrialized world are far less toxic than those used a century ago, the "perfect rodenticide," one that effectively kills rodents but is not toxic to humans or pets, has yet to be discovered or synthesized. Instead, a wide variety of less-than-ideal rodenticides are commercially available, differing from one another in chemical composition, mechanism for killing rodents, and human toxicity.[43,60,61,73,84] Purportedly "effective and harmless" products are periodically introduced, only to be subsequently withdrawn when the true human toxicities become known.[50,53,58,69,90,91] Moreover, some of these products may remain in basements, on hardware store shelves, or in use by professional pest control operators long after they are officially withdrawn from sale.

■ EPIDEMIOLOGY

In 2007 and 2008, AAPCC-NPDS recorded about 15,000 rodenticide exposures in the United States each year, of which over 80% involved children younger than 6 years of age (Chap. 135). Despite the very large number of exposures, only one death from rodenticides was reported in 2006 and only two in 2007. The specific types of rodenticides tracked by AAPCC include anticoagulants of the long-acting/superwarfarin type, anticoagulants-warfarin type, α-naphthyl thiourea (ANTU), bromethalin, cholecalciferol, cyanide, monofluoroacetate, strychnine, vacor, zinc phosphide, and other/unknown.

Of the 11 rodenticide deaths reported by AAPCC between 2003 and 2007, second-generation long-acting anticoagulants accounted

for three, strychnine accounted for two, bromethalin for two, zinc phosphide for one, and other/unknown accounted for three. However, in assessing the true human toll resulting from rodenticide exposures, it is important to recognize that the AAPCC database does not consider as a rodenticide exposure an encounter with a pesticide that is not labeled for use as a rodenticide, even when used by consumers for that purpose. An example of such product misuse is provided by a series of 35 cases referred to the New York City Poison Control Center from 1994 to 1997 involving an aldicarb insecticide illegally imported and sold as "Tres Pasitos" rodenticide.[74] Aldicarb, a carbamate cholinesterase inhibitor, can legally be used as an *insecticide* in some parts of the United States, but is not registered for use as a rodenticide, though it is sold that way in some neighborhood stores predominantly serving Dominican communities.

Children constitute the largest group of patients exposed to rodenticide; but the elderly; suicidal adults; potential homicide victims; intoxicated, psychiatric, or impaired persons; and pest control operators are also at substantial risk for intentional or unintentional exposures. The large number of unintentional ingestions of rodenticides placed in food containers or dishes, with or without added bait such as meal or peanut butter prompted EPA in 2008 to restrict the use of some rodenticides and require the use of tamper-resistant traps for all others.

■ DEFINITION AND CLASSIFICATION OF RODENTICIDES

A rodenticide is any product commercially marketed to kill rodents, mice, squirrels, gophers, and other small animals. Rodenticides are a heterogeneous group of chemicals bearing little or no relationship to one another, apart from their current or historic use as rodenticides. Rodenticides have been classified in several different ways: (1) as inorganic and organic compounds; (2) by animal selectivity; (3) by nature and onset of symptoms; and (4) according to their LD$_{50}$ in rats.[5] Classification by LD$_{50}$ is emphasized in this chapter and used to organize all of the rodenticides listed in Table 108–2.

■ INORGANIC AND ORGANIC COMPOUNDS

Inorganic compounds include the salts of arsenic (Chap. 88), thallium (Chap. 100), phosphorus (Chap. 111), barium (Chap. 109), and zinc (Chap. 101). Organic compounds include sodium monofluoroacetate (Chap. 110), ANTU, warfarin (Chap. 59), red squill[99,113] strychnine (Chap. 112), norbormide, and Vacor.[5,50,53,58,69,90,91]

TABLE 108–2. Management of Specific Rodenticide Ingestions

Rodenticide Name	Physical Characteristics	Toxic Mechanism	Estimated Fatal Dose	Signs and Symptoms	Onset	Antidote and/or Treatment*
Highly Toxic Signal Word: DANGER^a (LD$_{50}$ < 50 mg/kg)						
Thallium (Chap. 100)	White, crystalline, odorless, tasteless	Combines with mitochondrial sulfhydryl groups, interferes with oxidative phosphorylation	14 mg/kg	Anorexia, abdominal pain, diarrhea, painful neuropathy, delirium, coma, seizures, alopecia (late), Mees lines	GI symptoms acutely, other symptoms 12–14 h delay	Activated charcoal, Prussian blue
Sodium monofluoroacetate (SMFA, compound 1080)	White, crystalline, odorless, tasteless, water soluble	Fluoroacetate to fluorocitrate; interferes with Krebs cycle	3–7 mg/kg	Seizures, coma, tachycardia, PVCs, VT, VF, ST-T wave changes, rhabdomyolysis (hypocalcemia)	1/2–20 h	Experimental regimens: see text
Sodium fluoroacetamide (compound 1081) (Chap. 110)	Same as SMFA	Same as SMFA; fluoride toxicity	13–14 mg/kg	Same as SMFA	Same as SMFA	Same as SMFA
Strychnine (Chap. 112)	Bitter taste	Glycine receptor antagonist on spinal cord motor neurons	Children: 15 mg Adults: 1–2 mg/kg	Restlessness, anxiety, twitching, hyperextension alternating with relaxation, intense pain, trismus or facial grimacing ("risus sardonicus"), inability to swallow, opisthotonos	10–20 min	Quiet room, IV, benzodiazepines, neuromuscular blockade
Zinc phosphide (Chap. 101)	Heavy, gray, crystalline powder, water insoluble, "rotten fish" or "phosphorus" odor; normally used as 1% concentration	Releases phosphine on contact with water or acid or in GI tract	40 mg/kg in rats	"Rotten fish" breath odor, black vomitus, GI and cardiovascular toxicity, acute lung injury, agitation, coma, seizures, hepatic/renal toxicity	Within hours; inhalation may have delayed onset	Dilution with NaHCO$_3$ water or milk
Elemental phosphorus (yellow or white phosphorus) (Chap. 111)	Yellow, waxy paste, fat soluble, water insoluble	Local irritation and burns on contact followed by GI, liver, and renal damage, and interferes with clotting	1 mg/kg (more toxic if dissolved in alcohol, fats, oils)	Skin and GI burns, "smoking" luminescent vomitus and stools with garlic odor, jaundice, dysrhythmias, coma, delirium, seizures, cardiac arrest	1–2 h	Supportive care
Arsenic trioxide (Chap. 88)	White, crystalline powder	Combines with sulfhydryl groups and interferes with a variety of enzymatic reactions	1–4 mg/kg	Dysphagia, nausea and vomiting, bloody diarrhea, cardiovascular collapse, (VT, Torsades) garlic odor, altered mental status, late sensory/motor neuropathy	Symptoms: 1 h Death: 1–24 h	Succimer, dimercaprol until urine arsenic concentration <50 μg/L Hemodialysis to remove chelation compound if renal failure.
Barium (soluble forms: carbonate, chloride, hydroxide) (Chap. 109)	Yellow, white, slightly lustrous lump	Hypokalemia, neuromuscular blockade	20–30 mg/kg	Headache, paresthesias, peripheral weakness, paralysis, nausea, vomiting, diarrhea, abdominal pain, prolonged QT, dysrhythmias, cardiac and pulmonary failure	1–8 h	Orogastric lavage with Na$_2$SO$_4$, potassium replacement

(*Continued*)

TABLE 108–2. Management of Specific Rodenticide Ingestions (*Continued*)

Rodenticide Name	Physical Characteristics	Toxic Mechanism	Estimated Fatal Dose	Signs and Symptoms	Onset	Antidote and/or Treatment*
PNU (*N*-3-pyridylmethyl-*N'*-p-nitrophenyl urea, Vacor)	Yellow, resembling cornmeal or yellow green powder in bait; odor: peanuts	Interferes with nicotinamide metabolism in pancreas (destroying pancreatic beta cells), central and peripheral nervous system, and heart	5 mg/kg	Nausea and vomiting abdominal pain, severe orthostatic hypotension, hyperglycemia with or without ketoacidosis, GI perforation, pneumonia, neuropathy	4–48 h	Nicotinamide (Niacinamide) 500 mg IV or IM, manage diabetic ketoacidosis
Tetramine (tetramethylene disulfotetramine, TETS, TEM)	White powder	Non-competitive, GABA antagonism by direct blockade of chloride ionophore	5–10 mg/kg	Refractory status epilepticus, fainting, coma, coronary ischemia	1/2–13 h	Benzodiazepines Barbiturates, Neuromuscular blockers
Moderately Toxic Signal Word: WARNING[a] (LD$_{50}$, 50–500 mg/kg)						
α-Naphthylthiourea (ANTU)	Odorless, slightly bitter, fine, blue-gray powder, water-insoluble	Acute lung injury	>4 g/kg	Hypothermia, dyspnea, crackles, clear pulmonary froth, cyanosis	?	Supportive care
Cholecalciferol (vitamin D$_3$)	0.075% pellets, 364 pellets/oz; (1 pellet = 2308 U vitamin D)	Hypercalcemia	?	Headache, lethargy, weakness, fatigue, polyuria, renal injury and failure, hypertension, hypercalcemia	Hours to days	Fluids; if severe: furosemide, prednisone, calcitonin, bisphosphonates hemodialysis
Low Toxicity Signal Word: CAUTION[a] (LD$_{50}$, 500–5000 mg/kg)						
Red squill (Chap. 64)	Bitter taste	Cardioactive steroid poisoning	?	Myocardial irritability, blurred vision, hyperkalemia	30 min-6 h	Digoxin-specific Fab, atropine
Norbormide (dicarboximide)	Yellow cornmeal bait, peanut butter, 1% concentration	Vasoconstriction and ischemia in rats only via specific norbormide receptor in rat smooth muscle	Unknown, toxicity at <300mg	Transient hypothermia and hypotension	?	Supportive care
Bromethalin	7.5% concentrate, green pellets, with Bitrex (denatonium benzoate)	Uncouples oxidative phosphorylation; interrupts nerve impulse conduction	?	Muscle tremors, myoclonic jerks, flexion of major muscles, coma?, ataxia, focal motor seizures	Immediate	Supportive care
Anticogulants: Short Acting (Chap. 59)						
Warfarin	Yellow cornmeal, rolled oats (0.025%)	Anticoagulation via interference with clotting factors II, VII, IX, X	>5–20 mg/d for >5 d	Elevated INR; bleeding death from hemorrhage	12–48 h	Vitamin K$_1$, fresh frozen plasma (FFP) as indicated Activated factor VII Prothrombin complex concentrate
Prolin	Warfarin (0.025%) plus sulfaquinoxalin (0.025%)	Anticoagulant antibiotic combination eliminates intestinal vitamin K producing organisms	NA	Elevated INR; bleeding, death from hemorrhage		

Anticoagulants: Long Acting						
Hydroxycoumarins						
4-Hydroxycoumarin (brodifacoum, difenacoum)	0.005% grain-based bait	Anticoagulation via interference with clotting factors II, VII, IX, X	?	Elevated INR; bleeding death from hemorrhage	Delayed several days	Vitamin K_1, fresh frozen plasma (FFP) as indicated Activated factor VII
Warfacide (coumafuryl)	0.5% for dilution to 0.025% white powder, tasteless, odorless					Prothrombin complex concentrate
Indandiones						
Pindone (Pival)	Moldy, acrid odor, fluffy yellow powder, concentrations 0.005–2.5%	Anticoagulation via interference with clotting factors II, VII, IX, X	?	Chronic ingestion possibly produces cardiac and neurologic symptoms elevated INR; bleeding, death from hemorrhage	Delayed several days	Vitamin K_1, fresh frozen plasma (FFP) as indicated Activated factor VII Prothrombin complex concentrate
Pivalyn	0.5%					
Diphacinone	0.005–2.0%					
Chlorophacinone	0.005–2.5%					
Valone	0.005–2.5%					

[a]The LD_{50} values used in this table are derived from data on acute oral ingestions of the commercial product by rats. In some cases, the commercial product contains a very small percentage of active ingredient. The signal words that appear on labels of registered products may differ from the signal word assigned to the acute oral LD_{50} test because the label may also reflect another study (acute dermal or inhalational LD_{50}) requiring a more severe signal word. See Table 108-1 for the Consumer Product Safety Commission definitions and use of signal words as indicators of potential hazard of toxicity. Peacock D, Biologist, Registrations Division Office of Pesticide Programs, EPA, Washington, DC.

∗Gastrointestinal decontamination should be provided as appropriate (Chap. 7); only unique or controversial aspects are discussed in this table.

■ ANIMAL SELECTIVITY

The cardioactive steroid *red squill* was promoted as a safe rodenticide because humans and other animals presumably would vomit the highly emetogenic xenobiotic prior to experiencing any cardiotoxic effects, whereas rats do not vomit and therefore would be expected to experience the cardiotoxic effects of red squill.[99,113] *Norbormide,* an irreversible smooth-muscle constrictor, causes widespread ischemic necrosis and death in rats, but does not appear to affect other animals or humans because it has been thought to act on a specific norbormide receptor found only in the smooth muscle of rats. ANTU, a relatively selective rodenticide, is a derivative of phenylthiourea, without the bitter taste characteristic of the thiourea. ANTU causes acute lung injury in rats that have not developed tolerance to it. ANTU, however, is only relatively selective: Although rats are more sensitive to it than other animals, large doses (greater than 4 g/kg) can also be lethal to primates.

All of the rodenticides classified as inorganic, and organic rodenticides such as strychnine and sodium fluoroacetate, are nonselective and of extreme concern when ingested by humans and domestic animals. Use of this entire group of rodenticides is restricted to commercial pest control operators and government agencies.

■ NATURE AND ONSET OF SYMPTOMS

Although a rodenticide classification system based purely on the nature and onset of symptoms would seem to be very appealing, such a system may be unreliable, may create a false sense of security, and may result in inappropriate management and/or inadequate followup. Many different rodenticides cause neurologic and/or gastrointestinal signs and symptoms, whereas characteristic or pathognomonic signs such as *risus sardonicus* from strychnine, or alopecia from thallium, may not be recognized, do not always occur consistently (especially after ingesting small amounts), or, as in the case of thallium-induced alopecia, would not occur until days after an acute ingestion. Classifying rodenticides by the time of onset of symptoms may similarly lump together within a late-onset group some of the least toxic (regular warfarin-type, cholecalciferol) and most toxic, (long-acting warfarin type, thallium) rodenticides.

■ LD$_{50}$ IN RATS

Probably the most clinically useful way of classifying rodenticides at present is by toxicity based on LD$_{50}$ data in rats. With a few noteworthy exceptions, the relative degree of toxicity per kilogram and the characteristic adverse effects generally hold among different mammals, allowing the healthcare provider the opportunity to consider a combination of historical and characteristic physical evidence to diagnose or exclude various rodenticides and to decide on an optimal management plan. The limitations of this classification system, however, must be understood to use it appropriately: (1) in rare cases, the LD$_{50}$ may vary unpredictably among species as was the case with Vacor[50,53,58,69,90,91]; and (2) repeated ingestions of less toxic rodenticides (eg, short-acting anticoagulants, cholecalciferol) may, in fact, make them highly toxic (Table 108–2).

■ HIGHLY TOXIC RODENTICIDES (SIGNAL WORD: "DANGER")

According to FIFRA, highly toxic rodenticides are those substances with a single-dose LD$_{50}$ of less than 50 mg/kg body weight. The label "Danger" is the strongest warning issued by the Consumer Product Safety Commission for a potential toxic hazard. Lower hazard levels

are denoted by "Warning" and "Caution" (Table 108–1). The highly toxic "Danger" group includes thallium (Chap. 100), sodium monofluoroacetate (SMFA, compound 1080) and fluoroacetamide (compound 1081) (Chap. 110), strychnine (Chap. 112), zinc phosphide (Chap. 101), elemental phosphorus (Chap. 111), arsenic (Chap. 88), barium carbonate[57,70,87,97,104,105,117] (Chap. 109) and Vacor (N-3-pyridylmethyl-N′-p-nitrophenyl-urea)[3,50,53,58,69,90,91,101] (see Table 108–2 and the 7th edition of this text for an extensive discussion of Vacor).

■ MODERATELY TOXIC RODENTICIDES (SIGNAL WORD: "WARNING")

Moderately toxic rodenticides, those with an LD$_{50}$ of 50 to 500 mg/kg body weight, include the "selective" rodenticide ANTU and *cholecalciferol (vitamin D$_3$),* one of the newer and increasingly popular rodenticides.

α-Naphthyl-Thiourea (ANTU)   ANTU was first synthesized and tested in the United States during World War II in an effort to prevent rat-borne epidemics.[52] ANTU kills rats by causing acute lung injury (ALI) and pleural effusion, probably by damaging the lung capillaries, resulting in increased permeability.[11,96] Both morphine[23] and fructose-1,6-diphosphate (FDP)[64] appear to prevent or ameliorate ANTU-induced lung injury. Morphine modulates inducible nitric oxide synthetase and FDP inhibits activated neutrophils from producing oxygen free radicals that have been implicated in the pathogenesis of ALI and the resultant pulmonary edema. Young rats and rats exposed initially to small, nonlethal doses are relatively resistant to the lethal effects of ANTU, possibly by developing pulmonary cell hyperplasia.[9] The heart appears to be unaffected by ANTU.[11,96]

There are no well-documented human cases or series of human ANTU exposures from which human toxicity can be accurately determined. In several older series of combined ANTU plus chloralose ingestions, it appears that the respiratory symptoms are more severe from the combination than from chloralose alone, suggesting pulmonary effects of ANTU in humans. Of the 14 patients poisoned by the combination, 11 required intubation because of tracheobronchial hypersecretion.[36,43] Recommended treatment for ANTU ingestions is administration of activated charcoal (AC).[73] Supportive and symptomatic care should be provided, as there is no known antidote.

Cholecalciferol   Cholecalciferol (vitamin D$_3$, Quintox®, Rampage®) was first registered and marketed in the United States in 1984 and can legally be purchased and applied by both pest control operators and consumers. Cholecalciferol mobilizes calcium from the bones of rodents and rabbits and in toxic doses produces hypercalcemia, osteomalacia, and metastatic calcification of the cardiovascular system, kidneys, stomach, and lungs; death typically occurs in 2 to 5 days.[66–68] Although all animals are susceptible to the effects of cholecalciferol, rats and mice succumb to much lower doses than do larger animals such as cats and dogs.[67,68] Cholecalciferol appears to be an effective rodenticide when either a large amount is consumed at one time, or smaller amounts consumed over a 2- to 3-day period.[67,68,92] Because death is not immediate and cholecalciferol does not impart unusual characteristics to the bait, the type of bait shyness that occurs with zinc phosphide, ANTU, strychnine, and other rodenticides typically does not occur.[66–68] Nevertheless, investigators in New Zealand hypothesized but failed to prove that dextromethorphan could prevent any acquired memory of sickness and cholecalciferol-induced anorexia by rats eating poisoned bait (resulting in poison shyness) though they claim that anorexia was reduced from 17 to 8 days.[41] The closely related vitamin D$_2$ (or ergocalciferol) has been used as a rodenticide in Europe and Canada since 1978, without the development of resistance reported to date.[66–68]

Although rats manifest signs of severe acute hypercalcemia, including lethargy and ultimately death from myocardial infarction in 2–5 days,[92] no serious human toxicity or deaths from the rodenticide form of cholecalciferol have been reported to date. It is important to note that all of the advice for managing human ingestions of cholecalciferol rodenticide is based on experience in the treatment of those poisoned from the therapeutic forms of vitamin D. One case of cholecalciferol poisoning in an industrial setting may be particularly relevant because, as might be the case of a child repeatedly ingesting small amounts of rodenticide, the exposure described was to small doses over a 32-day period resulting in prolonged hypercalcemia.[48]

Calciferol concentrations are not readily available, but a normal serum calcium concentration obtained 48 hours after an acute ingestion almost certainly will exclude any significant toxicity. Immediate intervention that may be considered after a large acute ingestion includes gastric emptying followed by gastric decontamination with AC, sorbitol, and multiple-dose activated charcoal (MDAC), but there is no data to confirm the effectiveness of this approach.

Treatment for moderate to severe degrees of hypercalcemia (greater than 11.5 mg/dL) includes IV fluid therapy with 0.9% sodium chloride solution, if the patient is hypovolemic and can tolerate a fluid load. Furosemide should be administered and potassium and magnesium concentrations monitored and maintained.

■ LOW-TOXICITY RODENTICIDES (SIGNAL WORD: "CAUTION")

The remaining rodenticides, with one exception, are of low toxicity (LD_{50}, 500 to 5000 mg/kg). This category includes red squill (*Urginea maritima*)[99,113] (Chap. 64), norbormide, bromethalin, and the anticoagulants (Chap. 59). The first-generation warfarin-based anticoagulant rodenticides and the second-generation long-acting superwarfarin forms together are responsible annually for more than 80% of the reported exposures, and the long-acting anticoagulants alone for 3 of the 11 deaths attributed to rodenticides between 2003 and 2007. Norbormide and bromethalin are discussed in the following sections.

Norbormide   Norbormide, an irreversible smooth-muscle constrictor, appears to uniquely affect rats and has no known human toxicity. Rats die as a result of intense generalized vasoconstriction, resulting in tissue anoxia.[73] In vitro, norbormide promotes calcium entry into smooth muscle cells, inducing a myogenic contraction, selective for the small vessels in rats, whereas in the arteries of other mammals (and in the rat aorta), norbormide behaves like a calcium channel blocker.[12] Norboromide stimulates the opening of the rat mitochondrial permeability transition pore (mPTP) and induces changes in the fluidity of the lipid interior of the rat mitochondrial membranes, though the drug regulation of mPTP activity does not appear to be related to its lethal effects. The norbormide-sensitive mPTP target appears to be present in all species, and the selectivity may depend on unique properties of the system transporting norbormide to the internal matrix side of the rat mitochondria.[95,119] Following exposure, it is sufficient to achieve gastric decontamination with AC.

Bromethalin   The commercial product formulation of bromethalin, is considered to be of low toxicity as defined previously. Bromethalin was registered with the EPA in 1982, became available in 1986.

From the time that bromethalin first became available, concern had been expressed about its potential toxicity.[66] However, the first possible bromethalin-induced case of human toxicity was not reported until 1996,[16] perhaps because as late as 1997, bromethalin had been registered in only six states. Two human deaths caused by bromethalin were reported by AAPCC in 2005, confirming fears of its potential lethality. From 2003 to 2007, AAPCC annually reported between 533 and 643 annual exposures, including 388 to 510 in children younger than 6 years of age. The outcome of the exposures has been almost entirely "none" to "moderate," except for the two deaths reported in 2005.

Bromethalin is considered a highly effective, single-feeding rodenticide with a mode of action reportedly involving the uncoupling of oxidative phosphorylation in the mitochondria, resulting in decreased adenosine triphosphate (ATP) production, increased fluid accumulation, and consequent increased pressure on nerve axons interrupting nerve impulse conduction.[67]

The pathologic changes resulting from a 1.5-mg/kg oral dose of bromethalin administered to cats, included spongy changes, hypertrophied fibrous astrocytes, and hypertrophied oligodendrocytes in the white matter of the cerebrum, cerebellum, brainstem, spinal cord, and optic nerve.[30,32] Prior to sacrifice of the animal, the clinical manifestations of bromethalin poisoning in these cats included ataxia, focal motor seizures, decerebrate posture, decreased proprioception, and depressed level of consciousness. Dogs given oral doses of 6.25 mg/kg of bromethalin developed hyperexcitability, tremors, seizures, depression, and death within 15 to 63 hours of exposure.[31] Death in animals is also usually preceded by paralysis and loss of tactile sensation.[114,115]

A 2006 report described the case of a 21-year-old man who presented with altered mental status a day after ingesting a bromethalin-based rodenticide. Over the next 7 days he developed obtundation, increased cerebrospinal fluid pressure, and cerebral edema, followed by death. Autopsy findings included diffuse histologic vacuolization in the CNS white matter on microscopic examination, and the presence of demethylated bromethalin in the liver and brain by gas chromatography-mass spectrometry. As predicted, clinical signs and microscopic pathology are clearly similar to that seen in animals poisoned with bromethalin.[81] Additional parallels to the clinical courses of exposed animals are the delay in appearance of clinical symptoms and signs, behavioral changes, anisocoria, cerebral edema, elevated CSF pressure, and subsequent death.[81]

Symptomatic and supportive care should be provided to patients exposed to bromethalin; there is no known antidote.

■ DANGEROUS OLD, NEW, AND UNUSUAL RODENTICIDES: THE GLOBAL PROBLEM

The confusion caused by nonrodenticide pesticides inappropriately used as rodenticides is compounded when a dangerous rodenticide favored in one part of the world is introduced and used in a different area, or when a highly toxic, previously abandoned rodenticide is "rediscovered." All three situations have become problematic in recent years. Widespread accessibility to products (including by the internet) and global travel probably contributes.

Tetramethylene Disulfotetramine (Tetramine, TETS, TEM)   During the past decade, several reports have appeared in the medical literature describing the toxicity of the illegal Chinese rodenticide tetramine.[8,25] Patented as a rodenticide in the United States in 1953, tetramine was first used and then banned in China in 1984.[8] But this fast-acting, single-dose poison is still produced illegally in many parts of China and continues to be identified in unintentional or deliberate poisonings there and elsewhere. In China in September 2002, a deliberate adulteration of restaurant food with tetramine by a competing restaurant owner poisoned 300 people and caused 42 deaths, all in schoolchildren. In that same year, the first known case of tetramine poisoning in the United States resulted from a 15-month-old infant playing with the white powder brought back from China by her parents and applied to a kitchen corner.[8] The child developed convulsive status epilepticus refractory to lorazepam, phenobarbital, and pyridoxine and required intubation. She was left with multiple neurologic deficits that included

persistent absence seizures, possible cortical blindness, multiple epileptogenic foci months later, and developmental delay 1 year later.[8]

Tetramine is an indirect-acting, γ-amino butyric acid (GABA) antagonist similar in some respects to picrotoxin and with an LD_{50} of 0.1–0.3 mg/kg.[35] Tetramine is more lethal than sodium fluoroacetate, the registered pesticide considered to be the most lethal by the World Health Organization (WHO). Tetramine may also be 100 times more toxic (on a g/kg basis)[8] to humans than potassium cyanide,[8] and as little as 5–10 mg/kg may be lethal.[25] Because of its high stability in water, tetramine is a relatively persistent environmental contaminant that theoretically could cause secondary poisonings.[25]

In addition to its most common manifestation of toxicity—refractory seizures[63]—tetramine also causes coma and possibly coronary ischemia. Symptoms begin from 30 minutes to 13 hours after exposure, and death may occur within 3 hours. A variety of methods have been used to treat tetramine poisoning in China, including AC, hemoperfusion, and hemodialysis, but none have proven to be uniformly successful and there are no proven antidotes for tetramine. Recently the use of sequential hemoperfusion (HP) and continous venovenous hemofiltration (CVVH) has been explored and in one study of 18 patients with severe tetramine poisoning treated this way, the 8 patients whose treatment was initiated within 24 hours of exposure had a higher cure rate than the 10 whose treatment began later.[27] Standard management includes gastrointestinal decontamination with AC, benzodiazepines for seizures, and effective airway protection.[118]

α-Chloralose (Glucochloral, Chloralosane) α-Chloralose is a crystalline powder (usually colored pink or blue) that is formed by the condensation of glucose with trichloroacetaldehyde (chloral). α-Chloralose is a central nervous system depressant, still used as a veterinary anesthetic.[100] Its effects in humans include sedation, anesthesia, spontaneous myoclonic movements, and generalized convulsions.[36,54] Most human exposures are nonfatal, and most current reports appear to emanate from France and Europe.[13,36,37,54] Management is supportive, with the use of airway protection and the administration of AC.

Salmonella-based Rodenticides *Salmonella enteritides*, a human pathogen, is an active ingredient in rodenticides still produced and used in Central America and Asia. The currently available formulation is made by coating rice grains with a combination of *S. enteritides* and warfarin. The strain of *Salmonella*—phage type 6a—is similar to the strain of *Salmonella* that was in a rodenticide used in Europe until the 1960s[79] and was responsible for human illness and deaths.[79] In 1954 and 1967, the WHO recommended against using *Salmonella*-based rodenticides because of the threat to human health. Since 1980, *S. enteritides* has been responsible for a global pandemic of foodborne illness associated with eggs and poultry.[79] In addition to inadvertent exposures, *Salmonella*-based rodenticides have been used intentionally to cause human illness.

■ MANAGING THE PATIENT EXPOSED TO AN UNKNOWN RODENTICIDE

For the patient exposed to an unknown rodenticide, the approach is more complicated than for a patient who ingests a known common commercial rodenticide, such as warfarin or cholecalciferol. First, as always, adequate breathing and circulation must be assured, as the patient is briefly examined. If the patient is initially stable, the next priority is to make every effort to fully identify the type and quantity of rodenticide ingested.

If the rodenticide and its package material do not accompany the patient, someone should be sent to retrieve them because identifying a harmless rodenticide ingestion early on is more cost-effective and less traumatic to the patient than treating for an unknown ingestion. If the

rodenticide container is labeled, and the information is telephoned back to the health care provider, care should be taken to obtain the full name and not just the brand name. Rodenticide product and brand names are frequently used interchangeably by manufacturers. For example, until 1986, a line of rodenticides all carried the "Pied Piper" name on a variety of very different products: Pied Piper for Rats and Mice contained ANTU and warfarin; whereas Pied Piper Kwik-Kill Mouse Seed contained strychnine; and Pied Piper Rodenticide contained red squill. Many manufacturers still use similar names for dissimilar poisons.

Although full identification of the rodenticide is important, a careful physical examination should always be performed in all cases, searching for toxic signs that indicate specific rodenticides:

- Gastrointestinal symptomatology, paresthesias, and the late onset of hair loss are characteristic of thallium poisoning (Chap. 100).[10,26,28,44,49,62,72,75,83]
- Irritability or "apprehension" followed by seizures, coma, and death from respiratory failure or ventricular tachycardia and fibrillation are produced by SMFA, fluoroacetamide[18,19,20,21,40,78,86,93,107,110] (Chap. 110), and tetramine.
- Central nervous system stimulation, opisthotonos, prolonged recurrent motor seizures, and medullary paralysis followed by death suggest strychnine poisoning (Chap. 112).[6,15,33,46,51,56,59,76,77,80,85,94,102,108,112,116]
- Hypotension, vomitus with a rotten or "fishy" odor, cardiopulmonary collapse, coma, renal damage, and leukopenia suggest various metal phosphide exposures (Chap. 101).[1,2,4,17,22,39]
- Oral and skin burns, luminescent "smoking" vomitus, stools with a garlic odor, and gastrointestinal and biliary damage characterize yellow phosphorus (Chap. 111).[29,65,88,98,106,111]
- Dysphagia, muscle cramps, seizures, hematemesis, and bloody diarrhea followed by cardiovascular collapse suggest arsenic (Chap. 88).[55,103]
- The combination of striking hyperglycemia with or without ketoacidosis, severe postural hypotension, autonomic and peripheral neuropathies, and ileus and esophageal or GI perforation characterize Vacor poisoning (see Goldfrank's Toxicologic Emergencies, 7th ed., Chap. 90)[3,34,38,42,45,47,50,53,58,69,71,90,91,101]
- Muscle tremors, myoclonic jerks with flexion of major muscle groups, and unresponsiveness may be the human manifestations of bromethalin poisoning.
- Dyspnea, crackles, acute lung injury, pleural effusions, and hypothermia are seen with massive ingestions of ANTU.
- Nausea, vomiting, diarrhea, and abdominal pain will probably be the only effects of ingesting red squill, but when combined with signs of ventricular irritability (premature ventricular contractions and ventricular fibrillation), these signs and symptoms suggest exposure to this potent cardioactive steroid (Chap. 64).[82,99,113]
- Evidence of a bleeding disorder and abnormal coagulation or international normalized ratio (INR), or low concentrations of coagulation factors, point to either a large acute ingestion of a second-generation superwarfarin rodenticide, such as brodifacoum, or repeated (chronic) ingestion of a first-generation regular warfarin-type rodenticide (Chap. 59).[14]
- Signs and symptoms of hypercalcemia following (massive or chronic) rodenticide ingestion(s) suggests cholecalciferol (vitamin D_3).

If a toxic syndrome is identified, aggressive management, including the use of specific antidotes, may be indicated or necessary (see Table 108–2). Immediately following an ingestion and prior to the development of signs and symptoms of toxicity, there is no rodenticide currently in use for which orogastric lavage followed

by AC (and possibly even an intestinal evacuant cathartic) is contraindicated—although they may be unnecessary. Once the patient is symptomatic however, orogastric lavage, AC, and catharsis must be individualized according to the specific toxin and the patient's clinical condition.

If every effort to identify the rodenticide fails, the following diagnostic evaluation may be indicated: A complete blood cell count and INR will help diagnose and manage repetitive ingestions of first-generation warfarin-type anticoagulant rodenticides, chronic ingestions of second-generation superwarfarin anticoagulant rodenticides, and a large single ingestion of a second-generation anticoagulant a few days later. Following acute ingestions, the CBC and INR will not be useful for at least 48 hours. Repetitive ingestions of the otherwise harmless first-generation warfarins is an important consideration for children who have pica, and for institutionalized, emotionally disturbed adults who may try to nibble rodenticides repeatedly. Tamper-resistant bait traps now mandated in the United States will hopefully reduce these risks further. Serum glucose, potassium, and bicarbonate concentrations will identify hyperglycemia and ketoacidosis caused by Vacor, and an elevated serum calcium concentration suggests cholecalciferol (vitamin D_3) ingestion. Liver enzyme, BUN, and creatinine concentrations are useful baseline determinations for rodenticides that cause hepatic or renal damage, respectively (eg, zinc phosphide, yellow phosphorus, cholecalciferol). A serum sample and 50 mL of urine should be obtained and sent to the toxicology laboratory with the request to hold it for possible heavy metals screening, especially if the patient is vomiting. Finally, if indicated by history or symptomatology, additional specimens may be collected for specific rodenticide determinations (eg, thallium, strychnine), and a digoxin concentration may point to red squill ingestion. Chest and abdominal radiographs may be useful because of the radiopaque nature of some of the uncommonly used rodenticides (Chap. 5).

If there is any doubt about the reliability of the patient (or parents) after the diagnostic evaluation, the patient should be admitted for observation. No matter what type of rodenticide was ingested, a determination should be made regarding the cause of the exposure, whether the ingestion was unintentional, a suicide gesture or attempt, or a manifestation of abuse or neglect.[7] A psychiatric assessment is, of course, indicated for any possible suicide attempt.

SUMMARY

As both the industrialized and underdeveloped parts of the world continue to experiment with and use exotic and sometimes lethal rodenticides, it will be even more important to be able to discriminate between the expected sequelae of known or suspected rodenticides and unexpected sequelae from other pesticides or xenobiotics used inappropriately for that purpose. The key to managing a patient who has ingested a rodenticide is to identify the rodenticide and the quantity ingested, its potential toxicity, and any available specific antidote. Toxic ingestions should be excluded or treated immediately; conversely, patients exposed to the most common commercial product acute anticoagulants, bromethalin, or cholecalciferol rodenticides should not be overtreated.

CHAPTER 109
BARIUM

Andrew Dawson

Barium (Ba)

Atomic number	=	56
Atomic weight	=	137.33 daltons
Normal concentrations		
Serum	=	0.2 mg/L (1.46 µmol/L)

Barium is commonly utilized as a pesticide, a depilatory, and a radio-graphic contrast material. Acute exposures following ingestion or inhalation are most common outside the hospital setting. Exposures during radiologic procedures are associated with aspiration during oral studies, intravasation during rectal procedures, and iatrogenic intravenous administration. Rapid recognition is essential to address these potentially life-threatening exposures.

HISTORY AND EPIDEMIOLOGY

Barium poisoning is a rare cause of exposure or poisoning as far fewer than 100 cases were reported to the AAPCC database in recent years (see Chap. 135). Toxicity is most commonly reported following the intentional ingestion of soluble salts found in rodenticides,[9] insecticides, or depilatories.[10] Barium carbonate has an appearance that is similar to flour and has been responsible for most unintentional barium poisonings.

Barium salts and barium hydroxide are extensively employed in industry particularly in thermoplastics and the manufacture of synthetic fibers, soap manufacture, and in lubricants (see Table 109–1). Toxicity has also followed occupational exposure to barium salts through ingestion or inhalation. An explosion of the propellant barium styphnate caused extensive burns and trauma in a 50-year-old man. The individual also developed significant barium toxicity within 2 hours of exposure that persisted for at least 4 days.[13] Despite the fact that barium sulfate is insoluble, rare cases of unintentional toxicity have been reported during radiographic procedures and include complications associated with oral[20] and rectal administration.[12,17,19,22] Toxicity and death occurred when soluble barium salts unintentionally contaminated contrast solution[24] and flour.[8]

CHEMISTRY

Barium is a soft metallic element that was first isolated by Sir Humphry Davey in 1808. With an atomic weight of 137.3 barium is located at number 56 in the periodic table (between cesium and lanthanum). The metal oxidizes easily when exposed to water or alcohol, has a melting point of 727°C (1341°F) and a boiling point of 1870°C (3398°F). Elemental barium is not found in nature; it normally occurs as an oxide, dioxide, sulphate (barite), or carbonate (witherite). Chemically, barium resembles calcium more than any other element. While some barium salts are naturally occurring, most used commercially are produced from the more commonly found carbonate or oxides. Barium salts are typically classified as either water soluble or insoluble, but the solubility of all barium salts increases as the milieu becomes more acidic. The soluble salts acetate, chloride, hydroxide, oxide, nitrate, and (poly)sulfide are the most commonly associated with toxicity (Table 109–1). Barium (poly)sulfide also produces toxicity through the formation of hydrogen sulfide when ingested and exposed to gastric hydrochloric acid.

The solubility of barium carbonate is low at physiological pH, but increases significantly as the pH is lowered. In addition, in gastric acid conversion to barium chloride occurs, which is highly soluble. The other insoluble barium salts such as arsenate, chromate, fluoride, oxalate, and sulfate are rarely associated with toxicity. However, toxicity has occurred in the unusual situation of intravasation of barium sulfate (see Toxicokinetics).

TOXICOKINETICS

Toxicity can result from ingestion of as little as 200 mg of a barium salt. Oral lethal doses are reported to range from 1 to 30 g of a barium salt. In ambient air, inhaled concentrations greater than 250 mg/m^3 are considered dangerous.[32]

Following ingestion, 5%–10% of soluble barium salts are absorbed,[14] with the rate of absorption dependent on the degree of water solubility of the salt. The time to peak serum concentration is 2 hours.[14]

The toxicokinetics are characterized by a rapid redistribution phase, followed by a slow decrease of serum barium concentrations with a reported half-life ranging between 18 and 85 hours.[14,23] Renal elimination of the absorbed dose accounts for 10%–28% of total barium excretion, with the predominant route of elimination through the gastrointestinal tract in the feces.

Death is uncommon following exposure but occurs most commonly following ingestion, and rarely following inhalation.[15] Death from an ingestion with barium chloride was associated with the following barium concentrations at autopsy: blood, 9.9 mg/L; bile, 8.8 mg/L; urine, 6.3 mg/L; and gastric contents, 10 g/L.[15]

Intravasation is a rare but serious complication of radiologic studies that administer barium sulfate under pressure, such as a barium enema. Following a small perforation, barium sulfate leaks into the peritoneal cavity or portal venous system.[19] Although sudden cardiovascular collapse may occur, it is unclear whether this is the result of venous occlusion (pulmonary embolism), overwhelming sepsis, or barium toxicity.[6,27,31] In at least one case report of intravasation, signs and symptoms were consistent with barium toxicity and elevated concentrations were confirmed.[20] If hypokalemia is present, then barium toxicity should be assumed.

Additionally, intravenous administration of barium sulfate has occurred as the result of iatrogenic error. Rapid recognition followed by aspiration through a central venous catheter was associated with a good outcome.[25]

PATHOPHYSIOLOGY

At a cellular level barium induces hypokalemia by two synergistic mechanisms. Barium is a competitive blocker of the potassium rectifier channel which is responsible for the efflux of intracellular potassium out of the cell. It may also directly increase cell membrane permeability to sodium. This causes a secondary increase Na$^+$-K$^+$ pump electrogenesis leading to a shift of extracellular potassium into the cell.

Intracellular trapping of potassium leads to depolarization and paralysis.[16] Additionally, the inhibition of potassium channels increases vascular resistance and reduces blood flow[3,5] and is the likely mechanism for hypertension and metabolic acidosis with elevated lactate concentration.

TABLE 109–1. Barium Salts: Solubility and Common Usages

Barium Salt	Solubility[a]	Common Uses
Acetate	58.8	Textile dyes
Carbonate	0.02 g/L increases in an acid pH; also, can be converted to barium chloride by gastric acid (HCl)	Rodenticide, welding fluxes, pigments, glass, ceramics, pyrotechnics, electronic devices, welding rods, ferrite magnet materials, optical glass, manufacture of caustic soda and other barium salts
Chloride	375	Textile dyes, barium salts, pigments, boiler detergents, in purifying sugar, as mordant in dyeing and printing textiles, as water softener, in manufacture of caustic soda and chlorine, polymers, stabilizers
Fluoride	1.2	Welding fluxes
Nitrate	87	Optical glass, ceramic glazes, pyrotechnics (green light), explosives, antiseptic preparation
Oxide	34.8	In glass, ceramics, refining oils and sugar, as an additive in petroleum products and also as materials of plastics, pharmaceuticals, polymers, glass and enamel industries
Styphenate	–	Propellent used in manufacture of explosive detonators
Sulfate	0.002	Radiopaque contrast media, manufacture of white pigments, paper making
Sulfide	Slightly soluble in H_2O	Depilatories, manufacture of fluorescent tubes

While severe hypokalemia is a major contributor to paralysis, some authors have found that muscle weakness correlates better with barium concentrations than with potassium concentrations.[21,28] This suggests a possible direct effect of barium on either skeletal muscle or neuromuscular transmission.

CLINICAL MANIFESTATION

Abdominal pain, nausea, vomiting, and diarrhea commonly occur within 1 hour of ingestion. Esophageal injury[1] and hemorrhagic gastritis are also reported.[15]

Severe hypokalemia is the cardinal feature of barium toxicity and can occur within 2 hours following oral or parenteral exposure. Hypokalemia may be exacerbated by blood transfusions, suggesting that fresh red blood cells provide a new reservoir for K^+ sequestration.[13] Progressive hypokalemia is associated with severe ventricular dysrhythmias, hypotension, profound flaccid muscle weakness, and respiratory failure (see Chap. 16).

Other effects less commonly reported include metabolic acidosis with elevated lactate concentration, hypophosphatemia, and rhabdomyolysis.[14] Altered level of consciousness, seizures,[7] and parkinsonism with MRI findings of bilateral hyperintensity of the basal ganglia are reported.[11] It is unclear whether these later findings are due to direct toxicity, deposition of barium or secondary to tissue ischemia.

DIAGNOSTIC TESTING

Barium can be measured by a variety of techniques. Mass spectrometry and graphite furnace atomic absorption spectrometry (GF-AAS) can quantitate barium in blood and urine.[16] Serum barium concentrations are not readily available, but values greater than 0.2 mg/L are considered abnormal.[4]

Following acute exposures, patients should have serum electrolytes (particularly potassium and phosphate) measured hourly while performing continuous ECG monitoring. CPK and acid base status and renal function should also be measured. A plain abdominal radiograph may show barium, but the sensitivity and specificity of radiography has never been determined for barium poisoning.[16]

DIFFERENTIAL DIAGNOSIS

Other causes of acute hypokalemia (see Chap. 16) associated with paralysis such as periodic hypokalemic paralysis, toluene toxicity, and diuretic use should be considered if there is no history or laboratory confirmation of barium exposure. Other toxicologic etiologies for flaccid paralysis such as hypermagnesemia, botulism, and the administration of neuromuscular blockers should also be considered.

MANAGEMENT

Patients should be admitted to an intensive care unit with expectant management of respiratory compromise support. Patients who are asymptomatic at 6 hours following ingestion with normal potassium concentrations can be discharged.

■ DECONTAMINATION

Activated charcoal is unlikely to be effective. Orogastric lavage should be considered in patients who present early after ingestion, but lavage is unlikely to provide substantial benefit in patients who are already symptomatic or who have had spontaneous emesis. Oral sodium sulfate administration may prevent absorption by precipitating unabsorbed barium ions as insoluble, nontoxic barium sulfate. Oral magnesium sulfate has had similar efficacy.[18] The oral dose of magnesium sulfate is 250 mg/kg for children and 30 g for adults. Intravenous magnesium sulfate or sodium sulfate is not advised as it may lead to renal failure due to precipitation of barium in the renal tubules.[21,30]

Patients in respiratory failure should receive assisted ventilation. Aggressive correction of hypokalemia is important to minimize the risk or to treat cardiac dysrhythmias. Large doses of potassium replacement (400 mEq in 24 hours) may be required to correct serum potassium although repletion may be inadequate to improve the

resting membrane potential or muscle strength[16] (see Chap. 16). As hypokalemia is due to intracellular sequestration of potassium, potassium supplementation increases the total body potassium load. In this situation, rebound hyperkalemia may occur when barium is eliminated, especially in patients with impaired renal function. Observation for this clinical complication is essential.

Elimination Enhancement If the correction of hypokalemia does not restore normal motor function and muscle strength, hemodialysis can be considered. Hemodialysis for the management of severe barium toxicity is associated with rapid clinical improvement.[2,23,26,29] Additionally, in a case report, CVVHDF tripled the measured barium elimination, reduced serum barium half-life by a factor of three, stabilized serum potassium concentrations, and rapidly improved motor strength, with complete neurological recovery within 24 h.[16] Either method of enhanced elimination should be considered in any severely symptomatic patient who does not respond to correction of hypokalemia.

Management of Intravasation Following intravasation, patients should be admitted to an intensive care unit. Expectant management should include considerations of intraabdominal sepsis, hemorrhage and trauma, pulmonary embolus, and barium toxicity.[19] Prophylactic antibiotics seem reasonable and serial determinations of serum potassium concentrations are warranted. CT scanning of the chest and abdomen can demonstrate both the location and extent of the barium sulfate administered.[27]

SUMMARY

Although poisoning by barium salts is rare these salts are widely used in industry and therefore represent a substantial risk for human exposure. Barium salts typically produces a rapid onset of symptoms and can produce life-threatening toxicity. In addition to good supportive care the mainstay of treatment is rapid correction of hypokalemia.

CHAPTER 110

SODIUM MONOFLUOROACETATE AND FLUOROACETAMIDE

Fermin Barrueto, Jr.

Sodium monofluoroacetate (SMFA) occurs naturally in plants native to Brazil, Australia, and South and West Africa, in the gifblaar (*Dichapetalum cymosum*).[11] The highest concentration (8.0 mg/g) is found in the seeds of a South African plant, *Dichapetalum braunii*.[11] In the 1940s, SMFA was released as a rodenticide (CAS No. 62-74-8) and assigned the compound number 1080, which was registered as its trade name. Fluoroacetamide, a similar pesticide, is known as Compound 1081. These compounds are used as poisons against most mammals and some amphibians.[23] Both products were banned in the United States in 1972, except in the form of collars intended to protect sheep and cattle from coyotes. Collars embedded with SMFA are placed around the neck of livestock, the typical point of attack for coyotes.

Sodium monofluoroacetate is used extensively in New Zealand and Australia to control the possum population and other animal species considered pests that have no natural predators. Its continued use is extremely controversial, but, following a recent review of the ramifications of the use of the compound, the government of New Zealand has retained both the aerosolized and collar applications.

PHARMACOKINETICS AND TOXICODYNAMICS

Sodium monofluoroacetate is an odorless and tasteless white powder with the consistency of flour. When it is dissolved in water, it is said to have a vinegar-like taste. Sodium monofluoroacetate and fluoroacetamide (CAS No. 640-19-7) are well absorbed by the oral and inhalational routes.[10,11,12,24] Detailed toxicokinetic data are lacking in humans, but in sheep, up to 33% can be excreted unchanged in the urine over 48 hours. Glucuronide and glutathione conjugates have also been isolated.[11] Substantial defluorination is not thought to occur in vivo. The serum half-life is estimated to be 6.6 to 13.3 hours in sheep.[10] Sodium monofluoroacetate has an LD_{50} of 0.07 mg/kg in dogs.[17] The oral dose thought to be lethal to humans is 2 to 10 mg/kg.[3]

PATHOPHYSIOLOGY

Sodium monofluoroacetate, a structural analog of acetic acid (Fig. 110–1), is an irreversible inhibitor of the tricarboxylic acid cycle (Fig. 12-3). Monofluoroacetic acid enters the mitochondria, where it is converted to monofluoroacetyl-coenzyme A (CoA) by acetate thiokinase. Once inside the mitochondria, citrate synthase joins the monofluoroacetyl-CoA complex with oxaloacetate to form fluorocitrate. Fluorocitrate then covalently binds aconitase, preventing the enzyme from any further interaction in the tricarboxylic acid cycle.[15] Thus, fluorocitrate acts as a "suicide inhibitor" of aconitase, producing a biochemical dead end. The presence of fluorocitrate and the subsequent increase in citrate, which chelates divalent cations, causes hypocalcemia. The toxicity caused by fluorocitrate results from

the increase in substrate prior to inhibition of aconitase and the depletion of substrate after the step catalyzed by aconitase.

This inhibition of aconitase impairs energy production, leading to anaerobic metabolism and metabolic acidosis with an elevated lactate concentration. Additionally, other tricarboxylic acid cycle intermediates increase in concentration, contributing to the toxicity. α-Ketoglutarate depletion, caused by the lack of isocitrate, leads to glutamate depletion since α-ketoglutarate is a precursor of glutamate synthesis. Glutamate depletion leads to urea cycle disruption and ammonia accumulation. Impaired fatty acid oxidation leads to ketosis.

Disruption of the tricarboxylic acid and urea cycles affects every system in the human body, but the most consequential effects occur in the central nervous system (CNS) and the cardiovascular system. Fluoride toxicity from enzymatic defluorination of sodium monofluoroacetate and fluoroacetamide does not occur substantially in vivo and is of minor significance.

CLINICAL MANIFESTATIONS

The majority of the clinical experience with SMFA is associated with intentional self-poisoning; fluoroacetamide poisoning is presumed to have a similar presentation.[9,14,16,26] Most patients develop symptoms within 6 hours after exposure. In the largest case series of 38 Taiwanese patients who ingested SMFA, 7 died.[6] The most common clinical findings recorded at the time of emergency department (ED) presentation were nausea and vomiting (74%), diarrhea (29%), agitation (29%), and abdominal pain (26%).[6] The mean time to presentation to the hospital was 10.9 ± 5.7 hours for those who died and 3.4 ± 0.6 hours for the survivors. All deaths occurred within 72 hours of admission to the hospital. The presence of respiratory distress and/or seizures was a poor prognostic indicator of death. All seven patients who died had systolic blood pressures less than 90 mm Hg on presentation to the ED, a finding noted in only 16% of the survivors.[6]

In a case series involving two patients, invasive hemodynamic monitoring revealed persistent low systemic vascular resistance and increased cardiac output despite adequate fluid resuscitation.[7] The authors theorized that the cardiovascular response may have been triggered by ATP depletion and inhibition of gluconeogenesis.[7] Anaerobic metabolism, mitochondrial inhibition, and sensitivity of the vasculature to SMFA are all also confounding factors.

The initial neurologic manifestations are agitation and confusion with progression to seizures. Neurologic sequelae such as cerebellar dysfunction may be permanent.[27] One case report describes a 15-year-old girl who survived an initial exposure to SMFA, but later developed cerebellar dysfunction and cerebral atrophy, demonstrated by brain computed tomography.[27] QT interval prolongation, premature ventricular contractions, ventricular fibrillation, ventricular tachycardia, and other dysrhythmias have been documented.[6] SMFA has negative inotropic effects, except in one case report that described episodic hypertension.[22] Signs and symptoms associated with severe poisoning are seizures, respiratory distress, and hypotension.

DIAGNOSTIC TESTING

The presence of SMFA and fluoroacetamide in the blood and urine can be confirmed with gas chromatography-mass spectrometry and thin-layer chromatography.[1,5,18] Simultaneous analysis for other rodenticides that can induce seizures, for example, fluoroacetamide and "tetramine," has been performed by gas chromatography in China, where exposure to these xenobiotics is more probable.[2,4,28] An elevated serum citrate concentration has been proposed as a useful marker for exposure to
FIGURE 110–1. Structural similarities among acetyl-CoA, sodium monofluoroacetate, and fluoroacetamide.

SMFA.[4] However, none of these studies can be performed in a clinically relevant period. A combination of history, signs, symptoms, and common laboratory tests can assist with the diagnosis.

Hypokalemia, anion gap metabolic acidosis, and an elevated creatinine concentration[8] are associated with severe poisoning but are very nonspecific.[6] The predominant electrolyte abnormality will be hypocalcemia, though hypokalemia can result from renal insufficiency and gastrointestinal losses. Creatinine, liver enzyme, and bilirubin concentrations may also be elevated as a result of multisystem organ toxicity. Ketones may be present in urine and serum. A complete blood cell count may reveal leukocytosis due to demargination. An electrocardiogram is valuable in the diagnosis of SMFA exposure; a prolonged QT interval, atrial fibrillation with a rapid ventricular response, ventricular tachycardia, and other dysrhythmias may be present. An initial brain computed tomography scan of the brain may be normal, but subsequent scans may reveal cerebral atrophy.[27]

TREATMENT

Initial decontamination should include removal of clothes and cleansing of skin with soap and water. Because there is no antidote for SMFA or fluoroacetamide poisoning, orogastric lavage should be considered for exposed patients who present to the ED prior to significant emesis. Appropriate patients should receive 1 g/kg of activated charcoal (AC) orally. A rat study showed that colestipol is more effective in binding SMFA than activated charcoal.[19] By extension, it seems reasonable to consider the use of colestipol, if available, for the treatment of life-threatening exposures in humans, although there are no data to support this statement. A typical oral starting dose would be 5 grams.

In animal models, ethanol and glycerol monoacetate (monacetin) are suggested to be antidotal. In this context, they function as acetate donors for ultimate incorporation into citrate in place of fluoroacetate.[26] Both ethanol and glycerol monacetate are converted to acetyl-CoA and compete with monofluoroacetyl-CoA for binding of citrate synthase. This may prevent the "suicide-inhibition" of aconitase, subsequent increase in citrate, and the formation of the toxic metabolite fluorocitrate.[26]

Ethanol has been used in human cases, although the appropriate dose is unknown and there is not enough evidence to support its use as a single antidote.[6,7,21] A reasonable therapeutic dose is the amount of ethanol required to obtain and sustain an ethanol serum concentration of 100 mg/dL (Antidotes in Depth A32: Ethanol) One intriguing case report involves a patient who ingested 240 mg of SMFA (typically a lethal dose) mixed with a Taiwanese wine (30% ethanol) and survived.[6] It is possible that the ethanol decreased or delayed the toxicity of SMFA.

In a mouse model,[20] use of a combination of calcium salts, sodium succinate, and α-ketoglutarate improved survival. The rationale of using these antidotes is to provide tricarboxylic acid cycle intermediates distal to the inhibited aconitase in an attempt to improve energy production. These antidotes were not effective unless calcium was co-administered, emphasizing the importance of replenishing electrolytes, particularly the divalent cations that are chelated by citrate.[13,25]

If a patient develops hypotension and shock, rapid administration of intravenous fluids should be followed by a vasopressor, such as norepinephrine, and/or vasopressin. Supportive care, correction of electrolyte abnormalities (calcium and potassium), ethanol infusion, and monitoring for dysrhythmias (prolonged QT interval) and seizures are the practical mainstays of treatment.

SUMMARY

Sodium monofluoroacetate and fluoroacetamide are potent pesticides that inhibit the tricarboxylic acid cycle, resulting in disrupted cellular energy production. Patients who are exposed to SMFA typically present with nausea, vomiting, agitation, and abdominal pain, which may be followed by hypotension, respiratory distress, shock, seizures, and death. Lactate accumulation, hypokalemia, hypocalcemia, metabolic acidosis, and elevation of serum creatinine also occur. Treatment of SMFA and fluoroacetamide poisoning involves replenishing electrolytes, correcting hypotension with intravenous fluids and vasopressors if necessary, monitoring for dysrhythmias, and treating seizures. Ethanol, although not a perfect antidote, is relatively familiar, is readily available, and can be administered safely. The efficacies of other experimental antidotes are unknown.

CHAPTER 111
PHOSPHORUS

Michael C. Beuhler

Phosphorus (P)

Atomic number	=	15
Atomic weight	=	30.97 daltons
Normal concentrations		
Serum		3–4.5 mg/dL (1–1.4 mmol/L)

Elemental phosphorus is used for the production of matches, fireworks, rodenticides, and munitions. The more toxic form, white phosphorus, spontaneously combusts in air and has significant hepatic and renal toxicity when taken internally. The other common form, red phosphorus, has limited human toxicity. Although in many areas the prevalence of poisonings from phosphorus has markedly decreased, morbidity is high and treatment options remain limited.

HISTORY AND EPIDEMIOLOGY

Phosphorus is a nonmetallic element not naturally found in its elemental form; it was isolated from distilled urine by Hennig Brandt in 1669. White phosphorus has been used in munitions (mortar rounds, grenades, artillery shells, bombs) since World War I for its antipersonnel effect as well as its warning, incendiary, and smoke-producing properties. It is also used in fireworks made in countries other than the United States and China, in the production of matches, and for selected chemical synthetic processes (including some pesticides). White phosphorus was used extensively in the past as a rodenticide, but is no longer employed for this purpose in the United States. Because of its potential use for illicit drug manufacture, its sale is carefully monitored by the US Drug Enforcement Administration (DEA), which limits its availability in the United States. Before modern regulation, it was used in scientifically unfounded remedies primarily because its phosphorescent and reactive qualities suggested potency. Its occasional use as a homicidal agent was limited by its glowing, smoking qualities leaving obvious clues. It remains a common method of suicide in some countries.

Phosphorus was used extensively at the beginning of the 20th century in millions of "strike anywhere" matches (lucifers). However, safety concerns with the matches and illnesses in the workers producing the matches prompted a shift from using the more dangerous white phosphorus in the match heads to substituting the safer red phosphorus in the strikers. Workers chronically exposed to white phosphorus developed "phossy jaw," an illness characterized by disfiguring osteonecrosis of the mandible along with multiple draining abscesses.

CHEMISTRY

Phosphorus, atomic number 15, is a group 5A nonmetallic element sharing chemical properties with nitrogen (above) and arsenic (below) in the same periodic group. Elemental phosphorus can exist in several different allotropes (polymorphs); the two common forms considered here are red phosphorus and the highly reactive white phosphorus. The

relatively nontoxic and nonreactive black form will not be considered further.

White phosphorus is a waxy whitish to yellow solid with a melting point of 44.1°C.[26] Often a small amount of red phosphorus being present results in discoloration, explaining its other name, "yellow" phosphorus. The word *phosphorus* means light-bearer, which originates from its property of glowing when exposed to air, likely due to the formation of reactive luminescent phosphorus oxide species on its surface. It is insoluble in water and often stored under it; it will dissolve in carbon disulfide and other organic solvents.[26] White phosphorus is very reactive, igniting spontaneously in air at approximately 34°C and oxidizing to form phosphorus pentoxide (P_4O_{10}), which has a cage-shaped molecular structure and usually appears as a white fume having a garliclike smell. Phosphorus pentoxide is hydroscopic and reacts with water to form phosphoric acid (H_3PO_4); it also reacts with organic molecules in dehydrating reactions and is irritating to biological membranes.

Red phosphorus is a red powdery compound of limited toxicologic significance. It is not luminescent, it does not combust in air, and its toxicity is orders of magnitude less than that of white phosphorus.

PHARMACOKINETICS AND TOXICOKINETICS

White phosphorus is insoluble in water, but it is soluble in lipids and lipophilic solvents. It is well absorbed from the intestinal tract and coingestion with fats, alcohol, and liquids has been associated with increased toxicity, probably from increased absorption.[8,9] White phosphorus is also well absorbed through skin, with dermal burns contributing to the absorption and significant morbidity and mortality arising from large surface areas burns. White phosphorus can also be absorbed by inhalation, but this route is rare with modern industrial hygiene. After ingestion, phosphorus is found in high concentrations in the blood, liver, and kidneys within 3 hours.[5,14]

Internally absorbed white phosphorus has significant toxicity. A dose of only about 1 mg/kg of white phosphorus in adults is likely to cause significant morbidity, but a lethal dose of 3 mg in a child is reported.[3] The mortality from white phosphorus ingestion is difficult to estimate since the majority of reported cases occurred before critical care was as advanced as it is now, but one can estimate a 25% mortality rate from a significant ingestion.[12]

PATHOPHYSIOLOGY

The mechanism of *dermal* injury from white phosphorus differs significantly from that of *ingested* white phosphorus. Externally, white phosphorus reacts with oxygen to form phosphorus pentoxide and other phosphorus oxides. Phosphorus pentoxide readily reacts with water in an exothermic reaction producing corrosive phosphoric acid.[17] Additionally, phosphorus pentoxide chemically reacts with (dehydrates) some organic molecules. These three mechanisms (exothermic, acid-producing, and dehydrating reactions) all contribute to the tissue injury observed, although the most damaging mechanism is the thermal injury from the heat of the reaction, as evidenced by the relatively short distance of tissue penetration by the acid and the relatively large amount of available water.[7,25] The evidence for describing white phosphorus as a cytoplasmic toxin is mostly derived from electron microscopy, which demonstrates an initial cytoplasmic injury of the rough endoplasmic reticulum rather than initial nuclear or mitochondrial changes.[13]

Red phosphorus has limited direct toxicological significance. It can cause gastrointestinal (GI) distress when ingested in significant amounts, but it is orders of magnitude less toxic than white phosphorus.

A resurgence of toxicity and human injury indirectly related to red phosphorus has resulted from the recent increase in North American domestic methamphetamine production. Red phosphorus is used in conjunction with elemental iodine to produce hydroiodic acid, the ultimate reducing agent required to convert ephedrine to methamphetamine. In this situation, red phosphorus contributes to human injury by causing fire because of its unintentional conversion to highly flammable white phosphorus. Additional pathology occurs because during heating, the reaction products of iodine and red phosphorus often generate phosphine (PH_3) a pulmonary irritant gas (see Chap. 124). Phosphine is only produced in significant amounts during an active methamphetamine "cook" using the red phosphorus method. This gas most likely contributes to some of the pulmonary symptoms occurring with chronic methamphetamine laboratory exposure, as well as several of the deaths resulting from performing the synthesis in an area with limited ventilation in order to hide the methamphetamine laboratory characteristic odors.[27] Unless specifically stated, all further references to phosphorus in this chapter refer to white phosphorus.

CLINICAL MANIFESTATIONS

■ GENERAL

Oral phosphorus poisoning was previously classified in three clinical stages. The initial symptoms may be delayed for a few hours, and the presence of a delay depends on the dose. During the first phase, patients experience vomiting, hematemesis, and abdominal pain, with hypotension and death occurring within 24 hours after large ingestions.[9,15] During the second stage, there is transient resolution of symptoms. During the third stage the patient develops hepatic injury with coagulopathy and jaundice as well as renal failure with oliguria and uremia. However, several case series demonstrate that three distinct phases is the exception rather than the rule, with significant overlap or absence of the "quiescent" second stage and death potentially occurring within hours of ingestion.[4,8,19,22,28] In the first 6 hours postexposure poor prognostic signs include altered sensorium, cyanosis, hypotension, metabolic acidosis, elevated prothrombin time, and hypoglycemia.[8,22] Survival to 3 days serves as a good prognostic sign; however, deaths delayed after several days have been reported.[9] Recovery usually occurs over 1 to 2 weeks.

■ GASTROINTESTINAL

Initial symptoms after ingestion of phosphorus include nausea, vomiting, and abdominal pain. Diarrhea, as well as constipation are reported, but are much less common. The breath and vomitus are sometimes described as having a garlic or musty sweet odor. The vomitus and diarrhea are sometimes luminescent and smoking, but this specific finding occurs in the minority of patients.[4,6,16] The smoking material is caused by the combustion of phosphorus upon its reexposure to air after being eliminated from the GI tract. Phosphorus causes an inflammatory injury to the GI tract characterized by local hemorrhage and hematemesis, but generally perforations do not occur. Massive GI bleeding later in the clinical course leading to mortality is occasionally reported, particularly when hepatic failure and coagulopathy occur.[12]

■ RENAL/ELECTROLYTES

In a rat model of dermal burns from phosphorus an initial diuresis occurs followed by renal failure manifested by hyperkalemia, hyponatremia, and hyperphosphatemia.[1] Renal cell swelling and necrosis with vacuolar degeneration of proximal convoluted tubules was also observed.[1] Poisoned patients demonstrated an increase in urinary white blood cells (WBC) and red blood cells (RBC) as well as casts and proteinuria.[3,15] Renal injury from phosphorus in humans is most likely acute tubular necrosis resulting from hypotension and salt and water depletion as well as a direct toxic effect.[9]

Significant electrolyte disturbances may result from both ingestion and dermal absorption of phosphorus. Hypocalcemia is common, but hypercalcemia is also occasionally reported.[17] Hyperphosphatemia may accompany the hypocalcemia but is not universal and can occur at any time in the clinical course.[3] The hyperphosphatemia is partially due to the conversion of absorbed phosphorus to phosphate; in an animal model those that died had increased concentrations of phosphorus, decreased concentrations of calcium, and hyperkalemia as early as 1 hour postexposure.[2] Hyperkalemia is occasionally reported in humans and may be secondary to tissue injury and renal failure.[1] The electrolyte disturbances are likely a leading cause of early mortality from phosphorus.

■ CARDIOVASCULAR

Death within 24 hours of the ingestion is likely the result of cardiovascular collapse. One human series of 41 suicide attempts demonstrated a variety of initial electrocardiogram (ECG) abnormalities. T-wave changes predominated in 24 patients but the series also had two cases of ventricular fibrillation. An increasing number of abnormalities occurred in those with larger ingestions, although the electrolyte abnormalities were not described in many patients.[9] An animal model of phosphorus exposure demonstrated prolonged QT interval and ST segment changes along with electrolyte abnormalities suggesting that many of the ECG changes might be due to these electrolyte abnormalities.[2] A small study of phosphorus exposure of rats observed a decrease in amino acid uptake in myocytes suggesting a direct effect beyond secondary effects due to electrolyte changes (hypocalcemia and hyperkalemia). Human autopsies have demonstrated fatty degeneration of the myocardium and vacuolated cytoplasm in a few patients many hours postingestion.[24]

■ HEPATIC

White phosphorus is a potent hepatoxin. Increase in prothrombin time, hyperbilirubinemia, and hypoglycemia usually occur within 3 days, with earlier signs of hepatic failure such as jaundice and coagulopathy indicative of a poor prognosis.[9,15,18] The increase in hepatic aminotransferases occurs over several days usually peaking at or below 1000 IU/L and almost always less than 3000 IU/L.[12] Other biochemical effects demonstrated by experimental phosphorus toxicity include an increase in glucose-6-phosphate activity and impairment of triglyceride metabolism. When death occurs after several days (as opposed to within 24 hours), hepatic injury is usually implicated. If survival occurs the hepatic damage usually resolves over several months, although persistent periportal fibrosis has been reported.[18]

With absorption of sufficient quantities, phosphorus causes a dose-related zone 1 or periportal hepatic injury, in contrast to the centrilobular pattern (zone 3) that occurs with other hepatotoxins (such as acetaminophen and carbon tetrachloride; see Chap. 26). Fatty degenerative changes and fatty infiltrates are also observed within 6 hours of ingestion.[8] Other histological changes include acute necrosis with large vacuoles and inflammatory changes. Electron microscopy in a rat model demonstrated an increase in the rough endoplasmic reticulum and an increase in the cytoplasmic fat without initial mitochondrial or nuclear injury.[13] Although the early pathological effects appear to be predominantly cytoplasmic, the formation of nuclear vacuoles can occur as well.[18]

NERVOUS SYSTEM

CNS effects include headache, altered mental status, coma, and rarely seizures. The altered mental status is probably due mostly to the presence of other organ dysfunction and shock; one example of the former is the encephalopathy secondary to hepatic injury. Patients with initial alterations in mental status or coma have an increased mortality rate independent of the presence of any electrolyte abnormalities.[19]

DERMAL/MUCOUS MEMBRANES

Dermal phosphorus exposure causes extensive burns, frequently in the military setting. Depending on the release conditions, white phosphorus can be a solid or liquid. Liquid white phosphorus splatters and can penetrate clothing; burning clothing commonly exacerbates the burn area.[17,20] Dermal penetration may be partially due to its lipophilicity as well as the compromise of the dermal barrier caused by the burn injury. The smoke produced by burning white phosphorus contains phosphorus pentoxide and is irritating to the conjunctiva and mucosa of the oropharynx and lungs.

Following a large burn, systemic illness manifested by electrolyte, cardiovascular, and hepatic abnormalities may result from absorbed phosphorus.[1,2] A 12% to 15% body surface area burn in a rat was lethal 50% of the time due to cardiovascular effects; human morbidity from large skin burns is similarly high. Rats with dermal burns from phosphorus also developed renal and hepatic injury. Healing time from phosphorus-induced burns is prolonged compared with thermal burns.[7]

DIAGNOSTIC TESTING

Serum elemental phosphorus concentrations are not clinically available and a serum phosphorus concentration does not reflect the serum elemental phosphorus concentration. Diagnosis of phosphorus poisoning must rely on history and physical examination. However, for optimal supportive care of the patient, many laboratory factors must be monitored such as electrolytes, serum pH, hepatic function, glucose, renal function, and coagulation parameters (see Management section).

MANAGEMENT

PROTECTION OF HEALTHCARE WORKERS

Caution should be exercised in decontamination and subsequent storage of contaminated clothing. After phosphorus ingestion, the patient's vomitus and diarrhea must be considered potentially hazardous and carefully handled. Any phosphorus fragments removed from the patient as well as all potentially contaminated clothing items should be kept under water. Fires and explosions are reported during GI decontamination efforts.[21]

GENERAL

General supportive care is the mainstay of treatment. Cardiac monitoring, frequent electrolyte analysis of calcium, phosphorus and potassium concentrations, and serial ECGs are essential for patients with a history of significant ingestions and/or overt toxicity, as dysrhythmias may occur rapidly.[9] Electrolyte disturbances such as hyperkalemia, hypocalcemia, and hypercalcemia should be corrected. With significant exposure to phosphorus, hepatic injury will occur and thus directed supportive care should be provided such as fresh frozen plasma, vitamin K, and lactulose when indicated. Adequate serum glucose concentrations are required to provide reducing equivalents (reduced form of nicotinamide adenine dinucleotide [NADH] and nicotinamide adenine dinucleotide phosphate [NADPH]) through glycolysis and the glucose-6-phosphate dehydrogenase (G6PD) pathways. Increased glucose concentrations may also theoretically offer protection by competing with phosphorus reuptake in the kidney, but the contribution to human morbidity is unclear. Steroids have not been shown to improve outcome following ingestions of white phosphorus.[18] Direct contact of phosphorus with the eye can result in serious ocular injury. Immediate copious ocular decontamination with water but not with copper sulfate is recommended.[23] A careful opthalmologic examination should be conducted by an ophthalmologist whenever possible.

DERMAL EXPOSURE

Initial treatment is to halt continuing injury by extinguishing combustion of the phosphorus. This is performed by submerging the affected area in cool water or, more practically, covering any areas with clean materials soaked in water or 0.9% sodium chloride solution to limit the white phosphorus contact with atmospheric oxygen. Decontamination is undertaken by removing the patient's clothing and using large amounts of cool water to remove any phosphorus fragments. In the past, sodium bicarbonate decontamination solution was recommended, but because the tissue injury is not due to the production of acid and because no clinical benefit was demonstrated, there is no role for specific neutralization fluids.[7,25] Water dilutes any phosphoric acid present and reacts with the phosphorus pentoxide to limit the dehydrating reactions.

Careful débridement is the next critical step as wounds that have not undergone adequate decontamination heal poorly, requiring additional débridement. Smoking pieces of phosphorus are not necessarily hot enough to cause thermal burns, but the oxidation process must be arrested. Fragments from the wound should be placed under water to prevent a fire hazard. Particles of phosphorus can be visualized by using a woods lamp as the chemical burns have a yellowish fluorescence. One author recommends turning off the lights to look for the glow of the phosphorescent particles; presumably this will only work if there has not been any copper metal wash solution used (see following paragraphs).[10] Because of the increased solubility of phosphorus in hydrophobic solvents, it is important not to use ointments until the wound is completely decontaminated.

A copper (II) sulfate solution was previously recommended for decontamination. Copper sulfate reacts with phosphorus to produce copper phosphide, a dark compound that is much more easily visualized in the tissues. This dark material coats the particle but the entire particle is not converted to copper phosphide. The use of high concentrations of copper sulfate solutions on exposed human flesh is no longer recommended because of potential systemic toxicity such as hemolysis caused by the copper (see Chap. 93).[23] This is especially concerning in patients at increased risk for oxidant injury, such as those with G6PD deficiency. The solutions of copper sulfate historically used ranged around 2% to 5% and were applied for several hours to the wounds, resulting in substantial amounts of copper absorption and morbidity.

However, copper sulfate solutions may have a role in the complete approach to the treatment of phosphorus wounds. A dilute copper sulfate solution 0.5% to less than or equal to 1.0% applied once to the wound and then rinsed off with water may not result in the morbidity that occurs with the more concentrated rinses and may provide temporary neutralization of the outer surface of the phosphorus. This approach may assist in identification of the small pieces of phosphorus that are difficult or impossible to visualize, especially in those with less experience débriding these wounds. The use of pads soaked in copper sulfate is *not* recommended. Wounds that are not treated with a copper solution may be at greater risk of requiring repeat débridement because of the persistence of small phosphorus particles missed during the initial decontamination efforts. Animal models have suggested

improved healing from the initial treatment with a dilute copper solution, but a relatively large human case series did not find a difference in those who were treated with copper sulfate compared with those who were not.[7] The copper phosphide–coated particles must be removed as they still react slowly and can potentially cause toxicity. It is important to remember that the dilute copper sulfate solution is not a decontamination therapy, but a temporizing treatment that allows for better visualization for physical débridement and must be rinsed away immediately after application.[10]

Silver nitrate is suggested as a potential solution to replace the use of copper sulfate. It forms an insoluble, minimally reactive silver phosphide as well. Its use and preparation is similar to that described above; silver nitrate should be considered as a temporary neutralization tool and not a decontamination therapy. However, there is very limited experience with this approach in the literature and no detailed human data. Silver forms an insoluble precipitate with chloride and cannot be combined with 0.9% sodium chloride solutions; therefore, the amount of soluble silver ion that reaches the imbedded phosphorus may be more limited than with copper because of the presence of relatively large amounts of chloride ion in living tissues.[29]

After decontamination, good wound care and burn management is required as these burns (like other chemical burns) can require an extended period of time to heal. As mentioned, incomplete decontamination is a common reason for delayed wound healing. For significant burns, the patient should be admitted to a burn unit intensive care unit (ICU) for close monitoring of cardiovascular, renal, and electrolyte status. Because of the potential instability of these patients, it is important to weigh the risk-benefit ratio of transfer to a specialized center. The experience of the receiving center with phosphorus burns along with the acuity of the injury are important factors in making this decision.

■ GASTROINTESTINAL EXPOSURE

There is no evidence that GI decontamination or antidotal therapy following phosphorus ingestion is efficacious. In the past, several different lavage fluids were recommended in the past, ranging from the mostly benign (sodium bicarbonate) to the potentially dangerous (potassium permanganate). Milk might also be potentially harmful because of its lipophilic components. Some authors postulate better outcome with earlier GI decontamination, but there are no reliable studies available.[18] Activated charcoal may bind to white phosphorus and could be considered, although there are no data to support its use either. However, despite the lack of data of efficacy, given the poor outcome with large ingestions of phosphorus, decontamination efforts should be strongly considered. If lavage is considered, a nasogastric tube would not be expected to remove much because of the insoluble, solid nature of phosphorus. The tissue injury caused by phosphorus is not expected to cause early esophageal perforation and the use of an orogastric (OG) tube is therefore best. Caution to protect caregivers should be exercised with any lavaged material. After a fire and explosion, one author recommends keeping the free end of the OG tube under water while inserting and instilling small amounts of water (not air) to check for proper placement.[21]

N-acetylcysteine (NAC) is suggested as a potential adjunct in the treatment of phosphorus toxicity. Although NAC was used in a limited human series, the numbers were not great enough to demonstrate any benefit.[12] The use of superoxide dismutase (SOD) in an animal model suggested benefit but did not limit morbidity, suggesting that limiting oxidant injury may play a role in treatment.[11] There is no theoretical harm in using NAC for phosphorus toxicity and so it might reasonably be added to the treatment regimen. Methionine was used many years ago in the treatment of a few patients, but the number of treated patients was too few to draw any conclusions.[8]

SUMMARY

White phosphorus has been used in recent times in warfare, causing morbidity through dermal burns. These burns require large amounts of water irrigation and adequate débridement while protecting the health-care workers. Following ingestion, typically following suicide attempts, morbidity remains quite high and treatment options are limited to unproven decontamination therapies. Signs and symptoms of white phosphorus toxicity include vomiting, abdominal pain, confusion, dysrhythmias, hepatic injury, and renal failure. As early mortality is believed to be due to electrolyte abnormalities and cardiac dysrhythmias, vigilant critical care is the mainstay of therapy. *N*-acetylcysteine may be used, but it has not been shown to alter human outcomes.

CHAPTER 112
STRYCHNINE

Yiu-cheung Chan
Strychnine alkaloid can be found naturally in *Strychnos nux-vomica*, a tree native to tropical Asia and North Australia, and in *Strychnos ignatii* and *Strychnos tiente*, trees native to South Asia. The alkaloid was first isolated in 1818 by Pelletier and Caventou.[5,17] It is an odorless and colorless crystalline powder that has a bitter taste when dissolved in water. Besides strychnine, the dried seeds of *S. nux-vomica* contain brucine, a structurally similar, although less potent, alkaloid.[89] In addition to the naturally occurring alkaloidal form, strychnine is available from commercial sources in its salt form, usually as nitrate, sulfate, or phosphate. In the past, strychnine poisoning was responsible for significant mortality, especially in children. Meticulous, supportive care remains the most important component of the management of the strychnine-poisoned patient.

HISTORY

Strychnine was first introduced as a rodenticide in 1540, and in subsequent centuries was used medically as a cardiac, respiratory, and digestive stimulant,[49] as an analeptic,[93] and as an antidote to barbiturate[92] and opioid overdoses.[60] Nonketotic hyperglycemia,[9,39,81] sleep apnea,[77] and snake bites[17] were also once considered indications for strychnine use. In 1982, at least 172 commercial products were found to contain strychnine, including 77 rodenticides, 25 veterinary products, and 41 products made for human use.[84] Currently, strychnine is used mainly as a pesticide and rodenticide (for moles, gophers, and pigeons),[84] and a research tool for the study of glycine receptors. Most commercially available strychnine-containing products contain about 0.25% to 0.5% strychnine by weight.[84]

EPIDEMIOLOGY

Between 1926 and 1928, strychnine killed more than three Americans every week.[5,30] In 1932, it was the most common cause of lethal poisoning in children,[5,84,99] and one-third of the unintentional poison-related deaths in children younger than 5 years were attributed to strychnine.[61] Currently, strychnine poisoning is rare and continues to decrease in the United States, although deaths are still reported. The Toxic Exposure Surveillance System (TESS) and National Poison Data System (NPDS) data of the American Association of Poison Control Centers (AAPCC) reports 1309 strychnine exposures during the past 10 years with only nine deaths (Chap. 135).

Strychnine poisoning has resulted from deliberate exposure with suicidal and homicidal intent,[12,30] from unintentional poisoning by a Chinese herbal medicine (Maqianzi),[18] a Cambodian traditional remedy (slang nut),[52,54,87] and adulteration of street drugs.[14] Maqianzi is used to treat limb paralysis, severe rheumatism, and inflammatory disease, whereas slang nut is used to treat gastrointestinal illness. The bitter taste and lethality of strychnine allow it to be substituted for heroin[46] and cocaine.[14,25,65] There are also reports of strychnine poisoning from adulterated amphetamines,[25] ecstasy (3,4-methylenedioxymethamphetamine [MDMA]),[28] Spanish fly,[13] and from the ingestion of gopher bait.[55]

TOXICOKINETICS

Standard references list the lethal dose of strychnine as approximately 50 to 100 mg[20,36,37,71,95] (1–2 mg/kg). However, mortality resulting from doses as low as 5 to 10 mg and, alternatively, survival following ingestions of 1 to 15 g of strychnine are reported.[6,20,98,83] Some of this variation may be attributed to the route of administration, with parenteral administration being more toxic than oral, and the limitations of self-reports of exposure quantities.

Strychnine is rapidly absorbed from the gastrointestinal tract and mucous membranes. There is also one case report of poisoning as a result of dermal absorption of strychnine from an alkaline solution, in which strychnine exists in the nonionized, alkaloid form.[38] Protein binding is minimal and strychnine is rapidly distributed to peripheral tissues[94] with a large volume of distribution (13 L/kg).[43] Based on postmortem findings, the highest concentrations of strychnine are found in the liver,[58,71,79] bile,[71] blood,[71] and gastric contents.[71,79] Relatively less strychnine is identified in kidney, urine, and brain.[79]

Strychnine is metabolized by hepatic P450 microsomes[1,62] producing strychnine-*N*-oxide as the major metabolite,[1] and this metabolism is increased by P450 induction.[47,51] Several urinary metabolites are identified,[66] and 1% to 30% of strychnine is excreted unchanged in urine,[10,42,70] in decreasing proportions when larger amounts are ingested.[82,94] In human case reports, strychnine follows first-order kinetics with an elimination half-life of 10 to 16 hours.[29,70,96]

◼ PATHOPHYSIOLOGY

Glycine, one of the major inhibitory neurotransmitters in the spinal cord, opens a ligand-gated chloride channel, thus allowing the inward flow of Cl⁻ (see Fig. 13–12).[21] As Cl⁻ moves inward the cell becomes hyperpolarized or inhibited. Strychnine competitively inhibits the binding of glycine to the α-subunit of the glycinergic chloride channel.[14,22,97,99] Although strychnine affects all parts of the central nervous system in which glycine receptors are found, the most significant effect is in the spinal cord. With loss of the glycine inhibition to the motor neurons in the ventral horn, there is a loss of inhibitory influence on the normally suppressed reflex arc. The result is increased impulse transmission to the muscles, producing generalized muscular contraction. Rabbits pretreated with glycine were found to have a 40% increase in the strychnine "seizure" threshold, illustrating the competitive nature of strychnine and glycine activity on the glycinergic chloride channel.[19,78] Tetanus toxin (tetanospasmin) causes an identical clinical syndrome of muscular contractions, but does so by preventing the release of presynaptic glycine and does not function as a competitive antagonist. In dogs, strychnine also has positive chronotropic and inotropic effects on the heart,[85] but this effect is unlikely to exert a major effect in human poisoning.

◼ CLINICAL MANIFESTATIONS

Strychnine poisoning is characterized by a rapid onset of signs and symptoms beginning within 15 to 60 minutes of ingestion[35] and,

although less well documented, even sooner after parenteral or nasal administration. Delayed onset of clinical effects are rarely reported.[26,37] The typical symptoms of poisoning are involuntary, generalized muscular contractions resulting in neck, back, and limb pain. The contractions are easily triggered by trivial stimuli (such as turning on a light) and each episode usually lasts for 30 seconds to 2 minutes.[84] Recurrent episodes may last as long as 12 to 24 hours. Differences in the strength of various opposing muscle groups result in the classic signs of opisthotonus, facial trismus, and risus sardonicus, with flexion of the upper limbs and extensions of lower limbs predominating. Hyperreflexia, clonus, and nystagmus[11,63] are also evident on examination. Because strychnine affects glycine inhibition mainly in the spinal cord, the patient typically remains fully alert until metabolic complications arise. The combination of convulsive motor activity involving both sides of the body in the conscious patient has often resulted in imprecise descriptions such as "conscious seizure" or "spinal seizure." Hemodynamically, both hypotension,[27,29,65] or hypertension[14,32,64] in the presence of bradycardia[16,27,29,65] or tachycardia[14,16] are reported. Hyperthermia, presumably from increased muscular activity, is typical, and temperatures as high as 109.4°F (43°C) are reported.[14] Other nonspecific signs and symptoms include dizziness, vomiting, and chest and abdominal pain.[63]

Early in the course of strychnine poisoning, mortality is mainly due to hypoventilation and hypoxia secondary to muscular contractions.[32] Later, life-threatening complications include rhabdomyolysis with subsequent myoglobinuria and acute renal failure,[16] hypoxia or hyperthermia-induced multiorgan failure, aspiration pneumonitis,[86] anoxic brain injury, and pancreatitis.[45] Rarely, local neuromuscular sequelae such as weakness, myalgia, and anterior tibial compartment syndrome are reported.[14] As might be expected, the prognosis is related to the duration and extent of the episodes of muscle contractions.[34]

DIFFERENTIAL DIAGNOSIS

The diagnosis of strychnine poisoning is mainly established on clinical grounds, based on exposure history and compatible clinical manifestations, but can be confirmed by detection of strychnine in biological specimens. Several diagnoses need to be considered, the most important of which is tetanus because it produces similar muscular hyperactivity. With tetanus, however, the onset of symptoms is more gradual and the duration much longer than in the case of strychnine poisoning. Frequently, the diagnosis of tetanus is suggested by a history of recent injury, or the finding of an obvious wound. In general, patients with tetanus have either undocumented or incomplete tetanus immunization.

Strychnine poisoning can be differentiated from generalized seizures by the presence of a normal sensorium during the period of diffuse convulsions. That is, most patients with bilateral convulsions are having generalized seizures, which by definition involve the reticular activating system, producing unconsciousness. It is conceivable, although extraordinarily rare, to have bilateral focal seizures producing apparent "generalized" convulsions; in this case, because the reticular activating system may not be involved, the patient's mental status may be preserved. The diagnostic utility of the presence of consciousness in a patient with a generalized convulsion to establish the diagnosis of strychnine poisoning or tetanus is true at least in the early phase of the clinical course. At later times this finding may be obscured by metabolically induced alterations in sensorium.[19] When there is an alteration in the level of consciousness an electroencephalogram may be helpful, if it documents an absence of focal neurological deficits. A computed tomography (CT) scan can help to exclude structural brain lesions, and a lumbar puncture is helpful to exclude meningitis or encephalitis. Hypocalcemia, hyperventilation, and myoclonus secondary to renal or hepatic failure are evaluated by appropriate routine laboratory testing.

Although a drug-induced dystonic reaction should be considered when there is a relevant drug history, dystonic reactions are usually static, whereas strychnine poisoning results in dynamic muscular activity. Serotonin syndrome, malignant hyperthermia, neuroleptic malignant syndrome, and stimulant use should be considered, if the medical history is supportive.

DIAGNOSTIC TESTING

Respiratory and metabolic acidosis both commonly occur in strychnine-poisoned patients. Metabolic acidosis correlates with serum lactate concentrations,[14] whereas respiratory acidosis is secondary to hypoventilation resulting from diaphragmatic and respiratory muscle failure. Survival of patients with serum pHs in the range of 6.5 to 6.6 is well documented.[14,32,33,35,56,96] The lowest pH and highest lactate concentration reported in a patient who subsequently had full recovery was 6.5 and 32 mmol/L,[14,96] respectively. Thus, profound acidemia in strychnine poisoning is not necessarily associated with a poor prognosis. One proposed reason is that the serum pH does not correlate with the intracellular pH in the vital organs, namely the brain and heart.[7,8,14,74] In contrast to the metabolic acidosis with elevated lactate concentration that occurs in shock, the elevated lactate concentration of strychnine poisoning results from overactivity of the muscle instead of undersupply or underutilization of oxygen and nutrients.

Besides acidosis, other laboratory abnormalities expected from prolonged muscular activity include hyperkalemia and those associated with rhabdomyolysis, and acute renal failure.[14] There is also stress-induced leukocytosis,[14,45] elevated liver enzymes concentrations[45,63,91] hypocalcemia,[14,43] hypernatremia,[35] and hypokalemia.[31,63,86] The electrocardiogram is expected to remain normal or reflect changes consistent with the above electrolyte disturbances.[43] Chest radiography may show evidence of aspiration pneumonia or acute lung injury.

Strychnine can be detected by a variety of methods such as thin-layer chromatography,[48,67,90] high-performance liquid chromatography,[2,23] ultraviolet spectrometry,[67] a simple colorimetric reaction,[67] gas chromatography–mass spectrometry,[15,16,58,70,79] gas chromatography–flame ionization detector,[95] and capillary electrophoresis.[100] With the exception of the bedside colorimetric reaction, none of these tests are routinely available in a time frame useful to assist in clinical decisions. Strychnine is also detectable in amounts as low as 0.01 ppm in tissue,[2,24,59,73] and strychnine resists postmortem putrefaction. Additionally, even when available, quantitative concentrations do not correlate with clinical toxicity. Reported blood strychnine concentrations in fatal poisoning ranged from 0.5 to 61 mg/L.[95] Conversely, the highest initial blood concentration associated with survival was 4.73 mg/L from blood drawn 1.5 hours postingestion[96]; a concentration as low as 0.06 mg/L was found in a patient who solely had muscular irritability.[29]

MANAGEMENT

In strychnine poisoning, induced vomiting is absolutely contraindicated because of the risk of aspiration and loss of airway control following rapid onset of muscle contractions. Orogastric lavage should be considered on an individual basis after evaluating potential benefits and risks.[3] When orogastric lavage is thought to be indicated, it may be important to protect and secure the airway with an endotracheal tube before attempting lavage. Activated charcoal (AC) binds strychnine effectively at a ratio of approximately 1:1; 1 g of AC will bind 950 mg of strychnine.[4,89] In animal models, pretreatment[68] and posttreatment[72] with AC increase the median lethal dose in 50% of test subjects (LD_{50}) for strychnine. Clinical evidence of the effectiveness of AC for strychnine ingestion was first demonstrated in 1831, when Professor Touery

survived the ingestion of a lethal dose of strychnine and AC in front of the French Academy of Medicine.

Currently, there is no evidence to recommend the use of multiple-dose AC or whole-bowel irrigation for strychnine poisoning. Although forced diuresis was once suggested as an effective means of enhancing the elimination of strychnine,[89] subsequent data failed to demonstrate an increase in clearance[82] and it is therefore no longer recommended. Peritoneal dialysis, hemodialysis, and hemoperfusion have not been extensively studied. Because strychnine is rapidly distributed to the tissues[94] with a large volume of distribution (13 L/kg), extracorporeal drug elimination procedures are unlikely to be useful and therefore not justified given their risks.

Supportive treatment remains the most important aspect of management in the majority of cases. The focus of care is to stop the muscular hyperactivity as soon as possible to prevent the metabolic and respiratory complications. At all times, unnecessary stimuli and manipulation of the patient should be avoided, as these activities trigger muscle contractions. Benzodiazepines remain the first-line treatment for strychnine-induced muscular hyperactivity.[84,96] Although much of the evidence concerning the efficacy of benzodiazepines is based on diazepam,[41,50,53,65] any of the other commonly used benzodiazepines (midazolam or lorazepam) would likely have similar effects. The initial dose of the benzodiazepine chosen should be the standard dose used for other indications, although doses of more than 1 mg/kg diazepam or its equivalent may be needed.[44,57] In case of failed intravenous access, lorazepam or midazolam can be given intramuscularly. Dosing should be repeated until the patient demonstrates muscle relaxation and the contractions cease. In addition to benzodiazepines, barbiturates and propofol are also effective, although considered secondary therapies, in stopping the strychnine-induced hyperactivity[40,54,75,88] Benzodiazepines and barbiturates both work through agonism of γ-aminobutyric acid (GABA) receptor chloride complexes to increase the inhibitory neurotransmission to the spinal cord from the brain, and thus raise the reflex arc threshold.[80] If these measures fail to control the muscular hyperactivity, a nondepolarizing neuromuscular blocker (NMB) should be administered. Only nondepolarizing NMBs should be used, as succinylcholine itself, a depolarizing NMB, induces muscle contractions.[14,29,54,65,82] It is important to remember that strychnine has no direct effects on consciousness, so that sedation must always accompany neuromuscular blockade. Generally, therapy is continued for about 24 hours, at which time the medications are slowly withdrawn, as tolerated.

The most important therapy for the metabolic complications of strychnine poisoning is to stop the further production of metabolic byproducts by terminating the muscular hyperactivity as soon as possible. Hyperthermia should be treated aggressively by active cooling with ice water immersion, cooling blanket, or mist and fan, depending on the magnitude of temperature elevation. Means to prevent rhabdomyolysis-induced acute renal failure include adequate fluid administration to ensure good urine output (greater than 1 mL/kg/h), the potential use of urinary alkalinization with sodium bicarbonate,[76] and temporary renal replacement therapy, if acute renal failure occurs. Metabolic acidosis rapidly resolves when muscular activity is controlled.[14,69]

Effective management in the first few hours of strychnine poisoning is crucial for survival. If the patient can be supported adequately for the first 6 hours, this may be considered a good prognostic sign.[14,37] All significantly poisoned patients should be managed in an intensive care unit with the help of a regional poison center or medical toxicologist. For patients unintentionally exposed to strychnine who remain asymptomatic, an observation period of 12 hours is sufficient to exclude significant risk.

SUMMARY

Strychnine is a lethal poison no longer frequently encountered, except in areas where it is used to exterminate small animals. A "conscious seizure" is the characteristic presentation of strychnine toxicity, and is rapidly followed by life-threatening metabolic and respiratory consequences. The mainstay of treatment is supportive care with the goal of rapidly terminating muscular contractions, providing adequate airway management, and rapidly treating hyperthermia and/or metabolic abnormalities. Although benzodiazepines are generally sufficient, neuromuscular paralysis with a nondepolarizing NMB may be required. Generally, the prognosis of strychnine poisoning is good, if the patient can be adequately supported and survives the first few hours of toxicity.

CHAPTER 113

INSECTICIDES: ORGANIC PHOSPHORUS COMPOUNDS AND CARBAMATES

Michael Eddleston and Richard Franklin Clark

Globally, anticholinesterase insecticides likely kill more people each year than acute poisoning by any other xenobiotic. An estimated 200,000 die in rural Asia where intentional self-harm is common and extremely toxic organic phosphorus insecticides are widely used in agriculture.[53,84] An estimated 3000 to 6000 ventilators are constantly required in Asia alone to provide mechanical ventilation to poisoned patients.[84] Banning of the most toxic organic phosphorus insecticides has resulted in a 50% decrease in total suicides in Sri Lanka, showing that governmental regulation can be effective.[85] Severe occupational or unintentional poisoning also happens where such insecticides are used[199] but deaths are generally less common. Anticholinesterase poisoning is less important in industrialized countries where access to toxic insecticides is controlled. However, when anticholinesterase poisoning does occur, patients often require intensive care with long hospital stays.[65,155] A further threat is the terrorist use of organic phosphorus insecticides such as parathion to poison a water supply or flour used in bread baking. Such an event may result in many hundreds of casualties being treated by clinicians with limited experience of this potentially lethal toxic syndrome.

HISTORY AND EPIDEMIOLOGY

The first potent synthetic organic phosphorus anticholinesterase, tetraethylpyrophosphate (TEPP), was synthesized by Clermont in 1854. Clermont's report described the taste of the compound, a remarkable achievement because a few drops should be rapidly fatal.[94] In 1932, Lange and Krueger wrote of choking and blurred vision following inhalation of dimethyl and diethyl phosphorofluoridates. This account inspired Schrader in Germany to begin investigating these xenobiotics, initially as insecticides, and later for use in warfare (Chap. 131). During this research, Schrader's group synthesized hundreds of compounds, including the popular insecticide parathion and the chemical warfare agents, sarin, soman, and tabun. Allied scientists were also motivated during the same period by the work, and independently discovered other extremely toxic compounds such as diisopropylphosphofluoridate (DFP).[187] Since that time, it is estimated that more than 50,000 organic phosphorus compounds have been synthesized and screened for insecticidal activity, with dozens being produced commercially.[34]

The history of carbamates was first recorded by Westerners in the 19th century when they observed that the Calabar bean (*Physostigma venenosum* Balfour) was used in tribal cultural practice in West Africa.[95] These beans were imported to Great Britain in 1840, and in 1864 Jobst and Hesse isolated an active alkaloid component they named "physostigmine." Vée and Leven (1865) claimed to have obtained physostigmine in crystallized form, and named it *eserine*, from ésére, the African term

for the "ordeal bean". Physostigmine was first used medicinally to treat glaucoma in 1877.[95] In the 1930s, the synthesis of aliphatic esters of carbamic acid led to the development and introduction of carbamate insecticides, marketed initially as fungicides. In 1953 the Union Carbide Corporation developed and first marketed carbaryl, the insecticide being prepared at the plant in Bhopal, India, during the catastrophic release of methyl isocyanate in 1984 (Chap. 2).[4,167]

Organic phosphorus compounds (OPs) and carbamates are the two groups of cholinesterase-inhibiting insecticides that commonly produce human toxicity. Although the term "organophosphate" is often used in clinical practice and in the literature to refer to all phosphorus-containing insecticides that inhibit cholinesterase, phosphates are compounds in which the P atom is surrounded by four O atoms, and there are other derivatives of phosphoric and phosphonic acids such as phosphonates that can exhibit cholinesterase inhibition. Some chemicals, such as parathion, contain thioesters, whereas others are vinyl esters. Those cholinesterase-inhibitors (anticholinesterases) that contain phosphorus will be collectively termed organic phosphorus compounds in this chapter. Those that contain the OC=ON linkage will be termed carbamates.

Anticholinesterases are broadly grouped according to their toxicity by the World Health Organization's Classification of Insecticides into five groups: Class Ia "Extremely hazardous," Class Ib "Highly hazardous," Class II "Moderately hazardous," Class III "Slightly hazardous," and "Active ingredients unlikely to present acute hazard in normal use."[204] This classification is based on comparative rat oral LD_{50} (median lethal dose in 50% of test subjects) data of the active ingredient. It seems useful to distinguish very toxic OPs (such as parathion, rat oral LD_{50} 13 mg/kg) that have killed many thousands of people from relatively safe OPs (such as temephos, rat oral LD_{50} 8600 mg/kg) that have not been reported to cause harm. The rat LD_{50} seems to be less useful to distinguish between insecticides within the same class. Here, the differential toxicity may be a result of differences in response to treatment, speed of onset, or coformulants.[58]

The case fatality ratio for OP and carbamate poisoning will vary according to which insecticides are used in local agriculture and the prehospital, healthcare, and hospital facilities available. Where fast acting, highly toxic insecticides are used in agriculture and for self-harm (as in much of the rural developing world), deaths will occur before patients present to a hospital. Hospital-based data therefore have a falsely low case fatality, although it is often still quite high at 10% to 30%.[53]

Before the recent ban of parathion in Germany, case fatality in the Munich toxicology intensive care unit was approximately 40%.[65,208] This was likely because the ambulance services in Germany were able to resuscitate and transport patients, before death but after they had become symptomatic with this fast-acting OP. Some had already aspirated or suffered hypoxic brain injury prior to arrival of the ambulance. Despite resuscitation at the scene, many of these patients subsequently died from their complications. Few of these patients would have survived to hospital admission in the developing world.

During the 5-year period from 2002 to 2006, the American Association of Poison Control Centers (AAPCC) recorded almost 30,000 exposures to organic phosphorus compounds and more than 14,000 exposures to carbamates. Although these totals are large, the number of reported exposures to both classes of insecticide have each dropped annually since 2002, likely due in part to a phase-out of their residential use during this period.[175] However, the number of fatalities reported to the AAPCC remained constant during this time, averaging about five per year. These insecticides still rank as the most lethal insecticides in use in the United States, and among the most lethal poisonings (see Chap. 135).

Since the overall case fatality ratio for OP and carbamate insecticide poisoning is approximately 10% to 20%, the 200,000 deaths a year in rural Asia must represent one million to two million poisonings. Respiratory failure is a major problem with OP and carbamate poisoning. Modeling suggests that the 20% to 30% of patients who develop respiratory failure will receive 1.1-2.3 million days of ventilation every year.[84] This will require constant use of 3140 to 6280 ventilators worldwide solely for managing self-poisoning with these insecticides.[84]

Patients typically present following unintentional or suicidal ingestion, or after working in areas recently treated. Children and adults can develop toxicity while playing in or inhabiting a residence recently sprayed or fogged by an insecticide applicator.[209] Direct dermal contact with certain types of these insecticides may be rapidly poisonous.[126] Outbreaks of mass poisoning regularly occur in the developing world, and less commonly in the United States, from contamination of crops or food.[26,35,47,48,64,156,190] Epidemics of cholinergic toxicity have also been reported among groups illegally importing and using the potent carbamate aldicarb.[140,152] Organic phosphorus compounds and carbamates have also been used for committing homicide.[22,46,158,179,192]

PHARMACOLOGY

■ ORGANIC PHOSPHORUS COMPOUNDS

Poisoning from OPs results in a rise in the concentration of acetylcholine (ACh) at muscarinic and nicotinic cholinergic receptors, which, in turn, leads to a syndrome of cholinergic excess. Figure 113–1 shows the basic formula for cholinesterase-inhibiting OPs.[72,181] The "X" or "leaving group" determines many of the characteristics of the OP and provides a means of classifying OPs into four main groups (Table 113–1). Group 1 OPs contain a quaternary nitrogen at the X position, and are collectively termed phosphorylcholines. Originally developed as weapons of war, these powerful cholinesterase inhibitors can also directly stimulate cholinergic receptors, presumably because of their structural resemblance to ACh. Group 2 OPs are called fluorophosphates because they possess a fluorine molecule as the leaving group. Like group 1 compounds, these OPs are volatile and highly toxic, making them well suited for chemical warfare. The leaving group of group 3 OPs is a cyanide molecule or a halogen other than fluorine. The most well-known members in this group are cyanophosphates such as tabun.

The fourth group is the broadest and comprises various subgroups based on the configuration of the R_1 and R_2 groups, with the majority falling into the category of either a dimethoxy or diethoxy compound. Most of the OPs in use today fall into this last class.[72]

"Direct-acting" OPs ("oxons") inhibit acetylcholinesterase (AChE) without first being metabolized in the body. However, many OPs, such as parathion and malathion, are "indirect" inhibitors (prodrugs or "thions") requiring partial metabolism (to paraoxon and malaoxon, respectively) within the body to become active. Desulfuration to the oxon occurs in the intestinal mucosa and liver following absorption.[111,176]

The OPs bind to a hydroxyl group at the active site of the AChE enzyme. As the leaving group of the OPs is split off by AChE, a stable

$$R_2 — \overset{\displaystyle R_1}{\underset{\displaystyle X}{P}} = O \text{ (or S)}$$
FIGURE 113–1. General structure of organic phosphorus insecticides. X represents the leaving group. R_1 and R_2 may be aromatic or aliphatic groups that can be identical.

but reversible bond results between the remaining substituted phosphate of the OP and AChE, effectively inactivating the enzyme (Fig. 113–2, normal metabolism; Fig. 113–3, inactivation; see Fig. 11–6 for a more detailed analysis).

Although splitting of the choline–enzyme bond in normal ACh metabolism is completed within microseconds, the severing of the OP–enzyme bond is prolonged. The half-life of this reaction depends on the chemistry of the substituted phosphate. The in vitro half-life for spontaneous reactivation of human AChE inhibited by dimethoxy OPs is 0.7 to 0.86 hour; that of diethoxy inhibition is 31 to 57 hours.[67] Spontaneous reactivation is therefore far quicker with dimethoxy OPs.

Oximes, such as pralidoxime or obidoxime, markedly speed up the rate of reactivation.[67] However, if the phosphorus is allowed to remain bound to the AChE, because of late or inadequate administration of oximes, an alkyl group is nonenzymatically lost (see Fig. 113–2)—a process called "aging." Once aging has occurred, the AChE can no longer be reactivated by oximes. Again, the half-life of this reaction is determined by the substituted phosphorus. The in vitro half-life of aging of human AChE after poisoning with dimethoxy OPs is 3.7 hours; after diethoxy poisoning it is 31 hours.[67] Clinically, this means that patients who present to a hospital 4 hours after poisoning with a dimethoxy OP may already have as much as 50% of their AChE irreversibly inhibited; after 14 hours, the patients will be completely refractory to oxime therapy. In contrast, patients poisoned by diethoxy OPs presenting within 14 hours will have very little aged AChE and be responsive to oximes. De novo synthesis of AChE is required to replenish its supply once aging has occurred.[181]

OPs also vary by lipid solubility,[17] rate of activation (conversion from thion to oxon), rate of AChE inhibition,[67] and relative inhibition of the plasma butyrylcholinesterase. Some OPs do not fulfill the usual dimethoxy or diethoxy classification and have one of the alkyl groups linked to the phosphorus by a sulfur molecule, rather than oxygen (eg, profenofos, methamidophos). Aging seems to be particularly rapid for these OPs.[55] Spontaneous reactivation, aging, metabolism, and elimination are competing processes. The exact kinetics of these processes are poorly defined, making predictions about the course of any particular organic phosphorus compound in a particular individual quite difficult to predict (Tables 113–2 and 113–3).

■ CARBAMATES

Carbamate insecticides are *N*-methyl carbamates derived from carbamic acid (Fig. 113–4).[15] Medicinal carbamate compounds include physostigmine, pyridostigmine, and neostigmine.[181] Xenobiotics such as meprobamate and various urethanes are carbamate derivatives, but do not inhibit cholinesterase. Thiocarbamate fungicides and herbicides (eg, maneb, zineb, nabam, and mancozeb) also do not inhibit AChE and do not produce the cholinergic toxic syndrome (Chap. 115).

When exposed to carbamate compounds, AChE undergoes carbamylation in a manner similar to phosphorylation by OPs,[202] allowing ACh to accumulate in synapses. Aging cannot occur and the carbamate–AChE bond hydrolyzes spontaneously, reactivating the enzyme. As such, the duration of cholinergic symptoms in carbamate poisoning is generally less than 24 hours. However, severe complications from the cholinergic syndrome, in particular aspiration, can persist.

PHARMACOKINETICS AND TOXICOKINETICS

■ ORGANIC PHOSPHORUS COMPOUNDS

Organic phosphorus compounds are well absorbed from the lungs, gastrointestinal tract, mucous membranes, and conjunctiva following

---

TABLE 113–1. The Classification of Organic Phosphorus Compounds by Groups. Leaving Groups and Examples of Each Group Are Included

Group 1–phosphorylcholines
    Leaving group: substituted quarternary nitrogen
        Echothiophate iodide
Group 2–fluorophosphates
    Leaving group: fluoride
        Dimefox, sarin, mipafox

Group 3–cyanophosphates, other halophosphates
    Leaving group: CN^-, SCN^-, OCN^-, halogen other than fluoride
        Tabun
Group 4–multiple constituents
    Leaving group:
        Dimethoxy
            Azinphos-menthyl, bromophos, chlorothion,
            crotoxyphos, dicapthon, dichlorvos, dicrotophos,
            dimethoate, fenthion, malathion, mevinphos,
            parathion-methyl, phosphamidon, temephos, trichlorfon
    Diethoxy
        Carbophenothion, chlorfenvinphos, chlorpyriphos,
        coumaphos, demeton, diazinon, dioxathion, disulfoton,
        ethion, methosfolan, parathion, phorate, phosfolan, TEPP
    Other dialkoxy
        Isopropyl paraoxon, isopropyl parathion

    Diamino
        Schradan

    Chlorinated and other substituted dialkoxy
        Haloxon

    Trithioalkyl
        Merphos

    Triphenyl and substituted triphenyl
        Triorthocresyl phosphate (TOCP)

    Mixed substituent
        Crufomate, cyanofenphos

Echothiophate iodide

Sarin

Tabun

Parathion
Triorthocresyl phosphate (TOCP)

---

inhalation, ingestion, or topical contact.[72] Although absorption through intact skin appears to be limited,[78] percutaneous exposure to highly toxic compounds can cause severe toxicity.[36,38,126,198] The presence of any dermatitis or skin damage and of higher environmental temperatures will enhance cutaneous absorption.[72]

Poisonings can be chronic or acute, although the differentiation has little clinical relevance. The difficulty in removing these compounds

from the skin and clothing may explain some chronic poisonings, and inadequate skin and respiratory protection during insecticide application is responsible for most of the remainder of occupational exposures.

The time to peak serum concentration after self-poisoning is unknown. Human volunteer studies, using very low doses of chlorpyrifos, found C_{max} to be around 6 hours after oral ingestion.[141] However, patients ingesting large amounts of oxon or fast-acting thion OPs can
FIGURE 113–2. Normal metabolism of acetylcholine by acetylcholinesterase to choline and acetic acid.

become symptomatic within minutes,[65,118] suggesting that absorption can be rapid.

Most OPs are lipophilic[17] and are therefore predicted to have a large volume of distribution and to rapidly distribute into tissue and fat where they are protected from metabolism. Radiolabeled parathion injected into mice distributes most rapidly into the cervical brown fat and salivary glands, with high concentrations also measured in the liver, kidneys, and other adipose tissue.[70] Adipose tissue gradually accumulates the highest concentrations. Redistribution from these stores
FIGURE 113–3. Mechanism of inhibition of acetylcholinesterase by an organic phosphorus compound. The X is the leaving group. A serine residue at the active site of the enzyme gives up a hydrogen atom to combine with the leaving group while the active site undergoes phosphorylation and inhibition. This initial inhibition is reversible with pralidoxime. However, as the inhibited phosphorylated enzyme "ages," one of the R groups is lost. The aged phosphorylated enzyme is unable to be rejuvenated by pralidoxime.

TABLE 113–2. Pharmacologic Properties of Dimethoxy Organic Phosphorus Insecticides

Compound	Bioactivation	Relative Lipophilicity[a]	Comments
Acephate	Liver	+	Hepatic metabolism
Azinphos-methyl	Yes (liver?)	+++	
Dimethoate	Liver	+	Hepatic metabolism
Fenthion	Liver	++++	
Malathion	Low C = 1A2/2B6 High C = 3A4	++	Inhibits BuChE > AChE Metabolism by CYP1A2
Methyl Parathion	Low C = 1A2/2B6 High C = 3A4	++	
Phosmet	Yes (liver?)	++	

For all dimethoxy compounds in this table, the half-life of spontaneous reactivation is about one hour, and the half-life of aging is about 4 hours.

[a]Derived from log P = octanol/water coefficient; C = concentration.

may allow for measurement of circulating OP concentrations for up to 48 days postingestion.[42,74,161]

Cholinergic crisis may recur in patients when unmetabolized OPs are mobilized from fat stores.[72] The more lipophilic compounds such as fenthion and dichlofenthion are particularly likely to cause this phenomenon.[42,58,129] Dimethoate, methamidophos, and oxydemeton methyl are three common OPs that are not lipophilic, with predicted small volumes of distribution and high serum OP concentrations.[43]

The distribution of OPs into fat will likely include both activated and unactivated compound. When released from the fat hours to days

TABLE 113–3. Pharmacologic Properties of Diethoxy Organic Phosphorus Insecticides

Compound	Bioactivation	Relative Lipophilicity[a]	Comments
Chlorpyrifos	Low C = 1A2/2B6 High C = 3A4	++++	Inhibits BuChE = AChE Metabolism by CYP1A2
Diazinon	Low C = 1A2/2B6 High C = 3A4	+++	Metabolism by CYP1A2
Parathion	3A4/5 and 2C8	+++	Hepatic metabolism
Phorate	Liver	+++	Inhibits BuChE > AChE Hepatic metabolism
Terbufos	Liver	++++	Hepatic metabolism

For all diethoxy compounds in this table, the half-life of spontaneous reactivation is 31-57 hours, and the half-life of aging is 31 to 94 hours.

[a]Derived from log P = octanol/water coefficient; C = concentration.

FIGURE 113–5. Pathophysiology of cholinergic syndrome as it affects the autonomic and somatic nervous systems.

later, the unactivated thion will require activation to cause clinical manifestations.

Thion OPs are activated by cytochrome P450 (CYP) enzymes in the liver and intestinal mucosa. The precise CYP enzymes responsible appear to vary according to the concentration of the OP. For example, chlorpyrifos, diazinon, parathion, and malathion are all activated by CYP1A2 and CYP2B6 at low concentrations.[27,28] However, at the higher concentrations more likely after self-poisoning, CYP3A4 becomes dominant. The particular enzymes involved in metabolism of the active oxon to inactive metabolites are less clear.

Studies have investigated possible relationships between human serum paraoxonase (PON) activity and susceptibility to acute and chronic effects of organic phosphorus poisoning.[37,168,170] PON can hydrolyze the active (oxon) metabolites of some OPs. Activity differs significantly among animal species. Some animal models of organic phosphorus poisoning demonstrate protection from toxicity when exogenous PON is administered, and greater susceptibility to poisoning when enzyme-deficient animals (such as genetically engineered knockout mice) are exposed.[168] Some authors have postulated that genetic polymorphisms in human PON activity may lead to variations in interindividual susceptibility to some OPs.[37]

■ CARBAMATES

Carbamates are absorbed across skin and mucous membranes, and by inhalation and ingestion. Peak blood cholinesterase inhibition occurs within 30 minutes of oral administration in rats.[143] Most carbamates undergo hydrolysis, hydroxylation, and conjugation in the liver and intestinal wall, with 90% excreted as metabolites in the urine within 3 to 4 days.[15]

There is a view that carbamates, unlike OPs, do not easily enter the brain. However, carbamates cause central nervous system (CNS) depression in humans[152] and are lipophilic,[17] and rat studies show inhibition of brain cholinesterases with multiple carbamates.[143] Furthermore, postmortem studies have shown high concentrations of carbamates in cerebrospinal fluid (CSF) and brain.[92,131,132] The evidence at present therefore suggests that they do not differ from OPs other than with regard to aging.

■ PATHOPHYSIOLOGY

Acetylcholine is a neurotransmitter found at both parasympathetic and sympathetic ganglia, skeletal neuromuscular junctions (NMJs), terminal junctions of all postganglionic parasympathetic nerves, postganglionic sympathetic fibers to most sweat glands, and at some nerve endings within the CNS (Fig. 113–5).[200] As the axon terminal is depolarized, vesicles containing ACh fuse with the nerve terminal, releasing ACh into the synapse or NMJ. ACh then binds postsynaptic receptors leading to activation (G proteins for muscarinic receptors and ligand-linked ion channels for the nicotinic receptors). Activation alters the flow of K^+, Na^+, and Ca^{2+} ionic currents on nerve cells, and alters membrane potential of the postsynaptic membrane, resulting in propagation of the action potential.
Organic phosphorus insecticides and carbamates are inhibitors of carboxylic ester hydrolases within the body, including variably AChE (Enzyme Commission [EC] number 3.1.1.7), butyrylcholinesterase (plasma or pseudocholinesterase; BuChE; EC number 3.1.1.8), plasma and hepatic carboxylesterases (aliesterases), paraoxonases (A-esterases), chymotrypsin, and other nonspecific proteases.[31]

AChE hydrolyzes ACh into two inert fragments: acetic acid and choline. Under normal circumstances, virtually all ACh released by the axon is hydrolyzed almost immediately, with choline undergoing reuptake into the presynaptic terminal and being used to resynthesize ACh.[200] AChE is found in human nervous tissue and skeletal muscle, and on erythrocyte (red blood cell [RBC]) cell membranes.[123] Acutely, RBC AChE activity correlates well with the function of nervous system AChE.[185]

BuChE is a hepatic-derived protein that is found in human plasma, liver, heart, pancreas, and brain. Although the function of this enzyme is not well understood, its activity can be easily measured and has important clinical implications in anesthesia (Chaps. 66 and 68).

Inhibition of AChE is generally thought to account for all, or the majority, of clinical features of both OP and carbamate poisoning. However, many other enzymes are also inhibited.[31] The clinical effects of these interactions are not yet understood.

In addition, people ingest formulated OPs rather than pure active ingredient. OPs sold for agricultural use are typically emulsifiable concentrates in which an active ingredient such as dimethoate is mixed with an organic solvent such as xylene or cyclohexanone and a surfactant/emulsifier. Unfortunately, the xenobiotics used for coformulation are highly variable, being optimized by each company for each OP. As a result, coformulants often differ between the same OP produced by two companies, and for two OPs produced by one company.

The clinical effect of poisoning with these coformulants, in addition to the carbamate or OP, is poorly studied and uncertain. Complications of surfactant poisoning have been well described in glyphosate poisoning[24] but not with OPs. The acute toxicity of the solvents appears to be low—for example, the rat oral LD_{50}s for xylene and cyclohexanone are 4000-5000 and 1620 mg/kg, respectively. However, early respiratory arrest occurred in minipigs poisoned by dimethoate formulated

with cyclohexanone at a point when red cell AChE was less than 30% inhibited, suggesting a non-AChE mechanism (Eddleston and Clutton, unpublished). Early work showed that dimethoate toxicity could be increased markedly by changing its solvent[32]; more recent work with chlorpyrifos has shown a modest change in toxicity after changing the solvent.[189] While potentially important, the major differences in clinical syndromes noted in Sri Lanka between dimethoate EC40, chlorpyrifos EC40, and fenthion EC50 cannot be attributed to the solvent since most Sri Lankan insecticides are generic, using 40% xylene as the solvent.[58]

A further effect of the solvents and surfactants occurs after aspiration. Ingestion of both OPs and carbamates can cause rapid loss of consciousness and respiratory arrest, increasing the risk of aspiration with the OP, solvent, and surfactant. Aspiration pneumonia is a major clinical problem in OP poisoning and cannot be effectively treated with oximes and atropine.

CLINICAL MANIFESTATIONS

■ ACUTE TOXICITY–ORGANIC PHOSPHORUS COMPOUNDS

Clinical findings of acute toxicity derive from excessive stimulation of muscarinic and nicotinic cholinergic receptors by ACh in the central and autonomic nervous systems, and at skeletal NMJs (see Fig. 113–5). The classically described patient with severe OP poisoning is one who is unresponsive, with pinpoint pupils, muscle fasciculations, diaphoresis, emesis, diarrhea, salivation, lacrimation, urinary incontinence, and an odor of garlic or solvents. Less severe poisoning is often not so typical.

The onset of symptoms varies according to the route, the degree of exposure, and particularly the OP. This is important since a more rapid onset of poisoning will reduce the likelihood of the patient reaching health-care safely, before the need for intubation and ventilation, or the onset of complications such as aspiration. Onset of respiratory failure outside of a hospital in many parts of the world will result in the patient's death.

Patients ingesting large amounts can become symptomatic as quickly as 5 minutes following ingestion. Most patients with acute poisoning become symptomatic within a few hours of exposure, and practically all who will become ill show some features within 24 hours.

Oxon OPs (such as mevinphos and monocrotophos) are already active on exposure and patients become symptomatic very soon after ingestion. One man was reported to have died within 15 minutes of mevinphos ingestion.[118] Some thion OPs are very rapidly converted to oxons and can similarly produce symptoms rapidly, with patients ingesting parathion becoming unconscious within minutes.[65] In contrast, patients ingesting thions that are slowly converted to active oxons may not develop symptoms for hours.

The speed of onset will also be affected by the quantity ingested and the toxicity[67] of the individual OP. Patients ingesting very large doses or highly toxic compounds will more rapidly inhibit a clinically significant proportion of their AChE and exhibit features earlier.

Lipid solubility also likely affects time to onset—fat-soluble OPs such as fenthion will rapidly distribute to fat stores, in the process reducing their concentration in extracellular fluid where they impart their clinical effect.[58] Significant poisoning with such OPs is commonly delayed—respiratory failure with fenthion, for example, typically occurs after 24 hours, in contrast to the more rapid time course for less fat-soluble OPs.[61]

Symptoms following OP exposure may last for variable lengths of time, again based on the OP and the circumstances of the poisoning. For example, the more lipophilic compounds, such as dichlofenthion or fenthion, can cause recurrent cholinergic effects for many days following ingestion as they are released from fat stores.[42,129,150]

A variety of CNS findings are reported after OP exposure. Many patients present awake and alert, complaining of anxiety, restlessness, insomnia, headache, dizziness, blurred vision, depression, tremors, or other non-specific symptoms.[13,138] The level of consciousness may deteriorate rapidly to confusion, lethargy, and coma, and patients may display inappropriate behavior. Where careful observational studies have been done, convulsions appear to be uncommonly associated with OP insecticide exposure compared with OP nerve agent poisoning.[58,194] The convulsions occurring with OPs may be due to hypoxia secondary to acute cholinergic toxicity.

The effects of excessive ACh on the autonomic nervous system may be variable because cholinergic receptors are found in both the sympathetic and parasympathetic nervous systems (see Fig. 113-5). Excessive muscarinic activity can be characterized by several mnemonics, including "SLUD" (salivation, lacrimation, urination, defecation) and "DUMBBELS" (defecation, urination, miosis, bronchospasm or bronchorrhea, emesis, lacrimation, salivation). Of these, miosis may be the most consistently encountered sign. Bronchorrhea can be so profuse that it mimics pulmonary edema.[138]

Although muscarinic findings are emphasized in these mnemonics, muscarinic signs may not always be clinically dramatic or initially predominant. Parasympathetic effects can be offset by excessive autonomic activity from stimulation of nicotinic adrenal receptors (resulting in catecholamine release) and postganglionic sympathetic fibers.[181] Mydriasis, bronchodilation, and urinary retention can occur as a result of sympathetic activity. Increased sympathetic activity usually induces white blood cell demargination, resulting in leukocytosis.[136,138]

Excessive adrenergic influences on metabolism cause glycogenolysis[182] with resultant hyperglycemia and ketosis simulating ketoacidosis.[127,206] Hypoglycemia can also occur, although the mechanism is unclear.[97] Disturbances of glucose metabolism do not seem to be common. A recent study of 79 patients with OP or carbamate poisoning showed hyperglycemia in only six patients[169]; an older study demonstrated it in seven of 105 patients.[88] It is possible that effects on glucose metabolism may be associated with specific OPs, such as malathion[97] and diazinon,[162] rather than all OPs. Larger cohorts of patients exposed to a single OP are required to determine whether such associations exist.

Hyperamylasemia appears to be relatively common in OP poisoning, occurring in four of 47 (9%) adult cases in one series[160] and five of 17 (29%) pediatric cases in a second series.[197] However, both included various anticholinesterases; a case series of only malathion poisoning reported 47 of 75 (63%) cases with hyperamylasemia.[39] The amylase likely comes from the pancreas since animal studies show OP-induced damage[98] and human poisoning cases show associated pancreatic edema and/or necrotizing pancreatitis.[25,87,144] The incidence of subclinical and clinical pancreatitis probably varies according to the OP ingested, and possibly the coformulants. Elevations of hepatic enzymes can also occur following OP exposures.[142,151,207]

Cardiovascular manifestations reflect mixed effects on the autonomic nervous system (including increased sympathetic tone), together with the consequences of OP-induced hypoxia and hypovolemia. The heart rate on admission is usually normal, with relatively few patients expressing a tachycardia or bradycardia. Patients who have received atropine before admission may be tachycardic. The literature is filled with reports of OP-associated QT interval prolongation and ventricular dysrhythmias.[14,79,109,157,159] However, most patients included had an electrocardiogram (ECG) done before they received any atropine or were so ill that atropine was ineffective. The first report described 46 patients with OP or carbamate poisoning in which ECG recordings taken on arrival were selected for analysis before the start of atropine treatment.[159] These cardiac rhythms are strongly confounded by the hypoxia and hypovolemia that characterizes the cholinergic syndrome. In a second study, 29 of the 35 patients with such dysrhythmias died.[120]

Hypotension may occur because of stimulation of vascular receptors by excessive circulating ACh.[9,105] Severe hypotension is a particularly significant problem in poisoning with the unusually fat-insoluble OP dimethoate.[43,58] Fatal poisoning is characterized by early respiratory failure followed by hypotension that can be treated only transiently with vasopressors. Such a syndrome was not found in poisoning with other fat-soluble OPs such as chlorpyrifos and fenthion.[58] The exact role of direct cardiotoxicity and peripheral vasodilatation is not yet clear, and whether this syndrome occurs with other fat-insoluble OPs, such as methamidophos and oxydemeton methyl, is also uncertain.[43]

Respiratory complications of OP poisoning include the direct pulmonary effects of bronchorrhea and bronchoconstriction, muscular junction failure of the diaphragm and intercostal muscles, and loss of central respiratory drive.[45] If severe and occurring before patients reach medical care, these effects can lead to hypoxemia and respiratory arrest, the most common cause of death after OP poisoning.[72] Both bronchorrhea and bronchoconstriction respond to adequate atropine therapy. Unfortunately, neither NMJ failure nor loss of central respiratory drive responds to atropine, and patients must be intubated and ventilated until respiratory function returns. An additional early respiratory complication is hydrocarbon aspiration that may occur after ingestion of formulated insecticides. The incidence of aspiration and the consequences of aspiration—whether pneumonia, chemical pneumonitis, or acute respiratory distress syndrome—are not yet known and likely differ according to the particular OP ingested.

Acetylcholine stimulation of nicotinic receptors governs skeletal muscle activity. The effects of excessive cholinergic stimulation at these sites are similar to that of a depolarizing neuromuscular blocking agent (succinylcholine) and initially result in fasciculations or weakness. This effect is considered to be the most reliable sign of parathion toxicity[138]; however, many severely poisoned patients lack this feature. Acute cranial nerve abnormalities are uncommon. Severe poisoning results in paralysis.[195] Rarely, patients may present only with paralysis from nicotinic effects without any other initial signs and symptoms suggestive of OP toxicity.[68,76] Extrapyramidal effects such as rigidity and choreoathetosis occur uncommonly after severe poisoning, but can persist for several days after cholinergic features have resolved.[7,21,114,134]

■ ACUTE TOXICITY–CARBAMATES

The effects of poisoning from carbamate insecticides appear identical to those of OPs except for the relative short duration of cholinergic features due to rapid hydroxylation of the carbamate–AChE bond. Persistent cholinergic features are not reported for carbamate poisoning.

■ DELAYED SYNDROMES

Intermediate Syndrome   A syndrome of delayed muscle weakness resulting in respiratory failure without cholinergic features or fasciculations was first reported in 1974[195] and further refined in 1987.[164] This "intermediate syndrome" was defined as occurring 24 to 96 hours after acute OP poisoning, and following resolution of the cholinergic crisis.[106,164,195] Patients typically develop proximal muscle weakness, especially of the neck flexors, cranial nerve palsies, and progress to respiratory failure that may last for up to several weeks.[106] Consciousness is preserved unless complicated by hypoxia or pneumonia. The syndrome is important since apparently well patients can suddenly develop a respiratory arrest; therefore, an evaluation must occur in all poisoned patients if deaths are to be prevented.[16,145] The first sign is often weakness of neck flexion such that patients cannot lift their heads off the bed.

The exact pathophysiology of the syndrome is unknown. It is clearly due to dysfunction of the NMJ, with respiratory failure resulting from weakness affecting the diaphragm and intercostal muscles. Preservation

of consciousness suggests that the central respiratory drive is unlikely to be involved. Clinicians have proposed that overwhelming NMJ stimulation causes downregulation of the NMJ synaptic mechanisms.[44,164] This dysfunction will require time to be repaired, even after the insecticide has been removed from the body, explaining the long periods of time that many patients require assisted ventilation.[61]

Case reports and small case series have been reported from around the world, with resulting comments that the intermediate syndrome is more common with certain OPs, such as parathion, methylparathion, malathion, and fenthion. Unfortunately, large cohorts of poisoning with specific OPs receiving standardized treatments have been rarely reported, making comparisons of incidence between OPs difficult. However, two cohorts have shown that the intermediate syndrome causing respiratory failure is much more common in fenthion poisoning than chlorpyrifos, malathion, or fenitrothion poisoning.[61,194]

Clinical examination remains the most reliable means of identifying the occurrence of intermediate syndrome.[106] Electromyograms (EMGs) will often show tetanic fade in these patients, and suggest both pre- and postsynaptic involvement.[106] Recent work has noted characteristic electrophysiological features, in particular the decrement-increment phenomenon, that can be identified before onset of neurological features and respiratory paralysis.[100] The majority of patients developing weakness in this series did not progress to respiratory failure, indicating that the intermediate syndrome is a spectrum disorder.

A study of severely poisoned patients suggested that the occurrence of intermediate syndrome strongly correlated with the initial degree of cholinergic crisis, and seemed to be a continuum with the neuromuscular paralysis resulting from the early stages of poisoning.[101] This view is supported by an earlier work[44] and a more recent study of dimethoate poisoning, which showed that peripheral NMJ dysfunction can occur simultaneously with the cholinergic syndrome.[61] Patients with moderate to severe dimethoate poisoning typically require intubation for respiratory failure soon after ingestion, during the acute cholinergic syndrome. However, this is relatively short lived and patients recover consciousness after a few days. As the cholinergic syndrome diminishes and patients regain consciousness, with recovery of the central respiratory drive, they still require ventilator support. Similar to patients with classical intermediate syndrome, they require ventilatory support for several weeks until their NMJ recovers function. In addition, this case series demonstrated that the classic intermediate syndrome—respiratory failure after resolution of the cholinergic syndrome—can occur before 24 hours and after 96 hours.[61]

These studies suggest that the original intermediate syndrome is just one important aspect of OP-induced peripheral NMJ dysfunction. It seems likely that the relative incidence and timing of the intermediate syndrome or delayed NMJ dysfunction for different OPs is determined by the rapidity and quantity of AChE inhibition. Where inhibition is intense, with fat-insoluble OPs like dimethoate that have very high blood concentrations, NMJ dysfunction develops at an early stage, before recovery from the cholinergic crisis. Fat-soluble OPs, such as fenthion, cause a more protracted AChE inhibition, likely explaining why fenthion-induced NMJ dysfunction and respiratory failure occur later.[61]

Some authors have suggested that insufficient oxime therapy explains the intermediate syndrome.[18] Of note, both dimethoate- and fenthion-inhibited AChE respond poorly to oximes, in contrast to chlorpyrifos, which responds well to oximes and has a much lower incidence of intermediate syndrome.[58,61] The occurrence of NMJ dysfunction in chlorpyrifos poisoning may well be due to inadequate oxime therapy. However, adequate oxime therapy after, for example, malathion poisoning[174] may be irrelevant since this dimethyl OP responds poorly to oximes. Overall, delayed NMJ dysfunction may be caused by ineffective

AChE reactivation, whether due to inadequate oxime therapy or to poisoning with OPs that do not respond to oxime therapy.

The treatment of intermediate syndrome is supportive with airway protection and mechanical ventilation. There are no substantial data demonstrating that pralidoxime or atropine is effective in the treatment of this disorder, although patients may require these medications to control concurrent cholinergic symptoms. Pralidoxime may be able to reverse the intermediate syndrome if given early in its development. Administration after the NMJ failure occurs is unlikely to be effective. The weakness and paralysis commonly resolve in 5 to 18 days.[61,89,100,101]

Organic Phosphorus–Induced Delayed Neuropathy Peripheral neuropathies can occur with chronic OP exposures or days to weeks following acute exposures. Organic phosphorus–induced delayed neuropathy (OPIDN) results from inhibition by phosphorylation of the enzyme neuropathy target esterase (NTE, now identified as a lysophospholipase [lysoPLA]) within nervous tissue.[30,75,102,103] This enzyme catalyzes breakdown of endoplasmic reticulum–membrane phosphatidylcholine, the major phospholipid of eukaryotic cell membranes. Neuropathic OPs cause a transient loss of NTE-lysoPLA activity, putatively disrupting membrane phospholipid homeostasis, axonal transport, and glial–axonal interactions.[75]

Such neuropathies may result from exposure to OPs that neither inhibit red blood cell cholinesterase nor produce clinical cholinergic toxicity.[33] The more commonly implicated chemicals include triaryl phosphates, such as triorthocresyl phosphate (TOCP), and dialkyl phosphates, such as mephosfolan, mipafox, and chlorpyrifos.[102] Pathologic findings demonstrate effects primarily on large distal neurons, with axonal degeneration preceding demyelination (see Chaps. 2 and 18).

Contaminated foods and beverages were responsible for epidemics of OP-induced delayed polyneuropathies and encephalopathy. In the 1930s, thousands of individuals in the United States became weak or paralyzed after drinking a supplement containing TOCP—an outbreak nicknamed "Ginger Jake paralysis" (see Chap. 2).[8,130] Contaminated cooking and mineral oils were responsible for outbreaks of delayed polyneuropathies in Vietnam and Sri Lanka.[47,163] Vague distal muscle weakness and pain are often the presenting symptoms and may progress to paralysis.[82] The administration of atropine or pralidoxime does not alter the onset and clinical course of these symptoms.[193] Pyramidal tract signs can appear weeks to months after acute exposures. EMGs and nerve conduction studies may be helpful in diagnosing this disorder by identifying the type of neuropathy (such as axonopathy, myelinopathy, or transmission neuropathy) and differentiating it from similar presentations such as Guillain-Barré syndrome.[1] The recovery of these patients is variable, commonly with residual deficits, and occurs over months to years.[130,163]

Delayed neuropathies are not usually associated with carbamate insecticides. One reason for this difference is presumed to be that aging of the neuropathy target esterase insecticide complex is a requirement for neuronal degeneration. Paradoxically, one study suggested that subgroups of carbamates may actually bind neuropathy target esterase and exert a protective effect against more toxic OPs.[3] However, several cases of delayed neuropathy associated with carbamates have been reported.[50,191,205] These cases involved ingestions of carbaryl, *m*-tolyl methyl carbamate, and carbofuran; included both sensory and motor tracts; and tended to resolve over 3 to 9 months.

CHRONIC TOXICITY–ORGANIC PHOSPHOROUS COMPOUNDS

Illness may also result from chronic exposure to excessive amounts of OPs. Chronic exposure most commonly occurs in workers who have regular contact with these xenobiotics, but may also occur in individuals who have repeated contact with excessive amounts of insecticides in their living environments. Chronic exposure to cholinergic ophthalmic preparations can also result in toxicity.[121] Although tolerance to acute cholinergic systemic effects of OPs (including death in rats) may be observed with long-term exposures,[72] persons who have long-term exposures begin to describe symptoms after a substantial length of time. These effects can range from vague neurological complaints, such as weakness and blurred vision, to miosis, nausea, vomiting, diarrhea, diaphoresis, and other cholinergic effects.[5,6,121,172] BuChE activity is usually the most sensitive measure of exposure, and workers in contact with these chemicals should have baseline BuChE testing for comparison and monitoring.[72,93]

Recent literature has linked Parkinson disease with chronic exposure to insecticides including OPs.[49,173] Some individuals may have a genetic susceptibility.[21] Additionally, significant acute exposures to OPs can lead to self-limited movement disorders resembling parkinsonism that resolve over weeks to months (see above). Although statistics derived from some epidemiologic studies suggest the connection,[63,91] other studies have failed to a find an association between OPs and parkinsonism.[180]

■ BEHAVIORAL TOXICITY

Behavioral changes may also occur after acute or chronic exposure to OPs.[66] Signs and symptoms include confusion, psychosis, anxiety, drowsiness, depression, fatigue, and irritability. Electroencephalographic changes may be noted and can last for weeks.[80] Single photon emission computed tomography (SPECT) scanning revealed morphologic changes in the basal ganglia of one child following poisoning.[23] Recent studies have shown a deficit in cognitive processing after acute OP self-poisoning lasting for at least 6 months and not found in matched patients who had poisoned themselves with paracetamol.[40,41] Thus far there appears to be no clear evidence for neuropsychiatric deficits resulting from subclinical exposure to OPs.[66]

DIAGNOSTIC TESTING

■ ORGANIC PHOSPHORUS COMPOUNDS

When confronted with a patient in cholinergic crisis who presents with a history of acute exposure to an OP, the diagnosis is straightforward. Although textbooks list a variety of clinical signs for the cholinergic crisis (DUMBELS, SLUD—see above), most patients with significant poisoning can be identified by the presence of pinpoint pupils, excessive sweat, and breathing difficulty.[56] However, when the history is unreliable or does not suggest poisoning, the clinician must turn to other means to confirm the diagnosis of OP or carbamate poisoning. Treatment of an ill patient with a cholinergic syndrome should not await confirmation of the diagnosis.

The most appropriate laboratory tests for confirming cholinesterase inhibition by insecticides are tests that measure (1) specific OPs and active metabolites in biologic tissues and (2) cholinesterase activity in plasma or blood. Unfortunately, although urine and serum assays for OPs and their metabolites are available,[2,86,99,112] such testing is rarely obtainable within hours. Moreover "normal" ranges and toxic concentrations are not established for most. Currently, therefore, verifying cholinesterase inhibitor poisoning relies on measurement of cholinesterase activity.[55,72]

Cholinesterase Activity The two cholinesterases commonly measured are butyrylcholinesterase (BuChE, plasma cholinesterase, EC 3.1.1.8) and red cell acetylcholinesterase (AChE, EC 3.1.1.7). The former is produced by the liver and then secreted into the blood, where it metabolizes xenobiotics, including succinylcholine and cocaine. Red

cell AChE is expressed from the same gene as the enzyme found in neuronal synapses. The main difference is in their mechanism of membrane attachment which is due to posttranslational modification (red cell AChE is glycosylphosphatidyliositol anchor [GPI]-linked to the red cell while neuronal AChE is secreted and forms dimers and tetramers that are attached to the postsynaptic membrane by other proteins[123]). Inhibition of red cell AChE or BuChE only serves as a marker for cholinesterase inhibitor poisoning, since inhibition of these enzymes does not contribute to signs and symptoms of poisoning. However, red cell AChE activity seems to accurately reflect AChE activity in the NMJ soon after poisoning.[185]

There is tremendous interindividual and interchemical variability in the degree and duration with which the OPs affect particular cholinesterases. After a significant exposure, BuChE activity usually falls first, followed by a decrease in red cell AChE activity. The sequence may be highly variable, but by the time patients present with acute symptoms, both cholinesterase activities have usually fallen well below baseline values.[138] Of note, the presence of BuChE, AChE, and other esterases varies markedly between species,[115] complicating the interpretation of animal studies. Furthermore, AChE occurs at very low concentrations in human plasma or serum; therefore, papers citing human serum AChE activity (eg, [11,188]) are likely measuring serum BuChE.

Butyrylcholinesterase BuChE activity usually recovers before red cell AChE activity, returning to normal within a few days after a mild exposure in the absence of a repeat exposure to the inciting OP.[38] However, BuChE activity is less specific for exposure than red cell AChE activity.[72] Low BuChE activity can be found in patients with a number of disorders, including hereditary deficiency of the enzyme, malnutrition, hepatic parenchymal disease, chronic debilitating illnesses, and iron deficiency anemia.[107]

The wide normal range of BuChE activity allows for patients with high normal activity to suffer significant falls in activity, yet still register near normal BuChE activity on laboratory assay.[38] Additionally, day-to-day variation in the activity of this enzyme in healthy individuals may be as high as 20%.[72] Since BuChE inhibition varies between OPs and does not cause clinical effects, an admission activity by itself is of little value in predicting outcome. An admission activity can only be used to predict outcome if the ingested OP is known and its clinical usefulness has been studied specifically for that OP.[59]

Red Cell Acetylcholinesterase Red cell AChE activity is thought to more accurately reflect nervous tissue AChE activity because the AChE in red blood cells is true AChE. Some authors suggest that clinical OP poisoning occurs when red blood cell cholinesterase activity falls to below 50% of baseline.[138] Neuromuscular dysfunction is associated with a value of 30% of normal or less.[185] A major advantage of AChE is that its activity can be related to hemoglobin (Hb) concentration, reducing variation due to varying hematocrit.[203] Most people have a normal concentration of 600 to 700 mU/μmol Hb; a small study of Caucasians reported a mean of 651 ± 18 mU/μmol Hb.[203]

After poisoning, in the absence of oximes, red cell AChE may take many weeks to recover since erythrocytes in circulation at the time of OP exposure must be replaced. An average of 66 days may be necessary for red cell AChE activity to recover following severe inhibition (assuming no treatment with oxime). Rat studies suggest that neuronal AChE activity may return to normal more rapidly than red cell AChE.[83] Patients have been reported to have normal NMJ activity and no cholinergic features, yet low red cell AChE activity. For this reason, in subacute poisoning with OPs, it is difficult to accurately predict the actual time of onset or duration of exposure when only the red cell AChE activity is known.

Depressed red cell AChE activity may be the result of exposures or conditions other than OP or carbamate poisoning, for example, in

TABLE 113–4. Interpreting Cholinesterase Concentrations

	Red Cell Cholinesterase	Butyrylcholinesterase
Advantage	Better reflection of synaptic inhibition	Easier to assay, declines faster
Site	RBC (reflects CNS gray matter, motor end plate)	CNS white matter, plasma, liver, pancreas, heart
Regeneration (untreated)	1%/day	25%–30% in first 7–10 days
Normalization (untreated)	35–49 days	28–42 days
Use	Unsuspected prior exposure with normal butyryl cholinesterase	Acute exposure
False depression in concentration	Pernicious anemia, hemoglobinopathies, antimalarial treatment, oxalate blood tubes	Liver dysfunction, malnutrition, hypersensitivity reactions, xenobiotics (succinylcholine, codeine, morphine), pregnancy, genetic deficiency

CNS, central nervous system; RBC, red blood cell.

pernicious anemia and during therapy with antimalarials or antidepressants (Table 113–4).[108,133]

Blood samples for cholinesterase activity must be obtained in the appropriate blood collecting tubes. Tubes containing fluoride will permanently inactivate the enzymes, yielding falsely low activity, and should not be used. Specimens for red cell AChE are usually drawn into tubes containing a chelating anticoagulant such as ethylenedi-aminetetraacetic acid (EDTA) to prevent clot formation. BuChE does not require an anticoagulant and can be drawn into a tube without chelators or anticoagulants. Of note, OPs and oximes in collected blood samples will continue to interact with red cell AChE; small differences in time between sampling and assay can result in marked artificial variation in results. The safest way to take blood for AChE is to immediately dilute it 1:20 or 1:100 into saline or water cooled to 4°C at the bedside, before rapidly freezing the sample. This process slows down both inhibitory and reactivating reactions in the tube, allowing more uniform results.[55,203] Such rapid reactions do not occur with BuChE, and bedside dilution and cooling are therefore not required.

Protein Adducts Current research is addressing means of detecting OP exposure many weeks after the event. New techniques using mass spectrometry are being developed to identify phosphorylated proteins, such as albumin or BuChE, in blood samples.[147,177]

■ CARBAMATES

Carbamates inhibit neuronal and red cell AChE, and BuChE. The relative ease with which spontaneous decarbamylation of cholinesterases takes place may result in the measurement of relatively normal red cell AChE activity despite severe cholinergic symptoms if the assay is not performed within several hours of sampling.[140] This emphasizes the importance of cooling and then freezing the blood sample within minutes of collection (see above). As in the case of OP poisoning, the

wide "normal" range of BuChE activity makes interpretation of BuChE activity difficult at times when the patient's baseline concentrations are unknown. Unlike OPs, carbamates generally do not produce persistently depressed red cell AChE and BuChE activities.

■ ATROPINE CHALLENGE

An atropine challenge may be helpful in diagnosing cholinergic poisoning in a patient who presents with findings suggestive of this disorder, but in whom no history is available to suggest excessive exposure to an OP or carbamate. In an individual not exposed to significant amounts of insecticide a test dose of 1 mg of atropine in adolescents or adults, or 0.05 mg/kg in children up to an adult dose with a minimum of 0.1 mg, should produce classic antimuscarinic findings, in particular a tachycardia as well as mydriasis and dry mucous membranes. Conversely, the persistence of cholinergic signs and symptoms after an atropine challenge strongly suggests the presence of anticholinesterase poisoning.[138] However, some patients suffering from mild anticholinesterase poisoning may respond to this dose of atropine. Therefore, the reversal of cholinergic findings does not completely exclude cholinergic poisoning by one of these compounds.

■ ELECTROMYOGRAM STUDIES

Although measuring cholinesterase activity is the test most often used to estimate tissue and neuronal AChE activity, studies support the use of repetitive nerve stimulation testing as an accurate method of quantifying AChE inhibition at the NMJ.[10,19,100] Spontaneous repetitive potentials or fasciculations following single-nerve stimulation resulting from persistent acetylcholine at nerve terminals can be a sensitive indicator of AChE inhibition at the motor end plate, and may be useful in the early diagnosis of anticholinesterase poisoning.[19] This type of evaluation may also be of benefit in early detection of rebound cholinergic crisis caused by continued absorption or redistribution from adipose tissue or the onset of an intermediate syndrome.[10,19,100]

■ DIFFERENTIAL DIAGNOSIS

The differential diagnosis for cholinergic poisoning includes three main categories (Table 113–5). The first comprises insecticides and other noninsecticidal cholinesterase inhibitors including the medicinal anticholinesterases neostigmine, pyridostigmine, physostigmine, and echothiophate iodide. The patients who most commonly suffer cholinergic poisoning syndrome from medicinal cholinesterase inhibitors are those with myasthenia gravis who are given excessive doses of pyridostigmine. This entire group of xenobiotics should produce low BuChE and low red cell AChE activity.

TABLE 113–5. Categories of Cholinergic Poisoning

Cholinesterase Inhibitors	Cholinomimetics	Nicotine Alkaloids
Organic phosphorus insecticides	Pilocarpine Carbachol	Coniine Lobeline
Organic phosphorus ophthalmic medications	Aceclidine Methacholine	Nicotine
Carbamate insecticides	Bethanechol	
Carbamate medications	Muscarine-containing mushrooms	

The second category of compounds that produce a syndrome of cholinergic poisoning include those with cholinomimetic activity. These compounds directly stimulate muscarinic or nicotinic cholinergic receptors, but do not inhibit AChE. In individuals exposed to these compounds, BuChE and red cell AChE activity should be normal. Cholinomimetic medications include preparations of carbachol, methacholine, pilocarpine, and bethanechol. Nonpharmaceuticals such as muscarine-containing mushrooms can be cholinomimetic (Chap. 117). Finally, a third group of xenobiotics, the nicotine alkaloids (eg, nicotine, lobeline, and coniine) cause CNS, autonomic, and skeletal muscle symptoms similar to those occurring in OP and carbamate toxicity (Chap. 84).

MANAGEMENT

■ ORGANIC PHOSPHORUS INSECTICIDES

The primary cause of death after anticholinesterase poisoning is respiratory failure with subsequent hypoxemia. This results from muscarinic effects on the cardiovascular and pulmonary systems (bronchospasm, bronchorrhea, aspiration, bradydysrhythmias, or hypotension), nicotinic effects on skeletal muscles (weakness and paralysis), loss of central respiratory drive, and rarely seizures. Therefore, initial treatment for a patient exposed to OPs is directed at ensuring an adequate airway and ventilation, and at stabilizing cardiorespiratory function by reversing excessive muscarinic effects.[55,56] Seizures not secondary to hypoxemia are treated with standard anticonvulsants such as benzodiazepines.

Maintenance of the patient's airway is best assured by early endotracheal intubation and positive pressure ventilation in patients who are comatose, have significant weakness, or who are unable to handle copious secretions that may accompany the poisoning. Only a neuromuscular blocker that is not primarily metabolized by cholinesterases should be used to induce pharmacologic paralysis. The duration of action of the depolarizing agent succinylcholine and the nondepolarizing agent mivacurium, for example, will be extended in the presence of low BuChE activity, resulting in paralysis that can be prolonged for several hours.[148,165,166]

Antimuscarinic Therapy Simultaneously, with airway stabilization excessive muscarinic activity should be controlled since this will aid respiration and oxygenation. Atropine competitively antagonizes ACh at muscarinic receptors to reverse excessive secretions, miosis, bronchospasm, vomiting, diarrhea, diaphoresis, and urinary incontinence.[71,90,138] For adolescents and adults, intravenous doses should begin with boluses of 1 to 3 mg depending on the severity of symptoms; doses for children should start at 0.05 mg/kg up to adult doses with a minimum of 0.1 mg dose. Although many authors state that repeat doses of 1 to 5 mg should be given every 2 to 20 minutes until "atropinization" occurs, the most rapid method of obtaining control in severe cases is to give doubling doses every 5 minutes if the response to the previous dose has been inadequate.[54,56]

"Atropinization" is classically said to occur when patients exhibit dry skin and mucous membranes, decreased or absent bowel sounds, tachycardia, reduced secretions, no bronchospasm (in absence of other causes such as aspiration), and usually mydriasis.[54] However, patients die from cardiorespiratory compromise, not wet skin or miosis. Therefore, cardiorespiratory parameters, not pupil size or the presence of sweating, should guide administration of atropine. Atropine dosing should aim to reverse bronchorrhea and bronchospasm, and to provide adequate blood pressure and heart rate for tissue oxygenation (for example, systolic BP greater than 90 mm Hg and heart rate greater than 80 bpm). All can be easily and rapidly assessed.

Once atropinization occurs, it can be maintained by a constant infusion of atropine, typically initially giving 10% to 20% of the total loading

dose per hour (usually maximum 2 mg/h). Regular assessment for signs of under- or overatropinization should guide the use of a further bolus or halting the infusion, followed by changes in the infusion rate.[56] Children have been managed with continuous infusions of atropine starting at 0.025 mg/kg/h.[23] Continuous infusions will be needed for patients severely poisoned by very fat-soluble OPs that continue to redistribute from the fat and freshly inhibit AChE. Such infusions have been used for as long as 32 days.[74]

Absent bowel sounds, marked tachycardia (greater than 120 bpm in a well-hydrated patient not withdrawing from alcohol), mydriasis, and urinary retention may indicate overatropinization or atropine toxicity. This is unnecessary and possibly dangerous because of associated hyperthermia, confusion, and agitation.[56] Tachycardia is not, however, an absolute contraindication to atropine therapy since it can result from hypovolemia, aspiration pneumonitis, or agitation. Isolated pulmonary manifestations may respond to administration of nebulized atropine or ipratropium, and this treatment can accompany parenteral administration of these medications. However, the risk/benefit of this pulmonary-specific treatment has not yet been assessed.

Large doses of atropine may be needed to reverse the bronchospasm, bronchorrhea, and bradycardia associated with severe OP toxicity.[138] Some patients with mild symptoms need only 1 or 2 mg of atropine to reverse cholinergic toxicity, but a moderately poisoned adolescent or adult commonly requires total doses as large as 40 mg.[52,54] Severe poisonings may necessitate even higher doses. Some adults have received over 1000 mg of atropine in 24 hours (with adequate pralidoxime dosing) without demonstrating antimuscarinic effects,[52,196] and total doses as high as 11,000 mg during the course of treatment have been reported.[96] However, the additional benefit of such extreme doses over more modest doses is unclear. One study reported that much smaller doses of around 1 mg/h were associated with adequate control of muscarinic features after initial atropinization.[186]

Atropine does not reverse nicotinic effects. Therefore, patients who improve after receiving atropine must still be closely monitored in an intensive care setting for impending respiratory failure from delayed NMJ dysfunction. Patients should be regularly clinically examined for proximal muscle weakness (in particular neck flexor weakness); once noted, tidal volume measurements should be made at least every 6 hours to detect impending respiratory failure and allow early initiation of ventilatory support.

When antimuscarinic CNS toxicity becomes evident, yet peripheral cholinergic findings such as bradycardia, bronchorrhea, or vomiting necessitate the administration of more atropine, glycopyrrolate can be substituted for atropine because its quaternary ammonium structure limits CNS penetration.[154] One randomized clinical trial compared atropine with glycopyrrolate in intensive care unit (ICU) management of OP poisoning but was too small to detect any difference between regimens.[12] The initial intravenous dose of glycopyrrolate for adults and adolescents is 1 to 2 mg, repeated as needed, or in children 0.025 mg/kg up to adult doses. As with atropine, much higher doses of glycopyrrolate may be required to stabilize patients with severe poisonings. Although scopolamine (hyoscine) has been used in place of atropine,[114,154] it may cause more pronounced CNS effects. If standard atropine supplies are exhausted during therapy, atropine ophthalmic preparations and other antimuscarinic agents such as diphenhydramine may be used.

However, in a large case series of Sri Lankan patients treated by necessity outside of an ICU, patients were safely atropinized without CNS toxicity by slowing atropine infusions whenever absent bowel sounds, confusion, or hyperthermia were detected.[56,58] It is therefore unclear whether glycopyrrolate or scopolamine is required for OP poisoning as long as the atropine regimen is adjusted and there is an adequate quantity for each patient.

■ OXIMES

Although phosphorylated AChE undergoes hydrolytic regeneration at a very slow rate, this process can be enhanced by using an oxime such as pralidoxime chloride (2-PAM) or obidoxime (Fig. 113–6).[67] Regeneration of AChE lowers ACh concentrations, improving both muscarinic and nicotinic effects. An immediate rise in red cell AChE activity, presumably paralleling a rise in neuronal AChE activity, can occur after effective administration of pralidoxime.[58,184]

As discussed above, phosphorylated AChE becomes aged, and therefore unresponsive to oximes at different rates according to the chemistry of the OP.[67] Oximes therefore have to be given early, within a few hours of exposure, after dimethoxy OP poisoning. In contrast, they can still be highly efficacious 48 hours after diethoxy poisoning, with some effects even when given several days after exposure. Oximes can also be efficacious weeks after poisoning with a fat-soluble OP. Therefore, some AChE may still be undergoing new inhibition for days or weeks after exposure in symptomatic patients, and such inhibition may be reversible by pralidoxime.[201] Case reports support this reasoning by noting dramatic effects in reversing paralysis, weakness, and cholinergic symptoms even after late administration of pralidoxime.[129,137]

However, the clinical effectiveness of oximes in significant OP poisoning is debated. The first clinical experience with pralidoxime was reported in the late 1950s when five patients with occupational parathion poisoning were treated.[137] All patients responded well to around 1 g of pralidoxime intravenously. As expected from occupational inhalational exposure, none of the patients were very ill. The use of much higher doses of pralidoxime, of 1 to 2 g infused over 20 to 30 minutes followed by 0.5 g/h, in patients with severe parathion poisoning was subsequently reported.[139] It was also noted that some OPs, including malathion, did not respond well to pralidoxime.[136]

Clinical experience of various intravenous pralidoxime regimens in Asia has led to debate about the efficacy of oximes.[62,104,149,153,178] However, a recent Indian clinical trial showed that very high doses of pralidoxime iodide, a 2-g loading dose followed by 1 g/h, reduced death and length
FIGURE 113–6. Mechanism of reactivation of acetylcholinesterase by pralidoxime. The positively charged aromatic nitrogen of pralidoxime is "attracted" to the anionic site of acetylcholinesterase, allowing the reactive oxime portion of the molecule to position itself over the phosphorylated active site of the enzyme. Pralidoxime then becomes phosphorylated, reactivating acetylcholinesterase.

of ventilation in moderately poisoned patients who presented early and were treated in an ICU.[146] However, we have found that similar doses of pralidoxime chloride did not reactivate AChE in severe poisoning with dimethoate and other dimethoxy insecticides.[58] Furthermore, analysis of a Sri Lankan cohort including 235 symptomatic OP insecticide poisoned patients was unable to find benefit from traditional doses of pralidoxime.[57] The exact role of oximes is currently unclear; however, the best quality evidence at present suggests that oximes should be given as soon as possible after exposure to increase the chance of benefit. The dosing regimens and length of pralidoxime therapy remain controversial for various OPs and clinical presentations.

Side effects of oximes are usually minimal at normal doses.[67,81,125] Rapid infusion causes emesis, hypertension (particularly diastolic), and possibly mild cholinergic effects because of transient blockade of AChE, and is said to cause neuromuscular blockade.[181] Occasional visual complaints are also reported in patients receiving pralidoxime. However, the recent Sri Lankan randomized, controlled trial suggests that sustained use of oximes at high concentrations may increase the risk of significant adverse effects.[57]

Some effects of oximes are not well understood. Their quaternary ammonium compound structures are thought to reduce their passage across the blood–brain barrier and prevent CNS effects.[181] However, obidoxime has been detected in CSF[67] and at least one case report describes pralidoxime-induced improvements in mental status and electroencephalograms not attributable to improved ventilation or perfusion.[119]

DIAZEPAM

Animal studies demonstrate that administering diazepam along with oximes in the treatment of poisoning with OP nerve agents or the insecticide dichlorvos can increase survival and decrease the incidence of seizures and neuropathy.[51,135] Diazepam can also decrease cerebral morphologic damage resulting from OP-related seizures.[20,124] One study suggests that diazepam may help attenuate OP-induced respiratory depression,[51] postulating that the benzodiazepines attenuate the overstimulation of central respiratory centers caused by OPs. However, seizures have been uncommon in large case series of patients poisoned by OPs,[58,194] and no clinical studies have yet been performed to determine whether benzodiazepines offer benefit to humans.[122] In the absence of this evidence, diazepam should be used to treat OP-related seizures and agitation and aid intubation, but not be given routinely to all cases (see Antidotes in Depth A24: Benzodiazepines).[122]

DECONTAMINATION

Cutaneous absorption of OPs and carbamates necessitates removal of all clothing as soon as possible. Medical personnel should avoid self-contamination by wearing neoprene or nitrile gloves. Double gloving with standard vinyl gloves may be protective. Skin should be triple washed with water, soap, and water, and rinsed again with water. Although alcohol-based soaps are sometimes recommended to dissolve hydrocarbons,[69] these products can be difficult to find, and expeditious skin cleansing should be the primary goal. Cutaneous absorption can also result from contact with OP and carbamate compounds in vomitus and diarrhea if the initial exposure was by ingestion. Oily insecticides may be difficult to remove from thick or long hair, even with repeated shampooing, and shaving scalp hair may be necessary. Exposed leather clothing or products should be discarded because decontamination is very difficult once impregnation has occurred.

Military institutions are now experimenting with cholinesterase sponges for cutaneous organic phosphorus decontamination.[77] The sponge consists of a cholinesterase enzyme covalently linked and immobilized in a polyurethane matrix. The sponge reportedly is effective in removing OPs from skin and surfaces.[77]

In substantial acute ingestions, if emesis has not occurred and the patient presents within several hours after ingestion, evacuation of stomach contents by lavage using a nasogastric tube can be done. Because the onset of coma, seizures, and paralysis can be rapid, airway protection is necessary to perform the procedure safely. Although there are data suggesting that activated charcoal (AC) may adsorb some OPs, a study of 1310 patients with OP or carbamate poisoning found no benefit from the use of multiple-dose activated charcoal.[60] Thus, the current recommendation is that patients with anticholinesterase poisoning receive only a single dose of 1 g/kg AC if the patient's airway is stable.

Healthcare providers must always maintain caution when coming into contact with stomach contents or other body fluids when managing these cases.[117] Bystanders have been poisoned by providing mouth-to-mouth resuscitation to a victim of an intentional ingestion of diazinon.[110] There have also been reports of nosocomial poisoning in emergency department (ED) staff.[29,73,117,171] A consensus statement on nosocomial poisoning has been developed.[117]

DISPOSITION

After atropinization, patients with cholinesterase-inhibitor poisoning should be continuously observed for evidence of (1) deteriorating neurologic function and potential paralysis, and (2) need for increases or reductions in atropine dosing.

Red cell AChE and BuChE activities can be measured intermittently after the institution of pralidoxime therapy.[65,67,183,201] Effective oxime therapy will normalize AChE activity but usually does not affect BuChE activity. In the absence of effective oxime therapy, red cell AChE activity may be markedly depressed long after neuronal AChE activity has returned to normal. Therefore, an individual who remains asymptomatic may be discharged home with subnormal cholinesterase activity. BuChE begins to rise when no more OP is left in the body.[55] A sudden fall in BuChE activity suggests that OP is being redistributed from fat stores. The relevance of a fall in BuChE activity that is not clinically apparent is uncertain. Overall, there is little evidence at present that repeated testing of AChE or BuChE activity improves management and outcome over clinical monitoring alone. Such testing is, however, important for research assessing new interventions.

When available, EMG studies to detect signs of motor end plate dysfunction and early AChE inhibition may be a more sensitive method for identifying recurrent cholinergic toxicity.[19] Again, the clinical usefulness of this approach has not yet been studied.

A patient who becomes asymptomatic, not requiring pralidoxime or atropine for 1 to 2 days, may be discharged. Although recurrent cholinergic crises and/or respiratory failure can occur after several days, such patients have usually previously shown clinical signs of some form. Patients should not be allowed to go home wearing clothing that was worn when the poisoning occurred. The clothing should be disposed of as medical waste and destroyed.

CARBAMATES

The treatment of patients with carbamate poisoning is identical to that of OP poisoning with two exceptions. First, the use of oximes in carbamate exposure is controversial and many providers will not administer them. Historical animal data had implied that pralidoxime might increase AChE inactivation in carbaryl poisoning.[113,116] Recent reports suggest aldicarb poisoning may also benefit from oxime therapy[152] and that the dose of pralidoxime may be important in carbaryl poisoning.[128] Comparative human data investigating the

use of pralidoxime in carbamate poisonings are currently lacking. Fortunately, because of the rapid hydrolysis of the carbamate–AChE complex, symptoms, including weakness and paralysis, usually resolve within 24 to 48 hours without pralidoxime therapy. However, administering pralidoxime to a poisoned patient in a cholinergic crisis is appropriate when it is not known whether the patient is suffering from OP or carbamate insecticide poisoning. If the poisoning is from a carbamate insecticide, pralidoxime therapy may not be necessary, but if used will likely not prove detrimental.

Second, significant inhibition of red cell AChE and BuChE by carbamates generally does not last for more than 1 to 2 days, assuming absorption is complete. Patients exposed to carbamates usually have normal cholinesterase values by the time of discharge. There are no reported cases of recurrent or delayed poisonings following carbamate insecticide poisoning. Therefore, repeating cholinesterase activities after patients are asymptomatic is usually unnecessary. However, of note, complications of poisoning with carbamates—such as aspiration and hypoxic brain injury—can last many days.

SUMMARY

Organic phosphorus and carbamate insecticides kill hundreds of thousands of people each year. However, poisoning with these insecticides is not uniform; they differ markedly in their human toxicity, pharmacokinetics, clinical syndrome, and response to therapy. Symptoms result from inhibition of AChE and overstimulation of muscarinic and nicotinic receptors in synapses of the autonomic and central nervous systems and at the NMJ. Patients with substantial poisoning present with the cholinergic crisis and respiratory failure due to bronchospasm, bronchorrhea, loss of central respiratory drive, and dysfunction of NMJ. Resuscitation requires preservation of the airway, oxygen provision and ventilatory support as necessary, together with rapid administration of intravenous fluids and, for severe poisoning, doubling doses of atropine. Once stabilized, atropine should be administered as an infusion to sustain cardiorespiratory function. The clinical effectiveness of oximes for OP poisoning is still debated, but current evidence suggests that they are most effective if given soon after exposure and are more effective for poisoning with diethoxy compounds. Patients may develop NMJ dysfunction that progresses to respiratory failure; such patients often require ventilatory support for weeks. This respiratory failure can develop after several days and after the cholinergic features have settled; conscious patients in the days after exposure especially neck flexors have to be closely monitored for onset of proximal muscle weakness and reductions in tidal volume. Cholinergic features can recur many days after ingestion of very fat-soluble compounds such as fenthion because of redistribution from fat stores. Poisoning after ingestion of extremely toxic OPs such as parathion can develop within minutes, so that severely ill patients die before reaching medical care. Others become unconscious rapidly and aspirate the insecticide and stomach contents, so that a common cause of death is aspiration pneumonia. Regulation to withdraw the most toxic OPs and carbamates from agricultural practice may be the only way to rapidly reduce the number of deaths globally.

PRALIDOXIME

Mary Ann Howland

Pralidoxime

Obidoxime

Asoxime (HI6)
Pralidoxime chloride (2-PAM) is the only cholinesterase-reactivating xenobiotic currently available in the United States.[55] It is used concomitantly with atropine in the management of patients poisoned by organic phosphorus (OP) compounds. Administration should be initiated as soon as possible after exposure, but could be effective even days after an exposure and therefore should be administered to all symptomatic patients independent of delay. Continuous infusion is preferable to intermittent administration for patients with serious toxicity, and a prolonged therapeutic course may be required.

CHEMISTRY

Pralidoxime chloride is a quaternary pyridinium oxime with a molecular weight of 173 daltons. The chloride salt exhibits excellent water solubility and physiologic compatibility. Another salt, pralidoxime iodide, with a molecular weight of 264 daltons, is less water soluble and can potentiallly induce iodism.[3]

REACTIVATION OF CHOLINESTERASES FOLLOWING ORGANIC PHOSPHORUS POISONING

Organic phosphorus compounds are powerful inhibitors of carboxylic esterase enzymes, including acetylcholinesterase (AChE; true cholinesterase, found in red blood cells, nervous tissue, and skeletal muscle) and plasma cholinesterase or butyrylcholinesterase (found in plasma, liver, heart, pancreas, and brain).[49] The OP binds firmly to the serine-containing esteratic site on the enzyme, inactivating it by phosphorylation (Fig. 113–3).[32,50,73] This reaction results in the accumulation of acetylcholine at muscarinic and nicotinic synapses in the peripheral and central nervous systems, leading to the clinical manifestations of OP poisoning. After phosphorylation, the enzyme is inactivated and can undergo one of three processes: endogenous hydrolysis of the phosphorylated enzyme; reactivation by a strong nucleophile, such as pralidoxime; and aging, which involves biochemical changes that stabilize the inactivated phosphorylated molecule.

Endogenous hydrolysis of the bond between the enzyme and the OP is generally extremely slow and is considered insignificant. This is in contrast to the rapid hydrolysis of the related bond between the enzyme and many carbamates. Studies in the 1950s demonstrated the ability of oximes to reactivate cholinesterase bound to OP compounds.[81,83,84] The positively charged quaternary nitrogen of pralidoxime is attracted to the negatively charged anionic site on the phosphorylated enzyme, bringing it in close proximity to the phosphorous moiety (Fig. 113–6). Pralidoxime then exerts a nucleophilic attack on the phosphate moiety, successfully releasing it from the AChE enzyme.[80] This action liberates the enzyme to a variable extent depending on the OP in question and restores enzymatic function.[40] It was previously believed that OP compounds with small substituted side chains were more easily reversed by oximes because of better steric positioning, allowing easier access for the oximes.[83] However, available data now refute that theory, but continue to emphasize the importance of spatial and steric considerations.[86]

In contrast to the usefulness of pralidoxime in the management of the cholinergic syndrome, current understanding of the pathophysiology of the intermediate syndrome is inadequate to determine whether pralidoxime can prevent the development of the syndrome.[71] However, if cholinergic receptor desensitization is responsible for the cause of the muscle weakness, then pralidoxime would be unlikely to prevent the syndrome, especially after large intentional ingestions.[12] Additionally, certain OP pesticides may lead to the development of delayed onset neurotoxicity, which involves inhibition of neurotoxic esterases that cannot be prevented or treated by pralidoxime.[18,43]

EFFICACY RELATED TO TIME OF ADMINISTRATION AFTER POISONING

Early in vitro evidence suggested that the successful use of cholinesterase reactivators depended on administration within 24 to 48 hours of exposure to the OPs; afterwards, the acetylcholinesterases would be irreversibly inactivated.[4,14,28,29,64] However, according to currently available information there is no absolute time limitation on reactivator

function. The 48-hour limit was derived from in vitro experiments using a small number of tightly bound compounds and reactivators and data from plasma cholinesterase enzyme activity, which is now recognized to be relatively resistant to oxime-nucleophilic attack. These early data were accepted without consideration of their relevance to human systems, the use of newer and less tightly bound OP compounds, temperature and pH variation, blood flow, fat solubility, active metabolites, and species specificity. Fat-soluble OP compounds redistribute from fat stores over time, acting similarly to sustained-release products. Even if they have not aged, they continue to reinhibit AChE for days.

An in vitro experiment assessed the effect of aging on the ability of pralidoxime to regenerate rat erythrocyte and brain cholinesterases using three different OP compounds.[77] The rate of reactivation of erythrocyte and brain cholinesterases was significantly decreased over time for fenitrothion and methyl parathion, with no reactivation occurring at 48 hours. This is partly because dimethylated (dimethyl, dimethoxy) OP pesticides age more quickly than diethylphosphorylated agents.[18] In contrast, a very high reactivation rate for ethyl parathion was still apparent at 48 hours. Thus the structure of the OP compound is important in the rates of aging and reactivation with pralidoxime. Fenitrothion and methyl parathion are both O'O dimethyl OP compounds as is dimethoate, whereas ethyl parathion is an O'O diethyl OP compound.[77] Other studies also suggest that pralidoxime is effective long after the previously suggested 48-hour window of therapy.[2,5,8,13,16,18,19,47,79]

CARBAMATES

Acetylcholinesterases inactivated by most carbamates spontaneously reactivate with half-lives of 1 to 2 hours, and typical clinical recovery occurs in several hours. However, in severe cases, cholinergic findings may persist for 24 hours.[10,25] Pralidoxime is rarely indicated for carbamate poisoning, but it is not generally contraindicated as was previously suggested. This erroneous conclusion was based solely on data regarding a single carbamate, carbaryl, and inappropriately applied to all carbamates. Pralidoxime decreased the rate of carbamylation of 16 insecticidal carbamates, though it modestly increased the rates for three, one of which was carbaryl.[15] In vitro experiments demonstrated that pralidoxime had no effect on the reactivation of erythrocyte AChE carbamylated by aldicarb, methomyl, and carbaryl.[37] Furthermore, animal studies demonstrated the beneficial effects of pralidoxime in decreasing the lethality of several carbamate insecticides,[51,70] though it worsened the toxicity of carbaryl. It was suggested that this is possibly because the carbamate-oxime complex may actually be a more potent cholinesterase inhibitor than carbaryl alone.[25,51,70] However, even in the presence of carbaryl, the combination of atropine plus an oxime, a more clinically relevant situation, resulted in survival data comparable to that of atropine alone.[25] Previous animal data may also be confounded by using inappropriately high doses and potential overdoses of pralidoxime.[45] This evidence suggests that although pralidoxime is not usually a necessary adjunct to atropine for a patient with a pure carbamate overdose, it may nevertheless occasionally improve morbidity and mortality.[10] Thus pralidoxime should never be withheld in a seriously poisoned patient out of concern that a cholinergic xenobiotic may be a carbamate.[37] However, pralidoxime should be used in conjunction with atropine and never as the sole therapeutic agent.

PHARMACOLOGY

Pralidoxime is important at nicotinic sites where atropine is ineffective, most often improving muscle strength within 10 to 40 minutes after administration.[50,73] This effect is vital to maintaining the muscles of

respiration. Pralidoxime is also synergistic with atropine, it liberates cholinesterase enzyme so that additional acetylcholine can be metabolized while atropine inhibits the effects of acetylcholine at cholinergic receptors. This suggests that pralidoxime should rarely, if ever, be used alone.[22,50] Some OP compounds respond much better to pralidoxime than others, depending on the affinity of pralidoxime for the particular type of phosphorylated enzyme, its reactivating ability, concentrations of both the oxime and the OP, aging, and OP redistribution from a depot site such as fat.[21,84]

The central nervous system (CNS) benefits of pralidoxime are controversial, as the molecule is a quaternary nitrogen compound and not expected to cross the blood–brain barrier.[42,50] Animal studies suggest conflicting results.[46] Rat studies using radiolabeled pralidoxime demonstrated a lack of any radioactivity in the CNS after intravenous (IV) administration.[76] Following exposure to IV fenitrothion, IV administration of pralidoxime in rats failed to improve survival or to reactivate brain cholinesterase, whereas intramedullary pralidoxime partially restored brain cholinesterase and eliminated fatalities.[76] A more recent rat experiment using a microdialysis technique demonstrated only 10% CNS penetration of pralidoxime.[63]

Clinical observations, however, have certainly suggested a CNS action of pralidoxime with a prompt return of consciousness reported in some cases.[49,50,58,80] A 3-year-old child who was comatose from parathion was given 500 mg of 2-PAM IV over 15 minutes with continuous electroencephalographic (EEG) monitoring. Within 2 minutes there was a dramatic response on the EEG, followed rapidly by normalization of consciousness.[31]

Early work with feline models led to a proposal that a serum concentration of greater than or equal to 4 µg/mL was a desired therapeutic concentration for pralidoxime.[72] However, more recent in vitro work with human erythrocytes and a mouse hemidiaphragm model suggests that higher serum concentrations are actually needed.[84] Twenty percent reactivation was achieved in 5 minutes with serum concentrations of 10 µg/mL.[84] A simulation and analysis suggests that plasma concentrations between 10 and 15 µg/mL (50–100 µmol/L) are necessary for optimal treatment of severely poisoned patients.[19,86] These recommendations await validation in poisoned patients. Serum concentrations are not available in a timely manner but may help in the design of future pralidoxime dosing protocols.

Organic phosphorous compounds inhibit butyrylcholinesterase (plasma cholinesterase) and AChE to different extents.[17] If performed correctly, butyrylcholinesterase may act as a surrogate marker for OP or carbamate elimination from the body.[34] Likewise, the reactivation of butyrylcholinesterase by pralidoxime is dependent on the concentration of pralidoxime and often has a flat dose response. For example, in an in vitro model of human blood taken from healthy volunteers and treated with paraoxon, pralidoxime was able to reactivate 1.3% and 18.1% of AChE at pralidoxime concentrations of 10 µM and 100 µM, respectively, compared with 1% and 5.5% of butyrylcholinesterase with 10 and 100 µM concentrations of pralidoxime.[31] Unless the effect of the specific OP on butyrylcholinesterase is known, there is no role for following serial butyrylcholinesterase concentrations.

PHARMACOKINETICS AND PHARMACODYNAMICS

Pralidoxime chloride pharmacokinetics are characterized by a two-compartment model. Pharmacokinetics values vary depending on whether calculations are determined in healthy volunteers or poisoned patients. The volume of distribution is larger in poisoned patients and most likely accounts for the prolonged elimination phase.[19]

In volunteers, the volume of distribution is about 0.8 L/kg and the half-life is 75 minutes.[30,56,69] Pralidoxime is renally excreted, and within 12 hours, 80% of the dose is recovered unchanged in the urine.[68]

A dose of 10 mg/kg of pralidoxime administered intramuscularly (IM) to volunteers results in peak serum concentrations of 6 µg/mL (reached 5–15 minutes after IM injection) and a half-life of approximately 75 minutes.[68] Following a standard IV 30-minute infusion dose of 1 g of pralidoxime in a 70-kg man, the serum concentration fell to less than 4 µg/mL (no longer thought to be a goal serum concentration) at 1.5 hours. In a simulated model, a continuous infusion of 500 mg/h of pralidoxime led to a concentration greater than 4 µg/mL after 15 minutes, which could be maintained throughout the infusion.[74] In a human volunteer study, an IV loading dose of 4 mg/kg over 15 minutes followed by 3.2 mg/kg/h for a total of 4 hours maintained serum pralidoxime concentrations greater than 4 µg/mL for 4 hours. The same total dose, 16 mg/kg, administered over 30 minutes only maintained those concentrations for 2 hours.[44] In poisoned patients receiving continuous infusions of pralidoxime as opposed to intermittent infusions, both the volume of distribution and the half-life are increased.[75] A volume of distribution of 2.77 L/kg, an elimination half-life of 3.44 hours, and a clearance of 0.57 L/kg/h were reported in poisoned adults given a mean loading dose of 4.4 mg/kg followed by an infusion of 2.14 mg/kg/h.[80] In poisoned children and adolescents, the volume of distribution varied with severity of poisoning from 8.8 L/kg in the severely poisoned patients to 2.8 L/kg in moderately poisoned patients.[65] After a mean loading dose of 29 mg/kg followed by a continuous infusion of about 14 mg/kg/h, a steady-state serum concentration of 22 µg/mL, a half-life of 3.6 hours, and a clearance of 0.88 L/kg/h were calculated.[65]

Oral administration of salts of pralidoxime (not used clinically because of OP poisoning–induced vomiting) demonstrated a peak concentration at 2 to 3 hours, a half-life of 1.7 hours, and an average urine recovery of 27% of unchanged pralidoxime in humans, and clinical efficacy in a mice model.[9,35] Autoinjector administration of 600 mg of pralidoxime chloride in an adult man (9 mg/kg) produced a concentration above 4 µg/mL at 7 to 16 minutes, a maximum serum concentration of 6.5 µg/mL at about 28 minutes, and a half-life of 2 hours.[56,67] Using traditional needle and syringe IM administration requires a longer time to achieve comparable serum concentrations. The autoinjectors more widely disperse the medication in the tissues resulting in faster absorption.[60,69]

OTHER REVERSAL AGENTS

The dihydropyridine derivative of pralidoxime, known as pro-2-PAM,[6] acts as a "prodrug" that allows passage through membranes such as the blood–brain barrier. Once across the membranes, spontaneous in vivo oxidation converts pro-2-PAM to the active form, demonstrating a 13-fold higher concentration of 2-PAM in the brain than when 2-PAM itself is administered under similar conditions. Further experiments support the significantly increased CNS effects of pro-2-PAM.[62] The toxicity of this compound has decreased enthusiasm for further investigation. The use of sugar oximes (the molecular combination of glucose with 2-PAM derivatives) to promote CNS penetration also appears promising.[38,59]

Obidoxime (Toxogonin) is an oxime used outside the United States that contains two active sites per molecule and is considered by some to be more effective than pralidoxime.[21,22,84] An in vitro study using human erythrocyte AChE supported the superiority of obidoxime to pralidoxime in reactivating AChE inhibited by the dimethyl phosphoryl (malaoxon, mevinphos) and diethyl phosphoryl OP compounds (paraoxon). On a molar basis, obidoxime is approximately 10 to 20 times

more effective in reactivating AChE than pralidoxime.[84] A potential disadvantage is the concern that the phosphoryloxime generated from the reactivation of AChE by obidoxime could reinhibit AChE if not metabolized by a plasma enzyme similar or identical to human paraoxonase 1 (PON1). PON1 exhibits polymorphism[19] and one in 20 patients may not be able to metabolize this phosphorylobidoxime compound. Phosphorylpralidoxime is unstable and does not accumulate. The H series of oximes (named after Hagedorn; HI-6, HIo-7) were developed to act against the chemical warfare nerve agents.[7] These oximes have superior effectiveness against sarin, VX, and certain types of newer pesticides (eg, methyl-fluorophosphonylcholines).[3,11,33,36,39,61,84,85] Unfortunately, they are less efficacious for traditional OP insecticide poisoning, and their toxicity profile is inadequately defined.[11,33,36,39,61,84,85] In addition to reactivating AChEs, the Hagedorn oximes demonstrate direct central and peripheral anticholinergic effects at supratherapeutic concentrations.[61]

HUMAN TRIALS

There are four randomized clinical trials examining the efficacy of pralidoxime for the management of OP poisoning. Two of these trials were done in the 1990s in India using doses of pralidoxime now considered to be inadequate.[18] Neither study demonstrated a benefit for pralidoxime and, in fact, suggested an increase in mortality in patients receiving the higher but still inadequate dose of pralidoxime. Other criticisms include a delay in administration and too short a duration of treatment. The third clinical trial included 200 patients in India who were moderately to severely poisoned with an OP pesticide.[52] All patients received a 2-g loading dose of pralidoxime iodide over 30 minutes before being randomized to receive 1 g over 1 hour every 4 hours for 48 hours or a continuous infusion of 1 g/h for 48 hours. Beyond 48 hours all patients received 1 g every 4 hours until no longer ventilator dependent. In the continuous pralidoxime infusion arm the authors demonstrated reduced atropine requirements, a smaller number of patients requiring intubation, fewer intubated days, and a reduction in mortality from 8% to 1%. It should be noted that the iodide salt of pralidoxime was used and would equate to about 650 mg/h of the chloride salt.[20] Even though the majority of the patients by history ingested dimethoate, a dimethoxy compound with high lethality and rapid aging, the time to admission and administration of pralidoxime was very short with a median time of 2 hours. Criticisms of the study include a lack of blinding, no measurement of AChE or pesticide concentrations, and no objective monitoring of neuromuscular function.[20] In contrast, the most recent trial performed in Sri Lanka was unable to demonstrate a beneficial effect of pralidoxime in 121 patients compared to 114 patients treated with placebo.[18a] There was no difference in mortality between groups although pralidoxime effectively reactivated red cell AChE inhibited by diethyl OP insecticides. It also reactivated red cell AChE inhibited by dimethyl OP insecticides, but less so, as expected. In comparison to the third study[52] these patients arrived later (4.4 vs 2h), and the extent of supportive care was inferior. The exact reasons for these disparate results are unclear.

DURATION OF TREATMENT

The signs and symptoms of OP poisoning usually manifest within minutes but may be delayed up to 24 hours.[50] Delayed manifestations occur with the fat-soluble compounds, such as fenthion or chlorfenthion. The route of exposure may also influence the onset of systemic symptoms; for example, there may be a delay following dermal contact, which does not occur following ingestion or inhalation. When symptoms are either delayed or prolonged, or when treatment is delayed, extended therapy with pralidoxime may be indicated.[1,8,47] In one case of

poisoning with the fat-soluble compound fenthion, 5 days elapsed before cholinergic symptoms appeared, and some symptoms then persisted for 30 days.[47] Pralidoxime and atropine were administered continuously in varying doses for the time that the patient was symptomatic. Ordinarily the recommendation is to continue the pralidoxime until atropine has not been needed for 12 to 24 hours.[17] Other proposals for estimating the duration of pralidoxime therapy include (1) measuring the serum or urinary concentration of the OP compound; (2) measuring serial determinations of plasma cholinesterase (increasing concentrations suggests the elimination of the OP compound); (3) incubating the patient's serum with an exogenous source of AChE or butyrylcholinesterase to look for inhibition; (4) incubating the patient's inhibited red blood cell cholinesterase with a high concentration of oxime in vitro, checking for reactivation.[19] In all cases, patients should be observed for recrudescent toxicity after termination of pralidoxime. If symptoms return, therapy should be continued for at least 24 hours.

ADVERSE EFFECTS

At therapeutic doses of pralidoxime in humans, adverse effects are minimal.[23,24,48-50,58,74] Transient dizziness, blurred vision, and elevations in diastolic blood pressure may be related to the rate of administration.[30,44] Doses of 45 mg/kg produce blood pressure elevations that may persist for several hours, but may be reversed with IV phentolamine.[67] The most recent randomized clinical trial revealed a higher percentage of patients with tachycardia and hypertension associated with pralidoxime compared to placebo after both the loading dose and the continuous infusion (75% vs 49% and 30% vs 14%). Rapid IV administration has produced sudden cardiac and respiratory arrest due to laryngospasm and muscle rigidity.[53,66,82] Other adverse effects reported following IM administration in normal volunteers include diplopia, dizziness, headache, drowsiness, nausea, tachycardia, increased systolic blood pressure, hyperventilation, decreased renal function, muscular weakness, and pain at the injection site.[56] Elevations in liver enzymes concentrations were observed in volunteers administered autoinjector doses of 1200 to 1800 mg; these enzyme concentrations returned to normal in 2 weeks.[56]

Pralidoxime is pregnancy category C and should be used as clinically indicated to protect the maternal fetal dyad.

DOSING AND ADMINISTRATION

The optimal dosage regimen for pralidoxime is unknown. A maintenance dose in adults of 1 g/h of the iodide salt of pralidoxime was used in the study from India and is approximally equal to 650 mg of pralidoxime chloride.[52] The package insert, last updated in 2004, recommends an adult dose of 1 to 2 g in 100 mL of 0.9% sodium chloride given intravenously over 15 to 30 minutes, with additional doses given every 3 to 8 hours as long as signs of poisoning recur. Difficulties arise because a target plasma concentration in humans has not been established, although in vitro studies suggest a target concentration closer to 17 μg/mL compared with the 4 μg/mL previously suggested.[19,21,31] This is complicated by the possibility that there is a ceiling dose and that some OP compounds are likely to be more easily reactivated than others. In addition, pharmacokinetic studies in volunteers suggest that a continuous infusion maintains a target concentration with less variation compared with intermittent boluses. Based on all of the above, we recommend a loading dose of pralidoxime chloride of 30 mg/kg (up to 2 grams) over 30 minutes followed by a maintenance infusion of 8 to 10 mg/kg/h (up to 650 mg/h).

Although IV administration is preferred, IM administration is acceptable using a 1-g vial of pralidoxime reconstituted with 3 mL of

sterile water or 0.9% sodium chloride for injection to provide a solution containing 300 mg/mL (concentrations above 35% weight/volume produce muscle necrosis in animals).[55,68] This could be used until an IV site is established. Patients with reduced renal function may require dosage adjustment, but there are no specific recommendations on how to accomplish this.[55] In patients with acute lung injury the dose can be given as a 5% solution by a slow IV injection over at least 15 to 30 minutes.[55,68]

Depending on the severity of a nerve agent exposure, one to three injections with a pair of autoinjectors containing atropine and pralidoxime should be administered. The number of autoinjector doses administered to a child depends on the child's age and weight.[26,41] For children aged 3 to 7 (13–25 kg), one autoinjector of atropine and one autoinjector of pralidoxime should be administered, which should result in a projected pralidoxime dose of 24 to 46 mg/kg. For children aged 8 to 14, two autoinjectors of atropine and two autoinjectors of pralidoxime should be administered. These injections should result in a projected pralidoxime dose of 24 to 46 mg/kg. For anyone older than 14 years of age, three autoinjectors of atropine and pralidoxine should be administered. This results in a projected dose of pralidoxime of less than 35 mg/kg. For children younger than 3 years, during an emergency, one autoinjector of atropine and one of pralidoxime may be administered in accordance with a risk-benefit analysis. If time permits and only autoinjector doses are available, its contents may be transferred to a small sterile vial for traditional IM administration with a needle and syringe.[27]

In most cases, pralidoxime is continued for a minimum of 24 hours after symptoms have resolved and atropine is no longer required. Extended dosing may be necessary, depending on the patient's clinical condition and the nature of the OP.[78]

AVAILABILITY

Pralidoxime chloride (Protopam) is supplied in 20-mL vials containing 1 g of powder, ready for reconstitution with sterile water or 0.9% sodium chloride for injection.[54,55,57]

The addition of 20 mL of sterile water for injection to the 1-g vial of 2-PAM results in a 5% solution (50 mg/mL). Following reconstitution, the 2-PAM should be used within several hours. This solution can be further diluted to a volume of 100 mL of normal saline for IV infusion.

As noted above, pralidoxime chloride is also available for IM administration by an autoinjector containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 20 mg benzyl alcohol and 11.26 mg glycine. The 2-PAM autoinjector is also packaged in a kit containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 40 mg benzyl alcohol and 22.5 mg glycine, accompanied by an autoinjector containing 2.1 mg of atropine in 0.7 mL of a sterile solution containing 12.47 mg glycerin and not more than 2.8 mg phenol. This kit is called a "Mark 1 Nerve Agent Antidote Kit (NAAK)" and is designed to be used IM by first responders in case of a nerve agent attack. The needles extend 0.8 inch in length. The Mark 1 NAAK has recently been replaced by the DuoDote Autoinjector System, which uses technology that sequentially administers 2.1 mg in 0.7 mL atropine followed by 600 mg in 2 mL pralidoxime chloride IM through the same syringe. The 23-gauge needle is 0.8 inches in length.

SUMMARY

Pralidoxime is an effective reactivator of AChE in many OP compound poisonings. It primarily reverses neuromuscular manifestations but also has some CNS effects. New oximes may improve CNS penetration and efficacy. Pralidoxime and atropine are synergistic and should be

used together in the management of patients with OP poisonings. If a patient requires multiple doses of atropine for muscarinic symptoms, then the use of 2-PAM is indicated. In symptomatic patients, AChE is partially inactivated and will remain so until new enzyme is synthesized or inactivated enzyme is reactivated. The resolution of all signs or symptoms with atropine alone indicates only that AChE inactivation is less than 50% and that endogenous hydrolysis by nonphosphorylated enzyme is sufficient to eliminate symptoms. This clinical response by no means indicates, however, that the enzyme systems are fully active; patients may still benefit from enzyme regeneration with the safe and effective antidote pralidoxime.

Finally, because newer fat-soluble OP pesticides are currently available, it may be necessary to administer atropine and 2-PAM for more prolonged periods of time than previously indicated based on the clinical manifestations and the predicted kinetics of the highly fat-soluble pesticides.[8]

ANTIDOTES IN DEPTH (A34)

ATROPINE

Mary Ann Howland
Atropine is the prototypical antimuscarinic xenobiotic. It is a competitive antagonist at both central and peripheral muscarinic receptors, used to treat patients with symptoms following exposures to muscarinic agonists such as pilocarpine, and acetylcholinesterase inhibitors and *Clitocybe* mushrooms. The latter group includes pesticides, such as carbamate and organic phosphorous (OP) compounds, OP chemical warfare nerve agents, and some xenobiotics used to treat patients with Alzheimer disease (eg, donepezil, rivastigmine).

HISTORY

Many plants contain the alkaloids atropine and/or scopolamine. One notable example is *Atropa belladonna*, named by Linnaeus after Atropos, the goddess of fate in Greek mythology who could cut short a person's life. Belladonna means beautiful woman in Italian and comes from the practice by Italian women of placing belladonna extract in their eyes to produce aesthetically pleasing dilated pupils.[8] In the early 1800s, atropine was isolated and purified from plants. In the 1860s Fraser experimented with the dose–response relationship between atropine and physostigmine involving various organs such as the heart and the eye.[16] Experiments in the 1940s with cholinesterase inhibitors demonstrated that atropine reversed many of the effects of these xenobiotics and protected against doses two to three times the LD_{50} (median lethal dose in 50% of test subjects) in animals.[43]

CHEMISTRY

Atropine (dl-hyoscyamine), like scopolamine (l-hyoscine), is a tropane alkaloid with a tertiary amine structure that allows central nervous system (CNS) penetration. Tropane alkaloids are bicyclic nitrogen-containing compounds that are naturally found in the plants of the families Solanaceae (eg, deadly nightshade, datura) and Erythroxylaceae (eg, coca) and have a long history of use as poisons and therapeutic agents. Only l-hyoscyamine is active and found in nature. The process of isolation results in racemization and forms dl-hyoscyamine. Quaternary amine antimuscarinic agents such as glycopyrrolate, ipratropium, tiotropium, methylhomatropine bromide, and methylatropine bromide do not cross the blood–brain barrier into the CNS.

PHARMACOLOGY

Cholinergic receptors consist of muscarinic and nicotinic subtypes. Muscarinic receptors are coupled to G proteins and either inhibit adenylyl cyclase (M_2, M_4) or increase phospholipase C (M_1, M_3, M_5). Muscarinic receptors are widely distributed throughout the peripheral and central nervous systems.[19]

The competitive blockade of muscarinic receptors in normal individuals results in dose-dependent clinical effects that vary by organ system based on the degree of endogenous parasympathetic tone.[8,19] In adults, low doses (0.5 mg) of atropine cause a paradoxical bradycardia, and some drying of the mouth and sweat glands. Higher doses of atropine (2 mg) produce noticeable dryness; subjective feeling of warmth; slight flushing; slight tachycardia; reactive, slightly dilated pupils; blurred near vision; mild drowsiness; some postural hypotension; and urinary hesitation. At higher doses of 3 to 5 mg of atropine all the aforementioned symptoms are exaggerated, with escalating degrees of hyperthermia, tachycardia, drowsiness, difficulty voiding, prolonged gastrointestinal (GI) transit time, and decreased GI tone. Doses of greater than or equal to 10 mg of atropine produce incapacitation with hot, dry, flushed skin; dilated pupils; blurred vision; very dry mouth; tachycardia; urinary retention; constipation; increased drowsiness or disorientation; hallucinations; stereotypical movements; bursts of laughter; delirium; and finally, coma, and rarely death.[8,18]

This paradoxical bradycardia produced at low doses of atropine is thought to be a consequence of the inhibition of peripheral M_1 presynaptic postganglionic parasympathetic neurons; stimulation of these receptors by acetylcholine inhibits the further release of acetylcholine, and atropine interferes with this negative feedback.[8,41]

Centrally acting muscarinic antagonists include atropine, scopolamine, and homatropine. Glycopyrrolate, ipratropium, and tiotropium act peripherally. Scopolamine is about 10 times more potent than atropine.[25] Homatropine is at least one-tenth as potent as atropine depending on the measured outcome and route of administration.[24]

Cholinesterase inhibitors prevent the breakdown of acetylcholine by acetylcholinesterase, thereby increasing the amount of acetylcholine available to stimulate cholinergic receptors at both muscarinic and nicotinic subtypes, though the degree of effect varies widely among the class. Muscarinic agonists (eg, muscarine, methacholine, and pilocarpine) typically only stimulate muscarinic receptors. Atropine is a competitive antagonist of acetylcholine only at muscarinic receptors and not nicotinic receptors.[10]

Miosis from the topical instillation of a cholinesterase inhibitor into the eye will not be reversed by the systemic administration of atropine.[18] The systemic administration of 354 mg of atropine made one patient floridly anticholinergic but did not counteract the ophthalmic effects of a previously instilled topical cholinesterase inhibitor.[18]

PHARMACOKINETICS AND PHARMACODYNAMICS

Atropine is absorbed rapidly from most routes of administration including inhalation, oral, and intramuscular (IM).[3] Oral ingestion of 1 mg of atropine produces maximal effects on heart rate and on salivary

secretions in 1 and 3 hours, respectively. The duration of action may last from 12 to 24 hours depending on the dose.

The distribution half-life of atropine following intravenous (IV) administration is approximately 1 minute. The apparent volume of distribution (Vd) is about 2 to 2.6 L/kg.[24] As a result of the rapid distribution, 10 minutes after IV administration less than 5% of the dose remains in the serum. The serum concentrations of atropine are similar at 1 hour following either 1 mg IV or IM in adults.[3,6] The elimination half-life is 6.5 hours.[34]

Following IM administration of 0.02 mg/kg in adults the absorption rate and elimination rates are comparable for the racemic dl-hyoscyamine and the active l-hyoscyamine at 8 minutes and 2.5 hours, respectively. The mean peak serum concentration and the area under the curve (AUC) are higher for the racemic mixture indicating a stereochemical difference in pharmacokinetics.[24] Renal elimination accounts for 34% to 57% of the excretion of the dose, and the majority of renal elimination occurs within 6 hours.[3] Serum concentrations of l-hyoscyamine correlate with effects on heart rate and the antisialagogue effects. Serum concentrations below 0.5 μg/L cause bradycardia, whereas higher concentrations cause tachycardia.[24]

Atropine autoinjectors are now given to first responders for use during chemical terrorist attacks. The administration of 2 mg of atropine by autoinjector was compared with 2 mg administered by conventional needle and syringe into the deltoid of six adult subjects.[39] The onset of tachycardia and the time to maximal increase in heart rate occurred sooner with the autoinjector (16 minutes versus 23 minutes, and 34 minutes versus 41 minutes, respectively). An analysis of radiographs of contrast material injected by autoinjector or conventional IM administration into a dog's leg demonstrated that the autoinjector appeared to "spray" the material into a larger tissue area accounting for a faster rate of absorption.[39]

Ophthalmic instillation of atropine causes cyclopegia and mydriasis by blocking the M_3 muscarinic receptor on the iris sphincter muscle.[28] The peak mydriatic effect occurs within 30 to 40 minutes and persists for 7 to 10 days. In contrast, the effects of topical homatropine on the eye occur sooner than topical atropine (10–30 minutes for mydriasis and 30–90 minutes for cycloplegia) and are shorter in duration (6–48 hours).

An investigation of the bioavailability of atropine eye drops in healthy adults revealed on average 65% systemic absorption, but with a wide individual variability.[23] The time to maximum serum concentration was 30 minutes and the elimination half-life was 2.5 hours.

The pharmacokinetics of three inhaled doses of atropine from a metered-dose nebulizer was compared with 2 mg of IM atropine in healthy adults.[20] Peak concentrations were comparable for the 2-mg inhaled and 2-mg IM atropine doses. The time to peak concentration following inhalation averaged 1.3 hours. A novel nanoatropine dry powder inhaler is being developed to rapidly achieve blood concentrations of atropine in the hopes of circumventing IM administration.[2]

CLINICAL USE

One of earliest descriptions of the effectiveness of atropine in parathion and tetraethylpyrophosphate insecticide poisoning was published in 1955.[17] The report emphasized improved survival when atropine was administered early and continued with adequate maintenance doses in conjunction with intubation and ventilation. The report also found that after parathion and tetraethylpyrophosphate insecticide exposure, dogs were more likely to develop heart block and bronchoconstriction, whereas humans were more likely to develop a relative rather than absolute bradycardia. Additionally, humans were more likely to die from respiratory causes stemming from central apnea, diaphragmatic weakness, and bronchorrhea.

In 1971, a landmark case series and review of OP insecticide poisonings was published. Included in this report was a table classifying the severity of poisoning along with treatment protocols for each level of severity.[29] This regimen served as the foundation of treatment regimens (atropine and pralidoxime) for many years.

In the 1930s and 1940s, the Germans synthesized OP insecticides (acetylcholinesterase inhibitors) that were further developed as chemical warfare nerve agents (Chap. 131).[38] Although these agents inhibit acetylcholinesterase in a manner similar to traditional OP insecticides, these so-called "nerve agents" also affect other cholinesterases, and at high doses, directly affect nicotinic and muscarinic receptors. Atropine was chosen in the late 1940s as the standard antidote for these nerve agents. The dose of atropine needed to antagonize these nerve agents is much less than that needed to effectively antagonize traditional OP insecticides, largely because of differences in pharmacokinetics. The benefits of adding pralidoxime to atropine were noted in the 1950s, and in the 1960s, pralidoxime was established as a standard antidote in addition to atropine for these agents (see Antidotes in Depth A33: Pralidoxime).

ADVERSE EFFECTS AND TOXICITY

When atropine is used in the absence of a xenobiotic that increases or mimics acetylcholine, adverse effects begin at 0.5 mg IV in the adult and include dry mouth and decreased sweat. However, in the presence of a muscarinic agonist or an anticholinesterase, these effects may not occur until many milligrams of atropine are administered.

Intravenous doses of greater than 10 mg of atropine and oral doses of 500 to 1000 mg have been administered with full recovery. Deaths from atropine use are usually correlated with hyperthermia.

An unintentional atropine dose of 1 g orally resulted in typical manifestations of anticholinergic poisoning that began within a short time and lasted 4 days.[1] In 2 hours the patient went from feeling hot and flushed with blurred vision to stuporous. Over the ensuing 24 hours he became tachycardic, hyperthermic, and comatose with dilated, nonreactive pupils and shallow respirations. By 40 hours he started to respond to his name and his temperature had normalized, but he remained dry with dilated and nonreactive pupils. He went from comatose to restless, hallucinating, and paranoid. At 4 days he regained a normal mental status with amnesia for the previous 4 days.

A survey of pediatric emergency departments in Israel reported on 240 children who were unintentionally injected with atropine autoinjectors during the Persian Gulf crisis.[4] Half of the children developed systemic effects that correlated with the doses of atropine administered. Eight percent of effects were serious but there were no seizures or deaths.

Systemic atropine toxicity may even occur when too large a dose of atropine, scopolamine or homatropine are instilled in the eye, especially in children.[31] Excessive absorption from other routes of administration (eg, rectal, inhaled) would also be expected to result in toxicity.[37] In the event of an atropine overdose, physostigmine, a reversible, CNS active, cholinesterase inhibitor, is the antidote of choice[30] (see Antidotes in Depth A12–Physostigmine Salicylate). Psychiatric patients in the 1950s were often given atropine as a remedy. Within 15 to 20 minutes of getting 32 to 212 mg of IM atropine, patients become restless and often confused. This progressed to muscular incoordination, ataxia, weakness, and garbled speech.[15] The patients then progressed to disorientation with illusions, visual hallucinations, and delirium, to coma. The coma often lasted for 4 to 6 hours and then patients recovered in a manner that in some respects is the reverse of intoxication. Regardless of the dose of atropine required to induce the coma, physostigmine 4 mg IM completely reversed it within 20 minutes, but the reversal only lasted for 30 to 45 minutes.[15,30]

Other precautions or contraindications to consider when administering atropine include those associated with all antimuscarinics and include narrow angle closure glaucoma, obstructive uropathy, gastroparesis, emptying, relaxation of the lower esophageal sphincter, and myasthenia gravis. Of course these issues must be weighed in light of the possible life-threatening nature of OP, carbamate, and chemical nerve agent poisoning.

Atropine is classified by the Food and Drug Administration (FDA) as pregnancy category C. Atropine crosses the placenta and may cause tachycardia in the fetus near term.[40]

DOSING AND ADMINISTRATION

The dosage regimen of atropine for an OP pesticide poisoning in adults has never been studied in a randomized, controlled trial, and there is considerable variation in textbook recommendations.[12] A recent prospective, observational study suggests that a dose doubling, titrated protocol provided equal efficacy with less atropine toxicity compared with a less-preplanned ad hoc dosing protocol.[33] Experience suggests that atropine should be initiated in adults in doses of 1 to 2 mg IV for mild to moderate poisoning and 3 to 5 mg IV for severe poisoning with unconsciousness.[29] This dose can be doubled every 3 to 5 minutes until improvement has begun, at which time dose doubling can stop and similar or smaller doses can be used.[13,35] We believe that the most important end point for adequate atropinization is clear lungs, and the reversal of the muscarinic toxic syndrome. It is, however, important not to confuse abnormal focal ausculatory sounds associated with pulmonary aspiration with those of extensive bronchorrhea.[13,35] Some authors suggest clear lungs, heart rate greater than or equal to 80 beats/min, and systolic blood pressure greater than or equal to 80 mm Hg as most important, and dry axillae and wider than pinpoint pupils as additional goals.[14] Once these end points have been achieved, a maintenance dose of atropine needs to be started. One group suggests administering 10% to 20% of the loading dose as an IV infusion every hour as a starting point with meticulous frequent reevaluation and titration.[12,13] The atropine can be diluted in 0.9% sodium chloride with rates of 0.5 to 1.5 mg/h of atropine commonly used.[33] For example, if a patient received atropine IV 2 mg, then 4 mg in 5 minutes, and 8 mg in 5 minutes when improvement in bronchorrhea is noticeable, the total loading dose to initial control would be 14 mg in 10 minutes. The initial IV infusion dose of atropine would be 1.4 mg/h. This could be prepared by mixing 10 mg of atropine in 100 mL of 0.9% sodium chloride to make a concentration of 0.1 mg/mL and infuse it at 14 mL (14 mg)/h. If too much atropine is administered, the patient demonstrates classic signs of peripheral and central anticholinergic toxicity as described above. The IV starting dose of atropine in children is 0.02 mg/kg up to the adult dose.[35,42] A continuous infusion of 0.025 mg/kg/h has been successfully used in a 2 year old following a fenthion poisoning.[7]

In the event that a person is exposed to a chemical warfare nerve agent, atropine should be administered in a dosage suitable for both the severity of the poisoning and the age of the patient. In a conscious adult with mild to moderate cholinergic effects, 2 mg of atropine IV or IM should be administered every 5 to 10 minutes until shortness of breath improves and drying of secretions occurs.[38] One adult autoinjector of atropine for IM administration, Mark 1 Nerve Agent Antidote Kit (NAAK), contains 2 mg of atropine, and therefore multiple injectors may be required. Total doses of 2 to 4 mg of atropine are usually all that is needed, which is much lower than the dose for most OP pesticide exposures. Patients who are unconscious or apneic require higher total doses with 5 to 15 mg usually sufficing.[38]

The appropriate total Mark 1 autoinjector doses of atropine for children depend on age and weight.[21,26] For ages 3 to 7 (13–25 kg), one autoinjector (2 mg) of atropine and one autoinjector of pralidoxime (600 mg) should be administered resulting in a projected atropine dose of 0.08 to 0.15 mg/kg. For ages 8 to 14, two autoinjectors of atropine and two autoinjectors of pralidoxime should be administered resulting in a projected atropine dose of 0.08 to 0.15 mg/kg. For patients older than 14 years of age, three autoinjectors of atropine and pralidoxime should be administered resulting in a projected dose of atropine of less than 0.11 mg/kg. In an emergency for children younger than 3 years of age a risk-benefit analysis would suggest injecting one autoinjector of atropine and one of pralidoxime. If time permits and only one autoinjector is available for use, its contents may be transferred to a small sterile vial for traditional IM administration with a needle and syringe.[22] Some experts recommend that children under the age of 1 be administered one pediatric atropine autoinjector (0.5 mg), AtroPen (Meridian Medical Technologies) if available, and children over the age of 1 be administered the Mark 1 autoinjector as described above.

When IV administration is not feasible, atropine may also be administered intraosseously at the standard IV dose. However, the dose for endotracheal administration in adults should be two to two-and-a-half times the IV dose, diluted in 5 to 10 mL of normal saline or sterile water. For children the 2005 American Heart Association guidelines for pediatric advanced life support recommend 0.03 mg/kg with a minimum dose of 0.1 mg in a child endotracheally followed by a flush of 5 mL of normal saline and then five manual ventilations to enhance absorption.[32]

AVAILABILITY

Atropine sulfate injection is available in many different strengths, with the following concentrations in each 1 mL vial or ampule: 50 µg, 300 µg, 400 µg, 500 µg, 800 µg, and 1 mg. Atropine sulfate is also available in prefilled 5-mL or 10-mL syringes with a concentration of 0.1 mg/mL for adults and in 5-mL syringes with a concentration of 0.05 mg/mL for pediatrics.

The AtroPen Auto-Injector is a prefilled syringe designed for IM injection by an autoinjector into the outer thigh.[5] It is available in four strengths: 0.25 mg, 0.5 mg (blue label), 1 mg (dark red label), and 2 mg (green label).

Atropine is also packaged in a kit designed for IM injection with a second autoinjector containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 40 mg benzyl alcohol and 22.5 mg glycine. The pralidoxime injector is accompanied by an atropine autoinjector containing 2.1 mg of atropine in 0.7 mL of a sterile solution containing 12.47 mg glycerin and not more than 2.8 mg phenol. This particular combination kit is called a "Mark 1 Nerve Agent Antidote Kit" and is designed for IM use in case of a nerve agent attack. The needles are 0.8 inches in length.[27] The Mark 1 NAAK has recently been replaced by the DuoDote Autoinjector System, which uses technology that sequentially administers 2.1 mg in 0.7 mL atropine followed by 600 mg in 2 mL pralidoxime chloride IM through the same syringe. The 23-gauge needle is 0.8 inches in length.

Atropine is available orally in 300 µg, 400 µg, and 600 µg tablets.

In case of a shortage during an emergency, in vitro evidence suggests that outdated atropine retains its potency and that an extemporaneously prepared atropine solution from powder is stable for at least 3 days.[11,36] Other sources of atropine to consider in an emergency during a shortage would be atropine eye drops, which come as a 1% concentration (10 mg/mL). Homatropine, available as eye drops in a 2% or 5% concentration, compared favorably with atropine in preventing lethality when administered IM in a pretreatment rodent model using dichlorvos. In this experimental model, homatropine appeared to be half as potent as atropine.[9]

SUMMARY

Atropine has many clinical uses as a competitive antagonist at both central and peripheral muscarinic receptor sites. The use of atropine is extensive for patients with bradycardias, in advanced cardiac life support, and in those exposed to acetylcholinesterase inhibitors in the workplace, in the home, and potentially on the battlefield.

CHAPTER 114

INSECTICIDES: ORGANIC CHLORINES, PYRETHRINS/PYRETHROIDS, AND INSECT REPELLENTS

Michael G. Holland

Organic chlorine pesticides are complex, cyclic, polychlorinated hydrocarbons having molecular weights generally in the range of 300 to 550 daltons. They are nonvolatile solids at room temperature. Most act as central nervous system (CNS) stimulants. In contrast, chlorinated hydrocarbon solvents and fumigants are low-molecular-weight, alkyl compounds that are volatile liquids or gases, and generally have CNS-depressant effects (Chap. 106). The pyrethrins, which are extracted from chrysanthemum flowers, are highly effective contact poisons. When properly used they have almost no mammalian systemic toxicity. These molecules are rapidly hydrolyzed and broken down by light with no environmental persistence or bioaccumulation.

ORGANIC CHLORINES

■ HISTORY AND EPIDEMIOLOGY

Until the 1940s, commonly available pesticides included highly toxic arsenicals, mercurials, lead, sulfur, and nicotine. When Nobel Prize–winning chemist Paul Müller demonstrated the insecticidal properties of dichlorodiphenyltrichloroethane (DDT) in the early 1940s, a whole new class of pesticides was introduced.[51] The organic chlorine insecticides were inexpensive to produce, nonvolatile, environmentally stable, and had relatively low acute toxicity when compared to previously available insecticides. Most organic chlorines have a negative temperature coefficient, making them more insecticidal at lower temperatures, and less toxic to warm-blooded organisms (Table 114–1).[172] Widespread use of these xenobiotics occurred from the 1940s until the mid-1970s. They were highly effective and revolutionized modern agriculture, allowing unprecedented crop output from each acre of arable land. Because of their stability, organic chlorines were used extensively in structural protection (from termites, carpenter ants) and soil treatments. Medical and public health applications of DDT and its analogues were also found in the control of typhus and eradication of malaria by eliminating the mosquito vector.[41] By 1953, DDT alone was credited for saving an estimated 50 million lives, and for averting one billion cases of human disease. It is suggested that because of this consequential impact on human health, DDT is the single most important factor in the population explosion that occurred between 1950 and 1970.[52]

However, the properties that made these chemicals such effective insecticides also made them environmental hazards: they are slowly metabolized, lipid soluble, chemically stable, and environmentally persistent. In her 1962 book, *Silent Spring*, Rachel Carson, a biologist with the US Fish and Wildlife Service, demonstrated that organic chlorines are bioconcentrated and biomagnified up the food chain.[19] She alleged that this persistence could eventually lead to future increases in cancer.

Numerous publications since then have shown that organic chlorine residues in predatory birds, most notably grebes, peregrine falcons, bald eagles, and pelicans, caused eggshell thinning and decreased reproductive success.[51] However, conflicting results occurred when DDT-laced feedstuffs were administered in high concentrations to experimental birds. Testing on domesticated birds such as Japanese quail,[21,27,131] and chickens,[170] showed little or no eggshell thinning, whereas testing in mallard ducks showed thinning.[47,48] Hearings before the Environmental Protection Agency (EPA) regarding DDT registration also focused on the unproven fear of placing future generations at risk for cancer. This and the demonstration of persistent DDT residues in all humans, even those living in areas where DDT was never used such as Inuits, led to the severe restriction or total ban of DDT and most other organic chlorines in North America and Europe.[41] There is considerable evidence that since DDT was banned, the limited efficacy of the available alternative pesticides has placed many millions at risk for malaria and is responsible, at least in part, for millions of deaths from this disease.[104,128,129] Not surprisingly, DDT is still considered a highly effective mosquito control agent with a low order of acute toxicity, and is very inexpensive compared with newer replacement insecticides. For these reasons, the World Health Organization (WHO) exempted DDT from its list of banned pesticides, and it is still widely used for malaria control programs in many countries, since alternatives are more expensive and must be applied more often. Current use of DDT for indoor residual spraying is ongoing in endemic areas in Africa, and has been shown to be safe and effective as a public health initiative to control malaria, even in areas with resistant strains.[138] More recently, in the United States another organic chlorine was banned: in 2006, the EPA officially cancelled lindane's registration, and all use in agriculture will cease in 2009.[8]

The organic chlorine pesticides can be grouped into four categories based on their chemical structures and similar toxicities: (1) DDT and related analogues; (2) cyclodienes (the related isomers aldrin, dieldrin, and endrin; and heptachlor, endosulfan), and related compounds (toxaphene, dienochlor); (3) hexachlorocyclohexane, the primary organochlorine pesticide still in clinical use (more commonly termed lindane, the γ isomer, also referred to by the misnomer γ-benzene hexachloride). Isomerism is important, because the β and δ isomers are CNS depressants and have no insecticidal properties[3,32,117]; and (4) mirex and chlordecone (see Table 114–1; Fig. 114–1). These organic chlorine insecticides differ substantially, both between and within groups, with respect to toxic doses, skin absorption, fat storage, metabolism, and elimination.[41] The signs and symptoms of toxicity in humans, however, are remarkably similar within each group.

■ TOXICOKINETICS

Absorption All of the organic chlorine pesticides are well absorbed orally and by inhalation; dermal absorption is variable, depending on the particular compound. Absorption by any route may be affected by the vehicle and the physical state (solid or liquid) of the pesticide. None of the organic chlorines are water soluble, and are usually either dissolved in organic solvents or manufactured as powders for dusting.

DDT and its analogues are very poorly absorbed dermally, unless dissolved in a suitable hydrocarbon solvent.[126] DDT has limited volatility, so that air concentrations are usually low and toxicity by the respiratory route is unlikely.

All of the cyclodienes have significant dermal absorption rates. Cutaneous absorption of dieldrin is approximately 50% that of the oral route. Oral absorption of the cyclodienes is also high, and significant poisonings have occurred when foodstuffs were contaminated with these pesticides.[17,22] Although toxaphene is poorly absorbed through the skin, acute and chronic exposures occur.[143]

TABLE 114–1. Classification of Organic Chlorine Insecticides

Class	CAS[a] Registry #	Brand Name(s)	Current EPA Registration (US)	Acute Oral Toxicity (Man)	Dermal Absorption	Lipid Storage	Specific Characteristics
Hexachloro-cyclohexanes	Lindane (gamma isomer) 58–89–9	Kwell; Gustafson Flowable; Sorghum Guard	Topical scabicide; agricultural use cancelled 2006	Moderate	High	Low	Topical scabicide: seizures, CNS excitation; musty odor
DDT and Analogues	DDT (dichlorodiphenyltrichloroethane) 50–29–3	Neocid, Ixodex, Anofex, others	Cancelled 1972	Low to moderate	Low	Highest	Tremors, CNS excitation; odorless
	Methoxychlor 72–43–5	Marlate	Cancelled 2003	Low	Low	Moderate	Less toxic DDT substitute
	Dicofol 115–32–2	Kelthane	Residential use banned 1998; cotton, citrus, apple	Low	Low	Low	
	Chlorobenzilate 510–15–6	Benzilan, BenzoChlor	Cancelled 1983	Low	Low	Low	Much less environmental persistence than DDT
Cyclodienes and Related Compounds	Aldrin 309–00–2	Aldrex, Octalene, Toxadrin	Cancelled 1974	High	High	High	Rapidly metabolized to dieldrin; mild "chemical" odor
	Dieldrin 60–57–1	Dieldrite, Octalox, Quintox	Cancelled 1974	High	High	High	Stereoisomer of endrin; early and late seizures; odorless
	Endrin 72–20–8	Hexadrin	Cancelled 1974	Highest	High	None	Most toxic organic chlorine; rapid onset seizures, status epilepticus
	Chlordane 57–74–9	Octachlor, Toxichlor, others	Cancelled 1988	Moderate	High	High	Early and late seizures
	Endosulfan 115–29–7	Thiodan, Cyclodan, others	RED[b] 2002	High	High	Low	Strong sulfur odor
	Heptachlor 76–44–8	Drinox	Restricted: fire ant control soil treatment	Moderate	High	High	Toxic metabolite heptachlor epoxide; camphor odor
	Isobenzan 297–78–9	Telodrin	Never registered	High	Moderate	High	Also inhibits Mg^{++}-ATPase; mild "chemical" odor
	Dienochlor 2227–17–0	Pentac	Cancelled	NA	Low	Low	Toxic metabolite binds to GSH
	Toxaphene (polychlorinated camphene) 800–35–2	Alltox, Chemphene, Toxakil, others	Cancelled 1982	Moderate to high	Low	Low	Seizures; turpentinelike odor, often mixed with parathion
Chlordecone and Mirex	Chlordecone 143–50–0	Kepone	Cancelled 1977	Moderate	High	High	"Kepone shakes"; structurally similar to mirex
	Mirex 2385–85–5	Dechlorane	Cancelled 1976	Low	High	High	Metabolized to chlordecone, similar toxicity.

[b] RED, Re-registration Eligibility Decision.

CNS, central nervous system; GSH, glutathione.
FIGURE 114–1. Structures of various organic chlorine insecticides.

In adults, lindane is well absorbed following topical application; the forearm skin absorption rate is 9.3% after 24 hours.[61] Anatomic sites vary in their absorptive capacities: axillary rates are 3.6 times greater and scrotal absorption is 42 times greater than forearm rates.[16,66,81,151] Animal studies and case reports suggest that the young, the malnourished, and those who receive repeated topical doses may have increased accumulation and toxicity.[118] Hot baths, occlusive clothing, or bandages, the vehicle for the lindane, and a disturbed cutaneous integrity, such as eczema, fissures, and other violations of the skin, all enhance dermal penetration.[150,151] The state of hydration of the skin also affects the amounts absorbed, so that bathing just prior to application can enhance absorption and increase the likelihood of toxicity.[102,151] Lindane is a stable compound and volatilizes easily when heated. It was used extensively in the past in home vaporizers, and toxicity was common via inhalation, or when vaporizer tablets were unintentionally ingested by children. Review of data following oral use of lindane as an antihelmintic demonstrates that 40 mg/d for 3 to 14 days generally produced no symptoms.[41]

Mirex and chlordecone are efficiently absorbed via skin, by inhalation, and orally.[60]

Distribution All organic chlorines are lipophilic, a property that facilitates penetration to many sites.[29] The fat-to-serum ratios at equilibrium are high, in the range of 660:1 for chlordane,[71] 220:1 for lindane,[144] and 150:1 for dieldrin.[42] Central nervous system redistribution to the blood and then to fat may account for the apparent rapid CNS recovery despite a persistent substantial total body burden. In the rat model, there is a direct correlation between the concentration of DDT or dieldrin in the brain and the clinical signs produced after a single dose of the insecticide.[41,45]

Serum lindane concentrations peak at 6 hours and have a half-life of 18 hours after topical application.[62]

Metabolism The high lipid solubility and very slow metabolic disposition of DDT, DDE (dichlorodiphenyl dichloroethylene, metabolite of DDT), dieldrin, heptachlor, chlordane, mirex, and chlordecone causes significant adipose tissue storage and increasing body burdens in chronically exposed populations.[60] Organic chlorines that are rapidly metabolized and eliminated, such as endrin (an isomer of dieldrin), endosulfan, lindane, methoxychlor, dienochlor, chlorobenzilate, dicofol, and toxaphene, tend to have less persistence in body tissues, despite being highly lipid soluble.[126]

Most organic chlorines are metabolized by the hepatic cytochrome P450 (CYP) enzyme systems by dechlorination and oxidation, with subsequent conjugation. However, metabolism may result in the production of a metabolite with more toxicity than the parent compound, such as heptachlor to heptachlor epoxide, chlordane to oxychlordane, and aldrin to dieldrin.

In animals, most organic chlorine pesticides are capable of inducing the hepatic microsomal enzyme systems.[40,174] Enzyme induction changes the biodegradation of the pesticide in rodents,[157] and in certain animal models the acute toxicity of organic phosphorus (OP) compounds and carbamates may be reduced by the administration of organic chlorines. Since this protective effect does not occur when the cytochrome P450 (CYP) inhibitor piperonyl butoxide is administered, it shows that hepatic microsomal enzyme induction by the organic chlorine and subsequent increased metabolism of the OP compound is responsible for this reduced toxicity of the OP in this rodent model.[41,174] However, induction of hepatic enzymes is rarely described in man.[60,71]

Elimination The half-lives of fat-stored compounds and poorly metabolized organic chlorines such as DDT and chlordecone are measured in months or years. The elimination half-life of lindane is 21 hours in adults.[103] The primary route of excretion of the organic chlorines is in the bile, but most also have detectable urinary metabolites. However, as with other compounds excreted in bile, most of the organic chlorines such as mirex and chlordecone have significant enterohepatic or enteroenteric recirculation.[14,31,60] All of the lipophilic compounds are excreted in maternal milk.[132]

■ MECHANISMS OF TOXICITY

The same neurotoxic properties that make the organic chlorines lethal to the target insects make them potentially toxic to higher forms of life. The organic chlorines exert their most important effects in the CNS. Electrophysiologic studies demonstrate that the organic chlorine insecticides affect the neuronal membrane by either interfering with repolarization, prolonging depolarization, or impairing the maintenance of the polarized state of the neuron. The end result is hyperexcitability of the nervous system and repetitive neuronal discharges.[52]

The voltage-gated sodium channel is a common site of action for natural and synthetic neurotoxins. There are at least 10 separate binding sites on the sodium channel, including those for local anesthetics and anticonvulsants. DDT, as well as the pyrethroids, bind at the same site on these channels. They preferentially bind when the channel is in the open state, allowing prolonged inward sodium conductance, repetitive action potentials, and extended tail currents. Prolonged axonal firing and repetitive stimuli eventually lead to nerve paralysis and death in target insects, whose sodium channels have much greater affinity for these insecticides than those of mammals.[108,109,111,152] In mammals, low-level stimuli cause exaggerated responses, manifested clinically as prominent tremors and abnormal startle reflexes observed in test animals.[79,166] This primary mechanism of action is demonstrated by the amelioration of DDT-induced tremor by pretreatment with phenytoin, a sodium channel blocker, which reduces the ability of voltage-dependent Na channels to recover from inactivation.[79,165]

The cyclodienes and lindane act as γ-aminobutyric acid (GABA) antagonists. They inhibit GABA binding at the GABA$_A$ receptor–chloride ionophore complex in the CNS, by interacting at the picrotoxin binding site.[3,11,32,70,74,110,117] In fact, the degree of binding at this site correlates well with the amount of Cl$^-$ influx inhibited and the relative neurotoxicity of each insecticide (Figs. 13–9, 13–10, and 114–2).[11,70] Indeed, development of cyclodiene resistance seems to be related to alterations of the GABA$_A$ receptor–chloride ionophore complex in
FIGURE 114–2. Chloride channel. (A) Under resting conditions, a tonic influx of chloride maintains the nerve cell in a polarized state. (B) Binding of GABA (⬤) or an indirect-acting GABA agonist (benzodiazepine, barbiturate, volatile anesthetic) opens the chloride channel. The subsequent chloride influx hyperpolarizes the cell membrane, making the neuron less likely to propagate an action potential in response to a stimulus. (C) GABA antagonists, such as picrotoxin, close the chloride channel, reducing chloride influx. The resulting decreased membrane polarity causes the neuron to become hyperexcitable to even those stimuli that are normally subthreshold in nature (Chap. 13).

these affected insects.[12,109] This also explains the efficacy of GABA agonists, such as benzodiazepines and phenobarbital, in treating seizures and neurotoxicity that result from the cyclodienes[75] and lindane.[178] Toxaphene also inhibits GABA binding at the GABA$_A$ receptor–chloride ionophore complex.[143]

The mechanisms of action of mirex and chlordecone are not as well understood. They inhibit Na$^+$–K$^+$-ATPase, and Ca^{2+}-ATPase. However, lindane, DDT, and the cyclodienes also inhibit these enzymes yet produce very different symptoms of toxicity, suggesting that these effects are not responsible for the clinical manifestations associated with mirex and chlordecone toxicity. Phenytoin and serotonin agonists exacerbate the prominent tremor associated with chlordecone poisoning, but conversely attenuate the tremors occurring with DDT poisoning, which further supports differing mechanisms of toxicity for the two compounds.[52] Mirex and chlordecone are poor inhibitors of GABA binding at the GABA$_A$ receptor–chloride ionophore complex; therefore, their

mechanism of action is also likely not at this site,[60] and seizures have not been described with mirex or chlordecone.

Organic chlorines can predispose test animals to cardiac dysrhythmias,[126] likely via the same mechanism as the chlorinated hydrocarbon solvents (Chap. 106).

■ DRUG INTERACTIONS

There are theoretical consequences of liver enzyme induction, such as enhanced metabolism of therapeutic drugs and/or reduced efficacy. Dysfunctional uterine bleeding was attributed to enhanced oral contraceptive metabolism induced by chlordane, but this was in a single patient with weeks of excessive exposure to chlordane.[71] A large group of workers poisoned by chlordecone over many months had increased hepatic microsomal activity, but no evidence of drug interactions or adverse clinical effects.[60] Thus, induction of the hepatic microsomal enzyme system by organic chlorines probably occurs only following extended, substantial exposures.[126] There are no definitive reports of human enhanced metabolism of therapeutic drugs or adverse reactions due to microsomal enzyme induction.

■ CLINICAL MANIFESTATIONS

Acute Exposure In sufficient doses, organic chlorines lower the seizure threshold (DDT and related sodium channel agents) or remove inhibitory influences (antagonism to GABA effects) and produce CNS stimulation, with resultant seizures, respiratory failure, and death.[20,22,30,74,75,87,88,135,137] After DDT exposure, tremor may be the only initial manifestation. Nausea; vomiting; hyperesthesia of the mouth and face; paresthesias of face, tongue, and extremities; headache; dizziness; myoclonus; leg weakness; agitation; and confusion may subsequently occur. Seizures only occur after massive exposures, typically following the ingestion of large amounts.[52,75] DDT has a relatively low order of acute toxicity, and high doses of DDT (10 mg/kg or more) are usually necessary to produce symptoms.[75] There often are no prodromal signs or symptoms, and more often than not, the first manifestation of toxicity following exposure to lindane, the cyclodienes, and toxaphene is a generalized seizure.[20,22,51,52,75,88,135,154] If seizures develop, they often occur within 1 to 2 hours of ingestion when the stomach is empty, but may be delayed as much as 5 to 6 hours when the ingestion follows a substantial meal.[75]

Seizures related to dermal application of 1% lindane for treatment of ectoparasitic diseases may occur following a single inappropriate application,[95,118,162] or, more commonly, after repetitive prolonged exposures.[90,122] The time from application to seizure onset can vary from hours to days. The seizures are often self-limited, but may recur or result in status epilepticus. An epidemic of lindane poisoning related to the unintentional substitution of lindane powder for sugar in coffee demonstrated a delay of 20 minutes to 3 hours before the onset of nausea, vomiting, dizziness, facial pallor, severe cyanosis of the face and extremities, collapse, convulsions, and hyperthermia. Affected patients ingested an average of 86 mg/kg of lindane in a single time.[41]

The cyclodienes are also notable for their propensity to cause seizures that may recur for several days following an acute exposure. If the seizures are brief and hypoxia has not occurred, recovery is usually complete. Electroencephalographic (EEG) abnormalities are noted before, during, and following seizures.[88] Hyperthermia secondary to central mechanisms, increased muscle activity, and/or aspiration pneumonitis is common.[52]

The ingestion of combinations of xenobiotics such as for DDT and lindane may result in significantly increased toxicity because of synergy.[75]

Lindane: Specific Risks Patients are at risk for developing CNS toxicity from improper topical therapeutic use such as exceeding recommended

application times or amounts, repeated applications, application following hot baths, and use of occlusive dressings or clothing shortly after application. Toxicity also occurs after unintentional ingestion of topical preparations. Young children appear at greatest risk, possibly because of greater skin permeability, increased ratio of body surface area to mass, or immature liver enzymes.[122,161,162] The elderly may also be at increased risk because of impaired hepatic metabolism, atrophic skin, and perhaps age-related increased sensitivity. Preexisting conditions causing increased risk of seizures include chlorpromazine treatment, CNS disease, or skin absorption changes.[5,43,62,90,95,112,118,122,150,151,161,162]

Despite the availability of safer and equally or more effective treatments such as permethrin, lindane continues to be used because of its low cost and generally good safety profile, when used according to directions. An evaluation of published English-language case reports and those submitted to the FDA divided toxicity into those associated with concentrations of lindane greater than or less than 1%.[90] Only six of 26 cases could be considered probably related to 1% lindane; six others were the result of ingestion or inappropriate skin application.[5] The sale of lindane-containing products for use in humans was recently banned in California because of its toxicity and environmental concerns.[17] In 1995, the FDA changed the labeling requirements for lindane adding a black-box warning, and relegating it to second-line therapy for ectoparasitic skin infections, because of its toxicity and the superior safety and efficacy of other products.[7]

Chronic Exposure Chlordecone (Kepone), unlike the other organic chlorines, produces an insidious picture of chronic toxicity related to its extremely long persistence in the body. Because of poor industrial hygiene practices in a makeshift chlordecone factory in Hopewell, Virginia, 133 workers were heavily exposed for 17 months from 1974 to 1975. They developed a clinical syndrome known as the "Hopewell epidemic," which consisted of a prominent tremor of the hands, a fine tremor of the head, and trembling of the entire body, known as the "Kepone shakes." Other findings included weakness, opsoclonus (rapid, irregular, dysrhythmic ocular movements), ataxia, mental status changes, rash, weight loss, and elevated liver enzyme concentrations. Idiopathic intracranial hypertension, oligospermia, and decreased sperm motility were also found in some of these workers. Severely affected workers even exhibited an exaggerated startle response, remarkably similar to that seen in animal studies. The exposures were so intense that some workers went home covered with chlordecone, and several workers' wives developed neurological symptoms, presumably from exposures while laundering their husbands' work clothes.[31,60]

This event led to substantial concern in environmental health centers with regard to persistent organic chemicals, such as the organic chlorine residues and polychlorinated biphenyls (PCBs). A recent review of the world literature reveals that since many of the organic chlorines are outlawed in many processes and countries, human burden appears to be decreasing.[98]

Carcinogenicity. DDT and other organic chlorine insecticides have estrogenic effects.[44,153] These estrogenic compounds adversely affect birds because differentiation of the avian reproductive system is estrogen dependent.[68] Breast cancer incidence rates in the United States have climbed 1% per year since the 1940s, coinciding with, among many other factors, the worldwide use of DDT. Because lifetime exposure to excess estrogen is a known risk factor for human breast cancer, it has been postulated that women who have higher concentrations of estrogenic organic chlorine compounds such as DDT and PCBs may be at greater risk for developing breast cancer.[139,176]

Several small case-control studies of women with breast cancer showed that women with the disease had higher average body burdens of DDT, DDE, and PCBs than their age-matched controls. These

studies implicated the organic chlorines as a possible cause of human breast cancer. However, more recently, larger studies have shown no increased risk of breast cancer because of exposure to organic chlorines,[18] and that currently accepted hereditary and lifestyle risk factors were present in the patients with cancer.[80,91,139–141] In fact, other natural dietary estrogens such as flavonoids, lignans, sterols, and fungal metabolites are present in the human diet, and have much higher estrogenic potency; the organic chlorine contribution is probably minimal by comparison.[69] A recent meta-analysis of 22 studies found strong evidence to discard the putative relationship between p,p'-DDE (dichlorodiphenyldichloroethane) and breast cancer risk.[97]

The organic chlorines can induce liver tumors in mice, but have not been shown to do so in rats or hamsters.[76] Some reports suggest an association between long-term exposure to organic chlorine insecticides and hematologic disorders such as aplastic anemia, leukemia, and drug-induced thrombocytopenic purpura.[75,123,136] However, there is no convincing evidence that any of these xenobiotics are carcinogenic in humans. Workers heavily exposed to DDT and dieldrin do not have an increased incidence of neoplasms.[76] Epidemiologic evidence suggests that the incidence of deaths from liver cancer has steadily decreased since 1930, which includes the more than 50 years since the introduction of the organic chlorines.[75,76] There is some evidence that DDT can be a facilitator of carcinogenesis induced by other xenobiotics, such as aflatoxin, and that chlordane may have the same facilitative character regarding diethylnitrosamine.[75] A comprehensive review found no evidence of human cancer risk from exposure to aldrin or dieldrin.[156]

■ DIAGNOSTIC INFORMATION

The history of exposure to an organic chlorine insecticide is the most critical piece of information, because exposure is otherwise rare. By US law, the package label of these products must list the ingredients, the concentrations, and the vehicle. The EPA-registered use of the insecticide may be helpful in determining which agent is involved (Table 114–2). The presence of an unusual odor in the mouth, in the

TABLE 114–2. Common Household Insecticides

Pest	Typical Recommendation
Ants	Baygon, bendiocarb, chlorpyrifos, diazinon, permethrin, resmethrin, silica gel pyrethrum, boric acid
Bedbugs	Permethrin
Cockroaches	Baygon, bendiocarb, chlorpyrifos, diazinon, permethrin, resmethrin, silica gel pyrethrum, tetramethrin, boric acid
Fleas	Baygon, bendiocarb, chlorpyrifos, d-limonene, permethrin, pyrethrins, silica gel pyrethrum, resmethrin, tetramethrin
Flies (house)	Allethrin, pyrethrum, resmethrin, tetramethrin
Mosquitoes	Allethrin, pyrethrum, pyrethrins, resmethrin, tetramethrin
Silverfish	Baygon, bendiocarb, boric acid, chlorpyrifos, diazinon, silca gel pyrethrum
Spiders	Baygon, bendiocarb, chlorpyrifos, diazinon, permethrin, pyrethrins, resmethrin, tetramethrin
Termites	Restricted in use for application by certified applicators
Ticks	Baygon, chlorpyrifos, diazinon, malathion, tetramethrin

vomitus, or on the skin may be helpful. Toxaphene, a chlorinated pinene, has a mild turpentine-like odor, and endosulfan has "rotten egg" sulfur odor (see Table 114–1). Following ingestion, an abdominal radiograph may reveal the presence of a radiopaque chlorinated insecticide, since chlorine increases the radiopacity of the xenobiotics (Chap. 5). A large number of other xenobiotics lead to seizures as the first manifestation of toxicity, and must be considered in the differential of an unknown exposure (Chaps. 13 and 18).

■ LABORATORY TESTING

Gas chromatography can detect organic chlorine insecticides in serum, adipose tissue, and urine.[42,80] If confirmation is indicated for purposes of documentation of source, it may be necessary to measure concentrations of organic chlorines. If the patient's history and toxidrome are obvious, then laboratory evaluation is unnecessary, as this determination will not alter the course of management, and these blood tests are not available on an emergent basis. At present, there are no data correlating health effects and tissue concentrations. Routine surveillance of serum concentrations in the occupationally exposed is not currently performed.[42]

Most humans studied have measurable concentrations of DDT in adipose tissue. In a study of a community with a very large exposure to DDT, serum DDT concentrations increased proportionally with age. These increasing concentrations were not associated with any apparent adverse health effects, but there was an association with increasing concentrations of the liver enzyme γ-glutamyltransferase (GGT), but significant hepatotoxicity did not occur. The Centers for Disease Control and Prevention's (CDC's) Third National Report on Human Exposure to Environmental Chemicals has demonstrated the presence of numerous organic chlorine insecticide residues in the lipid fraction of serum of US residents. These levels tend to increase with patient age, consistent with the bioaccumulation and fat-storing properties of the chemicals.[24] More recently, studies of occupationally exposed pesticide applicators and persons living in targeted regions confirmed higher serum concentrations over those not exposed, but no ill health effects are documented.[138]

Serum lindane concentrations document exposure, and most laboratories report toxic ranges. Lindane-exposed workers with chronic neurologic symptoms showed a blood lindane concentration of 0.02 mg/L.[5,75] A limited series of patients with acute lindane ingestion suggests that a serum concentration of 0.12 mg/L correlates with sedation, and that 0.20 mg/L is associated with seizures and coma.[5] After cutaneous application, lindane concentrations in the CNS are three to 12 times higher than serum concentrations.[31,46,151] In a group of factory workers with a prolonged exposure to chlordecone, clinical signs and symptoms of toxicity correlated with blood concentrations.[31]

■ MANAGEMENT

As in the care of any patient who presents with an altered mental status, the administration of dextrose and thiamine (in an adult) should be considered. Skin decontamination is essential, especially in the case of topical lindane exposure. Clothing should be removed and placed in a plastic bag that should be disposed of appropriately as biohazardous waste, and the skin washed with soap and water. Healthcare providers should be protected with rubber gloves and aprons. Because these insecticides are almost invariably liquids, a nasogastric tube can be used to suction and lavage gastric contents, if clinically indicated. This is most appropriate only with a very recent ingestion (Chap. 7). Activated charcoal (AC) can be used after or instead of gastric lavage,

when lavage is not indicated.[75,101] However, the ability of AC to adsorb the various organic chlorines has not been adequately studied, and mixtures containing petroleum distillates would obviously preclude the use of AC (see Chap. 7). Because the organic chlorines are all neurotoxins, the risk of complications associated with seizures probably outweighs the risk of any of the gastrointestinal (GI) decontamination strategies in most acute settings. A murine model of lindane toxicity following intragastric administration showed a trend, but not a statistically significant benefit, of AC.[85] The use of cholestyramine, a nonabsorbable, bile acid–binding anion exchange resin, in the same murine model did show a statistically significant benefit by raising both the convulsive dose and the lethal dose.[85] Cholestyramine should be administered to all patients symptomatic from chlordecone, and possibly other organic chlorine exposures. Chlordecone undergoes both enterohepatic and enteroenteric recirculation, which can be interrupted by cholestyramine at a dosage of 16 g/d. Cholestyramine increased the fecal elimination of chlordecone three- to 18-fold in industrial workers exposed during the Hopewell epidemic, resulting in clinical improvement.[31]

Oil-based cathartics should never be used, as they may facilitate absorption. There is some evidence that sucrose polyester (olestra, a nonabsorbed synthetic dietary oil substitute) can increase excretion of a wide variety of fat-soluble organic chlorine chemicals.[82,106] It is useful for dioxin-poisoned patients when administered in potato chips.[72] This was most recently successfully used in treating Ukrainian President Viktor Yushenko.[155] This would be an inexpensive and more palatable alternative to cholestyramine in the effort to diminish toxicity by increasing excretion in patients with significant body burdens following chronic organic chlorine exposure.

Seizures should be controlled with a benzodiazepine followed by pentobarbital or a propofol infusion and, if necessary, neuromuscular blockade to control the peripheral manifestations of seizures, thereby preventing metabolic acidosis and rhabdomyolysis. As has been shown in other toxic exposures, phenytoin is much less effective in these cases, particularly with the GABA-chloride ionophore antagonists lindane, toxaphene, and the cyclodienes.[126] Hyperthermia should be managed with external cooling.

PYRETHRINS AND PYRETHROIDS

The pyrethrins are the active extracts from the flower *Chrysanthemum cinerariaefolium*. These insecticides are important historically, having been used in China since the first century AD[41] and developed for commercial application by the 1800s. They are produced by organic solvent extraction from ground Chrysanthemum flowers. The resulting concentrates have greater than 90% purity. Pyrethrum, the first pyrethrin identified, consists of six esters derived from chrysanthemic acid and pyrethric acid. These insecticides are highly effective contact poisons, and their lipophilic nature allows them to readily penetrate insect chitin (exoskeleton) and paralyze their nervous systems through Na^+ channel blockade.[29,107,126,152] When applied properly, they have essentially no systemic mammalian toxicity because of their rapid hydrolysis. Pyrethrins break down rapidly in light and in water, and therefore have no environmental persistence or bioaccumulation. This fact makes them extremely safe after human exposures, but unsuitable for commercial agriculture, since the constant reapplication would be cost prohibitive.

The pyrethroids are the synthetic derivatives of the natural pyrethrins (Table 114–3 and Fig. 114–3). They were developed in an effort to produce more environmentally stable products for use in agriculture. Originally, the pyrethroids were divided into two groups based on the poison syndromes they elicited in test animals. The

TABLE 114–3. Synthetic Pyrethroids in Common Use

Class	Generic Name, CAS #	Trademark Brand Names	Generation of Pyrethrold, Dates Introduced (if Available)
Type I	Allethrin 584–79–2	Pynamin	1st generation; first synthetic pyrethroid, 1949
	Bioallethrin 584–79–2	D-trans	2nd generation, 1969: trans isomer of allethrin
	Dimethrin 70–38–2	Dimetrin	2nd generation
	Phenothrin 26002–80–2	Fenothrin, Forte, Sumithrin	2nd generation, 1973
	Resmethrin 10453–86–8	Benzofluroline, Chrysron, Crossfire, pyrethrum Premgard, Pynosect, Pyretherm, Synthrin	2nd generation, 1967; 20× strength of pyrethrum
	Bioresmethrin 28434–01–7		2nd generation, 1967; 50× strength of pyrethrum, isomer of resmethrin
	Tetramethrin 7696–12–0	Neo-Pynamin	2nd generation, 1965
	Permethrin 52645–53–1	Ambush, Biomist, Dragnet, Ectiban, Elimite, Ipitox, Ketokill, Nix, Outflank, Perigen, Permasect, Persect, Pertox, Pounce, Pramex, etc.	3rd generation, 1972; effective topical scabicide and miticide, low toxicity
	Bifenthrin 82657–04–3	Capture, Talstar	4th generation
	Prallethrin 23031–36–9	SF, Etoc	4th generation
	Imiprothrin 72963–72–5	Multicide, Pralle, Raid Ant and Roach	3rd generation, 1998
Type II	Fenvalerate 51630–58–1	Belmark, Evercide, Extrin, Fenkill, Sanmarton, Sumicidin, Sumifly, Sumipower, Sumitox, Tribute	3rd generation, 1973
	Acrinathrin 103833–18–7	Rufast	4th generation
	Cyfluthrin 68359–37–5	Baythroid, Countdown, Cylense, Laser, Tempo, Bulldock, Cyfoxylate, Eulan SP, Solfac	4th generation
	Cyhalothrin 91465–08–6	Demand, Karate, Ninja 10WP , Scimitar, Warrior	4th generation
	Cypermethrin 52315–07–8	Ammo, Barricade, CCN52, Cymbush, Cymperator, Cynoff, Cypercopal; Cyperkill, Cyrux, Demon, Flectron, KafilSuper, Ripcord, Siperin, Mustang, and Fury	4th generation
	Deltamethrin 52918–63–5	Butoflin, Butox, Crackdown, Decis, DeltaDust, DeltaGard, Deltex, K-Othrine, Striker, Suspend	4th generation
	Esfenvalerate 66230–04–4	Asana, Asana-XL, Hallmark, Sumi-alpha	4th generation
	Fenpropathrin 39515–41–8	Danitol, Herald, Meothrin, Rody	4th generation, 1989
	Flucythrinate 70124–77–5	AASTAR, Cybolt, Fluent, Payoff, Guardian, Cythrin, StockGuard	4th generation
	Fluvalinate 102851–06–9	Apistan, Klartan, Mavrik, Mavrik Aqua Flow, Spur, Taufluvalinate, and Yardex	4th generation
	Imiprothrin 72963-72-5	Pralle; Multicide (mixture with d-phenothrin)	4th generation,1998
	Tefluthrin 79538–32–2	Demand, Force, Karate, Scimitar, Evict, Fireban, Force, and Raze	4th generation
	Tralomethrin 66841–25–6	Dethmor, SAGA, Scout, Scout X-TRA, Tralex	4th generation

T syndrome (for *t*remor seen in rats) was produced by intravenous administration of pyrethrin and most (15 of 18) of the pyrethroids that did not contain a cyano group at the central ester linkage. The CS syndrome (for *c*horeoathetosis and *s*alivation) was produced by 12 of the 17 pyrethroids that had an α-cyano group at the ester linkage. The original studies delineating the T or CS method of classification did not test several new currently registered pyrethroid pesticides, and the testing methods involved intravenous or intracerebral administration, which are not relevant to human exposures.[149]

The predominant classification scheme used today is based on the structure of the pyrethroid (see Fig. 114–3), its clinical manifestations in mammalian intoxication, its actions on insect nerve preparations, and its insecticidal activity. Type I pyrethroids have a simple ester bond at the central linkage without a cyano group. Commonly used type I pyrethroids include permethrin, allethrin, tetramethrin, and fenothrin. The type II pyrethroids have a cyano group at the carbon of this ester linkage. Type II pyrethroids in common use include cypermethrin, deltamethrin, fenpropathrin, fluvalinate, and fenvalerate. The cyano group greatly enhances neurotoxicity of the type II pyrethroids in both

mammals and insects, and type II agents tend to produce the CS syndrome in test animals and are generally considered more potent and toxic than the type I pyrethroids.[51,100,124,126,149]

The development of the pyrethroids can be divided into "generations," based on efficacy and dates of introduction.[172] The first generation began in 1949, with the development of allethrin. The second generation began in 1965, with the introduction of tetramethrin. The major advance of the second generation was a dramatic increase in potency compared with the pyrethrins. The third generation, introduced in the 1970s and including fenvalerate and permethrin, were the first pyrethroids with practical agricultural use. They are more potent and more environmentally stable, with efficacious crop residues lasting 4 to 7 days. The current fourth generation includes mostly type II pyrethroids, which have even greater insecticidal activity, are photostable (do not undergo photolysis "splitting" in sunlight), have minimal volatility, and provide extended residual effectiveness for up to 10 days under optimum conditions.[100,172]

There are more than 1000 pyrethroids, of which 16 to 20 are in widespread use today.[15,41] Pyrethrins and pyrethroids are found in more than 2000 commercially available products. These insecticides have a rapid paralytic effect ("knock down") on insects. On the other hand,

most mammalian species are relatively resistant, because the pyrethrins can be rapidly detoxified by ester cleavage and oxidation.[116] Toxicity of the pyrethrins and pyrethroids is enhanced in insects by combination with microsomal enzyme inhibitors such as piperonyl butoxide (a synthetic analogue of sesamin, the methylenedioxyphenyl component of sesame oil) or *N*-octyl bicycloheptene dicarboximide.[10,120]

Permethrin, a type I pyrethroid, is used medicinally as a topical treatment for ectoparasitic conditions in humans, and when impregnated in clothing and mosquito netting as an insect repellant. It has an excellent safety profile, with less than or equal to 2% being dermally absorbed.[102] Recent comprehensive reviews have confirmed that 5% permethrin is the drug of choice for scabies treatment, with the best efficacy versus safety profile of topical treatments for scabies and lice.[133,171] There are concerns of pediculosis resistance to the 1% over-the-counter product, but comparison trials still demonstrate clinical superiority as well as safety advantage compared with lindane.[17]

West Nile virus (WNV) was first identified in the United States in 1999, and rapidly spread to most U.S. states by 2006. Outbreaks of encephalitis caused by WNV occur in the late summer and early autumn months in the United States. Although birds are the reservoirs for WNV, transmission to humans occurs via mosquito bites, and hence many states and municipalities have increased their aerial spraying in an effort to control mosquito vectors of this disease. Most spraying programs use pyrethroid insecticides because of their favorable safety profile, and their efficacy against the adult mosquito. The widespread spraying programs have increased the potential for human exposures to these xenobiotics. A CDC study of pyrethroid spraying did not reveal an increase in detectable pyrethroid metabolites in the general public living in the sprayed areas.[9] Another study of asthma surveillance showed no increases in emergency department (ED) visits because of asthma-related conditions for the periods after pyrethroid spraying.[83]

■ TOXICOKINETICS

Absorption Pyrethrins are well absorbed orally and via inhalation, but skin absorption is poor. Piperonyl butoxide is also well absorbed orally, but likewise has poor dermal penetration.[120] The oral toxicity of pyrethrins in mammals is extremely low, because they are so readily hydrolyzed into inactive compounds. Dermal toxicity is even lower, due to slow penetration and rapid metabolism.[52,116]

The pyrethroids are more stable than the natural pyrethrins, and significant systemic toxicity has occurred following ingestion.[77] An average of 35% (range 27%–57%) of orally administered cypermethrin was absorbed in human volunteers.[177] Most exposures are from dermal absorption, the rate of which varies depending on the solvent vehicle. In the same volunteer study noted above, a mean of 1.2% (range 0.85%–1.8%) of dermally applied cypermethrin in soybean oil vehicle was absorbed systemically.[177] Intradermal metabolism of pyrethroids occurs in test animals, and likely further limits systemic absorption.[15] Direct absorption of pyrethroids through the skin to the peripheral sensory nerves probably accounts for the facial paresthesias that occur in these cases, as symptoms were prominent in areas of direct contact.[28,94] Absorption probably also occurs through the oral mucosa, as noted by a large study of Chinese insecticide sprayers who frequently used their mouths to clear clogged spray nozzles. The pyrethroids are also absorbed via inhalation; however, in these same sprayers, inhalation was not found to be a clinically significant route of exposure as analyzed by breathing zone assays.[28] The pyrethroids are not volatile compounds, so inhalation is always due to powders or sprayed mists, and mucosal and pulmonary toxicity may be because of hydrocarbon solvent vehicles. Systemic absorption and resultant effects may follow massive exposures, such as occurs in enclosed spraying or other extreme conditions.

Distribution The pyrethroids and pyrethrins are lipophilic and as such are rapidly distributed to the CNS. Because they are rapidly metabolized, there is no storage or bioaccumulation, which limits chronic toxicity.[51,52]

Metabolism Natural pyrethrins are readily metabolized by mammalian microsomal enzymes, and hence are essentially nontoxic to humans. They can induce CYP3A and CYP2B isoforms in vitro in human cultured hepatocytes, but clinical significance is doubtful.[119]

The synthetic pyrethroids are readily metabolized in animals and man by hydrolases and the CYP microsomal system. The metabolites are of lower toxicity than the parent compounds.[149] Piperonyl butoxide, a P450 inhibitor, enhances the potency of pyrethrins and pyrethroids 10- to 300-fold to target insects. It is often added to insecticide preparations to ensure lethality, as the initial "knock down" effect of a pyrethroid alone is not always lethal to the insect.[51] Testing of piperonyl butoxide on antipyrine metabolism (measure of CYP enzyme function) in humans at a dose exceeding 50 times that received in all-day confined-space pesticide spraying revealed no effect on this enzyme system.[120]

Elimination There is no evidence that the pyrethroids undergo enterohepatic recirculation. Deltamethrin disappeared from the urine of exposed workers within 12 hours, and fenvalerate disappeared within 24 hours.[28] Parent compounds and metabolites of the pyrethroids are found in the urine.[126] The most commonly assayed metabolites are 3-PBA (3-phenoxybenzoic acid, a nonspecific metabolite of multiple pyrethroids), cis-DCCA (cis-3-[2,2-dichloroethenyl]-dimethyl cyclopropane carboxylic acid, a metabolite of cis-permethrin, cypermethrin, and cyfluthrin), trans-DCCA (trans-3-[2,2-dichloroethenyl]-dimethyl cyclopropane carboxylic acid, a metabolite of trans-permethrin, cypermethrin, cyfluthrin), and Br2CA (3-[2,2-dibromovinyl]-2,2-dimethylcyclopropanecarboxlic acid, a metabolite of deltamethrin). The metabolite CDCA (chrysanthemumdicarboxylic acid) is also a nonspecific metabolite of natural pyrethrin I and the synthetic pyrethroids allethrin, resmethrin, and tetramethrin.[96,158] Monitoring of these metabolites is used in population-based studies for pesticide exposures. However, a recent review revealed that commonly assayed pyrethroid metabolites also occur in the environment from natural degradation. Therefore, the detection of these metabolites in the urine may be from a subject's exposure to the parent compound or from its metabolite in the environment.

■ PATHOPHYSIOLOGY

Like DDT, pyrethrins and pyrethroids prolong the activation of the neuronal voltage-dependent Na^+ channel by binding to it in the open state, causing a prolonged depolarization, as evidenced by an extended tail current associated with squid axon voltage clamp experiments (Chaps. 8 and 22).[108,109] Indeed, DDT and pyrethrin/pyrethroids bind to the same site on insect Na^+ channels, and resistance to one class causes cross-resistance to the other class as well.[111] The voltage-sensitive sodium channel binding is responsible for the insecticidal activity, and the toxicity of the pyrethroids to nontarget species. Natural pyrethrins and type I synthetic pyrethroids induce repetitive or "burst discharges" following a single stimulus, because they hold the Na^+ channel in its open state for shorter periods. The actual amplitude of the tail current is determined by the concentration of the pyrethroids, regardless of type. Type II pyrethroids cause the Na^+ channel to remain open longer, and allow a prolonged period of depolarization of the resting membrane potential, causing a longer duration of the tail current.[152,169] Type II pyrethroids are thus more potent, and lead to significant after-potentials and eventual nerve conduction block. The mammalian voltage-dependent sodium channel, unlike the insect, has many isoforms, and may help explain the relative resistance in mammalian species. Different pyrethroids have varied effects on mammal Na^+ channels; the effects are not additive and, in fact, may be antagonistic. Structure-activity relationship is important as well, because some pyrethroid trans isomers at the ester linkage are not insecticidal, but the cis isomers are, and some isomers are insecticidal but lack mammalian toxicity because of this isomerism.[149]

Pyrethroids also have activity at certain isoforms of the voltage-sensitive neuronal calcium channel, which may explain the neurotransmitter release that occurs in pyrethroid poisoning. Additionally, pyrethroids block voltage-sensitive chloride channels in test animals, producing the salivation seen in the CS syndrome. These effects may contribute to enhanced CNS toxicity,[149] and is likely responsible for the choreoathetosis that occurs in animal models of severe type II poisonings.[125] Some studies show some interference of the type II pyrethroids with the $GABA_A$-mediated inhibitory chloride channels, but only in high concentrations.[29,107] Antagonism of the $GABA_A$-chloride channels likely has a significant role in human pyrethroid exposures, and probably contributes to the seizures seen after severe poisoning by type II agents.[107,125] The pyrethroids may also act at the peripheral benzodiazepine receptor, as evidenced by decreased salivation in test animals when this receptor is blocked. The clinical significance of this is currently unknown.[15]

Natural pyrethrins and type I pyrethroids have a negative temperature coefficient, similar to DDT, and are more selectively toxic to non–warm-blooded target species. Type II pyrethroids have a positive temperature coefficient, which makes them more insecticidal at higher ambient temperatures, and thus more useful in agricultural applications.[172] However, this may also at least partly explain the greater mammalian toxicity of type II pyrethroids as compared to type I.[107]

■ CLINICAL MANIFESTATIONS

Pyrethrum probably has an LD_{50} (median lethal dose in 50% of test subjects) of well over 1 g/kg in man, as extrapolated from animal data. Most cases of toxicity associated with the pyrethrins are the result of allergic reactions.[116,173] Theoretically, those at highest risk for allergic reactions would be patients who are sensitive to ragweed pollen, 50% of whom may cross-react with chrysanthemums (ragweed and chrysanthemum are in the same botanical family). These allergic reactions have been postulated to be due to residual natural components present in the extracts.[126] However, recent reviews have cast some doubt on this explanation. First, there have been only four cases of life-threatening respiratory reactions reported in the literature, three of which were in known asthmatics.[120] Second, the presence of residual natural proteins is unlikely, as the purification procedures would allow little, if any, residuals. Third, most reported cases of contact urticaria have been erroneously classified as type I hypersensitivity reactions.[67] The synthetic pyrethroids can cause histamine release in vitro,[49] but generally do not induce IgE-mediated allergic reactions.[17]

In animals, type I pyrethroid poisoning most closely resembles that of DDT, with extensive tremors, twitching, increased metabolic rate, and hyperthermia. Excluding the rare possibility of skin irritation or allergy, the type I pyrethroids are unlikely to cause systemic toxicity in humans. Experimentally, pyrethroids have greater than 1000-fold more affinity for insect Na^+ channels than for mammals, explaining their low toxicity in higher life forms. This selectivity, along with the negative temperature coefficient and slower insect metabolism, combines to make the type I pyrethroids approximately 15,000 times more toxic in insects than in humans.[109] The type II pyrethroids are generally more potent and cause profuse salivation, ataxia, coarse tremor, choreoathetosis, and seizures in animals. In humans, type II pyrethroids cause paresthesias (secondary to sodium channel effects in cutaneous

sensory nerves after topical exposure),[94] salivation, nausea, vomiting, dizziness, fasciculations, altered mental status, coma, seizures, and acute lung injury.[77] A review of more than 500 cases of acute pyrethroid poisoning from China highlights some similar manifestations between a massive acute type II pyrethroid overdose and an OP compound overdose. However, serious atropine toxicity and death have resulted when poisoning from a type II pyrethroid was mistaken for an OP compound, and treatment was directed at these seemingly cholinergic signs.[77] Features such as acute lung injury may be because of solvents and surfactants present in the agricultural products.[10] Although the type II pyrethroids contain a cyanide moiety, cyanide poisoning does not occur, and cyanide antidotal therapy is not indicated.

Most significant unintentional exposures are dermal, especially in occupational settings, and local symptoms predominate in the majority of these cases. Systemic effects from insecticidal sprayings have been reported from wind drift or inappropriate handling, and the more potent type II pyrethroids predominate in both case reports. An exposure of workers possibly affected by wind drift from a mixture of 32 oz of the type II pyrethroid cyfluthrin mixed with 18.5 gal of petroleum oil and 1800 gal water was reported in California in 2006. Spraying occurred in a citrus grove, and 23 female workers in an adjacent vineyard were possibly exposed. These workers complained of a "chemical" odor, and felt ill with headaches, nausea, eye irritation, weakness, anxiety, and shortness of breath. They were all evaluated in local EDs and discharged home. Despite the fact that no cyfluthrin was detected on these workers' clothing or on foliage in the field where they were alleged to have been exposed, the report concluded that cyfluthrin was the cause; no estimate of the contribution of the petroleum vehicle to the symptoms was posited.[25] The predominant feature after significant cutaneous exposures is local paresthesias in the areas of skin contact, due to Na^+-channel effects on cutaneous sensory nerves. Local skin irritation occurs in up to 10% of workers spraying pyrethroid insecticides, but rarely occurs after medicinal use of the pyrethroid creams and shampoos. Ocular contact causes more severe symptoms, including immediate pain, lacrimation, photophobia, and conjunctivitis.[15]

Intentional ingestions represent the most serious exposures, because of the higher doses involved and the greater exposures to vehicles and solvents. However, a study of 48 cases of permethrin/xylene/surfactant mixtures (38 were suicidal ingestions) revealed that mild GI signs and symptoms predominated (73%: sore throat, mouth ulcerations, dysphagia, epigastric pain, vomiting). Pulmonary signs and symptoms were documented in 29%, and eight patients (including one death) had aspiration pneumonitis. Thirty-three percent had CNS symptoms including confusion, coma, and seizures. The involvement of the CNS and lungs were less common, but clinically more significant.[180] The relative contributions of the xylene and surfactant were likely responsible for much of the GI and pulmonary effects, though they were not discussed in the report.

■ CHRONIC EXPOSURES

Since the pyrethroids are rapidly metabolized and are not biopersistent, they have not been shown to cause cumulative toxicity. A single case of motor neuron disease resulted from heavy daily inhalation exposure to pyrethroid mixtures in a confined space for 3 years, which resolved after exposure ceased.[50] Some investigators have expressed concerns regarding possible neurotoxicity of the pyrethroids. However, a recent review noted that regulatory studies in multiple species have shown no evidence supporting gross neurodevelopmental toxicity or adult neuronal loss in man.[125] In Germany, numerous civil lawsuits allege multiple chemical sensitivity (MCS) is caused by pyrethroid exposures. Scientific study of this phenomenon yields no scientific data to support this contention,[13] but the controversy is fueled by civil litigation and

sensationalized by popular media, subsequently causing public fear,[6] not unlike the "toxic mold" concerns in the United States.[26,181]

■ TREATMENT

Initial treatment should be directed toward skin decontamination, as most poisonings occur from exposures by this route. Patients with large oral ingestions of a type II pyrethroid should be treated with a single standard dose of AC, provided the diluent of the pyrethroid does not contain a petroleum solvent. Contact dermatitis and acute systemic allergic reactions should be treated in the usual manner, using histamine blockers, corticosteroids, and β-adrenergic agonists as clinically indicated.

Treatment of systemic toxicity is entirely supportive and symptomatic, because there is no specific antidote. Benzodiazepines should be used for tremor and seizures. Topical vitamin E oil (dl-α-tocopherol) is especially effective in preventing and treating the cutaneous paresthesias due to topical pyrethroid exposures.[15,126]

INSECT REPELLENTS

Mosquitoes transmit more diseases to humans than any other biting insect. Worldwide, more than 700 million people are infected yearly by mosquito bites that transmit such diseases as viral encephalitis, yellow fever, dengue fever, bancroftian filariasis, and epidemic polyarthritis. Malaria alone is responsible for three million deaths annually.[63] In the United States, eight people died from WNV in New York City in 1999, and by January 2005 the virus, carried by mosquitoes from infected birds, had spread to all lower 48 states. By 2006, over 3000 cases of WNV infection were reported to the CDC. Since then, reducing the incidence of mosquito bites has become a major public health concern, not just control of an annoying insect, although utilization rates remain low in the US population.[92] Mosquito repellants are important public health tools, and DEET has been the time-tested primary tool for the past 5 decades. However, much controversy continues to surround DEET despite a remarkable safety profile with over a half-century of global use by billions of people. A growing trend in the United States and many Western cultures has been a chemophobia against synthetic products like DEET. Many people favor plant-based "natural" or "organic" repellents, paralleling the increasing consumer preference for natural or organic foods. Several xenobiotics have been proposed, but thus far few have been shown by objective blinded studies to even approach the efficacy of DEET, much less surpass it. Numerous comprehensive reviews of the subject have demonstrated the clear superiority of DEET in most cases, and DEET remains the insect repellent standard by which all others are measured (Table 114–4).

■ DEET

The topical insect repellent, *N,N*-diethyl-3-methylbenzamide (DEET, former nomenclature *N,N*-diethyl-*meta*-toluamide), was patented by the US Army in 1946, and commercially marketed in the United States since 1956. Currently, it is used worldwide by more than 200 million persons annually. The EPA estimates that 38% of the US population uses DEET each year. Despite the current search for alternatives, DEET is still the most effective insect repellant available, and that with the most clinical toxicity information.[64,65]

DEET can be purchased without prescription in concentrations ranging from 5% to 100%, and in multiple formulations of solutions, creams, lotions, gels, and aerosol sprays. DEET formulations can feel greasy or sticky, and can dissolve or damage some plastics (eyeglass frames, watches) and synthetic fabrics.

TABLE 114–4. Comparative Efficacy and Toxicity of Commonly Available Insect Repellents

Insect Repellent	EPA Approval	EPA Toxicity Rating[a]	Efficacy in Laboratory and Field Studies[b]	Notes
DEET	1957 (1980)	III	Most efficacious in laboratory and field studies; protective against ticks and mosquitoes	>50 years of experience, billions of users 10%–30% soln: safe, effective when used as directed
Picaridin	2001	IV	20% solution: Laboratory: Equivalent to DEET Field: Equivalent to DEET	All studies done on 20% picaridin; no studies done with 7% or 15 % (US formulas) Recommended by CDC as a DEET alternative[65]
IR3535	1999	IV	Laboratory: Inferior to DEET[65] Field: None available	Recommended by CDC as a DEET alternative[65]
Oil of lemon eucalyptus (p-menthane diol)	2000	IV (I, ocular)	Equivalent to DEET for mosquitoes; not tested for tick bite prevention	Recommended by CDC as a DEET alternative[65]
BioUD	2007	IV	Laboratory: Equivalent to 7% DEET Field: Equal to 25% and 30% DEET	Studies performed by patent holders and developers IR, no impartial evidence
Citronella oil	1948	IV	Laboratory: ineffective[56]	Candles only provide some repellency when within 1 meter

[a] EPA Acute Toxicity Ratings: Category I = very highly or highly toxic; Category II = moderately toxic; Category III = slightly toxic; Category IV = practically nontoxic.

[b] Lab tests: arm in cage studies for mosquito repellency; field studies: actual biting or tick attachment assays in natural conditions.

Mosquitoes are attracted to their hosts by temperature and chemical attractants, principally CO_2 and lactate. The mechanism by which DEET repels insects was thought to be because of some interference with the mosquito's chemoreceptors, rendering them unable to detect lactic acid and CO_2.[65,121] However, recent novel work has demonstrated that DEET does not simply "jam the signal"; rather, DEET is actually detected by mosquitoes' olfactory receptors and repels them independently of whether the normal physical or chemical attractants are present.[160]

Toxicokinetics DEET is extensively absorbed via the GI tract. Skin absorption is significant, depending on the vehicle and the concentration. It does not bind to stratum corneum, and only 0.08% or less of a dose remains in the skin 8 hours after application.[121] DEET is lipophilic, and skin absorption usually occurs within 2 hours, although it is eliminated from serum within 4 hours. The volume of distribution is large, in the range of 2.7 to 6.21 L/kg in animal studies. DEET is extensively metabolized by oxidation and hydroxylation by the hepatic microsomal enzymes, primarily by the isozymes CYP2B6, -3A4, -2C19, and -2A6.[167] DEET is excreted in the urine within 12 hours, mainly as metabolites, with 15% or less appearing as the parent compound.[64,121]

DEET has been extensively reviewed in terms of acute and chronic toxicity. It has been found safe for use in pregnant and lactating women[89]; it was found to have no specific target organ toxicity or oncogenicity in any observed rat, mouse, or dog studies[147]; and chronic DEET exposure together with other insecticides showed no increased cancer risks.[115]

Pathophysiology The exact mechanism of DEET toxicity is unknown. Recent reviews of adverse reactions to DEET have noted a total 26 reported cases with major morbidity including encephalopathy, ataxia, convulsions, respiratory failure, hypotension, anaphylaxis, or death, particularly after ingestion or dermal exposure to large amounts.[23,64,113,114,163,168] These primarily neurologic adverse reactions occurred mainly in children, and most involved prolonged use and

excessive dosing beyond what is currently recommended. One fatal case involved a child who was known to be heterozygous for ornithine carbamoyl transferase (OCT) deficiency, and death was because of a Reyelike syndrome with hyperammonemia. This child had experienced prior episodes of hyperammonemia unrelated to DEET use, and DEET does not appear to affect, or be affected by, OCT activity in humans.[114] There is currently no evidence that enzyme polymorphism affects DEET metabolism or influences individual susceptibility to toxicity.

Although single, large, acute oral doses (1–3 g/kg) in rats produced seizures and CNS damage,[145] smaller, acute doses (500 mg/kg and less) and chronic multigenerational dosing in another rat study produced no obvious toxicity.[146] Teratogenicity studies in rats and rabbits failed to demonstrate toxicity except at the highest doses,[147,179] and DEET was not found to be carcinogenic.[121,147] In view of the billions of applications, the number of reports of toxicity appears exceedingly small, and suggests a remarkably wide margin of safety.[64,73,113,114,130,159]

Clinical Manifestations Most calls to poison centers regarding DEET exposures involve minor or no symptoms, and symptomatic exposures occur primarily when DEET is sprayed in the eyes or inhaled.[168] Except for suicidal ingestions, most serious reactions consist of seizures in children overexposed via the dermal route; in fact, some of these cannot be definitely attributed to DEET.[73,114] Most symptoms resolve without treatment and the majority of patients with serious toxicity recover fully with supportive care.

Treatment DEET exposures are treated with supportive care aimed at the primarily neurologic symptoms. In cases of dermal exposures skin decontamination should be a priority to prevent further absorption. Patients with intentional oral ingestions should receive a single dose of AC if clinically indicated.

An extensive review of the safety risk of DEET repellent use confirms its safe use for all populations when used according to labeling guidelines.[159] Despite its good safety profile, overuse of DEET must be

avoided. The American Academy of Pediatrics (AAP) recently revised its recommendations for insect repellent use because of the emergence of WNV infections (prior recommendations were for use of products with DEET less than 10%).[148] They found that DEET-containing products are the most effective mosquito repellents available, and are also effective against a variety of other insects, including ticks. Insect repellants with a DEET concentration from 10% to 30% (the maximum recommended for children) appear to be equally safe when used according to the directions on the product labels. The safety of DEET does not appear to relate to differences in these concentrations, and higher concentrations have longer durations of effect.[1] As indicated in the AAP handbook, repellents are not recommended for children younger than 2 months of age.[2]

The higher concentrations prolong the repellency period, but there is a plateau at about 50% DEET concentration, and about 6 hours may be the maximum protection time from any single application. Newer longer-acting DEET formulations in lipids or polymers cause the DEET to evaporate more slowly, which affords protection for greater than 6 hours and also less systemic absorption.[86,142] Since mosquitoes are most active for a few hours preceding and following dusk, DEET should be promptly washed off the child's skin when protection is no longer needed. Soaking the skin is not more effective and may contribute to toxicity. DEET should be applied only to exposed skin. Use on abraded skin or skin with rashes should be avoided. Care should be taken to avoid exposure to eyes and sensitive skin areas. Avoid use on children's hands, so that the child does not wipe on eyes, mouth, genitalia, and so on. Adults should apply DEET to their own hands and then wipe onto the child's face, rather than spraying onto a child's face.

DEET combination products that include sunscreen should not be used, since it has been shown that these combination products mutually enhance the percutaneous absorption of each component in both a porcine in vivo study[84] and an in vitro mouse skin model.[134] Since mosquitoes are most active near dusk, there is clearly no need for the sunscreen component. Other options for protection include mechanical means, such as mosquito netting, as well as permethrin-impregnated clothing for tick prevention.

■ NEWER INSECT REPELLENTS

The efficacy of any xenobiotic, treatment, or repellent is directly related to compliance with the treatment. Despite its demonstrated efficacy and safety, many people view chemical insect repellents such as DEET as potentially harmful and avoid their use. Several survey results in the United States and Canada revealed that 56% of people believe repellents are likely to be harmful to children, and 45% believed insect repellents are likely to sicken adults.[175] This has led to an intense search for effective alternatives to DEET-based repellents.

Picaridin Picaridin (chemical name 2-(2-hydroxyethyl)-1-piperidinecarboxylic acid 1-methylpropyl ester) is a piperidine derivative and has low acute oral, dermal, and inhalation toxicity. The EPA classifies it as Toxicity Category IV for acute inhalation toxicity and primary dermal irritation, the lowest rating available, but category III for oral ingestion. It is not a dermal sensitizer, and no developmental toxicity was observed in chronic animal feeding studies. It was also not shown to be mutagenic in a battery of tests, and is not considered carcinogenic.[58] Picaridin is nearly as efficacious as DEET in comparison studies of the 20% solution used in Australia and Europe, but unfortunately no studies have compared the 7% formulation marketed in the United States (Cutter Advanced™; Avon Skin So Soft with Picaridin™). Since duration of protection is generally related to concentrations of the repellent (clearly shown with DEET), it would

be reasonable to assume the 7% United States formula would not have as long a duration of effect.

Oil of Lemon Eucalyptus Oil of lemon eucalyptus occurs naturally in the lemon eucalyptus plant (*Eucalyptus citriodora*, also known as *Corymbia citriodor).* The natural oil can be extracted from the eucalyptus leaves and twigs; commercially the active ingredient, *p*-menthane-3,8-diol (PMD), is chemically synthesized, and is structurally similar to menthol. In its pure form, it is a solid at room temperature, and has a faint mintlike odor. PMD is placed into Toxicity Category IV for acute oral toxicity, dermal toxicity, and skin irritation, and Toxicity Category II for the end-use product for eye irritation. It is not a skin sensitizer. The EPA has determined that there is reasonable certainty of no harm to the general population or subpopulations, including infants and children, as the result of the use of PMD to formulate insect repellents.[59]

IR3535™ (CAS #52304-36-6) IR3535 (3-[N-butyl-N-acetyl]-aminopropionic acid, ethyl ester) is a substituted β amino acid structurally similar to naturally occurring β-alanine. The US EPA has classified IR3535 as a biochemical, based on the fact that it is functionally identical to naturally occurring β-alanine, and both repel insects, the basic molecular structure is identical, the end groups are not likely to contribute to toxicity, and it acts to control the target pest via a nontoxic mode of action. It is a liquid that contains 98% active ingredient and 2% inert ingredients. It has been used as an insect repellent in Europe for over 20 years with no substantial adverse effects. Toxicity tests show that IR3535 is not harmful when ingested, inhaled, or used on skin.[54,55]

2-Undecanone A newly formulated natural repellent, 2-undecanone, was approved for use as an insect repellant by the EPA in 2007, and is known by the brand name of BioUD™. Its active ingredient is derived from the wild tomato plant, *Lycopersicon hirsutum* Dunal f. *glabratum* C. H. Mull.[175] 2-Undecanone (also known as methyl nonyl ketone) was originally registered in 1966 as a dog and cat repellent/training aid and an iris borer deterrent. It received EPA approval as a topical insect repellent in 2007. The EPA Reregistration Eligibility Decision (RED) documents that in studies using laboratory animals, methyl nonyl ketone exhibited no toxicity via the oral and inhalation routes and was placed in Toxicity Category IV. Methyl nonyl ketone has slight dermal toxicity (Toxicity Category III) resulting in eye and dermal irritation as well as skin sensitization. Since it has a long history of safe use, is from a natural source, and is an approved food additive, it is considered nontoxic. Methyl nonyl ketone is currently found in only one insect repellent in the form of both a lotion and a spray.[57] The manufacturer lists an unpublished study on its website of a field test showing protection from mosquito bites that surpassed that of a 30% DEET product at 6 hours, and was equivalent at 4 hours.[78] A recent study done by the inventors and patent holders showed it was only as efficacious as lower DEET concentration products in laboratory arm-in-cage trials, but field trials revealed efficacy equivalent to 25% to 30% DEET formulations.[175]

Oil of Citronella Oil of citronella has been used for over 50 years as an insect repellent and as an animal repellent in candles and topical skin products. These products, which have little efficacy, are not expected to cause harm to humans, pets, or the environment when used according to the label.[56]

INSECTICIDES, DEET, AND THE GULF WAR SYNDROME

During operations Desert Shield/Desert Storm in 1991, nearly 700,000 Americans served in the Persian Gulf. Some returning troops began reporting a variety of symptoms and illnesses they attributed initially to exposure to burning oil well fires in Kuwait. Approximately 10% of

these veterans have registered with the Persian Gulf Registry Health Examination Program. This program was initiated to study whether veterans were experiencing adverse health effects related to exposures encountered in the Persian Gulf War. The most common symptoms are largely nonspecific and multiorgan and include fatigue, rashes, headache, muscle aches, memory problems, dyspnea, insomnia, and GI symptoms. Multiple studies and expert panels have studied these veterans in an attempt to identify a causative xenobiotic responsible for this "Persian Gulf syndrome," now more accurately termed "Gulf War illness"(GWI).

Some investigators have suggested that combinations of DEET, permethrin, and pyridostigmine have additive neurotoxic effects and could be a cause of the symptoms.[93] Although there is laboratory evidence of synergistic neurotoxicity when large doses of these xenobiotics are gavaged or injected in test animals,[4,99] it is difficult to apply this methodology to human experience in the Gulf War. The exposures in the veterans were primarily dermal, and concomitant use at toxic dosages for any sustained time period was thought to be unlikely or a rare occurrence. Given the diversity and multisystem nature of symptoms experienced by these veterans, it has generally been felt that it was unlikely that use of these xenobiotics is responsible for the symptom complexes reported.[105] The newest report by the Research Advisory Committee (discussed below) chronicled many interviews with exposed soldiers, revealing that insecticide use and exposures were more intense than originally imagined, and in many ground troops were clearly excessive.

The Institute of Medicine Gulf War Committee initially evaluated the association of this GWI and multiple exposures. Six comprehensive review volumes have been authored by the Institute of Medicine (IOM) and published by the National Academy of Science from 2000 to 2008, along with three updates; the two most recent were published in July 2008. The committee found that although veterans of the first Gulf War report significantly more symptoms of illness than soldiers of the same period who were not deployed, studies have found no cluster of symptoms that constitute a syndrome unique to Gulf War veterans.[38,164] Moreover, there was evidence of an association with stress and many of the disorders and symptom complexes experienced by these veterans.[39] Earlier reports revealed that there was inadequate/insufficient evidence to link exposure to pyridostigmine and long-term health effects.[35] Extensive review has consistently shown that there is not enough evidence to link long-term health problems with exposure to depleted uranium,[33] or with exposure to low doses of sarin.[34] There was an association of exposure to combustion products and certain cancers such as lung, laryngeal, and bladder.[37] One volume found some limited evidence to link neurobehavioral effects with exposure to certain solvents and OP insecticides, but in the majority of cases, there was not enough evidence to determine whether there is an association between exposure and certain health effects.[36]

In November 2008, the Veteran's Administration's Research Advisory Committee on Gulf War Veterans' Illnesses published a comprehensive review of all of the research and epidemiology to date. This committee concluded that (1) the GWI was a complex syndrome, and that the inability to define a conventional diagnostic category or disease was the reason this disorder has heretofore *not* been recognized as a true illness; (2) despite a long safety history of pyridostigmine in myasthenia gravis treatment, use of the drug was associated with development of GWI; concomitant exposures to certain OP and carbamate insecticides was also causally linked; (3) a strong case can be made for a causal relationship between these two exposure types and GWI; and (4) the symptoms were not due to posttraumatic stress disorder (PTSD). The committee sent their report along to the IOM for expert review and analysis in November 2008.[127] Such a divergent conclusion made 17 years later and based largely on epidemiologic studies of exposure

intensities raises the question of recall bias in those most affected. The controversy over this symptom complex will likely continue.

Despite the continued controversy, the prevalence of GWI complex among the veterans of that conflict is staggering. Estimates range that from one in seven to greater than 25% of US veterans of the war have some symptoms, and in the United Kingdom, 17% of Gulf War veterans have symptoms of "Gulf War syndrome." Similar postwar syndromes consisting of chronic pain, fatigue, depression, and other symptoms have plagued returning soldiers after every war in the 20th century. These syndromes have gone by a variety of names such as Da Costa syndrome, irritable heart, shell shock, neurocirculatory asthenia, and battle fatigue. After more than a decade of study, using more than $340 million of federally funded medical research, the cause of this medically unexplained syndrome continues to be investigated, and remains in dispute. Although Gulf War veterans have been shown to have an increased incidence of multisystem complaints such as multiple chemical sensitivity, chronic fatigue syndrome, and fibromyalgia, many investigators continue to feel that GWI likely represents, at least in part, a manifestation of PTSD.[53]

LEGAL STANDARDS FOR AN INSECTICIDE LABEL

The Federal Insecticide, Fungicide, and Rodenticide Act of 1962 (Table 108–1) established criteria for a "signal word" on an insecticide label, which implies the degree of toxicity based on an oral LD_{50}. Also, the label on the original container of these products is usually instructive and should always be brought to the medical facility (Chap. 108).

SUMMARY

The ideal insecticide is one that has low acute toxicity to humans and nontarget species (pyrethroids, DDT), is inexpensive to apply and produce (OP compounds, DDT), and would have no environmental persistence or bioaccumulation (OP compounds, pyrethroids). With research and development coupled with mass production techniques, some of the newer pyrethroids may come closer to this ideal than those most commonly used today. Until that goal is achieved, however, the neurotoxic organic chlorines will continue to be used. In January 2000, the Associated Press reported that 21 people in Iran were poisoned, and three died when DDT powder was inadvertently used in food preparation instead of flour, underscoring the continued clinical importance of organochlorine exposures in some areas of the world. Although organic chlorine pesticides are banned in North America and Europe, they are still widely used elsewhere, and will have important implications for toxicologists for some time to come.

CHAPTER 115
HERBICIDES

Darren M. Roberts

An herbicide is any chemical that regulates the growth of a plant, which encompasses a large number of xenobiotics of varying characteristics. Herbicides are used around the world for the destruction of plants in the home environment and also in agriculture where weeds are particularly targeted. Poisoning may occur following acute (intentional or unintentional poisoning) or chronic (such as occupational) exposures. Depending on the herbicide and the characteristics of the exposure, this may lead to clinically significant poisoning, including death.

Not all herbicide exposures are clinically significant. In developed countries, most acute herbicide exposures are unintentional and the majority of patients do not require admission to hospital. The National Poisoning and Exposure Database of the American Association of Poison Control Centers describes approximately 10,000 herbicide exposures each year. Over the last 12 years, there were only approximately five deaths per year and 20 patients per year with clinical outcomes categorized as "major" that were attributed to herbicide poisoning (see Chap. 135). Most deaths were due to paraquat and diquat, although more recently glyphosate and phenoxy acid compounds are more commonly implicated. Cases of severe poisoning that required hospitalization usually occurred following intentional self-poisoning. Significant toxicity may also occur with unintentional (eg, storage of a pesticide in food or drink containers) or criminal exposures.

This chapter focuses on the most widely used herbicides and also those associated with significant clinical toxicity. In particular, it discusses risk assessment and the management of patients with a history of acute herbicide poisoning.

HISTORY, CLASSIFICATION, AND EPIDEMIOLOGY

■ HISTORY

Prior to the 1940s, the main method of weed control and field clearance was manual labor, which was time consuming and expensive. A range of xenobiotics was tested including metals and inorganic compounds; however, their efficacy was limited. The first herbicide marketed was 2,4-dichlorphenoxyacetic acid during the 1940s, followed by other phenoxy acid compounds. Paraquat was initially marketed in the early 1960s and was followed by the benzoic acid compound dicamba later that decade. Since then there has been a progressive increase in the use and development of herbicides, which remains an active area of research. Increasing numbers of herbicide formulations are marketed every year including a number of novel structural compounds for which clinical toxicology data are unavailable. Hundreds of xenobiotics are classified as herbicides and a much larger number of commercial preparations are marketed. Some commercial preparations contain more than one herbicide to improve plant destruction. From another perspective, crops are being developed that are resistant to particular herbicides to maximize the selective destruction of weeds without reducing crop production.

Herbicides are the most widely sold pesticides in the world, accounting for more than 35% of the total world pesticide market and for more than 45% of the pesticide market in the United States. Home and garden domestic use accounts for 13% of the overall herbicide use in the United States, while the remainder is consumed by agriculture, government (for example, vegetation control on highways and railways), and industry. Sixteen herbicides are among the top 25 used pesticides in the United States and four herbicides are ranked in the top five: glyphosate is most widely used, followed by atrazine, acetochlor, and 2,4-dichlorophenoxyacetic acid. There was a decline in the overall total quantity of herbicides used worldwide between 1982 and 1987, which has since stabilized. In contrast, the domestic use of herbicides consistently increased between 1997 and 2001.[60]

■ CLASSIFICATION

Hundreds of xenobiotics are known to have herbicidal activity and they may be subclassified by a number of methods. Most commonly they are categorized in terms of their spectrum of activity (selective or nonselective), chemical structure, mechanism of action (contact herbicides or hormone dysregulators), use (preemergence or postemergence), or their toxicity to rats. Sometimes xenobiotics are classified as plant growth regulators rather than herbicides, but in this chapter all are considered to be herbicides.

Table 115–1 lists the extensive range of herbicides in current use.[56] By convention, they are subclassified according to their chemical class and their World Health Organization (WHO) hazard classification. Unfortunately, the utility of these (or any other) methods of classification has not been proven for predicting the hazard to humans with self-poisoning.

The WHO categorizes pesticides by their LD_{50}, which is the dose of pesticide required to kill 50% of test animals, usually rats, within a certain number of days in the absence of treatment. The WHO does not address morbidity or the effect of treatments. Further, the LD_{50} varies among studies in the same type of animal, and in particular among different species. For example, in the case of paraquat the LD_{50} in rats, monkeys, and guinea pigs was observed to be approximately 125 mg/kg, 50 mg/kg, and 25 mg/kg, respectively.[21,84] Therefore, extrapolation of the rat LD_{50} to estimate the toxicity in humans appears to be an imprecise approach to risk assessment. This variability was confirmed in preliminary studies with pesticide self-poisoning.[31,102] It should be emphasized that the intended application of this hazard classification is to achieve risk assessment for occupational exposures to operators who use the product as intended. Furthermore, the LD_{50} is determined by using pure herbicides, whereas proprietary formulations that result in poisoning also contain coformulants, which may have a significant influence on toxicity.

Herbicides within a single chemical class can manifest different clinical toxicity; for example, glyphosate is an organic phosphorus compound that does not inhibit acetyl cholinesterase. The mechanism of action of herbicides in plants usually differs from the mechanism of toxicity in humans; indeed, for some herbicides the mechanism of human toxicity is poorly described.

■ CONTRIBUTION OF COFORMULANTS

Commercial herbicides are generally identified by their active ingredients, but proprietary formulations almost always contain coformulants that may contribute to clinical toxicity. Hydrocarbon-based solvents and surfactants improve the contact of the herbicide with the plant and enhance penetration. Coformulants are generally considered "inactive" or "inert" because they lack herbicidal activity; however, increasingly their contribution to the toxicity is being realized.

The most widely discussed example of a coformulant dominating the toxicity of an herbicide product is that of glyphosate-containing

TABLE 115–1. Characteristics of the Major Herbicides, Categorized By Chemical Class and WHO Hazard Classification

Chemical Class[a]	Applications, Usage Data, and Mechanism of Action in Plants, If Known[b]	WHO Hazard Class[c]	Compounds Included	Clinical Effects, Potential Specific Treatments and Supportive Care
Alcohol and aldehyde	Broad-spectrum contact herbicide	Ib	Allyl alcohol (2-propen-1-ol) and acrolein (the metabolite of allyl alcohol)	Local irritation, cardiotoxicity, pulmonary edema, and death. Administer sulfhydryl-donors such as acetylcysteine or mesna.
Amide Fig. 115–1	Selective for grasses pre- or postemergence In 2001, acetochlor, propanil, alachlor, metolachlor, and dimethenamid are listed in the top 25 pesticides used in the United States. Propanil was among the top 10 pesticides used in the domestic sector Multiple mechanisms of action, including inhibition of photosynthesis at photosystem II and/or inhibition of dihydropteroate synthase and/or inhibition of cell division through inhibition of the synthesis of very-long-chain fatty acids and/or inhibition of acetolactate synthase (interferes with branched amino acid synthesis) and/or inhibition of microtubule assembly Some compounds may also be included in other chemical classes, including asulam (carbamate); oryzalin (dinitroaniline); clomeprop (phenoxy); diclosulam, flumetsulam, and metosulam (triazolopyrimidines)	III U	*Anilide derivatives*: Acetochlor, alachlor, dimethachlor, flufenacet, mefluidide, metolachlor, propachlor, propanil (DCPA) *Nonanilide derivatives*: Chlorthiamid, diphenamid *Anilide derivatives*: Butachlor, clomeprop, diclosulam, flamprop, flumetsulam, metosulam, mefenacet, metazachlor, pentanochlor, pretilachlor *Nonanilide derivatives*: Asulam, bromobutide, dimethenamid, isoxaben, napropamide,oryzalin, propyzamide, tebutam	See text for anilide derivatives. There are limited human data about the nonanilide derivatives. Lethargy or sedation preceded death in animals exposed to chlorthiamid. Behavioral changes, ataxia, and prostration were noted in animals exposed to diphenamid. Drowsiness and tachypnea were noted in goats following acute poisoning with napropamide
Aromatic acid	In 2001, dicamba was one of the top 25 pesticides used in the United States and the 7th most used in the domestic sector Dicamba is commonly coformulated with phenoxyacetic acid compounds Inhibits acetolactate synthase /or inhibition of microtubule assembly and/or indole acetic acid-like (synthetic auxins)	III U	Dicamba, 2,3,6-trichlorobenzoic acid (2,3,6-TBA) Bispyribac, chloramben (amiben), chlorthal, clopyralid, pyriminobac, pyrithiobac, quinclorac, quinmerac	Bispyribac causes gastrointestinal irritation, sedation, mortality (2.7%). Human data are limited for all other compounds, particularly single-agent exposures. In animals, myotonia, dyspnea, and death are reported with dicamba and 2,3,6-TBA poisoning
Arsenical	Unknown	III	Dimethylarsinic acid (cacodylic acid), methylarsonic acid (MAA)	See Chap. 88
Benzothiazole	Indole acetic acid-like (synthetic auxins) and/or inhibits photosynthesis at photosystem II	U	Benazolin, methabenzthiazuron	Limited human data
Bipyridyl	Nonselective, postemergence, contact herbicide Photosystem-I-electron diversion These compounds are part of a larger group of quaternary ammonium herbicides, including difenzoquat, which is also a pyrazole compounds (see below)	II	Paraquat, diquat	See text for paraquat and diquat

(*Continued*)

TABLE 115–1. Characteristics of the Major Herbicides, Categorized By Chemical Class and WHO Hazard Classification (*Continued*)

Chemical Class[a]	Applications, Usage Data, and Mechanism of Action in Plants, If Known[b]	WHO Hazard Class[c]	Compounds Included	Clinical Effects, Potential Specific Treatments and Supportive Care
Carbanilate	Inhibits photosynthesis at photosystem II and/or inhibits mitosis or microtubule organization	U	Carbetamide, desmedipham, phenmedipham, propham	Limited human data
Cyclohexane oxime	Postemergence, selective for grasses	III	Butroxydim, sethoxydim, tralkoxydim	Limited human data
	Inhibits acetyl-CoA carboxylase (lipid biosynthesis inhibitors)	U	Alloxydim, cycloxydim, cyhalofop	
Dinitroaniline	Preemergence, selective for grasses	III	Fluchloralin, pendimethalin	Pendimethalin induces mild clinical toxicity in most cases, but seizures and death due to respiratory failure are reported. Limited human data for the others
	In 2001, trifluralin and pendimethalin were among the top 25 pesticides used in the United States overall, while benfluralin and pendimethalin were among the top 10 used in the domestic sector	U	Benfluralin (benefin), butralin, dinitramine, ethalfluralin, oryzalin, prodiamine, trifluralin	Aniline metabolites are reported from trifluralin and oryzalin, which may induce methemoglobinemia and hemolysis with prolonged exposures. In rats, fluchloralin induces hyperexcitability, tremors, and convulsions prior to death. Many of these compounds are poorly absorbed and may be subject to enterohepatic recycling. Agitation, trembling, and fatigue occur in rats following lethal doses of trifluralin
	Inhibits microtubule assembly			
Diphenyl ether	Postemergence (particularly broad leaves)	III	Acifluorfen, fluoroglycofen	Limited human data
	Contact herbicide, inhibits protoporphyrinogen oxidase, and/or inhibits carotenoid biosynthesis	U	Aclonifen, bifenox, chlomethoxyfen, oxyfluorfen	
	Aclonifen is also an amine compound			
Halogenated aliphatic	Inhibit lipid synthesis	U	Dalapon, fluopropanate	Limited human data
Imidazolinone	Inhibit acetolactate synthase, interfering with branched amino acid synthesis	U	Imazamethabenz, imazapyr, imazaquin Imazethapyr	Limited human data. In a small case series, imazapyr induced sedation, respiratory distress, metabolic acidosis, hypotension, and hepatorenal dysfunction
Inorganic	Nonselective	III	Sodium chlorate	Nausea, vomiting, diarrhea, metabolic acidosis, renal failure, hemolysis, methemoglobinemia, rhabdomyolysis, and disseminated intravascular coagulation. Treatment includes hemodialysis, erythrocyte, and plasma transfusion. Methemoglobinemia is unresponsive to methylene blue, but sodium thiosulphate has been trialed
Nitrile	Pre-emergence, selective for grasses.	U	Ammonium sulfamate	Limited human data
	Inhibits photosynthesis at photosystem II &/or inhibition of cell wall (cellulose) synthesis	II	Bromoxynil, ioxynil	Limited human data; uncouples oxidative phosphorylation in animals.
	Commonly co-formulated with phenoxyacetic acid compounds	U	Dichlobenil	

Dinitrophenol	Uncoupling (membrane disruption)	Ib	Dinoterb, DNOC (4,6-dinitro-o-cresol)	Limited human data; methemoglobinemia is reported in animals. Dinitrophenol uncouples oxidative phosphorylation
Organic phosphorus	Bensulide: preemergence selective for grasses. Glyphosate and glufosinate and nonselective postemergence herbicides	II	Butamifos, bialaphos (bilanafos), anilofos, bensulide, piperophos	Limited human data. Bialaphos is metabolized to glufosinate in plants, but in humans only the metabolite L-amino-4-hydroxymethyl-phosphonoyl-butyric acid (L-AMPB) has been found. Clinical effects of poisoning include apnea, amnesia, and metabolic acidosis. Anilofos and bensulide are shown to inhibit acetyl cholinesterase
	In 2001, glyphosate was the most used pesticide in the United States and the second most used in the domestic sector			
	Bialaphos and glufosinate inhibit glutamine synthetase, bensulide inhibits lipid synthesis, and glyphosate inhibits EPSP synthase, which interferes with aromatic amino acid synthesis	III	Glufosinate	See text for glufosinate, Fig. 115–5
		U	Fosamine, glyphosate	See text for glyphosate, Fig. 115–7. Limited human data for fosamine
Phenoxy Fig. 115–5	Postemergence, selective for grasses	II	*Phenoxyacetic derivatives*: 2,4-D *Nonphenoxyacetic derivatives*: haloxyfop, quizalofop-P	See text for phenoxyacetic derivatives; similar clinical features of toxicity are noted for the chlorinated nonphenoxyacetic acid compounds. Mild clinical toxicity from fenoxaprop-ethyl. Limited human data on poisoning for others. Fluazifop 0.07 mg/kg was safely administered to humans in a volunteer study
	In 2001 2,4-D was the 5th most used pesticide in the United States but the most used in the domestic sector (mecoprop was 5th)			
	Inhibits acetyl-CoA carboxylase (lipid biosynthesis inhibitors; 'fops) or indole acetic acid-like (auxin growth regulators; chlorinated compounds)	III	*Phenoxyacetic derivatives*: MCPA, 2,4,5-T *Nonphenoxyacetic derivatives*: Bromofenoxim, 2,4-DB, dichlorprop, diclofop, fluazifop, MCPB, mecoprop (MCPP), quizalofop, propaquizafop	
	Clomeprop is also an amide compound	U	*Nonphenoxyacetic derivatives*: Clomeprop, fenoxaprop-ethyl	
Pyrazole	May relate to inhibition of 4-hydroxyphenyl-pyruvate-dioxygenase or photosystem-I-electron diversion (difenzoquat is also a quaternary ammonium compound)	II	Difenzoquat	Limited human data
		III	Pyrazoxyfen, pyrazolynate	
		U	Azimsulfuron	
Pyridazine	Preemergence application. Inhibits photosynthesis at photosystem II	III	Pyridate	Limited human data
Pyridazinone	Inhibits photosynthesis at photosystem II or inhibits carotenoid biosynthesis at the phytoene desaturase step	U	Chloridazon, norflurazon	Limited human data. In animals, chloridazon appears to interfere with mitochondrial function. Respiratory distress, seizures and paralysis precede death
Pyridine	Inhibits carotenoid biosynthesis at the phytoene desaturase step and/or inhibits microtubule assembly and/or indole acetic acid-like (synthetic auxins)	III	Triclopyr	Limited human data on poisoning; triclopyr 0.5 mg/kg was safely administered to humans in a volunteer study. Picloram 5 mg/kg was safely administered to humans in a volunteer study
		U	Diflufenican, dithiopyr, fluroxypyr, fluthiacet, picloram	
Thiocarbamate	Preemergence, selective for grasses	II	EPTC, molinate, pebulate, prosulfocarb, thiobencarb, vernolate	Limited human data, including effects on cholinesterase. Some compounds display variable inhibition of nicotinic receptors, esterases, and aldehyde dehydrogenase in animals. Cycloate induces neurotoxicity in rats
	In 2001 EPTC was one of the top 25 pesticides used in the United States	III	Cycloate, esprocarb, tri-allate	
	Inhibits lipid synthesis	U	Tiocarbazil	
Triazine Fig. 115–6	Mostly preemergence and nonselective	II	Cyanazine, terbumeton	See text
	In 2001 atrazine was the 2nd most used pesticide in the United States and simazine was in the top 25	III	Ametryn, desmetryn, dimethametryn, simetryn	
	Inhibits photosynthesis at photosystem II	U	Atrazine, prometon, prometryn, propazine, simazine, terbuthylazine, terbutryn, trietazine	

(*Continued*)

TABLE 115–1. Characteristics of the Major Herbicides, Categorized By Chemical Class and WHO Hazard Classification (*Continued*)

Chemical Class[a]	Applications, Usage Data, and Mechanism of Action in Plants, If Known[b]	WHO Hazard Class[c]	Compounds Included	Clinical Effects, Potential Specific Treatments and Supportive Care
Triazinone	Inhibits photosynthesis at photosystem II	II III	Metribuzin, hexazinone Metamitron	Limited human data. With hexazinone, rats and guinea pigs experience lethargy and ataxia, progressing to clonic seizures prior to death, while dogs were not particularly sensitive. Goats experience sedation, lethargy, and impaired respiration with metamitron poisoning
Triazole	Postemergent, nonselective Commonly coformulated with ammonium thiocyanate Inhibits lycopene cyclase; chlorophyll or carotenoid pigment inhibitor	U	Amitrole (aminotriazole)	Limited human data on single-agent exposures. Ingestion of 20 mg/kg in a human and >4000 mg/kg in rats did not induce symptoms
Triazolone	Inhibits acetolactate synthase	U	Flucarbazone	Limited human data
Triazolopy-rimidine	Inhibits acetolactate synthase. These herbicides are also amide compounds	U	Diclosulam, flumetsulam, metosulam	Limited human data. Asthma is reported from occupational exposures to flumetsulam
Uracil	Mostly preemergence. Inhibit photosynthesis at photosystem II	U	Bromacil, lenacil, terbacil	Limited human data
Urea	Both pre- and postemergence Inhibits acetolactate synthase (interferes with branched amino acid synthesis) and/or inhibits photosynthesis at photosystem II and/or inhibition of carotenoid biosynthesis	III U	Isoproturon, isouron, tebuthiuron Bensulfuron, chlorbromuron, chlorimuron, chlorotoluron, cinosulfuron, cyclosulfa muron, daimuron, dimefuron, diuron, fenuron, fluometuron, linuron, methyldymron, metobromuron, metoxuron, metsulfuron, monolinuron, neburon, nicosulfuron, primisulfuron, pyrazosulfuron, rimsulfuron, siduron, sulfometuron, thifensulfuron, triasulfuron, tribenuron, triflusulfuron	Limited human data. Some urea herbicides are metabolized to aniline compounds, which induce methemoglobinemia and hemolysis (similar to propanil, see text). Given the limited experience in treating poisonings with urea herbicides, it is reasonable to apply treatments described for amide herbicide poisoning (see text). Methemoglobinemia has been reported in products containing both metobromuron and metolachlor, which resolved with methylene blue. Wheeze is reported from occupational exposures to chlorimuron Animal studies suggest that isoproturon causes CNS depression and tebuthiuron causes lethargy, ataxia, and anorexia
Miscellaneous	Clomazone may be coformulated with propanil Clomazone and fluridone: chlorophyll or carotenoid pigment inhibitor	II	Clomazone, endothal	Limited human data; in one case vomiting and gastric and pulmonary hemorrhage preceded death. Animal studies suggest that clomazone inhibits acetylcholinesterase and endothal induces lethargy, respiratory, and hepatic dysfunction
	Bentazone: pre- and postemergence for control of broadleaf plants. Inhibit photosynthesis	III	Bentazone, quinoclamine	Bentazone: gastrointestinal irritation, hepatic and renal failure, dyspnea, muscle rigidity, confusion, death

[a] Many of these classes can be further subclassified on the basis of chemical structure; however, the relationship between structure and clinical effects is not adequately described. The classification listed here is adapted from http://www.alanwood.net/pesticides/class_herbicides.html (accessed April 9, 2008).

[b] The mechanism by which a number of herbicides regulate plant growth is not fully described. The mechanisms listed here are adapted from http://www.plantprotection.org/HRAC/MOA.html (accessed April 9, 2008) and http://www.ces.purdue.edu/extmedia/WS/WS-23-W.html (accessed September 27, 2008).

[c] WHO Hazard Classification scale for oral liquid exposures of the technical grade ingredient based on rat LD_{50} (mg/kg body weight): Ia, "extremely hazardous," less than 20 mg/kg; Ib, "highly hazardous," 20 to 200 mg/kg; II, "moderately hazardous," 200 to 2000 mg/kg; III, "slightly hazardous," greater than 2000 mg/kg; and U, "technical grade active ingredients of pesticides unlikely to present acute hazard in normal use."

products, which is discussed below. Another example is imazapyr, which has an LD_{50} in rats of 1500 mg/kg intraperitoneally (IP), compared with 262 mg/kg IP when administered as the product ARSENAL®. This difference is attributed to the surfactant nonylphenol ethoxylate used in this product, which has an LD_{50} of 75 mg/kg IP.[40] In vitro studies with a number of formulations demonstrate increased cardiovascular toxicity compared with the technical herbicides.[18] Similarly, coformulants increase in vitro toxicity from phenoxyacetic acid derivatives and glufosinate.

Impurities may also be generated during manufacture or storage of the herbicide formulation, which contributes to toxicity. For example, phenolic byproducts from the manufacture of phenoxyacetic acid herbicides may be found as impurities in commercial formulations.

Some proprietary products contain a combination of herbicidal compounds that probably have additive effects, further complicating the risk assessment.

■ EPIDEMIOLOGY

The majority of herbicide exposures leading to severe poisoning or death are due to intentional self-harm and the specific herbicide taken, depending on local availability. Trends in herbicide poisoning usually reflect those of sales in the domestic sector because these products are most readily accessible to people with thoughts of self-harm.

Herbicide poisoning is a major issue in developing countries of the Asia-Pacific region where subsistence farming is common. In comparison, more recently the incidence of severe herbicide poisoning has decreased in developed countries because of restricted availability of highly toxic or concentrated solutions. In rural areas, the incidence of severe pesticide poisoning may be higher compared with urban regions because of easier access (see Chaps. 113 and 136).

Regulatory restrictions influence the herbicide exposures that are reported. For example, paraquat poisonings are now rare in the United States, while glyphosate poisonings are increasing. Similarly, paraquat was banned in Japan in the late 1980s and since then there has been an increase in the number of glufosinate poisonings.

■ REGULATORY CONSIDERATIONS

When properly used, the majority of herbicide formulations have a low potential toxicity for applicators because of their poor absorption across the skin and respiratory membranes. When inappropriately used, their toxicity is pronounced through enteral (or rarely parenteral) exposures.

The toxicity of herbicides varies among individual xenobiotics, but as a group, they appear to be intrinsically more toxic than medications when ingested with suicidal intent. Restrictions to the availability and formulation of toxic herbicides by regulatory authorities may improve outcomes from herbicide poisoning. For example, in the context of self-poisoning, the replacement of highly toxic pesticides with less toxic compounds may decrease the overall mortality[102] without altering agricultural outputs.[76] Prospective cohort studies have been useful for estimating the case fatality of individual herbicides so that the relative human toxicities were determined, as follows: fenoxaprop-P-ethyl 0%,[111] bispyribac 2.7%,[3] glyphosate 3.5%,[99] MCPA (4-chloro-2-methylphenoxyacetic acid) 4.4%,[103] propanil 10.7%,[101] and paraquat 50% to 90%.[33]

Regulatory bodies must also consider other factors, including the cost and efficacy of herbicides and their fate in the environment. An ideal herbicide is one that is selective for the target plant and does not migrate far from the site of application. Selective targeting may occur as a result of rapid inactivation or strong binding to soil components. For example, paraquat and glyphosate are inactivated when they come in contact with soil, which is favorable because they will remain in the

region of application. In contrast, atrazine is more mobile, allowing it to leach into groundwater and migrate many kilometers. While the concentration at distant sites is low, there is concern that atrazine may have the potential to disrupt the growth and development of nontarget organisms.

GENERAL COMMENTS FOR THE MANAGEMENT OF ACUTE HERBICIDE POISONING

■ DIAGNOSIS

Herbicide poisoning is diagnosed following a specific history or other evidence of exposure (such as an empty bottle) and associated clinical symptoms. A detailed history, including the type of herbicide, amount, time since poisoning, and symptoms, is essential. Depending on local laboratory resources it may be possible to confirm the diagnosis with a specific assay, such as paraquat and glufosinate.

Because the principal criterion for diagnosis of acute herbicide poisoning is a history of exposure, a high index of suspicion is necessary. Because of the low incidence of herbicide poisoning in some regions it may not be considered in the differential diagnosis of patients presenting to hospital who are unable to provide a history. Therefore, clinicians should be familiar with the features of herbicide poisoning.

The pathophysiology of acute herbicide poisoning, and therefore the clinical manifestations, varies widely among individual compounds. Some herbicides induce multisystem toxicity due to interactions with a number of physiological systems. The mechanism of toxicity and pathophysiological changes in humans are discussed below for each herbicide individually.

■ INITIAL MANAGEMENT

An accurate risk assessment is necessary for the proper triage and subsequent management of patients with acute herbicide poisoning. Risk assessment involves consideration of the dose ingested, time since ingestion, clinical features, patient factors, and availability of medical facilities. All intentional exposures should be considered significant. If a patient presents to a facility that is unable to provide sufficient medical and nursing care or does not have ready access to necessary antidotes, then arrangements should be made to rapidly and safely transport the patient to a healthcare facility where these are available.

For many herbicides the initial management of an acute poisoning is empiric. All patients should receive prompt resuscitation paying close attention to airway, breathing, and circulation. Gastrointestinal toxicity, such as nausea, vomiting, and diarrhea, is common, leading to dehydration requiring administration of antiemetics and intravenous fluids to the patient.

Gastrointestinal decontamination may decrease absorption of the herbicide from the gut, decreasing systemic exposure. Gastric lavage is generally not recommended in acute poisoning because patients usually present too late or have self-decontaminated from vomiting and diarrhea. Lavage has been used by some practitioners for patients presenting shortly after an ingestion of a liquid formulation for which treatment options are limited. Depending on the procedure used, this treatment may cause harm and should only be conducted by an experienced clinician when the airway is protected. Oral activated charcoal may be given if the patient presents within 1 to 2 hours of ingestion.

Specific antidotes are available for only a few herbicides, which is in part because of their ill-defined mechanisms of toxicity.

Extracorporeal techniques, including hemoperfusion and hemodialysis, may decrease the systemic exposure by increasing the rate of

elimination. The role of these treatments is discussed below for each pesticide.

Dermal decontamination is necessary if the patient has incurred clothing and cutaneous exposure. The patient should be washed with soap and water and contaminated clothes, shoes, and other leather materials should be removed and safely discarded in plastic bags.

Laboratory investigations may be useful for determining the evolution of organ toxicity, including serial measurement of biomarkers of liver and renal function, electrolytes, and acid–base status. Abnormalities should be corrected where possible. Respiratory distress and hypoxia with focal respiratory crackles soon after presentation are likely to result from aspiration pneumonitis, which can be confirmed on chest X-ray.

Patients with a history of acute ingestion should be observed for a minimum of 6 hours. Patients with a history of intentional ingestion and gastrointestinal symptoms should be observed for at least 24 hours given that clinical toxicity may progress or be delayed in some cases.

■ OCCUPATIONAL AND SECONDARY EXPOSURES (INCLUDING NOSOCOMIAL POISONING)

There is much concern regarding the risk of nosocomial poisoning to staff and family members who are exposed to patients with acute pesticide poisoning. The risk of nosocomial poisoning for health staff providing clinical care is low compared with other occupations, such as agricultural workers in whom toxicity is rarely observed. Universal precautions using nitrile gloves are most likely to provide sufficient protection for staff members.[73]

Few cases of secondary poisoning, if any, have been confirmed, and symptoms in these individuals were generally mild, such as nausea, dizziness, weakness, and headaches, probably relating to inhalation of the hydrocarbon solvent. These symptoms usually resolve after exposure to fresh air. Biomarkers for monitoring occupational exposures, as in the case of pesticide applicators, are outside the scope of this chapter.

■ AMIDE COMPOUNDS, IN PARTICULAR ANILIDE DERIVATIVES

Anilide compounds are the most widely used amide herbicides, of which propanil (3',4'-dichloropropionanilide, also known as DCPA), alachlor (2-chloro-2',6'-diethyl-N-methoxymethylacetanilide), and butachlor (N-butoxymethyl-2-chloro-2',6'-diethylacetanilide) are particularly common. Other amide herbicides and available toxicity data are listed in Table 115–1. In 2001, acetochlor, propanil, alachlor, metolachlor, and dimethenamid were each listed in the top 25 pesticides used in the United States, while propanil was among the top 10 pesticides in domestic use.[60] Anilide compounds are selective herbicides used mostly in rice cultivation in many parts of the world. Acute self-poisoning is reported particularly in Asia where subsistence farming is common. Data are limited for most compounds except propanil, butachlor, and alachlor. The case fatality of propanil is 10.9% compared with a combined mortality of 2.7% for butachlor and alachlor. Poor outcomes may reflect the inadequacies of current treatment regimens.

■ PHARMACOLOGY

Most of the clinical manifestations of propanil poisoning are mediated by its metabolites. 3,4-dichlorophenylhydroxylamine appears to be the most toxic metabolite because it directly induces methemoglobinemia and hemolysis in a dose-related manner.[78,80,112] 3,4-dichlorophenylhydroxylamine is cooxidized with oxyhemoglobin (Fe^{2+}) in erythrocytes to produce methemoglobin (Fe^{3+}) (see Chap. 127).[80,112]

However, toxicity may not be solely attributed to methemoglobinemia. Usually methemoglobin greater than 50% is required for severe poisoning and death, but fatal propanil poisoning is reported with methemoglobin as low as 40%.[22,87,127,128] Therefore, it seems likely that other toxic mechanisms contribute to clinical outcomes. Rats show signs of toxicity despite inhibition of hydrolytic enzymes and in the absence of methemoglobinemia, which may reflect direct toxicity from propanil itself.[112] Coformulants may also contribute.

The hydroxylamine metabolite has been shown to deplete glutathione, which may induce toxicity, although this is not consistently reported. Other possible toxicities from the metabolism of propanil include nephrotoxicity, lipoperoxidation, myelotoxicity, and immune dysfunction; the significance of these is not determined.

Para-hydroxylated aniline and other compounds are products of alachlor, butachlor, and acetochlor (2-chloro-N-ethoxymethyl-6'-ethylacet-o-toluidine) metabolism and may reduce glutathione and induce hepatotoxicity or cancer, particularly in rats.

■ PHARMACOKINETICS AND TOXICOKINETICS

Absorption is rapid in animals, with a peak concentration 1 hour postingestion. The volume of distribution (Vd) of propanil has not been determined, but is expected to be large given that both propanil and 3,4-dichloroaniline are highly lipid soluble. This Vd is consistent with data in the channel catfish where uptake and distribution of propanil was noted to be extensive. Anilide compounds interact with adenosine triphosphate (ATP)-binding cassette transporters, which may also influence the kinetics.

Anilide compounds undergo sequential metabolic reactions that produce toxic xenobiotics (Fig. 115–1). The first reaction is hydrolysis of the anilide to an aniline compound. This reaction is catalyzed by an esterase known as arylamidase, which has a high capacity in humans compared to rats (K_m = 473 μM and 271 μM, respectively) and sometimes by the cytochrome P450 system.[20] Examples include the bioconversion of propanil to 3,4-dichloroaniline[78,80,112] and also conversion of alachlor and butachlor to 2,6-diethylaniline.[20] These aniline intermediates are then oxidized by cytochrome P450, although the responsible isoenzyme has not been determined. N-hydroxylation of 3,4-dichloroaniline produces the hydroxylamine compound that

A. Common Anilide Xenobiotics
B. Bioconversion of propanil:
FIGURE 115–1. Structure of common anilide compounds and the bioconversion of propanil.

induces hemolysis and methemoglobinemia, which are the obvious manifestations of propanil poisoning.[78,80,112]

These bioactivation reactions appear to be fairly rapid, where 3,4-dichloroaniline and methemoglobin are formed within 2 to 3 hours of parenteral administration of propanil to animals.[80] The hydroxylation of 3,4-dichloroaniline may be saturable (K_m = 120 μM in rats)[79] and slower than arylamidase, leading to a prolonged elimination of 3,4-dichloroaniline following large exposures.

In the case of alachlor, butachlor, and acetochlor, para-hydroxylated aniline compounds are produced, which appear to be carcinogens, particularly in rats.

These metabolic reactions are similar to those of dapsone, which are well characterized: the severity of methemoglobinemia relates to the amount of the dapsone metabolite; hydroxylamine, which varies with dose, and cytochrome P450 activity (see Chap. 127).

Propanil displays nonlinear toxicokinetics in humans with prolonged absorption continuing for approximately 10 hours following ingestion. Bioconversion to 3,4-dichloroaniline occurs largely within 6 hours, although it is particularly variable, which may reflect interindividual differences in esterase activity, dose, or coexposure to other pesticides. The median apparent elimination half-life of propanil is 3.2 hours compared with 3,4-dichloroaniline, which has a highly variable elimination profile. In general, the concentration of 3,4-dichloroaniline exceeds that of propanil and remains elevated for a longer period. In a case of coingestion of carbaryl the peak 3,4-dichloroaniline concentration was observed at 24 hours,[50] while in a fatal case the concentration of 3,4-dichloroaniline continued to increase until at least 30 hours postingestion.[101]

By 36 hours postingestion the concentration of 3,4-dichloroaniline is low in survivors, so clinical toxicity is unlikely to increase beyond this time.

PATHOPHYSIOLOGY

The predominant clinical manifestation in acute poisoning is methemoglobinemia. Methemoglobin is unable to bind and transport oxygen, inducing a relative hypoxia at the cellular level despite adequate arterial oxygenation. This leads to end-organ dysfunction, including central nervous system depression, hypotension, and acidosis. Because the serum concentration of 3,4-dichloroaniline remains elevated, methemoglobinemia persists for a similar time.[50,87,127] Sedation due to the direct effect of propanil or a hydrocarbon coformulant solvent may cause hypoventilation, which contributes to cellular hypoxia. Failure to correct these abnormalities may lead to irreversible cellular toxicity and death.

CLINICAL MANIFESTATIONS

Methemoglobinemia, hemolysis and anemia, coma, and death have also been reported following acute propanil poisoning. These manifestations occur in the clinical context of cyanosis, acidosis, and progressive end-organ dysfunction, which are consistent with severe and prolonged methemoglobinemia. A case fatality as high as 10.7% is reported and the median time to death was 36 hours. Patients who died were older with a depressed Glasgow coma scale (GCS) score and elevated concentration of propanil. Nausea, vomiting, diarrhea, tachycardia, dizziness, and confusion are also reported in patients who do not develop severe poisoning.[101]

Alachlor and butachlor appear to be less toxic than propanil, with a case fatality of 2.9% with self-poisoning. Hypotension and coma preceded death and other major symptoms included seizures, rhabdomyolysis, acidosis, renal failure, and cardiac dysrhythmias. Markers of milder clinical toxicity included gastrointestinal symptoms, agitation,

dyspnea, and abnormal liver enzymes.[75] Methemoglobinemia was not reported, although it is unclear whether it was investigated for. Hepatic dysfunction has also occurred following dermal occupational exposure to butachlor.

Cyanosis was reported following acute ingestion of mefenacet (2-benzothiazol-2-yloxy-*N*-methylacetanilide) and imazosulfuron (1-[2-chloroimidazo(1,2-*a*)pyridin-3-ylsulfonyl]-3-[4,6-dimethoxypyrimidin-2-yl]urea) in the context of normal cooximetry, which was attributed to formation of a green pigment; green-colored urine was also reported. No other symptoms of toxicity were observed.[110]

Acute metolachlor (2-chloro-*N*-[6-ethyl-*o*-tolyl]-*N*-[(1*RS*)-2-methoxy-1-methylethyl]acetamide) poisoning in goats induced predominantly neuromuscular symptoms, including tremors, ataxia, and myoclonus, which progressed rapidly to death. Renal and hepatocellular toxicity were also noted. Acute acetochlor exposures in rats induced methemoglobinemia and hepatocellular toxicity.

DIAGNOSTIC TESTING

Specific investigations for the diagnosis of acute anilide herbicide poisoning are not widely available.

Patients with a history of propanil poisoning should be investigated for the presence of methemoglobinemia (see Chap. 127).

While the concentrations of propanil and 3,4-dichloroaniline appear to reflect clinical outcomes, this relationship is less marked for 3,4-dichloroaniline during the first 6 hours, which probably relates to the time for bioconversion from propanil.[101] However, propanil and 3,4-dichloroaniline assays are not commercially available and this observation has not been validated. Further, the relationship between concentration and outcomes varies with the time since ingestion and may depend on patient comorbidities.

MANAGEMENT

The minimum toxic dose has not been determined and the potential for severe poisoning and death is high, so all oral ingestions should be treated as significant and these patients should be monitored for a minimum of 12 hours. Symptomatic ingestions should be treated cautiously, including continuous monitoring for 24 to 48 hours, preferably in an intensive care unit.

Routine clinical observations are sufficient to detect the presence of poisoning, in particular, sedation and clinical cyanosis. Until more data are available it seems reasonable to focus treatment on reversal of methemoglobinemia. There is sufficient time to initiate specific treatments in propanil poisoning given that clinical signs of poisoning are noted early postingestion, yet the time to death is usually greater than 24 hours. There are no controlled clinical or laboratory data available on the effect of any specific treatment in acute symptomatic propanil poisoning, so management is largely empirical.

Resuscitation and Supportive Care Prompt resuscitation and close observation are required in all patients. Patients should be monitored clinically including pulse oximetry, and receive supportive care including supplemental oxygen, intravenous fluids, and ventilatory and hemodynamic support as required. In the absence of cooximetry analysis, significant methemoglobinemia is suspected when cyanosis does not correct with high-flow oxygen and ventilatory support. Euglycemia should be ensured since adequate glucose concentrations are required for endogenous reduction and maximizing the efficacy of methylene blue.

Hemoglobin concentrations should be monitored to detect hemolysis, and folate supplementation may be necessary during the recovery phase if anemia is significant.

Gastrointestinal Decontamination Toxicokinetic studies of propanil have demonstrated a prolonged absorption phase, so it is reasonable to administer activated charcoal to the patient a number of hours postingestion. Although a recent trial that did not demonstrate clinical benefits from activated charcoal in patients with pesticide poisoning included patients with propanil poisoning, subgroup analyses were not conducted.[32]

Extracorporeal Removal Treatment with combined hemodialysis and hemoperfusion was associated with a propanil elimination half-life of 1 hour, although clearance was not directly measured.[87] However, half-lives as short as 1 hour have been reported in patients who have not received this treatment[101] so its efficacy remains unknown. Exchange transfusion has the potential to decrease the concentration of propanil and free hemoglobin while replacing reduced hemoglobin and hemolyzed erythrocytes. But the function of transfused erythrocytes is temporarily impaired posttransfusion because of depletion of 2,3-bisphosphoglycerate (BPG) during storage. Further, transfusion reactions such as acute lung injury may occur, which is of concern when oxygenation is already impaired. In the absence of controlled studies, the role of such treatments in the routine management of acute propanil poisoning is poorly defined (see Chap. 9).

Antidotes Antidotes are largely used for the treatment of methemoglobinemia. Methylene blue (see Antidotes in Depth A41: Methylene Blue) is considered the first-line treatment for methemoglobinemia. Methylene blue has a half-life of 5 hours, which is commonly shorter than that of 3,4-dichloroaniline, so rebound poisoning (ie, an increase in methemoglobin following an initial recovery postadministration of methylene blue) is likely when a bolus regimen is used. This occurred in a previous case of propanil poisoning[127] and may be prevented by administration of methylene blue to the patient as a constant infusion.

Other potential treatments include toluidine blue, *N*-acetylcysteine, ascorbic acid, and cimetidine, but no clinical studies have assessed the role of these potential antidotes in the management of propanil poisoning.

BIPYRIDYL COMPOUNDS, PARAQUAT, AND DIQUAT
Bipyridyl compounds are nonselective contact herbicides. The most widely used is paraquat (1,1'-dimethyl-4,4'-bipyridinium), but diquat (1,1'-ethylene-2,2'-bipyridyldiylium) is commonly used also. Paraquat is one of the most toxic pesticides available, as ingestion of as little as 10 to 20 mL of the 20% wt/vol solution is sufficient to cause death. Overall, the mortality varies between 50% and 90%, but in cases of intentional self-poisoning with concentrated formulations, mortality approaches 100%. Diquat is less toxic than paraquat so it may be coformulated with paraquat (allowing a lower concentration of paraquat) or used as an alternative in countries where paraquat is severely restricted. Because more data are available on paraquat than diquat, much of the following discussion and information relates particularly to paraquat.

■ PHARMACOLOGY

Paraquat and diquat formulations are highly irritating and often corrosive, causing direct toxicity. Paraquat induces intracellular toxicity by the generation of reactive oxygen species that nonspecifically damage the lipid membrane of cells, inducing cellular toxicity and death. Once paraquat enters the intracellular space it is oxidized to the paraquat radical. This radical is subsequently reduced by diaphorase in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) to reform the parent paraquat compound and superoxide radical, a reactive oxygen species. This process is known as redox cycling (Fig. 115–2). The superoxide radical is susceptible to further reactions by other intracellular processes, leading to formation of other reactive oxygen species, including hydroxyl radicals and peroxynitrite. Reactive oxygen species are potent inducers of cytotoxicity. Paraquat redox cycling continues as long as NADPH and oxygen are available. Depletion of NADPH prevents recycling of glutathione and interferes with other intracellular processes, including energy production and active transporters, exacerbating toxicity. Intracellular protective mechanisms such as glutathione, superoxide dismutase, and catalase are overwhelmed or depleted following large exposures. Taken together, these cytotoxic reactions induce cellular necrosis, which is followed by an influx of neutrophils and macrophages. The reactions contribute to the inflammatory response and promote fibrosis and destruction of normal tissue architecture over a number of days.[23,27]

The lung is particularly susceptible to the effects of paraquat. Acute pneumonitis and hemorrhage occur, followed by ongoing inflammation and progressive pulmonary fibrosis.[27,109] Supplemental oxygen probably increases the generation of reactive oxygen species.

The highest concentration of paraquat is in the kidneys. Renal toxicity is commonly observed in acute paraquat and diquat poisoning, which is important since both are eliminated by the kidneys. Paraquat induces acute tubular necrosis due to direct toxicity to the proximal tubule in particular, and to a lesser degree distal structures. Other factors influencing the development of acute renal impairment include hypoperfusion from hypovolemia and/or hypotension and direct glomerular injury. Varying degrees of oliguria, proteinuria, hematuria, and glycosuria are reported.[17]

■ PHARMACOKINETICS AND TOXICOKINETICS

Absorption is limited following dermal exposures, although prolonged exposures (at least several hours) to concentrated formulations may degrade the epithelial barrier, allowing some systemic absorption. Absorption across the respiratory epithelium is also limited because of large droplets that impact the oropharynx or larger proximal airways rather than more permeable distal airways.

The oral bioavailability of paraquat varies among animal species, but it is overall quite low.[21,85,109] The bioavailability of paraquat in humans is estimated to be less than 5%,[21] yet an oral exposure of as little as 10 mL allows sufficient paraquat to be absorbed for significant clinical toxicity to occur. Absorption is rapid and the peak concentration occurs within 1 hour.[85] Coingestion of food may decrease the absorption of paraquat. Recently, paraquat was reformulated with an increased emetic concentration along with an alginate that formed a gelatinous mixture on contact with gastric acid, limiting release of the paraquat into the stomach. This formulation led to a decrease in paraquat absorption in animals[44] and improved outcomes from self-poisoning in humans (mortality of 64% compared to 74% with the standard preparation).[124]

Paraquat binds minimally to serum proteins. Paraquat and diquat rapidly distribute to all tissues where they accumulate but may redistribute
FIGURE 115–2. Toxicology of paraquat (PQT) and proposed mechanisms of action of potential treatments. PQT$^\bullet$ = paraquat radical; NO$^\bullet$ = Nitric oxide; ONOO$^-$ = peroxynitrite; OH$^\bullet$ = hydroxyl radical.

back to the central circulation.[85] In humans the distribution half-life is approximately 5 hours.[52] Paraquat accumulates in alveolar cells so the concentration exceeds that of the blood,[85,104] with a peak occurring at around 6 hours postingestion in patients with normal renal function and a delay being recognized with renal impairment.[10] However, this accumulation appears to be a reversible process given that paraquat redistributes back to the systemic circulation as its concentration falls. This is possibly due to impaired function of the pneumocytes from acute lung injury.[5] The uptake of paraquat is an energy-dependent process that continues as long as the blood concentration of paraquat remains elevated.[104] This transporter also facilitates the uptake of endogenous polyamine compounds. In contrast, while there is some uptake of diquat this occurs to a limited extent.[104]

Paraquat is not metabolized and elimination is primarily renal[85] with more than 90% of a dose being excreted within the first 24 hours of poisoning if renal function is maintained.[52] Its clearance initially exceeds that of creatinine mostly because of active secretion, but also to a lesser degree through increased renal blood flow.[17] Renal clearance may be reduced by exogenous compounds or an acidic urine pH.[17] Renal impairment is commonly reported with paraquat and diquat poisoning, which decreases excretion and exacerbates clinical toxicity.[10] Elimination is prolonged with a terminal half-life of around 80 hours in humans.[52] Paraquat is detected in the urine of surviving patients beyond 30 days despite serum concentrations being quite low 48 hours

postingestion.[7,109] In animals, the terminal elimination half-life of paraquat is more than 50 hours.[85]

■ **PATHOPHYSIOLOGY**

Paraquat induces nonspecific cellular necrosis. Pulmonary and renal toxicity is prominent in acute paraquat poisoning because of the high concentrations found in these cells. Acute pneumonitis reduces oxygen diffusion and induces dyspnea and hypoxia, which interfere with normal cellular function. Acute renal impairment interferes with normal fluid and electrolyte homeostasis, as well as interfering with paraquat elimination, which promotes systemic toxicity. Necrosis of the gut limits intake and causes fluid shifts that contribute to hypotension induced by direct vascular toxicity. Hypotension impairs tissue perfusion and if uncorrected progresses to irreversible shock. Failure to correct these abnormalities may lead to irreversible cellular toxicity and death.

■ **CLINICAL MANIFESTATIONS**

Topical exposures may induce painful irritation to the eyes and skin, progressing to ulceration or desquamation depending on the concentration of the solution, duration of exposure, and adequacy of decontamination. Intravenous administration induces severe poisoning from small exposures.

Most oral exposures to bipyridyl compounds induce clinical toxicity. Gastrointestinal toxicity occurs early, including nausea, vomiting, and abdominal and oral pain. Diarrhea and ileus are also reported. Necrosis of mucous membranes (occasionally referred to as pseudo-diphtheria)[114] and ulceration are prominent and painful symptoms that generally occur within 12 hours. Injury has even been observed in cases where exposure to paraquat solution occurred without swallowing, despite the brief contact time as a result of immediate spitting and removal from the mouth. Dysphagia and odynophagia follow large exposures and may progress to esophageal rupture, mediastinitis, subcutaneous emphysema, and pneumothorax, which are preterminal events.

Respiratory symptoms are prominent in paraquat poisoning, including acute respiratory distress syndrome manifesting as dyspnea, hypoxia, and increased work of breathing. Ingestions of greater than 20 mL of 20% wt/vol formulation usually leads to severe respiratory dysfunction and multiorgan dysfunction with rapid onset of death within 24 to 48 hours. In particular, marked hypotension, acute kidney injury, hepatic dysfunction, severe diarrhea, and hemolytic anemia are reported in such patients.

In contrast, acute respiratory impairment is less marked with diquat ingestion or following smaller exposures of paraquat (less than 20 mL of 20% wt/vol formulations). In the case of paraquat the acute respiratory impairment is often followed by progressive pulmonary fibrosis and death weeks or months postingestion. Varying degrees of acute kidney injury and hepatic dysfunction can also occur in these patients.[9,55] Acute kidney injury peaks around 5 days postingestion and resolves within 3 weeks in survivors.[61]

Diquat does not concentrate in the pneumocytes as readily as paraquat. Therefore, if the patient survives the multiorgan dysfunction that occurs in the acute phase of poisoning, pulmonary fibrosis is less likely to occur.[129] Seizures have been reported with diquat poisoning.

■ DIAGNOSTIC TESTING

A diagnosis of paraquat poisoning is made on the basis of a history of exposure and the clinical symptoms, so a high index of clinical suspicion is required. Differential diagnoses include other corrosive exposures, sepsis, or other cellular poisons such as phosphine, colchicine, or iron.

Determination of the presence of a bipyridyl compound in blood confirms exposure, although such assays are increasingly of limited availability. The urinary dithionite test is a simple and quick method for confirming (or excluding) paraquat and diquat poisoning. Various methods are reported, including the addition of 1 g of sodium bicarbonate and 1 g of sodium dithionite, or 1% sodium dithionite in 1 M sodium hydroxide, to 10 mL of urine. A color change (blue for paraquat and green for diquat) confirms ingestion—the darker the color the higher the concentration.[7,105] If the test is negative on urine beyond 6 hours after ingestion, a large exposure is unlikely, but repeat testing should be conducted over 24 hours.

Given that outcomes from paraquat poisoning are generally poor, diagnostic tests may help differentiate patients who may survive from those in whom death is almost certain. The dose of paraquat is a well-established predictor of death, although this information may not be accurately known at the time of admission.[33] A range of investigations in patients with acute paraquat poisoning have attempted to determine the severity of poisoning and better define prognosis. Unfortunately, few have been validated so their predictive ability is unconfirmed. The range of prognostic tests were recently reviewed[33] and a selection of these are discussed below.

Quantitative analysis of the concentration of paraquat in plasma is useful for prognostication, and a number of similar nomograms have been developed to assist with this process (Fig. 115–3). The paraquat concentration must be interpreted relative to the time since ingestion. Determination of the concentration of paraquat in the urine of exposed patients has also been shown to predict outcomes. As mentioned, the availability of quantitative paraquat assays is increasingly limited and the turnaround time may be too long for the test to be clinically useful; in most cases interpretation requires an accurate time of poisoning to be known.[33]

Nomograms for serum paraquat concentrations. **A.** Compilation of three nomograms proposed by: Proudfoot et al.[96a] Schermann et al.[107a] and Jones et al.[58a] **B.** Hart paraquat nonogram. Hart et al.[43a] In A, concentrations below lines predict survival. In B, lines link concentrations of equal probability of survival. (Derived from Eddleston, et al.[33] by permission of Oxford University Press.)

Other methods for predicting outcomes from paraquat poisoning have used various combinations of simple laboratory tests including blood gas analysis, complete blood count, electrolytes, renal function, and liver function tests.[33] A raised admission creatinine concentration predicts death (86% versus 40% if the concentration is normal), but is neither sensitive nor specific, which probably relates to differences in time to presentation. The higher the creatinine concentration, the higher the odds ratio of death.[61] The rate of increase in creatinine concentration is a simple test that may be a better predictor of prognosis. An increase less than 3 µmol/L/h over 5 hours predicts survival,[97] or greater than 5.4 µmol/L/h predicts death.[100] With such calculations, serial samples can be collected and the rate of increase determined irrespective of the time of poisoning. Paraquat and diquat interfere with creatinine assays using the Jaffe method causing a false elevation, although this largely occurs at concentrations exceeding 100 mg/L, which is rarely observed and likely to be associated with severe clinical toxicity.[95]

Other biomarkers that may inform prognosis include pulmonary surfactant protein-A and -B (but not -D), type IV collagen, and tissue inhibitor of metalloproteinase-1 (TIMP-1), but further research is required.

■ MANAGEMENT

Because death can occur following ingestion of as little as 10 to 20 mL of paraquat, all exposures should be treated as potentially life threatening. Patients suspected of ingesting paraquat should be observed in hospital for at least 6 hours postingestion or until a urinary dithionite test can be conducted.

Many medical interventions have been proposed for the treatment of patients with acute paraquat poisoning and these are described below. Unfortunately, data supporting the efficacy of any of these are lacking, largely because of the inadequacy of the clinical studies. Dose–response studies to determine the optimal dose are also lacking for most of the therapeutic interventions. The literature is complicated by case reports describing survival in patients who were administered one or a combination of therapies.

In countries where paraquat poisoning is relatively common, many clinicians elect to administer a number of therapies to patients concurrently in the hope of a benefit because of the high likelihood of death in patients with acute paraquat poisoning. Administration of activated charcoal, *N*-acetylcysteine, vitamins C and E, immunosuppressants, and hemodialysis and/or hemoperfusion to a patient is not uncommon.

The choice of which interventions should be administered to a patient is best made on a case-by-case basis by the treating physician in consultation with relevant resources. Detailed discussion with the patient and relatives early in the presentation is recommended to determine their preference for treatment modalities. In general, a comprehensive treatment regimen is reasonable in patients who present very early (within 2 hours of poisoning) or those with a faintly positive dithionite urinary test. Treatments that reduce the exposure to paraquat by either reducing absorption or increasing clearance should be initiated promptly. Immunosuppression with cyclophosphamide and corticosteroids, and probably administration of salicylates, is also reasonable even though the risk-benefit in such patients has not been determined. In contrast, these treatments seem unlikely to be of assistance to patients in whom this test is strongly positive, or those with evolving multiorgan dysfunction. Instead, palliation should be the priority, including oxygen for hypoxia and morphine for dyspnea and oropharyngeal and abdominal pain.

Serial pulse oximetry measurements and chest radiographs will demonstrate progression of the pneumonitis and pulmonary fibrosis. Lung transplantation has been trialed in patients who develop pulmonary fibrosis, but it was largely unsuccessful because of the prolonged elimination half-life of paraquat.[9,59] Patients developing acute kidney injury should receive hemodialysis or hemofiltration per usual guidelines if active treatment is to be pursued, and these treatments may also enhance elimination of herbicide.

A range of tests has been proposed for prognostication in acute paraquat poisoning, as discussed above. Where available, these might assist with decisions regarding whether patients should be actively treated, palliated, or discharged with confidence that harm will not occur.

Resuscitation and Supportive Care All patients should receive prompt routine resuscitation and close observation. Oxygen should be administered to patients for palliation only when there is confirmed hypoxia and the clinical assessment suggests that death is likely. Although controlled hypoxia does not prevent the development of pulmonary injury,[9] unnecessary supplemental oxygen can theoretically hasten the progression of injury. Intravenous fluids should be administered to patients who are volume depleted from poor intake, diarrhea, or third-space shifts, as this may reduce the extent of acute kidney injury and promote renal clearance of paraquat. Electrolyte abnormalities may also occur and these should be corrected as required.

Analgesia for oral and abdominal pain should be administered to patients, including intravenous opioids such as morphine and possibly topical anesthetics such as lidocaine.

Gastrointestinal Decontamination Paraquat is coformulated with an emetic so self-decontamination may have occurred by the time of presentation to hospital. Fuller's Earth and activated charcoal have been advocated to decrease absorption of paraquat. Data demonstrating the clinical superiority of Fuller's Earth over activated charcoal are not available. Fuller's Earth is now of limited supply, but activated charcoal appears to adsorb paraquat to a similar extent as Fuller's Earth.[8] However, given that paraquat is rapidly absorbed if activated charcoal is to be administered to a patient who has ingested paraquat, this should occur within 1 hour of ingestion. Gastric lavage has not been shown to improve outcomes and may even be harmful if administered to patients ingesting less than 30 mL.[125]

Extracorporeal Removal Extracorporeal techniques, including charcoal hemoperfusion and hemodialysis, aim to decrease the systemic exposure by increasing the rate of elimination. Hemoperfusion is more efficient than hemodialysis, and clearance is maximized when treatment is initiated within the first couple of hours because the plasma concentration is high.[46] Further, given that paraquat rapidly distributes from the circulation, prompt treatment is necessary to limit the uptake into pulmonary and other tissues. Experimentally, hemoperfusion reduces mortality in dogs only when it is commenced within a few hours of poisoning, and repeated treatments do not increase clearance to a large extent.[92]

Unfortunately, current experience suggests that these treatments do not sufficiently improve mortality in humans, particularly when the concentration is greater than 3 mg/L.[43] In some cases there may be a rebound in serum paraquat concentrations with intermittent regimens that may be minimized using continuous techniques. Hemoperfusion followed by continuous venovenous hemofiltration may prolong the time to death compared with hemoperfusion alone without changing the overall mortality in a randomized, controlled trial. All patients in this study also received high-dose dexamethasone and ascorbic acid.[63]

Extracorporeal techniques may also induce harm because of the requirement for central venous access, metabolic disequilibrium, or increased clearance of antidotes. Therefore, the use of extracorporeal techniques requires careful consideration.

Antidotes A large number of potential antidotes have been trialed in the treatment of acute paraquat poisoning. They attempt to counteract

the effects of paraquat by targeting various steps in the pathogenesis of organ dysfunction or to alter cellular uptake (see Fig. 115–3). Unfortunately, none of these antidotes are proven to reduce mortality. However, two interventions that decrease paraquat exposure (either decreasing absorption[124] or increasing elimination[63]) prolonged the time to death, suggesting a beneficial effect. Combining these treatments with effective antidotes in a multimodal approach to treatment may reduce mortality. More research is required to support the use of such treatments in routine clinical care.

Immunosuppression with corticosteroids (dexamethasone or methylprednisolone) and cyclophosphamide are the most extensively trialed antidotes, including human randomized, controlled trials. These medicines aim to reduce inflammation, and initial studies were promising but not conclusive[33,72] because of serious concerns with the study design.[16,41] Regimens vary, including cyclophosphamide 10 to 15 mg/kg/d for 2 days, and methylprednisolone 15 mg/kg/d (up to 1 g) for 3 days, which is followed by dexamethasone 4 to 10 mg every 6 to 8 hours until recovery. In some reports cyclophosphamide was repeated if leukopenia did not develop, and pulse doses of methylprednisolone may also be repeated if deterioration is observed. Mesna was coadministered to patients in some series, and sirolimus has been trialed as an alternative immunosuppressant.

Generation of reactive oxygen species is an important step in the pathogenesis of paraquat poisoning (see Fig. 115–3). This leads to cytotoxicity, the extent of which depends on the concentration of paraquat at the cellular level and the efficiency of protective mechanisms. Endogenous scavenger defense mechanisms against reactive oxygen species include antioxidants such as vitamin C (ascorbic acid), vitamin E (alpha-tocopherol), and glutathione. Administration of these vitamins and/or a glutathione donor (such as acetylcysteine, S-carboxymethylcysteine, or captopril) to patients did not improve outcomes in every human or animal study. Poor intracellular penetration to the site of redox cycling may limit the effect of some compounds.[115] Potentially, vitamin C might increase oxidative toxicity.[27] These interventions have also been used in patients with acute poisoning. Typical doses include vitamin E 300 mg orally twice daily, vitamin C 25 mg/kg/d or 3 g/d for 7 days, and N-acetylcysteine 150 mg/kg over 3 hours as a loading dose followed by 500 mg/kg/d by continuous infusion. The scavenging agents superoxide dismutase and amifostine and the iron chelator desferrioxamine have also been trialed, but results were not encouraging.

Some treatments may influence the toxicokinetics of paraquat at the cellular level. Agents that decrease the uptake of paraquat by pneumocytes have been trialed such as putrescine, spermidine, and desferrioxamine, but their effect is limited and they do not alter efflux. Induction of P-glycoprotein with dexamethasone (100 mg/kg) increased cellular efflux and excretion of paraquat in rats, which is also promising.[26] Cyclophosphamide has also been shown to increase the efflux of paraquat from pneumocytes.[9]

Salicylates are proposed to inhibit multiple steps in the pathogenesis of paraquat poisoning, including decreasing production of reactive oxygen species, inhibition of NF-κB, antithrombotic effects, and chelation of paraquat.[25,29] Sodium salicylate 200 mg/kg decreased reactive oxygen species production and inflammation and improved survival in rats.[29] Similarly, lysine acetylsalicylate 200 mg/kg was noted to be the optimum dose to improve survival and minimize toxicity in rats.[28] A clinical study assessing the effect of intravenous acetylsalicylic acid in acute paraquat poisoning is currently under way in Sri Lanka.

Other antidotes and treatments have also been proposed, but less information regarding their effect is available and it is outside of the scope of this chapter to discuss every possible treatment.

GLUFOSINATE
Glufosinate ([2RS]-2-amino-4-[hydroxy(methyl)phosphinoyl]butyric acid) is a nonselective herbicide used predominantly in Japan, which is where most cases of acute poisoning are reported. Commercial preparations contain 14% to 30% glufosinate as the ammonium salt and anionic surfactants. A case fatality as high as 17.7% has been reported from glufosinate poisoning.

■ PHARMACOLOGY

Glufosinate is neurotoxic, although the specific mechanism is incompletely described. Since it is structurally similar to glutamate, studies have explored whether it interferes with glutamate in the central nervous system. Rat studies have demonstrated both agonism[77,86] and antagonism[36] to glutamate receptors and no effect on other receptors in the brain.[42] Although glufosinate also interferes with glutamine synthetase activity,[30] this effect is unlikely to be significant given the limited alterations in the concentrations of ammonia or glutamate that result.[42]

Glufosinate was not found to inhibit cholinesterase enzymes in rat studies,[42] although it has been reported in humans on occasion, including one case where it decreased to around 40% of the lower limit of normal with subsequent recovery.[122] Ammonia concentrations were not markedly altered in rats[42]; however, serum ammonia was elevated in some patients with self-poisoning, which might contribute to clinical toxicity.[122]

The extent to which the surfactant contributes to clinical toxicity has not been confirmed. Rat studies suggest that hemodynamic changes due to glufosinate ammonium formulations are entirely caused by the surfactant component rather than glufosinate itself.[65] Surfactants may also cause uncoupling of oxidative phosphorylation, although this was not observed in a single case report of glufosinate ammonium poisoning.[74]

■ PHARMACOKINETICS AND TOXICOKINETICS

Kinetic analysis of glufosinate is limited to animal studies and a few human case reports. Minor differences in kinetics of the D- and L-glufosinate enantiomers are observed between patients, the clinical implications of which are not known.

The rate of absorption of glufosinate is slower in rats than mice, although this corrected when administered to the animals as the formulated product, and the concentration peaks at 1 hour postingestion. Less than 15% of a dose is absorbed by rats.

Glufosinate does not appear to bind to serum proteins to a significant extent. The Vd was calculated to be 1.44 L/kg in a case of acute poisoning by assuming that the renal excretion of glufosinate is similar to animals.[45] Glufosinate distributes to the central nervous system, and in a case of acute poisoning the cerebrospinal fluid concentration was one-third the serum concentration 27 hours postingestion. The rate of distribution to the cerebrospinal fluid has not been characterized, but

it is theorized that glufosinate might distribute to the central nervous system slowly (perhaps due to active transporters) where it accumulates, which is why the onset of respiratory depression is delayed.[51] This theory was not supported in a case where glufosinate was not detected in the cerebrospinal fluid 6 hours after a seizure that occurred 30 hours postingestion.[118] Indeed, seizures have occurred in some patients after glufosinate was no longer detectable in the blood.[122] Seizures occur 3 hours postadministration of intracerebral glufosinate in rats, which further challenges the theory that distribution kinetics influence the delayed onset of seizures in humans.[42]

Glufosinate is subject to minimal metabolism and the majority of the bioavailable dose of glufosinate is excreted unchanged in urine.[37]

The elimination half-life in rats is 4 hours,[30] while in rabbits elimination is biphasic with a terminal elimination half-life of 1.9 hours, which was not dose dependent.[64] Kinetic data in humans are limited to a small number of cases of acute intentional poisoning where the elimination profile appeared biphasic with a distribution half-life of 2 to 4 hours and a terminal elimination of 10 to 18 hours.[45,49,116]

■ PATHOPHYSIOLOGY

It is not known whether the manifestations of glufosinate poisoning represent a primary (toxic) or secondary (downstream) effect. The most important manifestations are neurological, which interfere with respiration and subsequent oxygen delivery to vital organs, compromising normal cellular function. Hypotension also impairs tissue perfusion and if uncorrected progresses to shock. Failure to correct these abnormalities may lead to irreversible cellular toxicity and death.

■ CLINICAL MANIFESTATIONS

Nausea and vomiting are early features of acute poisoning. Altered level of consciousness may precede severe neurotoxicity, which occurs between 4 and 30 hours postingestion in the available reports, and includes seizures and central respiratory failure requiring ventilatory support. These symptoms may persist for a number of days. In rats, the onset of seizures is also delayed by a number of hours; however, the time to onset of the seizures decreases in a dose-dependent manner following the intraperitoneal administration of glufosinate.[77]

Other symptoms are reported including cardiac dysrhythmias, fever, amnesia, diabetes insipidus, and rhabdomyolysis. Refractory hypotension may be preterminal.

■ DIAGNOSTIC TESTING

Glufosinate poisoning is diagnosed clinically in the context of a history of exposure. Japanese clinicians and scientists have developed glufosinate assays for clinical use and a nomogram was developed for predicting clinical outcomes (Fig. 115–4).[47] Clinical chemistry assays including renal function, arterial blood gases, electrolytes, creatine kinase, and ammonia concentrations may support clinical management.

■ MANAGEMENT

Severe symptoms have been reported following unintentional ingestion, so all patients with oral exposures should be carefully monitored. Patients with confirmed exposures should be monitored for a minimum of 48 hours because of the possibility of delayed onset in clinical toxicity.

Resuscitation and Supportive Care Routine resuscitation, close observation, and supportive care are required. Careful monitoring for the
FIGURE 115–4. Glufosinate nomogram as described by Hori et al.[47] Concentrations above the line represent patients experiencing a greater degree of severity.

onset of respiratory failure is necessary and early intubation and ventilation is recommended. Given that glufosinate and metabolites are primarily renally cleared, intravenous fluids to maintain a consistent urine output is suggested. Seizures should be treated along standard lines, including benzodiazepines as first-line and possibly barbiturates if required. This approach is suggested to be effective on the basis of animal studies. Biochemical and acid–base abnormalities should be corrected where possible.

Gastrointestinal Decontamination In most reports of glufosinate poisoning gastric lavage and activated charcoal were administered, but it is not possible to determine whether these interventions improved clinical outcomes. The high incidence of seizures and respiratory failure from glufosinate poisoning is a relative contraindication to the administration of activated charcoal to patients. However, if the airway is secured then activated charcoal could potentially be administered to the patient per usual recommendations, although there are insufficient data confirming that this is effective.

Extracorporeal Removal Hemodialysis and hemoperfusion have been used in the management of acute glufosinate poisoning. Hemodialysis appears to be superior to hemoperfusion in terms of extraction from whole blood in vitro,[119] with an extraction ratio of 80%.[118] However, the clearance by hemodialysis is less than 60% of renal clearance.[45] Although prompt hemodialysis in patients on admission to hospital decreased the concentration of glufosinate, this may not prevent the development of seizures a number of hours later. Thus, while hemodialysis appears to decrease the serum concentration, there is insufficient data to confirm its role in routine management. It is reasonable to attempt such treatments if the patient presents with renal impairment.

Antidotes Specific antidotes are not available. Rat studies did not demonstrate benefit with the use of atropine and pralidoxime.

GLYPHOSATE
Glyphosate (*N*-[phosphonomethyl]glycine; Fig. 115–7) is a nonselective postemergence herbicide. It is used extensively worldwide, most

commonly as the isopropylamine salt. Glyphosate-containing herbicides are available in various formulations, approximately 1% to 5% glyphosate (ready to use) or approximately 30% to 50% (concentrate requiring dilution before use). In 2001, glyphosate was the most frequently used pesticide in the United States and the second most commonly used pesticide in the domestic sector.[60] Products containing glyphosate trimesium are less widely used and may differ with respect to their toxicity profile.

■ PHARMACOLOGY

Glyphosate inhibits 5-enolpyruvylshikimate-3-phosphate synthase in plants, which interferes with their aromatic amino acid synthesis. Because this enzyme is not present in humans glyphosate appears to be relatively selective for plants.

The mechanism of toxicity of glyphosate-containing herbicides to humans has not been adequately described. The formulation is irritating, particularly high concentrations which are corrosive, causing direct toxicity to the gastrointestinal tract. Despite being an organic phosphorus compound, glyphosate is not considered to inhibit acetylcholinesterase. Patients with severe poisoning manifest multisystem effects, suggesting that the formulation is either nonspecific in its action or that it interferes with a physiological process common to a number of systems. Proposed mechanisms include disruption of cellular membranes and uncoupling of oxidative phosphorylation, although these may be interrelated.[11,88,90] Indeed, the mechanism of toxicity may vary between different formulations of glyphosate. In two cases of glyphosate trimesium poisoning cardiopulmonary arrest occurred within minutes of ingestion.[82,113] Since this is not reported from glyphosate isopropylamine, it is possible that these products differ in the mechanism of toxicity.

Experimentally, there appears to be minimal (if any) mammalian toxicity from glyphosate itself. Glyphosate is categorized as WHO class "U" (Unlikely to present acute hazard in normal use; LD_{50} greater than 4000 mg/kg).[56] Surfactant coformulants are considered the more toxic component in glyphosate-containing herbicides.[11,18,53,126] Polyoxyethyleneamine (POEA; tallow amine; LD_{50} equal to 1200 mg/kg) is the most common surfactant formulated in these products, but others are also used. Systemic exposure to surfactants induces hypotension, which is primarily due to direct effects on the heart and blood vessels.[18] Surfactants disrupt cellular and subcellular membranes by direct toxicity, including those of mitochondria, which has the potential to lead to systemic symptoms.[39] Coformulated potassium and isopropylamine may also contribute to toxicity. Isopropylamine has a rat LD_{50} of 111 to 820 mg/kg, decreases vascular resistance, and may either increase or decrease cardiac contractility and rate.[57,96]

■ PHARMACOKINETICS AND TOXICOKINETICS

The kinetics of the surfactant has not been described. Data about the kinetics of glyphosate are available but the importance of this is debated given that glyphosate is not considered very toxic to humans. However, the role of plasma concentrations for predicting outcomes in acute poisoning (as a surrogate marker of exposure) is currently being explored and will require kinetic data for proper interpretation. Ingestion is the most significant route of exposure of glyphosate-containing herbicides because they do not penetrate the skin to a significant extent. Up to 40% of an oral dose is absorbed in rats, although this could increase following exposure to concentrated solutions due to direct toxicity to the gastrointestinal epithelium. The peak glyphosate concentration occurs within 2 hours, distribution is limited, and there is minimal

metabolism. Glyphosate is predominantly eliminated unchanged in the urine within 24 hours.[11,13,123] Glyphosate does not appear to readily cross the placenta on the basis of an ex vivo model.[83]

Human toxicokinetic data are limited to a few cases. These confirmed rapid elimination of glyphosate (undetectable in plasma within 12 hours because of a half-life of less than 4 hours) and minimal metabolism.[11,48]

■ PATHOPHYSIOLOGY

It is not known whether the manifestations of glyphosate poisoning represent a primary (toxic) or secondary (downstream) effect. Disruptions of oxidative phosphorylation globally impair normal cellular function as a result of limited energy supply (discussed further with the pathophysiology of phenoxy herbicides). Similarly, direct toxicity to cell membranes (including those of the mitochondria) interferes with normal cellular processes such as ion channels. Both disruptions induce multiorgan toxicity. Hypotension and dysrhythmias impair tissue perfusion, and hepatic and renal toxicity induce metabolic disequilibria and acidosis, which impairs normal physiological processes. Pulmonary toxicity may lead to hypoxia, which further compromises normal cellular functioning. Failure to correct these abnormalities may lead to irreversible cellular toxicity and death.

■ CLINICAL MANIFESTATIONS

Abdominal pain with nausea, vomiting, and/or diarrhea are the most common manifestations of acute poisoning. These may be mild and self-resolving, but in severe poisoning there may be inflammation, ulceration, or infarction. Severe diarrhea and recurrent vomiting may induce dehydration. Gastrointestinal burns and necrosis occurs with high doses of concentrated formulations and may be associated with hemorrhage. Extensive erosions of the upper gastrointestinal tract is associated with more severe systemic poisoning and a prolonged hospitalization.[19,54]

Severe poisoning manifests as hypotension, cardiac dysrhythmias, renal and hepatic dysfunction, hyperkalemia, pancreatitis, pulmonary edema or pneumonitis, altered level of consciousness, and metabolic acidosis. These effects may be transient or severe, progressing over 12 to 72 hours to shock and death. The mechanism of hypotension may relate to both hypovolemia (fluids shifts and increased losses) and direct cardiotoxicity.[11,71,117]

Intravenous self-administration of glyphosate-containing herbicide caused hemolysis in one patient, and intramuscular self-administration caused rhabdomyolysis in another.

In a recent review of the literature,[11] death occurred in 10.1% of all published cases of acute poisoning with this herbicide (38 of 377; largely retrospective case series), but more cases have since been reported. A subsequent prospective study reported a case fatality of 3.5% (10 of 286 patients) in patients presenting to rural hospitals in Asia where resources are limited.[99] It is possible that improved availability of intensive care facilities may improve outcomes.

Respiratory, ocular, and dermal symptoms may occur following occupational use of these preparations but are usually of minor severity. Significant skin reactions from topical exposure are also reported.

■ DIAGNOSTIC TESTING

Acute poisoning with a glyphosate-containing herbicide is diagnosed on the basis of a history of exposure and clinical symptomatology.

Quantitative glyphosate or surfactant assays are not routinely available for clinical use, and other specific diagnostic tests are not available. The differential diagnoses are wide, including any xenobiotic or medical condition associated with gastrointestinal symptomatology and progressive multisystem toxicity.

A number of clinical criteria for the classification of severity have been suggested, but none have been validated.[11,99,117,120] There are no clinical investigations to guide management, including specific biomarkers or tools to estimate prognosis in acute poisoning. Patients who develop marked nonspecific organ toxicity (eg, renal failure, pulmonary edema, sedation, dysrhythmias) appear more likely to die.[67,68]

Targeted laboratory and radiological investigations should be conducted in patients demonstrating anything more than mild gastrointestinal symptoms. Pulse oximetry and blood gas measurements may be useful for detection of metabolic disequilibria and respiratory impairment. Endoscopy can diagnose erosions or ulceration following exposures to the concentrated formulation. However, this procedure may be complicated by perforation, and therefore its use requires careful consideration.

Glyphosate serum concentration greater than 1000 mg/L is associated with severe poisoning, although the relevance of this is debated since glyphosate is not thought to induce clinical toxicity itself.[11] It might, however, be a reasonable biomarker of exposure to the product, but more research is required to explore this relationship.

■ MANAGEMENT

Retrospective studies suggest a correlation between dose, severity of poisoning, and death.[68,107,120] All patients except for those with trivial exposures should be observed for a minimum of 6 hours. In particular, patients presenting with intentional self-poisoning or ingestion of concentrated formulation must be carefully monitored. If gastrointestinal symptoms are noted then the patient should be observed for a minimum of 24 hours given that clinical toxicity may progress. Because the toxicity of individual surfactants has not been determined, treatment does not vary depending on specific coformulants.

Resuscitation and Supportive Care All patients should receive prompt resuscitation, close observation, and routine supportive care; other treatments are largely empiric. The airway is usually maintained but respiratory failure and respiratory distress occur, which require supplemental oxygen and possibly mechanical ventilation. The optimum management of hypotension is complicated because its etiology is potentially related to hypovolemia, negative inotropism, and reduced vascular resistance. A detailed clinical review is required, followed by cautious administration of intravenous fluids to the patient. If the response to prompt administration of 20 to 30 mL/kg intravenous fluid to the patient is insufficient or there is increasing pulmonary congestion, vasopressors should be used. Cardiac investigations such as echocardiography, central venous pressure, or pulmonary artery catheter may also guide management, if available.

Biochemical and acid–base abnormalities, such as hyperkalemia, should be corrected where possible. The contribution of uncoupling of oxidative phosphorylation to clinical toxicity and death has been proposed, but no specific treatment is available if this develops. In the context of acute poisoning with glyphosate-containing herbicides, signs suggestive of uncoupling of oxidative phosphorylation such as hyperthermia, metabolic acidosis with elevated lactate concentration and hypoglycemia may be a preterminal event (see Chap. 15).

Hemodialysis or hemofiltration should be administered to patients developing acute kidney injury per usual guidelines if active treatment is to be pursued.

Gastrointestinal Decontamination No data exist to support the role of gastrointestinal decontamination in acute poisoning with glyphosate-containing herbicides beyond the usual recommendations discussed above.

Extracorporeal Removal Patients have survived severe poisoning and received hemodialysis; however, other patients have died despite this treatment. Plasmapheresis has also been trialed but clearances were not determined. Early initiation of any of these treatments may be required for best results. The role of extracorporeal removal in routine care is not known given that there are limited quantitative data reporting direct clearances.

Antidotes No specific antidote has been proposed or tested for the treatment of acute poisoning with glyphosate-containing herbicides, which probably relates to the unknown mechanism of toxicity of these products.

PHENOXY HERBICIDES (PHENOXYACETIC DERIVATIVES), INCLUDING 2,4-D AND MCPA

Phenoxy compounds are selective herbicides that are widely used in both developing and developed countries. A large number of compounds are included in this category; however, the most widely used are the phenoxyacetic derivatives. This includes 2,4-dichlorophenoxyacetic acid (2,4-D), 4-chloro-2-methylphenoxyacetic acid (MCPA), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T; no longer available), and mecoprop (MCPP; 2-[4-chloro-2-methylphenoxy]propionic acid; Fig. 115–5). Other phenoxy herbicides and available toxicity data are listed in Table 115-1. In 2001, 2,4-D was the fifth most commonly used pesticide in the United States but the most commonly used pesticide in the domestic sector (MCPP was fifth most commonly used in the domestic sector).[60]

Agent orange, a defoliant popularly used during the Vietnam War, was composed of an equal mixture of 2,4-D and 2,4,5-T. This product also contained the contaminant dioxin (2,3,7,8-tetrachlorodibenzo-dioxin; TCDD), which was a byproduct of the manufacture of phenoxy herbicides. Dioxin is a persistent organic pollutant that is alleged to induce chronic health conditions and cancer, although this has been debated. This chapter discusses only the outcomes of acute exposures to phenoxy herbicides.
FIGURE 115–5. Structure of common phenoxy herbicides.

PHARMACOLOGY

The mechanism of toxicity of phenoxy compounds is not well described. As with other herbicide products, the formulation is irritating or corrosive, causing direct toxicity to the gastrointestinal tract. Patients with severe poisoning manifest multisystem effects, suggesting that the formulation is either nonspecific in its action or that it interferes with a physiological process common to a number of systems. As with other herbicide preparations, this may reflect the contribution of coformulants such as surfactants.

In rats, high serum concentrations of MCPA damage cell membranes and induce toxicity, but the correlation between serum concentrations, membrane damage, and toxicity is poor.

Uncoupling of oxidative phosphorylation also may contribute to the development of severe clinical toxicity. Phenoxyacetic derivatives demonstrate concentration-dependent uncoupling of rat mitochondria in vitro, although the specific process that is disrupted is not sufficiently described.[14,130] Features of uncoupling of oxidative phosphorylation were observed antemortem in clinical studies of patients with large phenoxy herbicide exposures.[103]

Phenoxy acid compounds inhibit the voltage-gated chloride channel CLC-1 in skeletal muscles, which is thought to contribute to the neuromuscular toxicity of these compounds. Dysfunction of CLC-1 induces myotonia due to hyperpolarization of the cell membrane. Other CLC channels are important for normal renal physiology. There are differences in the degree of inhibition between individual phenoxy acid compounds, which may contribute to the variability in animal LD_{50} and possibly clinical features.[2,69,70]

Other possible mechanisms of toxicity relate to their similarity to acetic acid, interfering with the utilization of acetylcoenzyme A (acetyl-CoA), or action as a false messenger at cholinergic receptors.[12]

PHARMACOKINETICS AND TOXICOKINETICS

Animal studies and human case reports have shown nonlinear kinetics for the phenoxy herbicide compounds. Dose-dependent changes in absorption, protein binding, and clearance all occur, and each will influence the concentration-time profile.

Absorption is usually first order[1]; however, the time to peak concentration may be delayed with increasing doses, which may suggest saturable absorption.[66,121]

As the dose of MCPA increases there is a change in the semilogarithmic serum concentration-time profile from linear to a biphasic convex profile. The inflection of this elimination curve in rats is approximately 200 mg/L,[34,35,121] which may reflect saturation of albumin binding. As the serum concentration exceeds this point the proportion of herbicide that is free (unbound) increases. This may increase the Vd and prolong the apparent plasma elimination half-life.

Another contributing mechanism to the observed biphasic convex concentration-time profile is saturation of renal clearance for which there is some interspecies variability. Dose-dependent renal clearance is attributed to saturation of an active transport process or direct nephrotoxicity. Renal clearance also varies with urine flow because of reabsorption from the distal tubule.

Similar to data from animal studies, the semilogarithmic serum concentration-time curve of phenoxy herbicides in humans with acute poisoning is generally convex, with an apparent inflection from a longer to shorter elimination half-life between 150 and 300 mg/L. The elimination half-lives are prolonged, which may explain the persistence of clinical toxicity and why death may occur a number of days postingestion of a phenoxyacetic herbicide.

Alterations in blood pH may also change tissue distribution because phenoxyacetic herbicides are weak acids (pKa approximately 3). Here, acidosis increases the proportion that is nonionized, and therefore lipophilic, which increases tissue binding and distribution. This has been observed in vitro and is similar to that observed for salicylates (see Chap. 35). Similarly, an alkaline plasma pH is expected to decrease tissue (and probably receptor) binding and increase plasma concentrations.

Experience with acute human poisonings noted a poor correlation between serum herbicide concentrations and peak toxicity.[103] This may reflect a discordance between serum (measured) and intracellular (eg, mitochondrial) concentrations.

■ PATHOPHYSIOLOGY

Direct toxicity to the gastrointestinal tract may cause vomiting and diarrhea, which induces hypovolemia and electrolyte abnormalities.[12] Nonspecific cellular toxicity and uncoupling of oxidative phosphorylation interfere with normal function of ion channels and other cellular functions, preventing normal physiological processes.

Uncoupling of oxidative phosphorylation may be caused by chemicals that disrupt mitochondrial function, and causes inefficiency in energy production. At a cellular level it describes an increase in oxygen consumption and heat production out of proportion to the generation of ATP due to mitochondrial dysfunction. Varying degrees of uncoupling of oxidative phosphorylation may occur. The initial physiological response to uncoupling is to increase mitochondrial respiration to maintain the supply of ATP, which increases heat production and respiratory rate. As ATP falls there is an increase in glycolysis, causing lactic acidosis and hypoglycemia. If the mitochondrial defect persists then there will be hyperthermia and insufficient ATP for essential cellular functions including active transport pumps such as Na^+,K^+-ATPase. This is followed by a loss of cellular ionic and volume regulation, which, if persistent, is irreversible and cell death occurs. Because mitochondria are the primary supplier of ATP for most physiological systems, uncoupling of oxidative phosphorylation is expected to induce multisystem toxicity.

■ CLINICAL MANIFESTATIONS

Vomiting, myotonia (confirmed on electromyography), and miosis are prominent features of 2,4-D poisoning in dogs. Severity varies in a dose-dependent manner, peaking 12 to 24 hours postingestion and persisting for a number of days.[6]

Gastrointestinal toxicity including nausea, vomiting, abdominal or throat pain, and diarrhea are common. Other clinical features include neuromuscular features (myalgia, rhabdomyolysis, weakness, myopathy, myotonia, and fasciculations), central nervous system features (agitation, sedation, confusion, miosis), tachycardia, hypotension, renal toxicity, hypocalcemia, and hypokalemia. In some patients, these effects persist for a number of days.

Tachypnea with respiratory alkalosis occurs in patients with phenoxy herbicide poisoning, some of who died, which may be consistent with increased mitochondrial respiration from mild uncoupling. More severe poisoning may be characterized by metabolic acidosis, hyperventilation, hyperkalemia, hyperthermia, elevated creatine kinase, generalized muscle rigidity, hypotension, pulseless electrical activity, or asystole.[12,24,89,103]

The mortality from acute phenoxy herbicide poisoning is potentially high. A systematic review of all acute phenoxy herbicide poisoning described severe clinical toxicity in most patients, including death in one-third of the cases.[12] Subsequently, a prospective study of MCPA exposures in Sri Lanka demonstrated minor toxicity in greater than

80% of patients and a mortality of 4.4% (eight of 181 patients).[103] When death occurs, it is usually delayed by 24 to 48 hours postingestion and results from cardiorespiratory arrest. The exact mechanism of death is inadequately described, but it may relate to uncoupling of oxidative phosphorylation or other metabolic dysfunction including renal toxicity, as discussed above.

■ DIAGNOSTIC TESTING

Commercial assays for the specific measurement of phenoxy herbicides are not available to assist in the diagnosis of acute poisoning. Further, their role in the management of acute poisoning is not confirmed because the relationship between serum phenoxy herbicide concentration and clinical toxicity is not adequately defined. Sedation is reported with a serum phenoxy concentration above 80 mg/L,[98] while concentrations more than 500 mg/L are associated with severe toxicity.[38] A patient survived severe MCPA poisoning (hypotension and limb myotonia) with a serum concentration of 546 mg/L. The myotonia persisted for a number of days and resolved when the MCPA serum concentration was less than 100 mg/L.[108] In contrast, death has been reported following MCPA poisoning at serum concentrations as low as 107 mg/L to 230 mg/L.[58,93,103]

Monitoring of electrolytes, renal function, pulse oximetry, and blood gases is recommended to detect progression of organ toxicity. Creatine kinase should also be determined since rhabdomyolysis may occur following acute poisoning. Urinalysis might be useful for identifying myoglobinuria. There are insufficient data describing the role of these measurements for prognostication.

■ MANAGEMENT

All significant poisonings, particularly symptomatic oral ingestions, should be treated cautiously, including continuous monitoring for 24 to 48 hours preferably in an intensive care unit. Initial mild toxicity (for example, gastrointestinal symptoms but normal vital signs and level of consciousness at presentation) does not preclude subsequent severe toxicity and death.[103]

Animal studies suggest that phenoxy herbicide toxicity increases when elimination is impaired. Empirically, this supports the use of treatments that decrease exposure either by decreasing absorption or increasing elimination. Unfortunately, there is insufficient evidence to recommend specific interventions in patients with acute phenoxy herbicide poisoning. However, an adequate urine output (greater than 1 mL/kg/h) may optimize the renal excretion of phenoxy herbicides as well as decreasing renal toxicity from rhabdomyolysis. Since signs consistent with uncoupling of oxidative phosphorylation are likely to be associated with a poor outcome, more advanced treatments such as hemodialysis can be considered in these patients.[12,103]

Resuscitation and Supportive Care All patients should receive routine resuscitation, close observation, and supportive care. It is reasonable to correct electrolyte abnormalities and acidosis given that this may promote the distribution of weak acids and increase the intracellular concentration.

Gastrointestinal Decontamination Gastrointestinal decontamination can be administered to patients per the guidelines listed above (see also Chap. 7). Delayed administration of activated charcoal to patients is reasonable given that absorption appears to be saturable, although clinical data supporting this are not available.

Extracorporeal Removal Because phenoxy compounds are small and water soluble, and subject to saturable protein binding with large exposures (increasing the free concentration), they are likely to be cleared by extracorporeal techniques. Extracorporeal elimination using resin hemoperfusion, hemodialysis, or plasmapheresis has been trialed in a few cases, with clearances approaching 75 mL/min. Hemodialysis should be considered in patients with severe toxicity if facilities are available.

Antidotes There are no specific antidotes for phenoxy herbicides, but sodium bicarbonate or other alkalinizing agents may have a role in management by altering the kinetics of phenoxy herbicides.

Data from animal studies and case reports suggest that urinary alkalinization increases the elimination of phenoxy herbicides. Increases in urinary pH increase clearance due to "ion trapping" of the phenoxy herbicide. For example, renal 2,4-D clearance was increased from 5.1 mL/min to 63 mL/min when urine pH increased from 5.0 to 8.0.[94] Compared with a total clearance of approximately 30 mL/min or less in volunteer studies,[62,106] this increase in renal clearance has the potential to be clinically significant. Prospective, randomized studies are required to confirm the efficacy of urinary alkalinization in humans.

Plasma alkalinization may also limit the distribution of phenoxy compounds from the central circulation by "ion trapping."

It is reasonable to consider plasma and urinary (urine pH greater than 7.5) alkalinization in patients who are symptomatic, particularly if there are features of uncoupling of oxidative phosphorylation or metabolic acidosis. Alkalinization is rarely associated with adverse effects when administered to patients with care and close observation (see Antidotes in Depth A5: Sodium Bicarbonate).

TRIAZINE COMPOUNDS, INCLUDING ATRAZINE

The 1,3,5-triazine or s-triazine compound (Fig. 115–9) is central to a large number of compounds, including herbicides, other pesticides (eg, cyromazine), resins (eg, melamine), explosives (RDX or C-4) and antiinfectives. Triazine herbicides are widely used, and in 2001 atrazine and simazine were among the 25 most used pesticides in the United States.[60] However, cases of acute poisoning are infrequent. Other herbicides included in this group are listed in Table 115–1. These selective herbicides may be used pre- or postemergence for weed control.

The safety of atrazine from an environmental health perspective is debated because of its persistence and propensity to spread across water systems and potential toxicity from chronic exposure. This led to restrictions on the use of triazine compounds recently in the European Union, but not elsewhere.

■ PHARMACOLOGY

Mechanism of toxicity is not fully determined, although it might relate to uncoupling of oxidative phosphorylation.[15] Atrazine is a direct arteriolar vasodilator.[18] Some metabolites of atrazine, particularly those remaining chlorinated, are thought to retain some biological activity.[4] Similarly, clinical features of prometryn poisoning resolved posthemodialysis despite persistence of the parent herbicide, suggesting that toxic metabolites were eliminated.[15]
FIGURE 115–9. Structure of common triazine herbicides.

■ PHARMACOKINETICS AND TOXICOKINETICS

Approximately 60% of an oral atrazine dose is absorbed in rats. The absorption phase of triazine compounds appears to be prolonged in humans where the serum concentration continues to increase during treatment with hemodialysis.[15,91] This is consistent with atrazine data in rats where the concentration peaks beyond 3 hours.[81] Atrazine is rapidly dealkylated to a metabolite that binds strongly to hemoglobin and serum proteins, allowing it to be detected in the blood for months. Metabolites are excreted in the urine and around 25% of them are conjugated to glutathione.[81]

The metabolism of atrazine has been studied in humans following occupational exposures, and animals, and a range of metabolites are described, in particular those derived from glutathione conjugation. Other metabolic products as a result of dealkylation and oxidation are also present.

Dermal absorption of atrazine is incomplete but increases with exposure to the proprietary formulation. Atrazine metabolites are readily measured in the urine of atrazine applicators.

■ CLINICAL MANIFESTATIONS

There are limited cases of triazine herbicide poisoning. Vomiting, depressed level of consciousness, tachycardia, hypertension, acute kidney injury, and lactic acidosis were described in a patient with acute prometryn and ethanol poisoning.[15] Similar clinical signs, in addition to hypotension with a low peripheral vascular resistance, were noted in a case of poisoning with atrazine, amitrole (see Table 115–1), and other toxic compounds. This was followed by progressive multiorgan dysfunction and death due to refractory shock 3 days later.[91]

■ DIAGNOSTIC TESTING

In a single case report, clinical toxicity did not directly relate to the concentration of prometryn, but the relationship to the concentration of metabolites has not been determined.[15] Routine biochemistry and arterial blood gases are useful for monitoring for the development of systemic toxicity.

■ MANAGEMENT

Few publications of triazine herbicide poisoning are available to guide management of patients with acute triazine poisoning.

Resuscitation and Supportive Care Routine resuscitation, close observation, and supportive care should be provided to all patients. Ventilatory support and correction of hypotension and metabolic disequilibria is reasonable.

Gastrointestinal Decontamination It is reasonable to administer activated charcoal to patients beyond 1 hour because of the slow absorption of these compounds.

Extracorporeal Removal Hemodialysis corrected metabolic acidosis in a case of prometryn poisoning without decreasing the serum concentration of prometryn, which might reflect ongoing absorption. In the absence of direct measurements of clearance, the efficacy of hemodialysis in removing prometryn cannot be determined but is probably limited.[15] Hemodialysis clearance of atrazine was 250 mL/min (extraction ratio 76%), but only 0.1% of the dose was removed after 4 hours of treatment. Further, similar to the previous case, atrazine concentrations continued to increase during the treatment.[91]

Antidotes No antidotes are available for the treatment of triazine herbicide poisoning.

SUMMARY

A large number of heterogeneous xenobiotics are classified as herbicides, and for many their toxicity in humans is incompletely described. Coformulants such as surfactants and solvents probably contribute to clinical toxicity in commercial preparations. Many herbicides induce multisystem toxicity for which treatments are often unsatisfactory, although some compounds induce organ-specific toxicity. All patients with acute intentional poisoning should be carefully observed for the development of poisoning. The priorities of treatment include a prompt resuscitation, a detailed history, ongoing monitoring, and supportive care. More research is required to better define the clinical syndromes associated with herbicide poisoning, the toxicokinetics of relevant compounds, and the efficacy of treatments including antidotes.

CHAPTER 116
METHYL BROMIDE AND OTHER FUMIGANTS

Keith K. Burkhart

Fumigants are applied to control rodents, nematodes, insects, weed seeds, and fungi anywhere in soil, or on structures, crops, grains, and commodities.[20] Although many different chemical classes were used as fumigants, only a few remain in use today in the United States. Many fumigants, especially halogenated solvents, were abandoned because of their toxicity. In the 1987 Montreal Protocol an international agreement was adapted to phase out ozone-depleting chemicals such as methyl bromide, which was scheduled to be discontinued in 2005. Unfortunately many agricultural companies received exemptions, as satisfactory substitutes for some of its uses have not emerged.

Although fumigants exist as solids, liquids, or gases, they are most commonly used in the gaseous form or as volatile liquids, explaining why inhalation is the most common route of exposure (Table 116–1). Because of their gaseous forms, fumigants are generally heavier than air. Therefore, they will stay concentrated above the ground surface and lower floors of buildings. In addition, many do not have good warning properties. Several, such as methyl bromide and sulfuryl fluoride, are colorless and the toxic concentrations are below the odor threshold, making them particularly dangerous. While phosphides have a "rotten fish" or garliclike odor, toxic exposures are often debilitating, not allowing for escape.

METHYL BROMIDE

■ HISTORY AND EPIDEMIOLOGY

Methyl bromide (CH_3Br) was used as an anesthetic in the early 1900s, but fatalities halted this practice. It was used as a fire retardant during World War II, a role that persisted into the 1960s in Europe. Like many other halogenated hydrocarbons, methyl bromide was also used as a refrigerant, methylating agent, chemical precursor, and as a fumigant in fruit packaging. Industrial use and its naturally occurring environmental production in oceans have led to low concentrations of methyl bromide in ambient air, water, and food.[27] Diets that are high in marine products and fruits may increase environmental exposure to methyl bromide.[27]

Occupational and environmental exposures to methyl bromide as a fumigant are most common. Hazardous materials incidents are reported for methyl bromide, both during use and transport,[9,39] but they are relatively uncommon in residents and plant employees, living or working adjacent to agricultural fields where methyl bromide is applied.[8,9,20,39] Methyl bromide and other fumigants can also escape from fumigated structures into adjoining rooms, and adjacent or conjoined buildings, resulting in severe illness and fatalities.[33,50] For example, pipes adjoining sections of a greenhouse have led to exposures.[24] Fatalities have occurred when workers entered tanks containing fumigant residues.[30] Workers who repeatedly transfer methyl bromide between containers have developed severe neuropsychiatric sequelae. Defective or leaking canisters of methyl bromide are another source of exposure. In Europe, indoor and outdoor exposures to the contents of old fire extinguishers have caused severe poisoning and fatalities. Most symptoms reported by unintentionally exposed individuals are related to chloropicrin,

which is usually formulated as 2% of the methyl bromide concentration. The overlap of the irritant and nonspecific symptoms of methyl bromide and chloropicrin make it difficult to absolutely differentiate between the two at the time of the exposure.[20] Rarely, fumigants are inhaled or ingested with suicidal intent.

■ OCCUPATIONAL EXPOSURE

Methyl bromide fumigation may expose workers to high concentrations at many steps in the process.[49] The Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) is 20 parts per million (ppm). The American Conference of Governmental Industrial Hygienists (ACGIH) has recommended an 8-hour TWA (time-weighted average) of 3.9 mg/m³ for methyl bromide; 1 mg/m³ is 3.88 ppm.

Work clothes concentrations of 50 ppm have been recorded. Depending on ventilation conditions, concentrations up to 55 ppm occurred when the plastic sheets were removed 7 days after a soil application. Dermal and ocular exposures may occur during application secondary to employee error or equipment failure.[9] Leather and rubber gloves enhance skin contact with methyl bromide, and tight-fitting clothing may trap gas close to the skin.[9] Because of these properties, leather and rubber should be avoided for all applications, and work clothes should be changed after the application.

Methyl bromide is listed in the International Agency for Research on Cancers (IARC) as Group 3, or not classifiable as to its carcinogenicity in humans secondary to inadequate animal and human evidence.

■ TOXICOKINETICS

Methyl bromide is rapidly absorbed by oral, inhalational, and dermal routes. Life-threatening toxicity has been reported within the first hour of exposure. After absorption, bioactivation by oxidative metabolism by the cytochrome P450 enzymes occurs. These reactive metabolites can form protein adducts with albumin and hemoglobin.

There is significant individual variability for cytochrome P450 oxidative metabolism and patients exposed to methyl bromide demonstrate this variability. Three of seven methyl bromide workers had high hemoglobin adduct concentrations despite performing the same job as the other four.[46] S-methylcysteine albumin and hemoglobin adducts may persist for weeks.[7] Cysteine residues, at number 104 of the α chain and 93 of the β chain, appear to be preferentially methylated,[19] although it is unknown what role methylation plays in the toxic manifestations that follow methyl bromide metabolism.

■ PATHOLOGY/PATHOPHYSIOLOGY

Energy deprivation secondary to methylation of the sulfhydryl groups of metabolic enzymes is proposed as a common mechanistic pathway.[46] Pathologic examinations demonstrate the neurotoxicity of methyl bromide. Symmetric neuronal loss and gliosis have been described in both the central and peripheral nervous systems. The associated neurologic deficits have sometimes been irreversible. The cerebral lesions are reportedly similar to thiamine deficiency and Wernicke encephalopathy.

■ CLINICAL MANIFESTATIONS

Exposure to methyl bromide may lead to immediate life-threatening toxicity including a rapid loss of consciousness followed by seizures, dysrhythmias, and death. In contrast, symptoms may be delayed for days following low-level exposure. Cardiac, pulmonary, hepatic, neurologic, and renal toxicity may also develop following toxicity from methyl bromide exposure (Table 116–2). Some individuals may initially manifest irritant symptoms of the eye, nasopharynx, and oropharynx. These irritant symptoms may help differentiate upper

[a] Ethylene dibromide has been banned and is no longer in use, but it is included for historical reference.

[b] Commodity fumigant, which is a class term used by the Environmental Protection Agency to refer to fumigation of a food or agricultural product.

respiratory and gastrointestinal viral syndromes from methyl bromide exposure. In some cases, the initial symptoms of methyl bromide poisoning are misdiagnosed as influenza or a viral like illness such as gastroenteritis.[33] In more severe poisonings pulmonary symptoms begin with cough or shortness of breath that may rapidly progress to bronchitis, pneumonitis, acute lung injury (ALI), and hemorrhage.

The neurologic effects of methyl bromide poisoning are the most consequential and may occur without antecedent irritant effects. Initial central nervous system signs and symptoms that may manifest in the first few hours after exposure include headache, vomiting, dizziness, drowsiness, euphoria, confusion, diplopia, dysmetria, dysarthria, and mood disorders or inappropriate affect. Those that may progress rapidly in the first day or manifest over the next few days include ataxia, psychotic delirium, intention tremor, fasciculations, myoclonus, seizures, and coma.

Many patients develop skin lesions such as erythema, vesicles, and bullae predominantly in moist areas or pressure points, including the

TABLE 116–2. Comparison of Clinical Effects of Fumigants

Clinical Effect	Chloropicrin	Dichloropropene	Ethylene Dibromide	Metam Sodium	Methyl Bromide	Phosphine	Sulfuryl Fluoride

groin, axilla, and wrist.[52] In one report, erythema and multiple vesicles developed on all four limbs of a fumigator who used protective respiratory gear.[31] This patient's skin lesions healed after 5 weeks, but he had a persistent peripheral neuropathy.

Patients chronically exposed may present with varied neurologic features including optic atrophy, nystagmus, paresthesias, dysesthesias, hypesthesia, hyporeflexia, and hyperreflexia. Visual loss associated with optic nerve degeneration may be permanent.[11] One chronically exposed worker had multiple presentations for psychosis before the underlying etiology of methyl bromide poisoning was determined.[51] Chronic exposure to methyl bromide is also associated with hepatotoxicity and nephrotoxicity. It is likely that acute poisoning produces similar effects and that critically ill patients simply may not survive to manifest fulminant hepatic failure. Autopsy findings have included acute tubular necrosis and degenerative nephritis.[33] Recovery of renal function is typical in survivors.

■ DIAGNOSTIC TESTING

Standard baseline laboratory tests should be obtained after an acute exposure, although they usually will be normal initially. Hepatic dysfunction should be assessed with hepatic aminotransferases and ammonia concentrations. Serum bromide concentrations are not readily available in most laboratories. Although a serum bromide concentration does not facilitate the clinical management of a methyl bromide–poisoned patient, the concentration may help confirm the diagnosis. Serum bromide concentrations may remain elevated for a week or more following an acute exposure. The elevation of the serum bromide, however, does not always correlate with the severity of the exposure.[24] An elevated serum bromide concentration may also cause a false elevation in serum chloride, when assayed using an ion selective electrode meter (see Chap. 16). Alternatively, in the setting of known methyl bromide exposure, the residual air concentration of methyl bromide can be measured.

■ TREATMENT

Treatment for methyl bromide poisoning relies on general and supportive care, and may require intensive care unit (ICU) management of coma, seizures, ALI, and hepatic and renal failure. Seizures are common and difficult to control with traditional anticonvulsants such as benzodiazepines and phenytoin. Pentobarbital coma and propofol have been required for many cases.[24] Decontamination should include the removal of clothing, as methyl bromide may bind to clothing, including rubber and leather. Clinical staff should exercise standard precautions using personal protective equipment. Irrigation of the eyes with saline and skin decontamination with soap and water should be performed by healthcare professionals using personal protective equipment. It is also reasonable to administer at least one dose of oral activated charcoal (AC) following ingestion.

Although hemodialysis can rapidly clear serum bromide, methyl bromide is probably completely metabolized by the time dialysis is considered. When dialysis is provided postdialysis neurological improvement was reported, but severe disabilities may remain. There is little evidence to support routine hemodialysis. Tissue injury following fumigant exposure occurs as the bromide is released into the serum, suggesting that the methylation of neuronal proteins has already occurred and the neurologic injury occurs so early that hemodialysis is unlikely to affect outcome.

■ PROGNOSIS

Most patients who develop seizures and coma will not survive and the few survivors of methyl bromide exposure who are described in the literature, with rare exception, had neuropsychiatric sequelae. These sequelae may or may not be permanent and have included myoclonus, cognitive deficits, paranoid delusions, depression, anxiety, mood disorders with rapid behavioral swings, and suicidal and homicidal thoughts.[7,48]

METHYL IODIDE

Iodomethane or methyl iodide (CH_3I) is currently under review by the Environmental Protection Agency (EPA). It is proposed fumigant to replace methyl bromide. However, a few reports from Europe suggest that the toxicity of methyl iodide may be similar to that of methyl bromide.[22,41] A recent report describes dermal exposure with severe burns and delayed neuropsychiatric sequelae, again similar to methyl bromide exposures.[43] This case of occupational exposure resulted from a breach in a protective suit.

DICHLOROPROPENE
■ HISTORY AND EPIDEMIOLOGY

Dichloropropene was introduced in 1945 and is primarily used as a soil fumigant for nematodes. Exposures are reported during production, application, and ingestion.

■ OCCUPATIONAL EXPOSURE

Chronic subclinical changes in hepatic and renal function have been reported in Dutch flower bulb soil fumigators using dichloropropene.[6] Hematologic cancers including lymphoma and histiocytic lymphoma were reported in firemen after dichloropropene exposure.[32] The threshold limit value (TLV) for dichloropropene is 1 ppm. The Dutch occupational exposure limit is 5 mg/m[3] (equivalent to 1 ppm).

■ TOXICOKINETICS

Inhalation is the primary method of toxicity for 1,3-dichloropropene. In a human volunteer study, dermal absorption of dichloropropene was only 2% to 5% of inhalational absorption.[28] The metabolism of 1,3-dichloropropene is probably similar to that of other chlorinated hydrocarbon solvents such as carbon tetrachloride and chloroform (see Chap. 106). Glutathione depletion has been documented in the rat model.[21] The dose and route correlate with toxicity and outcome in rodent models of 1,3-dichloropropene toxicity. At 100 mg/kg in mice, hepatotoxicity occurs by the intraperitoneal route, but not after oral gavage. At 700 mg/kg administered by the intraperitoneal route hepatic failure and death resulted.[3] The higher dose correlated with a 130-fold increase in dichloropropene epoxide formation. Interestingly, in a rat hepatocyte model, pretreatment with the antioxidant, α-tocopherol, prevented cell death.[47]

■ CLINICAL MANIFESTATIONS

There are only a few reports of systemic dichloropropene toxicity. A patient died following the unintentional ingestion of a glass of dichloropropene.[23] Within 2 hours he developed tachycardia, tachypnea, hypotension, sweating, and abdominal pain, followed by hematochezia, acute respiratory distress syndrome (ARDS), rhabdomyolysis, metabolic acidosis, and hyperglycemia prior to death.[23] A hazardous materials incident exposed nine firemen to dichloropropene during cleanup operations. Symptoms included headache, neck pain, nausea, and difficulty breathing.[32] Other exposed individuals developed contact dermatitis and allergies to dichloropropene.[16] Healing of the skin leaves pigmented lesions.

■ DIAGNOSTIC TESTING

Hepatic and renal function should be monitored following acute poisoning, as autopsy has revealed extensive hepatic and renal necrosis after ingestion.[23] No additional tests are recommended beyond those needed for supportive care. Biomonitoring for exposure to dichloropropene is under development.[6] Hepatic γ-glutamyl transpeptidase (GGTP) concentrations were increased in fumigators, but the increase was not statistically significant. This finding, however, suggests hepatic enzyme induction. In fumigators erythrocyte glutathione S-transferase (GST) and glutathione (GSH) concentrations decreased with increased serum creatinine concentrations and increased urine concentrations of albumin and retinol-binding protein compared with controls.

■ MANAGEMENT

Because of off-gassing, the patient's clothes should be removed and bagged to avoid continued inhalational and dermal exposure of the patient and the healthcare worker, which demonstrates the benefits of personal protective equipment (PPE). If ingestion occurs, one dose of AC should be administered. There are no data to support specific therapies beyond supportive care, although the use of antioxidant therapy and *N*-acetylcysteine (NAC) warrant further study.

PHOSPHIDES AND PHOSPHINE

■ HISTORY AND EPIDEMIOLOGY

Phosphides are usually found as powders or pellets, usually in the form of zinc Zn_3P_2 or aluminium phosphide (AlP). Calcium and magnesium phosphides are also available. Phosphine gas (PH_3) is formed from phosphides after contact with water, particularly if acidic. Workers not using respiratory protective equipment may develop toxicity during the manufacturing of phosphides. Phosphide tablets are often placed in grain stores, such as ships, allowing the phosphine to be released once the storage sites are sealed. Phosphine is also available as a compressed gas in metal cylinders. Phosphine exposures and toxicity, both from phosphide salts or from compressed gas, have occurred during grain fumigation in both transport and storage areas, particularly if entry to the storage site occurs prior to proper ventilation. Many reports of serious and fatal phosphide poisonings originate from India, the Middle East, and developing countries. Aluminium phosphide consumption is commonly chosen as a means of suicide in India. In the United Kingdom a review of exposures by the National Poisons Information Service found most cases to be the result of unintentional agricultural exposures.[4] Clandestine methamphetamine laboratories that use the ephedrine/hydriodic acid/red phosphorus manufacturing method may generate phosphine gas at high reaction temperatures. Fatalities at these sites are reported, and first responders have also been exposed to high phosphine concentrations.[8]

■ TOXICOKINETICS AND PATHOPHYSIOLOGY

Phosphides produce toxicity rapidly, generally within 30 minutes of ingestion, and death may follow in less than 6 hours. The ingestion of fresh, unopened tablets consistently results in death. Toxicity from inhalation of phosphine gas is almost instantaneous. Phosphine disrupts mitochondrial function by blocking cytochrome c oxidase.[45] In addition to producing energy failure in cells, free radical generation increases, resulting in lipid peroxidation.[12,13,45] Phosphine also inhibits cholinesterases in rats, but people do not typically present with a cholinergic syndrome.[34]

■ CLINICAL MANIFESTATIONS

Phosphide ingestions of over 500 mg are often fatal. Unopened packets are more potent, as once opened, atmospheric moisture may react with tablets to decrease their potency. Phosphides are potent gastric irritants; profuse vomiting and abdominal pain are often the first symptoms to occur following ingestion. Respiratory signs and symptoms include tachypnea, hyperpnea, dyspnea, cough, and chest tightness that may progress to ALI over days. In significant exposures, hypotension and dysrhythmias often develop.[17] Phosphine-induced dysrhythmias include atrial fibrillation and flutter, heart block, and ventricular tachycardia and fibrillation. Echocardiography and electrocardiography have demonstrated reversible myocardial injury (ST elevations and inversions) and left ventricular hypokinesis.[1,26] Central nervous system toxicity includes coma, seizures, and delirium. Pancreatitis and esophageal strictures are occasionally delayed complications of oral exposures. Obstructive airways disease has been reported following occupational inhalational exposure.[5]

■ DIAGNOSTIC TESTING

The diagnosis is usually established from the history and confirmatory laboratory testing such as elevated lactate concentrations. Further laboratory testing is dictated by the need for supportive care. Headspace gas chromatography with a nitrogen-phosphorus detector was used to detect phosphine gas from postmortem tissue.[35]

■ MANAGEMENT

Patients who ingest phosphides frequently vomit from the irritant effects. Off-gassing from emesis, theoretically, may expose healthcare workers to phosphine vapor. The emesis should be placed in sealed containers and disposed of properly, as wet phosphides will continue to generate phosphine gas.

The toxicology literature describes many theoretical approaches to prevent the postingestion generation of phosphine gas and its absorption. All of these efforts will be hampered by the vomiting that usually occurs along with the possible aspiration of gastric contents and administered agent. Because the extent to which AC binds phosphides is generally unknown and there is a lack of clinical outcome data for AC, administration of oral AC may be considered appropriate but of uncertain value. Dilution with bicarbonate solution has been recommended, as bicarbonate decreases the gastric hydrochloric acid concentration, which normally assists in the conversion of phosphides to phosphine gas. Also unproven is the use of diluted potassium permanganate to oxidize the phosphides. Case reports from India and Nepal describe the use of vegetable oil for gastric lavage fluid and the use of coconut oil with sodium bicarbonate, based upon the theory that fats and oils are nonmiscible and may prevent the release of phosphine gas.[44] Clinical outcome studies have not been performed for any of these theoretical therapies and therefore cannot be recommended at this time.

Trimetazidine, which is not currently available in the United States, is used elsewhere for the treatment of cardiac toxicity[17] as it may diminish the oxidant stress caused by phosphine.[13] Internationally, trimetazidine is used as an antianginal agent. The drug may improve the energy state within cardiac myocytes by shifting from oxidative metabolism to glucose utilization. Preliminary research using rat models in India suggests possible benefits, including increased survival time with the use of N-acetylcysteine (an antioxidant) and pralidoxime (a cholinesterase reactivator).[2,34] Intravenous magnesium acting as an antiperoxidant has also been proposed as a benefit following aluminium phosphide ingestion. An unblinded trial of 50 subjects reported reduced mortality (42% compared with 20%) in those treated with repeated intravenous doses of magnesium.[14] All of these proposed therapies, however, require further study. At this time the use of NAC and magnesium are of uncertain benefit but appropriate for use.

SULFURYL FLUORIDE

$$O = \overset{\overset{\displaystyle F}{|}}{\underset{\underset{\displaystyle F}{|}}{S}} = O$$
■ HISTORY AND EPIDEMIOLOGY

Sulfuryl fluoride has been used since 1957 as a structural fumigant insecticide to control wood-boring insects such as termites in homes. Structure or tent fumigation is performed by completely enclosing a house or other structure in plastic or a tarpaulin; the sulfuryl fluoride is pumped in as a compressed gas. Chloropicrin is typically added as a warning agent. Although sulfuryl fluoride is commonly used in Florida, California,[37] and Washington, a 5-year review of fumigant illness did not contain any reports of sulfuryl fluoride toxicity.[8]

■ TOXICOKINETICS AND PATHOPHYSIOLOGY

Little is known about the toxicokinetics of sulfuryl fluoride in humans. At high concentrations (above 4000 ppm) rats developed seizures followed by respiratory arrest.[36] At lower concentrations and with chronic exposure, rats and rabbits developed respiratory inflammation, renal lesions, and cerebral vacuolation.[18] The mechanism of toxicity is not understood. The measurable fluoride concentrations in patients suggest that the release of fluoride may be a major pathophysiologic mechanism.[37] In models of chronic, low concentration exposures, fluorosis developed. The TLV-TWA for sulfuryl fluoride is 5 ppm; TLV–short-term exposure limit (STEL) is 10 ppm; IDLH (immediately dangerous to life and health) is 200 ppm. Sulfuryl fluoride was not found to be teratogenic in rats or rabbits.[21]

■ CLINICAL MANIFESTATIONS

Case reports of sulfuryl fluoride exposure describe acute and subacute courses that have many similarities to methyl bromide. As is the case in animal studies, severe exposures in humans affect the cardiopulmonary and nervous systems. Initial symptoms may be gastrointestinal, including nausea, vomiting, diarrhea, and abdominal pain, or respiratory, including cough and dyspnea. Irritation of mucosal surfaces may produce salivation and nasopharyngitis lacrimation with conjunctivitis.

A husband and wife reentered their home after it was cleared by the fumigators, although checks for residual sulfuryl fluoride concentrations were not provided.[37] Within 24 hours both became symptomatic. The husband complained of dyspnea and cough that became severe. Approximately 36 hours after the exposure, he had a seizure followed by cardiopulmonary arrest. His wife initially had nausea and vomiting. Over 3 days she became progressively weaker and unable to walk. She developed severe dyspnea followed by ventricular fibrillation. She had a serum fluoride concentration of 0.5 mg/L (normal is less than 0.2 mg/L) 5 days after the exposure began. Autopsies listed the cause of death as pulmonary edema for both victims. Another report describes suspected suicide by sulfuryl fluoride inhalation.[42] A 19-year-old woman who reentered apparently to retrieve some personal items was found unconscious, but became alert after removal from the home. Her complaints included coughing and chest pain. Approximately 6 hours later she developed carpal/pedal spasm, tetany, and cardiac dysrhythmias followed by death. Her serum fluoride concentration was 20 mg/L. All three autopsies were remarkable for pulmonary edema. Neurotoxicity may also result from low concentrations and acute or chronic exposures. Subclinical effects in memory and dexterity testing were noted in structural fumigation workers exposed to both methyl bromide and sulfuryl fluoride.[10]

■ DIAGNOSTIC TESTING

Patients with sulfuryl fluoride exposure require frequent monitoring of serum calcium concentrations, as the fluoride complexes with calcium ions as well as potassium and magnesium monitoring (see Chap. 105). Continuous cardiac monitoring should follow the QT interval, as hypocalcemia may precipitate dysrhythmias. Serum fluoride concentrations, although not helpful for the acute management, may help with confirmatory diagnostic testing.

■ MANAGEMENT

After removal from the scene to fresh air, the patient should be disrobed to avoid further exposure and to avoid the possibility of off-gassing of any sulfuryl fluoride gas. In treating sulfuryl fluoride poisoning, aggressive treatment of hypocalcemia may be needed. Patients should have electrocardiograms (ECGs) performed and be attached to continuous cardiac monitoring to observe for QT interval prolongation. Similar to the management of methyl bromide, supportive care may be needed for the seizures, cardiac dysrhythmias, and management of ALI and bronchospasm (see Chap. 105).

METAM SODIUM

$$H_3C - NH - \overset{\overset{\displaystyle }{}}{\underset{\underset{\displaystyle S^- \quad Na^+}{|}}{C}} = S$$
Metam sodium is used as a soil fumigant to control weeds, nematodes, and fungi, ranking as the third most commonly used agricultural pesticide in the US.[40] It is an agent listed among the more common occupational exposures to fumigants.[9] In Sacramento, California, a train derailment resulted in a metam sodium release with persistent air concentrations for days.[15] Many exposed individuals developed irritant-induced asthma or reactive airways disease syndrome (RADS) following the spill. In the cleanup, prolonged exposure to wet clothing from river water containing 20 to 40 parts per billion (ppb) of metam sodium caused dermatitis.[29] Metam sodium, which breaks down into methyl isothiocyanate, is a potent sensitizer. Off-site drift following soil fumigation to a nearby community produced symptoms in 179 of 200 residents evaluated.[38] Almost all patients complained of ocular tearing or upper respiratory burning. Other less common, nonspecific symptoms included headache, nausea, and vomiting.[33] Subjects complained of lower respiratory tract symptoms including cough, dyspnea, wheezing, and chest pain. Patients with underlying pulmonary disease, especially bronchospastic conditions such as asthma and chronic obstructive pulmonary disease, appeared to be more sensitive.[38] Sheltering in place in homes with central air conditioning compared with window units may have provided some protection by preventing the entry of metam sodium into the homes.

SUMMARY

Exposures to fumigants and their presentations can be highly variable depending on the route and level of exposure. Most unintentional exposures will occur via the inhalational route, while intentional exposures may predominantly be by the oral route with large life-threatening amounts ingested. Low-level inhalational exposures to most of the fumigants may resemble viral syndromes, but manifest delayed neuropsychiatric symptoms. Diagnosis largely relies on the history of exposure, as most confirmatory diagnostic tests are not readily available. Treatment

is mainly supportive, often provided in an ICU. The administration of calcium, however, for severe sulfuryl fluoride poisoning may be lifesaving. Fumigant use is vital to enhancing crop production in today's global agricultural economy. Extensive research and testing have not yet led to the development of suitable replacements for the toxic compounds described in this chapter.

L.
NATURAL TOXINS AND ENVENOMATIONS

CHAPTER 117
MUSHROOMS

Lewis R. Goldfrank

The diversity of mushroom species is evident in our grocery stores, our restaurant menus, and our environment. The diversity of the American population has led to experimentation by young and old—old citizens and our newest immigrants as well as our young children reaching for what might become an innocuous or a serious ingestion. Rigor in analyzing the possible ingestion is indispensable for poison center staff and emergency physicians treating a patient who has ingested a mushroom of concern. This chapter offers general information of the most consequential toxicologic groups of mushrooms.

EPIDEMIOLOGY

Unintentional exposures to mushrooms represent a small but relatively constant percentage of consultations requested from poison centers (see citations for American Association of Poison Control Centers [AAPCC] data in Chap. 135). A summary of a quarter century of AAPCC data reveals that mushrooms represent far less than 0.5% of the reported human exposures. Combined data accumulated by the AAPCC and the Mushroom Poisoning Registry of the North American Mycological Association indicates that approximately five patient exposures to toxic mushrooms per 100,000 population occur per year. Some variations result from geographic and climatic conditions and mycologic habitats.[109] Although the methods of analysis of patients with mushroom exposures have changed over the past quarter century, cumulative AAPCC data consistently demonstrate the relative benignity of the vast majority of exposures. The inability of most healthcare providers to correctly identify the ingested mushroom and the rarity of lethal ingestions are demonstrated by the accumulated data. In 85% to 95% of cases, the exact species was unidentified.[109] More than 50% of exposed individuals had no symptoms. Most patients were treated at home and rarely had major toxicity. During the quarter century covered by the AAPCC data, fewer than 100 patients died of their ingestions. Of the mushrooms associated with a death, most were *Amanita* spp, and several were hallucinogens, *Boletus* spp, gyromitrin-containing mushroom, while others remained unidentified. All reported deaths occurred in adults. Hallucinogens and gastrointestinal (GI) toxins were the most common exposures yet they accounted for less than 10% of exposures. All other presumed exposures represented less than 2% of the total number of identified. Because 85% to 95% of mushrooms involved in exposures are never identified, a strategy for making significant decisions with incomplete data is essential.

CLASSIFICATION AND MANAGEMENT

This chapter does not address molds, mildews, and yeasts, which in addition to mushrooms are all categorized as fungi. The unifying principle for fungi is the lack of the photosynthetic capacity to produce nutrition. Survival is achieved by the enyzymatic capacity of these organisms to integrate into living materials and digest them. Molds are ubiquitous and often associated with varied adverse health effects such as rhinitis, rashes, headaches, and asthma.[19] An example of a mold-related mycotoxin is discussed in Chap. 132 on biological weapons. All other molds are not associated with toxicologic emergencies and are not addressed in this chapter.

Because mushroom species vary widely with regard to the toxins they contain, and because identifying them with certainty is difficult, a clinical system of classification is more useful than a taxonomic system (Table 117–1). In many cases, management and prognosis can be determined with a high degree of confidence from the history and the geographic origin of the mushroom, the initial signs and symptoms, the organ system or systems involved, and coexistent factors or conditions.[28,53,68,69,95] Groups of toxins are identifiable as cyclopeptides, gyromitrin, muscarine, coprine, ibotenic acid and muscimol, psilocybin, general GI irritants, orellinine, allenic norleucine, acromelic acids, and myotoxins.[28,53,68]

■ GROUP I: CYCLOPEPTIDE-CONTAINING MUSHROOMS
α-Amanitin

Most mushroom fatalities in North America and worldwide are associated with cyclopeptide-containing species.[4,29,121] These mushrooms include a number of *Amanita* species, including *A. verna*, *A. virosa*, and *A. phalloides*; *Galerina* spp, including *G. autumnalis*, *G. marginata*, and *G. venenata*; and *Lepiota* species, including *L. helveola*, *L. josserandi*, and *L. brunneoincarnata* (Figure 117–1).

Early differentiation of cyclopeptide poisonings from other types of mushroom poisoning is difficult. Patients poisoned with cyclopeptides may present to an emergency department (ED) with a seemingly innocuous picture of nausea, vomiting, abdominal pain, and diarrhea, which

TABLE 117–1. Mushroom Toxicity Overview

Representative Genus/Species	Xenobiotic	Time of Onset of Symptoms	Primary Site of Toxicity	Symptoms	Mortality	Specific Therapy[a]
I						
Amanita phalloides, A. tenuifolia, A. virosa	Cyclopeptides Amatoxins	5–24 h	Liver	Phase I: GI toxicity–N/V/D	0%–30%	Activated charcoal Hemoperfusion/hemodialysis
Galerina autumnalis, G. marginata, G. venenata	Phallotoxins			Phase II: Quiescent		Penicillin G *N*-acetylcysteine Silibinin
Lepiota josserandi, L. helveola				Phase III: N/V/D, jaundice, ↑ AST, ↑ ALT		
II						
Gyromitra ambigua, G. esculenta, G. infula	Gyromitrin (metabolite: monomethylhydrazine)	5–10 h	CNS	Seizures, abdominal pain, N/V, weakness, hepatorenal failure	Rare	Benzodiazepines, Pyridoxine 70 mg/kg IV
III						
Clitocybe dealbata, Omphalotus olearius, most Inocybe spp	Muscarine	0.5–2 h	Autonomic nervous system	Muscarinic effects–salivation, bradycardia, lacrimation, urination, defecation, diaphoresis	Rare	Atropine– Adults: 1–2 mg Children: 0.02 mg/kg with a minimum of 0.1 mg
IV						
Coprinus atramentarius	Coprine (metabolite: 1-aminocyclopropanol)	0.5–2 h	Aldehyde dehydrogenase	Disulfiramlike effect with ethanol, tachycardia, N/V	Rare	Symptomatic care
V						
Amanita gemmata, A. muscaria, A. pantherina	Ibotenic acid, muscimol	0.5–2 h	CNS	GABAergic effects, rare delirium, hallucinations, dizziness, ataxia	Rare	Benzodiazepines during excitatory phase
VI						
Psilocybe caerulipes, P. cubensis	Psilocybin, psilocin	0.5–1 h	CNS	Ataxia, N/V, hyperkinesis, hallucinations	Rare	Benzodiazepines
Gymnopilus spectabilis						
Psathyrella foenisecii						
VII						
Clitocybe nebularis	Various	0.5–3 h	GI	Malaise, N/V/D	Rare	Symptomatic care
Chlorophyllum molybdites, C. esculentum	GI irritants					
Lactarius spp, *Paxillus involutus*						
VIII						
Cortinarius orellanus, C. speciosissimus, C. rainierensis	Orelline, orellanine	>24 h days to weeks	Renal	Phase I: N/V Phase II: Oliguria, renal failure	Rare	Hemodialysis for renal failure
IX						
Amanita smithiana	Allenic norleucine	0.5–12 h	Renal	Phase I: N/V Phase II: Oliguria, renal failure	None	Hemodialysis for renal failure
X						
Tricholoma equestre	Unidentified myotoxin	24–72 h	Muscle (skeletal and cardiac)	Fatigue, nausea, muscle weakness, myalgias, ↑ CPK, facial erythema, diaphoresis, myocarditis	25%	NaHCO₃ Hemodialysis for renal failure

(Continued)

TABLE 117–1. Mushroom Toxicity Overview (*Continued*)

Representative Genus/Species	Toxin	Time of Onset of Symptoms	Primary Site of Toxicity	Symptoms	Mortality	Specific Therapy[a]
XI						
Clitocybe acromelalga, C. amoenolens	Acromelic acids	24 h	Peripheral nervous system	Erythromelalgia paresthesias—hands and feet, dysesthesias, erythema, edema	None	Symptomatic care
XII						
Pleurocybella porrigens	Unknown	1–31 days	CNS	Encephalopathy, convulsions, myoclonus in patients with chronic renal failure	High ?30%	Hemodialysis
Hapalopilus rutilans	Polyporic acid	>12 h	GI, CNS	N/V, abdominal pain, vertigo, ataxia, drowsiness, encephalopathy	None	Symptomatic care
XIII						
Paxillus involutus, ? Clitocybe claviceps, ? Boletus luridus	Immune mediated response to involutin	Following repeated exposure 0.5–3 h	Red blood cell kidney	Hemolytic anemia, acute renal failure	Rare	Hemodialysis
XIV						
Lycoperdon perlatum, L. pyriforine, L. gemmatum	Spores	Hours	Pulmonary, GI	Cough, shortness of breath, fever, nausea, vomiting	None	Prednisone

D, diarrhea; N, nausea; V, vomiting.

[a] Supportive care (fluids, electrolyes, and antiemetics) as indicated.

FIGURE 117–1. Group I: Cyclopeptide-containing mushrooms. (**A**) *Amanita phalloides* and (**B**) *Amanita virosa*. *(Images contributed by John Plischke III)*.

often is attributed to other causes. Such patients may be sent home, only to return moribund on a subsequent day. The delayed onset of more serious symptoms is typical of cyclopeptide toxicity and is a critical consideration in assessing any potential toxicologic emergency.

A. phalloides contains 15 to 20 cyclopeptides with an approximate weight of 900 Da. The amatoxins (cyclic octapeptides), phallotoxins (cyclic heptapeptides), and virotoxins (cyclic heptapeptides) are the best studied.[32,64,116] There is no evidence for the toxicity of virotoxins in humans. Of these three chemically similar cyclopeptide molecules, phalloidin (the principal phallotoxin) appears to be a rapid-acting toxin, whereas amanitin tends to cause more delayed manifestations.[98] Phalloidin crosses the sinusoidal plasma membranes of hepatocytes by a carrier-mediated process. This process is shared by bile salts and can be prevented in the presence of extracellular bile salts, suggesting a competitive inhibition. A sodium-independent bile salt transporting system may be responsible for phalloidin hepatic uptake, elimination, and detoxification.[76] Phalloidin interrupts actin polymerization and impairs cell membrane function, but because of its limited oral absorption it appears to have minimal toxicity, restricted mostly to GI dysfunction.

The amatoxins are the most toxic of the cyclopeptides, leading to hepatic, renal, and central nervous system (CNS) damage. These polypeptides are heat stable.[32] α-Amanitin is the principal amatoxin responsible for human toxicity following ingestion. Approximately 1.5 to 2.5 mg amanitin can be obtained from 1 g dry *A. phalloides*, and as much as 3.5 mg/g can be obtained from some *Lepiota* spp.[83,87,116] A 20-g mushroom contains well in excess of the 0.1 mg/kg amanitin considered lethal for humans.[31] α-Amanitin and β-amanitin have comparable toxicity in animal models.[31]

α-Amanitin absorption appears to be facilitated by a sodium-dependent bile acid transporter. Several studies demonstrate that the

sodium taurocholate cotransporter polypeptide, a member of the organic anion–transporter polypeptide (OATP) family localized in the sinusoidal membranes of human hepatocytes, facilitates hepatocellular α-amanitin uptake.[52,71] Once inside the cells the cytotoxicity of α-amanitin results from its interference with RNA polymerase II, preventing the transcription of DNA.[74,102] The amanitins are poorly but rapidly absorbed from the GI tract,[57] and α-amanitin may be enterohepatically recirculated. Target organs are those with the highest rate of cell turnover, including the GI tract epithelium, hepatocytes, and kidneys. Amatoxins do not appear to cross the placenta, as demonstrated by the absence of fetal toxicity in severely poisoned pregnant women.[6,12,106]

Amatoxins show limited protein binding and are present in the plasma at low concentrations for 24 to 48 hours.[57] In an intravenous radiolabeled amatoxin study in dogs, 85% of the amatoxin was recovered in the urine within the first 6 hours, whereas less than 1% was found in the blood at that time.[33] Amatoxins can be detected by high-performance liquid chromatography,[57] thin-layer chromatography, ion trap mass spectrometry,[37] and radioimmunoassay in gastroduodenal fluid, serum, urine, stool, and liver and kidney biopsies for several days following an ingestion.[31,32,63]

Some of the toxicokinetic analyses following unquantified ingestions demonstrate 12 to 23 μg amatoxin excretion in the urine over 24 to 66 hours, of which 60% to 80% occurred during the first 2 hours of collection. The extreme variabilities of the type and quantity of ingestant, the host, and the management make interpretations exceedingly difficult.[112] In another series, total maximal urinary α- and β-amanitin excreted over 6 to 72 hours were 3.19 and 5.21 mg, respectively. Two-thirds of the patients had total amanitin toxin excretion greater than 1.5 mg.[57] Urinary amanitin excretion concentrations differ by several orders of magnitude. Whether the variation results from exposure dose, time following ingestion, or laboratory technique is unclear. Several techniques for quantitative and qualitative evaluation of urinary amanitin are under investigation. The sensitivity and specificity of these determinations are under investigation.[15,16,87,105]

Clinical Phase I of cyclopeptide poisoning resembles severe gastroenteritis, with profuse watery diarrhea not occurring until 5 to 24 hours after ingestion. Some consider the early onset (less than 8 hours) of diarrhea as a predictive factor for hepatic failure and the need for liver transplan-

tation.[30] Supportive fluid and electrolyte replacement leads to transient improvement during phase II, which occurs between 12 and 36 hours after ingestion.[87,121] However, despite such supportive care, phase III, manifested by hepatic and renal toxicity and death, may ensue 2 to 6 days after ingestion.[4] Pancreatic toxicity may rarely occur.[43] The initial hepatotoxicity begins within the second phase, but clinical hepatotoxicity (Chap. 26) with elevated concentrations of bilirubin, aspartate aminotransferase (AST), and alanine aminotransferase (ALT), hypoglycemia, jaundice, and hepatic coma are not manifest until 2 to 3 days after ingestion. Pathologic manifestations include steatosis, central zonal necrosis, and centrilobular hemorrhage, with viable hepatocytes remaining at the rims of the larger triads. Lobular architecture remains intact (see Fig. 26–2).[4]

Cyclopeptide toxicity alters the hormones that regulate glucose, calcium, and thyroid homeostasis, resulting in widespread endocrine abnormalities.[61] Insulin and C-peptide concentrations are elevated at a stage of poisoning prior to hepatic and renal compromise.[26,61] These findings are suggestive of direct toxicity to pancreatic β cells, resulting in release of preformed hormone or induction of hormone synthesis. This insulin release necessitates vigilance for hypoglycemia prior to hepatocellular damage. Serum calcitonin concentrations may be elevated, and hypocalcemia may be present. Thyroxine concentrations may be depressed and triiodothyronine concentrations undetectable, whereas thyroid-stimulating hormone concentrations may not be elevated. These thyroid-related findings were reported in a single study and merit further investigation.[61]

In a series of 10 patients exposed to diverse *Lepiota* spp, 50% developed a mixed sensory and motor polyneuropathy. Most of the patients spontaneously recovered within 1 year, although a single patient developed progressive clinical and electromyographic deterioration.[89] These neuropathic findings have not been recognized in other case reports.

Treatment The search for treatments has been vigorously pursued in Europe because of the persistently large number of amatoxin victims each year.[42] Survival rates in case series of variable numbers of patients poisoned by *A. phalloides* who received any of the following: supportive care, fluid and electrolyte repletion, high-dose penicillin G, dexamethasone, and thioctic acid, are between 70% and 100%.[42,51,56,79,81,91,121] Many of these case series have excellent survival rates with extremely variable therapeutic interventions, limiting the capacity to determine the need for or efficacy of most of the standard conservative therapeutic regimens.
FIGURE 117–2. In the more highly specialized and evolved mushrooms, various protective tissues cover the fruit body and its constituent parts during its development. In the mushroom shown, an *Amanita* species, two veils of tissue are involved—one an outer enclosing bag, the universal veil, which ruptures as the fruit body expands to leave a volva at the base and fragments on the cap; the other an inner partial veil covering the developing gills that is pulled away as the cap opens to leave a ring on the stem. (Redrawn, with permission, from Kibby G: *Mushrooms and Toadstools, A Field Guide.* Oxford, Oxford University Press, 1979, p. 14.)

Fluid and electrolyte repletion and treatment of hepatic compromise are essential. Intravenous 0.9% sodium chloride solution and electrolytes usually are necessary because of substantial fluid loss due to vomiting and diarrhea. Dextrose repletion may be necessary because of nutritional compromise, hepatic failure, or glycogen depletion. Activated charcoal both adsorbs the amanitins and improves survival in laboratory animals.[31] Emesis, lavage, and catharsis are not necessary unless the patient is seen within several hours after the ingestion, because the toxin usually induces emesis and catharsis. Activated charcoal is safe, logical, and a valuable therapeutic strategy. Although the clinical presentation often is delayed, 1 g/kg body weight of activated charcoal should be given orally every 2 to 4 hours (if the patient is not vomiting) or by continuous nasogastric infusion.

Thioctic (α-lipoic) acid initially was reported to be beneficial in treating the amatoxin-induced liver toxicity in several different animal models, and a number of uncontrolled clinical trials in humans followed.[4] Because of its potential effects as a coenzyme in the tricarboxylic acid cycle or as a free radical scavenger, thioctic acid was credited for the survival of 39 of 40 patients reportedly poisoned by *A. phalloides*.[66] Hypoglycemia is a common feature of thioctic acid therapy for *Amanita* poisoning, but whether hypoglycemia results from direct toxicity of the drug or is secondary to hepatic damage is unclear. Despite the initial success, thioctic acid was not effective in various other studies and is no longer recommended.[40,41]

Several laboratory investigations in mice and rats suggest that 1 g/kg penicillin G (l g = 1,600,000 Units) may have a time- and dose-dependent protective effect.[44,45] These results are limited because the amatoxins were administered intraperitoneally, resulting in the death of untreated animals 12 to 24 hours later. Additional investigations demonstrated that 1 g/kg penicillin G administered 5 hours after sublethal doses of α-amanitin decreased clinical and laboratory toxicity.[44] The mechanisms suggested include displacing α-amanitin from albumin, blocking its uptake from hepatocytes, binding circulating amatoxins, and preventing α-amanitin binding to RNA polymerase. None of these mechanisms is substantiated. Although the hepatoprotective effects of penicillin remain unclear,[29] we recommend a dose of 1,000,000 Units of penicillin G/kg/d intravenously (IV) be used as it is safe and possibly efficacious.[62,63,100]

The active complex of milk thistle (*Silybum marianum*) is silymarin, which is a lipophilic extract composed of three isomeric flavonolignans: silibinin, silychristin, and silydianin. Silibinin represents approximately 50% of the extract, but is 70% to 80% of the marketed product.[55] Silibinin may modify or occupy cell membrane receptor sites, thereby inhibiting hepatocellular penetration by α-amanitin. Use of silibinin 50 mg/kg in dogs 5 and 24 hours following exposure to α-amanitin suppressed chemical evidence of hepatotoxicity and lethality. Although silibinin is routinely available as a nonprescription supplement in most pharmacies and appears to be safe and well tolerated in patients with chronic liver disease, no reduction in mortality, improvement in histology at liver biopsy, or biochemical marker has been identified in a systematic review and meta-analysis.[55] A dose of silibinin 20 to 50 mg/kg/d should be used in humans, even though it is not approved as a therapeutic for hepatic disease by the Food and Drug Administration (FDA) in the United States.[63,115]

Because of its hepatoprotective effects, *N*-acetylcysteine should be given as an antidote, but no evidence for any specific benefit has been demonstrated. When fulminant hepatic failure is present, *N*-acetylcysteine should be administered until the patient recovers from the encephalopathy because of its presumptive benefits under these circumstances (see Antidotes in Depth 4–*N*-Acetylcysteine).

In animals, cimetidine (a potent cytochrome P450 system inhibitor) may have a hepatoprotective effect against α-amanitin by inhibiting metabolism,[96] but it shows no protective effect against phalloidin toxicity.[98] Cimetidine is proposed as a therapeutic intervention,[97] but no available human data support its use.

A recent randomized murine model of α-amanitin intraperitoneal poisoning treated with rescue postexposure *N*-acetylcysteine, benzylpenicillin, cimetidine, thioctic acid, and silybin was unable to show any benefit in hepatotoxicity with regard to aminotransferase concentrations or histologic hepatonecrosis.[107]

Forced diuresis, hemodialysis, plasmapheresis,[58,59] hemofiltration, and hemoperfusion[35] may be effective shortly after ingestion, but most studies offer neither clinical evidence of benefit nor supportive pharmacokinetic data for any of these therapies.[63,86,87,112,114] Most studies suggest that no circulating amatoxins are present by the time the need for transplantation is evident.[27] "Shortly after" is not defined, although these techniques are indicated within 24 hours of a documented ingestion.[36] Plasmapheresis, which is dependent on effective clearance, high plasma protein binding, and a low volume of distribution, does not remove more than 10 μg of amatoxin. Because of the absence of prospective, controlled studies of exposure to amatoxins in addition to the extreme variability of success with many regimens, multiple-dose activated charcoal and supportive care remain the standard therapy. Early recognition of exposure to amanitin is an indication for hemoperfusion, but most patients likely will no longer have the potential for benefit at the time they develop clinical manifestations of toxicity.[59] Future therapeutic interventions may be dependent on improved understanding of the hepatocellular bile acid transporter, which is a member of the OATP family.[52,67,71]

Extracorporal albumin dialysis[34] and molecular absorbent regenerating system[23] are variant detoxification techniques used in patients with fulminant hepatic failure to remove water-soluble and albumin-bound toxins while providing renal support. These two techniques permit time for hepatic regeneration or sufficient bridging time to orthotopic liver transplantation. The criteria and timing for liver transplantation in this setting are far less established than for fulminant viral hepatitis, where grade III or IV hepatic encephalopathy, marked hyperbilirubinemia, and azotemia are the well-established criteria for transplantation (Chap. 26).[85] Successful transplantations were performed in individuals whose resected livers showed 0% to 30% hepatocyte viability. In these cases, the authors did not wait for progression past grade II encephalopathy or for development of azotemia or marked hyperbilirubinemia.[85] Criteria for patient selection are essential to avoid unnecessary risk while offering the potential for survival to appropriate candidates who have no functional liver. The grim prognosis associated with hepatic coma secondary to *Amanita* poisoning has led several transplant groups to consider hepatic transplantation for encephalopathic patients with prolonged international normalized ratios (INRs; greater than 6), persistent hypoglycemia, metabolic acidosis, increased concentrations of serum ammonia and AST, and hypofibrinogenemia.[30,48,49,62,85] There are now case reports of successful liver transplantation for fulminant hepatic failure from presumed *Amanita ocreata*,[62,120] *A. phalloides*,[57,60,85] *Amanita vivosa*,[14] *L. helveola*,[77] and *L. brunneoincarnata* poisoning.[89]

To enhance the likelihood of success, several authors suggest that individuals who manifest symptoms suggestive of hepatotoxic *Amanita*, *Galerina*, or *Lepiota* spp exposure should be told of the potential need for transplantation and, with their consent, be rapidly transferred to a regional liver transplantation center.

■ GROUP II: GYROMITRIN-CONTAINING MUSHROOMS

$$CH_3-CH=N-N\begin{array}{l}CH_3\\CHO\end{array}$$
Members of the gyromitrin group include *Gyromitra esculenta*, *Gyromitra californica*, *Gyromitra brunnea*, and *Gyromitra infula*. *G. esculenta* enjoys a reputation of being edible in the Western United States but of being toxic in other areas. The most common error occurs in the spring, when an individual seeking the nongilled brainlike

FIGURE 117–3. Group II: Gyromitrin-containing mushrooms. A true morel (*Morchella spp*) on the left is compared to a false morel (*Gyromitra escuelenta*) on the right. *(Image contributed by John Trestrail)*.

Morchella esculenta (morel) finds the similar *G. esculenta* (false morel) (Figure 117–3).

These mushrooms are found commonly in the spring under conifers and are easily recognized by their brainlike appearance. Poisonings with these mushrooms are exceptionally uncommon in the United States, representing less than 1% of all recognized events, whereas these poisonings are considered more common in Europe. Certain cooking methods may destroy the toxin, but inhalation of the fumes while cooking may cause toxicity. Because of the potential for toxicity, all members of this mushroom family should be avoided.

Gyromitra mushrooms contain gyromitrin (*N*-methyl-*N*-formyl hydrazone), which on hydrolysis splits into acetaldehyde and *N*-methyl-*N*-formyl hydrazine. Gyromitrin is unstable and therefore unlikely to exist in its free form. Subsequent hydrolysis yields monomethylhydrazine. The hydrazine moiety reacts with pyridoxine, resulting in inhibition of pyridoxal phosphate-related enzymatic reactions. This interference with pyridoxal phosphate disrupts the function of the inhibitory neurotransmitter γ-aminobutyric acid (GABA).[68] The implications of this decrease in GABA, which is thought to contribute to intractable seizures associated with isoniazid or gyromitrin toxicity in a fashion identical to isoniazid toxicity, is discussed in Antidotes in Depth A15–Pyridoxine.

The initial signs of toxicity for these mushrooms occur 5 to 10 hours after ingestion and include nausea, vomiting, diarrhea, and abdominal pain. Patients manifest headaches, weakness, and diffuse muscle cramping. Rarely in the first 12 to 48 hours, patients develop delirium, stupor, convulsions, and coma. Most patients improve dramatically and return to normal function within several days. Infrequently, patients develop a hepatorenal syndrome and require extensive in-hospital care.

Activated charcoal 1 g/kg body weight should be given. Benzodiazepines are appropriate for initial management of seizures. Under most circumstances, supportive care is adequate treatment. Pyridoxine in doses of 70 mg/kg IV up to 5 g in an adult may be useful in limiting seizures (Antidotes in Depth A15–Pyridoxine).

There are no rapid diagnostic strategies in the laboratory, although thin-layer chromatography, gas-liquid chromatography, and mass spectrometry can be used for subsequent identification of the various hydrazine and hydrazone metabolites.

■ GROUP III: MUSCARINE-CONTAINING MUSHROOMS
Mushrooms that contain muscarine include numerous members of the *Clitocybe* genus, such as *C. dealbata* (the sweater) and *C. illudens* (*Omphalotus olearius*), and the *Inocybe* genus, that in turn include *I. iacera* and *I. geophylla. Amanita muscaria* and *Amanita pantherina* contain limited quantities of muscarine (Figure 117–4a, b).

Clinical manifestations, which typically are mild, usually develop within 0.5 to 2 hours and last several additional hours. Muscarine and acetylcholine are similar structurally and have comparable clinical effects at the muscarinic receptors. Peripheral manifestations typically include bradycardia, miosis, salivation, lacrimation, vomiting, diarrhea, bronchospasm, bronchorrhea, and micturition. Central muscarinic manifestations do not occur because muscarine, a quaternary ammonium compound, does not cross the blood–brain barrier. No nicotinic manifestations such as diaphoresis or tremor occur. The effects of muscarine often last longer than those of acetylcholine. Because muscarine lacks an ester bond, it is not susceptible to acetylcholinesterase hydrolysis.

Significant toxicity is uncommon, limiting the need for more than supportive care. Rarely, atropine (1–2 mg given IV slowly for adults or 0.02 mg/kg with a minimum of 0.1 mg IV for children) can be titrated and repeated as frequently as indicated to reverse symptomatology.

No current, clinically available, analytic techniques can identify muscarine, although high-performance liquid chromatography would be appropriate for investigative purposes.

FIGURE 117–4. Group III: Muscarine- and coprine-containing mushrooms. (**A**) Clitocybe dealbata. (**B**) Omphalotus olearius and Group IV: (**C**) Coprinus atramentarius (the inky cap). *(Images contributed by John Plischke III)*.

■ GROUP IV: COPRINE-CONTAINING MUSHROOMS
Coprine

1-Aminocyclopropanol

Coprinus mushrooms, particularly *C. atramentarius*, contain the toxin coprine (Figure 117–4c). These mushrooms grow abundantly in temperate climates in grassy or woodland fields. They are known as "inky caps" because the gills that contain a peptidase autodigest into an inky liquid shortly after picking. The edible member of this group, *Coprinus comatus* (shaggy mane) is nontoxic, and probably its misidentification results in collectors' errors. Coprine, an amino acid, its primary metabolite, 1-aminocyclopropanol,[18,75,108] or, more likely, a secondary in vivo hydrolytic metabolite, cyclopropanone hydrate, has a disulfiramlike effect (see Chap. 79).[119] Although both of these metabolites appear to inhibit aldehyde dehydrogenase, the most stable in vivo inhibitory effect is present in cyclopropane hydrate.[119] Inhibition of acetaldehyde dehydrogenase results in buildup of acetaldehyde and its accompanying adverse effects, which occur if the patient ingests alcohol concomitantly or for as long as 48 to 72 hours after the mushroom ingestion. Within 0.5 to 2 hours of ethanol ingestion, an acute disulfiram effect is noted, with tachycardia, flushing, nausea, and vomiting. Interestingly, alcohol ingested simultaneously does not result in clinical manifestations because inhibition of aldehyde dehydrogenase is slightly delayed during coprine metabolism. Treatment is symptomatic with fluid repletion and antiemetics such as metoclopramide or ondansetron, although clinical manifestations usually are mild and resolve within several hours. Prophylactic use of fomepizole immediately following ingestion of ethanol and coprine-containing mushrooms has a theoretical basis, but no case reports or studies are published. This group of mushrooms rarely causes fatalities.

■ GROUP V: IBOTENIC ACID– AND MUSCIMOL-CONTAINING MUSHROOMS
Ibotenic acid
Muscimol
GABA

Most of the mushrooms in this class are primarily in the *Amanita* genus, which includes *A. muscaria* (fly agaric), *A. pantherina*, and *A. gemmata* (Figure 117–5). They exist singly and are scattered throughout the US woodlands. The brilliant red or tan cap (pileus) is that of the mushroom commonly depicted in children's books and is easily recognized in the fields during summer and fall.

Small quantities of the isoxazole derivatives ibotenic acid and muscimol are found in these mushrooms, which have been used in religious

FIGURE 117–5. Group V: Muscimol-containing mushrooms. This image of *Amanita muscaria* highlights different developmental forms and colors. *(Image contributed by John Plischke III)*.

customs throughout history. Ibotenic acid is structurally similar to the stimulatory neurotransmitter glutamic acid. The stereochemistry of muscimol is very similar to that of the neurotransmitter GABA and may act as a GABA agonist.

Most patients who develop symptoms intentionally ingested large quantities of these mushrooms while seeking a hallucinatory experience. Within 0.5 to 2 hours of ingestion, these mushrooms produce the GABAergic manifestations of somnolence, dizziness, hallucinations, dysphoria, and delirium in adults, the excitatory glutamatergic manifestations of myoclonic movements, seizures, and other neurologic findings predominate in children.[7]

Treatment is invariably supportive. Most symptoms respond solely to supportive care, although a benzodiazepine is appropriate for excitatory CNS manifestations.

■ GROUP VI: PSILOCYBIN-CONTAINING MUSHROOMS
Psilocybin
Psilocin
Serotonin

Psilocybin-containing mushrooms include *Psilocybe caerulescens*, *Psilocybe cubensis*, *Conocybe cyanopus*, *Panaeolus foenisecii*, *Gymnopilus spectabilis*, and *Psathyrella foenisecii* (Figure 117–6). These mushrooms have been used for native North and South American religious experiences for thousands of years. They grow abundantly in warm, moist areas of the United States. Drug culture magazines and Internet sources advertise mail-order kits containing *P. cubensis* spores to grow "magic mushrooms" domestically.
FIGURE 117–6. Group VI: Psilocybin-containing mushrooms. Three examples of hallucinogenic mushrooms: *Psilocybe cyanescens, Psilocybe caerulipes,* and *Gynopilus spectabilis.* *(Images contributed by John Plischke III)*.

Toxicity from this group is common because of the popularity of hallucinogens.[10] The quality, quantity, and variety of mushroom ingested may or may not be related to the hallucinogenic effects. Psilocybin is rapidly and completely hydrolyzed to psilocin in vivo. Serotonin, psilocin, and psilocybin are very similar structurally and presumably act at a similar 5-HT$_2$ receptor site. The effects of psilocybin as a serotonin agonist and antagonist are discussed in Chaps. 13 and 82.

The psilocybin and psilocin indoles, like those of lysergic acid diethylamide (LSD), rapidly (within 1 hour of ingestion) produce CNS effects, including ataxia, hyperkinesis, visual illusions, and hallucinations.[54] Rare cases of renal failure,[46,88] seizures, and cardiopulmonary arrest[10] are associated with psilocybin-containing species. However, such associations should always be questioned when reported in a substance-using population potentially simultaneously exposed to other xenobiotics.

Some patients manifest tachycardia, anxiety, hallucinations, tremor, agitation, and mydriasis. Anxiety and light-headedness may develop quite rapidly (less than 1 hour), and most manifestations are recognized within 4 hours of ingestion with a return to normalcy within 6 to 12 hours. A single patient who intravenously administered an extract of *Psilocybe* mushrooms experienced chills, weakness, dyspnea, headache, severe myalgias, vomiting associated with hyperthermia, hypoxemia, and mild methemoglobinemia.[24]

Treatment for hallucinations usually is supportive, although a benzodiazepine may be necessary when reassurance proves inadequate.

◼ GROUP VII: GASTROINTESTINAL-TOXIN-CONTAINING MUSHROOMS

By far the largest group of mushrooms is a diverse group that contains a variety of ill-defined GI toxins. Many of the hundreds of mushrooms in this group fall into the "little brown mushroom" category. Some *Boletus*, *Lactarius* spp, *O. olearius*, *Rhodophyllus* spp, *Tricholoma* spp, *Chlorophyllum molybdites*, and *Chlorophyllum esculentum* are mistaken for edible or hallucinogenic species. A frequently reported error[3,47,111] is the confusion of the jack-o'-lantern (*Omphalotus illudens*) with the edible species of chanterelle (*Cantharellus cibarius*).

The toxins associated with this group are not identified. The malabsorption of proteins and sugars such as trehalose, and the ingestion of a mushroom infected or partially digested by microorganisms or allergy may be responsible for symptoms. GI toxicity occurs 0.5 to 3 hours after ingestion when epigastric distress, malaise, nausea, vomiting, and diarrhea are evident. Treatment with regard to fluid resuscitation, vomiting, and diarrhea is supportive. The clinical course is brief and the prognosis excellent.

Rarely, clinical presentations are life threatening, with hypovolemic shock necessitating fluids and vasopressors.[103] Resolution of symptoms

usually occurs within 6 to 24 hours. The clinical courses associated with specific mushroom ingestions are variable.[7] Death is rare.

◼ GROUP VIII: ORELLANINE- AND ORELLININE-CONTAINING MUSHROOMS
Orellanine

Cortinarius mushrooms, such as *Cortinarius speciosissimus* (Figure 117–7) and *Cortinarius orellanus*, are commonly found throughout Europe. *Cortinarius rainierensis* is a common North American species.[17,99] The *C. orellanus* toxin orellanine is reduced by photochemical degradation to orellinine, another bipyridyl agent that is further reduced to the nontoxic orelline.[2,82,92] The toxic compound orellanine is a hydroxylated bipyridine compound activated by its metabolism through the cytochrome P450 system. Toxicologically, these molecules are similar

FIGURE 117–7. Group VIII Orellanin- and Orellinine-containing mushrooms: *Cortinarius Speciosissimus*. *(Image contributed by Astrid Holmgren, Swedish Poisons Information Centre)*.

to paraquat and diquat and may have comparable mechanisms of action, although precise knowledge is limited (Chap. 115). Other nephrotoxins, such as cortinarines, are isolated from certain *Cortinarius* species[105] and result in tubular damage, interstitial nephritis, and tubulointerstitial fibrosis.

Orellanine is rapidly removed from the plasma within 48 to 72 hours and concentrated in the urine in a soluble form. It can be detected in the plasma at the time of clinical symptoms by some investigators[90] but not by other investigators.[93] Thin-layer chromatography on renal biopsy material can detect orellanine long after clinical exposure.[90,93]

Initial symptoms occur 24 to 36 hours after ingestion and include headache, chills, polydipsia, anorexia, nausea, vomiting, and flank and abdominal pain. The largest case review demonstrated that numerous patients repetitively ingested the *Cortinarius* spp prior to diagnosis.[25] Oliguric renal failure may develop several days to weeks after initial symptoms.[11] The only initial laboratory abnormalities may be hematuria, leukocyturia, and proteinuria. Nephrotoxicity is characterized by interstitial nephritis with tubular damage and early fibrosis of injured tubules with relative glomerular sparing.[17,99] Hepatotoxicity is rarely reported.[11] Hemoperfusion, hemodialysis, and renal transplantation are used for treatment.[11,25] No evidence suggests that secondary detoxification by plasmapheresis or hemoperfusion is of any benefit in preventing chronic renal failure even when initiated in the first 48 hours.[25,63,90] The data are inadequate to define management or prognosis precisely, as many patients improve rapidly, while some require acute hemodialysis and others require chronic therapy for renal failure.[11] No laboratory or clinical parameters to assist in predicting the individual reactions to the toxins are available. Although case reports in the literature commonly lack definitive proof of ingestion or confirmation of toxin presence, the more rapid the onset of GI and renal manifestations, the greater the risk of both acute and chronic renal failure appear to be.[25]

■ GROUP IX: ALLENIC NORLEUCINE-CONTAINING MUSHROOMS

$$CH_2=C=CH-CH_2-CH-COOH$$
$$\underset{NH_2}{|}$$

Allenic norleucine
The 13 cases of *Amanita smithiana* poisoning reported have all occurred in the Pacific Northwest (Figure 117–8).[70,110,113] Because the mature specimen often lacks any evidence of a partial or universal veil, these mushrooms are not recognized as *Amanita* species. It appears that all of the poisoned individuals were seeking the edible pine mushroom
FIGURE 117–8. Group IX Allenic norleucine-containing mushrooms: (**A**) *Amanita smithiana* compared to (**B**) *Tricholoma magnivelare* (*matsutake,* the mushroom with which it has been mistaken). *(Images contributed by John Plischke III).*

matsutake (*Tricholoma magnivelare*), a highly desirable look-alike. The *A. smithiana* and *Aminata abrupta* possess two amino acid toxins: allenic norleucine (amino-hexadienoic acid) and possibly l,2-amino-4-pentynoic acid.[21,84,122] In vitro renal epithelial tissue cultured with allenic norleucine developed necrotic morphologic changes similar to those that occur following *A. smithiana* ingestion.[84] In mice the extract of *A. abrupta* was also demonstrated to be hepatotoxic, which suggests that hepatotoxins and nephrotoxins are present in this species.[122]

Initial symptoms were noted from 30 minutes to 12 hours following ingestion of either raw or cooked specimens. GI manifestations, including anorexia, nausea, vomiting, abdominal pain, and diarrhea, occurred frequently, accompanied by malaise, sweating, and dizziness. In some cases, vomiting and diarrhea persisted. The patients typically presented for care 3 to 6 days after ingestion, at which time they were oliguric or anuric. Acute renal failure manifested 4 to 6 days following ingestion with marked elevation of BUN and creatinine. ALT and lactate dehydrogenase concentrations frequently were elevated, whereas amylase, AST, alkaline phosphatase, and bilirubin were only infrequently abnormal.

Risk of toxicity was greatest in older patients and in patients with underlying renal insufficiency. Patients who required hemodialysis underwent the procedure two to three times per week for approximately 1 month until recovery. None of the patients in the three series died.

There is no known antidote for these nephrotoxins. Activated charcoal, although of no proven benefit, should be used in standard doses when a patient in the Northwest United States presents with early GI manifestations after mushroom ingestions. The clinician will be forced to consider the circumstances of ingestion to assess the probability of *A. smithiana* ingestion as opposed to ingestion of mushrooms containing a GI toxin.

In view of the substantial morbidity associated with *A. smithiana* ingestions, historic, clinical, and/or temporal evidence of this ingestion should lead to activated charcoal hemoperfusion or hemodialysis as a strong consideration when the patient presents in the early phase of exposure. When a patient presents with renal compromise several days, as opposed to weeks, following mushroom ingestion and with a history of early, as opposed to delayed, GI manifestations, the clinician may be able to differentiate *A. smithiana* from *Cortinarius* spp exposure.

■ GROUP X: RHABDOMYOLYSIS-ASSOCIATED MUSHROOMS

There are several reports of *Tricholoma equestre* (*Tricholoma flavovirens*) ingestions in Europe: in Poland and France, where although this mushroom is considered "edible choice," it has resumed in significant myotoxicity.[22,80] In the first report 12 patients who ingested *T. equestre* mushrooms for 3 consecutive days developed severe rhabdomyolysis that was lethal in three cases.[5] All patients developed fatigue, muscle weakness, and myalgias 24 to 72 hours following the last mushroom meal. The individuals also developed facial erythema, nausea without vomiting, and profuse sweating. The mean maximal creatine phosphokinase (CPK) was 226,067 U/L in women and 34,786 U/L in men, with some values greater than 500,000 U/L. Electromyography revealed muscle injury with myotoxic activity. The biopsies showed myofibrillar injury and edema consistent with an acute myopathy.

Dyspnea, muscle weakness, pulmonary congestion, acute myocarditis, dysrhythmias, cardiac failure, and death ensued in three patients. Autopsy demonstrated myocardial lesions identical to those found in the peripheral muscles. Although muscle toxicity was reproduced using *T. equestre* extracts in a mouse model, the etiology of the toxicity is not defined.[5] All the triterpenoids, sterols, indoles, and acetylenic compounds extracted from these mushrooms previously were assumed

to be without toxicity. Currently all the clinical experience originates from Europe where these mushrooms are considered choice and eaten extensively; no cases are reported in the United States.

GROUP XI: ERYTHROMELALGIA–ACROMELIC ACID CONTAINING MUSHROOMS

Acromelic acids D and E
D: R₁ = COOH; R₂ = H
E: R₁ = H; R₂ = COOH
A poorly defined syndrome originally recognized in Japan[78] and more recently in France[8] following the ingestion of various *Clitocybe* species (*C. acromelalga, and C. amaenoleans*). The toxic substances acromelic acids A–E have been isolated. These molecules are similar to kainic acid and are of the pyrrolidine dicarboxylic acid family, which act as ionotropic glutamate receptors. The syndrome typically occurs more than 24 hours following ingestion. Patients typically develop paraesthesias of distal extremities followed by paroxysms of severe burning dysesthesias lasting several hours. The extremities show edema and erythema. These manifestations respond variably to symptomatic and supportive care and resolve completely within several months.

GROUP XII: POLYPORIC ACID AND OTHER MUSHROOM CONSTITUENTS RESULTING IN ENCEPHALOPATHY
Two groupings of toxic mushroom ingestion syndromes result in encephalopathy. In the first group *Pleurocybella porrigens* commonly eaten in Japanese miso soup without any adverse effects when ingested by patients with chronic renal failure resulted in delayed manifestations of encephalopathy.[50] Three quarters (24 of 32) of the affected patients were undergoing hemodialysis at the time of the presumed poisoning. The delay from time of ingestion to the development of

an altered consciousness, convulsions, myoclonus, dysarthria, dysesthesias, ataxia, respiratory failure, or death was between 1 and 31 days. No prior toxic link or known toxin in these commonly ingested mushrooms is recognized.

The second group of mushrooms associated with encephalopathy is the *Hapalopilus rutilans* noted in Germany. More than 12 hours after ingestion an adult and two children developed nausea, vomiting, and abdominal pain; aminotransferase and creatine concentration elevations; and CNS abnormalities. Vertigo, ataxia, visual disturbances, and somnolence were reported.[65,95] In each case the urine was a violet color, the color being noted when polyporic acid is placed in an alkaline solution. Polyporic acid, a dehydroquinone derivative (2,5-dihydroxy-3,6-diphenyl-1,4 benzoquinone), a constituent of these mushrooms, is a dehydroorotate dehydrogenase inhibitor that resulted in comparable clinical and biochemical manifestation when administered to rats.[65] Symptomatic treatment is indicated with more specific therapy should hepatic or renal compromise be significant.

GROUP XIII: IMMUNE-MEDIATED HEMOLYTIC ANEMIA

A small number of patients with ingestions of *Paxillus involutus*, and possibly *Clitocybe claviceps* and *Boletus luridus*, develop a mild GI syndrome followed by an immune-mediated hemolytic anemia, hemoglobinuria, oliguria, and renal failure. IgG antibodies to a *Paxillus*-extract-containing involution[63] were detected by a hemagglutination test in these patients.[117,118]

GROUP XIV: LYCOPERDONOSIS

Puffball mushrooms (*Lycoperdon perlatum*, *Lycoperdon pyriforme*, or *Lycoperdon gemmatum*) are edible in the fall and can (upon decay or drying) release large numbers of spores by compression or agitation (Figure 117–9). Lycoperdonosis is directly related to massive exposure to spores, although many consider the syndrome an allergic bronchoalveolitis. This syndrome occurs in patients following acute inhalation of spores as an alternative or complementary therapy for epistaxis[104] and in adolescents for various experimental reasons.[20] Massive inhalation, insufflation, and chewing of spores can lead to the development of nasopharyngitis, nausea, vomiting, and pneumonitis within hours. Over a period of several days, cough, shortness of breath, myalgias, fatigue, and fever develop. Rarely, patients require intubation because of pulmonary compromise associated with diffuse reticulonodular infiltrates.[20] Lung biopsy demonstrates an inflammatory process with the presence of *Lycoperdon* spores.[104] Patients treated with prednisone and antifungals such as amphotericin B recovered within several weeks without sequelae.

FIGURE 117–9. Puff balls: (**A**) Lycoperdon pyriforme and (**B**) Lycoperdon perlatum. *(Images contributed by John Plischke III)*.

MANAGEMENT

Because ingestion of certain mushrooms may lead to toxicity with substantial mortality, patients with suspected mushroom ingestions require rigorous management. A serious effort at precise identification of the genus and species involved will make assessment, management, and follow-up easier and more logical. The basic regimen of adsorption should be initiated if potentially toxic mushrooms are ingested. If nausea and vomiting persist, an antiemetic can be used to ensure that the patient can retain activated charcoal 1 g/kg. Appropriate life support measures should be instituted as necessary. Fluid, electrolyte, and glucose repletion, as needed, are essential.

There is a wide variability in quantity and type of toxin present in mushrooms according to geography, local conditions, and individual susceptibility. The clinical course for *A. smithiana* poisoning has led us to suggest an alteration in the initial approach to patients in the northwest United States who have early onset (0.5–6 hours) of GI distress following mushroom ingestion. Prior to the recognition of this mushroom poisoning, all patients who had early onset of nausea, vomiting, diarrhea, and abdominal cramps were presumed to be poisoned by a member of the groups containing either the GI toxins or muscarine. The routine use of specific antidotes should be avoided because they usually are unnecessary.

DISPOSITION

It is important to remember that many patients with mushroom ingestions present with signs and symptoms suggestive of mixed poisonings. Whereas some ingestions produce "purer" symptom complexes than others, some ingestions, such as those of *A. muscaria,* produce GI and CNS effects, and still other ingestions, such as those of *Cortinarius* spp, have acute GI and delayed renal manifestations. Treatment or partial treatment may further confound the assessment. In addition, it is essential to remember that any acute GI disorder actually may be the manifestation of mushroom toxicity. In the spring and fall, in areas with moderate weather and humidity, it is particularly important to consider intentional or unrecognized exposure to mushroom toxins, although a logical approach to management is impossible in the absence of a precise history.

Because the clinical course of mushroom poisoning can be deceptive, all patients who manifest early symptoms (less than 3 hours) and remain symptomatic despite supportive care (Tables 117–1 and 117–2) should be admitted to the hospital. In this group of patients inhabiting the Pacific Northwest, *A. smithiana* should be of particular concern. Patients whose delayed initial presentation (greater than or equal to 5 hours) is suggestive of amatoxin exposure should be hospitalized, as should any patient postingestion who cannot be followed safely or reliably as an outpatient. Tables 117–1 and 117–2 list the characteristic times of appearance and evolution of symptoms caused by mushroom toxins and groups. Confusion may result from atypical clinical manifestations or, commonly, ingestion of several different mushrooms species, some of which may produce early symptoms and others delayed toxicity. Patients with certain types of ingestions may appear to improve initially with only supportive care. This latency period, which is characteristic of *Amanita* spp, may not be appreciated when several different species are eaten simultaneously. However, because hepatotoxicity leading to death may not appear until 2 to 3 days after ingestion (amatoxins) and nephrotoxicity may not appear for 3 to 21 days (orellanine and allenic norleucine), all patients with symptoms require subsequent follow-up.

IDENTIFICATION

■ GENERAL

Visualizing and analyzing the gross, microscopic, or chemical characteristics of the ingested mushroom remain vital strategies that are infrequently used. When the whole mushroom or parts are unavailable, the diagnosis must be based on the clinical presentation. No rapidly available studies in EDs or clinical chemistry laboratories are available to assist with management. The development of a rapid clinical test for amatoxins,[15,16,63] gyromitrin, orellanine, and allenic norleucine would be useful and permit early use of hemoperfusion and greater vigilance with regard to use of hemodialysis. We have not yet achieved the ability to use thin-layer chromatography, high-performance liquid chromatography, gas chromatography, or gas chromatography-mass spectrometry for clinically relevant circumstances.

Although mushroom identification is a difficult task, this section may be helpful to the clinician dealing with a suspected case of mushroom toxicity. However, it is generally best to rely on symptomatology,

TABLE 117–2. Mushroom Toxicity: Correlation Between Organ System Affected, Time of Onset of Symptoms, and Mushroom Constituent

Time to Symptoms		Mushroom Constituent		
		Early <3 h	Middle 5–24 h	Late >24 h
Organ systems	Gastrointestinal	Muscarine	Amatoxin	Orelline and orellanine
		Gastrointestinal toxins	Allenic norleucine	
		Allenic norleucine	Gyromitrin	
	Hepatic			Amatoxin
	Immunologic	Spores		
		Involutin		Gyromitrin
	Neurologic	Ibotenic acid and muscimol	Gyromitrin	Acromelic acid
		Psilocybin		Polyporic acid
	Renal			Orelline and orellanine
				Allenic norleucine

not mushroom appearances, to confirm a diagnosis. As a general rule, positive identification of the mushroom should be left to the mycologist or toxicologist.[38]

The most important anatomic features of both edible and poisonous mushrooms are their pileus, stipe, lamellae or gills, and volva.

- *Pileus:* Broad, caplike structure from which hang the gills (lamellae), tubes, or teeth.

- *Stipe:* Long stalk or stem that supports the cap; the stipe is not present in some species.

- *Lamellae:* Platelike or gill-like structures on the undersurface of the pileus that radiate out like the spokes of a wheel. The spores are found on the lamellae. Some mushrooms have pores or tooth-like structures on their pili, which contain the spores. The mode of attachment of the lamellae to the stipe is noteworthy in making an identification.

- *Volva:* Partial remnant of the veil found around the base of the stipe in some species.

- *Veil:* Membrane that may completely or partially cover the lamellae, depending on the stage of development. The "universal" veil covers the underside, the spore-bearing surface of the pileus.

- *Annulus:* Ringlike structure that may surround the stipe at some point below the junction, with the cap that is a remnant of the partial veil.

- *Spores:* Microscopic reproductive structures that are resistant to extremes in temperature and dryness, produced in the millions on the spore-bearing surface (see Lamellae). Of all the characteristics of a particular mushroom species, spores are the least variable, although many mushrooms have similar-appearing spores. A spore print is helpful in establishing an identification. A spore print viewed microscopically is comparable to a bacterial Gram stain. Spore colors range from white to black and include shades of pink, salmon, buff, brown, and purple. Spore color in general is constant for a species.

■ THE UNKNOWN MUSHROOM

1. The most important determinant is whether the ingested mushroom is one of the deadly varieties, especially *Amanita.* Outside of the Pacific Northwest, the onset of GI symptoms within 3 hours of ingestion does not result from amatoxin poisoning. In the Pacific Northwest, symptoms may represent *A. smithiana* (allenic norleucine) poisoning (see Tables 117–1 and 117–2).

2. Attempt to obtain either the collected mushrooms or a detailed description of their features. Arrange for transport of the mushroom in a dry paper bag (not plastic). Ensure that the mushroom is neither moistened nor refrigerated, either of which will alter its structure. Remember that gastric contents may contain spores that can be crucial for analysis.

3. If the mushroom cap is available, make a spore print by placing the pileus spore-bearing surface side down on a piece of paper for at least 4 to 6 hours in a windless area. The spores that collect on the paper can be analyzed for color. White spore prints can be visualized more easily on white paper by tilting the paper and looking at it from an angle.

4. Concomitant with step 3, contact a mycologist and use the best resources available for identification. A botanical garden usually has expert mycologists on staff, or a local mycology club can locate a mycologist. A regional poison center almost always can provide this expertise or locate an expert.

5. If none of the resources in step 4 is accessible, Melzer reagent can be useful in differentiating look-alike species and defining the presence of an amatoxin. A positive reaction is indicated by the development of a dark blue color upon contact with Melzer reagent.[72] Melzer reagent is a solution of 20 mL water, 1.5 g potassium iodide, 0.5 g iodine, and 20 g chloral hydrate. Staining a sample of the spores with one drop of reagent and then viewing the sample under a microscope helps to determine whether the mushroom is a deadly *Amanita,* with bluish-black "amyloid"-reacting round spores.

6. An additional test used by some is the Meixner reaction. Several drops of 10N to 12N hydrochloric acid are applied to an amatoxin-containing mushroom sample squeezed onto newspaper, resulting in a blue reaction.[63] The reliability of this test is doubtful, and most mycologists prefer to use Melzer reagent. Although the Meixner test is sensitive, false-negative and false-positive tests are of concern.[9]

POISONING PRINCIPLES: MYTHS AND SCIENCE

Differentiating myths from science is a difficult task in any field of medicine. This effort is even more complex when discussing mushrooms. The following principles are of great value in developing a logical approach to a potential ingestion.

1. Wild mushrooms should never be eaten unless an experienced mycologist can absolutely identify the mushroom. Even experts have trouble identifying some mushrooms, yet some foragers boldly indicate that distinguishing edible from toxic mushrooms is "as easy as telling brussels sprouts from broccoli." Remember the saying, "There are old mushroom hunters, and bold mushroom hunters; but there are no old, bold mushroom hunters."

2. The toxicology of any species can vary, depending on geographic location.

3. If toxicity is suspected, attempt to obtain samples of the mushrooms eaten and identify them. Every ED should have a readily available resource on mushrooms, such as one of the major mycology field guides.[1,13,72,73,94,101] In any case, identification is best made with the aid of the poison center's consultant mycologist.

4. Mushrooms often are implicated as the cause of an illness when, in fact, infections or other diseases are responsible. Other etiologies include the mode of preparation (the sauce or wine) or the cooking utensil.

5. There are no absolute generic approaches for evaluating the potential toxicity of a mushroom. Myths suggesting the safety or lack of safety by staining of silver, presence of insects or slugs, peeling off the mushroom cap, or the area of mushroom growth are unreliable or false. Neither odor nor taste is a good predictor of toxicity. Pure white mushrooms, little brown mushrooms, large brown mushrooms, and red- or pink-spored boletus (a mushroom without lamellae) should be considered potentially toxic.

6. Cooking may inactivate some toxins but not others. In general, no wild mushroom should be eaten raw or in large quantities. Examples of toxicity associated with lack of cooking include *Armillariella mellea* (honey mushroom), which usually is well tolerated when cooked but not raw, and *Verpa bohemica* (a morel-like mushroom), which is edible but causes illness if eaten in excess.

7. Associated phenomena may be responsible for or contribute to toxicity. Could insecticides have been sprayed on the mushrooms? Is it an alcohol-related response? Besides the well-known disulfiram reaction involving *C. atramentarius*, other good edibles, including the black morel (*Morchella angusticeps*) and the sulfur polypore (*Laetiporus sulfureus*), can cause adverse reactions if consumed with alcohol. The etiology of these adverse reactions is not understood.

8. "Edible" mushrooms that are allowed to deteriorate become toxic. Therefore, only young, recently matured specimens should be eaten when adequate mycologic support is available.

9. The finding that only some people who ate a mushroom species manifested characteristic toxicity should not exclude the diagnosis of mushroom poisoning. The degree of toxicity may be dose related or genetically determined, or a person may have a pathologic predisposition to toxicity.

10. Mushroom allergy can manifest as an anaphylactic reaction.

11. Most poisonous mushrooms resemble edible mushrooms at some phase of their growth. For this reason, even careful examination of the ring, cap, consistency, form, and color may not reliably identify the edible species. Also, characteristic features of specific toxic mushrooms may not be present under certain conditions. Although the deadly *A. phalloides* and *A. virosa* usually have remnant patches of tissue from the universal veil that envelops the mushroom in its "button" stage, rain may wash these remnants away. Similarly, a subterranean basal cup may not be noticed if the mushroom is cut at the ground level by a novice forager (Fig. 117–1).

12. Even the new in-vogue "wild mushrooms" in the specialty markets may not be entirely safe.

CHAPTER 118
PLANTS

Mary Emery Palmer and Joseph M. Betz

Five to ten percent of all human exposures reported to poison centers involve plants. Probably because plants are so accessible and attractive to youngsters, in approximately 80% of these cases the individuals are younger than 6 years of age. As indoor plants have become ever more popular the incidence of plant exposures has increased dramatically. Data compiled by the American Association of Poison Control Centers (AAPCC) give some indication of which plants are more commonly involved (see Chap. 135), but these plants typically have relatively limited toxicity. More than 80% of patients reported to the AAPCC as being exposed were asymptomatic, less than 20% had minor to moderate symptomatology, and less than 7% necessitated a healthcare visit. The benignity of these ingestions is represented by a fatality rate of less than 0.001%. This chapter addresses the toxicologic principles associated with the most potentially dangerous plants.

CLASSIFICATION OF PLANT XENOBIOTICS

Aconitine, from monkshood, exemplifies the rich history of plant toxicology. It was believed by the Greeks to be the first poison—"lycotonum"—created by the goddess Hecate from foam of the river Cerebrus. Alkaloid constituents are responsible for its toxic (and therapeutic) effects. Alkaloids represent one of several classes of organic molecules found in plants as defined by the science of pharmacognosy. The pharmacognosy approach is consistent with the literature of plant efficacy and is applied here to their toxicity (Table 118–1). Unfortunately, the science of pharmacognosy is not always straightforward, and systems of classification may vary depending on the pharmacognosist. Hence our approach borrows primarily from two groups of authors[70,190] to keep the classification as consistent as possible. The major groups are as follows:

1. *Alkaloids:* Molecules that react as bases and contain nitrogen, usually in a heterocyclic structure. Alkaloids typically have strong pharmacologic activity that defines many major toxidromes.

2. *Glycosides:* Organic compounds that yield a sugar or sugar derivative (the glycone) and a nonsugar moiety (the aglycone) upon hydrolysis. The aglycone is the basis of subclassification into saponin or steroidal glycosides (including steroidal cardiac glycosides [defined as cardioactive steroids in Chap. 64], cyanogenic glycosides, anthraquinone glycosides), and others such as atractyloside and salicin.
