3. *Terpenes and resins:* Assemblages of five-carbon units (isoprene unit) with many types of functional groups (eg, alcohols, phenols, ketones, and esters) attached. This is the largest group of secondary metabolites; approximately 20,000 are identified. Most essential oils are mixtures of monoterpenes, and the terpene name depends on the number of isoprene assemblages. Monoterpenes have two units ($C_{10}H_{16}$), sesquiterpenes have three isoprene units (C_{15}), diterpenes have four isoprene units (C_{20}), and triterpenes have six (C_{30}). These molecules often play an active role in plant defense mechanisms.

4. *Proteins, peptides, and lectins:* Proteins consist of amino acid units with various side chains, and peptides consist of linkages among amino acids. Lectins are glycoproteins classified according to the number of protein chains linked by disulfide bonds and by binding affinity for specific carbohydrate ligands, particularly galactosamines. The toxalbumins (eg, ricin) are lectins. These components tend to be neurotoxins, hemagglutinins, or cathartics.

5. *Phenols and phenylpropanoids:* Phenols contain phenyl rings and have one or more hydroxyl groups attached to the ring. Phenylpropanoids consist of a phenyl ring attached to a propane side chain. These compounds are devoid of nitrogen, even though some are derived from phenylalanine and tyrosine. They constitute a major group of secondary metabolites and among plant toxins include *coumarins* (lactone side chains), *flavonoids* (built upon a flavan 2,3-dihydro-2-phenylbenzopyran nucleus, such as naringenin and rutin), *lignans* (two linked phenylpropanoids, such as podophyllin), *lignins* (complex polymers of lignans that bind cellulose for woody bark and stem), and *tannins* (polymers that bind to protein and can be further hydrolyzed or condensed).

Plant chemistry is complex. The simplified presentation of one xenobiotic per plant per symptom group used in Table 118–1 overlooks the fact that plants contain multiple xenobiotics that work independently or in concert. Additionally, different plant families may contain similar, if not identical, xenobiotics (either from conservation of biochemical pathways inherited from a common ancestor or through convergent evolution). In some cases, xenobiotics remain unidentified and are grouped in the section Unidentified Toxins.

Dissimilar molecules from diverse pharmacognosy classes that share effects are grouped together for pragmatic purposes in the section Effects Shared Among Different Classes of Xenobiotics. They are further categorized into plant–xenobiotic interactions, sodium channel effects, antimitotic alkaloids and resins, and plant-induced dermatitis.

Our focus is on exposures to flowering plants (angiosperms) related to foraging, dietary, or occupational contact, except for some gymnosperms or algae and, rarely, medicinal contact (medicinal use as herbals is discussed in Chap. 43).[132] Because our understanding of plant toxicity is poor relative to that of pharmaceuticals, animal research is included to provide a more comprehensive foundation for comparison with human experiences that may otherwise go unrecognized without such precedent, or may likewise prove ultimately incorrect. The science of plant toxicology formally began in the United States as a response to significant poisonings of livestock. The overall quality of literature for human exposures is poor and primarily available as case reports. Many of these cases lack clear links between toxin exposure and illness, and qualitative or quantitative analyses are generally unavailable. Uncertainty is compounded by the fact that plants themselves are inherently variable, and potency and type of toxin depend on the season, geography, growing environment, plant part, and methods of processing.

IDENTIFICATION OF PLANTS

Positive identification of the plant species should be attempted whenever possible, especially when the patient becomes symptomatic. Communication with an expert botanist, medical toxicologist, or poison center is highly recommended and can be facilitated by transmission of digital images or a fax.[148] Provisionally, simple comparison of the species in question with pictures or descriptions from a field guide of flora may help exclude the identity of the plant from among the most life-threatening in Table 118–1. A plant identification can also be compared with those searched in the PLANTOX database (http://vm.cfsan.fda.gov/~djw/readme.html) managed by the Food and Drug Administration (FDA). To date, with some exceptions laboratory analysis is generally not timely enough to be useful except as a tool in an investigatory or forensic analysis. As the state of analytical science

TABLE 118–1. Primary Toxicity of Common Important Plant Species

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
Abrus precatorius (Euphorbiaceae)[a]	Prayer beans, rosary pea, Indian bean, crab's eye, Buddhist's rosary bead, prayer bead, jequirity pea	Gastrointestinal	Abrin	Protein, lectin, peptide, amino acid
Aconitum napellus and other *Aconitum* spp (Ranunculaceae)[a]	Monkshood and others	Cardiac, neurologic	Aconitine and related compounds	Alkaloid
Acorus calamus (Araliaceae)	Sweet flag, rat root, flag root, calamus	Gastrointestinal	Asarin	Phenol or phenylpropanoid
Aesculus hippocastanum (Hippocastanaceae)	Horse chestnut	Hematologic	Esculoside (6-β-D glucopyranosyloxy-7-hydroxycoumarin)	Phenol or phenylpropanoid
Agave lecheguilla (Amaryllidaceae)	Agave	Dermatitis, photosensitivity in animals	Aglycones, smilagenin, sarsasapogenin	Saponin glycoside
Aloe barbadensis, Aloe vera, others (Liliaceae/Amaryllidaceae)	Aloagave	Gastrointestinal	Barbaloin, iso-barbaloin, aloinosides	Anthraquinone glycoside
Anabaena and *Aphanizomenon*[a]	Blue-green algae	Neurologic	Saxitoxin equivalents	Guanidinium compound
Anacardium occidentale, many others (Anacardaceae)	Cashew, many others	Contact dermatitis	Urushiol oleoresins	Terpenoid
Anthoxanthum odoratum (Poaceae)	Sweet vernal grass	Hematologic	Coumarin	Phenol or phenylpropanoid
Areca catechu (Aracaceae)	Betel	Cholinergic	Arecoline	Alkaloid
Argemone mexicana (Papaveraceae)	Mexican pricklepoppy	Gastrointestinal	Sanguinarine	Alkaloid
Argyreia nervosa	Hawaiian baby woodrose seeds	Neurologic	Lysergic acid amide	Alkaloid
Argyreia spp (Convolvulaceae)	Morning glory	Neurologic	Lysergic acid derivatives	Alkaloid
Aristolochia reticulata, Aristolochia spp (Aristolochiaceae)[a]	Texan or Red River snake root	Renal, carcinogenic	Aristolochic acid	Alkaloid relative as derivative of isothebaine
Artemisia absinthium (Compositaceae/Asteraceae)[a]	Absinthe	Neurologic	Thujone	Terpenoid
Asclepias spp (Asclepidaceae)[a]	Milk weed	Cardiac	Asclepin and related cardenolides	Cardioactive steroid
Astragalus spp (Fabiaceae)[a]	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
Atractylis gummifera (Compositaceae)[a]	Thistle	Hepatic	Atractyloside, gummiferine	Glycoside
Atropa belladonna (Solanaceae)[a]	Belladonna	Anticholinergic	Belladonna alkaloids	Alkaloid
Azalea spp (Ericaceae)[a,b]	Azalea	Cardiac, neurologic	Grayanotoxin	Terpenoid
Berberis spp (Ranunculaceae)	Barberry	Oxytocic, cardiovascular	Berberine	Alkaloid
Blighia sapida (Sapindaceae)[a]	Ackee fruit	Metabolic, gastrointestinal, neurotoxic	Hypoglycin	Protein, lectin, peptide, amino acid
Borago officinalis (Boragniaceae)[a]	Borage	Hepatic (venoocclusive disease)	Pyrrolizidine alkaloids	Alkaloid
Brassaia spp[b]	Umbrella tree	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
Brassica nigra (Brassicaceae)	Black mustard	Dermatitis, irritant	Sinigrin	Glucosinolate (isothiocyanate glycoside)
Brassica olearacea var. capitata	Cabbage	Metabolic (precursor to goitrin, antithyroid compound)	Progoitrin	Isothiocyanate glycoside
Cactus spp[b]	Cactus	Dermatitis, mechanical	Nontoxic	None

TABLE 118–1. Primary Toxicity of Common Important Plant Species (*Continued*)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
Caladium spp (Araceae)[b]	Caladium	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
Calotropis spp (Asclepidaceae)[a]	Crown flower	Cardiac	Asclepin and related cardenolides	Cardioactive steroid
Camellia sinensis (Theaceae)	Tea, green tea	Cardiac, neurologic	Theophylline, caffeine	Alkaloid
Cannibis sativa	Cannibis, marijuana, Indian hemp, hashish, pot	Neurologic	Tetrahydrocannabinol	Terpenoid, resin, oleoresin
Capsicum frutescens, Capsicum annuum, Capsicum spp (Solanaceae)[b]	Capsicum, cayenne pepper	Dermatitis, irritant	Capsaicin	Phenol or phenylpropanoid
Cascara sagrada = Rhamnus purshiana = Rhamnus cathartica (Rhamnaceae)	Cascara, sacred bark, Chittern bark, common buckthorn	Gastrointestinal	Cascarosides, *O*-glycosides, emodin	Anthraquinone glycoside
Cassia senna, Cassia angustifolia (Fabaceae)	Senna	Gastrointestinal	Sennosides	Anthraquinone glycoside
Catha edulis (Celastaceae)	Khat	Cardiac, neurologic	Cathinone	Alkaloid
Catharanthus roseus (formerly *Vinca rosea*) (Apocynaceae)	Catharanthus, vinca, madagascar periwinkle	Gastrointestinal	Vincristine	Alkaloid
Caulophyllum thalictroides (Berberidaceae)	Blue cohosh	Nicotinic	*N*-Methylcytisine and related compounds	Alkaloid
Cephaelis ipecacuanha, Cephaelis acuminata (Rubiaceae)[a]	Ipecac	Gastrointestinal, cardiac	Emetine/cephaline	Alkaloid
Chlorophytum comosum[b]	Spider plant	Dermatitis, contact and allergic	Urushiol oleoresins	Terpenoid
Chondrodendron spp, *Curarea* spp, *Strychnos* spp[a]	Tubocurare, curare	Neurologic	Tubocurarine	Alkaloid
Chrysanthemum spp, *Taraxacum officinale,* many other Composi-taceae (Asteraceae)[b]	Chrysanthemum, dandelion, other Compositaceae	Contact dermatitis	Sesquiterpene lactones	Terpenoid
Cicuta maculata (Apiaceae/Umbelliferae)[a]	Water hemlock	Neurologic	Cicutoxin	Alcohol
Cinchona spp (Rubiaceae)[a]	Bitter orange	Cardiac, neurologic	Synephrine	Alkaloid
Citrus aurantium (Rutaceae)[a]	Cinchona	Cardiac, cinchonism	Quinidine	Alkaloid
Citrus paradisi (Rutaceae)	Grapefruit	Drug interactions	Bergamottin, naringenin, or naringen	Phenol or phenylpropanoid
Claviceps purpurea, Claviceps paspali (Claviceptacea = fungus)[a]	Ergot	Cardiac, neurologic, oxytocic	Ergotamine and related compounds	Alkaloid
Coffea arabica (Rubiaceae)	Coffee	Cardiac, neurologic	Caffeine	Alkaloid
Cola nitida, Cola spp (Sterculiaceae)	Kola nut	Cardiac, neurologic	Caffeine	Alkaloid
Colchicum autumnale (Liliaceae)[a]	Autumn crocus	Multisystem	Colchicine	Alkaloid
Conium maculatum (Apiaceae/Umbelliferae)[a]	Poison hemlock	Nicotinic, neurologic, respiratory, renal	Coniine	Alkaloid
Convallaria majalis[a]	Lily of the valley	Cardiac	Convallatoxin, strophanthin (~40 others)	Cardioactive steroid
Coptis spp (Ranunculaceae)	Goldenthread	Oxytocic, cardiovascular	Berberine	Alkaloid

(Continued)

TABLE 118–1. Primary Toxicity of Common Important Plant Species (*Continued*)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
Crassula spp[b]	Jade plant	Gastrointestinal	Nontoxic	None
Crotalaria spp (Fabaceae)[a]	Rattlebox	Hepatic (venoocclusive disease)	Pyrrolizidine alkaloids	Alkaloid
Croton tiglium and *Croton* spp (Euphorbiaceae)	Croton	Carcinogen, gastrointestinal	Croton oil	Lipid and fixed oil, also contains tropane alkaloid and diterpene
Cycas circinalis[a]	Queen sago, indu, cycad	Neurologic	Cyacasin	Glycosides
Cytisus scoparius (Fabaceae)[a]	Broom, Scotch broom	Nicotinic, oxytocic	Sparteine	Alkaloid
Datura stramonium (Solanaceae)[a]	Jimson weed, stramonium, locoweed	Anticholinergic	Belladonna alkaloids	Alkaloid
Delphinium spp (Ranunculaceae)[a]	Larkspur, others	Cardiac, neurologic	Methylaconitine	Alkaloid related compounds
Dieffenbachia spp (Araceae)[b]	Dieffenbachia	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
Digitalis lanata[a]	Grecian foxglove	Cardiac	Digoxin, lanatosides A–E (contains ~70 cardiac glycosides)	Cardioactive steroid
Digitalis purpurea[a]	Purple foxglove, Grecian foxglove	Cardiac	Digitoxin	Cardioactive steroid
Dipteryx odorata, Dipteryx oppositifolia (Fabaceae)	Tonka beans	Hematologic	Coumarin	Phenol or phenylpropanoid
Ephedra spp, especially *sinensis* (Ephedraceae/ Gnetaceae = Gymnosperm)[a]	Ephedra, Ma-huang	Cardiac, neurologic	Ephedrine and related compounds	Alkaloid
Epipremnum aureum (Araceae)[b]	Pothos	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
Erythroxylum coca	Coca	Neurologic, cardiac	Cocaine	Alkaloid
Eucalyptus globus or spp[b]	Eucalyptus	Dermatitis, contact and allergic	Eucalyptol	Terpenoid
Euphorbia pulcherrima, Euphorbia spp (Eurphorbiaceae)[b]	Poinsettia	Dermatitis, contact and allergic	Phorbol esters	Terpenoid
Galium triflorum (Rubiaceae)	Sweet-scented bedstraw	Hematologic	Coumarin	Phenol or phenylpropanoid
Ginkgo biloba (Ginkgoaceae)	Ginkgo	Dermatitis, contact and allergic	Urushiol oleoresins	Terpenoid
		Hematologic	Ginkgolides A–C, M	Terpenoid
		Neurologic	4-Methoxypyridoxine in seeds only	Alkaloid, pyridine
Gloriosa superba (Liliaceae)[a]	Meadow saffron	Multisystem	Colchicine	Alkaloid
Glycyrrhiza glabra[a]	Licorice	Metabolic, renal	Glycyrrhizin	Saponin glycoside
Gossypium spp	Cotton, cottonseed oil	Metabolic	Gossypol	Terpenoid
Hedeoma pulegioides (Lamiaceae)[a]	Pennyroyal	Hepatic, neurologic, oxytoxic	Pulegone	Terpenoid
Hedera helix (Araliaceae)[b]	Common ivy	Not absorbed	Hederacoside C, α-hederin, hederagenin	Cardioactive steroid
Hedysarium alpinum (Fabiaceae)	Wild potato	Metabolic, neurologic	Swainsonine	Alkaloid
Heliotropium spp (Compositae/Asteraceae)[a]	Ragwort	Hepatic (venoocclusive disease)	Pyrrolizidine alkaloids	Alkaloid
Helleborus niger[a]	Black hellebore, Christmas rose	Cardiac	Hellebrin	Cardioactive steroid

TABLE 118–1. Primary Toxicity of Common Important Plant Species (*Continued*)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
Hydrastis canadensis (Ranunculaceae)[a]	Goldenseal	Neurologic, oxytocic, cardiovascular, respiratory	Hydrastine, berberine	Alkaloid
Hyoscyamus niger (Solanaceae)[a]	Henbane, hyoscyamus	Anticholinergic	Belladonna alkaloids	Alkaloid
Hypericum perforatum (Clusiaceae)	St. John's wort	Dermatitis. photosensitivity, neurologic, hepatic drug interactions	Hyperforin, hypericin	Terpenoid
Ilex paraguariensis (Aquifoliaceae)	Maté, Yerba Maté, Paraguay tea	Cardiac, neurologic	Caffeine	Alkaloid
Ilex spp berries (Aquifoliaceae)[b]	Holly	Gastrointestinal	Mixture. Alkaloids, polyphenols, saponins, steroids, triterpenoids	Unidentified
Illicium anasatum (Illiciaceae)[a]	Japanese Star anise	Neurologic	Anasatin	Terpenoid
Ipomoea tricolor and other *Ipomoea* spp (Convolvulaceae)	Morning glory	Neurologic	Lysergic acid derivatives	Alkaloid
Jatropha curcas (Euphorbiaceae)	Black vomit nut, physic nut, purging nut	Gastrointestinal	Curcin	Protein, lectin, peptide, amino acid
Karwinskia humboldtiana[a]	Buckthorn, wild cherry, tullidora, coyatillo, capulincillo, others	Neurologic, respiratory	Toxin T-514	Phenol or phenylpropanoid
Laburnum anagyroides (syn. *Cytisus laburnum*; Fabaceae)[a]	Golden chain, laburnum	Nicotinic	Cytisine	Alkaloid
Lantana camara (Verbenaceae)	Lantana	Dermatitis, photosensitivity	Lantadene A and B, phylloerythrin	Terpenoid
Lathyrus sativus[a]	Grass pea	Neurologic, skeletal	β-*N*-oxalylamino-L-alanine (BOAA); β-aminopropionitrile (BAPN)	Protein, lectin, peptide, amino acid
Lobelia inflate (Campanulaceae)	Indian tobacco	Nicotinic	Lobeline	Alkaloid
Lophophora williamsii	Peyote or mescal buttons	Neurologic	Mescaline	Alkaloid
Lupinus latifolius and other *Lupinus* spp (Fabaceae)	Lupin	Nicotinic	Anagyrine	Alkaloid
Lycopersicon spp (Solanaceae)[a]	Tomato (green)	Gastrointestinal, neurologic, anticholinergic	Tomatine, tomatidine	Glycoalkaloid
Mahonia spp (Ranunculaceae)	Oregon grape	Oxytocic, cardiovascular	Berberine	Alkaloid
Mandragora officinarum (Solanaceae)[a]	European or true mandrake	Anticholinergic	Belladonna alkaloids	Alkaloid
Manihot esculentus (Euphorbiaceae)[a]	Cassava, manihot, tapioca	Metabolic, neurotoxic, motor spastic paresis and vision disturbance with chronic use	Linamarin	Cyanogenic glycoside
Melilotus spp (Fabaceae/Legumaceae)	Sweet clover (spoiled moldy)	Hematologic	Dicumarol	Phenol or phenylpropanoid
Mentha pulegium (Lamiaceae)[a]	Pennyroyal	Hepatic, neurologic, oxytocic	Pulegone	Terpenoid
Microcystis and *Anabaena* spp	Blue-green algae (cyanobacteria)	Hepatotoxic, dermatitis, photosensitivity	Microcystin	Protein, lectin, peptide, amino acid

(*Continued*)

TABLE 118–1. Primary Toxicity of Common Important Plant Species (*Continued*)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
Myristica fragrans	Nutmeg, pericarp = mace	Neurologic (hallucinations)	Myristicin, elemicin	Terpenoid
Narcissus spp and other (Amaryllidaceae, Liliaceae)	Narcissus	Dermatitis, mechanical and cytotoxic	Lycorine, homolycorin	Alkaloid
Nerium oleander[a]	Oleander	Cardiac	Oleandrin	Cardioactive steroid
Nicotiana tabacum and other *Nicotiana* spp (Solanaceae)[a]	Tobacco	Nicotinic	Nicotine	Alkaloid
Oxytropis spp (Fabiaceae)	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
Papaver somniferum	Poppy	Neurologic	Morphine/other opium derivatives	Alkaloid
Paullinia cupana (Sapindaceae)	Guarana	Cardiac, neurologic	Caffeine	Alkaloid
Pausinystalia yohimbe (Rubiaceae)[a]	Yohimbe	Cardiac, cholinergic	Yohimbine	Alkaloid
Philodendron spp (Araceae)[b]	Philodendron	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
Phoradendron spp (Loranthaceae or Viscaceae)	American mistletoe	Gastrointestinal	Phoratoxin, ligatoxin	Protein, lectin, peptide, amino acid
Physostigma venenosum (Fabaceae)[a]	Calabar bean, ordeal bean	Cholinergic	Physostigmine	Alkaloid
Phytolacca americana (Phytolaccaceae)[a]	American cancer Pokeweed, poke	Gastrointestinal	Phytolaccotoxin	Protein, lectin, peptide, amino acid
Pilocarpus jaborandi, Pilocarpus pinnatifolius (Rutaceae)[a]	Pilocarpus, jaborandi	Cholinergic effects	Pilocarpine	Alkaloid
Piper methysticum[a]	Kava kava	Hepatic, neurologic	Kawain, methysticine yangonin, other kava lactones	Terpenoid, resin, and oleoresin
Plantago spp	Plantago (seed husks)	Gastrointestinal	Psyllium	Carbohydrate
Podophyllum emodi (Berberidaceae)[a]	Wild mandrake	Multisystem	Podophyllin (lignan)	Phenol or phenylpropanoid
Podophyllum peltatum (Berberidaceae)[a]	Mayapple	Multisystem	Podophyllin (lignan)	Phenol or phenylpropanoid
Populus spp (Salicaceae)	Poplar species	Salicylism	Salicin	Glycoside
Primula obconica (Primulaceae)	Primrose	Dermatitis, contact, allergic	Primin	Phenol or phenylpropanoid
Prunus armeniaca, Prunus spp, *Malus* spp (Rosaceae)[a]	Apricot seed pits, wild cherry, peach plum, pear, almond, apple and other seed kernels	Metabolic, acidosis, respiratory failure, coma, death	Amygdalin, emulsin	Cyanogenic glycoside
Pteridum spp (Polypodiaceae)	Brachen fern	Carcinogen, thiaminase	Ptaquiloside	Terpenoid
Pulsatilla spp (Ranunculaceae)	Pulsatilla	Dermatitis, contact	Ranunculin, protoanemonin	Glycoside
Quercus spp	Oak	Metabolic, livestock toxicity	Tannic acid	Phenol or phenylpropanoid
Ranunculus spp (Ranunculaceae)	Buttercups	Dermatitis, contact	Ranunculin, protoanemonin	Glycoside
Rauwolfia serpentine (Apocynaceae)	Indian snakeroot	Cardiac, neurologic	Reserpine	Alkaloid
Remijia pedunculata (Rubiaceae)[a]	Cuprea bark	Cardiac, cinchonism	Quinidine	Alkaloid
Rhamnus frangula (Rhamnaceae)	Frangula bark, alder buckthorn	Gastrointestinal	Frangulins	Anthraquinone glycoside

TABLE 118–1. Primary Toxicity of Common Important Plant Species (*Continued*)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
Rheum officinale, Rheum spp (Polygonaceae)	Rhubarb	Gastrointestinal	Rhein anthrones	Anthraquinone glycoside
Rheum spp (Polygonaceae)	Rhubarb species	Urologic	Oxalates	Carboxylic acid
Rhododendron spp (Ericaceae)[a]	Rhododendron	Cardiac, neurologic	Grayanotoxins	Terpenoid including resin and oleoresin
Ricinus communus (Euphorbiaceae)[a]	Castor or rosary seeds, purging nuts, physic nut, tick seeds	Gastrointestinal	Ricin, curcin	Protein, lectin, peptide, amino acid
Robinia pseudoacacia (Fabiaceae)[a]	Black locust	Gastrointestinal	Robin (robinia lectin)	Protein, lectin, peptide, amino acid
Rumex spp (Polygonaceae)	Dock species	Urologic	Oxalates	Carboxylic acid
Salix spp (Salicaceae)	Willow species	Salicylism	Salicin	Glycosides, other
Sambucus spp (Caprifoliaceae)	Elderberry	Metabolic	Anthracyanins	Cyanogenic glycoside
Sanguinaria canadensis (Papaveraceae)	Sanguinaria, bloodroot	Gastrointestinal	Sanguinarine	Alkaloid
Schefflera spp (Araceae)[b]	Umbrella tree	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
Schlumbergera bridgesii[b]	Christmas cactus	Dermatitis, mechanical	Nontoxic	None
Senecio spp (Compositae/Asteraceae)[a]	Groundsel	Hepatic (venoocclusive disease)	Pyrrolizidine alkaloids	Alkaloid
Sida carpinifolia (Malvaceae)	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
Sida cordifolia (Malvaceae)[a]	Bala	Cardiac, neurologic	Ephedrine and related compounds	Alkaloid
Solanum americanum (Solanaceae)[a]	American nightshade	Gastrointestinal, neurologic, anticholinergic	Solasodine, soladulcidine, solanine, chaconine	Glycoalkaloid
Solanum dulcamara (Solanaceae)[a,b]	Bittersweet woody nightshade	Gastrointestinal, neurologic, anticholinergic	Solanine, chaconine, belladonna alkaloids, eg, atropine	Alkaloid
Solanum nigrum (Solanaceae)[a]	Black nightshade, common nightshade	Gastrointestinal, neurologic, anticholinergic	Solanine, chaconine, belladonna alkaloids (atropine)	Alkaloid
Solanum tuberosum (Solanaceae)[a]	Potato (green), leaves	Gastrointestinal, neurologic, anticholinergic	Solanine, chaconine	Alkaloid
Spathiphyllum spp (Araceae)[b]	Peace lily	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
Spinacia oleracea (Chenopodiaceae)	Spinach, others	Urologic	Oxalates	Carboxylic acid
Strychnos nux-vomica, Strychnos ignatia (Loganiaceae)[a]	Nux vomica, Ignatia, St. Ignatius bean, vomit button	Neurologic	Strychnine, brucine	Alkaloid
Swainsonia spp (Fabiaceae)	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
Symphytum spp (Boragniaceae)[a]	Comfrey	Hepatic (venoocclusive disease)	Pyrrolizidine alkaloids	Alkaloid
Tanacetum vulgare (= *Chrysanthemum vulgare*; Compositaceae/Asteraceae)[a]	Tansy	Neurologic	Thujone	Terpenoid
Taxus baccata, Taxus brevifolia, other *Taxus* spp (Taxaceae)[a]	English yew, Pacific yew, yew	Cardiac	Taxine	Alkaloid
Theobroma cacao (Sterculiaceae)	Cocoa	Cardiac, neurologic	Theobromine	Alkaloid
Thevetia peruviana[a]	Yellow oleander	Cardiac	Thevetin	Cardioactive steroid

(Continued)

TABLE 118–1. Primary Toxicity of Common Important Plant Species (*Continued*)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
Toxicodendron radicans, Toxicodendron toxicarium, Toxicodendron diversilobum, Toxicodendron vernix, Toxicodendron spp, many others (Anacardaceae)[b]	Poison ivy, oak, sumac, many others	Dermatitis, contact and allergic	Urushiol oleoresins	Terpenoid
Tribulus terrestris (Fabaceae)	Caltrop, puncture vine	Dermatitis, photosensitivity in animals	Steroidal saponins (aglycones, diosgenin, yamogenin)	Saponin glycoside
Trifolium pratense and other (Fabaceae/ Legumaceae)	Red clover	Phytoestrogen hematologic	Formononetin, Biochanin A coumarin	Phenol (isoflavone)
Tussilago farfara (Compositae/Asteraceae)[a]	Coltsfoot	Hepatic (venoocclusive disease)	Pyrrolizidine alkaloids	Alkaloid
Urginea maritima, Urginea indica[a]	Red, or Mediterranean squill, Indian squill, sea onion	Cardiac	Scillaren A, B	Cardioactive steroid
Veratrum viride, Veratrum album, Veratrum californicum (Liliaceae)[a]	False hellebore, Indian poke California hellbore	Cardiac	Veratridine	Alkaloid
Vicia fava, Vicia sativa (Fabaceae)	Fava bean, vetch	Hematologic	Vicine, convicine	Glycoside
Viscum album (Loranthaceae or Viscaceae)	European mistletoe	Gastrointestinal	Viscumin	Protein, lectin, peptide, amino acid, lignan, polypeptide
Wisteria floribunda (Fabiaceae)	Wisteria	Gastrointestinal	Cystatin	Protein, lectin, peptide, amino acid

[a] Reports of life-threatening effects from plant use.

[b] Plants reported commonly among calls to poison centers.

advances, however, it may soon be possible to confirm a diagnosis once a preliminary hypothesis based on botanical identification or symptomology has been made.

In cases where expert identification cannot be immediately achieved, preliminary recognition of taxonomic families of poisonous plants is the simplest first step to identify or exclude poisonous plants, but is most easily achieved when the plant is in flower or fruit. For instance, if the flower is described or looks like a flower from a tomato or potato, it probably is in the Solanaceae family. Plants of this family typically produce gastroenteritis or anticholinergic findings following ingestion. It then would be appropriate to consider management with a specific antidote such as physostigmine. This approach will be less useful for xenobiotics such as pyrrolizidine alkaloids that occur in numerous different families.

APPROACH TO THE EXPOSED PATIENT AND UNDERSTANDING RISK

Identified plant species most frequently reported to poison centers are indicated in Table 118–1. In most cases, these species provide reassurance because most exposures result in benign outcomes, and only a few among these are regularly life threatening depending on the circumstances of the exposure. Given the relatively poor understanding of toxins and in the absence of complete information about

an exposure, expectant management and supportive care are the rule. Even if a plant is not marked as life threatening or commonly reported, the patient should undergo a period of observation and follow-up, given the relatively immature science of plant toxicology relative to that of pharmaceuticals.

The difficult task in human plant toxicology is the lack of adequate data to determine risk (see examples in Chap. 129). Typically, evaluations of risk are based on poison center data and usually cite the numerous calls without clinical consequence as a part of the risk equation (Chap. 135).[117,135,159,244] However, poison center data are dominated by unconfirmed exposures and cases with unsubstantiated clinical manifestations (Chap. 135). These cases often represent small or nonexistent exposures, and their inclusion in the database may mask real risks by diluting "true" hazardous exposures with trivial or nonexistent exposures.[95] Furthermore, misidentification of the plant may occur because of either similar appearance or similar nomenclature.

In summary, basic decontamination and supportive care should be instituted as appropriate for the clinical situation, with consultation to a poison center. The most consequential and dangerous plant xenobiotics for humans are discussed here, and those that can produce life-threatening signs acutely are denoted in Table 118–1.

Potential symptoms listed in Table 118–1 are organized by plant name and the associated *major* organ system effects for quick reference as to the type of symptoms and their potential for morbidity or mortality. For

instance, life-threatening symptoms such as dysrhythmias or seizures can be searched by "cardi-" or "neuro-" in the third column and compared with the plant(s) in question. The plants and xenobiotics that present life-threatening symptoms are so noted. Exposures associated with one of these plants or xenobiotics or major organ system symptoms dictate the need for possible prompt gastric emptying, decontamination, individualized therapy, and hospitalization. Note that nonspecific symptoms such as nausea and vomiting are listed only when they are a major cause of morbidity or mortality (toxalbumins such as ricin), but nausea and vomiting are nearly ubiquitous among acute poisonings of clinical consequence.

TOXIC CONSTITUENTS IN PLANTS, TAXONOMIC ASSOCIATIONS, AND SELECTED SYMPTOMS

■ ALKALOIDS: TOXIC MANIFESTATIONS

The term *alkaloid* refers to nitrogen-containing basic xenobiotics of natural origin and limited distribution. They figure prominently in the history of human–plant interaction, ranging from epidemics of poisoning caused by ergot-infested rye bread in the Middle Ages to dependency on cocaine, heroin, and nicotine in contemporary time. Numerous examples of toxic constituents of these families are given in the following discussion, which begins with a description of the major toxidromes that involves alkaloids. See also Sodium Channel Effects under Effects Shared Among Different Classes of Xenobiotics later in this chapter for descriptions of additional life-threatening alkaloids.

Anticholinergic Effects: Belladonna Alkaloids The belladonna alkaloids are from the family Solanaceae and the plants can be identified as members of this family by their characteristic flowers (most familiar from nightshade, potato, or tomato flowers). The belladonna alkaloids have potent antimuscarinic effects. Ingestion produces classic signs of this toxidrome: tachycardia, hyperthermia, dry skin and mucous membranes, skin flushing, diminished bowel sounds, urinary retention, agitation, disorientation, and hallucinations (Chap. 3). Since the 1970s, the quest for recreational "highs" has surpassed unintentional ingestions as the main source of toxicity. Hallucinatory effects are sought in seeds and teas, especially in late summer, when jimsonweed (*Datura stramonium*) seeds (Figure 118–1) become available.[31,33,91,214] One hundred of these

FIGURE 118–1. Jimsonweed, *(Datura stramonium)* initially has a showy white tubular flower which becomes a prickly fruit (pod) following maturation. Inset: The pod (inset) of Jimsonweed holds multiple small seeds containing atropine and scopolamine. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program.)*

seeds contain up to 6 mg atropine and related alkaloids, and an ingestion of this amount can be fatal.[23]

Although several anticholinergic alkaloid-containing species and even individual plants within species bear differing concentrations of several different phytochemicals, the clinical manifestations usually are similar. Following ingestions of the plant the onset of symptoms typically occurs 1 to 4 hours postingestion, or more rapidly if the plants are smoked or consumed as a tea infusion. The duration of effect is partly dose dependent and may last from a few hours to days.[31] The course of anticholinergic poisoning is not substantially altered by use of physostigmine, though this may be lifesaving in patients with seizures or an agitated delirium (see Antidotes in Depth A12–Physostigmine Salicylate).[59,200] Although methods for detection of atropine and scopolamine in clinical specimens are improving, anticholinergic toxicity may be observed without detectable atropine, scopolamine, or hyoscyamine concentrations in biological fluids and is better left as a clinical and not a laboratory diagnosis.

Solanine and chaconine are glycoalkaloids contained in many members of the Solanaceae family, but they are structurally and pharmacologically dissimilar to the belladonna alkaloids. The aglycone solanidine is a steroidal alkaloid. Solanine inhibits cholinesterase in vitro, although cholinergic symptoms are not noted clinically. Nonetheless, reports of solanine-induced central nervous system (CNS) toxicity include hallucinations, delirium, and coma.[149,209] However, most symptomatic patients typically develop nausea, vomiting, diarrhea, and abdominal pain that begins 2 to 24 hours after ingestion, which, like CNS toxicity, may persist for several days. Although solanine is present in most of the 1700 species in the genus *Solanum,* solanine toxicity in humans is rarely encountered. The content of glycoalkaloids in tubers is usually 10 to 100 mg/kg and the maximum concentrations do not exceed 200 mg/kg. Green potatoes and the green potato plant itself are most commonly associated with symptoms, which is not surprising because the alkaloids are most concentrated in those items. The ingestion of 1 to 3 mg of glycoalkaloid per kilogram of body weight is likely to produce clinical symptoms.[198] Most reports of death come from the older literature,[3] and consumption of 2 to 5 g of green components of potatoes per kilogram of body weight per day is not predicted to cause acute toxicity.[177]

Nicotine and Alkaloids with Nicotinelike Activity: Nicotine, Anabasine, Lobeline, Sparteine, *N*-Methylcytisine, Cytisine, and Coniine Nicotine toxicity (other than from inhaled sources) occurs via ingestion of leaves of *Nicotiana tabacum,* cigarette remains, organic products, and insecticides, and transdermally among farm workers harvesting tobacco (green tobacco sickness).[182] A topical folk remedy made from the leaf of *Nicotiana glauca* (tree tobacco) caused anabasine toxicity in an infant.[162] The free bases of nicotine and anabasine are pale yellow oils at room temperature and readily penetrate the intact dermis. A dose of nicotine as small as 1 mg/kg of body weight can be lethal to an adult.[145] Overstimulation of the nicotinic receptors by high doses of the alkaloid produces nicotinism, a toxidrome that progresses from gastrointestinal (GI) symptoms to diaphoresis, mydriasis, fasciculations, tachycardia, hypertension, hyperthermia, and seizures, respiratory depression, and death (Chap. 84). Wearing of protective clothing is essential for tobacco farm workers to prevent green tobacco sickness.[8]

These manifestations are also produced by alkaloids other than nicotine.[236] There are no recent reports of nicotinic toxicity from lobeline (found in all parts of *Lobelia inflata),* although its use in the 18th century resulted in morbidity and mortality.

Sparteine from broom (*Cytisus scoparius*) and *N*-methylcytisine from blue cohosh (*Caulophyllum thalictroides*)[184] are examples of alkaloids that produce nicotinelike effects. Laburnum or golden chain (*Cytisus laburnum*) contains cytisine, which reportedly is responsible

for mass poisonings and fatalities in children and adults who eat the plants or parts thereof (even as little as 0.5 mg/kg, or a few peas).[158] Unfortunately, such reports have resulted in thousands of unnecessary hospital admissions for patients without morbidity and mortality after ingestion of this plant, demonstrating the difficulty in separating hazard from risk and in obtaining accurate dose–response information in the setting of plant exposures and human variability.[95]

The most famous description of the end stages of nicotinic toxicity dates from approximately 2400 years ago by an observer of Socrates' fatal ingestion of a decoction of poison hemlock (*Conium maculatum*).[187]

> . . . the person who had administered the poison went up to him and examined for some little time his feet and legs, and then squeezing his foot strongly asked whether he felt him. Socrates replied that he did not and said to us when the effect of the poison reached his heart, Socrates would depart.

Birds do not experience coniine toxicity but provide a vector for poisoning. According to the book of Exodus, quail that fed on seeds (presumably from poison hemlock) became toxic and passed the toxicity on to the Israelites who ate the fowl.[20] In the 20th century, people have succumbed to hemlock poisoning following their avian repasts. This is especially well documented in Italy, where the toxic alkaloid coniine subsequently was detected in bird meat, as well as in the blood, urine, and tissue of some individuals.[189,203]

The age of the plant seems to be directly correlated with increasing concentrations of coniine, whereas the toxin γ-coniceine occurs in greater amounts in new growth; hence, the plant remains toxic over the entire growing season.[60] Fatal poisonings are reported on multiple continents, and death may result from respiratory arrest.[18] Of 17 poisoned Italian patients, all had elevated liver aminotransferases and myoglobin concentrations, and five had acute tubular necrosis. Death developed 1 to 16 days following ingestion.[189]

Cholinergic Effects in Alkaloids: Arecoline, Physostigmine, and Pilocarpine Betel chewing has been a habitual practice in the East since ancient times. The "quid" consists of betel nut (*Areca catechu*) and other ingredients. The effects of acute exposure to arecoline, the major alkaloid, include sweating, salivation, hyperthermia, and rarely death.[55] Prolonged use is linked to dental decay and oral cancer. Physostigmine is an alkaloid derived from the Calabar bean (*Physostigma venenosum*), where it is present in concentrations of 0.15% (see Antidotes in Depth A12–Physostigmine Salicylate). Pilocarpine is derived from *Pilocarpus jaborandi* from South America. Its stimulatory effects on muscarinic receptors have proven valuable in the treatment of glaucoma.[70] Reversal of toxicity can be achieved by atropine.

Psychotropic Alkaloids: Lysergic Acid and Mescaline Hallucinations from the direct serotonin effects of lysergic acid diethylamide (LSD) and its derivatives, and from the amphetaminelike serotonin effects of the mescaline alkaloids are reported following ingestion of morning glory seeds (*Ipomoea* spp) and peyote cactus (*Lophophora williamsii*), respectively (Chap. 82). Despite their chemical relatedness to LSD, molecules such as lysergic acid amide and lysergic acid ethylamide, found in Hawaiian baby woodrose seeds (*Argyreia nervosa*) produce anticholinergic symptoms.[22]

Alkaloidal Central Nervous System Stimulants and Depressants: Ephedrine, Synephrine, Cathinone, and Opioids The use of ephedrine-containing *Ephedra* spp. in herbal dietary supplement products was banned by the FDA in 2004 because of the associated cardiovascular toxicity and deaths.[205] Varieties of *Sida cordifolia* also contain ephedrine. Synephrine, a xenobiotic structurally related to ephedrine, occurs in bitter orange (*Citrus aurantium*), which is ingested as a plant, in foods such as marmalades, as a dietary supplement, or as a traditional medicine. Deaths and drug interactions can ensue from their use.

Although illegal in the United States, another plant ingested for its CNS stimulant activity is khat (*Catha edulis*). The plant contains cathinone (α-aminopropiophenone) and cathine [(+)-norpseudoephedrine]. In addition, opioids derived from the poppy plant (*Papaver* spp) are prototypic CNS depressants and analgesics (Chap. 38).

Pyrrolizidine Alkaloids Pyrrolizidine alkaloids are widely distributed both botanically and geographically. Approximately half of the 350 different pyrrolizidine alkaloids characterized to date possess the structural characteristics to render them toxic when ingested. Pyrrolizidine alkaloids are found in 6000 plants and in 13 plant families, but are most heavily represented within the Boraginaceae, Compositae, and Fabaceae families. Within these families, the genera *Heliotropium*, *Senecio*, and *Crotalaria*, respectively, are particularly notable for their content of toxic pyrrolizidine alkaloids.[220] These hepatotoxic alkaloids all contain an unsaturated 1-hydroxymethyl pyrrolizidine system.[80] The hepatic cytochrome P450 (CYP) system converts these compounds to highly reactive pyrroles in vivo. Chronic exposures can result in diagnostic hepatic venoocclusive disease (HVOD) by stimulating proliferation of the intima of hepatic vasculature. Poisonings occur as a result of use of pyrrolizidine-rich plants for medicinal purposes[193,194] and by contamination of food grain with seeds of pyrrolizidine-alkaloid-containing plants. Acute poisoning resulting in loss of hepatocellular function can occur following ingestion of 10 to 20 mg of pyrrolizidine alkaloid and is probably caused by an oxidant effect producing hepatic necrosis. An estimated 20% of patients with acute pyrrolizidine alkaloid poisoning die, 50% recover completely, and the rest develop subacute or chronic manifestations of HVOD.[13] Pyrrolizidine alkaloids are teratogenic and are also transmitted through breast milk. Pyrrolizidine alkaloids may be present in bee pollen and have been reported in honey.[21] Other types of plant-associated hepatic disorders are discussed in Effects Shared Among Different Classes of Xenobiotics.

Isoquinoline Alkaloids: Sanguinarine, Berberine, and Hydrastine Adverse effects on human health due to consumption of edible mustard oil adulterated with argemone oil have been reported. The clinical manifestation of the disease are described as dropsy.[48] Sanguinarine was detected in 26 family members who consumed a mustard oil contaminated with seeds of *Argemone mexicana*.[207] All patients suffered GI distress followed by peripheral edema, skin darkening, erythema, skin lesions, perianal itching, anemia, and hepatomegaly. Ascites developed in 12%, and myocarditis and congestive heart failure occurred in approximately a third of affected individuals. Alterations in redox potentials and antioxidants in plasma may be responsible for the histopathological changes including swollen hepatocytes, fluid accumulation in spaces of Disse Kupffer cell hyperplasia.[12] Medicinally, sanguinarine is used for dental hygiene.[99] In North America, sanguinarine is found in blood root (*Sanguinaria canadensis*), which like *Argemone,* is in the Ranunculaceae family.

Berberine is structurally similar to sanguinarine and reportedly also has cardiac depressant effects.[129] A number of medicinal plants contain berberine, including goldenseal (*Hydrastis canadensis*), Oregon grape (*Mahonia* spp), and barberry (*Berberis* spp). It causes myocardial and respiratory depression and contraction of smooth muscle in vasculature and the uterus. Strychninelike movement disorders are described following ingestion of hydrastine, which makes up 4% of goldenseal.

Miscellaneous Other Alkaloids: Emetine/Cephaline, Strychnine/Curare, and Swainsonine Emetine and cephaline are derived from *Cephaelis ipecacuanha,* a tropical plant native to the forests of Bolivia and Brazil. They are the principal active constituents in syrup of ipecac, which produces emesis. Chronic use of syrup of ipecac, typically by patients with eating disorders or Munchausen syndrome by proxy, can lead to

cardiomyopathy, smooth muscle dysfunction, myopathies, electrolyte and acid–base disturbances related to excessive vomiting, and death (see Antidotes in Depth A1–Syrup of Ipecac). Poisoning in patients ingesting plant material is not reported.

Curare was used as an arrow poison derived from plants of the genus *Strychnos* as well as *Chondrodendron,* but the plants and their phytochemicals produce very different clinical effects. The convulsant alkaloids strychnine and brucine are found in various members of the genus *Strychnos.* Although used to produce arrow poison, the more widespread use of *Strychnos* spp in Africa was for trial by ordeal.[176] The seeds of *Strychnos nux-vomica* are especially rich in strychnine, which causes muscular spasms and rigidity by antagonizing glycine receptors in the spinal cord and brainstem. The plant is used as an herbal remedy for arthritis pain called "maqianzi," which if improperly processed produces muscle spasm and weakness, including respiratory muscles (Chap. 112).

Curare is the name given to the unstandardized extract of the bark of *Chondrodendron tomentosum* and certain members of the genus *Strychnos.* The physiologically active xenobiotic of curare from *Chondrodendron* is d-tubocurarine chloride, a competitive antagonist of acetylcholine at nicotinic receptors in the neuromuscular junction. The pharmacology and potential applications of curare are great, as it is the molecule from which most nondepolarizing neuromuscular blockers are derived (Chap. 68). Plant poisoning is recorded solely with its traditional use as a hunting poison.[19,181]

Swainsonine has been isolated from *Swainsonia canescens,* *Astragalus lentiginosis* (spotted locoweed), *Sida carpinifolia,* other species of *Swainsonia* and *Astragalus,* as well as several species in the genera *Oxytropis* and *Ipomoea,* and several fungi.[43] After subsisting on seeds containing swainsonine for nearly 4 months, a naturalist forager manifested profound muscular weakness and died in the wilderness.[116] The compound is teratogenic and causes chronic neurologic disease called "locoism," with weakness and failure to thrive in livestock. Swainsonine inhibits the glycosylation of glycoproteins by α-mannosidase II of the Golgi apparatus, resulting in a lysosomal storage disease. Swainsonine was used with some success in clinical trials for treatment of advanced neoplasms. Adverse effects included hepatic, pancreatic, and respiratory manifestations, as well as lethargy and nausea.

■ GLYCOSIDES

Glycosides yield a sugar or sugar derivative (the glycone) and a nonsugar moiety (the aglycone) upon hydrolysis. The nonsugar or aglycone group determines the subtype of glycoside. For instance, the cardiac glycosides have saponin (steroid) aglycone groups and are placed among the saponin glycosides.

Saponin Glycosides: Cardiac Glycosides, Glycyrrhizin, Ilex Saponins

Poisoning by virtually all *cardioactive steroidal glycosides* is clinically indistinguishable from poisoning by digoxin (Chap. 64), which itself is a cardioactive steroid derived from *Digitalis lanata.* However, compared with toxicity from pharmaceutical digoxin, toxicity resulting from the cardioactive steroidal glycosides found in plants has markedly different pharmacokinetic characteristics. For example, digitoxin in *Digitalis* species has a plasma half-life as long as 192 hours (average 168 hours).

The pharmacologic properties are true across taxonomic boundaries. Poisonings by *Digitalis* spp,[166,183,188,208] squill (*Urginea* spp),[230] lily of the valley,[119] oleander (*Nerium* spp),[126,130,241] yellow oleander (*Thevetia* spp,[62,64] and *Cerbera manghas*[63] are clinically similar (Figure 118–2). The potency of these effects depends on the specific cardioactive glycoside constituents and their dose. For instance, lily of the valley is rarely
FIGURE 118–2. Saponin-glycoside containing plants: (**A**) Lily of the Valley (*Convallaria majalis*) contains the cardioactive steroid convallatoxin. (**B**) Yellow oleander (*Thevetia peruviana*) contains a cardioactive steroid, thevetin. (*Image contributed by Darren Roberts, M.D.*)

associated with morbidity or mortality, whereas ingestion of only two seeds of yellow oleander by adults can produce severe symptoms, and expected outcome is grave if more than four seeds are consumed.[62] Poisonings by oleander and yellow oleander occur predominantly in the Mediterranean and in the Near and Far East. These two plants are popular attractive ornamentals and commonly result in poisoning in the United States and Europe.

Patients experience vomiting within several hours, followed by hyperkalemia, conduction delays, and increased automaticity (bradycardia and tachydysrhythmias). Interestingly, the cardiac manifestations may be difficult to distinguish from those produced by plants with sodium channel blockers (see section sodium channel effects). Activated charcoal was beneficial in preventing death after suicide attempts with yellow oleander in Sri Lanka and its use should not be delayed in the face of uncertain plant identity.[53] Antibody therapy reduces mortality threefold from yellow oleander poisoning but is too expensive for developing countries where oleander-induced mortality is highest.[64,65] In addition, various cardioactive steroids respond differently to therapeutic use of digoxin-specific antibody fragments (Fab). Use of very large doses of digoxin-specific antibody (up to 37 vials reported in one case[188]) may be necessary to capitalize on the therapeutic cross-reactivity between antibody and the nondigoxin cardioactive steroids. The potential for success should lead to use of antibody therapy without delay when

available.[199] Similarly, there is variable cross-reactivity among the individual plant cardioactive steroids with regard to the degree to which each elevates diagnostic polyclonal digoxin assay measurements in clinical laboratories.[49] These measurements can be used only as qualitative proof of exposure but not as quantitative indicators of the exposure, because the elevations can result in marked *underestimation* of the "functional digoxin concentrations." Until more is known, any positive digoxin concentration following exposure to a plant should be assumed to be significant.

Glycyrrhizin. Glycyrrhizin is a saponin glycoside derived from *Glycyrrhiza glabra* (licorice) and other *Glycyrrhiza* spp. Glycyrrhizin inhibits 11-β-hydroxysteroid dehydrogenase, an enzyme that converts cortisol to cortisone.[186] When large amounts of licorice root are consumed chronically, cortisol concentrations rise, resulting in pseudo-hyperaldosteronism because of its affinity for renal mineralocorticoid receptors.[72] Chronic use eventually leads to hypokalemia with muscle weakness, sodium and water retention, hypertension, and dysrhythmias.[106,253] Assessment involves evaluation of the patient's fluid and electrolytes, and electrocardiogram. Potassium replacement is the most common necessary intervention.

Ilex Species. Holly berries from more than 300 *Ilex* spp are a common and attractive ingestant among children, especially during winter holidays. They contain a mixture of alkaloids, polyphenols, saponin glycosides, steroids, and triterpenes.[248] Saponin glycosides appear to be responsible for GI symptoms such as nausea, vomiting, diarrhea, and abdominal cramping that result from ingestion of the berries. Experimental data in animals suggest hemolysis as well as cardiotonic effects, but these are unreported in humans.[243] CNS depression was reported in a case in which a child consumed a "handful" of berries; however, this child was also treated with syrup of ipecac.[192] The toxic quantity is undefined, but one study suggested that no untoward effects are to be expected for ingestions of fewer than six berries.[243] Symptoms may be expected to be restricted to GI effects, and treatment is supportive.

Cyanogenic Glycosides: (S)-Sambunigrin, Amygdalin, Linamarin, and Cyacasin Cyanogenic glycosides yield hydrogen cyanide on complete hydrolysis. These glycosides are represented in a broad range of taxa and in approximately 2500 plant species.[235] The species that are most important to humans are cassava (*Manihot esculenta*), which contains linamarin, and *Prunus* spp, which contain amygdalin. Cycad toxins are neurotoxic or pseudocyanogenic. Rare reports of cyanide poisoning associated with (*S*)-sambunigrin in European elderberry (*Sambucus nigra*; sambunigrin) are more severe when these ingestions include leaves as well as berries.[34]

Many North American species of plants contain cyanogenic compounds, including ornamental *Pyracantha*, *Passiflora*, and *Hydrangea* spp, which either do not release cyanide or are rarely consumed in quantities sufficient to result in toxicity. On the other hand, although the fleshy fruit of *Prunus* spp in the Rosaceae are nontoxic (apricots, peaches, pears, apples, and plums), the leaves, bark, and seed kernels contain amygdalin, which is metabolized to cyanide.[30] Sufficient cyanide can be absorbed to cause acute poisoning.[223] Amygdalin was the active ingredient of Laetrile, an apricot pit extract promoted in the 1970s for its supposed selective toxicity to tumor cells. Its sale was restricted in the United States because it lacked efficacy and safety.[156] However, patients went to other countries for Laetrile therapy, which was marketed as "vitamin B-17," and available through alternative medicine providers.[250] The manifestations of cyanide poisoning and treatment involving use of the cyanide antidote kit are detailed elsewhere (Chap. 126 and Antidotes in Depth: A38 Sodium and amyl nitrite, A39 Sodium Thiosulfate; and A40 Hydroxcobalamin).

Acute and chronic cyanide toxicity (including deaths) associated with consumption of inadequately prepared cassava (*M. esculenta*)

are reported worldwide (Chap. 126).[2] Chronic manifestations include visual disturbances (amblyopia), upper motor neuron disease with spastic paraparesis, and hypothyroidism. These findings are associated with protein-deficient states and the use of tobacco and alcohol. The ataxic neuropathy resembles that produced by lathyrism (see section Proteins, Peptides, and Lectins). A unifying hypothesis about the etiology of these two similar diseases from seemingly very different sources is that thiocyanate accumulation may lead to degeneration of the α-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA)-containing neurons that are first stimulated and then destroyed in neurolathyrism.[212]

Similarly, seeds of cycads contain cycasin and neocycasin, which belong to the family of cyanogenic glycosides, as well as neurotoxins associated with consumption of indigenous food. The cyanogenic glycosides of cycads are considered pseudocyanogenic, with little potential to liberate hydrogen cyanide, but most typically produce violent vomiting 30 minutes to 7 hours after ingestion of one to 30 seeds.[40] On the island of Guam, indigenous peoples develop a devastating amyotrophic lateral sclerosis-parkinsonism dementia complex (ALS-PDC) that appears associated with ingestion of *Cycas circinalis* seeds or the flying foxes that feed extensively upon the cycads.[44] The implicated xenobiotic originally was believed to be an excitatory amino acid,[26] but more recently is identified as a sterol glycoside.[217] Research on the mechanism of this cycad-induced disease is ongoing, with the goal of understanding potential mechanisms of this disease and its links to ALS and Parkinson disease.[78]

Anthraquinone Glycosides: Sennoside and Others Anthraquinone laxatives are regulated both as nonprescription pharmaceuticals and as dietary supplements. These glycosides, such as sennoside, are metabolized in the bowel to produce derivatives that stimulate colonic motility, probably by inhibiting Na$^+$-K$^+$ adenosine triphosphatase (ATPase) in the intestine, which also promote accumulation of water and electrolytes in the gut lumen, producing fluid and electrolyte shifts that can be life threatening.[216]

Other Glycosides: Salicin, Atractyloside, Carboxyatractyloside, Vicine, Convicine Salicin is an inactive glycoside until it is hydrolyzed to produce salicylic acid (Chap. 35). The glycosidic bond is relatively resistant to stomach acid, and the hydrolysis must be accomplished by gut flora. The ability of individual human flora to produce the necessary enzymes varies significantly, resulting in variable clinical effects for salicin or plant material that contains salicin. However, sufficient hydrolytic capacity for some transformation of the glycoside into salicylic acid occurs in all individuals.

Atractylis gummifera was a favorite agent for homicide during the reign of the Borgias. Atractyloside, the toxic xenobiotic primarily inhibits oxidative phosphorylation in the liver by inhibiting the ADP/ATP antiporter blocking influx of adenosine diphosphate (ADP) into hepatic mitochondria and outflow of ATP to the rest of the cell (Chap. 12). Death or severe illness as a result of liver failure or hepatorenal disease following ingestion is reported.[98] *Callilepis laureola* is a South African medicinal plant that contains atractyloside and carboxyatractyloside and that has been reported to cause human poisonings.[218] Cocklebur (*Xanthium strumarium*) is an herbaceous plant with worldwide distribution. The seeds contain the glycoside carboxyatractyloside. The toxic mechanism is similar to that for atractyloside, and seed ingestion has resulted in human fatalities. Nine patients presented with acute onset abdominal pain, nausea and vomiting, drowsiness, palpitations, sweating, and dyspnea. Three developed convulsions followed by loss of consciousness and death. Laboratory findings showed raised liver enzymes indicating severe hepatocellular damage, raised BUN and creatine levels, and raised creatine phosphokinase-MB (CPK-MB) values indicating myocardial injury.[232]

Favism is a potentially fatal disorder brought about by eating fava beans or vetch seeds (*Vicia faba*, *Vicia sativa*, respectively). These seeds contain the pyrimidine glycosides vicine and convicine (divicine is the aglycone of vicine). Consumption of these compounds by individuals with an inborn error of metabolism (glucose-6-phosphate dehydrogenase deficiency) can cause acute hemolytic crisis (see Chap. 24, "Hematologic Principles").[115,127]

The effects of the glycosides sinigrin (from *Brassica nigra* seed and *Alliaria officinalis* [horseradish] root) and naringen (a polyphenolic glycoside from the grapefruit *Citrus paradisi*) are discussed in the sections on Plant-Induced Dermatitis and Plant–Xenobiotic Interactions, respectively.

■ TERPENOIDS AND RESINS: GINKGOLIDES, KAVA LACTONES, THUJONE, ANISATIN, PTAQUILOSIDE/THIAMINASE, AND GOSSYPOL

Ginkgolides in *Ginkgo biloba* are associated with antiplatelet aggregation effects. Reports of spontaneous bleeding associated with ingestion of *Ginkgo* leaf products as an herbal medicine are perhaps explained by this property.[196,233] Another xenobiotic found only in the seed, 4-methoxypyridoxine (pyridine alkaloid), is associated with seizures.[112,239] A mechanism similar to isoniazid-induced seizures is plausible, suggesting treatment with pyridoxine phosphate (Chap. 57 and Antidotes in Depth A15–Pyridoxine). The dermal effects of *Ginkgo* are discussed in the section Plant-Induced Dermatitis.

Kava lactones are a family of terpene lactones found in kava (*Piper methysticum*) that cause central and peripheral nervous system effects.[29,42,69] Kava has enjoyed a long, ceremonial history among islanders of the South Pacific, and observers visiting Oceania have recorded its acute and chronic effects (both pleasant and unpleasant) over the centuries. Importation of kava to Australia in 1983 was a measure to assist Aborigines with alcohol abuse problems. However, the kava itself became abused, and its subsequent ban has resulted in the growth of a black market for kava. Proposed mechanisms to explain the effects of kava lactones include effects at γ-aminobutyric acid type A (GABA$_A$) and GABA$_B$ receptors or local anesthetic effects. Acute symptoms following ingestion include peripheral numbness, weakness, and sedation. Chronic use leads to kava dermopathy and weight loss. More than 70 cases of hepatotoxicity, several requiring liver transplantation, are associated with both acute and chronic effects of kava extracts on cytochrome oxygenases or other yet-to-be-defined etiologies and prompted regulatory health measures in Europe and North America.[32,69]

Thujone is one of many terpenes associated with seizures. It is found in the wormwood plant (*Artemisia absinthium*), in absinthe (the liquor flavored with *A. absinthium*), and in some strains of tansy (*Tanacetum vulgare*). The α- and β-isomers of thujone are believed to act much like camphor to produce CNS depression and seizures. Invoking the structural similarity of thujone to tetrahydrocannabinol (THC), one of the terpenoids of marijuana, to explain the psychoactive effects is controversial (Chap. 83).[153]

Absinthism is characterized by seizures and hallucinations, permanent cognitive impairment, and personality changes. Acute and chronic absinthism led to a worldwide ban of the alcoholic beverage absinthe, which contained thujone, in the early 1900s.[172] Over the past several years, there has been a reexamination of the role of absinthe in the seizure disorders previously attributed to this liquor. Modern analytical procedures have been used to analyze the thujone content of vintage absinthe and modern products made using vintage recipes. Results have largely concluded that thujone content in the liquor was likely to be too low to have produced symptoms.[122] However, because the essential oil of wormwood is composed almost exclusively of thujone, it, but not absinthe, is a potent cause of seizures.[172] Wormwood oil for making homemade absinthe is currently available and is responsible for at least two reports of adverse reactions in people seeking its hallucinatory or euphoriant effects.[247]

Anisatin is found in *Illicium* spp. This terpenoid produces seizures as a noncompetitive GABA antagonist. The Chinese star anise (*Illicium verum*) is sometimes used in teas and occasionally is confused or contaminated with other species of *Illicium*, particularly Japanese star anise *Illicium anisatum*.[86] These contaminations have resulted in small epidemics of tonic–clonic seizures, particularly, but not exclusively, in infants after use of the tea to treat their infantile colic. Recently, in the United States, a case series of at least 40 individuals who had consumed teas brewed from "Star anise" experienced seizures, motor disturbances, other neurologic effects, and vomiting.[107] These cases include at least 15 infants treated for infantile colic with this home remedy. This trend prompted the FDA to issue an advisory regarding the health risk from remedies sharing the common name "Star anise."

Ptaquilosides are found in the bracken fern (*Pteridium aquilinum*), a plant that is extending its range and density worldwide. In foraging animals, consumption of ptaquilosides results in acute hemorrhage secondary to profound thrombocytopenia, whereas thiaminases produce cerebral disease.[71] Although no acute human poisonings are reported, these xenobiotics are transmitted through cow's milk and are associated with increased prevalence of gastric and esophageal cancer in areas where fern is endemic and consumed by cows whose milk is not diluted. Chronic toxicity through spore inhalation also produces pulmonary adenomas in animals.[252] More recently, research defined links between alimentary cancer in humans who previously consumed bracken fiddleheads.[4]

Gossypol is a sesquiterpene that is derived from cottonseed oil. It has been used experimentally as a reversible male contraceptive. The mechanism for its spermicidal effect is unclear, but the effects have been attributed to inhibition of plasminogen activation and plasmin activity in acrosomal tissue.[226] These effects are not currently reported to produce systemic bleeding. Gossypol also inhibits 11β-hydroxysteroid dehydrogenase, as does glycyrrhizin, but typically results in only isolated hypokalemia.[186]

■ PROTEINS, PEPTIDES, AND LECTINS: RICIN AND RICINLIKE, POKEWEED, MISTLETOE, HYPOGLYCIN, LATHYRINS, AND MICROCYSTINS

Lectins are glycoproteins that are classified according to their binding affinity for specific carbohydrate ligands, particularly galactosamines, and by the number of protein chains linked by disulfide bonds. Toxalbumins such as ricin and abrin are lectins that are such potent cytotoxins that they are used as biologic weapons (Chap. 131). Ricin, extracted from the castor bean (*Ricinus communis* [Figure 118–3a]*),* exerts its cytotoxicity by two separate mechanisms. The compound is a large molecule that consists of two polypeptide chains bound by disulfide bonds. It must enter the cell to exert its toxic effect. The B chain binds to the terminal galactose of cell surface glycolipids and glycoproteins. The bound toxin then undergoes endocytosis and is transported via endosomes to the Golgi apparatus and the endoplasmic reticulum.[201] There the A chain is translocated to the cytosol, where it stops protein synthesis by inhibiting the 28S subunit of the 60S ribosome. In addition to the GI manifestations of vomiting, diarrhea, and dehydration, ricin can cause cardiac, hematologic, hepatic, and renal toxicity. All contribute to death in humans and animals.[11] Despite the obvious toxicity of this compound, death probably can be prevented by early and aggressive fluid and electrolyte replacement after oral ingestion (but not injection or inhalation; Chap. 131). Allergic reactions to some of these lectin-bearing plants and their derivates are noted.[50,225]

FIGURE 118–3. Protein-, peptide-, and lectin-containing plants: (**A**) The castor bean plant. The seedpods come in bunches, two of which appear near the center of the image. Each seedpod typically contains three seeds. Inset: Castor beans *(Ricinus communus)* which contain the toxalbumin ricin. By interfering with protein synthesis, ricin may cause multiorgan system failure when administered parenterally. However, its oral absorption is poor, and most oral poisonings cause gastroenteritis. (**B**) Rosary pea *(Abrus precatorius)* containing abrin, a toxalbumin that inhibits protein synthesis. The peas are shown strung together as a rosary. (C) Pokeweed *(Phytolacca americana)* has a large rootstock. The unripe berries contain phytolaccatoxin that produces gastroenteritis, but the mature, purple berries are often consumed. *(Images contributed by the New York City Poison Center Toxicology Fellowship Program.)*

Just how lethal are ingestions of the ornamental seeds? The highest concentration of xenobiotic is in the hard, brown-mottled seeds. These seeds are both tempting and available, even to children in the United States, because they are attractive enough to be used to make jewelry, and their parent plants are showy enough to have been exported for horticultural purposes outside of their native India (including to the United States). Although mastication of one seed by a child liberates enough ricin to produce death, this outcome (or even serious toxicity) is uncommon, even if the seeds are chewed, probably because GI absorption of the xenobiotic is poor and supportive care is effective.[7,11] Activated charcoal should be administered promptly.

Other *ricinlike lectins* are found in *Abrus precatorius* (jequirity pea, rosary pea (Figure 118–3b),[56] *Jatropha* spp,[121,131] *Trichosanthes* spp (eg, *T. kirilowii* or Chinese cucumber), *Robinia pseudoacacia* (black locust),[152] *Phoradendron* spp (American mistletoe), *Viscum album* (European mistletoe), and *Wisteria* spp (wisteria).[195] These all produce at least one double-chain lectin that binds to galactose-containing structures in the gut or inhibits protein synthesis in a manner similar to ricin.

The most commonly ingested toxic plant lectins in the United States are from pokeweed (*Phytolacca americana* (Figure 118–3c), which is eaten as a vegetable but rarely causes toxicity or death. The mature, deep purple berries are less toxic. Pokeweed leaves are consumed after boiling without toxic effect if the water is changed between the first and second boiling (parboiling). When this detoxification technique is not followed, as in preparation of poke salad or pokeroot tea, violent GI effects can ensue 0.5 to 6 hours after ingestion. Nausea, vomiting, abdominal cramping, diarrhea, hemorrhagic gastritis, and death may occur. In addition, bradycardia and hypotension, perhaps induced by an increase in vagal tone, may be associated with nausea and vomiting.[96,191] Phytolaccatoxin and pokeweed mitogen are found in all plant parts, but the highest concentrations are found in the plant root. Pokeweed mitogen is a single-chain protein that inhibits ribosomal RNA by removing purine groups.[16,105] It produces a lymphocytosis 2 to 4 days after ingestion that may take up to 10 days to clear, but this is without clinical consequence.[16]

Mistletoe berries, both American and European, can produce severe gastroenteritis, especially when delivered as teas or extracts, or particularly as parenteral antineoplastic medicinal agents in Europe. As festive holiday plants they become seasonally available for children. Poison center data suggest that ingestion of three to five berries or one to five leaves of the American species may not cause toxicity, but these suggestions are based on limited evidence (see Chap. 135). Despite single reports of seizure, ataxia, hepatotoxicity, and death,[118,213] most authors performing such retrospective examinations conclude that mistletoe exposures are not a highly consequential risk.

Hypoglycin A (β-methylene cyclopropyl-ʟ-α-aminopropionic acid) and *hypoglycin B* (dipeptide of hypoglycin A and glutamic acid) are found in the unripe ackee fruit and seeds of *Blighia sapida* (Euphorbiaceae). The tree is native to Africa but was imported to Jamaica in 1778, and subsequently naturalized in Central America, southern California, and Florida. The scientific name of the plant derives from Captain William Bligh, the British explorer.[24] Epidemics of illness (Jamaican vomiting sickness) associated with consumption of the unripe ackee fruit (raw and cooked) occur in Africa but are more common in Jamaica, where ackee is the national dish.[35,111,151] The most toxic part is the yellow oily aril of the fruit,[41] which contains three large, shiny black seeds. Cases may also be associated with canned fruit.[150] Hypoglycin A is metabolized to methylene cyclopropyl acetic acid, which competitively inhibits the carnitine–acyl coenzyme (CoA) transferase system.[1,14,25] This prevents importation of long-chain fatty acids into the mitochondria, preventing their β-oxidation to precursors of gluconeogenesis. β-Oxidation and gluconeogenesis are further arrested by inhibition of various enzymes, such as glutaryl CoA dehydrogenase, which blocks the malate shunt (Chap. 12). In addition, increased concentrations of glutaric acid may inhibit glutamic acid decarboxylase, which produces GABA from glutamic acid. This not only depletes GABA but also increases concentrations of excitatory glutamate to produce seizures. Insulin concentrations remain unaffected by hypoglycin and metabolites.[155] Carboxylic and other organic acid substrates build up in the urine and serum as a result of these metabolic perturbations. Detection of these acids can help corroborate the diagnosis.[14] Jamaican vomiting sickness is characterized by epigastric discomfort and the onset of vomiting starting 2 to 6 hours after ingestion. Convulsions, coma, and death can ensue, with death occurring approximately 12 hours following consumption.[14] Laboratory findings are notable for profound hepatic aminotransferase and bilirubin abnormalities, and aciduria and acidemia without ketonemia. Cholestatic hepatitis can occur and is reported with chronic use.[128] Autopsy reveals fatty degeneration of liver, particularly microvesicular steatosis, and other organs with depletion of glycogen stores. Left untreated, patient mortality reaches 80%, with 85% of the fatal cases suffering seizures. Treatment with glucose and fluid replacement is essential. Benzodiazepines can control seizures, but may fail if the seizures are related to depletion of GABA. ʟ-Carnitine therapy may exert a theoretical therapeutic role similar to that noted with valproic acid toxicity (Chap. 47).[133]

The *lathyrins* β-*N*-oxalylamino-ʟ-alanine (BOAA) and β-aminopropionitrile (BAPN) are peptides from the grass pea (*Lathyrus sativus*) found in the seeds and leaves, respectively. BOAA produces neurolathyrism (seeds) and BAPN produces osteolathyrism (leaves) in individuals with a dietary dependence on this plant. Neurolathyrism is nearly indistinguishable from spastic paresis associated with consumption of improperly prepared cassava (see section Cyanogenic Glycosides: (*S*)-Sambunigrin, Amygdalin, Linamarin, and Cyacasin).[15,45] Thiol oxidation with depletion of nicotinamide adenine dinucleotide (NADH) dehydrogenase at the level of neuronal mitochondria (ie, excitatory AMPA receptors) may be the common etiology.[173,212] Epidemics have occured in Bangladesh, Ethiopia, Israel, and India. Exposure to BOAA results in degeneration of corresponding corticospinal pathways that becomes irreversible if consumption of undetoxified grass peas is not stopped early. BOAA stimulates the AMPA class of glutamate receptors to provide constant neuronal stimulation, eventual degeneration, and hence spasticity.[185] BAPN affects bone matrix and leads to bone pain and skeletal deformities that develop in adulthood.[15] These diseases occur in areas where the plants are endemic, the food is consumed for 2 months or more, and when diets are otherwise poor in protein and possibly in zinc.[85,123]

Microcystins are found in several cyanobacteria (blue-green algae) belonging to various species of the genera *Microcystis*, *Anabaena*, *Nodularia*, *Nostoc*, and *Oscillatoria*. They elaborate a series of peptides called microcystins and nodularins (*Nodularia spumigena*).[58] These compounds produce hepatotoxicity by inhibiting phosphatases and causing deterioration of the microfilament function in hepatocytes, leading to cell shrinkage and bleeding into the hepatic sinusoids.[51,58] Evidence indicates that these peptides are carcinogenic to humans.[57] Although most cases of untoward effects from blue-green algae occur in animals, the potential for harm was demonstrated by use of microcystin-contaminated water in a dialysis unit in Brazil.[110] Unfiltered water was identified as the risk factor for liver disease in 100 patients who attended the dialysis center (Chap. 9). Fifty of these patients died of acute liver failure following early signs of nausea, vomiting, and visual disturbances. Concerningly, certain species of *Cyanobacteria* are harvested and consumed as health foods[87] or may be consumed secondarily in fish.[139]

■ PHENOLS AND PHENYLPROPANOIDS: COUMARINS, CAPSAICIN, KARWINSKIA TOXINS, NARINGENIN AND BERGAMOTTIN, ASARIN, NORDIHYDROGUAIARETIC ACID, PODOPHYLLIN, PSORALEN, AND ESCULOSIDE

Phenols and phenylpropanoids represent one of the largest groups of plant secondary metabolites. Coumarins and their isomers are phenylpropanoids that are discussed in Chap. 59. Some coumarins are warfarinlike in their activity and are capable of producing a bleeding diathesis when plants are consumed in sufficiently large quantities.[102] Lignans are formed when phenylpropanoid side chains react to form bisphenylpropanoid derivatives. Lignins are high-molecular-weight polymers of phenylpropanoids that bind to cellulose and provide strength to cell walls of stem and bark. Tannins are polymers that bind to proteins and divide into two groups: hydrolyzable and condensed (called proanthocyanidins, eg, karwinol).

Capsaicin is derived from *Capsicum annuum* or other species of chile or cayenne peppers. It is a simple phenylpropanoid that causes release of the neuropeptide substance P from sensory C-type nerve fibers that act upon transient receptor potential (TRP) channels in diverse human tissues.[238] The immediate response to capsaicin is intense local pain and is the rationale for its use as "pepper spray." Eventual depletion of substance P prevents local transmission of pain impulses from these receptors to the spinal cord, blocking perception of pain by the brain, explaining its use in postherpetic neuralgia.

Painful exposures to capsaicin-containing peppers are among the most common plant-related exposures presented to poison centers. They cause burning or stinging pain to the skin.[246] If ingested in large amounts by adults or small amounts by children, they can produce nausea, vomiting, abdominal pain, and burning diarrhea.[229] Eye exposures produce intense tearing, pain, conjunctivitis, and blepharospasm. Fatality is rare, but has occurred after inhalation and infusion.[211]

Skin irrigation, dermal aloe gel, analgesics, and oral antacids are therapeutic agents that may be helpful as appropriate, but patients can be reassured that the effects are transitory and produce no long-term damage. Irritated eyes can be treated with irrigation and local analgesia, but generally resolve without sequelae within 24 hours.

Karwinskia toxins from plants commonly named Buckthorn, coyotillo, tullidora, wild cherry, or capulincillo (*Karwinskia humboldtiana*). These xenobiotics are identified by their molecular weights (T-514, T-496, T-516, T-544). Toxicity has been known for more than 200 years. In 1920, an epidemic of deaths was reported after 20% of 106 Mexican soldiers died following ingestion of foraged *Karwinskia* fruits.[143] Poisonings continue to occur. The fruits are attractive to children; epidemic poisonings have been reported in Central America and are possible wherever the shrub is found (in semidesert areas throughout the southwestern United States and in the Caribbean, Mexico, and Central America).[10] Uncoupling of oxidative phosphorylation or dysfunction of peroxisome assembly and integrity is described as the mechanism of action of T-514 on Schwann cells. Each xenobiotic exhibits similar cytotoxic effects at the cellular level, but with tropism for different organs in animal models.[143]

Within a few days of ingestion, a symmetric motor neuropathy ascends from the lower extremities to produce a bulbar paralysis that may lead to death. Deep-tendon reflexes are abolished in affected areas, but cranial nerve findings are absent. Distinction of this demyelinating motor neuropathy from Guillain-Barré syndrome, poliomyelitis, solvent, and other polyneuropathies is difficult without a history of the fruit ingestion,[168] but can be assisted by detection of T-514 in the blood of affected patients. The other recognized toxins are not detected in blood. Occasionally, axonal damage is observed, but demyelination is the predominant finding on biopsy. Nerve conduction studies always demonstrate loss or abolition of function in fast-conducting axons. Cerebrospinal fluid demonstrates normal protein, glucose, and cytology. Treatment is supportive, with mechanical ventilation as needed, and recovery typically is slow.

Naringin and *naringenin* are flavonoid, while *bergamottin* and *6′,7′-dihydroxybergamottin* are furanocoumarin phenylpropanoids derived from grapefruit that inhibit CYP3A4 in gut and liver.[82] Grapefruit juice consumption can increase circulating concentrations of drugs reliant on 3A4 for metabolic elimination, including carbamazepine, felodipine, and the statins. The most plausible mechanism is inhibition of enteric CYP3A4 and P-glycoprotein.[174] These effects are maximally achieved by a single glass of grapefruit juice.[137]

Comedication with St. John's wort resulted in decreased plasma concentrations of a number of xenobiotics.[138] Hyperforin is a phenylpropanoid found in St. John's wort (*Hypericum perforatum*) and is associated with plant–xenobiotic interactions through strong induction of CYP3A4-mediated drug metabolism as well as induction of P-glycoprotein. These combined mechanisms can cause subtherapeutic concentrations of xenobiotics metabolized via these pathways.[160,161]

Asarin is a term sometimes used for the naturally occurring mixture of α- and β-asarones found in the root of *Asarum europaeum*,

Asarum arifolium, and *Acorus calamus* (sweet flag). Essential oils of the plants have anthelmenthic and nematocidal activity, but putative euphoric and hallucinogenic effects that motivate recreational ingestion are in contrast to confirmed reports of unpleasant GI effects.[234]

Nordihydroguaiaretic acid (NDGA) is associated with hepatotoxicity after ingestion of chaparral (*Larrea tridentata*).[89] Podophyllin and psoralens are phenylpropanoids discussed in the sections Antimitotic Alkaloids and Resins, and Plant-Induced Dermatitis, respectively.

Esculoside (also called *esculin* or *aesculin)* has triterpene saponin side chains and is believed to be the toxic component in horse chestnut (*Aesculus hippocastanum*). Horse chestnut extracts are used medicinally in patients with venous insufficiency. Its therapeutic use at high doses (greater than 340 µg/kg) is associated with renal failure or a lupuslike syndrome.[92] Leaves, twigs, or horse chestnuts ingested by children or infused as teas result in a syndrome that resembles nicotine intoxication. The syndrome consists of vomiting, diarrhea, muscle twitching, weakness, lack of coordination, dilated pupils, paralysis, and stupor.[163] The mechanism of toxicity is not defined, but ingestion of chestnut approximately 1% of a child's weight is suggested to be poisonous to a child.

■ CARBOXYLIC ACIDS: ARISTOLOCHIC ACIDS, OXALIC ACID, AND OXALATE RAPHIDES

Nitrophenanthrene carboxylic acids, collectively called aristolochic acids, are present in most members of the genus *Aristolochia*, including those used ornamentally and as traditional medicines. Consumption of these compounds can cause aristolochic acid nephropathy (AAN), a progressive renal interstitial fibrosis frequently associated with urothelial malignancies (see Chap. 43).[54] Sources of exposure are via consumption of flour made from wheat contaminated with the seeds of *Aristolochia clematis* or other *Aristolochia* species (so-called Balkan endemic nephropathy),[93] or through use of certain traditional Asian medicines made from *Aristolochia* spp (Chinese herb nephropathy).[52,219]

Oxalic acid is the strongest acid among the carboxylic acids found in living organisms. It forms poorly soluble chelates with calcium and other divalent cations. Higher plants have varying ability to accumulate these include both soluble and insoluble oxalates, and many contain crystals of calcium oxalate called raphides. Certain plant families, such as the Araceae, Chenopodiaceae, Polygonaceae, Amaranthaceae, and several of the grass families, are rich in oxalates. Human dietary sources include rhubarb, spinach, strawberries, chocolate, tea, and nuts.[144] Human consumption of soluble oxalate-rich foods correlates with kidney stone formation.

The insoluble calcium oxalate raphides that are present in certain plants, usually in the Araceae family, are found in conjunction with a protein toxin that increases the painful irritation to skin or mucous membranes. This special manifestation is discussed in greater detail in the section Plant-Induced Dermatitis.

■ ALCOHOLS: CICUTOXIN

Cicutoxin, a diacetylenic diol, is found in *Cicuta maculata* (water hemlock), *Cicuta douglasii* (western water hemlock), and *Oenanthe crocata* (hemlock water dropwort). *O. crocata* is native to Europe where intoxications have been reported[61] and has been reported to be naturalized to the United States. Ingestion of any part of these plants constitutes the most common form of lethal plant ingestion in the United States. In a series of 83 ingestions from 1900 to 1975, the case fatality rate was 30%, and it dominated plant-related fatalities among the most recent 10-year reviews of the AAPCC data and

Centers for Disease Control and Prevention (CDC) plant-poisoning records (Chap. 135).[117] In contrast to most plant exposures in humans, which tend to involve children, these ingestions usually involve adults who incorrectly identify the plant as wild parsnip, turnip, parsley, or ginseng.[36] All plant parts are poisonous at all times, but the tuber is especially toxic, and more so during the winter and early spring. Absorption of cicutoxin is rapid and occurs through the skin as well as through the gut. Although the mechanism is not fully understood, cicutoxin may block potassium channels.[222]

Symptoms of mild or early poisonings consist of GI symptoms (nausea, vomiting, epigastric discomfort) and begin as early as 15 minutes after ingestion. Emesis may diminish the toxic load in the gut. Diaphoresis, flushing, dizziness, excessive salivation, bradycardia, hypotension, bronchial secretions with respiratory distress, and cyanosis occur and rapidly progress to violent seizures. Ingestion of as little as a 2-cm section of the sweet-tasting root of *Cicuta* can produce fatal status epilepticus.[100] Other complications include rhabdomyolysis with renal failure and severe acidemia. Immediate gastric evacuation should be performed if practical, and benzodiazepines should be administered for seizures. No specific antidote exists; supportive and symptomatic care should be provided.

■ UNIDENTIFIED TOXINS

Consistent with the inherent complexity of plants and the relatively early stage of the science, identification of the active ingredient(s) involved in poisoning is not always possible. An epidemic of the irreversible lung disease bronchiolitis obliterans developed in Taiwan in 1994. It involved more than 200 dieters who had been eating *Sauropus androgynous* as a weight-loss vegetable. The effects were dose related (usually approximately 100 g/d) and manifested by month 7 after approximately 10 weeks of use.[104] The cases were associated with at least four deaths and, in addition to pulmonary disease, included three cases of torsades des pointes.[136] This last complication is consistent with the plant's high concentration of papaverine, a toxin that produces dysrhythmias in animals, but papaverine does not cause the lung disease. Steroid and bronchodilator therapy consistently failed to improve pulmonary symptoms, and lung transplantation remains the only effective treatment for advanced cases.[136] A report of a later outbreak in Japan noted that the plant is eaten in Malaysia and that the case-associated *Sauropus* was consumed in an uncooked state.[171]

Milk sickness is a historic poisoning described by pioneer farmers. It was caused by transmission of the nontoxic ketone tremetone to humans via milk of animals grazing on white snake-root plants (*Eupatorium rugosum*).[206] Tremetone is transformed into an unknown, unstable toxin by hepatic microsomal enzymes.[17] Toxicity is cumulative. Milk sickness can be fatal in 1 to 21 days or is associated with a slow recovery marked by weakness for months or years, relapsing sometimes to death. A delay in the lactating animal's symptoms provided a lag time when xenobiotic-laden milk was taken from presymptomatic animals and thereby transmitted to humans before the problem was detected.

Breynia officinalis,[135] the air potato or bitter yam (*Dioscorea bulbifera*),[227] and commercial black cohosh (*Actaea racemosa*) preparations,[228] are associated with hepatotoxicity. Black cohosh hepatoxicity has come to light primarily through case reports,[140] but causality has been difficult to establish definitively.

Consumption of the food star fruit (*Averrhoa carambola*) and preexisting renal insufficiency are associated with development of intractable hiccups, vomiting, motor disabilities, paresthesias, confusion, seizures, and death unless patients receive supportive care and hemodialysis.[165,231] The unidentified toxin appears to be neuroexcitatory and active in the thalamus and right temporooccipital cortex.[39]

EFFECTS SHARED AMONG DIFFERENT CLASSES OF XENOBIOTICS

■ PLANT–XENOBIOTIC INTERACTIONS

By increasing the metabolic rate of CYP enzymes and P-glycoprotein, hyperforin in St. John's wort (*H. perforatum*) decreases concentrations of several drugs including amitriptyline, cyclosporine, digoxin, indinavir, irinotecan, warfarin, phenprocoumon, alprazolam, dextrometorphan, simvastatin, theophylline, and oral contraceptives.[108] Bergamottins and naringenin from grapefruit reduce activity of the CYP system enzymes and increase drug concentrations. Other *Citrus* species also appear to increase drug concentrations.[103]

Additive effects may be responsible for serotonin excess or mild serotonin syndrome when St. John's wort is used concurrently with tryptophan or serotonin reuptake inhibitors.[81,108,154] Additive effects also appear to be responsible for increased prothrombin time in patients taking *G. biloba* and various dugs to affect coagulation (eg, warfarin or aspirin) because the ginkgolides have antiplatelet activity.[81,108,154] Hawthorn (*Crataegus* spp), used medicinally for cardiac disorders, may produce an additive effect when taken concomitantly with digoxin, producing bradycardia. Excessive intake of broccoli provides enough vitamin K to competitively inhibit the negative effects of warfarin on vitamin K activation.

■ SODIUM CHANNEL EFFECTS: ACONITINE, VERATRIDINE, ZYGACINE, TAXINE, AND GRAYANOTOXINS

Several unrelated plants produce xenobiotics that affect the flow of sodium at the sodium channel. For instance, aconitine and veratrum alkaloids tend to open the channels to influx of sodium, whereas others (eg, taxine) tend to block the flow, and grayanotoxins both increase and block sodium flow.[240] The sodium channel opener aconitine from *Aconitum* spp or *Delphinium* spp has the most persistent toxicity and the lowest therapeutic index among the many active alkaloid ingredients of these toxic plants called aconite. Some of the related alkaloids are controlled medicinal substances in the People's Republic of China and Taiwan.[37] Aconite has been abused for its psychoactive "out of body" effects and for suicide and homicide. These alkaloids should be suspected in potentially poisoned patients who manifest cardiac toxicity, paresthesias, and seizures.[134]

The mechanism of action depends on the individual alkaloid.[79] Some compounds block and others activate sodium channels. Aconitine itself opens the voltage-dependent sodium channel at binding site 2 of the α-subunit, initially increasing cellular excitability. By prolonging sodium current influx, neuronal and cardiac repolarization eventually slows. It also has calcium channel–opening effects. Asian prescription medicines use the alkaloids to treat dysrhythmias and pain by reducing the excitability of the cardiac conducting system and sensory neurons, respectively.[5]

Approximately one teaspoon (2–5 mg) of the root may cause death. The aconitine alkaloids are rapidly absorbed from the GI tract, and the calculated half-life of aconitine is 3 hours.[157] CNS symptoms typically progress from paresthesias to CNS depression, respiratory muscle depression, paralysis, and seizures. Nausea, vomiting, diarrhea, and abdominal cramping occur. Cardiotoxicity resembles that caused by cardioactive steroidal glycosides, and typically progress from bradycardia with atrioventricular conduction blockade to increased ventricular automaticity resulting in a variety of rapid ventricular rates. Multifocal premature ventricular contractions, bidirectional ventricular tachycardia,[210] torsades des pointes, and ventricular fibrillation may occur.[134]

A history of paresthesias or muscle weakness may be useful in differentiating aconitine toxicity from that caused by a cardioactive steroids,[38] and hidden aconite poisoning can be diagnosed by detection of the alkaloids in urine by liquid chromatography-mass spectrometry.

Management should not be delayed while awaiting testing. Empiric use of digoxin-specific antibody fragments should be administered if cardioactive steroid poisoning is strongly considered, but these antibodies are ineffectual against aconitine. Antidysrhythmic success with lidocaine is limited, and amiodarone is currently the antidysrhythmic of choice.[134] Orogastric lavage, activated charcoal, and preparation for cardiac pacing, bypass, or balloon pump assist should be used as indicated, given the potential for rapid cardiovascular deterioration.[169]

Ingestion of veratridine and other veratrum alkaloids (from *Veratrum viride* and other *Veratrum* spp) generally results from foraging errors where the root appears similar to leeks (*Allium porrum*) and aboveground parts appear similar to gentian (*Gentiana lutea*) used for teas and wines in Europe.[46,204] Typical symptoms develop within an hour of ingestion and include headache followed by nausea, vomiting, and sometimes diarrhea. Vital signs in one case report were normal except for heart rates of 42 and 45 beats per minute in two patients. Laboratory findings were unremarkable, and electrocardiograms revealed sinus bradycardia.[254] The mechanism of action is similar to that of aconitine (sodium channel opening) but with shorter duration.[240] Although severe toxicity has been reported, management is supportive with fluids, atropine, and pressors. Deaths are rare.[204]

Zygacine from *Zigadenus* spp (death camus) and other members of the lily family produces the same toxic effects as veratridine alkaloids (vomiting, hypotension, and bradycardia).[215] Symptoms begin one to two hours after ingestion and usually result from errors while foraging for onions because of the plant's look-alike bulb.[101] Treatment options are the same as above with Veratrum alkaloids.

Taxine, derived from the yew, is another alkaloid mixture of sodium channel effectors that tend to close the channel (*Taxus baccata*) (Figure 118–4).[251] The toxicity of *Taxus* has been known since antiquity. Toxic alkaloids are contained within the bark, leaves, and hard central seed but not in the surrounding fleshy red aril, which partly explains the low rate of toxicity in reported cases of accidental exposure.[251] Taxine-derived alkaloids (eg, taxine A and B, isotaxine B, paclitaxel), taxane-derived substances (eg, taxol A and B), and glycosides (eg, taxicatine) are responsible for the toxicity of *Taxus* spp. Lethal oral doses (LD_{min}) of yew leaves in humans are estimated to be 0.6 to 1.3 g/kg of

FIGURE 118–4. The Yew (*Taxus sp.*) is a common garden shrub that produces taxine, a cardiotoxin. Though the fleshy red aril is nontoxic, the hard seed it contains is toxic. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program.)*

FIGURE 118–5. Mountain laurel (*Kalmia latifolia*), an evergreen shrub, contains the sodium channel opener grayanotoxin, which produces dysrhythmias. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program.)*

body weight, or 3.0 to 6.5 mg taxines/kg of body weight.[249,251] Suicide using leaves is reported despite the large number of leaves required.[245] Clinical manifestations of yew poisoning include dizziness, nausea, vomiting, diffuse abdominal pain, tachycardia (initially), and convulsions followed by bradycardia, respiratory paralysis, and death.[178]

Paclitaxel (Taxol) is an alkaloid component of the relatively rare Pacific yew (*Taxus brevifolia*) that is used as an antitumor chemotherapeutic xenobiotic because of its ability to promote the assembly of microtubules and to inhibit the tubulin disassembly process in mitotic cells. Within 1 hour after ingestion, toxicity progresses from nausea, abdominal pain, bradycardia, and cardiac conduction delays to wide-complex ventricular dysrhythmias, paresthesias, ataxia, and mental status changes.[73] Four prisoners who drank an extract of yew experienced profound hypokalemia, and two died of cardiac arrest.[73] Animal models indicate that bradycardia is responsive to atropine, but wide-complex tachydysrhythmia is unresponsive to sodium bicarbonate.[197]

Grayanotoxins (formerly termed *andromedotoxins*) are a series of 18 toxic diterpenoids present in leaves of various species of *Rhododendron*, *Azalea*, *Kalmia* (Figure 118–5), and *Leucothoe* (Ericaceae). They exert their toxic effects via sodium channels, which they open or close, depending on the toxin.[240] Grayanotoxin I increases membrane permeability to sodium and affected calcium channels in a manner similar to that of veratridine (and batrachotoxin).[94] Grayanotoxins become concentrated in honey made from the plants, mainly in the Mediterranean.[94] Accounts of poisoning by honey date back to at least 401 BC, when Xenophon's troops were incapacitated after they consumed honey made from nectar of *Rhododendron luteum*. These accounts are echoed by modern accounts of toxic honey in the same region.[94] Occasionally, grayanotoxin-containing plants or plant preparations rather than honey cause human poisonings.[180] Bradycardia, hypotension, GI manifestations, mental status changes ("mad honey"), and seizures are described in patients or animals suffering grayanotoxin toxicity.[94,125]

◼ ANTIMITOTIC ALKALOIDS AND RESINS: COLCHICINE, VINCRISTINE, AND PODOPHYLLUM

Consumption of colchicine from plant sources such as autumn crocus (*Colchicum autumnale*) produces a spectrum of symptoms, including nausea, vomiting, watery diarrhea, hypotension, bradycardia, electrocardiographic abnormalities, diaphoresis, alopecia, bone marrow depression, renal failure, hepatic necrosis, hemorrhagic acute lung injury, convulsions, and death.[28,224]

Confusion of the bulbs or leaves of this plant with those of wild onions or garlic occur as a foraging error. Unintentional consumption by children, or ingestion with suicidal intent, accounts for the other cases involving morbidity or mortality. The mechanism of toxicity is disruption of microtubule formation in mitotic cells.

Vincristine and vinblastine are two other indole alkaloids that are used as antineoplastics and are both isolated from the Madagascar periwinkle (*Catharanthus roseus*). No reports of poisoning by these alkaloids following ingestion of the plant could be found (Chap. 37).

Podophyllum resin is the dry, alcoholic extract of the rhizomes and roots of mayapple (*Podophyllum peltatum*) (Figure 118–6). The dry resin consists of up to 20% podophyllotoxin, α- and β-peltatin, desoxy-podophyllotoxin, and dehydropodophyllotoxin. These xenobiotics are originally present in the plant as β-D-glucosides. Podophyllum resin containing podophyllin is available by prescription for topical treatment of venereal warts. Its medicinal derivatives, etoposide, are used for a range of neoplastic diseases. Podophyllum is used as a popular traditional Chinese medicine. Podophyllotoxins make up 20% of the resin from the roots of mayapple (*P. peltatum*). As a group, they disrupt tubulin formation, producing multisystem organ failure. Poisonings are caused by misidentification and adulteration, possibly because the list of common names by which it is known includes mayapple, as well as mandrake, wild mandrake, American mandrake, and European mandrake.[77] Catharsis is prominent after ingestion, but onset of symptoms may be delayed (10 hours in a fatal ingestion). Acute, severe sensorimotor neuropathy and bone marrow suppression following transient leukocytosis can occur even after one-time acute exposures and may be directly related to inhibition of microtubule assembly. Lethargy, confusion, encephalopathy, autonomic instability, sensory ataxia, and death are described following large exposures,[167] but poisoning can also occur after "therapeutic" doses of a popular traditional Chinese medicine.[114]

FIGURE 118–6. The Mayapple (*Podophyllum peltatum*) develops from an initial nodding flower that grows from the stem of this low lying ground cover plant. The whole plant contains podophyllotoxin (podophylline), though the apple is generally considered the least toxic part. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program.)*

Glutamic acid has been used to prevent vincristine-induced peripheral neuropathy and would be a reasonable therapy following podophyllin ingestion.[109]

■ PLANT-INDUCED DERMATITIS

A large number of plants result in undesirable dermal, mucous membrane, and ocular effects (Chap. 29), the most common adverse effects reported to US poison centers and occupational health centers. Plant-induced dermal disorders can be readily categorized into four mechanistic groups, that is, dermatis that results from (1) mechanical injury, (2) irritant molecules that penetrate the skin, (3) allergy, or (4) photosensitivity (direct and hepatogenous) (see Chap. 29).[164,221]

There is much overlap between these categories (some plants can produce all types). Clinicians may have difficulty distinguishing between plant-induced dermatitis and skin disorders[146] or between plant-induced dermatitis and pseudophytodermatitides caused by arthropods, pesticides, or wax (used in fruit and vegetable packaging).[221] Agents that cause adverse skin reactions can also cause eye and local gastric mucosal irritation.

Dermatitis from mechanical injury often is combined with primary or allergic contact dermatitis. Stinging nettles (*Urtica dioica* and other species) have a specialized apparatus in the form of an elongated silicious cell (glandular trichome) that acts like a hypodermic syringe to deliver irritant chemicals into the skin. Contact with these stinging hairs shears off the tip of the hair, producing micromechanical injury and releasing irritant contents: acetylcholine, histamine, and 5-hydroxytryptamine.[170] Acute motor polyneuropathy associated with cutaneous exposure to *Urtica ferox* is reported within 48 hours of walking through a patch of the nettles, with recovery occurring over several weeks.[97] The barbed trichomes (spicules) of *Mucuna pruriens* (velvet bean, cowhage) evoke a histamine-independent itch that is mediated by a cysteine protease, mucunain.[124,221] Workers who handpick pineapples are subject to fissuring and loss of fingerprints after the proteolytic enzyme bromelain is introduced following dermal abrasion by raphides.

Exposures to commonly available household plants such as dumbcane (*Dieffenbachia* spp), *Philodendron* spp, and *Narcissus* bulbs can lead to mechanical injury and painful microtrauma produced by bundles of tiny needlelike calcium oxalate crystals called raphides.[84] Packages of hundreds of raphides called idioblasts contain proteolytic enzymes. *Dieffenbachia* (more than 30 species) (Figure 118–7) exposures are

FIGURE 118–7. This Dumbcane (*Dieffenbachia sp.*) plant is representative of the Arum family, which typically have variegated, waxy leaves. Many contain insoluble crystals of calcium oxalate arranged in idioblasts, which may be ejected following trauma to the leaf. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program.)*

commonly reported household or malicious plant exposures.[179] These exposures are rarely serious.[175] When the leaves are chewed, immediate oropharyngeal pain and swelling occur.[47] Severe oral exposures can be excruciating and progress to profuse salivation, dysphagia, and loss of speech.[84,242] Soothing liquids, ice, parenteral opioids, corticosteroids, and airway protection may be indicated, but antihistamines provide little relief. The edema and pain typically begin to subside after 4 to 8 days. Ocular exposure to the sap may produce chemical conjunctivitis, corneal abrasions, and, rarely, permanent corneal opacifications.

Similar exposures to oxalate raphide-containing household plants in the same family (*Philodendron*, *Brassaia*, *Epipremnum aureum*, *Spathiphyllum*, and *Scheflera* spp) are not as painful as those to dumbcane, presumably because the crystals are packaged differently and do not simultaneously deliver proteolytic enzymes.[159] One exception to their lower severity is a report of death in an 11 month old following complications arising from esophageal lesions induced by philodendron.[147]

Irritant dermatitis can result from low-molecular-weight xenobiotics such as phorbol esters (from Euphorbiaceae) that directly penetrate the skin without antecedent mechanical injury. Similar penetrance is achieved by products of glycoside hydrolysis. For instance, hydrolysis of ranunculin gives rise to anemonin in Ranunculaceae, the buttercup family, and hydrolysis of sinigrin in plants in the mustard family Brassicaceae yields allyl isothiocyanate. Exposures to primary irritants in Brassicaceae and Ranuculaceae usually are mild. Alternatively, dermatitis can occur without contact, as in cases of airborne contact dermatitis, in which typically exposed sites are the upper eyelids; neck; uncovered extremities, including antecubital fossae; and other skin folds (Chap. 29).[202]

Phorbol esters found in spurges (Euphorbiaceae) are contained in milky sap that is capable of producing erythema, desquamation, and bullae. The saps of some species are more irritating than others. For instance, the manchineel tree (*Hippomane mancinella*), found in the Caribbean and Florida, once was planted on graves to deter grave robbers, and juice from the tree has been used to brand animals and to blind people. In addition to dermal and ocular injury,[67] ingestion of some spurges can induce severe GI injury. Poinsettia (*Euphorbia pulcherrima*), crown of thorns (*Euphorbia splendens*), candelabra cactus (*Euphorbia lacteal*), and pencil tree (*Euphorbia tirucalli*) are spurges found in the home as holiday or other ornamentation that rarely produce serious injury, despite reputations to the contrary. The poinsettia plant, for instance, gained a reputation of significant toxicity based on a single, inadequately documented case report from Hawaii in 1919, involving the death of a 2-year-old child.[9] In a subsequent case, an 8-month-old child developed oral mucosal burns after chewing poinsettia.[66] Contact dermatitis, irritation of mucous membranes, and GI complaints such as nausea, vomiting, and abdominal pain are rare findings among the many reported exposures to poinsettia.[120]

Allergic contact dermatitis results from type IV hypersensitivity response and, unlike irritant dermatitis, requires repeat exposures to the agent before symptoms manifest. The most infamous of these xenobiotics are the urushiol oleoresins derived from catechols that are found in *G. biloba* (Ginkgoaceae) and members of the Proteaceae (eg, *Macadamia integrifolia*) and the Anacardaceae. The latter family is notable for inclusion of poison ivy (*Toxicodendron radicans*), poison oak (*Toxicodendron toxicarium, Toxicodendron diver-silobum*), and poison sumac (*Toxicodendron vernix*),[88] as well as mango (*Mangifera indica*), pistachio (*Pistacia vera*), cashew (*Anacardium occidentale*), and Indian marking nut "Bhilawanol" (*Semecarpus anacardium*). Upon first exposure, urushiol resins penetrate the skin and react with proteins to form antigens to which the body forms antibodies. Upon reexposure to urushiol resins, inflammatory mediators are released, leading to urticaria, itching, swelling, and pain.[75,76] In extreme cases,

these reactions can progress to type I hypersensitivity, as demonstrated by a 6% rate of anaphylaxis to mango among 580 patients who previously had mango-induced contact dermatitis.[6] Cross-reactivity between allergens is possible, and particular vigilance is required in sensitive individuals.[74,164] Prevention by removal of exposed objects that act as fomites for the oils and use of protective linaments are appropriate.[141,237] Therapy includes washing with soap and water and corticosteroid creams and, for those frequently exposed, desensitization (Chap. 29).[75]

Allergic contact dermatitis is the most common plant-induced occupational injury. In the United States, 33% of 462 floral shops surveyed reported that at least one employee had developed contact dermatitis.[202] Reactions are reported following exposure to tulips, *Narcissus*, Peruvian lily (*Alstroemeria* spp), and primroses (*Primula* spp). Exposure to the glycoside tuliposide A results in "tulip fingers," the dry, painfully fissured hyperkeratosis of fingers observed in horticultural workers who chronically handle tulips.[27] Upon hydrolysis, this compound yields α-methylene-butyrolactone, the true allergen. Cross-reactivity is possible among some of these xenobiotics. *Alstroemeria* spp, a common ornamental called *Peruvian lily,* contain tuliposide A and thus can cross-react with antigens in those persons already allergic to tulips, producing an allergic contact dermatitis. Primin (2-methoxy-6-*n*-pentyl-*p*-benzoquinone) from members of the Primulaceae family was responsible for the most frequently reported allergic plant dermatitis in northern Europe until workers refused to stock primroses. The "wood cutters dermatitis" of loggers occurs with development of sensitivity to compounds in liverwort (*Frullania* spp), which is cross-reactive to usnic acid in lichens and mosses found on the wood. Cross-reactivity with common weeds such as ragweed (*Ambrosia* spp) or dandelion (*Taraxacum* spp) initiate the risk of hypersensitivity from members of the Compositae family.[113] A myriad of other types of plants are involved in producing occupational dermatitides.[164,202]

Sensitivity to Compositae (daisy family) involves more than 600 sesquiterpene lactones in at least 200 of the 25,000 species in the family and is as ubiquitous as the distribution of species.[90] *Chrysanthemum* allergy is a common occupational hazard in Europe.

Direct photosensitivity dermatitis is produced when compounds such as psoralen or other linear furocoumarins come into direct contact with the skin or are digested and become bloodborne to dermal capillary beds, where they interact with sunlight.[68] These photosensitizing agents are activated by ultraviolet A radiation (320–400 nm), producing singlet oxygen and DNA adducts. In addition to severe sunburnlike symptoms (erythema, epidermal bullae), hyperpigmentation lasting for several months may result from exposure to these compounds. The mechanism by which this reaction is produced is unknown, but depletion of glutathione is postulated to indirectly stimulate melanogenesis by disinhibiting the normally suppressant tyrosinase.[142] More than 200 of these xenobiotics have been identified in at least 15 plant families, including food sources, such as Apiaceae (anise, caraway, carrot, celery, chervil, dill, fennel, parsley, and parsnip), Rutaceae (grapefruit, lemon, lime, bergamot, and orange), Solanaceae (potato), and Moraceae (figs) family.

Hepatogenous photosensitivity is produced when a xenobiotic that normally is harmlessly ingested, absorbed, and hepatically excreted gains access to the peripheral circulation through failure of a liver excretion or detoxification mechanism. An example is the photosensitivity that occurs when phylloerythrin, a product of chlorophyll digestion normally eliminated in the bile, accumulates in the blood as a result of liver dysfunction. The cyanobacterium *Microcystis aeruginosa*, as well as the plants *Lantana camara*, *Tribulus terrestris*, and *Agave lecheuilla* reportedly cause this type of photosensitization in animals.

SUMMARY

Plant xenobiotics can be organized by the principles of pharmacognosy. Examples are provided in which the xenobiotic has therapeutic use such as colchicine, taxine, physostigmine, and pilocarpine. Some xenobiotics act directly or are metabolized to toxic principals such as tremetone, whereas others are toxic through secondary contact in animal meat or milk such as coniine, tremetone, nitrates, pyrollizidine alkaloids, and ptaquiloside.

This analysis should not lead to the false conclusion that all toxic plants, all xenobiotics in plants, or all toxic mechanisms are known. Some reassurance can be achieved by excluding exposure to most life-threatening plants and plant xenobiotics or ascertaining whether a common exposure is toxic. This determination can be aided by basic taxonomy while awaiting expert input. Management should balance the relative risks of using invasive gastric emptying and use of activated charcoal if the plant induces sedation or vomiting or is nontoxic.

CHAPTER 119
ARTHROPODS

In-Hei Hahn

Arthropoda means "joint-footed" in Latin and describes arthropods' jointed bodies and legs connected to a chitinous exoskelelton.[2] The majority of arthropods are benign to humans and environmentally beneficial. Some clinicians regard bites and stings as inconsequential and more of a nuisance than a threat to life. However, some spiders have toxic venoms that can produce dangerous, painful lesions or significant systemic effects. Important clinical syndromes are produced by bites or stings from animals in the phylum Arthropoda, specifically the classes Arachnida (spiders, scorpions, and ticks) and Insecta (bees, wasps, hornets, and ants) (Table 119–1). Infectious diseases transmitted by arthropods, such as the various encephalitides, Rocky Mountain spotted fever, human anaplasmosis, babesiosis, and Lyme disease, are not discussed in this chapter.

Arthropoda comprises the largest phylum in the animal kingdom. At least 1.5 million species are identified, and half a million or more are yet to be classified. It includes more species than all other phyla combined (Fig. 119–1).[2] Araneism or arachnidism results from the envenomation caused by a spider bite. "Bites" are different from "stings." Bites are defined as creating a wound using the oral pole with the intention for either catching or envenomating prey or blood feeding.[84,185] "Stings" occur from a modified ovipositor at the aboral pole that is also able to function in egg laying as in bees and wasps. Stinging behavior typically is used for defense. Most spiders are venomous, and the venom weakens the prey, enabling the spider to secure, neutralize, and digest their prey. Spiders in general are not aggressive toward humans unless they are provoked. The chelicerae (mouthparts comprised of basal section and hinged fang) of many species are too short to penetrate human skin.

Spiders can be divided into categories based on whether they pursue their prey as hunters or trappers. Trappers snare their prey by spinning webs, feed, and enshrine excess victims in a cocoon silk to be eaten later. The order of spiders (Araneae) differs from other members of the class (Arachnida) because of various anatomic differences best assessed by an entomologist. Simplistically, the arachnids have four pairs of joined legs whereas insects have three pairs. The arachnid's body is divided into two parts (cephalothorax and unsegmented abdomen) connected by a small pedicel, and two, three, or four pairs of spinnerets from which silk is spun. Two pedipalps are attached anteriorly on the cephalothorax on either side of their chelicerae and are used for sensation. Spiders have eight eyes, although there are instances when they have two, four, six, or even no pairs of eyes and are quite myopic. Prey is localized by touch as they land in the spider's web. Most spiders use venom (except for the family Uloboridae) to kill or immobilize their prey. The spiders of medical importance in the United States include the widow spiders (*Latrodectus* spp), the violin spiders (*Loxosceles* spp), and the hobo spider (*Tegenaria agrestis*). In Australia, the funnel web spider (*Atrax robustus*) can cause serious illness and death. In South America, the Brazilian Huntsmen (*Phoneutria fera*) and Arantia Armedeira (*Phoneutria nigriventer*) are threats to humans.

Most information on the clinical presentation of spider bites continues to be unreliable, being based on case reports and case series. Frequently the cases do not have any expert confirmation of the actual spider involved, which can lead to propagation of misinformation about different spiders, particularly with necrotic arachnidism. For example, the white tail spider (*Lampona* spp) was suspected for more than 20 years to cause necrotic lesions. Only recently has a prospective study of confirmed spider bites refuted this myth by reporting more than 700 confirmed spider bites in Australia.[112,113,115] Because most arthropod-focused research involves characterizing the structure of spider toxins rather than verifying clinical presentations, it is important to produce clinical studies that have bites confirmed by the presence of the spider that is identified by an expert. Definite spider bites or stings are defined as the following[113,114]: (1) evidence of a bite or sting soon after the incident or the creature can be seen to bite or sting, (2) collection of the particular creature, either alive or dead, with positive identification of the creature by an expert biologist/taxonomist in the field relating to the creature.

HISTORY AND EPIDEMIOLOGY

Since the time of Aristotle, spiders and their webs were used for medicinal purposes. Special preparations were concocted to cure a fantastic array of ailments, including earache, running of the eyes, "wounds in the joints," warts, gout, asthma, "spasmodic complaints of females," chronic hysteria, cough, rheumatic afflictions for the head, and stopping blood flow.[219]

One *Latrodectus* species has an infamous history of medical concern, hence the name *mactans,* which means "murderer" in Latin.[174] Hysteria regarding spider bites peaked during the 17th century in the Taranto region of Italy. The syndrome tarantism, which is characterized by lethargy, stupor, and a restless compulsion to walk or dance, was blamed on *Lycosa tarantula*, a spider that pounces on its prey like a wolf. Deaths were associated with these outbreaks. Dancing the rapid tarantella to music was the presumed remedy. The real culprit in this epidemic was *Latrodectus tredecimguttatus*.[174] Other epidemics of arachnidism occurred in Spain in 1833 and 1841.[147] In North America, there was a rise of spider exposures during the late 1920s, Rome reported large numbers in 1953, and Yugoslavia reported a large number of cases between 1948 and 1953.[28,147] These epidemics may be related to actual reporting biases as well as climatic variations.[174] Spider bites are more numerous in warmer months, presumably because both spiders and humans are more active during that season.

Approximately 200 species of spiders are associated with envenomations.[182,186] Eighteen genera of North American spiders produce poisonings that require clinical intervention (Table 119–2). In one series of 600 suspected spider bites, 80% were determined to result from arthropods other than spiders, such as ticks, bugs, mites, fleas, moths, butterflies, caterpillars, insects, flies, beetles, water bugs, and *Hymenoptera*. Ten percent of the presumed bites actually were manifestations of other nonarthropod disorders.[184,186]

From 2006 to 2007, an annual average of 14,000 spider exposures and 44,000 insect exposures were reported to US poison centers.[31,32] No more than two fatalities were reported per year. One was from the *Hymenoptera* category and the other was an unknown spider exposure.[31] This could be because of greater public awareness, fewer calls made and recorded by the poison control centers, or some other unknown factor. Arachnophobia is a perceived danger that far exceeds the actual risk. Often the misdiagnosis of spider bites results from the wide presentation of dermatologic conditions. For example, cutaneous anthrax was mistaken for a cutaneous necrotic spider bite.[181] In most cases, mortality is rare if supportive care is available and the patient does not develop an anaphylactoid reaction to the envenomation or antidote.

TABLE 119–1. Insects and Other Arthropods that Bite, Sting, or Nettle Humans

Arthropod	Description
Honeybee (*Apis mellifera*)	Hairy, yellowish brown with black markings
Bumblebee and carpenter bee (*Bombus* spp and *Xylocopa* spp)	Hairy, larger than honeybees and colored black and yellow
Vespids (yellow jackets, hornets, paper wasps)	Short-waisted, robust, black and yellow or white combination
Schecoids (thread-waisted wasps)	Threadlike waist
Nettling caterpillars (browntail, Io, hag, and buck moths, saddleback and puss caterpillars)	Caterpillar shaped
Southern fire ant (*Solenopsis* spp)	Ant shaped
Spiders (*Arachnida*) black widow, brown recluse	Body with 2 regions: cephalothorax, and abdomen; 8 legs
Scorpions (*Centruroides*)	Eight-legged, crablike, stinger at the tip of the abdomen; pedipalps (pincers) highly developed (not a true insect)
Centipedes (*Chilopoda*)	Elongated, wormlike, with many jointed segments and legs; 1 pair of poison fangs behind head

TABLE 119–2. North American Spiders of Medical Importance

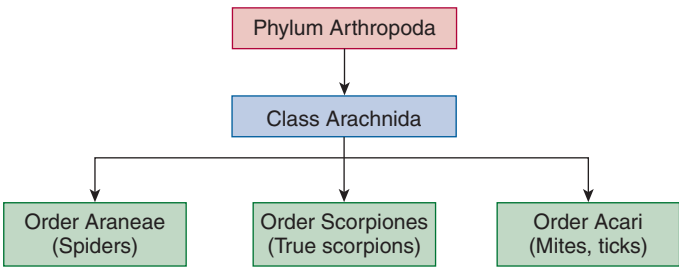
Genus	Common Name
Araneus spp	Orb weaver
Argiope aurantia	Orange argiope
Bothriocyrtum spp	Trap door spider
Chiracanthium spp	Running spider
Drassodes spp	Gnaphosid spider
Heteropoda spp	Huntsman spider
Latrodectus spp	Widow spider
Liocranoides spp	Running spider
Loxosceles spp	Brown, violin, or recluse spider
Lycosa spp	Wolf spider
Misumenoides spp	Crab spider
Neoscona spp	Orb weaver
Peucetia viridans	Green lynx spider
Phiddipus spp	Jumping spider
Rheostica (*Aphonopelma*) spp	Tarantula
Steatoda grossa	False black widow spider
Tegenaria agrestis	Hobo spider
Ummidia spp	Trap door spider


FIGURE 119–1. Taxonomy of the phylum Arthropoda.

BLACK WIDOW SPIDER (*LATRODECTUS MACTANS*; HOURGLASS SPIDER)

Five species of widow spiders are found in the United States: *Latrodectus mactans* (black widow; Figure 119–2a), *Latrodectus hesperus* (Western black widow), *Latrodectus variolus* (found in New England, Canada, south to Florida, and west to eastern Texas, Oklahoma, and Kansas), *Latrodectus bishopi* (red widow of the South), and *Latrodectus geometricus* (brown widow or brown button spider; Figure 119–2b). Dangerous widow spiders in other parts of the world include *L. geometricus* and *Latrodectus tredecimguttatus* (European widow spider found in southern Europe), *Latrodectus hasselti* (red-back widow spider found in Australia, Japan, and India; Figure 119–2c), and *Latrodectus cinctus* (found in

FIGURE 119–2. Widow spiders. (**A**) The North American Black Widow Spider, *Latrodectus mactans*. Note the hourglass on the abdomen. (**B**) The Brown Widow Spider, *Latrodectus geometricus*. (**C**) The Australian redback spider *Latrodectus hasselti*. (*Images contributed by the American Museum of Natural History*).

South Africa). These spiders live in temperate and tropical latitudes in stone walls, crevices, wood piles, outhouses, barns, stables, and rubbish piles. They molt multiple times and as a result can change colors. The ventral markings on the abdomen are species specific, and the classic red hourglass-shaped marking is noted in only *L. mactans*. Other species may have variations on their ventral surface, such as triangles and spots.

Typically, the female *L. mactans* is shiny, jet-black, and large (8–10 mm), with a rounded abdomen and a red hourglass mark on its ventral surface. Her larger size and ability to penetrate human skin with her fangs make her more venomous and toxic than the male spider, which resembles the immature spider in earlier stages of development and is smaller, lighter in color, and has a more elongated abdomen and fangs that usually are too short to envenomate humans (Table 119–3). Black widow females are trappers and inhabit large, untidy, irregularly shaped webs. Webs are placed in or close to the ground and in secluded, dimly lit areas that can trap flying insects, such as outdoor privies, barns, sheds, and garages.[2]

■ PATHOPHYSIOLOGY

The venom is more potent on a volume-per-volume basis than the venom of a pit viper and contains six active components with molecular weights of 5000 to 130,000 Da.[2] The six components are α-latrotoxin (α-LTX) affecting vertebrates, five latroinsectotoxins (α-, β-, γ-, δ-, ε-LITs) (insect-specific neurotoxin), and α-latrocrustatoxin (α-LCT) (crustacean-specific neurotoxin).[94] α-Latrotoxin binds, with nanomolar affinity, to the specific presynaptic receptors neurexin I-α and Ca²⁺-independent receptor for α-latrotoxin (CIRL), otherwise known as *latrophilin*.[25,102,111] The binding triggers a cascade of events: conformational change allowing pore formation by tethering the toxin to the plasma membrane, Ca²⁺ ionophore formation, and translocation of the N-terminal domain of α-LTX into the presynaptic intracellular space, and intracellular activation of exocytosis of norepinephrine, dopamine, neuropeptides, and acetylcholine, glutamate, and γ-aminobutyric acid (GABA), respectively.[2,162,165] Neurexin I-α receptors, otherwise known as type I or calcium-dependent receptors, are from a family of neuron-specific cell membrane proteins with one transmembrane domain neuron-specific cell-adhesion molecule.[142,165] Neurexin I-α is not required for the excitotoxic action of α-LTX. Neurexin I-α–deficient mice still are susceptible to α-LTX via stimulation of the CIRL receptor, or the type II receptor.[81] CIRL is a neuronal receptor that belongs to the family of 7-transmembrane domain G-protein–coupled receptors. Type II receptors bind to α-LTX independently of Ca²⁺ in the extracellular media. CIRL is thought to be coupled to phospholipase C, resulting in subsequent phosphoinositide metabolism that couples the function to secretion.[25,130] CIRL-1 and CIRL-3 are high-affinity neuronal receptors. CIRL-2 has 14 times less affinity to α-LTX than CIRL-1 but is expressed ubiquitously, specifically by placenta, kidney, spleen, ovary, heart, lung, and brain.[111] The nervous system is the primary target for α-LTX, but cells from other tissues also are susceptible to the α-LTX because of the presence of CIRL-2.[111]

■ CLINICAL MANIFESTATIONS

Widow spiders are shy and nocturnal. They usually bite when their web is disturbed or upon inadvertent exposure in shoes and clothing. One patient developed latrodectism following the intentional intravenous injection of a crushed whole black widow spider.[37] A sharp pain typically described as a pinprick occurs as the victim is bitten. A pair of red spots may evolve at the site, although the bite is commonly unnoticed.[43,146] The bite mark itself tends to be limited to a small puncture wound or wheal and flare reaction that often is associated with a halo (see Table 119–3). However, the bite from *L. mactans* may

produce *latrodectism,* a constellation of signs and symptoms resulting from systemic toxicity. Some cases do not progress; others may show severe neuromuscular symptoms within 30 to 60 minutes. The effects from the bite spread contiguously. For example, if a person is bitten on the hand, the pain progresses up the arm to the elbow, shoulder, and then toward the trunk during systemic poisoning. Typically, a brief time to symptom onset denotes severe envenomation.

One grading system divides the severity of the envenomation into three categories.[50] Grade 1 envenomations range from no symptoms to local pain at the envenomation site with normal vital signs. Grade 2 envenomations involve muscular pain at the site with migration of the pain to the trunk, diaphoresis at the bite site, and normal vital signs. Grade 3 envenomations include the grade 2 symptoms with abnormal vital signs; diaphoresis distant from the bite site; generalized myalgias to back, chest, and abdomen; and nausea, vomiting, and headache.

Hypertoxic myopathic syndrome of latrodectism involves muscle cramps that usually begin 15 minutes to 1 hour after the bite. The muscle cramps initially occur at the site of the bite but later may involve rigidity of other skeletal muscles, particularly muscles of the chest, abdomen, and face. The pain increases over time and occurs in waves that may cause the patient to writhe. Large muscle groups are affected first. Classically, severe abdominal wall spasm occurs and may be confused with a surgical abdomen, especially in children who cannot relate the history with the initial bite.[35] Muscle pain often subsides within a few hours but may recur for several days. Transient muscle weakness and spasms may persist for weeks to months.

Additional clinical findings include "*facies latrodectismica,*" which consists of sweating, contorted, grimaced face associated with blepharitis, conjunctivitis, rhinitis, cheilitis, and trismus of the masseters.[146] A fear of death, *pavor mortis*, is described.[146] The following symptoms also are reported: nausea, vomiting, sweating, tachycardia, hypertension, muscle cramping, restlessness, and rarely priapism, and compartment syndrome at the site of the bite.[2,51,107,206] The mechanism of compartment syndrome developing after a black widow spider envenomation is unclear, but two postulated theories include rhabdomyolysis and the venom affecting the blood vessels leading to engorgement and obstruction of the venous outflow. The compartment syndrome was treated with antivenom and the patient recovered without the need for a fasciotomy. Recovery usually ensues within 24 to 48 hours, but symptoms may last several days with more severe envenomations. *Life-threatening complications* include severe hypertension, respiratory distress, myocardial infarction, cardiovascular failure, and gangrene.[37,50,51,69,157,170,174] In the past 20 years, more than 40,000 presumed black widow spider bites have been reported to the American Association of Poison Control Centers. Death is rarely reported. There have been two fatalities in Madagascar from envenomation by *L. geometricus,* one from cardiovascular failure and the other from gangrene of the foot.[174] The most recent fatality reported from Greece resulted from myocarditis secondary to envenomation of *L. tredecimguttatus,*[173] confirmed by a local veterinarian. The patient developed severe dyspnea, hypoxemia, cyanosis, cardiomyopathy, and global hypokinesis of the left ventricle confirmed by echocardiography followed by death 36 hours later; antivenom was not available. On autopsy, diffuse interstitial and alveolar edema, with mononuclear infiltrate of the myocardium and degenerative changes, were noted and toxicologic analysis for xenobiotics, as well as all blood, urine, bronchial, and serologic viral cultures, were negative. The paucity of mortalities is presumed to result from the improvement in medical care, the availability of antivenom, or the limited toxicity of the spider.

■ DIAGNOSTIC TESTING

Laboratory data generally are not helpful in management or predicting outcome. According to one study, the most common findings

TABLE 119–3. Brown Recluse and Black Widow Spiders: Comparative Characteristics

	Brown Recluse *(Loxosceles spp)*	Black Widow *(Latrodectus spp)*
Description	Female brown, 6–20 mm, violin-shaped mark on dorsum of cephalothorax; female greater toxicity than male	Female jet black, 8–10 mm, red hourglass mark on ventral surface, female greater toxicity than male
Major venom component	Sphingomyelinase D	α-Latrotoxin
Pathophysiology of envenomation	Vascular injury, dermatonecrosis, hemolysis	Massive presynaptic discharge of neurotransmitters; lymphatic and hematogenous spread, neurotoxicity
Epidemiology	Bites more common in warmer months	Bites more common in warmer months in subtropical and temperate areas; perennial in tropics
	North America (southern and midwestern states): *L. reclusa*	North America: *L. mactans, L. Hesperus, L. geometricus*
	South America: *L. laeta, L. gaucho*	Europe: *L. tredecimguttatus*
	Europe: *L. rufescens*	Africa (southern): *L. indistinctus*
	Africa (southern): *L. parrami, L. spiniceps, L. pilosa, L. bergeri*	Australia: *L. hasselti*
	Asia/Australia: Rare	Asia/South America: Rare
Clinical effects	Cutaneous	Cutaneous
	Initial (0–2 h after bite): painless, erythema, edema	Initial (5 min–1 h after bite): local pain
	2–8 h: Hemorrhagic, ulcerates, painful	1–2 h: Puncture marks
	1 week: Eschar	Hours: Regional lymph nodes swollen, central blanching at bite site with surrounding erythema
	Months: Healing	
		CVS: Initial tachycardia followed by bradycardia, dysrhythmias, initial hypotension followed by hypertension
		GI: Nausea, vomiting, mimic acute abdomen
	Hematologic	Hematologic: Leukocytosis
	Methemoglobinemia, hemolysis, thrombocytopenia, DIC	
		Resolution over several days
		Metabolic
		Hyperglycemia (transient)
		Musculoskeletal: Hypertonia, abdominal rigidity, "facies latrodectismica"
		Neurologic
		CNS: Psychosis, hallucinations, visual disturbance, seizures
		Peripheral nervous system: Pain at the site
		Autonomic nervous system: Increased secretions; sweating, salivation, lacrimation, diarrhea, bronchorrhea, mydriasis, miosis, priapism, ejaculation
	Renal: Renal failure, acute tubular necrosis	Renal: Glomerulonephritis, oliguria, anuria
		Respiratory: Bronchoconstriction, acute lung injury
Treatment	Analgesia	Analgesia
	Wound care	Muscle relaxants
	Dapsone (?)	Antivenom
	Hyperbaric oxygen (local) (?)	
	Antivenom (?) not available universally	
	Corticosteroids	

include leukocytosis and increased creatine phosphokinase and lactate dehydrogenase concentrations.[50] Currently no specific laboratory assay is capable of confirming latrodectism. However, the clinical situation may warrant the need to check laboratory tests and other studies to evaluate the sequelae of the black widow spider envenomation.

■ MANAGEMENT

Treatment involves establishing an airway and supporting respiration and circulation, if indicated. Wound evaluation and local wound care, including tetanus prophylaxis, are essential.[230] The routine use of antibiotics is not recommended.

Pain management is a substantial component of patient care and depends on the degree of symptomatology. Using the grading system, grade 1 envenomations may require only cold packs and orally administered nonsteroidal anti-inflammatory agents. Grade 2 and 3 envenomations probably require intravenous (IV) opioids and benzodiazepines to control pain and muscle spasm.

Traditionally, 10 mL 10% calcium gluconate solution was given IV to decrease cramping. However, a retrospective chart review of 163 patients envenomated by the black widow concluded that calcium gluconate was ineffective for pain relief compared with a combination of IV opioids (morphine sulfate or meperidine) and benzodiazepines (diazepam or lorazepam).[50,126] Another study found greater neurotransmitter release when extracellular calcium concentrations were increased, suggesting that administration of calcium is irrational in patients suffering from latrodectism.[182] The mechanism of action of calcium remains unknown and its efficacy is anecdotal; therefore, we do not recommend calcium administration for pain management.

Although often recommended, methocarbamol (a centrally acting muscle relaxant) and dantrolene also are ineffective for treatment of latrodectism.[126,187] A benzodiazepine, such as diazepam, is more effective for controlling muscle spasms and achieves sedation, anxiolysis, and amnesia. Management should primarily emphasize supportive care, with opioids and benzodiazepines for controlling pain and muscle spasms, because the use of antivenom risks anaphylaxis and serum sickness.

Latrodectus antivenom is rapidly effective and curative. In the United States, the antivenom formulation is effective for all species but is available as a crude hyperimmune horse serum that may cause anaphylaxis and serum sickness. The morbidity of latrodectism is high, with pain, cramping, and autonomic disturbances, but mortality is low. Hence controversy exists over when to administer the black widow antivenom. The antivenom can be administered for severe reactions (eg, hypertensive crisis or intractable pain), to high-risk patients (eg, pregnant women suffering from a threatened abortion), or for treatment of priapism.[107,174] Use of antivenom probably should not be considered for patients unless systemic symptoms otherwise designated as grade 3 are present.[51] The usual dose is one to two vials diluted in 50 to 100 mL 5% dextrose or 0.9% sodium chloride solution, with the combination infused over 1 hour (Antidotes in Depth A35–Antivenom [Scorpion and Spider]). Skin testing may identify a highly allergic individual but does not eliminate the occurrence of hypersensitivity reactions; therefore, we do not recommend skin testing. Pretreatment with histamine H_1- or H_2-blockers or both, and epinephrine may be beneficial in preventing histamine release and/or anaphylaxis. Patients with allergies to horse serum products and those who have received antivenom or horse serum products are at risk for immunoglobulin IgE-mediated hypersensitivity reactions, and though efficacy is largely unproven may benefit from the pretreatment of antihistamines and steroids.

In Australia, a purified equine-derived IgG-F(ab)$_2$ fragment antivenom for the red-back spider *L. hasselti* (RBS-AV) is available. The RBS-AV (CSL, Melbourne, Australia) is administered intramuscularly and given as first-line therapy to patients presenting with systemic signs or symptoms in Australia. Since its introduction in 1956, there have been no deaths, and the incidence of mild allergic reactions to RBS-AV is reported as 0.54% in 2144 uses.[215]

However, an underpowered prospective cohort study of confirmed red-back spider bites failed to show that intramuscular antivenom was better than no treatment when all patients were followed up over 1 week.[115] This study did note that only 17% of patients were pain-free at 24 hours with antibody treatment. Therefore, intramuscular antivenom appears to be less effective than previously thought, and the route of administration requires review. Recently in Italy, an FM$_1$ Fab fragment specific for the alpha latroxin has been highly effective in neutralizing the toxin in vivo in mice and shows some promise for possible use in humans.[7,36] This single monoclonal antibody shows great promise in the treatment for severe black widow envenomation. Inadvertent use of RBS-AV successfully treated envenomations from the comb-footed spider (*Steatoda* spp).[114] And since the *Steatoda* venom and clinical effects are similar to the *Latrodectus* venom but milder in clinical presentation, the RBS-AV may have a future role in treating black widow spider envenomations in the United States.[92]

BROWN RECLUSE SPIDER (*LOXOSCELES RECLUSA*; VIOLIN OR FIDDLEBACK SPIDER)

Loxosceles reclusa was confirmed to cause necrotic arachnidism in 1957, although reports of systemic symptoms following brown spider bites have appeared since 1872.[6] This spider has a brown violin-shaped mark on the dorsum of the cephalothorax, three dyads of eyes arranged in a semicircle on top of the head, and legs that are five times as long as the body. It is small (6–20 mm long) and gray to orange or reddish brown (see Figure 119–3a). *Loxosceles* spiders weave irregular white, flocculent adhesive webs that line their retreats.[79] Spiders in the genus *Loxosceles* have a worldwide distribution. In the United States, other species of this genus, which include *L. rufescens*, *L. deserta*, *L devia*, and *L. arizonica*, are prominent in the Southeast and Southwest.[4] *L. rufescens* has been introduced and identified in New York City in several old buildings, though it is unclear how they initially arrived there (confirmed by Lou Sorkin BCE, entomologist, American Museum Natural History, New York).[203] They are hunter spiders that live in dark areas (wood piles, rocks, basements), and their foraging is nocturnal. They are not aggressive but will bite if antagonized (see Table 119–3). These spiders live up to 2 years and maybe even longer. They are resilient and can survive up to 6 months without water or food and can tolerate temperatures from 46.4°F to 109.4°F (8°C–43°C).[84] Like the black widow spider, the female is more dangerous than the male. *Loxosceles* venom has variable toxicity, depending on the species, with *Loxosceles intermedia* venom causing more severe clinical effects in humans.[10,11] The peak time for envenomation is from spring to autumn, and most victims are bitten in the morning.

■ PATHOPHYSIOLOGY

The venom is cytotoxic. The two main constituents of the venom are sphingomyelinase-D and hyaluronidase, though other subcomponents include deoxyribonuclease, ribonuclease, collagenase, esterase, proteases, alkaline phosphatase, and lipase.[59,134,225] Hyaluronidase is a spreading factor that facilitates the penetration of the venom into tissue but does not induce lesion development.[134] Sphingomyelinase-D is the primary constituent of the venom that causes necrosis and red blood cell hemolysis and also causes platelets to release serotonin.[134] Sphingomyelinase also reacts with sphingomyelin in the red blood cell membrane to release choline and *N*-acylsphingosine phosphate, which triggers a chain reaction releasing inflammatory mediators, such as thromboxanes,
FIGURE 119–3. Brown recluse spider. (**A**) *Loxosceles reclusa*. Note the image of the violin, which gives the spider its common name, "the fiddle back spider". *(Image contributed by Progeny Products,* www.brown-recluse.com*)* (**B**) A typical envenomation from the Brown Recluse Spider. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program.)*

leukotrienes, prostaglandins, and neutrophils, leading to vessel thrombosis, tissue ischemia, and skin loss.[134] Early perivascular collections of polymorphonuclear leukocytes with hemorrhage and edema progresses to intravascular clotting. Coagulation and vascular occlusion of the microcirculation occur, ultimately leading to necrosis.[198]

■ CLINICAL MANIFESTATIONS

The clinical spectrum of loxoscelism can be divided into three major categories. The first category includes bites in which very little, if any, venom is injected. A small erythematous papule may be present that becomes firm before healing and is associated with a localized urticarial response. In the second category, the bite undergoes a cytotoxic reaction. The bite initially may be painless or have a stinging sensation but then blisters and bleeds, and ulcerates 2 to 8 hours later (see Table 119–3). The lesion may increase in diameter, with demarcation of central hemorrhagic vesiculation, then ulcerate and develop violaceous necrosis, surrounded by ischemic blanching of skin and outer erythema and induration over 1 to 3 days. This is also known as the "red, white, and blue" reaction (Figure 119–3b).[127,235] Necrosis of the central blister occurs in 3 to 4 days, with eschar formation between 5 and 7 days. After 7 to 14 days,

the wound becomes indurated and the eschar falls off, leaving an ulceration that heals by secondary intention. Local necrosis is more extensive over fatty areas (thighs, buttocks, and abdomen).[134] The size of the ulcer determines the time for healing. Large lesions up to 30 cm may require 4 months or more to heal.

Upper airway obstruction was reported in a child who was bitten on his neck and subsequently developed progressive cervical soft tissue edema with airway obstruction and dermatonecrosis 40 hours later.[89] There has been one other report of stridor and respiratory distress following a brown recluse envenomation of the ear. Although the presentation is rare, respiratory compromise should be considered when an envenomation occurs near the airway.[83]

The third category consists of systemic loxoscelism, which is not predicted by the extent of cutaneous reaction, and occurs 24 to 72 hours after the bite. The young are particularly susceptible.[105,188] The clinical manifestations of systemic loxoscelism include fever, chills, weakness, edema, nausea, vomiting, arthralgias, petechial eruptions, rhabdomyolysis, disseminated intravascular coagulation, hemolysis that can lead to hemoglobinemia, hemoglobinuria, renal failure, and death.[22,39,76,144,192,233] However, in North America, the incidence of systemic illness is rare and mortality is low.[3]

■ DIAGNOSTIC TESTING

Bites from other spiders, such as *Cheiracanthium* (sac spider), *Phidippus* (jumping spider), *Argiope* (orb weaver), and *Tegenaria* (northwestern brown spider), can produce necrotic wounds. These spiders are often the actual culprits when the brown recluse is mistakenly blamed. Definitive diagnosis is achieved only when the biting spider is positively identified. No routine laboratory test for loxoscelism is available for clinical application, but several techniques are presently used for research purposes. The lymphocyte transformation test measures lymphocytes that have undergone blast transformation up to 1 month after exposure to *Loxosceles* venom. The lymphocytes incorporate thymidine into the nucleoprotein, providing a quantitative response.[5] A passive hemagglutination inhibition test (PHAI) has been developed in guinea pigs. The PHAI assay is based on the property of certain brown recluse spider venom components to spontaneously adsorb to formalin-treated erythrocyte membranes and the ability of the brown recluse spider venom to inhibit antiserum-induced agglutination of venom-coated red blood cells.[13] The test is 90% sensitive and 100% specific for 3 days postenvenomation and may prove useful for early diagnosis of brown recluse spider envenomation.[13] An enzyme-linked immunoassay (ELISA) specific for *Loxosceles* venom in biopsied tissue can confirm the presence of venom for 4 days postenvenomation.[13] The drawbacks of using a skin biopsy are the invasive nature of the procedure, which can result in further scarring with an increased potential for infection, and the lack of proof that skin biopsy can diagnose early envenomations prior to the development of dermatonecrosis. Another ELISA utilizing serum for detection of venom antigens has been developed that correctly discriminates the mice inoculated with antigens from *L. intermedia* venom. The ELISA immunoassay and antivenom may become useful diagnostic tools if envenomation can be proved or disproved early.[47] A venom-specific enzyme immunoassay that uses hair, skin biopsies, or aspirated tissue near a suspected lesion to detect the presence of venom up to 7 days after injury is under investigation.[132,152] In Brazil, ELISA is used to detect the venom of *Loxosceles gaucho* in wounds and patient sera, but the technique is not in widespread clinical use.[43]

Clinical laboratory data may be remarkable for hemolysis, hemoglobinuria, and hematuria. Coagulopathy may be present, with laboratory data significant for elevated fibrin split products, decreased fibrinogen levels, and a positive D-dimer assay. Other tests may show increased

prothrombin time (PT) and partial thromboplastin time (PTT), leukocytosis (up to 20,000–30,000 cells/mm³), spherocytosis, Coombs-positive hemolytic anemia, thrombocytopenia, or abnormal renal and liver function tests.[2,7,79,184,186,188,231]

■ TREATMENT

Optimal local treatment of the lesion is controversial. The most prudent management of the dermatonecrotic lesion is wound care, immobilization, tetanus prophylaxis, analgesics, and antipruritics as warranted (Table 119–4).[2,79,228,231] Early excision or intralesional injection of corticosteroids appears unwarranted.[179] Corrective surgery can be performed several weeks after adequate tissue demarcation has occurred. In one case series the use of curettage of the lesion to remove necrotic and indurated tissue from the lesion, thus eliminating any continuing action of the lytic enzymes on the surrounding tissue, showed promising results.[105] These patients had wound healing without further necrosis and minimal scarring. Electric shock delivered via stun guns was not found to be useful in a guinea pig envenomation model.[13] Cyproheptadine, a serotonin antagonist, was not beneficial in a rabbit model.[167] A randomized, controlled study evaluating the efficacy of topical nitroglycerin for envenomated rabbits showed no difference in preventing skin necrosis and suggested the possibility of increased systemic toxicity.[140] Antibiotics should be used to treat cutaneous or systemic infection, but should not be used prophylactically.

Early use of dapsone in patients who develop a central purplish bleb or vesicle within the first 6 to 8 hours may inhibit local infiltration of the wound by polymorphonuclear leukocytes.[127] The dosage recommended is 100 mg twice daily for 2 weeks.[178] However, prospective trials with large numbers of patients are lacking. One study compared the efficacy of erythromycin and dapsone therapy, erythromycin and antivenom therapy, and erythromycin, dapsone, and antivenom therapy (developed in rabbits based on a previous study).[177] Although the treatment groups were very small, all groups showed wound healing at approximately 20 days despite the different therapies used. This study's biggest limitation includes the definition of a spider bite diagnosis (the study used the following criteria: a patient feeling the spider bite, seeing the spider, or having a clinically plausible necrotic lesion). There was no expert confirming the identity of the spider. The study suggests that the use of dapsone may eliminate the need for surgery following bites and that antivenom therapy was most effective clinically if the patient never developed the necrotic lesion. Hence, the use of dapsone in the management of a local lesion should be considered

TABLE 119–4. Management of Brown Recluse Spider Bite

General Wound Care	Local Wound Care	Systemic
Clean	Serial observations	Antipruritic/antianxiety and/or analgesics
Tetanus prophylaxis as indicated	Natural healing by granulation	Antibiotics for secondary bacterial infection
Immobilize and elevate bitten extremity	Delayed primary closure	(?) Polymorphonuclear white blood cell inhibitors: dapsone, colchicine
Apply cool compresses; avoid local heat	Delayed secondary closure with skin graft	Antivenom (experimental)
	Gauze packing, if applicable	(?) Hyperbaric oxygen (local)

experimental until its use is validated by randomized, controlled clinical trials. Hepatitis,[180] methemoglobinemia, and hemolysis (Chap. 127) are associated with dapsone use. If dapsone therapy is used, a baseline glucose-6-phosphate dehydrogenase and weekly complete blood counts should be performed.

An underpowered animal study evaluated the effects on the size of skin lesions induced by *Loxosceles* envenomation by treatment with hyperbaric oxygen therapy, dapsone, and combined hyperbaric oxygen therapy and dapsone.[103] The study concluded that there was no clinically significant change in necrosis or induration by these treatment modalities. Further evaluation of these interventions remains appropriate. Another study using hyperbaric oxygen for treatment of *Loxosceles*-induced necrotic lesions in rabbits revealed no clinical improvement in the size of the lesion; however, the histology of the lesions improved. Whether this finding is of value in humans has not been determined.[208] Use of 1.2 mg colchicine, a leukocyte inhibitor, followed at 2-hour intervals with 0.6 mg for 2 days, then 0.6 mg every 4 hours for 2 additional days is sometimes recommended, but we do not advocate this treatment because of potential colchicine toxicity.[184] Rabbit-derived intradermal anti-*Loxosceles* Fab (α-Loxd) fragments attenuated the dermatonecrotic inflammation of rabbits injected with *L. deserta* venom in a time-dependent fashion.[86] At time 0 after envenomation, lesion development was blocked. At time 1 and 4 hours after envenomation, the α-anti-Loxd Fab antivenom continued to suppress the lesion areas, although the longer the delay in treatment, the smaller the difference in treatment and control lesion areas. At time 8 and 12 hours postenvenomation, there was no difference in lesion size. The typical 24-hour delay in lesion development makes the diagnosis difficult, and the antivenom would likely be useless if administered so late in the clinical course. Currently this antivenom is not available for commercial use.

One study shows promise for the treatment of *Loxsceles* envenomations. This preclinical study of a new antiloxoscelic serum was produced using recombinant sphingomyelinase D (SMase D is derived from the sphingomyelinase of the *L. intermedia* and *Loxosceles laeta* spiders). The isolated sphingomyelinase from the respective *Loxosceles* species carried the full biological effects of the entire venom. This antiloxoscelic serum when administered IV into rabbits that were given intradermal injections of the loxoscelic venom from *L. laeta* and *L. intermedia* had greater neutralizing activity then when compared to the existing antiarachnid serum, which is made by hyperimmunizing horses against the venom of *L. gaucho*, *P. nigriventer*, and the scorpion *Tityus serrulatus*. In Brazil and South America, most of the envenomations occur with the *L. laeta* and *L. intermedia*, not *L. gaucho*. Knowing which species envenomated the patient could help determine which antiserum should be used.[63] Patients manifesting systemic loxoscelism or those with expanding necrotic lesions should be admitted to the hospital. All patients should be monitored for evidence of hemolysis, renal failure, or coagulopathy. If hemoglobinuria ensues, increased IV fluids and urinary alkalinization can be used in an attempt to prevent acute renal failure. Hemolysis, if significant, can be treated with transfusions. Patients with a coagulopathy should be monitored with serial complete blood cell count, platelet count, PT, PTT, fibrin split products, and fibrinogen. Disseminated intravascular coagulopathy may require treatment, based on severity.

HOBO SPIDER (*TEGENARIA AGRESTIS*, NORTHWESTERN BROWN SPIDER, WALCKENAER SPIDER)

The hobo spider is native to Europe and was introduced to the northwestern United States (Washington, Oregon, Idaho) in the 1920s or 1930s.[227] These spiders build funnel-shaped webs within wood piles,

crawl spaces, basements, and moist areas close to the ground. They are brown with gray markings and 7 to 14 mm long. They are most abundant in the midsummer through the fall. They bite if provoked or threatened, but otherwise retreat quickly with disturbance.[18] The medical literature is sparse in reported hobo spider bites that are verified by a specialist. There is only one confirmed Hobo spider bite resulting in a necrotic lesion.[45] A 42-year-old woman with a history of phlebitis who felt a burning sensation on her ankle rolled her pants and found a crushed brown spider, which was later confirmed (unpublished source cited by MMWR) to be *T. agrestis*. She complained of persistent pain, nausea, and dizziness, and a vesicular lesion developed within several hours. The vesicle ruptured and ulcerated the next day. The lesion initially was 2 mm, but over the next 10 weeks enlarged to 30 mm in diameter and was circumscribed with a black lesion, at which time she sought medical advice. She was given a course of antibiotics, which did not limit the progression of this ulcer. Subsequently, the patient was unable to walk, and she was found to have a deep venous thrombosis. The other cases implicating Hobo spiders as a cause for dermatonecrotic injuries are based on proximity of the Hobo spider or other large brown spiders that are unidentified. *T. agrestis* envenomation induced on rabbit skin can produce hemorrhagic necrotic lesions dermally as well as systemically.[227,228] However, the venom from European Hobo spiders and US Hobo spiders was analyzed using liquid chromatography to address the question of variability between the two spiders. *T. agrestis* originated from Europe and is considered medically harmless. The authors suggest four possibilities for the discrepancy between the European Hobo and American Hobo spiders: (1) an evolutionary change may have accounted for the novel necrotic effects; (2) venom chemistry may be similar but the habitat might account for the difference in behavior; (3) venom chemistry and habitat may be similar but an extrinsic factor such as a bacterium found in the US Hobo spider might be the cause for the necrotic effects; (4) *T. agrestis* do not directly or indirectly cause necrotic arachnidism and have been falsely accused.[23] Liquid chromatography (European Hobo *T. agrestis* from the United Kingdom and American Hobo *T. agrestis* from Washington State, United States) found little variability between the two venoms to account for their differential necrotic effects.[23] The authors suggest that either a bacterium such as *Mycobacterium ulcerans*, known to cause slow-developing ulcers on human skin, might coexist on the chelicerae of the *T. agrestis*, which is highly unlikely because of the presence of antibacterial peptides in the venom,[101,234] or the more likely circumstance that *T. agrestis* has been falsely accused as being a cause for necrotic arachnidism. Misdiagnosis of spider bites is common. Wounds can be misleading and can occur from the reaction of other organisms such as ticks and other arthropods, superinfection with anthrax, and/or underlying medical conditions like diabetes and leukemia. The need to revisit the Hobo spider toxicity syndrome with further studies that show direct evidence of *T. agrestis* causing necrotic arachnidism in humans is warranted before one can conclude that any necrotic arachnidism in the Pacific Northwest is caused by *T. agrestis*.

■ PATHOPHYSIOLOGY

The toxin has been fractionated, with three peptides identified as having potent insecticidal activity, and no discernible effects in mammalian in vivo assays.[120] The peptide toxins TaITX-1, TaITX-2, and TaITX-3 exhibit potent insecticidal properties by acting directly in the insect central nervous system, and not at the neuromuscular junction.[120] Insects envenomated with *T. agrestis* venom and the insecticidal toxins purified from the venom developed a slowly evolving spastic paralysis. Currently, little is known about the toxin and its mechanism of action in humans.

■ CLINICAL MANIFESTATIONS

The toxicity of Hobo spider venom is questionable; however, it occasionally causes necrosis secondary to infection. Other causes of dermatonecrotic lesions should be considered. The most common symptom associated with the spider bite is a headache that may persist for 1 week.[45] Other symptoms, including nausea, vomiting, fatigue, memory loss, visual impairment, weakness, and lethargy, are reported.[45,228]

■ DIAGNOSTIC TESTING

No specific laboratory assay confirms envenomation with *T. agrestis* spider.

■ TREATMENT

Treatment emphasizes local wound care and tetanus prophylaxis, although systemic corticosteroids for hematologic complications may be of value. Surgical graft repair for severe ulcerative lesions may be warranted when there is no additional progression of necrosis.[45]

TARANTULAS

Tarantulas are primitive mygalomorph spiders that belong to the family Theraphosidae, a subgroup of Mygalomorphae (Greek word *mygale* for field mouse).[49,190] There are more than 1500 species, with 54 species found in the deserts of the western United States.[169] Because of their great size and reputation, tarantulas are often feared. They are the largest and hairiest spiders, popular as pets, and can be found throughout the United States as well as tropical and subtropical areas (Figure 119–4). The lifespan of the female can exceed 15 to 20 years. They have poor eyesight and detect their victims by vibrations. Despite their large size, at least one species is able to ascend vertical surfaces because of silk fibers secreted from their feet.[87] Their defense lies in either their painful bite with erect fangs or by barraging their victim with barbed urticating hairs that are released on provocation.[49] Only the New World tarantulas (tarantulas indigenous to the Americas) use the urticating hairs to defend themselves.[49]

FIGURE 119–4. The Mexican Redknee Tarantula, Brachypelma smithi. *(Image contributed by the American Museum of Natural History.)*

Tarantulas may bite when provoked or roughly handled. Based on the few case reports, their venom has relatively minor effects in humans but can be deadly for canines and other small animals, such as rats, mice, cats, and birds.[35,117] A study from Australia covering a 25-year span reported only nine confirmed bites by theraphosid spiders in humans and seven confirmed bites in canines—in two cases the owner was bitten after the dog.[117] Four genera of tarantulas (*Lasiodora, Grammostola, Acanthoscurria*, and *Brachypelma*) possess urticating hairs that are released in self-defense when the tarantulas rub their hind legs against their abdomen rapidly to create a small cloud.[84] There are seven different types of urticating hairs. Type 1 hairs are found on tarantulas in the United States and are the only hairs that do not penetrate human skin. Type 2 hairs are incorporated into the silk web retreat but are not thrown off by the spider. Type 3 hairs can penetrate up to 2 mm into human skin. Type 4 hairs belong to the South American *Grammostola* spider and cause severe respiratory inflammation.

■ PATHOPHYSIOLOGY

Tarantula venom, specifically the venoms of *Aphonopelma hentzi* (synonym *Dugesiella hentzi* [Arkansas tarantula]) and other members of the genus *Aphonopelma* (Arizona or Texas brown tarantula), contains hyaluronidase, nucleotides (adenosine triphosphate [ATP], adenosine diphosphate, and adenosine monophosphate), and polyamines (spermine, spermidine, putrescine, and cadaverine) that are used for digesting their prey.[38,125,190] The role of spermine is unclear, but hyaluronidase is a spreading factor that allows more rapid entrance of venom toxin by destruction of connective tissue and intercellular matrix. ATP potentiates death in mice exposed to the *A. hentzi* venom and lowers the LD_{50} in comparison to venom without ATP.[46,164] Both venoms cause skeletal muscle necrosis when injected intraperitoneally into mice.[78] The primary injury results in rupture of the plasma membrane, followed by the inability of mitochondria and sarcoplasmic reticulum to maintain normal levels of calcium in the cytoplasm leading to cell death. *Aphonopelma* venom is similar to scorpion venom in composition and clinical effects. Novel toxins have been discovered in the venom that can act on potassium channels, calcium channels, and the recently discovered acid-sensing ion channels that may elucidate the molecular mechanism of voltage-dependent channel gating and their respective physiologic roles.[70,71]

■ CLINICAL MANIFESTATIONS

Although relatively infrequent in occurrence, bites present with puncture or fang marks. They range from being painless to a deep throbbing pain that may last several hours without any inflammatory component.[117] Fever is associated in the absence of infection, suggesting a direct pyrexic action of the venom. Rarely, bites create a local histamine response with resultant itching, and hypersensitive individuals could have a more severe reaction and, less commonly, mild systemic effects such as nausea and vomiting.[84,117] Contact reactions from the urticating hairs are more likely to be the health hazard than the spider bite. The urticating hairs provoke local histamine reactions in humans and are especially irritating to the eyes, skin, and respiratory tract. Tarantula urticating hairs cause intense inflammation that may remain pruritic for weeks. Inflammation can occur at all levels from conjunctiva to retina. An allergic rhinitis can develop if the hairs are inhaled.[125] Tarantula hairs resemble sensory setae of caterpillars: both are type 3 that can migrate relentlessly and cause multiple foci of inflammation at all levels of the eye.[109] Ophthalmia nodosa, a granulomatous nodular reaction to vegetable or insect hairs, is reported with casual handling of tarantulas.[17,21] Other eye findings include setae in the corneal stroma, anterior chamber inflammation, migration into the retina, and secondary glaucoma and cataracts.[26]

■ TREATMENT

Treatment is largely supportive. Cool compresses and analgesics should be given as needed. All bites should receive local wound care, including tetanus prophylaxis if necessary. If the hairs are barbed, as in some species, they can be removed by using adhesive or cellophane tape followed by compresses or irrigation with 0.9% sodium chloride solution. If the hairs are located in the eye, then surgical removal may be required, followed by medical management of inflammation. Urticarial reactions should be treated with oral antihistamines and topical or systemic corticosteroids.

FUNNEL WEB SPIDERS

Australian funnel web spiders are a group of large Hexathelidae mygalomorphs that can cause a severe neurotoxic envenomation syndrome in humans. The fang positions of funnel web spiders (as well as the tarantulas) are vertical relative to their body, which requires the spider to rear back and lift the body to attack. The length of fangs can reach up to 5 mm. This spider can bite tenaciously and may require extraction from the victim.[154] *Atrax* and *Hadronyche* species have been found along the eastern seaboard of Australia. *A. robustus,* also called the Sydney funnel web spider, is the best known and is located around the center of Sydney, Australia.[154] Funnel web spiders tend to prefer moist, temperate environments.[154] They are primarily ground dwellers and live in burrows, crevices in rocks, and around foundations of houses. They build tubular or funnel-shaped webs.[84] At night, the spiders ascend the tubular web and wait for their prey. The Sydney funnel web spider is considered one of the most poisonous spiders. It was responsible for 14 deaths between 1927 and 1980, at which time the antivenom was introduced.[211,212]

■ PATHOPHYSIOLOGY

Robustotoxin (atracotoxin or atraxin) is the lethal protein component of *A. robustus* venom and is unique in its toxicity affecting primates and newborn mice in biological doses, although other mammals are susceptible in higher doses.[154,210,211,232] Robustotoxin produces an autonomic storm, releasing acetylcholine, noradrenaline, and adrenaline. A 5 μg/kg intravenous infusion dose of robustotoxin from male *A. robustus* spiders causes dyspnea, blood pressure fluctuations leading to severe hypotension, lacrimation, salivation, skeletal muscle fasciculation, and death within 3 to 4 hours when administered to monkeys.[160] Versutoxin, a toxin from the Blue Mountain funnel web spider, is closely related to robustotoxin and has demonstrated voltage-dependent slowing of sodium channel inactivation.[163]

■ CLINICAL MANIFESTATIONS

A biphasic envenomation syndrome is described in humans and monkeys.[211,212] Phase 1 consists of localized pain at the bite site, perioral tingling, piloerection, and regional fasciculations (most prominent in the face, tongue, and intercostals). Fasciculations may progress to more overt muscle spasm; masseter and laryngeal involvement may threaten the airway.[210] Other features include tachycardia, hypertension, cardiac dysrhythmias, nausea, vomiting, abdominal pain, diaphoresis, lacrimation, salivation, and acute lung injury, which often is the cause of death in phase 1.[232] Phase 2 consists of resolution of the overt cholinergic and adrenergic crisis; secretions dry up, and fasciculations, spasms, and hypertension resolve. This apparent improvement can be followed by the gradual onset of refractory hypotension, apnea, and cardiac arrest.[211]

■ TREATMENT

Pressure immobilization using the crepe bandage to limit lymphatic flow and immobilization of the bitten extremity may inactivate the venom and should be applied if symptoms of envenomation are present. Funnel web venom is one of the few animal toxins known to undergo local inactivation. Monkey studies and a human case report suggest the utility of pressure immobilization.[90,214] It has been shown by injecting *A. robustus* venom subcutaneously in monkeys that the pressure-immobilization technique increased survival in these monkeys by retarding the venom movement and also by the local peripheral enzymes inactivating the venom.[212,214] The patient should be transferred to the nearest hospital with the bandage in place and then stabilized and placed in a resuscitation facility with adequate ampules of antivenom readily available before the bandage is removed; otherwise, a precipitous envenomation may occur during the removal of the pressure bandage. A purified IgG antivenom protective against *Atrax* envenomations was developed in rabbits.[212] One ampule of the antivenom contains 100 mg purified rabbit IgG or 125 Units of neutralizing capacity per ampule.[232] It has been effective for more than 40 humans bitten by the *Atrax* species.[214] The starting dose is two ampules if systemic signs of envenomations are present, and four ampules if the patient develops pulmonary edema or decreased mental status. Doses are repeated every 15 minutes until clinical improvement occurs.[232] Up to eight ampules is common in a severe envenomation. Anaphylaxis has not been reported.[214] The manufacturer no longer recommends premedication. Serum sickness is rare after funnel web antivenom administration, with only one reported case in a patient who received five ampules of antivenom.[153]

SCORPIONS

Scorpions are invertebrate arthropods that have existed for more than 400 million years.[52] Of the 650 known living species, most of the lethal species are in the family Buthidae (Table 119–5). The genera of the family Buthidae include *Centruroides*, *Tityus*, *Leuirus*, *Androctonus*, *Buthus*, and *Parabuthus*.[52] Scorpions envenomate humans by stinging rather than biting. Their five-segmented metasoma (tail) contains a bulbous segment called the *telson* that contains the venom apparatus (Figure 119–5). More than 100,000 medically significant stings likely occur annually worldwide, predominantly in the tropics and North Africa.[1,20,,63,95,118,131] According to American Association of Poison Control Centers data from 1995 to

FIGURE 119–5. The Brazilian scorpion, *Tityus serrulatus*, shown here to demonstrate the typical features of scorpions. Note the telson (stinger) located on the tail. *(Image contributed by the American Museum of Natural History.)*

2003, approximately 11,000 to 14,000 scorpion annual exposures occurred in the United States, mostly in the southwestern region, but no deaths have been reported. These members of the class Arachnida rarely cause mortality in victims older than 6 years.[179] The venomous scorpions in the United States are *Centruroides exilicauda* and *Centruroides vittatus*. The most important is *C. exilicauda,* previously called *Centruroides sculpturatus* Ewing and *Centruroides gertschii* (bark scorpion; Table 119–6).[74]

■ PATHOPHYSIOLOGY

Components of scorpion venom are complex and species specific.[99,172,179,180] Buthidae venom is thermostable and consists of phospholipase, acetylcholinesterase, hyaluronidase, serotonin, and

---

TABLE 119–5. Scorpions of Toxicologic Importance[74,84]

Australia: *Lychas marmoreus, Lychas* spp, *Isometrus* spp, *Cercophonius squama, Urodacus* spp

India: *Buthus tamulus*

Mexico: *Centruroides sufusus*

Middle East: *Androctonus crassicauda, Androctonus Australis, Buthus minax, Androctonus Australis, Buthus occitanus, Leirus quinquestriatus*

Spain: *Buthus occitanus*

South Africa: *Androctonus crassicauda*

South America: *Tityus serrulatus*

United States: *Centruroides exilicauda*

TABLE 119–6. Envenomation Gradation for *Centruroides exilicauda* (Bark Scorpion)

Grade	Signs and Symptoms

I	Site of envenomation
	  Pain and/or paresthesias
	  Positive tap test (severe pain increase with touch or percussion)

II	Grade I in addition to Pain and paresthesias remote from sting site (eg, paresthesias moving up an extremity, perioral "numbness")

III	One of the following:
	  Somatic skeletal neuromuscular dysfunction: jerking of extremity(ies), restlessness, severe involuntary shaking and jerking, which may be mistaken for seizures
	  Cranial nerve dysfunction: blurred vision, wandering eye movements, hypersalivation, trouble swallowing, tongue fasciculation, upper airway dysfunction, slurred speech

IV	Both cranial nerve dysfunction and somatic skeletal neuromuscular dysfunction

neurotoxins. Components of *C. exilicauda* venoms are primarily neurotoxic. Four neurotoxins, designated toxins I to IV, have been isolated from *C. exilicauda*. Some of the toxins target excitable membranes, especially at the neuromuscular junction, by opening sodium channels. The results are repetitive depolarization of nerves in both sympathetic and parasympathetic nervous systems causing acetylcholine and catecholamine release, increased neurotransmitter release, catecholamine release from the adrenal gland, catecholamine-induced cardiac hypoxia, and action at the juxtaglomerular apparatus, causing increased renin secretion.[68,179] *Tityus* scorpion sting is related to elevated concentrations of interleukin (IL)-1β, IL-6, IL-8, IL-10, and tumor necrosis factor (TNF)-α, which correlate with the severity of envenomation and hyperamylasemia.[56,78] The kinin system participates in the pathogenesis of human *Tityus* envenomation.[77]

■ CLINICAL MANIFESTATIONS

Scorpion stings produce a local reaction consisting of intense local pain, erythema, tingling or burning, and occasionally discoloration and necrosis without tissue sloughing (see Table 119-6). Depending on the scorpion species involved, systemic effects may occur, including autonomic storm consisting of cholinergic and adrenergic effects. Cardiotoxic effects include myocarditis, dysrhythmias, and myocardial infarction.[60,73,97,150,189] Electrocardiographic (ECG) abnormalities may persist for several days and include sinus tachycardia, sinus bradycardia, bizarre broad notched biphasic T-wave changes with additional ST elevation or depression in the limb and precordial leads, appearance of tiny Q waves in the limb leads consistent with an acute myocardial infarction pattern, occasional electrical alternans, and prolonged QT interval.[97,99] Other reported effects include pancreatitis, coagulation disorders, acute lung injury (ALI), massive hemoptysis, cerebral infarctions in children, seizures, and a shock syndrome that may precede but usually follows the hypertensive phase.[19,66,73,97,98,189,201]

In the United States, *C. exilicauda* stings produce local paresthesias and pain that can be accentuated by tapping over the envenomated area (tap test) without local skin evidence of envenomation.[52,179] Symptoms begin immediately after envenomation, progress to maximum severity in 5 hours, and may persist for up to 30 hours.[52,179] Autonomic symptoms include hypertension, tachycardia, diaphoresis, emesis, and bronchoconstriction. The somatic motor symptoms reported include ataxia, muscular fasciculations, restlessness, thrashing, and opsoclonus; rarely, children require respiratory support (see Table 119–6).[68,172]

■ TREATMENT

Because most envenomations do not produce severe effects, local wound care, including tetanus prophylaxis and pain management, usually is all that is warranted. In young children or patients who manifest severe toxicity, hospitalization may be required. Treatment emphasizes support of the airway, breathing, and circulation. Corticosteroids, antihistamines, and calcium have been administered without any known benefit.[56]

The severity of envenomation dictates the need to use antivenom. Continuous IV midazolam infusion has been used for *C. exilicauda* scorpion envenomation until resolution of the abnormal motor activity and agitation occurs.[82] Atropine has been used to reverse the excessive oral secretions in *C. exilicauda* scorpion envenomation, with some success in healthy children.[209] Routine use is not recommended and should be limited to species such as such as *Parabuthus transvaalicus* in southern Africa,[209] whose envenomations cause a prominent cholinergic crisis. Potentiation of the adrenergic effects causing cardiopulmonary toxicity is reported.[14] Atropine use to reverse the effects of stings from scorpions from India, South America, the Middle East, and Asia is contraindicated, because these scorpions cause

an "autonomic storm" with transient cholinergic stimulation followed by sustained adrenergic hyperactivity.[15,209]

One grading system suggests using antivenom for severe grade III and grade IV envenomations, which include somatic and/or cranial nerve dysfunction (see Table 119–6).[56] A goat serum-derived anti-*Centruroides* antivenom is no longer available and was previously only available in Arizona, but was used successfully in a limited number of severe cases.[29] This approach is not universally accepted because of the safety profile of whole immunoglobins. Proponents believe antivenom may resolve symptoms sooner, whereas opponents cite serum sickness as a substantial concern (Antidotes in Depth 35–Antivenom [Scorpion and Spider]).[29] A retrospective chart review of children younger than 10 years who experienced severe *Centruroides* scorpion envenomation found that anti-*Centruroides* antivenom resulted in rapid resolution of all symptoms in all 12 patients treated.[29] Of the patients treated with antivenom, 3% developed immediate hypersensitivity reactions and 58% had a delayed rash or serum sickness.[139] An equine-derived F(ab')₂ product called Alacramyn, developed in Mexico against the *Centruroides limpidus* venom, can be used to treat *C. exilicauda* stings, but US use of this foreign pharmaceutical is controversial.[16,200] A very small randomized double-blind study of a scorpion-specific F(ab')₂ antivenom administered to critically ill children with neurotoxicity from scorpion stings demonstrated a rapid resolution of symptoms, decreased need for sedation, and reduced concentrations of circulating unbound venom.[29] These encouraging results will necessitate further generalizability, but are quite comparable to those results of previous uncontrolled Mexican studies with this antivenom.

Scorpion envenomation can be prevented by wearing shoes when walking, particularly at night, because of the nocturnal nature of scorpions. Shoes, sleeping bags, and tents should be shaken out prior to use. Cracks and crevices should be filled, wood piles and rubbish piles eliminated, and insecticides used in infested areas. The bark scorpion (*C. exilicauda*) as do all scorpions, fluoresce in the dark when using a Woods lamp.

TICKS

In 1912, Todd[222] described a progressive ascending flaccid paralysis after bites from ticks. Three families of ticks are recognized: (1) Ixodidae (hard ticks), (2) Argasidae (soft ticks), and (3) Nuttalliellidae (a group that has characteristics of both hard and soft ticks). The terms *hard* and *soft* refer to a dorsal scutum or "plate" that is present in the Ixodidae but absent in the Argasidae. Both types are characteristically soft and leathery, and both have clinical importance. Ixodidae females are capable of enormous expansion up to 50 times their weight in fluid and blood.[80] Ticks have four stages in their life cycle: egg, larva, nymph, and adult. The paralytic syndrome can occur during the larva, nymph, and adult stages and is related to the tick obtaining a blood meal. The following discussion focuses only on tick paralysis or tick toxicosis, and not on any of the infectious diseases associated with tick bites. Most of the major tick-borne diseases in North America are transmitted by Ixodid ticks except for relapsing fever, which is spread by the soft tick of the genus *Ornithodorus* or the *Pediculus* (louse).

In North America, *Dermacentor andersoni* (Rocky Mountain wood tick) and *Dermacentor variabilis* (American dog tick), and *Amblyomma americanum* (Lone Star tick) are the most commonly implicated causes of tick paralysis.[88,222] Typically, tick toxicosis occurs in the Southeastern, Rocky Mountain, and Pacific Northwest regions of the United States, but cases have been reported in the Northeastern area recently.[61] In Australia, the *Ixodes holocyclus* or Australian marsupial tick is the most common offender.[88,222] *I. holocyclus* also seems to be the most potent of the world's paralyzing ticks and has been known to paralyze dogs, cats, sheep, mice, foals, pigs, chickens, and humans.[145]

■ PATHOPHYSIOLOGY

Venom secreted from the salivary glands during the blood meal is absorbed by the host and systemically distributed. Paralysis results from the neurotoxin "ixobotoxin,"[159] which inhibits the release of acetylcholine at the neuromuscular junction and autonomic ganglia, very similar to botulinum toxin.[91,159] Both botulinum toxin and ixobotoxin demonstrate temperature dependence in rat models and show increased muscular twitching activity as the temperature is reduced.[53,145]

■ CLINICAL MANIFESTATIONS

Usually the tick must remain on the person for 5 to 6 days in order to cause systemic symptoms. Several days must pass before tick salivary glands begin to secrete significant quantities of toxin. Once secreted, the toxin does not act immediately and may undergo binding and internalization, in a similar sequence to botulinum toxin.[53,122] Ticks typically attach to the scalp but can be found on any part of the body, including the ear canals and anus. Children, particularly girls, and adult men in tick-infested areas are predominantly affected. One large series of 305 cases in Canada reported that 21% were adults older than 16 years.[194] Among the children, 67% were girls; in adults 83% were male. The distribution was attributed to the difficulty of detecting ticks in long hair and the possible greater exposure of adult men to tick-infested environments. Children may appear listless, weak, ataxic, and irritable for several days before they develop an ascending paralysis that begins in the lower limbs. Fever usually is absent. Other manifestations include sensory symptoms such as paresthesias, numbness, and mild diarrhea. These symptoms are followed by absent or decreased deep-tendon reflexes and an ascending generalized weakness that can progress to bulbar structures involving speech, swallowing, and facial expression within 24 to 48 hours, as well as fixed dilated pupils and disturbances of extraocular movements.[91,194] Other atypical presentations are reported and include the following: a child presenting with double vision and being unable to see before the neuromuscular changes occurred, and a healthy elderly male presenting with unilateral weakness and numbness in the left arm for 2 days. Both patients fully recovered after the removal of the tick.[61] If the tick is not removed, respiratory weakness can lead to hypoventilation, lethargy, coma, and death. Unlike the *Dermacentor* spp of North America, removal of the *I. holocyclus* tick does not result in dramatic improvement for several days to weeks. The maximal weakness may not be reached until 48 hours after the tick has been removed or drops off.[91] It is imperative to closely observe patients for possible deterioration.

The differential diagnosis includes Guillain-Barré syndrome (GBS); the Miller-Fisher variant of Guillain-Barré, poliomyelitis; botulism; transverse myelitis; myasthenia gravis; periodic paralysis; acute cerebellar ataxia; and spinal cord lesions. The cerebrospinal fluid remains normal and the rate of progression is rapid, unlike GBS and poliomyelitis.[72,191] The edrophonium test is negative. Nerve conduction studies in patients with tick paralysis may resemble those of patients with early stages of GBS: findings in both conditions include prolonged latency of the distal motor nerves, diminished nerve conduction velocity, and reduction in the amplitudes of muscle and sensory-nerve action potentials.[72] With GBS, there is a prolongation of the F wave, however, which does not occur with tick paralysis, reflecting the more proximal demyelination of the nerve root.[93]

■ TREATMENT

The most important aspect of treatment is considering tick paralysis in the differential diagnosis of any patient with ascending paralysis. Other than removal of the entire tick, which is curative, treatment is entirely supportive. Since *I. holocyclus* of Australia is considerably more toxic and patients are more likely to deteriorate before they improve, so they must be closely observed for several days until improvement is certain.[72] A hyperimmune serum prepared from dogs is the usual treatment for paralyzed animals, and has been used sparingly in severely ill humans because of the risk of acute reactions and serum sickness.[72]

Prevention of tick bites includes wearing protective clothing and spraying clothes with insect repellant. Diethyltoluamide (DEET) repels ticks, but does not kill them. Permanone is a new tick aerosol spray repellant for use on clothing. It contains permethrin, which kills ticks on contact.[129] According to one study, permethrin in concentrations of 0.036 to 2.276 mg/m^2 induces 90% to 100% tick mortality, with 100% effectiveness for 1 month, and a decrease in effectiveness to 52% after the first washing.[129] Close inspection of all body parts and especially the scalp is important. Proper removal of the tick is very important, otherwise infection or incomplete tick removal may occur. The tick should be grasped as close to the skin surface as possible with blunt curved forceps, tweezers, or gloved hands. Steady pressure without crushing the body should be used; otherwise, expressed fluid may infect the patient and lead to inoculating the patient with a higher dose of toxin or infectious agent. After tick removal, the site should be disinfected. Traditional methods of tick removal using petroleum jelly, topical lidocaine, fingernail polish, isopropyl alcohol, or a hot match head are ineffective and/or may induce the tick to salivate or regurgitate into the wound.[161] It should be remembered that the very same vectors responsible for tick toxicosis can also cause infectious illnesses such as babesiosis, Rocky Mountain spotted fever, anaplasmosis, tularemia, Colorado tick fever, tick-borne relapsing fever, and Lyme disease.

HYMENOPTERA: BEES, WASPS, HORNETS, YELLOW JACKETS, AND ANTS

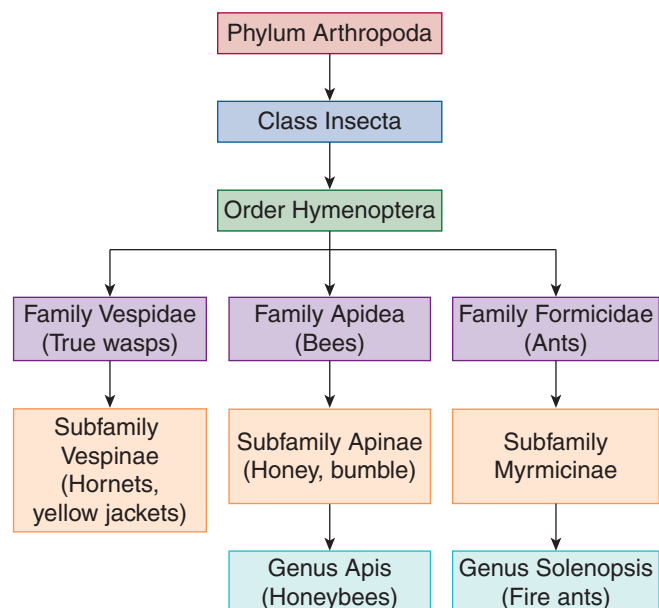
Within the order Hymenoptera are three families of clinical significance: Apidae (honeybees and bumblebees), Vespidae (yellow jackets, hornets, and wasps), and Formicidae (ants, specifically fire ants). These insects (Fig. 119–6) are of great medical importance because their stings are the most commonly reported and can cause acute toxic and fatal allergic reactions (Table 119–7). An estimated 40 deaths per year are attributed to anaphylaxis secondary to hymenoptera stings.[12,199]


FIGURE 119–6. Taxonomy of the order Hymenoptera.

TABLE 119–7. Classification of Reactions to Hymenoptera Sting

Reaction	Clinical Presentation
Local	
Minimal	Localized pain, pruritus, swelling
	Lesion <5 cm
	Duration several hours
Large	Localized pain and pruritus
	Contiguous swelling and erythema
	Lesion >5 cm
	Duration 1–3 days
Systemic	
Minimal	Localized pain, pruritus, swelling
	Distant and diffuse urticaria, angioedema, pruritus, and/or erythema, conjunctivitis
	Abdominal pain, nausea, diarrhea
Severe	Dermatologic
	Local: Pain, pruritus, and swelling
	Distant: Urticaria, angioedema, pruritus, and/or erythema
	Gastrointestinal
	Nausea, abdominal pain, diarrhea
	Respiratory
	Nasal congestion, rhinorrhea, hoarseness, bronchospasm, stridor, tachypnea, cough, wheezing
	Cardiovascular
	Tachycardia, hypotension, dysrhythmias, myocardial infarction
	Miscellaneous
	Seizures, feeling of impending doom, uterine contractions

Apis and *Bombus* species (honeybees and bumblebees) generally build nests away from humans and are passive unless disturbed, but nests of both the honeybees and bumblebees have been found in walls and rodent burrows near homes. Honeybees can only sting once because their stinger is a modified ovipositor that resides in the abdomen. The structure is barbed and has a venom sac attached. Once the stinger embeds into the skin, the stinger disembowels the bee. Bumblebees, however, can sting multiple times. Vespids, on the other hand, are more aggressive and build nests in human living areas, such as in trees and under awnings; yellow jackets inhabit shrubs, trees, and the ground. They, too, are able to sting multiple times.[84] The introduction of the Africanized honeybee in Brazil (because originally they were thought to be a more efficient honey producer) has caused significant economic and health issues. The bees have migrated toward the southern border of the United States, are less productive as a honey producer, and pose a greater threat to humans. African honeybees are characterized by large populations, can make nonstop flights of at least 20 km, and have a tendency toward mass attack with little provocation.[156]

■ PATHOPHYSIOLOGY

Several allergens (Table 119–8) and pharmacologically active compounds are found in honeybee venom. The three major venom proteins

TABLE 119–8. Composition of Hymenoptera Venom

Vespid (Wasps, Hornets, Yellow Jackets)	Apids (Honeybees)	Formicids (Fire Ants)
Biogenic amines (diverse)	Biogenic amines (diverse)	Biogenic amines (diverse)
Phospholipase A, phospholipase B	Phospholipase A, phospholipase B (?)	Phospholipase A
Hyaluronidase	Hyaluronidase	Hyaluronidase
Acid phosphatase	Acid phosphatase	Piperidines
Mast cell degranulating peptide	Minimine	
Kinin	Mellitin	
	Apamin	
	Mast cell degranulating peptide	

for the honeybee are melittin, phospholipase A_2, and hyaluronidase.[138] Other proteins include apamin, acid phosphatase, and other unidentified proteins. Phospholipase A_2 is the major antigen/allergen in bee venom.[27]

Melittin is the principal component of honeybee venom. It acts as a detergent to disrupt the cell membrane and liberate potassium and biogenic amines.[9] Histamine release by bee venom appears to be largely mediated by mast cell degranulation peptide. Apamin is a neurotoxin that acts on the spinal cord. Apamin binds to the Ca^{+2}-triggered K^{+1} channel and depresses delayed hyperpolarization to cause its toxicity, which is seen in the mouse model as uncoordinated movements leading to spasms, jerks, and convulsions of a spinal origin.[100] Adolapin inhibits prostaglandin synthase and has anti-inflammatory properties that may account for its use in arthritic therapy.[196] Phospholipase A_2 and hyaluronidase are the chief enzymes in bee venom.

Vespid venoms contain three major proteins that serve as allergens and a wide array of vasoactive peptides and amines.[138] The intense pain following by vespid stings is largely caused by serotonin, acetylcholine, and wasp kinins. Antigen 5 is the major allergen in vespid venom.[157] Its biologic function is unknown. Mastoparans have action similar to mast cell degranulation peptide, but weaker.[9] Phospholipase A_2 may be responsible for inducing coagulation abnormalities.[166]

■ CLINICAL MANIFESTATIONS

Normally, the honeybee sting is manifested as immediate pain, a wheal-and-flare reaction, and localized edema without a systemic reaction. Vomiting, diarrhea, and syncope can occur with a higher dose of venom resulting from multiple stings.[30] Rarely, a sting in the oropharynx produces airway compromise.[199]

Toxic reactions occur with multiple stings (more than 500 stings are described as possibly fatal, and occur with Africanized honeybees)[84] and include gastrointestinal (GI) symptoms, headache, fever, syncope and, rarely, rhabdomyolysis, renal failure, and seizures.[30] Other rare complications include idiopathic intracranial hypertension,[218] cerebral infarction, and ischemic optic neuropathy[193] and Parkinsonism[137] are thought to occur because of the proximity of the sting near the head and neck. Bronchospasm and urticaria are typically absent. This type of toxic reaction is different from the hypersensitivity reactions or anaphylactic reactions because it is not an IgE-mediated response, but rather a direct effect from the venom itself.

Hypersensitivity reactions, including anaphylaxis, occur from hymenoptera stings. These reactions are IgE mediated. The IgE antibodies attach to tissue mast cells and basophils in individuals who have been previously sensitized to the venom. These cells are activated, allowing for progression of the cascade reaction of increased vasoactive substances, such as leukotrienes, eosinophil chemotactic factor-A, and histamine. An anaphylactic reaction is not dependent on the number of stings. Patients who are allergic to hymenoptera venom develop a wheal-and-flare reaction at the site of the inoculum. The shorter the interval between the sting and symptom onset, the more likely the reaction will be severe. Fatalities can occur within several minutes; even initially mild symptoms may be followed by a fulminant course. Generalized urticaria, throat and chest tightness, stridor, fever, chills, and cardiovascular collapse can ensue.

■ TREATMENT

Application of ice at the site usually is sufficient to halt discomfort. The stinger should be removed by scraping with a credit card or scalpel, as opposed to pulling, which may release additional retained venom. Therapy is aimed at supportive care that includes standard therapy for anaphylaxis with epinephrine, diphenhydramine, and corticosteroids.

Prevention, especially in the allergic person, includes avoiding bright clothing, flowers, scented deodorants and shampoos, perfumes, and barefoot walks outdoors. An emergency kit containing a prefilled spring-loaded epinephrine syringe (EpiPen delivers 0.3 mg, EpiPen Jr. delivers 0.15 mg) with careful instructions from a physician, an antihistamine (diphenhydramine), and an emergency alert card or tag should be carried or worn by the sensitized individual. Individuals with a clear history of anaphylaxis should follow up with an allergist for skin testing and venom immunotherapy for positive results. Immunotherapy significantly reduces the potential risk of anaphylaxis with subsequent stings.[85,110] Commercial preparations of venom from the honeybee, yellow jacket, bald-faced hornet, and wasp can be used for diagnosis and immunotherapy for patients with life-threatening reactions to stings. Several authors have discussed the indications and safety of immunotherapy.[138,236]

FIRE ANTS

There are native fire ants in the United States, but the imported fire ants *Solenopsis invicta* and *Solenopsis richteri* are significant pests that have no natural enemies. They are native to Brazil, Paraguay, Uruguay, and Argentina, but were introduced into Alabama in the 1930s. They have spread rapidly throughout the southern United States, damaging crops, reducing biologic diversity, and inflicting severe stings to humans.[216] *S. invicta,* the most aggressive species, now infests 13 southern states and has been introduced into Australia.[202,205] Allergic reactions to ant stings were limited to the jumper ant (*Myrmecia pilosula*, other *Myrmecia* spp) and the greenhead ant (*Rhytidoponera metallica*; *Odontomachs*, *Cerapachys*, and *Brachyponera* spp) in Australia until February 2001, when the red imported fire ant was identified at two sites in Brisbane.[202] The mode of introduction is unknown but may have originated from the transport of infested sea cargo. Fire ants range from 2 to 6 mm in size. They live in grassy areas, garden sites, and near sources of water. The nests are largely subterranean and have large, conspicuous, dome-shaped above-ground mounds (up to 45 cm above the ground), with many openings for traffic. The mounds can contain 80,000 to 250,000 workers and one or more queens that live for 2 to 6 years and produce 1500 eggs daily.[229] Fire ants are named for the burning pain inflicted after exposure, and necrosis can result at the site. The imported fire ant attacks with little warning. By firmly grasping the

skin with its mandibles, both the fire ant and the jumper ant can repeatedly inject venom from a retractile stinger at the end of the abdomen. Pivoting at the head, the fire ant injects an average of seven or eight stings in a circular pattern.[205]

■ PATHOPHYSIOLOGY

The venom inhibits sodium and potassium adenosine triphosphatases, reduces mitochondrial respiration, uncouples oxidative phosphorylation, adversely affects neutrophil and platelet function, inhibits nitric oxide synthetase, and perhaps activates coagulation.[119,121] Unlike the venoms of wasps, bees, and hornets that contain mostly aqueous-containing proteins, the imported fire ant venom is 95% alkaloid, with a small aqueous fraction that contains soluble proteins.[143] Of the alkaloids, 99% is a 2,6-disubstituted piperidine that has hemolytic, antibacterial, insecticidal, and cytoxic properties.[64] These alkaloids do not cause allergic reactions, but produce a pustule and pain. The aqueous portion of the venom contains the allergenic activity of fire ant venom, *Sol i* I to IV.[104,205] The proteins identified in the venom include a phospholipase, a hyaluronidase, and the enzyme *N*-acetyl-β-glucosaminidase.[65,205]

■ CLINICAL MANIFESTATIONS

Three categories are suggested based on the reactions to the imported fire ant: local, large local, and systemic.[205] *Local reactions* occur in non-allergic individuals. *Large local reactions* are defined as painful, pruritic swelling at least 5 cm in diameter and contiguous with the sting site. *Systemic reactions* involve signs and symptoms remote from the sting site. The sting initially forms a wheal that is described as a burning itch at the site, followed by the development of sterile pustules. In 24 hours, the pustules umbilicate on an erythematous base. Pustules may last 1 to 2 weeks.[84] Late cutaneous allergic reactions can occur in some persons who experience indurated pruritic lumps at the site of subsequent stings.[64] Large reactions may lead to tissue edema sufficient to compromise blood flow to an extremity. Anaphylaxis occurs in 0.6% to 6% of persons who have been stung.[205] Often, healing occurs with scarring in 10 to 14 days.

■ DIAGNOSIS

Clinical clues such as pustule development at the sting site after 24 hours, species identification, and history may help to identify fire ant exposure. No laboratory assays to determine exposure are available. Fire ant allergy can be determined by correlating the clinical manifestation of fire ant sting reactions with imported fire ant–specific IgE determined by skin testing or radioallergosorbent test.

■ TREATMENT

Local reactions require cold compresses and cleansing with soap and water. Some authors recommend topical or injected lidocaine with or without 1:100,000 epinephrine, and topical vinegar and salt mixtures to decrease pain at the site of the bite and sting.[34,108,148,183]

Large local reactions can be treated with oral corticosteroids, antihistamines, and analgesics. Secondary infections should be treated with antibiotics. Systemic reactions should be treated with subcutaneous or intravenous epinephrine.

In the United States, residents of healthcare facilities who are immobile or cognitively impaired are at risk for fire ant attacks, especially when the facility lacks pest control techniques for fire ants.[65] Usually these pests are controlled with traditional insecticides, but there has been a push for environmentally safe insecticides. One

study looks at the use of the essential oil from the cinnamon tree, *Cinnamomum osmophloeum* leaf oil, which is similar to the constituents of the cinnamon cassia bark oil that is used for its aroma in the food industry.[48] The indigenous cinnamon leaf essential oil and trans-cinnamaldehyde had an excellent inhibitory effect in controlling the red imported fire ant. The LD_{50} values for both 2% leaf essential oil and 2% trans-cinnamaldehyde after open exposure were 105.0 minutes and 32.2 minutes, respectively; after close exposure they were were 18.5 minutes and 21.2 minutes, respectively, and 100% mortality at 40 minutes in close exposure. This may be a safe alternative for environmental control of the red fire ant.

BUTTERFLIES, MOTHS, AND CATERPILLARS

Butterflies and moths are insects of the order Lepidoptera. Several moth and butterfly families have species whose caterpillars are clinically important, that is, they contain spines or urticating hairs that secrete a poison that is irritating to humans on contact. *Lepidopterism* is a general term that describes the adverse effects to humans when humans are exposed to moths and butterflies.[158] These adverse reactions include urticarial dermatitis, allergic reactions, consumptive coagulopathy, and renal failure. Caterpillar, which means *hairy cat* in Latin, is the larval stage for moths and butterflies. In the United States, several significant stinging caterpillars are of note. The puss caterpillar (*Megalopyge opercularis*) often is considered one of the most important and toxic of the caterpillars in the United States because it has been reported to be such a nuisance, especially in Texas.[207] Other names for the puss caterpillar are woolly/hairy worm, wooly slug, opossum bug, tree asp, Italian asp, and little perrito in Spanish.[207] The caterpillars look furry and are covered in silky tan to brownish hairs that hide short spines containing an urticarial toxin. The spines are yellowish with black tips, and the hairs vary in color ranging from pale yellow and gray to brown.[24] Other significant stinging caterpillars in the United States are the flannel moth caterpillar (*Megalopyge crispata*), the Io moth (*Automeris io*), the saddleback caterpillar (*Sibine stimulata*), and the hickory tussock caterpillar (*Lophocampa caryae*).[136] In South America, especially Brazil, *Lonomia obliqua* caterpillars are notorious for causing severe pain and a hemorrhagic syndrome.[41,58] In Australia several caterpillars are of medical importance: mistletoe brown tail moth (*Euproctis edwardsi*), processionary caterpillars (*Ochrogaster lunifer*), cup moths (*Doratifera* spp), and the white-stemmed gum moth (*Chelepteryx collesi*).[8] Pine processionary caterpillars (*Thaumetopoea pityocampa*) are the most important defoliator of pine forests in the Mediterranean and central European countries, with significant consequential economic and occupational repercussions for workers who frequent these pine forests.[223]

PATHOPHYSIOLOGY

Little is known about the composition of the venom, which probably varies according to the different caterpillar species. Some toxins contain proteins that cause histamine release, such as thaumetopoien isolated from *T. pityocampa* or pine processionary caterpillar.[223,224] Another protein isolated from the *L. obliqua* caterpillar causes coagulopathy; its mechanism of action is not fully known but it somehow activates factors X and II.[67,124] The venom and hair structure of *Lagoa crispata*, which has often been confused with the southern Texas puss caterpillar, has been characterized.[136] The venom is stored at the base of the hollow setae (spines) where the poison sac and nervous tissue are located. Upon contact with these spines, the toxin is released. The toxin may be a protein or a substance that conjugates with proteins.[75] The varying differences of caterpillar venom and

their clinical effects emphasize the importance of positive identification of caterpillars.

■ CLINICAL MANIFESTATIONS

The clinical effects of caterpillar exposure can generally be separated into two types–stinging reaction and pruritic reaction—although overlap may occur. Stinging caterpillars, such as *M. opercularis*, envenomate by contact with their hollow spines containing venom. The reaction is characterized as a painful, burning sensation with local effects and, less commonly, systemic effects. The area may become erythematous and swollen, and papules and vesicles may appear. The classic gridlike pattern develops within 2 to 3 hours of contact. Reported symptoms include nausea, vomiting, fever, headache, restlessness, tachycardia, hypotension, urticaria, seizures, and even radiating lymphadenitis and regional adenopathy.[168] Another stinging caterpillar previously mentioned is the *L. obliqua* caterpillar, which causes the hemorrhagic syndrome that presents as a disseminating intravascular coagulopathy and as secondary fibrinolysis with skin, mucosal, and visceral bleeding, acute renal failure, and intracerebral hemorrhage.[41,124] Pruritic reactions occur upon exposure to the itchy caterpillars that have nonvenomous urticating hairs, which can produce a mechanical irritation, allergic reaction, or a granulomatous reaction from the chronic presence of the hairs. Several species that cause allergic reactions are the white-stemmed moth (*C. collesi*), Douglas fir tussock moth (*Orgyria pseudotsugata*), and gypsy moth caterpillar (*Lymantria dispar*).[158] Caterpillar hairs can cause ocular trauma, otherwise known as *ophthalmia nodosa*.[204] The range of ocular pathology depends on the penetration factor and the effect of the released urticating toxins.[40] The ocular spectrum has been classified into five types by Cadera et al[40]:

Type 1: Brief exposure time of 15 minutes. Symptoms of chemosis, inflammation, epiphora, and foreign body sensation may last for weeks.

Type 2: Chronic mechanical keratoconjunctivitis (hairs in bulbar/palpebral conjunctivitis). Foreign body sensation is relieved by removal of hairs. Cornea abrasions may be present.

Type 3: Gray-yellow nodules or asymptomatic granulomas.

Type 4: Severe iritis with or without iritis nodules. Hairs in the anterior chamber and possible intralenticular foreign body.

Type 5: Vitreoretinal involvement. Hairs may enter through the anterior chamber or iris lens or by transscleral migration. May cause vitreitis, cystoid macular edema, papillitis, or endophthalmitis.

■ TREATMENT

Treatment of ocular lesions depends upon the exposure classification. Most patients can be classified as type 1 or 2. Irrigation with saline should be followed by meticulous removal of setae, followed by topical steroids and antibiotics. Type 3 requires surgical excision of the nodules. Type 4 requires topical steroids with or without iridectomy for nodules or operative removal of setae. Type 5 requires local treatment with or without systemic steroids. Resistant cases may require vitrectomy with removal of setae. Treatment for dermal contact should be immediate, with removal of the embedded spines using cellophane tape and application of ice. Opioids may be necessary, if minor analgesics do not provide relief. If muscle cramps develop, benzodiazepines should be administered. One study recommended the use of 10 mL 10% calcium gluconate administered IV, which provided pain relief.[151] Topical corticosteroids can be used to decrease local inflammation. Antihistamines such as diphenhydramine (25–50 mg for adults and 1 mg/kg, maximum 50 mg, in children) can be used to relieve pruritus and urticaria.[151,168] Nebulized β-agonists and epinephrine administered

subcutaneously may be required for more severe respiratory symptoms and anaphylactoid/anaphylactic-type reactions. For hemorrhagic syndrome resulting from exposure to *L. obliqua* caterpillar, an antidote called the antilonomic serum (SALon) is available and is used for treatment of the hemorrhagic syndrome in Brazil.[58]

BLISTER BEETLES

Blister beetles are plant-eating insects that exude a blistering agent for protection. They can be found in the eastern United States, southern Europe, Africa, and Asia. Most are from the order Coleoptera, family Meloidae. *Epicauta vittata* is the most common of more than 200 blister beetles identified in the United States.[123] When the beetles sense danger, they exude cantharidin by filling their breathing tubes with air, closing their breathing pores, and building up body fluid pressure until fluid is pushed out through one or more leg joints.[84] Cantharidin is a potent blistering agent found throughout all 10 stages of life of the blister beetle.[44] Cantharidin is produced only by the male blister beetle and is stored until mating. The female loses most of her reserves as she matures. In the wild, the female repeatedly acquires cantharidin as copulatory gifts from her mates.[44] Cantharidin, also known popularly as *Spanish fly*, takes its name from the Mediterranean beetle *Cantharis vesicatoria*. It has been ingested as a sexual stimulant for millennia. The aphrodisiac properties are related to the ability of cantharidin to cause vascular engorgement and inflammation of the genitourinary tract upon elimination, hence the reports of priapism and pelvic organ engorgement.[220] Cantharidin has been used for treatment of bladder and kidney infections, stones, stranguria (bladder spasm), and various venereal diseases.[123] In the last century, cantharidin was commonly used for treatment of pleurisy, pneumonia, arthritis, neuralgias, and various dermatitides. A topical 1% commercial preparation can be used for removal of warts and molluscum contagiosum.[54,195] Cantharidin poisoning has been reported by cutaneous exposure,[33] unintentional inoculation,[171] and inadvertent ingestion of the beetle itself.[217] There is one case report of a child being treated for molluscum contagiosum with cantharidin preparation that included podophyllin and salicylic acid, also called Canthacur PS or Canthacur Plus.[195] The child developed varicelliform vesicular dermatitis in the distribution of the application of petrolatum. It is thought that the petrolatum used by the parents to moisturize her skin spread the lipophillic cantharidin preparation to the nearby areas causing the blistering reaction. Canthacur PS should not be used for molluscum contagiosum but is reserved for verrucae vulgaris on acral areas. Canthacur or Cantharone contains plain cantharidin and can be used for the treatment of molluscum contagiosum. Fewer than 30 cases of Spanish fly poisoning have been reported since 1900.[123]

■ PATHOPHYSIOLOGY

Cantharidin is a natural, defensive, highly toxic terpenoid (lethal dose for humans 0.5 mg/kg) produced by blister beetles and shares a structural similarity with the herbicide Endothall.[149] Endothall causes corrosive effects to the GI tract; cardiomyopathy and vascular permeability lead to shock. A single case report of lethal poisoning with 7 to 8 g of endothall has been reported and the healthy young male died of hemorrhage of the GI tract and lung, which is clinically similar to the cantharidin exposures. Although the mechanism of action has not been elucidated, one mechanism based on an in vitro study suggests that cantharidin inhibits the activity of protein phosphatases type 1 and 2A. This inhibition alters endothelial permeability by enhancing the phosphorylation state of endothelial regulatory proteins and results in elevated albumin flux and dysfunction of the

barrier.[128] Enhanced permeability of albumin may be responsible for the systemic effects of cantharidin, which lead to diffuse injury of the vascular endothelium and resultant blistering, hemorrhage, and inflammation.

■ CLINICAL MANIFESTATIONS

The clinical effects can mostly be attributed to the irritative effects on the exposed organ systems. The secretions of cantharidin from the beetle's leg joints cause an urticarial dermatitis that is manifested several hours later by burns, blisters, or vesiculobullae.[33] Symptoms may be immediate or delayed over several hours. In addition to the local effects, cantharidin can be absorbed through the lipid bilayer of the epidermis and cause systemic toxicity, with diaphoresis, tachycardia, hematuria, and oliguria from extensive dermal exposure.[220] If the periorbital region is contaminated, edema and blistering can evolve. Ocular findings from direct contact with the beetle or hand contamination include decreased vision, pain, lacrimation, corneal ulcerations, filamentary keratitis, and anterior uveitis.[171] Most human exposures involve inadvertent contact with the beetle or its secretions, resulting in dermatitis, keratoconjunctivitis, and periorbital edema secondary to hand–eye involvement, also called the *Nairobi eye*.[171]

When cantharidin is ingested, severe GI disturbances and hematuria can occur. Initial patient complaints may include burning of the oropharynx, dysphagia, abdominal cramping, vomiting, hematemesis followed by lower GI tract hematochezia, and tenesmus. An inadvertent blister beetle ingestion by a child who thought it was the edible *Eulepida mashona* or white grub resulted in hematuria and abdominal cramping.[217] Genitourinary effects include dysuria, urinary frequency, hematuria, proteinuria, and renal impairment. Most symptoms resolved over several weeks. However, death from renal failure with acute tubular necrosis has been reported.[220]

■ DIAGNOSTIC TESTING

Cantharidin toxicosis has been identified for equine and ruminant exposures by screening urine and gastric contents with high-performance liquid chromatography and gas chromatography-mass spectrometry.[175,176] This method has not been used in clinical practice.

■ TREATMENT

Treatment is largely supportive. Wound care and tetanus status should be assessed. For keratoconjunctivitis, an ophthalmologist should be consulted early in the clinical course and the patient treated with topical corticosteroids (prednisolone 0.125%), mydriatics (cyclopentolate 1%), and antibiotics (ciprofloxacin 0.3%).

SUMMARY

Healthcare providers should have an extensive knowledge regarding bites and stings by arthropods and arachnids so they can provide optimal care to their patients. And though arachnid envenomation tends to be more of a nuisance than a life threat, good supportive care, rapid identification of the arthropod, and, rarely, antivenom are the keys to the rapid recovery. This includes proper hygiene to prevent secondary infections, avoiding contact with arthropods, decreasing the arthropod population mechanically and/or chemically, and the use of repellents as important measures to decrease morbidity from arthropods. The patient should bring the arthropod to the hospital, if possible, to facilitate identification, and every attempt should be made to describe the evolution of the bite to assist in the differential diagnosis.

ANTIDOTES IN DEPTH (A35)

ANTIVENOM (SCORPION AND SPIDER)

Richard Franklin Clark

The terms *antivenom* (English) and *antivenin* (French and other countries) often are used interchangeably. In 1981, the World Health Organization determined that the preferred terms for the English language are "venom" and "antivenom." V*enin* is the French word for venom and *antivenin* is traditionally used in certain parts of the world, but Wyeth, the maker of Crotaline and *Micrurus* antivenom, and Merck and Company, the makers of *Latrodectus* antivenom, adopted *antivenin* in the brand names for their products.

Antivenom for spiders and scorpions is prepared in the same manner as other antivenom products by first immunizing animals with nontoxic amounts of venom.[4,35] Monkeys, horses, goats, sheep, chickens, camels, and rabbits have been used as sources of antivenom.[40] The animals are placed on an inoculation schedule to allow gradual production of immunoglobulins, most importantly immunoglobulin IgG. Sufficient antibody production usually takes up to 6 weeks. The choice of animal used to make an immune serum is more often dictated by the availability of a species, financial considerations, and tradition rather than by scientific modeling. Horses are used by the majority of antivenom producers since they are relatively easy to maintain, and large volumes of serum can be obtained at one time without harming the animals. Varying efforts are made during antivenom production to remove animal proteins such as albumin. To date, no studies have compared immune sera of different animals for human compatibility or tolerance.

The antidotal fraction of an antivenom exists as either whole IgG, or only Fab, or F(ab)$_2$. The IgG molecule is composed of two antigen-binding fragments (Fab fragments) that are fused together and attached to two larger complement-binding fragments (Fc fragments). The larger Fc portions are generally considered to be the most antigenic, initiating most of the undesirable histamine release on infusion. Digestion of the disulfide bonds of an IgG molecule with the enzyme pepsin will cleave the Fc fragments, allowing isolation of pure F(ab)$_2$ fragments (two fused Fab fragments). In contrast, digestion with papain cleaves the molecule more distally such that a larger Fc portion is removed from two separate Fab fragments. Both Fab and F(ab)$_2$ molecules can be isolated with affinity chromatography, while the highly antigenic Fc portion is discarded. Although Fab and F(ab)$_2$ are more difficult and more expensive to produce than their whole immunoglobin counterparts, they are generally regarded as less allergenic and therefore safer products.

Whole IgG antivenom has a molecular weight of 150 kDa, the largest of the three antivenom types. Because of its size, IgG is the least filterable at the glomerulus and has the smallest volume of distribution. IgG has a longer elimination half-life than either Fab or F(ab)$_2$.[26]

F(ab)$_2$ has an intermediate size (100 kDa) and elimination half-life. Preliminary pharmacokinetic studies of an F(ab)$_2$ antivenom for

scorpions demonstrate a mean time of residence within volunteers of 10 days.[58] While lowering the risk of anaphylaxis compared with whole IgG, the F(ab)$_2$ portion retains much of the allosteric configuration of the original IgG molecule that is lost when Fab are formed. This configuration theoretically allows for tighter binding to venom.

Fab is the smallest (50 kDa) antivenom molecule in size and is eliminated by the kidneys. It has the largest volume of distribution and the greatest ability to reach intracellular compartments. To be effective, antivenoms require similar pharmacokinetic properties to the venom on which they act.[26] Arachnid venoms that affect the central nervous system have low molecular weights and large volumes of distribution. Fab- and F(ab)$_2$-based antivenoms may therefore be best suited for this function.[26]

Immunoglobulin-based antivenoms can be given by the intramuscular (IM), intravenous (IV), or subcutaneous route. Intravenous administration achieves rapid peak serum concentrations, and the infusion can be stopped in the event of an allergic reaction.[27] Intramuscular injection has been used in instances where IV access is unobtainable. In a rabbit model, the elimination half-life of *Buthus occitanus* venom is shorter when antivenom is given by the IV route compared with similar doses given intramuscularly. Pharmacokinetic comparisons of venom and antivenom suggest that the lower-molecular-weight components of scorpion venom are absorbed and distributed faster than antivenom, when administered intramuscularly or given subcutaneously. Therefore, IV antivenom is the preferred route for neutralization of most venoms.[33,36,37]

The unavailability of specific antivenoms often necessitates symptomatic treatment or use of a comparable foreign antivenom. In the United States, *Centruroides* scorpion antivenom has not been available for some time. Similarly, in a study of 72 moderate scorpion stings in Para, Brazil, 33% who met criteria for antivenom administration did not receive treatment because of unavailability of the antivenom.[45] *Latrodectus* antivenom has been in short supply in the past, leading to studies of neutralizing *Latrodectus mactans* and *Latrodectus hesperus* venom with *Latrodectus hasseltii* antivenom.[18]

CENTRUROIDES SPECIES

Centruroides exilicauda (formerly known as *Centruroides sculpturatus*) is the only scorpion of medical importance in the United States. It is indigenous to the deserts of Arizona, but reportedly exists in Texas, New Mexico, California, and Nevada.[17] Occasionally, envenomations occur in nonindigenous areas of the country from "stowaway" scorpions in the luggage of travelers.[57]

Arizona poison centers receive several thousand calls annually for scorpion exposures (Chap. 119). Although the incidence of morbidity from these envenomations is significant, no deaths associated with the toxic effects of scorpion venom have been reported in the United States for almost 50 years. Deaths are associated with anaphylactic reactions to scorpion venom.[10] Antivenom for the *Centruroides* spp was produced in horses in Mexico as early as the 1930s.[17] In 1947, antivenom was produced from rabbits and cats immunized with *C. sculpturatus* and *Centruroides gertschi*.[51] The Antivenom Production Laboratory at Arizona State University (APL-ASU) began producing antivenom to *C. sculpturatus* in goats in 1965. This antivenom was used for treatment of scorpion stings in Arizona until 2004, when production ceased and

stockpiles expired. Treatment for *Centruroides* envenomation in this country is now limited predominantly to supportive care with airway maintenance and the administration of analgesics and benzodiazepines as needed. Without antivenom treatment available, hospital admissions following scorpion stings may have increased.[48]

Cross-neutralization of the venom of eight different species of *Centruroides*, including *C. exilicauda*, has been documented in vitro.[22] In Mexico, several antivenoms are used in the treatment of *Centruroides* spp envenomation. The Instituto Bioclon product Alacramyn antivenom may also be effective against North American *Centruroides* stings. Although antibody fragments (Fab) were developed experimentally in the United States from immune goat serum for treatment of *Centruroides* envenomation, they are not commercially available.[8] In June 2000, Silanes Laboratory obtained orphan drug status for a *Centruroides* scorpion antivenom, an equine-derived F(ab)$_2$ from *Centruroides limpidus*, *Centruroides noxius*, *Centruroides suffusus suffusus*, and *Centruroides meisei* (formerly known as *Centruroides elegans*). This product is manufactured by Instituto Bioclon of Mexico, and is at this time referred to as Anascorp. Clinical trials evaluating this scorpion F(ab)$_2$ are being done in Arizona. One vial of this scorpion antivenom contains sufficient F(ab)$_2$ to neutralize 150 mouse LD$_{50}$ of *Centruroides* venom,[41] and its safety and efficacy have been previously documented in both animals and humans.[1,12,24] In a rabbit model, the total serum concentration of scorpion venom increased after administration of F(ab)$_2$, suggesting that F(ab)$_2$ is capable of pulling venom from its site of action into serum.[12] A prospective evaluation of serum venom concentrations in 14 children clinically envenomated by scorpions was performed using enzyme-linked immunosorbent assay. After administration of antivenom, serum venom concentrations fell from 1000 to 4000 pg/mL to less than 200 pg/mL within 30 minutes and were unmeasurable within 2 hours.[24] Anascorp is administered by slow IV infusion, one vial at a time with observation for 30 to 60 minutes, and may be repeated. Dosing is similar in children and adults.

The incidence of allergic reactions to Anascorp is reported to be 2.7%, similar to the 3.4% previously reported for the APL-ASU goat serum product.[9,38] In a study of 15 children stung by *Centruroides* scorpions, 12 who received the APL-ASU antivenom had resolution of neurologic, respiratory, and cardiovascular symptoms within 3 hours of initiating therapy, compared with three patients who did not receive antivenom therapy where symptoms lasted 15 to 24 hours.[9] A current clinical trial of *Centruroides* F(ab')$_2$ in a very small randomized, double blind study in critically ill children with neurotoxicity from scorpion stings demonstrated a rapid resolution of symptoms, decreased need for sedation, and reduced concentration of circulating and bound venom.[11] Should this product prove safe, effective, and appropriate for a general population it may greatly improve treatment for scorpion stings.

LEIURUS SPECIES

The *Leiurus quinquestriatus* scorpion is indigenous to Africa, Asia, and the Middle East, including Egypt, Israel, Jordan, Kuwait, Lebanon, Oman, Qatar, Saudi Arabia, Syria, and Turkey. Antivenom to *L. quinquestriatus* is made in France, Germany, Israel, Saudi Arabia, Egypt, Tunisia, and Turkey. The clinical effects of this scorpion, such as acute lung injury and a variety of neurologic abnormalities, are relatively resistant to treatment with antivenom. The Turkish manufacturer of antiscorpion antivenom recommends a starting dose of 1 mL antivenom for treatment of envenomation. The usual dose for control of symptoms is 5 to 20 mL antivenom administered intravenously.

In observational studies, an IV infusion of 5 to 20 mL was needed to control venom effects, and only patients given antivenom within the first several hours demonstrated significant benefit.[2,32] The rate of allergic reactions for the Turkish antiscorpion antivenom is reported to be 1.6% to 6.6%.[32] The recommended dose of the Israeli *L. quinquestriatus* antivenom is 5 to 15 mL for IV use, although several authors report lack of clinical efficacy of this particular antivenom.[6,25,52]

L. quinquestriatus antivenom was successfully used to treat a 2-year-old boy with envenomation by *Androctonus crassicauda*. Symptoms resolved 2 hours after antivenom administration.[46]

TITYUS SPECIES

Tityus species of scorpions are endemic to South America, particularly Brazil. An F(ab)$_2$ antivenom for *Tityus serrulatus* is available from Fundação Ezequiel Dias (FUNED), in Belo Horizonte, Brazil. The usual dose of the antivenom is 20 mL as an IV infusion.[19]

In a series of 18 patients with *T. serrulatus* envenomation treated with antivenom, vomiting and local pain decreased within 1 hour, and cardiorespiratory manifestations disappeared within 6 to 24 hours in all patients except the two presenting with acute lung injury.[19] Sixteen patients recovered completely by 24 hours. Additionally, the Instituto Buntantan in Brazil produces Soro antiarachnidico and Soro antiscorpionico for treatment of *Tityus* spp.

ANDROCTONUS SPECIES

Scorpion antivenom in South Africa is an equine-derived antivenom available from the South African Vaccine Producers, formerly South African Institute for Medical Research (SAIMR), Johannesburg, South Africa.

Scorpifav, produced by Aventis Pasteur, is produced for treatment of *Androctonus* spp, *B. occitanus*, and *L. quinquestriatus*.

Buthus tamulus monovalent red scorpion antivenom serum produced by Central Research Institute of India is equine-derived lyophilized antivenom for the venom of *Mesobuthus tamulus*. Although the manufacturer recommends a dose of only one vial, five vials decreased mortality significantly in one study.[34,53]

In Pakistan, the treatment of scorpion stings was modified in 1991 to include the administration of five vials of antivenom. A retrospective case series of 950 patients treated with one vial and without antivenom was compared with 968 cases treated after the five-vial protocol was initiated. A statistically significant decrease in mortality resulted from the five-vial regimen. The last recorded death in Pakistan resulting from a scorpion sting occurred in 1991 in a patient who did not receive any antivenom.[53]

Parabuthus spp antivenom from South African Vaccine Producers is equine-derived antivenom to *Parabuthus* spp. In one study antivenom became unavailable, allowing for a unique design of matched pairing of patients. Patients who received antivenom had a significant decrease in hospital stay after receiving one (5-mL) vial. Pain, hypersalivation, fasciculations, tremor, and bladder distension responded best to antivenom, whereas dysphagia, ptosis, and local swelling were more resistent.[7] More recent studies from India show equivocal results for scorpion envenomation treated with antivenom when compared with treatment with prazocin.[5,43]

LATRODECTUS SPECIES (L. MACTANS, L. HESPERUS, L. BISHOPI, L. GEOMETRICUS, L. INDISTINCTUS)

The need to use antivenom in the treatment of black widow spider envenomation remains controversial. Although black widow bites are associated with severe muscle pain, cramping, and autonomic disturbances,

TABLE A35–1. Worldwide Availability of Scorpion and Spider Antivenom

Scorpions	Scorpions	Scorpions	Spiders

Androctonus species
    Algeria: Antiscorpion Serum, Institut Pasteur d'Algerie

			    Mexico: Aracmyn, Instituto Bioclon
			    Peru: Antiloxosceles Serum, Instituto Nacional de Salud, Centro Nacional de Production de Biologicos

mortality is low.[13,14] Symptomatic treatment with muscle relaxants and opioid analgesics is generally effective, although the duration of symptoms following severe envenomations may necessitate hospitalization for 1 to 2 days or more. The use of *Latrodectus* antivenom may shorten the length of symptoms dramatically, allowing outpatient care in some cases.[14,44,54] However, studies of reported *Latrodectus* envenomated patients in Australia have found little difference in clinical outcome after *Latrodectus* antivenom or placebo.[29] In addition, anaphylaxis is reported following the administration of *Latrodectus* antivenom.[14] These issues have led some authors to question its use.[49] Most toxicologists believe *Latrodectus* antivenom is safe and effective when used appropriately, and that it is generally indicated in cases of severe envenomation when muscle cramping, hypertension, diaphoresis, nausea, vomiting, and respiratory difficulty are present (Chap. 119).[13] *Latrodectus* antivenom has also been reported to successfully treat priapism that complicates severe bites.[28] Although the safety of antivenom has not been clearly established in the developing fetus, pregnancy is suggested as an added consideration for *Latrodectus* antivenom administration as the stress of severe pain and muscle cramps is likely to have adverse effects on fetal well-being.[3,50]

Antivenoms for a number of *Latrodectus* spiders are available worldwide (Table A35–1). *Latrodectus mactans* antivenom is produced by Merck and Company in North America. The Australian red-back spider *L. hasseltii* antivenom is manufactured in horses by CSL Ltd. South Africa (SAFR) produces antivenom for both the black widow (*L. indistinctus*) and the brown widow (*L. geometricus).* Aracmyn, a polyvalent F(ab)$_2$, is an equine-derived antivenom created for *L. mactans* in both Argentina and Mexico that is currently undergoing clinical trials in *Latrodectus* envenomated patients in the United States.

The *Latrodectus* antivenom produced by Merck and Company is equine-derived IgG. Each vial of this product contains 6000 antivenom units standardized by biologic assay in mice. Because the venoms of *Latrodectus* species are virtually identical by immunologic and electrophoretic mechanisms, antivenom created for *L. mactans* is presumed to be effective in other species of *Latrodectus* as well.[39] A recent shortage of Merck antivenom (Merck and Co) prompted the finding that antivenom against *L. hasseltii*, the Australian red-back spider, also neutralizes venom of *L. mactans* in a mouse model.[18] In a review of 163 cases of presumed *L. hesperus* and *mactans* envenomations, antivenom reduced the duration of symptoms from a mean of 22 hours to a mean of 9 hours. Symptoms usually subsided within 1 to 3 hours of administration of the antivenom. The hospital admission rate fell from 52% in those who were managed with opioids and muscle relaxants to 12% in those patients receiving antivenom.[14] Administration of this antivenom is reportedly effective even when given as late as 90 hours after envenomation.[44,54]

The starting dose of Merck antivenom is one vial (2.5 mL) diluted in 50 mL of saline for IV administration. Although black widow spider antivenom can also be given IM, this route carries the disadvantage of slower, more erratic absorption, less control over the rate of administration, and the inability to stop the administration should an allergic reaction occur. In addition, recent studies suggest IM injection of antivenom may not yield significant serum concentrations.[31] For these reasons, the IM route is not routinely recommended.

Despite the apparent efficacy of antivenom, the decision to give horse serum for a disease with limited mortality must be considered. Death from bronchospasm and anaphylaxis is a reported complication of antivenom administration, as is serum sickness.[13] The effect of black widow antivenom use during pregnancy is unknown.

In Australia, antivenom to the red-back spider (*L. hasseltii*, CSL Ltd) is made by immunizing horses for production of F(ab)$_2$. Horse-derived F(ab)$_2$ has a lower reported incidence of allergic reactions than IgG preparations, with early hypersensitivity reactions as low as 0.5% to 0.8%. The incidence of serum sickness is reported to be less than 5%.[55,56]

In a report covering 1995 to 1996, only 20% of patients with *L. hasseltii* (red-back spider) bites required antivenom administration.[59] When treatment was given, one vial was used in 76% of cases, two vials were used in 18% of cases, and three vials were administered in only 6% of cases.[59] In another study, three patients required six to eight vials of antivenom after failing to respond to the usual one to two vials.[30] No antihistamine or epinephrine pretreatment was given, and no allergic or serum sickness complications occurred.

FUNNEL-WEB SPIDER (*ATRAX* AND *HADRONYCHE*) ENVENOMATION

A rabbit IgG-based funnel-web spider (*Atrax robustus* and others) antivenom is available in Australia. Since the introduction of the antivenom, no deaths have been reported.[30] The initial dose is two vials in patients with any signs of envenomation. Patients with evidence of acute lung injury or decreased consciousness should receive four vials.[42] The dosage for children is the same as for adults.

In severe funnel-web spider envenomations, the following protocol should be used.[42] Two vials of (each 5 mL of 2.0% [100-mg] rabbit IgG) antivenom should be administered very slowly intravenously in both adults and children. The dose should be doubled for severe cases and the dose can be repeated in 15 minutes if no improvement occurs. A rapid response should occur. Administration of antivenom should be repeated until symptoms are completely reversed.[21] *Atrax robustus* envenomations may require more than three vials of antivenom.

LOXOSCELES SPECIES (*L. RECLUSA, L. LAETA, L. RUFESCENS, L. ARIZONICA, L. UNICOLOR*)

Envenomation by the brown recluse spider, *Loxosceles reclusa*, is associated with low, but significant, morbidity, particularly in the southeast United States. Anti-*Loxosceles* Fab blocks dermonecrosis in a rabbit model, but only when given within 24 to 48 hours of envenomation.[16,23,47] No commercially available antivenom exists in North America for treatment of *Loxosceles* envenomation; however, antivenom produced against South American *Loxosceles* spiders has cross-reactivity with North American species like *L. reclusa*.[20] The usual late presentation of patients with necrotic lesions from spider bites make antivenom use for *Loxosceles* difficult to study. National laboratories in Brazil and Argentina have produced antivenoms for *L. reclusa*, *L. boneti*, and *L. rufescens*.[4,20]

SUMMARY

The indications for antivenom administration in both spider and scorpion envenomations remain controversial. The decision to use antivenom should be individualized to the patient, weighing the risk of giving an immune serum, the level of available supportive care, the cost of supportive care, and the cost of obtaining or importing antivenom. Scorpion antivenom administration for some species may not improve outcome. When given, the preferred route of administration of these products is intravenous. One to two vials is the recommended dose for most scorpion and spider antivenoms; higher doses may be needed to alleviate symptoms in some cases.

CHAPTER 120
MARINE ENVENOMATIONS

D. Eric Brush

Human contact with venomous marine creatures is common and may result in serious injury from biological toxins or mechanical destruction inflicted by the stinging apparatus. Significant morbidity results from envenomation by spiny fish, cone snails, octopi, sea snakes, and several species of jellyfish. Despite significant advances in basic science research regarding the biochemical nature of marine toxins and their mechanisms of action, our knowledge of the pathophysiology related to clinical syndromes in humans and the optimal therapies for human envenomation remain limited. Evidence for effective treatment is primarily derived from in vitro and in vivo animal research without the benefit of controlled human trials. However, current research in toxinology coupled with clinical observations allows the development of cogent treatment guidelines for victims of marine envenomation.

INVERTEBRATES

■ CNIDARIA

The phylum Cnidaria (formerly Coelenterata) includes more than 9000 species, of which approximately 100 are known to injure humans. They are commonly referred to as *jellyfish*; however, their phylogenetic designations separate "true jellyfish" and other organisms into distinct classes (Table 120–1; Figure 120–1a). All species possess microscopic cnidae (the Greek *knide* means nettle), which are highly specialized organelles consisting of an encapsulated hollow barbed thread bathed in venom. Thousands of these stinging organelles, called *nematocysts* (or *cnidoblasts*), are distributed along tentacles. A trigger mechanism called a *cnidocil* regulates nematocyst discharge. Pressure from contact with a victim's skin, or chemical triggers such as osmotic changes, stimulates discharge of the thread and toxin from its casing. Penetration of flesh leads to intradermal venom delivery. Nematocysts of most Cnidaria are incapable of penetrating human skin, rendering them harmless. Cnidaria causing human envenomation, such as the box jellyfish, discharge threads capable of penetrating into the papillary dermis.[135]

Cubozoa Members of the class Cubozoa are not true jellyfish. Animals in the Cubomedusae order have a cube-shaped bell with four corners, each of which supports between one and 15 tentacles. Species from this order produce the greatest morbidity and mortality of all Cnidaria. The order has two main families of toxicologic importance: Chirodropidae and Carybdeidae.

The Chirodropidae family is well known for the box jellyfish *Chironex fleckeri* (Greek *cheiro* means hand, Latin *nex* means murderer; therefore, "assassin's hand").[131] When full grown, its bell measures 25 to 30 cm in diameter, and 15 tentacles are attached at each "corner" of the bell. These tentacles may extend up to 3 m in length. Another member of this family is *Chiropsalmus quadrigatus*, the sea wasp. Its pale blue color makes detection in water nearly impossible.

The Carybdeidae family is most notable for *Carukia barnesi*, the Irukandji jellyfish.[60] Its small size, with a bell diameter of 2.5 cm, limits detection in open waters.

Hydrozoa The Hydrozoa class, like the Cubozoa, are also not true jellyfish; however, they are capable of inflicting considerable pain and even death in humans. The order Siphonophora (Physaliidae family) includes two unusual creatures of toxicologic concern: *Physalia physalis*, the Portuguese man-of-war, and its smaller counterpart, *Physalia utriculus*, the bluebottle. They are pelagic (floating) colonial Hydrozoa, meaning they exist as a colony of multiple hydroids in a formed mass. The easily recognizable blue sail that floats above the surface of the water is filled with nitrogen and carbon monoxide. Tentacles of *P. physalis* may reach lengths in excess of 30 meters and contain more than 750,000 nematocysts in each of its numerous tentacles (up to 40). *P. utriculus* has only one tentacle, which measures up to 15 m.

The Milleporina order is well known for the sessile *Millepora alcicornis* (fire coral) that exists as a fixed colony of hydroids. It appears much like true coral and has a white to yellow-green lime carbonate exoskeleton. Small tentacles protrude through minute surface gastropores. The overall structure ranges from 10 cm to 2 m.

Scyphozoa True jellyfish belong to the class Scyphozoa and are extremely diverse in size, shape, and color. Common varieties known to envenomate humans are *Cyanea capillata* (lion's mane or hair jelly), *Chrysaora quinquecirrha* (sea nettle), and *Pelagia noctiluca* (mauve stinger). The mauve stinger is easily recognized; it appears pink in daylight and phosphorescent at night. Larvae of certain *Linuche unguiculata* cause sea bather's eruption (SBE). The larvae are pinhead sized and are seen only when they are grouped in large numbers near the surface of the water.

Anthozoa The Anthozoa class has a diverse membership, including true corals, soft corals, and anemones. Only the anemones are of toxicologic importance. They are common inhabitants of reefs and tide pools and attach themselves to rock or coral. Armed with modified nematocysts known as *sporocysts* located on their tentacles, they produce stings similar to those of organisms from other Cnidaria classes.

History and Epidemiology Stings from Cnidaria represent the overwhelming majority of marine envenomations. In Australia, approximately 10,000 stings per year are recorded from *Physalia* spp alone.[55] Most Cnidaria stings occur during the warmer months of the year. Stings occur with greatest frequency on hotter-than-average days with low winds, particularly during times of low precipitation. "Stinger nets" are used in high-risk areas of the Australian coastline; however, one study reported that 63% of stings requiring medical attention occurred within netted waters.[85] Each stinger season, the Royal Darwin Hospital in Australia treats approximately 40 patients with stings.[41] A prospective evaluation of stings presenting to that hospital during a 12-month period from 1999 to 2000 revealed that 70% resulted from the box jellyfish. The remaining 30% involved other Cubozoa such as *C. barnesi*.[106] Although this finding may indicate a predominance of box jellyfish as the cause of stings, it also suggests that stings from box jellyfish are more severe and require medical attention with greater frequency than stings from other species of Cnidaria.

Cases of SBE, a stinging rash evoked by contact with Cnidaria larvae, occur in clusters. Variation in intensity and frequency occurs from year to year as exemplified by a 25-year hiatus during which no cases were reported in Florida.[142] In 1992, more than 10,000 cases of SBE occurred in south Florida, with similar peaks in the 1940s and 1960s. Cases of SBE also are reported in Cuba, Mexico, the Caribbean, and occasionally in Long Island, New York.

Cnidaria common to the United States include the Portuguese man-of-war and sea nettle. Other species are widely distributed throughout the

TABLE 120–1. Characteristics of Common Cnidaria

Latin Name	Common Name	Habitat[a]
Cubozoa class		
Chironex fleckeri[b]	Box jellyfish	Tropical Pacific Ocean, Indian Ocean, Gulf of Oman
Carukia barnesi[b]	Irukandji jellyfish	North Australian coast
Chiropsalmus spp[b]	Sea wasp or fire medusa	North Australian coast, Philippines, Japan, Indian Ocean,
C. quadrigatus		Gulf of Mexico, Caribbean
C. quadrumanus		
Carybdea alata	Hawaiian box jelly fish	Hawaii
Carybdea rastoni	Jimble	Australia
Hydrozoa class		
Physalia physalis[b]	Portuguese man-of-war	Eastern US Coast from Florida to North Carolina, Gulf
		of Mexico, Australian coastal waters (rare reports)
Physalia utriculus	Bluebottle	Tropical Pacific Ocean, particularly Australia
Millepora alcicornis	Fire coral	Widespread in tropical waters, including Caribbean
Scyphozoa class		
Chrysaora quinquecirrha	Sea nettle	Chesapeake Bay, widely distributed in temperate and tropical waters
Stomolophus meleagris	Cabbage head or cannonball jelly fish	Gulf of Mexico, Caribbean
Stomolophus nomurai[b]		Yellow Sea between China and South Korea
Cyanea capillata	Lion's mane or hair jelly fish	Northwest US coast up to Arctic Sea, Norwegian and
		British coastlines as well as Australia
Pelagia noctiluca	Mauve stinger or purple-striped jelly fish	Wide distribution in tropical zones
Linuche unguiculata	Thimble jelly fish	Florida, Mexico, and Caribbean
Anthozoa[b] class		
Anemonia sulcata	European stinging anemone	Eastern Atlantic, Mediterranean, Adriatic Sea
Actinodendron plumosum	Hell's fire anemone	South Pacific
Actinia equina	Beadlet anemone	Great Britain, Ireland

[a] Represents most common areas where stings are reported.

[b] Well-documented human fatalities.

tropical and temperate waters of the globe (see Table 120–1). Locations with documented Cnidaria-related deaths include the United States (Florida, North Carolina, Texas), Australia, the Indo-Pacific region (Malaysia, Langkawi Islands, Philippines, Solomon Islands, Papua New Guinea), and the coast of China. Since 1884 the number of deaths in Australia attributed to *C. fleckeri* is approximately 70.[55,84] An estimated two to three deaths per year occur in Malaysia from an unknown species.[55] Approximately 20 to 40 deaths are reported yearly in the Philippines from an unidentified species of the Chirodropidae family.[55] Three deaths are well documented from *P. physalis* in the United States (Florida, North Carolina).[22,55,134] One death from *Chiropsalmus quadrumanus* occurred along the coast of Texas.[12] Eight fatalities in the Bohai waters of China (Yellow Sea) have been reported from *Stomolophus nomurai*.[55,158] Although Chirodropidae are found off the western coast of Africa, no fatalities in that region are documented in the medical literature.

Pathophysiology Cnidaria venoms contain a variety of components that may induce dermatonecrosis, myonecrosis, hemolysis, or cardiotoxicity, depending on the particular species. In rats, *C. fleckeri* venom evokes transient hypertension, followed by hypotension and cardiovascular collapse within minutes.[109] Cardiac effects in animals include negative inotropy, conduction delay, ventricular tachycardia, and decreased coronary artery blood flow.[41] However, experiments using

the purest venom extracts without contamination from tentacle material demonstrate cardiovascular collapse without electrocardiographic changes.[109] *C. fleckeri* venom also possesses dermatonecrotic and hemolytic fractions, although hemolysis in humans is not documented.[9] Two myotoxins from *C. fleckeri* cause powerful sustained muscle contractions in isolated muscle fibers.[45] Isolated heart models using *C. fleckeri* venom suggest its mechanism of action is nonspecific enhancement of cation conductance leading to increased Na^+ and Ca^{2+} entry into cells.[101] Other in vitro work confirms increased Na^+ permeability in cardiac tissue.[62]

C. barnesi, the Irukandji jelly, likely induces its dramatic vasopressor effects via catecholamine release. In rats the venom produces a pressor response that is blocked by α_1-adrenergic antagonism.[112] The pressor response is not dose dependent; therefore, catecholamines in the venom would not explain this effect. In vitro experiments suggest a sodium channel modulator effect leading to massive catecholamine release.[153] No electrocardiographic abnormalities occurred in envenomated rats.

Venom from *Physalia* spp blocks neural impulses in isolated frog sciatic nerve[81] and produces ventricular ectopy, cardiovascular collapse, hyperkalemia, and hemolysis in dogs.[71] *Physalia* spp venom inhibits Ca^{2+} entry into the sarcoplasmic reticulum.[81] Similar mechanisms

and renal necrosis.[100] *C. quinquecirrha*–induced hepatotoxicity is believed to be a direct toxin effect not mediated by pore formation or Ca^{2+} channel effects.[73] Equinatoxin II (EqtII), found in the venom of the anemone *Actinia equina*, creates pores in cell membranes leading to hemolysis.[1] This protein belongs to a group of anemone lysins known as *actinoporins* that bind to cell membranes and form pores via oligimerization.[90]

An immune-mediated response to venom may explain some sting-related symptoms. Elevated serum anti–sea nettle immunoglobulin IgM, IgG, and IgE may persist for years in patients with exaggerated reactions to stings compared with controls.[20] A direct correlation between titers against *Chrysaora* and *Physalia* and severity of a visible skin reaction to envenomation strongly suggests an allergic component.[123] Elevated IgG titers were demonstrated in one death from *P. physalis*.[134] Dermatonecrosis from *C. fleckeri* may involve the release of leukotrienes and other arachidonic acid derivatives as well as direct toxin-mediated cell damage.[42] Postenvenomation syndromes may result from an exaggerated, prolonged, aberrant T-cell response.[25,26] Erythema nodosum following a sting from *P. physalis* lends further support to a immunologic component.[5] SBE displays a characteristic delay in onset of symptoms and can be effectively treated with steroids, suggesting a primary immune-mediated process for this entity. This is further supported by histopathology revealing the presence of perivascular and interstitial infiltrates with lymphocytes, neutrophils, and eosinophils.[154]

Clinical Manifestations Most patients with stings are treated beachside and never require hospitalization. The vast majority of patients with stings who seek medical care have severe pain without evidence of systemic poisoning.[41] However, severe systemic manifestations may develop following stings from *C. fleckeri*, *C. barnesi*, *P. physalis*, and a few other Cnidaria.

Envenomation by *C. fleckeri* inflicts the most severe pain and is frequently associated with systemic toxicity. Common symptoms include immediate severe pain, followed by an erythematous whiplike linear rash with a "frosted ladder" appearance. The pain often is excruciating and may require parenteral analgesia. Systemic symptoms include nausea, vomiting, muscle spasms, headache, malaise, fever, and chills. Pain generally abates over several hours, although the rash may persist for days. In a prospective series of *C. fleckeri* stings, 58% manifested delayed hypersensitivity reactions in the form of an itchy maculopapular rash at 7 to 14 days.[106] Most resolved spontaneously; some were treated with antihistamines and topical corticosteroids.

Fatality is documented to occur with only 4 m of tentacle markings.[135] Death is rapid, preventing many victims from reaching shore. Cardiac arrest and pulmonary edema may develop in young, healthy patients without prior cardiopulmonary disease.[77,89,152] Survival is possible with immediate cardiopulmonary resuscitation (CPR).[151] *C. quadrumanus*, a close relative of the box jellyfish, induces symptoms that parallel *C. fleckeri* stings, including pulmonary edema and death.[12]

Previous reports suggesting a 15% to 20% fatality rate[118] following *C. fleckeri* envenomation likely represent a gross overestimation given the low number of documented fatalities in the context of the extraordinary number of yearly stings. A prospective study of stings from Cubozoa over 1 year in Australia revealed no dysrhythmias, pulmonary edema, or death.[106] No patient received antivenom, and analgesia was the only pharmacotherapy implemented. Hospital admission was not required for any victim. Although most victims suffer only local severe pain, serious systemic toxicity occurs occasionally, and may include vertigo, ataxia, paralysis, delirium, syncope, respiratory distress, pulmonary edema, hypotension, and dysrhythmia. The last 10 reported deaths from *C. fleckeri* occurred in children, suggesting vulnerability due to lower body mass and thinner dermis.[41]

FIGURE 120–1. (**A**) North Atlantic Portuguese Man-O-War *Physalia physalis* with multiple tentacles dangling in the water. The tentacles filled with venomous nematocysts, and extend several meters in length. *(Image contributed by Adam Laverty Reproduced with permission from Knoop et al., The Atlas of Emergency Medicine, 3e (c) 2010, McGraw-Hill Inc., New York, New York.)* (**B**) Linear eruption from contact with an unidentified jellyfish in the South Atlantic Ocean. *(Image contributed by David Goldfarb.)*

are proposed for *Chrysaora*, *Chiropsalmus*, and *Stomolophus*. *C. quinquecirrha* venom contains a 150-kDa polypeptide that induces atrioventricular block[19] and produces myocardial ischemia, hypertension, dysrhythmias, and nerve conduction block,[23,24] as well as hepatic

Irukandji syndrome is a severe form of envenomation following Cubozoa stings from *C. barnesi*.[74] However, nematocysts obtained from one fatality could not be identified, suggesting the existence of another causative species. Although the syndrome is considered unique to Australia, an unidentified species produced three cases of Irukandji-like syndrome in the Florida Keys.[68]

Individuals afflicted with Irukandji syndrome often notice a mild sting while they are in the water; however, skin findings typically are absent. Severe systemic symptoms develop within 30 minutes and mimic a catecholamine surge: tachycardia, palpitations, hyperpnea, headache, pallor, restlessness, apprehension, sweating, and a sense of impending doom. A prominent feature is severe whole-body muscle spasms that come in waves and preferentially affect the back. Spasms are described as unbearable and frequently require parenteral analgesia. Symptoms generally abate over several hours. Admission rates in patients presenting to medical care can exceed 50%.[85] Hypertension is universal and may be severe, with systolic blood pressures well over 200 mm Hg. Two fatalities are described involving severe hypertension (systolic 280/150 mm Hg and 230/90 mm Hg) resulting in intracranial hemorrhage.[51,74] Hypotension frequently follows, requiring vasopressor support. Pulmonary edema can develop within hours. Echocardiograms consistently reveal global ventricular dysfunction,[85,87,92] although focal hypokinesis may occur.[74] Restored cardiac function typically returns after several days.[86] A retrospective review of 116 cases of Irukandji presenting to Cairns Base Hospital identified elevated troponin I measurements in 22% of patients,[74] although a higher frequency is documented (78%).[87] Electrocardiographic changes are described as nonspecific.

P. physalis envenomation typically induces severe pain, bullae, and skin necrosis (see Figure 120–1b). Systemic symptoms include weakness, numbness, anxiety, headache, abdominal and back spasms, lacrimation, nasal discharge, diaphoresis, vertigo, hemolysis, cyanosis, renal failure, shock, and rarely death. Some patients experience local numbness and paralysis of the affected extremity that resolves spontaneously.[75] As with serious *C. fleckeri* stings, cardiovascular collapse and death can occur within minutes of envenomation.[22] However, fatalities can be delayed several days following envenomation and relate to complications such as myocardial infarction and aspiration pneumonitis.[134] An unusual presentation is reported of a 4-year-old child who was stung along the North Carolina coast and developed massive hemolysis requiring transfusions, followed by renal failure necessitating temporary dialysis.[69] In contrast to *P. physalis*, *P. utriculus* stings typically are mild, although systemic toxicity occasionally develops.[57]

M. alcicornis (fire coral) is a common cause of stings in southern United States and Caribbean waters. While a member of the same phylogenetic class as *P. physalis*, it produces far less significant injuries. It is a nuisance to divers who touch the coral and suffer moderate burning pain for hours. Untreated pain generally lessens within 90 minutes, with skin wheals flattening at 24 hours and resolving within 1 week. Hyperpigmentation may persist for up to 8 weeks.[15] The feather hydroid is the most numerous of the Hydrozoa and produces only mild stings.[94]

True jellyfish typically are less harmful to humans than Cubozoa or Hydrozoa. However, systemic toxicity and occasional deaths are reported from certain species such as *S. nomurai*, *C. capillata*, *C. quinquecirrha*, and *P. noctiluca*. *Stomolophus meleagris* is a common cause of stings; however, its weak venom produces only minor injury.[4] Larvae of *Linuche unguiculata* are the primary cause of a pruritic papular eruption on the skin of sea bathers in Florida, occurring mostly in areas covered by a bathing suit as a result of larvae trapped under the garments. Cases were first noted in 1949 and dubbed sea bather's eruption (SBE).[124] The larvae appear as pin-sized brown to green-brown

spheres in the upper 2 inches of the water and are typically unnoticed. In a retrospective review, 50% of people reported a stinging sensation while they were in the water, and 25% reported itching upon exiting the water.[154] The remainder of patients developed symptoms within 11 hours. Skin lesions develop within hours of itching and appear as discrete, closely spaced papules, with pustules, vesicles, and urticaria. Most lesions occur in areas covered by the bathing suit where the larvae accumulate; however, folds of skin such as the axilla, breasts, and neck may be affected. Itching often is severe and prevents sleep. New lesions may continue to develop over 72 hours. The average duration of symptoms is just under 2 weeks, and a small percentage of patients experience a recurrence of lesions several days later. Systemic symptoms such as chills, headache, nausea, vomiting, and malaise may occur.

Following stings from sea anemones, victims may develop either immediate or delayed pain. Skin findings range from mild erythema and itching to ulceration. A review of 55 stings from *Anemonia sulcata* presenting to a hospital in Yugoslavia (Adriatic Sea) revealed that, in addition to the local skin findings, many patients suffered nausea, vomiting, muscle aches, and dizziness.[91] Larvae of the anemone *Edwardsiella lineata* also cause SBE among ocean swimmers in Long Island, New York. The hell's fire anemone *Actinodendron plumosum* is native to the South Pacific and produces significant local pain. One death occurred in the Virgin Islands following envenomation from an unknown species described as a "white anemone with blue tips." The onset of hepatic and renal failure was rapid and required transplantation, after which the patient died.[64] Nonfatal elevation of hepatic enzyme concentrations following anemone sting also is reported.[16]

Diagnostic Testing Laboratory evaluation may be warranted in patients suffering systemic toxicity following Cnidaria envenomation. Serial measurement of serum cardiac markers should be obtained from victims of Irukandji stings or others with consequential cardiovascular toxicity. Following severe stings from a variety of Cnidaria, urinalysis, hematocrit, and serum creatinine measurements should be considered to detect the presence of hemolysis and subsequent renal injury. Chest radiography is indicated for complaints of dyspnea or abnormalities in oxygenation. Venom assays are not available, and serum antibody titers are not clinically useful.

Management Initial interventions after Cnidaria envenomation should follow standard management strategies. Secondary measures are directed toward the prevention of further nematocyst discharge, which could intensify pain and enhance toxicity. Many topical therapies have been used for this purpose, including sea water, vinegar, a commercial solution known as Stingose, methylated spirits, ethanol, isopropyl alcohol, dilute ammonium hydroxide, urine, sodium bicarbonate, papain, shaving cream, and sand.

Vinegar is a common first-line treatment for topical application following Cnidaria stings. In vitro trials with *C. fleckeri* tentacles demonstrate complete irreversible inhibition of nematocyst discharge following a 30-second application.[70] Additional study findings include massive nematocyst discharge with application of urine or ethanol, and no effect on discharge with use of sodium bicarbonate. Follow-up in vivo experiments demonstrate that vinegar is effective for other Cubozoa, including Morbakka (large Cubozoan in Australia),[50] *Carybdea rastoni*,[53] and *C. barnesi*.[54] Although massive nematocyst discharge occurs when vinegar is applied to *C. capillata* tentacles in vitro, clinical exacerbation following this treatment is not reported in humans.[49] Massive discharge also occurs with *C. quinquecirrha*.[28] A smaller degree of discharge (30%) occurs with *P. physalis*,[57] whereas nematocysts of *P. utriculus* are unaffected by application of vinegar.[70]

Stingose is a commercially available product designed to counteract venom of insects, bees, stinging plants, and marine stingers. It is an aqueous solution of 20% aluminum sulfate and 1.1% surfactant. Its purported mechanism of action is denaturing of proteins and

long-chain polysaccharides via interactions with the Al^{3+} ion, as well as osmotic removal of venom. A human volunteer trial involving stings from live tentacles of *C. fleckeri* demonstrated pain relief within 5 seconds of Stingose application.[72] Similar results were achieved following treatment of stings from *C. quinquecirrha*. Further investigation involved beachside evaluation of 17 *C. fleckeri* and 150 *P. utriculus* sting victims treated with Stingose immediately following injury. All victims reported rapid relief. However, placebo or alternative therapies were not used in this case series. The efficacy of treatment with vinegar, Stingose, methylated spirits, and salt water was measured in human volunteers following forearm application of *P. physalis* tentacles.[145] Vinegar demonstrated superior pain control compared with Stingose, whereas methylated spirits increased pain. The study assessed pain relief only and did not investigate the effects of the treatments on nematocyst discharge or systemic toxicity.

In many cases the identity of the "jellyfish" causing injury is unknown. In those cases, therapy must be guided by geographic location. In the United States, where *P. physalis* and *C. quinquecirrha* are of greatest consequence, sea water should be used to aid in tentacle removal given that vinegar enhances nematocyst discharge in those species. In the Indo-Pacific region, where *C. fleckeri* and *C. barnesi* are of greatest concern, vinegar should be used. Following a 30-second application, adherent tentacles must be carefully removed. This can be accomplished with a gloved or towel-covered hand, or with sand and gentle scraping with a credit card or other blunt, straight-edged tool.

In a nonrandomized trial, ice packs provided rapid, effective relief for patients with mild to moderate pain from Cnidaria stings in Australia.[46] Patients with severe pain were less likely to benefit from ice packs. Some authors suggest that the use of heat is not only ineffective for venom neutralization, but that it increases pain.[17] However, recent controlled trials designed to address this controversy highlight the efficacy of hot water immersion in lieu of cold packs for the treatment of stings from *Carybdea alata* and *Physalia* sp.[57,88,103,140,157] Hot-water immersion therapy for treatment of *C. fleckeri* stings has not been rigorously evaluated.

Pressure immobilization bandaging is a technique that applies sufficient pressure to a wound to impede lymphatic drainage and prevent the entrance of venom into systemic circulation. Its application for snake bites is commonplace, while its role following Cnidaria stings has sparked controversy. Given the rapid onset of symptoms, the utility of a technique that impedes lymphatic drainage is unlikely to provide benefit. Although the technique would be used only after tentacle removal, some microscopic nematocysts remain adherent to the skin after visible tentacles are removed. In vitro data investigating the effect of pressure on discharged nematocysts demonstrate not only that discharged nematocysts still contain venom, but that applying pressure forces more venom down the hollow tube.[108] This finding is correlated clinically as patients can deteriorate following pressure immobilization bandaging.[56] Given the lack of evidence suggesting benefit, coupled with clear in vitro evidence of increased venom delivery with this technique, it should not be implemented for treatment of Cnidaria stings.

Box jellyfish antivenom is sheep-derived whole IgG raised against the "milked" venom of *C. fleckeri.* It has been available in Australia since 1970. Combining *C. fleckeri* venom with box jellyfish antivenom prior to injection into pigs prevents all toxicity.[145] An isolated chick muscle experiment demonstrates that box jellyfish antivenom prevents the neurotoxicity and myotoxicity from *C. fleckeri* following pretreatment; however, there is no "rescue effect."[110] Given that antivenom in humans is always used as a rescue therapy, this research raises concerns regarding efficacy in the clinical setting. Pretreatment of rats with box jellyfish antivenom prevented cardiovascular collapse in 40%, but did not blunt the initial hypertensive effect.[111] In vitro data demonstrate that box jellyfish antivenom neutralizes the dermatonecrotic, hemolytic, and lethal fractions of venom from *Chiropsalmus* spp; however, the venom of *P. physalis* and *C. quinquecirrha* were not neutralized.[10] Other in vitro and in vivo data demonstrate incomplete neutralization of *Chiropsalmus* spp venom.[10,110]

There are no controlled studies in humans evaluating the efficacy of box jellyfish antivenom in the treatment of *C. fleckeri* envenomations, nor is there convincing evidence that its administration has saved human lives. Despite the frequency of hospital visits for stings from *C. fleckeri* in Australia, the use of box jellyfish antivenom is rare.[41] Evidence for its efficacy stems from case reports suggesting that pain abates rapidly after administration.[14,152] Although box jellyfish antivenom may improve pain control, patients still may require parenteral narcotics for analgesia following antivenom administration.[11] Significant morbidity and mortality still occur despite antivenom use.[40,89,135] Case reports of box jellyfish antivenom use for *C. barnesi* stings demonstrate no apparent benefit.[48]

Many serious stings occur in the Northern Territory of Australia, where stinger nets are not commonly used. Distance from medical care limits the ability to obtain antivenom in a timely fashion.[41] Although box jellyfish antivenom can be administered by paramedics via intramuscular (IM) injection,[56] poor IM absorption and incomplete venom neutralization with antivenoms, as well as delayed peak serum concentrations, limit the utility of this approach.[117] The amount of antivenom required to neutralize twice the lethal dose in humans is estimated at 12 vials.[41] The manufacturer recommends treating initially with one ampule intravenously (IV) diluted 1:10 with saline or three undiluted ampules (1.5–4 mL each) IM at three separate sites, if IV access is unavailable. Some authors who have treated multiple patients with antivenom suggest treating coma, dysrhythmia, or respiratory depression with one ampule IV, titrating up to three ampules with continuation of CPR in patients with refractory dysrhythmia until a total of six ampules have been administered.[106] For less serious envenomations, clinicians may consider administering one ampule if ice packs and parenteral analgesia prove ineffective.[106] Serious adverse events or delayed sequelae following the use of IV antivenom are uncommon, although allergic reactions are a consideration.[136]

Verapamil was evaluated as a treatment for *C. fleckeri* stings based on evidence that calcium entry into cells represents an important mechanism of toxicity. One animal model demonstrated synergy with use of verapamil in combination with box jellyfish antivenom,[27] whereas another showed verapamil pretreatment as well as rescue prolonged survival.[18] This is in contrast to other models demonstrating that verapamil negates the benefits of antivenom[111] and increases mortality.[141] Verapamil administration to animals with *C. quinquecirrha* envenomation demonstrated no benefit.[100] Interestingly, addition of magnesium to antivenom for treatment of *C. fleckeri* envenomation in rats prevented cardiovascular collapse in 100%, suggesting that magnesium may have a role in the treatment of stings from this species.[111] Given that animal data are inconsistent with regard to verapamil and that hypotension may develop with severe envenomation, use of calcium channel blockers is not recommended for treatment of *C. fleckeri* stings.

Treatment for Irukandji syndrome should focus on analgesia and blood pressure control. Several modalities for control of severe hypertension have been suggested and include phentolamine, IV magnesium sulfate and nitroglycerin.[39,52] Whereas hypotension may occur in late stages of toxicity, clinicians should also consider short-acting titratable agents such as esmolol, nitroprusside or nicardipine.

■ MOLLUSCA

The phylum Mollusca (Latin *mollis* meaning soft) includes the classes Cephalopoda (octopus, squid, and cuttlefish) and Gastropoda (cone

FIGURE 120-2. The Blue Ringed octopus, *Hapalochlaena maculosa*. (Image contributed by Dr. Roy Caldwell, Professor of Integrative Biology, University of California, Berkeley.)

snails). Cephalopod species of toxicologic concern are limited to the blue-ringed octopus *Hapalochlaena maculosa* and the greater blue-ringed octopus *Hapalochlaena lunulata*. The blue-ringed and greater blue-ringed octopi are found in the Indo-Pacific region, primarily in Australian waters (Figure 120–2). Of the 400 species of cone snails that belong to the genus Conus, 18 are implicated in human envenomations.

History and Epidemiology The blue-ringed octopus normally displays a yellow-brown color, but develops iridescent blue rings when threatened. The species is not aggressive and only bites humans when handled. A 1983 review of reported octopus envenomations uncovered a total of 14 cases, all of which occurred in Australia.[146] There were two deaths[61,133] and four serious envenomations. Other reviews suggest that up to seven deaths may have occurred prior to 1969, some outside Australia.[44]

Estimates of reported cone snail envenomations suggest only 15 human deaths have occurred worldwide.[47] *Conus geographicus* (fish hunting cone) is the most common species implicated, although *Conus textile* may also cause death in humans. Cone snails predominantly inhabit the Indo-Pacific, including all parts of Australia, New Guinea, Solomon Islands, and the Philippines. Two deaths from *C. geographicus* occurred in Guam.[83]

Pathophysiology The blue ringed octopus salivary gland secretes a toxin originally designated maculotoxin and later identified as tetrodotoxin.[128] The beak of the octopus creates small punctures in human skin through which venom is introduced. Tetrodotoxin blocks Na^+ conductance in neurons, leading to paralysis. Venom also contains serotonin (5-HT), hyaluronidase, tyramine, histamine, tryptamine, octopine, taurine, acetylcholine, and dopamine.[137] Rabbits subjected to bites develop rapid flaccid paralysis without cardiotoxicity and die from asphyxia.[137] Other animal models using venom gland extract demonstrate rapid onset of respiratory muscle paralysis and severe hypotension.[59] Death occurs despite artificial respiration and results from hypotension.

Cone snails have a hollow proboscis that contains a tooth bathed in venom. Envenomations occur when the shells are handled. The proboscis can extend the length of its shell, thereby envenomating the hand of someone touching the opposite end of the shell. Any *Conus* species contains approximately 100 peptides or *conotoxins* in its venom. Targets include voltage- and ligand-gated ion channels as well as G-protein–linked receptors (Table 120–2).[105,139] Many of these

TABLE 120–2. Conus Peptide Targets

Receptor Type	Peptide	Mechanism
Ligand-gated ion channels		
Nicotinic	α-Conotoxin	Competitive antagonism
	M1	Neuromuscular junction
	M2	Neuronal receptors
5-HT$_3$	σ-Conotoxin	Noncompetitive antagonism
NMDA	Conantokins	Inhibits conductance
Voltage-gated ion channels		
Ca^{2+}	ω-Conotoxin	Channel blockade
Na$^+$	μ-Conotoxin	Channel blockade
	δ-Conotoxin	Delayed channel activation
K$^+$	κ-Conotoxin	Channel blockade
G-protein linked		
Vasopressin receptor	Conopressin-G	Receptor agonism
Neurotensin receptor	Contulakin-G	Receptor agonism

peptides are used extensively in laboratory research for their ability to selectively target a variety of specific calcium channel subtypes. Venom from *Conus imperialis* (worm hunter) contains a substantial amount of 5-HT, a component not found in any other *Conus* venom tested thus far.[96] This species also contains a vasopressin-like peptide.[102] The neuropeptide ω- conotoxin, isolated from *Conus magnus*, is valued for its antinociceptive properties that arise from blockade of the N-type voltage-sensitive calcium channel in spinal cord afferents.[95] The Food and Drug Administration approved ziconotide (Prialt, Elan Pharmaceuticals) in 2004 for intrathecal (IT) infusion in patients with severe chronic pain that require IT therapy, and in whom other treatment modalities such as IT morphine are not tolerated or ineffective. Patients reported modest improvements in pain with long-term treatment.[148] Frequent side effects such as dizziness, nausea, confusion, and memory impairment limit the broad application of this novel therapy.

Clinical Manifestations The blue-ringed octopus creates one or two puncture wounds with its chitinous jaws, inflicting only minor discomfort. A wheal may develop with erythema, tenderness, and pruritus. Tetrodotoxin exerts a curarelike effect characterized by paralysis without depressing mental status. Symptoms include perioral and intraoral paresthesias, diplopia, aphonia, dysphagia, ataxia, weakness, nausea, vomiting, flaccid muscle paralysis, respiratory failure, and death. Detailed case reports describe rapid onset of symptoms.[146] Complete paralysis requiring intubation with findings of fixed and dilated pupils is followed within 24 to 48 hours by near-complete recovery of neuromuscular function.[146] In one reported death, a young man placed the octopus on his shoulder. He subsequently noted a small puncture wound, developed dry mouth, dyspnea, inability to swallow, and became apneic. Asystole occurred 30 minutes after arrival at the hospital despite artificial ventilation.[61] Another similar bite resulted in symptom onset at 10 minutes, followed by death at 90 minutes, despite bystander CPR.[137] With less severe envenomations, cerebellar signs may arise without paralysis. Near-total paralysis with intact mentation resolving over 24 hours is described in humans.[137]

Cone snail envenomation results from careless handling of the animal or rummaging through sand. Cone snails are nocturnal feeders, so

they may present more of a hazard to night divers. Localized symptoms range from a slight sting to excruciating pain, tissue ischemia, cyanosis, and numbness. Systemic symptoms include weakness, diaphoresis, diplopia, blurred vision, aphonia, dysphagia, generalized muscle paralysis, respiratory failure, cardiovascular collapse, and coma. Death is rapid and occurs within 2 hours. Based on military medical records of more than 30 cases predating 1970, the mortality rate approaches 25%, with *C. geographicus* causing the most deaths.[83] Other estimates suggest that, without medical care, mortality may reach 70%.[156] Given the rarity of severe human envenomation from cone snails, the manner of death, whether purely from respiratory insufficiency or direct cardiovascular toxicity, remains unknown.

Diagnostic Testing Laboratory testing following envenomation from octopi or cone snails should be directed by clinical findings. Coma, respiratory failure, and hypotension merit evaluation of serum metabolic parameters, chest radiography, and electrocardiogram. Although not a widely available assay, tetrodotoxin can be detected in the urine or serum using high-performance liquid chromatography with subsequent fluorescence detection.[104]

Management Primary interventions include maintenance of airway, breathing, and circulation. Some authors recommend hot water (45°–50°C, 113°–122°F) following cone snail stings for pain relief.[83] Unlike Cnidaria envenomations, where nematocysts full of venom can persist on the skin and lead to continued venom delivery, stings from the octopus and cone snail mirror those of snake bites, where venom delivery is an immediate and finite event. Therefore, pressure immobilization bandaging may blunt toxin distribution by decreasing lymphatic spread.[47] Additional measures include local wound care and tetanus prophylaxis. Antivenom is not available for octopus or cone snail venoms.

ECHINODERMATA, ANNELIDA, AND PORIFERA

The Echinodermata phylum includes sea stars,, brittle stars, sea urchins, sand dollars, and sea cucumbers. Annelida are segmented worms that include the Polychaetae family of bristle worms. Sponges are classified in the Porifera phylum. One feature that all three phyla share is the passive envenomation of people who mistakenly handle or step on the animals. Most stings from these creatures are mild.

History and Epidemiology Echinoderms, annelids, and sponges are ubiquitous ocean inhabitants. The crown-of-thorns *Acanthaster planci* is found in the warmest waters of Polynesia to the Red Sea and is a particularly venomous species because of its sharp spines that easily puncture human skin. Sea urchins inhabit all oceans of the world. Bristle worms such as *Hermodice carunculata* typically inhabit tropical waters such as those of Florida and the Caribbean. However, some species thrive in the frigid waters of Antarctica. The fire sponge *Tedania ignis* is a brilliant yellow-orange sponge identified in large numbers off the coast of Hawaii and in the Florida Keys. Other common American sponges are *Neofibularia nolitangere* (poison-bun sponge or touch-me-not sponge) and *Microciona prolifera* (red sponge). *Neofibularia mordens* (Australian stinging sponge) is a common Southern Australian variety. In the Mediterranean, sponges are often colonized with sea anemones that may inflict severe stings.[15]

Pathophysiology Sea urchins are covered in spines and pedicellariae. The pedicellariae are pincerlike appendages used for feeding, cleaning, and defense. They generally contain more venom than the spines and are more difficult to remove from wounds. Urchins laden with pedicellariae can evoke more severe stings than urchins with less pedicellariae. Venom contained within the spines consists of steroid glycosides, serotonin, hemolysin, protease, and acetylcholinelike

substances. Some species harbor neurotoxins. The most venomous are species of *Diadema*, *Echinothrix*, and *Asthenosoma*. Sea stars are less noxious because they generally have short, blunt spiny projections. The crown-of-thorns is the exception with its longer, sharp spines containing toxic saponins with hemolytic and anticoagulant effects as well as histaminelike substances.[138] Sea cucumbers excrete holothurin, a sulfated triterpenoid oligoglycoside, from the anus (organs of Cuvier) as a defense. The toxin inhibits neural conduction in fish, leading to paralysis. Some sea cucumbers eat Cnidaria and subsequently secrete their venom.

Bristle worms have many parapodia that have the appearance, but not the function, of legs. Several bristles extend from each parapodium giving the family (Polychaeta) its name (*poly* means many, *chaetae* means bristles). The bristles may penetrate human skin, leading to envenomation with an unknown substance.

Sponges have an elastic skeleton with spicules of silicon dioxide or calcium carbonate. They attach to the sea floor or coral beds. Toxins include halitoxin, odadaic acid, and subcritine, the nature of which is uncertain.[21] Dried sponges are nontoxic; however, on rewetting they may produce toxicity even after several years.[132]

Clinical Manifestations Most injuries from sea urchins are caused by inadvertently stepping on the spines or attempting to handle the animal. An intense burning with local tissue reaction occurs, including edema and erythema. Rarely, with multiple punctures, lightheadedness, numbness, paralysis, bronchospasm, and hypotension may reportedly occur, although this is not documented in the peer-reviewed medical literature.[3] Reports of death are not well substantiated. The Pacific urchin *Tripneustes* has a neurotoxin with a predilection for cranial nerves.[15] Mild elevations of hepatic enzymes are reported in one patient with foot cellulitis from an urchin sting.[155] Small cuts on the skin from handling starfish may allow venom to penetrate, leading to contact dermatitis. The crown-of-thorns may cause severe pain, nausea, vomiting, and muscular paralysis.[94] Cutaneous, scleral, or corneal exposure to sea cucumbers triggers contact dermatitis, intense corneal inflammation, and even blindness. Bristle worms are shrouded with bristles that can produce a reddened urticarial rash. Symptoms typically are mild and resolve over several hours to days.

Contact with the fire sponge, poison-bun sponge, or red-moss sponge causes erythema, papules, vesicles, and bullae that generally subside within 3 to 7 days. Victims may develop fever, chills, and muscle cramps. Skin desquamation occurs at 10 days to 2 months,[4] with chronic skin changes lasting several months.[21] Erythema multiforme and anaphylaxis are uncommon complications associated with *Neofibularia* spp exposure.[15] Contact with sponges that are colonized with Cnidaria can lead to dermatitis with skin necrosis, referred to as *sponge diver's disease.*

Management The primary objective following envenomation from sea urchins and crown-of-thorns starfish is analgesia. Submersion of the affected extremity in hot water (105°F–115°F, 40.6°C–46.1°C) and administration of oral analgesics often is sufficient.[47,94] Puncture wounds require radiographic evaluation to locate potential foreign bodies. Spines frequently crumble with attempted extraction. Intraarticular spines necessitate surgical removal. Decisions regarding spines in other locations should be influenced by ease of removal, presence of infection, and persistent pain. Tetanus immune status must be addressed. Decisions regarding antibiotic prophylaxis should be based on degree of injury and patient factors such as diabetes or other immunocompromise. Although most infections likely are secondary to human skin flora, marine flora such as *Mycobacterium marinum* and *Vibrio parahaemolyticus* are potential wound contaminants. Treatment of sponge exposures usually requires only removal of spicules using adhesive tape or the edge of a credit card. Antihistamines and topical steroids often provide no relief from stinging sponges.[21]

VERTEBRATES

■ SNAKES

Sea snakes are members of the class Reptilia and are divided into two subfamilies: Hydrophiinae and Laticaudinae. They are close relatives of the cobra and krait. Length typically does not exceed 1 m. Their tails are flattened, and their bodies often are brightly colored. Distinction from eels is made by the presence of scales and the absence of fins and gills. All 52 species of sea snakes are venomous and at least six species are implicated in human fatalities. The most common species cited in human envenomation are *Enhydrina schistosa*, the beaked sea snake and *Pelamis platurus*, the yellow-bellied sea snake.

History and Epidemiology Sea snakes are common to the tropical and temperate Indian and Pacific Oceans, but are also found along the eastern Pacific Coast of Central and South America and the Gulf of California. In the eastern Pacific region, the yellow-bellied sea snake is the only species known. There are no sea snakes in the Atlantic Ocean. The majority of envenomations occur along the coasts of Southeast Asia, the Persian Gulf, and the Malay Archipelago (Malaysia). Snakes tend to inhabit the turbid coastlines and deeper reefs of these regions.

The true incidence of sea snake envenomation is unknown because many bites are not recorded. Worldwide the number of deaths per year may approach 150, with an overall mortality rate estimated at 3%.[47] In a review of 120 documented bites, 51.7% of victims were fisherman handling nets.[116] The remainder of victims were wading or swimming along the coastline. In another review of 101 bites occurring from 1957 to 1964 in Northwest Malaysia, more than 50% of bites were from the beaked sea snake, including seven of the eight fatal bites in that series, bringing the mortality to 8% prior to the availability of antivenom.[114] However, 31 "dry bites" were excluded, suggesting that the overall mortality is somewhat lower. Among the 20% of patients in that series suffering "serious envenomation," half died despite supportive care.[114] A follow-up series of patients after the introduction of antivenom described two deaths out of 11 "serious envenomations," suggesting a decreased mortality resulting from this intervention. These were all retrospective reviews of published or personally communicated cases.

Pathophysiology All sea snakes have small front fangs. Their venom is neurotoxic, myotoxic, nephrotoxic, and hemolytic. Known components of the venom include acetylcholinesterase, hyaluronidase, leucine aminopeptidase, 5′-nucleotidase, phosphodiesterase, and phospholipase A. The neurotoxin is a highly stable 6000- to 8000-Da protein similar to that of the cobra and krait. In mice, beaked sea snake venom is four to five times more potent than cobra venom based on a µg/kg ratio; however, cobra venom yield is greater.[31] Venom homology exists across many species.[76] The neurotoxin targets postsynaptic acetylcholine (ACh) receptors creating a blockade at the neuromuscular junction. Presynaptic effects include initial enhanced ACh release and subsequent inhibition of ACh release.[99,119,147] In vitro research confirms direct nephrotoxicity of crude venom, and may partially explain the nephrotoxicity described clinically.[127] Rhabdomyolysis likely contributes to this clinical finding.

Clinical Manifestations Sea snakes generally are docile, except when provoked, or during the mating season. Bites typically are painless or inflict minimal discomfort. Between one and four fang marks are common; however, up to 20 fang marks are possible as a result of multiple bites. The diagnosis can be obscured, because victims may not associate the slight prick following the bite with later onset of ascending paralysis. Symptoms may progress within minutes, although a delay of up to 6 hours is possible. Neurotoxin-induced paralysis occurs in conjunction with muscle destruction stemming from myotoxic fractions. Painful muscular rigidity and myoglobinuria are hallmarks of sea

snake myotoxicity. Myoglobinuria develops between 30 minutes and 8 hours after the bite. Other classic symptoms include ascending flaccid paralysis, dysphagia, trismus, ptosis, aphonia, nausea, vomiting, fasciculations, and ultimately respiratory insufficiency, seizures, and coma.

Diagnostic Testing Laboratory diagnostics are directed toward identifying hemolysis, myonecrosis, hyperkalemia, and renal failure. Serum electrolytes, creatinine, and creatine phosphokinase, as well as hematocrit and urinalysis, should be obtained. Elevated concentrations of hepatic enzymes may indicate severe envenomation. Serial measurement of these parameters is recommended.

Management Prehospital management of sea snake bites mirrors treatment of terrestrial snake bites and includes immobilization of the extremity and consideration of a pressure immobilization bandage to impede lymphatic drainage. Currently no data regarding the efficacy of this technique for sea snake envenomations are available. Tourniquets that impede venous or arterial flow are not recommended and may be detrimental. Airway and respiratory effort require close monitoring because paralysis can develop rapidly.

The most commonly used antivenoms for sea snakes are equine IgG Fab fragments produced using the venom of beaked sea snake (*E. schistosa*) or terrestrial tiger snake (*Notechis scutatus*) (Table 120–3). In vitro experiments demonstrate that sea snake antivenom is effective for neutralizing all species of sea snakes tested (*Praescutata viperina* in Thailand, *P. platurus* in Central America, *Laticauda semifasciata* in the Philippines, *Laticauda laticaudata* in Japan, *Hydrophis cyanocinctus*, *Lapemis hardwickii*).[144] Optimal neutralization occurs within the subfamily Hydrophiinae, which contains *E. schistosa*; however, effective neutralization is demonstrated within the subfamily Laticaudinae. Terrestrial tiger snake antivenom also can neutralize sea snake venom in vitro. Based on the volume of antivenom required, tiger snake antivenom was superior for neutralization of all sea snake venoms tested except that of the beaked sea snake, for which sea snake antivenom was more effective.[7] This finding is expected because sea snake antivenom is raised against beaked sea snake venom. In contrast to volume comparisons, measurements of unit dosing demonstrate sea snake antivenom is more effective for all venoms tested. Another in vitro study comparing tiger snake and sea snake antivenom against venom *E. schistosa* demonstrated tiger snake antivenom was 10 times more effective in terms of milligram of venom neutralized per milliliter of antivenom.[98] In the

TABLE 120–3. Antivenoms

Organism	Derivation	Concentration
Box jellyfish		
C. fleckeri	Ovine, whole IgG	20,000 Units/ampule
Sea snake		
E. schistose (beaked sea snake)	Equine, IgG Fab	1000 Units/ampule
N. scutatus (terrestrial tiger snake)	Equine, IgG Fab	3000 Units/ampule
Stonefish		
S. trachynis	Equine, IgG Fab	2000 Units/ampule

CSL, Commonwealth Serum Laboratories, Melbourne, Australia manufacture these antivenom.

same study, the use of 17 different types of elapid antivenom resulted in poor neutralization of beaked sea snake venom.

In rescue experiments with mice using 11 sea snake venoms and four different antivenoms (*E. schistosa*, *E. schistosa-N. scutatus*, *N. scutatus*, and polyvalent sea snake *L. hardwickii, L. semifasciata, H. cyanocinctus*), tiger snake antivenom was superior to all others with respect to volume amount required to prevent death.[2,8,63] Another finding of the study was improved efficacy with early administration of antivenom.

No controlled human trials have evaluated the efficacy of sea snake antivenom, although case reports suggest improved outcomes and more rapid recovery with its use.[97,114] Anecdotal experience in Malaysia using sea snake antivenom suggests slow recovery from myalgias and weakness over 48 hours, compared with resolution over 2 weeks without antivenom (two cases, one control).[115]

Based on in vitro and in vivo research, selection of the optimal antivenom for treatment of sea snake bites is unclear. Both sea snake and tiger snake antivenom are effective in neutralizing a wide variety of sea snake venoms. Therefore, the most readily available antivenom should be used when needed. Commonwealth Serum Laboratories manufactures both monovalent sea snake and tiger snake antivenom for use in Australia. However, limited distribution to aquariums and zoos outside Australia occurs. The manufacturer's guidelines for use of monovalent sea snake antivenom recommend administration of one ampule (1000 Units) for systemic symptoms. However, because symptoms may be delayed and early administration is more likely to result in venom neutralization, any evidence of envenomation should prompt the administration of antivenom. The antivenom requires a 1:10 dilution with 0.9% sodium chloride solution followed by administered IV over 30 minutes. A 1:5 dilution can be used for small children. Skin testing is not recommended. Epinephrine and antihistamines should be readily available. No upper limit is suggested for the number of vials to administer, although larger amounts are more likely to result in serum sickness. Patients have received up to 7000 Units without adverse effect directly attributable to the antivenom.[97] One ampule (3000 Units) of tiger snake antivenom can be used as an alternative if sea snake antivenom is unavailable. Other treatments should focus on wound care, tetanus prophylaxis, analgesia, and fluid administration to minimize nephrotoxicity from myoglobinuria.

■ FISH

Stingrays are members of the class Chondrichthyes (order Rajiformes: skates and rays). Families include Dasyatidae (whip ray or sting ray), Urolophidae (round ray), Myliobatidae (batfish or eagle ray), Gymnuridae (butterfly ray), and Potamotrygonidae (river ray, freshwater).

Spiny fish of the family Scorpaenidae include a variety of venomous creatures (Table 120–4). Fish of the genus *Pterois* are commonly called *lionfish* (*P. volitans* and *P. lunulata*). Stonefish are grouped under the genus *Synanceja* and include *S. trachynis* (Australian estuarine stonefish), *S. horrida* (Indian stonefish), and *S. verrucosa* (reef stonefish). They are unattractively disguised to blend in with the rocky sea bottom (Figure 120–3). Scorpionfish have a similar appearance and belong to the genus *Scorpaena* (eg, *S. guttata*: California sculpin). Other Scorpaenidae include *Notesthes robusta* (bullrout) and *Gymnapistes marmoratus* (cobbler). The European weeverfish produce toxicity similar to members of Scorpaenidae and are classified under the family Trachinidae. This includes *Trachinus vipera* (lesser weever) and *Trachinus draco* (greater weever, aka adderpike, stingfish, seacat). These bottom dwellers are smaller and have fewer spines than Scorpaenidae and are much less ghoulish in appearance. Catfish also may envenomate humans. Although most live in freshwater, marine catfish such as *Plotosus lineatus* can inflict injury. Other venomous spiny fish include rabbitfish, stargazers, toadfish, ratfish, and even some sharks that have spines on their dorsal fins (Port Jackson shark, dogfish shark).

History and Epidemiology   There are 11 different species of stingrays in US costal waters (seven in the Atlantic, four in the Pacific). In the southeastern United States, *Dasyatis americana* is a common inhabitant.

TABLE 120–4. Spiny Fish

Latin Name	Common Name	Habitat
Scorpaenidae family		
Pterois		
P. volitans	Lionfish (also zebrafish, turkeyfish, or red firefish)	Indo-Pacific region, coast of Florida to North Carolina
P. lunulata	Lionfish or butterfly cod	(nonnative to US coast)
Synanceja		
S. trachynis	Australian estuarine stonefish	Indo-Pacific region (Pacific and Indian Oceans)
S. horrida	Indian stonefish	
S. verrucosa	Reef stonefish	
Scorpaena		
S. cardinalis	Red rock cod, scorpionfish	Coast of Australia
S. guttata	California sculpin, scorpionfish	Coast of California
Notesthes robusta	Bullrout	Coast of Australia
Gymnapistes marmoratus	Cobbler	Coast of Australia
Trachinidae family		
Trachinus		
T. vipera	Lesser weeverfish	Coasts of Great Britain to Northwest Africa, throughout
T. draco	Greater weeverfish (also adderpike, stingfish, or seacat)	Mediterranean and Black Seas

FIGURE 120–4. (**A**) The Lionfish, Pterois volitans. (**B**) This patient's hand was envenomated by his pet lionfish while cleaning his aquarium. *(Images contributed by the New York City Poison Center Toxicology Fellowship Program)*

Urolophus halleri is the most common species on the western coast of the United States. Some estimates suggest 1500 to 2000 stingray injuries occur yearly in the United States. Most envenomations occur when the animal is inadvertently stepped on. In one review a total of 17 fatalities resulting from trunk wounds, hemorrhage, or tetanus were identified worldwide.[47] Another review of 603 cases of stingray injuries identified two deaths resulting from intraabdominal trauma.[121]

Three populations are at highest risk for spiny fish envenomation: fishermen sorting the catch from nets, waders, and aquarium enthusiasts. Only five deaths from Scorpaenidae have been reported; all resulted from stonefish and are poorly documented.[38,47] No deaths from stonefish are reported in Australia, a country where they are commonly found in coastal waters.[41] The incidence of weeverfish stings is unknown, but they are a common occurrence in the summertime among Italian coastal towns.[30,130] Scorpaenidae inhabit waters throughout the tropical and temperate oceans. They exist as far north as the Gulf of Oman and Southern Japan and extend south beyond New Zealand. In the United States, Scorpaenidae stings occur in the Florida Keys, in the Gulf of Mexico, off the coast of California, and in Hawaii. Lionfish (genus *Pterois*) (Figure 120–4) are common to home aquariums and account for most poison center calls involving spiny

fish envenomation in the United States. The bullrout inhabits the eastern coast of Australia, along with the cobbler, which is found only in Australia. Weeverfish inhabit shallow temperate waters with sandy or muddy bottoms in the eastern Atlantic and Mediterranean, including the European Coast extending to the southern tip of Norway.[29] The marine catfish lives in the tropical Indo-Pacific waters.

Pathophysiology Tapered, bilaterally retroserrated spines covered by an integumentary sheath emanate from the stingray tail. The ventrolateral groove contains venom glands that saturate the spine with venom and mucus. The venom contains several amino acids, serotonin, 5′-nucleotidase, and phosphodiesterase.[4] In animal models venom induces local vasoconstriction, bradydysrhythmias, atrioventricular nodal block, subendocardial ischemia, seizures, coma, cardiovascular collapse, and death.[3,121] A rabbit model demonstrates initial vasodilation followed by vasoconstriction and cardiac standstill suggesting a direct cardiac effect.[122] Wound specimens reveal necrotic muscle and neutrophilic infiltrates.[6] Other reports show central hemorrhagic necrosis with surrounding lymphoid and eosinophilic infiltrates indicating an immune-mediated cause of delayed wound healing.[66]

Scorpaenidae have 12 to 13 dorsal, two pelvic, and three anal spines that are covered with an integumentary sheath. Glands at

the base contain 5 to 10 mg of venom each. Ornate pectoral fins are not venomous. Venom can remain stable for 24 to 48 hours after the fish dies.[93] Three main toxins have been isolated from various species of stonefish: stonustoxin (SNTX), verrucotoxin (VTX), and trachynilysin (TLY). SNTX, from *S. horrida*,[67] has two subunits, α and β (71,000 and 79,000 Da, respectively). It induces formation of hydrophilic pores in cell membranes.[32] Toxicity in animals includes hemolysis, local edema, vascular permeability, platelet aggregation, endothelium-dependent vasodilation, and hypotension. Decreased myocardial contractility occurs in rabbits.[125] Heating stonefish venom to 122°F (50°C) for 5 minutes prevents wound necrosis and hypotension in animal models.[150] VTX, isolated from *S. verrucosa*, shares homology with SNTX. It blocks cardiac Ca^{2+} channels.[65] TLY, isolated from *S. trachynis*, is a 159-kDa protein that forms pores in cell membranes. It allows Ca^{2+} entry and causes Ca^{2+}-dependent release of ACh from nerve endings at motor end plates and increased catecholamine release.[80,107,126] *S. trachynis* venom causes endothelium-dependent vasodilation and cardiovascular collapse in rats, which appears to be mediated by muscarinic and adrenergic receptors.[33] Hemolysis is demonstrated in animals but does not occur in human erythrocytes.[79] Other venoms of Scorpaenidae include hyaluronidase, proteinase, phosphodiesterase, alkaline phosphomonoesterase, arginine esterase, arginine amidinase, 5'-nucleotidase, acetylcholinesterase, and biogenic amines. Crude venom from *G. marmoratus*, *P. volitans*, and *S. trachynis* leads to increased intracellular Ca^{2+} and muscle contracture in vivo.[36] Toxins from other spiny fish include dracotoxin (*T. draco*), trachinine (*T. vipera*), and nocitoxin (*N. robusta*).[35] Effects mirror those of Scorpaenidae toxins.[129]

Clinical Manifestations Stepping on the body of a stingray causes a reflexive whip of the tail leading to wounds in the lower extremity. Intense pain out of proportion to the appearance of the wound is characteristic. Symptoms peak 30 to 90 minutes after injury and may persist for 48 hours. Local edema, cyanosis, erythema, and petechiae may follow rapidly and may lead to necrosis and ulceration. Systemic symptoms include weakness, nausea, vomiting, diarrhea, vertigo, headache, syncope, seizures, muscle cramps, fasciculations, hypotension, and dysrhythmias. Chest and abdominal wounds, as well as tetanus, have caused death.[113]

Stings from stonefish produce immediate, severe pain with rapid wound cyanosis and edema that may progress up the injured extremity. Pain reaches a maximum after 30 to 90 minutes and usually resolves over 6 to 12 hours, although pain may persist for days. Headache, vomiting, abdominal pain, delirium, seizures, limb paralysis, hypertension, respiratory distress, dysrhythmia, congestive heart failure, and hypotension characterize systemic toxicity.[82] Wound healing may require months.

A poison center case series from 1979 to 1988 identified 23 cases of *P. volitans* envenomation.[143] Reported symptoms included pain, swelling, nausea, numbness, joint pain, anxiety, headache, dizziness, and cellulitis. Another Poison Center series identified 51 Scorpaenidae stings (45 *P. pterois*, six *S. guttata*).[78] Intense pain was reported in 98%, extension of pain to the limb in 22%, swelling in 58%, and systemic signs (nausea, diaphoresis, dyspnea, chest pain, abdominal pain, weakness, hypotension, and syncope) in 13%. Thirteen percent of patients in the series developed wound infection; one patient's wound healing was delayed several weeks. Stings from weeverfish are similar to Scorpaenidae envenomation and rarely result in death.[13] Injury from catfish stings is comparable to that of other stinging fish.[43]

Management Wounds inflicted by stingrays and spiny fish should be carefully examined for imbedded foreign material. Radiographs may uncover retained spines. Stingray wounds can be extensive and require surgical attention for vascular or tendonous disruption.

Tetanus immune status should be addressed. Prophylactic antibiotics may decrease rates of wound infection.[37] In a series of 51 stings from *P. pterois* and *S. guttata,* 80% of patients had complete relief of local pain with hot water immersion.[78] Hot water produces similar relief for pain from weeverfish stings.[120] A review of 119 stingray envenomations demonstrates comparable efficacy with hot water immersion.[37] Although patients occasionally required a single dose of oral or parenteral analgesia, clinicians rarely prescribed pain medication upon discharge. In a human volunteer study in which subjects received a subcutaneous injection of stingray venom, severe pain developed immediately, and was alleviated with water heated to 122°F (50°C).[121] Pain increased with application of cold water. Local lidocaine infiltration provides an alternate modality for pain control.[58]

Stonefish antivenom, an equine-derived IgG Fab fragment, is raised against the venom of *S. trachynis*. Each ampule contains 2000 Units and neutralizes 20 mg venom. Between 1965 and 1981, antivenom was used in at least 267 cases.[41] Anecdotal reports suggest it provides effective relief from pain.[41,149] In a review of 26 documented cases in Australia where antivenom was administered IM, no acute adverse effects were identified.[136] Two of 15 patients who had follow-up visits suffered serum sickness. Rash may develop several days postinjection.[149] In vitro and in vivo research with the antivenom demonstrates neutralization of venom from *G. marmoratus*[34] and *P. volitans*[35]; however, the application for human therapy remains untested.

The manufacturer recommends IM administration of stonefish antivenom, although IV administration may be considered. Administration is indicated for systemic toxicity or refractory pain. The number of puncture wounds guides therapy: one vial for one to two punctures, two vials for three to four punctures, and three vials for five or more punctures. Epinephrine and diphenhydramine should be readily available for treatment of anaphylactic reactions.

SUMMARY

Fatalities from marine envenomations are rare. However, significant morbidity may result from bites and stings, including severe pain, retained foreign bodies, infection, respiratory compromise, hemodynamic instability, and a variety of other end organ toxicities. Interventions should focus on patient comfort and recognition of potential complications. A thorough understanding of the mechanisms of toxicity and expected clinical course following envenomations from marine creatures will provide clinicians with the ability to manage these injuries effectively.

CHAPTER 121
SNAKES AND OTHER REPTILES

Bradley D. Riley, Anthony F. Pizon, and Anne-Michelle Ruha

Snakes in North America are common, but venomous snakes are far more consequential elsewhere in the world. In Africa and Asia, morbidity and mortality remain far higher than in the United States, where most exposures occur among snake handlers and very effective antivenom is readily available. Recognition of the local species, protection of children, and respect for the risk associated with handling a dangerous snake limit injury. If envenomation occurs, appropriate first aid and rapid assessment help avoid substantial iatrogenic morbidity and lead to essential medical care.

HISTORY AND EPIDEMIOLOGY

■ INCIDENCE OF VENOMOUS SNAKEBITES IN THE UNITED STATES

There are 120 species of snakes native to North America, including approximately 30 venomous species and subspecies from two families, Viperidae and Elapidae (Table 121-1). Viperidae (subfamily Crotalinae) include the rattlesnakes (genera *Crotalus and Sistrurus*) along with the copperheads and water moccasins (genus *Agkistrodon*). The vast majority of venomous snakebites in the United States that occur annually are from Crotalinae, with about 55% of these being rattlesnake bites and the rest from copperheads and water moccasins. The other family of venomous snakes native to the United States is the Elapidae, which includes the coral snakes. Fewer than 5% of poisonous snakebites are from the coral snake.[6]

Venomous snakes are found throughout the United States, except Maine, Alaska, and Hawaii. They are common in the Appalachian states, the South, and the West but are rare in New England and the northern states. There are approximately 6000 to 8000 venomous snakebites per year in the United States. Mortality from snakebite is considered to be quite rare in the United States, with estimates ranging from five to 15 deaths per year.[25] Exact statistics are lacking, but mortality rates can be significantly higher in other countries. There may be as many as 27,000 rattlesnake bites and 100 fatalities per year in Mexico[14] and thousands of deaths per year in some Southeast Asian and African countries.

Because snakes hibernate in the winter, most bites in the United States occur between May and October. Snakebites may occur at night, but the most common time for envenomation is from 2 to 6 P.M.[61] Coral snakes are particularly known for their nocturnal habits. The majority of bites occur in the extremities, but bites to the face and tongue have been reported when snakes are purposefully held near the body. The striking range of a snake is approximately one-half its length.

Children, intoxicated individuals, snake handlers, and collectors are frequent victims. More than half of the bites occur while the individual is purposely handling a known venomous snake. There is a significant market for many illegal and dangerous reptiles, and a number of individuals keep and sell exotic venomous snakes as pets. Some religious groups handle poisonous snakes (usually rattlesnakes) as a routine ceremonial practice.

■ IDENTIFICATION OF A VENOMOUS SNAKE

Crotalinae The venomous Crotalinae in the United States have a triangular-shaped head, vertically elliptical pupils, and easily identifiable fangs (Fig. 121–1). These fangs are paired, needlelike structures that inject venom and can retract on a hinge-like mechanism into the roof of the mouth. An adult snake usually has two fangs, but the fangs may be single or multiple. Rattlesnakes have the longest fangs, reaching 3 to 4 cm. In addition to fangs, venomous snakes also have rows of small teeth that may cause additional injury during a bite. Snakes of the subfamily Crotalinae are also called pit vipers because of the presence of a pitlike depression of the skin behind the nostril that contains a heat-sensing organ used to locate prey. The undersurface of pit vipers has a single row of plates or scales, as opposed to the double row found on nonvenomous varieties. Rattlesnakes may or may not have rattles, depending on maturity, which are occasionally heard before a strike. Water moccasins are semiaquatic and have a distinct white mouth suggesting their common name (ie, cottonmouths). They are also reported to be quite aggressive and capable of underwater bites. Copperheads are known for their reddish-brown (copper) heads and hourglass markings on their bodies (Fig. 121–2).

Elapidae The coral snakes (genera *Micruroides* and *Micrurus*) are brightly colored Elapids indigenous to North America with easily identifiable red, yellow, and black bands along the length of their bodies. Coral snakes and the similarly colored nonpoisonous scarlet king snake are often confused. In one report, 23% of victims of coral snake bites were envenomated because they erroneously believed they were dealing with the nonpoisonous scarlet king snake.[35] Coral and king snakes can be distinguished by their color patterns. Whereas coral snakes have black snouts, king snakes have red snouts. Both species have red, yellow, and black rings, but in different sequences: the red and yellow rings touch in the coral snake but in are separated by black rings king snakes ("Red on yellow kills a fellow, red on black, venom lack") (Fig. 121–3).

The fangs of coral snakes are much smaller (1–3 mm) than those of rattlesnakes, and discrete fang marks may not be obvious after envenomation. Coral snakes often hang on to a victim or "chew" for a few seconds in an attempt to deliver venom, and a history of this activity may help identify a coral snakebite when the offending reptile cannot be located.

Exact identification of a snake is often not possible unless it is brought to the hospital. This is usually impossible and poses an additional threat to the victim and to prehospital personnel. Because of the excitement generated by the bite, the victim's identification of the snake may not be accurate. Identifying a snake by its color or markings is difficult for the novice. Knowledge of the indigenous venomous snakes is more helpful to medical personnel. Snake handlers and owners of pet snakes usually know the exact species responsible for the bite, but some are reluctant to offer specific information out of fear of prosecution or confiscation of the illegal snake by authorities.

■ CHARACTERISTICS OF A VENOMOUS SNAKEBITE

The severity and clinical manifestations of envenomation depend on a number of factors, including the number of strikes, depth of envenomation, potency and amount of venom injected, size and underlying health of the victim, and location of the bite. Larger snakes generally inject more venom, but the potency is species variable. Children and small adults, as well as those with underlying medical conditions, such

as diabetes and cardiovascular disease, may be more seriously affected by envenomation.[45] Envenomation usually occurs in subcutaneous tissues and less commonly in muscle. Systemic absorption occurs as a result of lymphatic and venous drainage of the envenomated sites. One rather bizarre observation is that individuals may be envenomated by rattlesnakes thought to be dead, even up to 60 minutes after decapitation. This is likely because of persistent reflexes in the venom apparatus.[56]

Pit vipers produce a characteristic bite when they strike, and distinct fang marks can usually be identified. The small delicate fangs of coral snakes may not produce easily identifiable fang marks. Fang marks may be single, double, and occasionally multiple. Although most snakes have two fangs, the exact number of fang marks may vary because of glancing blows or multiple strikes. Protection by clothing or shoes can

FIGURE 121–1. alter classical findings. The bites of rodents or lizards and even thorn or cactus injuries may be mistaken for the bite of a poisonous snake.

PHARMACOLOGY AND PATHOPHYSIOLOGY

Snakes use their venom while hunting to incapacitate and kill prey and, when threatened, in a defensive fashion. Crotaline venom also begins the digestive process. With these different functions, it comes as no surprise then that snake venom is a complex heterogeneous solution and suspension of various proteins, peptides, lipids, and carbohydrates, with complex actions that are, in many cases, not fully understood.

The content and potency of venom in any given snake vary with size, age, diet, climate, time of year, and possible crossbreeding between different species. Not every bite from a venomous snake results in the release of venom into the victim, with so called "dry bites" occurring in up to 20% of strikes.[37] Repeat strikes may result in additional envenomation because the snake's entire quantity of venom is not usually exhausted with the first attack. After it has been exhausted, approximately 3 to 4 weeks are necessary for the snake to replenish its supply of venom.[51]

Crotaline venom can simultaneously damage tissue directly, affect blood vessels and cellular elements of blood, and alter the myoneural junction and nerve transmission. It is difficult to attribute specific pathology or pathophysiology to any particular component of snake venom. In fact, clinical effects often occur as the result of action by several venom components (Table 121–2). For instance, local tissue damage results from the action of venom metalloproteinases and hyaluronidase, which both contribute to swelling through disruption of the extracellular matrix and basement membrane surrounding microvascular endothelial cells.[29] As a result of reduced blood flow through damaged capillaries, they may also contribute to myonecrosis, which results primarily from the action of phospholipase A_2 enzymes (PLA_2) on muscle.[29] Additionally, venom metalloproteinases contribute to dermatonecrosis, both directly and through activation of endogenous inflammatory mediators.[29,58]

Venom effects on the hematologic system are especially complex. Numerous components act as anticoagulants, and many others act as procoagulants. Similarly, platelets may be inhibited, activated, agglutinated, aggregated, or inhibited from aggregating by various venom components. Venom components can be grouped according to certain characteristics, such as structure and enzymatic activity, but as noted above with local tissue damage, components within several groups may contribute to similar effects. For instance, anticoagulants in snake venoms are found among the C-type lectin-like proteins (CLPs), PLA_2 enzymes, serine proteases, and metalloproteinases. Conversely, components within a single group may have many different actions. Various CLPs in venom act as anticoagulants, procoagulants, or platelet modulators. PLA_2 enzymes are especially diverse, acting as anticoagulants and platelet modulators in addition to producing myotoxic and neurotoxic effects. Platelet effects result mainly from the action of disintegrins, although CLPs, PLA_2 enzymes, and other proteinases also have platelet-modulating effects.[40,64]

Specific hematologic effects are species dependent, with no single venom containing all of the identified hemostatically active components. Of particular importance to North American rattlesnake envenomation are the thrombin-like enzymes and fibrino(geno)lytic enzymes. These are metalloproteinases and serine proteases that preferentially cleave fibrinopeptide A or fibrinopeptide B from fibrinogen. Unlike thrombin, they do not activate factor XIII. The end result is production of a poorly cross-linked fibrin clot that is easily degradable. Multiple other venom components exist, some of which affect the vascular system and contribute to the hypotension sometimes seen clinically after envenomation. Examples include bradykinin-potentiating peptides and vascular endothelial growth factors.

Coral snake venom contains neurotoxins with curare-like effects that produce systemic neurotoxicity as opposed to local tissue injury. Similar to other elapids, an α-neurotoxin binds and blocks acetylcholine receptors at motor endplates, leading to weakness. Phospholipase A_2 can also cause myotoxicity, although this appears to be of less clinical importance.

CLINICAL MANIFESTATIONS

■ CROTALINE ENVENOMATION

Local Reactions Symptoms may range from mild to severe, but the initial benign presentation of a pit viper bite may be very misleading[33] (Table 121–3). Generally, within minutes after significant envenomation from a pit viper, the area around the bite becomes swollen and painful. Edema may progress to involve an entire extremity within a few hours, and ecchymosis may be evident. Rarely, onset of appreciable swelling is delayed up to 10 hours. This is most often noted in lower extremity envenomations.

Hemorrhagic blisters (blebs) often form at the site of the bite after rattlesnake envenomations. This most commonly occurs after bites to the fingers but may occur at any bite location or even in dependent areas proximal or distal to the bite (Fig. 121–4). Blebs usually do not appear for several hours after the envenomation but can progress for several days. Tissue underlying blebs is often healthy, but extensive bleb development may signify underlying tissue necrosis.

In addition to local myonecrosis, generalized severe rhabdomyolysis may occur in the absence of impressive muscular swelling. This finding is considered characteristic after envenomation by the canebrake rattlesnake (*Crotalus horridus atricaudatus*) found in the Gulf Atlantic states.[11]

Systemic Signs Most bites from pit vipers that occur on the extremities are limited to local or regional pathology, but life-threatening systemic symptoms may develop. In the most severe cases, patients quickly

TABLE 121–2. Major Venom Components of Crotalinae Snakes

General Clinical Effect	Responsible Venom Components
Local tissue damage	Metalloproteinases Phospholipases A_2 Hyaluronidase
Coagulation effects[a]	C-type lectin-like proteins Metalloproteinases[b] Serine proteases[b] Phospholipases A_2
Platelet effects[c]	Disintegrins C-type lectin-like proteins Metalloproteinases Phospholipases A_2
Neurotoxic effects	Phospholipases A_2

[a] Venom contains both pro- and anticoagulants, with anticoagulant effects predominating in North American crotaline envenomation.

[b] Include thrombin-like enzymes as well as fibrino(geno)lytic enzymes.

[c] Venom may contain factors that inhibit, activate, or affect aggregation of platelets.

TABLE 121–3. Evaluation and Treatment of Crotaline Envenomation

Extent of Envenomation	Clinical Observations	Antivenom Recommended[a]	Other Treatment	Disposition
None ("dry bite")	Fang marks may be seen but no local or systemic symptoms after 8–12 hours	No	Local wound care Tetanus prophylaxis	Discharge after 8–12 hours of observation
Minimal	Minor local swelling and discomfort only with no systemic symptoms or hematologic abnormalities	No	Local wound care Tetanus prophylaxis	Admit to monitored unit for 24-hour observation
Moderate	Progression of swelling beyond area of bite with local tissue destruction, hematologic abnormalities, or systemic symptoms	Yes	IV fluids Cardiac monitoring Analgesics Follow laboratory parameters Tetanus prophylaxis	Admit to Intensive Care Unit
Severe	Marked progressive swelling and pain, with blisters, brusing, and necrosis Systemic symptoms such as vomiting, fasciculations, weakness, tachycardia, hypotension, severe coagulopathy	Yes	IV Fluids Cardiac monitoring Analgesics Follow laboratory parameters Oxygen Vasopressors as indicated Tetanus prophylaxis	Admit to Intensive Care Unit

[a] See Antidotes in Depth A36: Antivenom (Crotaline) for dosing recommendations.

develop circulatory shock or airway edema and obstruction. This may be caused by anaphylaxis or anaphylactoid reactions to venom. Rarely, patients may exhibit disseminated intravascular coagulation with spontaneous bleeding along with significant hypotension and multiorgan system failure.[22] This has been reported after intravascular envenomation.[16] Other systemic signs include confusion, vomiting, diarrhea, diaphoresis, tachycardia, metallic taste, and blurred vision. More often, early systemic symptoms are mild and include nausea, nonspecific weakness, or restlessness. Delayed systemic symptoms are also possible because venom travels by lymphatic and superficial venous channels and spreads rather slowly to reach the general circulation. Although crotaline venom may be directly nephrotoxic, renal failure is probably secondary to hemoglobinuria, myoglobinuria, or cardiovascular collapse.

Although local tissue destruction dominates the picture of Crotalinae envenomations, neurotoxic effects occur with certain species of snakes. The Mojave rattlesnake (*Crotalus scutulatus*) produces the neurotoxic Mojave toxin, which may cause weakness, cranial nerve dysfunction, and respiratory paralysis.[34] It acts at presynaptic terminals of the neuromuscular junction by inhibiting acetylcholine release. Mojave toxin is formed by a heterodimer protein made up of an acidic and a basic subunit, both of which need to be present to have a functional neurotoxin.[63] Interestingly, the production of Mojave toxin appears to be geographically distributed.[23] A western population in California produces functional Mojave toxin A, and neurotoxic effects occur but there is little to no tissue destruction. More eastern populations lack the acidic subunit and do not make functional Mojave toxin but do express metalloproteases that lead to necrosis. Mojave toxin has also been found in the venom of the Southern Pacific rattlesnake (*Crotalus halleri*) found in southern California, with envenomations leading to neurologic symptoms.[12,20] The Timber rattlesnake (*Crotalus horridus*) is noted to commonly cause rippling fasciculations of the skin (myokymia), particularly of the facial muscles.[5,38]

Hematologic Significant rattlesnake envenomation may produce rather dramatic hematologic abnormalities secondary to the venom's effects on the blood coagulation pathways, endothelial cells, and platelets.[3,8,50,55] Coagulopathy or thrombocytopenia may be present with a paucity of other local or systemic effects. An initial decrease in fibrinogen levels (to near zero) and platelet count (in the 10,000–50,000/mm³ range) along with immeasurably high prothrombin time may occur after moderate to severe crotaline envenomation. However, the vast majority of patients, regardless of which snake caused the envenomation, have no clinical bleeding, even with severe laboratory abnormalities. Thrombocytopenia appears to be especially common and often severe after the bite of the Timber rattlesnake (*Crotalus horridus horridus*).[3] The protein crotalocytin that is found in Timber rattlesnake venom causes platelet aggregation and is thought to be at least partially responsible for the thrombocytopenia.

Anaphylaxis Rarely, patients bitten by crotalines may experience classic anaphylaxis from the venom itself that may complicate evaluation or mimic a severe systemic reaction to venom. Previous sensitization to venom results in development of IgE antibodies to venom in these patients. This is thought to more often occur in patients who have previously experienced a snakebite but has also been observed in snake handlers who are thought to be sensitized through inhalation or skin contact with snake proteins. Antivenom is not indicated for the treatment of anaphylaxis, but differentiating anaphylaxis from envenomation is often clinically difficult. The presence of pruritus and urticaria or wheezing, uncommon with envenomation, should suggest anaphylaxis.[11]

Grading of Severity Envenomation is a dynamic and ever-changing process that can rapidly or unpredictably progress to serious local or

A

(Copyright © 2002, Department of Toxicology Good Samaritan Regional Medical Center)*

systemic involvement. It may require a number of hours for the full extent of envenomation to become evident. On rare occasions, symptoms may appear to be resolving, only to return minutes to hours later with greater intensity. As a general rule, however, it may be assumed that if no symptoms develop within 8 to 12 hours from the time of the bite, envenomation from a North American pit viper has not occurred (dry bite).

A major difficulty in objectively grading the severity of crotaline envenomation and following its progress is that no scoring system readily fits the wide range of presentations. Most patients exhibit only a subset of possible consequences, so all, some, or none of the anticipated signs and symptoms may develop in any given individual. In addition, some of the characteristics of envenomation (eg, nausea, tachycardia, restlessness, and tachypnea) may be related to fear rather than to envenomation. A validated severity score for the objective assessment of crotaline envenomation has been developed and can be useful for research and clinical evaluation.[17]

Agkistrodon (water moccasins and copperhead) bites generally tend to produce less severe local and systemic pathology than rattlesnake bites. Copperhead bites in particular rarely cause systemic symptoms, and pathology is usually limited to soft tissue swelling without

necrosis.[60] Although serious copperhead bites occasionally occur, no reports of death can be found in the medical literature.

■ ELAPID ENVENOMATION

Coral snake bites are characterized by a lack of local symptoms but potentially serious systemic symptoms. The effects of elapid envenomation are characteristically delayed for a number of hours. One report described a patient who had an asymptomatic period of 13 hours followed by a sudden and precipitous deterioration severe enough to require ventilatory support.[35] The neurologic abnormalities noted included slurred speech, paresthesias, ptosis, diplopia, dysphagia, stridor, muscle weakness, fasciculations, and respiratory paralysis.[37] The major immediate cause of death from coral snake envenomations is respiratory arrest secondary to neuromuscular weakness, with fewer cardiovascular effects occurring than in crotaline envenomation. Patients may develop total-body paralysis that may take weeks to months to resolve completely. With respiratory support, however, the paralysis is completely reversible. Pulmonary aspiration is a common sequela in the subacute phase.

It is difficult to judge initially which patients bitten by coral snakes will develop symptoms. In general, fewer than 40% of patients bitten by a coral snake are subsequently determined to have been envenomated, with rates for the Eastern coral snake species possibly higher.[35] The venom of the Eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*Micrurus tener*) are more potent than that of the Sonoran coral snake (*Micruroides euryxanthus*). In fact, there have been no reported cases of serious toxicity after the bite of the Sonoran coral snake, which is found primarily in Arizona and western New Mexico.

DIAGNOSTIC TESTING AND MANAGEMENT

■ OBJECTIVES FOR TREATMENT OF PATIENTS WITH ENVENOMATION

The specific treatment of a patient with a snakebite is controversial, and the literature contains confusing and contradictory recommendations. Folklore and home remedies abound. The benign natural history of many bites undoubtedly has accounted for many "miraculous cures" from such clearly unhelpful interventions as ethanol, electric shocks, carbolic acid, strychnine, cauterization, and cryotherapy. Many accepted treatment plans are based on anecdotal or biased information with conclusions drawn from animal studies or uncontrolled case reports. There are no universally accepted standards of care for many aspects of treatment.[61] The initial objectives are to determine the presence or absence of envenomation, provide basic supportive therapy, treat the local and systemic effects of envenomation, and limit or repair tissue loss or functional disability (see Table 121-3).

A combination of medical therapy (mainly supportive care and possibly antivenom) and conservative surgical treatment (mainly debridement of devitalized tissue), individualized for each patient, will provide the best results. In general, the more rapidly treatment is instituted, the shorter the period of disability, but no specific standard of care exists for the institution of various interventions.

■ OBSERVATION OF ASYMPTOMATIC PATIENTS

All patients reporting a history of snakebite from North American crotalines should be observed for 8 to 12 hours after the bite if the skin is broken and the offending snake cannot be positively identified as nonpoisonous. The initial presentation of pit viper bites may be misleading, and significant worsening of a seemingly benign bite may occur as long as 24 hours after presentation,[33] but such cases are unusual. Restlessness, anxiety, abdominal pain, nausea, and tachycardia are nonspecific symptoms but could signal systemic envenomation, and they should not be routinely dismissed as being a result of fear or anxiety. If the patient has been bitten by an exotic or nonnative snake, it would be prudent to extend the period of observation to 12 to 24 hours.

Eastern coral snake bites can initially be misleading with fang marks that are quite subtle and easily mistaken for scratches or teeth marks. Serious delayed neurologic and respiratory symptoms have been specifically noted, so patients bitten by these snakes should be observed for 24 hours regardless of their initial presenting symptoms. Sonoran coral snakes, indigenous to Arizona and California, have never been reported to cause significant toxicity, and bite victims can be discharged if the offending snake has been positively identified.

■ CROTALINE SNAKE BITES

Field Treatment for Snakebite Victims No first aid measures or specific field treatment has proven to positively affect the outcome from a crotaline envenomation, and undue importance has been placed on the immediate prehospital care of patients with snake bites. When the patient is not in extremis and medical attention is available within a few hours, the prudent approach is a conservative one. The excitement or hysteria generated by a possible poisonous snakebite compels some caregivers to intervene quickly with unproven or harmful procedures. In reality, both death and amputation are quite rare if proper medical attention is available within a few hours. Most morbidity stems from delayed treatment, either because of inaction on the patient's part (often related to alcohol intoxication) or because of inaccessible medical care. Prehospital care should generally be limited to immobilization of the patient's affected limb and rapid transport to a medical facility.[42]

In the past, various methods have been advocated to prevent systemic absorption of venom after snake bites. The traditional tourniquet that occludes venous and arterial flow is contraindicated and may compound the initial insult by increasing edema and aggravating ischemia. A constriction band is not a true tourniquet and is intended to collapse lymphatics and superficial veins; if it is applied properly, a finger may be easily placed between the band and the skin. The pressure immobilization technique with a constriction band has been used in the treatment of nonnecrotizing elapid snakebites in Australia, where systemic toxicity is the major concern and transit times can be prolonged.[62] Utility of this technique for the more necrotizing bite of North American crotalines has not been demonstrated. A randomized, controlled study of pressure immobilization versus observation in a porcine model with intramuscular injection of *Crotalus atrox* venom showed a prolonged time to death in the pressure immobilization group but also markedly increased compartment pressures. With local tissue necrosis, the major morbidity associated with North American crotaline envenomations, not death, the authors concluded that pressure immobilization with a compression bandage cannot be suggested as a routine field procedure.[9]

Incision and suction, whether by mouth or with a commercially available device, cannot be recommended as standard first aid in the field. Incision may lead to damage of underlying structures such as nerves and tendons, and mouth suction is unproven and may introduce bacteria into the wound. Commercially available plunger-type suction devices in human models provide no benefit, and additional injury is possible from the device. Venom extractors are currently unproved therapy and are not recommended.[1,10] Simple suction cups supplied in first aid kits are worthless.

It should be stressed that compression dressings and vacuum extraction should not be considered if the patient can rapidly reach a hospital. Minor pain or swelling is not an indication for zealous field treatment. Furthermore, these treatments are never a substitute for rapid transport, in-hospital evaluation, or antivenom therapy. The bitten area should not be placed in ice because cryotherapy is not effective in neutralizing venom and may compound the initial injury.[41]

Immediate In-Hospital Therapy The initial in-hospital assessment of a patient with a snakebite should focus on airway, breathing, and circulation. Early airway management with endotracheal intubation should be considered in all patients with bites to the face or tongue.[21] Intravenous (IV) lines should be placed and fluid boluses initiated. An epinephrine continuous infusion, starting at 0.1 µg/kg/minute and titrating as needed, is the vasopressor of choice for signs of shock. A complete medical history, including current tetanus immunization status and known allergies, should be obtained. A careful description of the bite and the extent of the local pathology should be documented, including measuring the diameter of the extremity and noting the extent of edema by marking the skin with a pen to help recognize progression of the envenomation. This evaluation should be repeated frequently as required by the clinical condition. A comprehensive physical examination should be done, with emphasis on vital signs, cardiorespiratory

and neurologic status, neurovascular status of the extremity, and evaluation for evidence of bleeding. A baseline complete blood count, electrolytes, urinalysis, creatinine, glucose, prothrombin time (PT), fibrinogen level, and platelet count should be obtained initially, with platelets, fibrinogen, and PT repeated in 4 to 6 hours.

Pain and anxiety should be alleviated and tetanus prophylaxis addressed. The extremity should be immobilized in a well-padded splint in near-full extension and elevated to avoid dependent edema. This is especially important with hand bites because significant swelling of the hand and forearm mimicking compartment syndrome may be avoided. The patient should be reassessed frequently with repeat physical examinations, specifically noting any progression of swelling. This may be accomplished by taking measurements of the circumference of the involved extremity at multiple points proximal to the wound.

Antivenom Therapy   For Crotalinae envenomations, antivenom should be considered as first line therapy for those patients with moderate to severe envenomations (see Table 121–3). Although each case must be individualized, in the vast majority of patients who have a moderate or severe envenomation, the benefits of antivenom therapy outweigh the risks. Antivenom given in a timely manner can reverse coagulopathy and thrombocytopenia and halt progression of local swelling. There is no evidence, however, that antivenom can prevent the development of tissue necrosis, so patients should be informed of the risk of tissue loss. This is most commonly noted with rattlesnake bites to the fingers, which occasionally lead to amputation of the digit despite appropriate treatment with antivenom.

The only currently available antivenom for North American pit viper envenomations is Crotalidae polyvalent immune Fab (CroFab™, Protherics, Savage Laboratories). CroFab is an ovine-derived Fab fragment antivenom developed from commonly encountered North American pit vipers. It is less allergenic than the previously available equine-derived Antivenin Crotalidae Polyvalent (Wyeth-Ayerst). CroFab is administered IV in an initial dose of four to six vials reconstituted in normal saline. The infusion is initiated at a slow rate, and if no signs of an anaphylactoid reaction develop, increased to complete the infusion over one hour. The patient should be reassessed after completion of the infusion for evidence of continued swelling or coagulopathy, and, if present, an additional four to six vial dose is infused. This process is repeated until control of symptoms is achieved. Control is generally considered cessation of progression of swelling and systemic symptoms in addition to improvement in coagulopathy and thrombocytopenia. After control has been gained, maintenance doses are given as two vials every 6 hours times three, for six total additional vials. Antivenom therapy is discussed in detail in Antidotes in Depth A36: Antivenom (Crotaline and Elapid).

Surgical Therapy   Envenomation may mimic a compartment syndrome by producing distal paresthesias, tense soft tissue swelling, pain on passive stretch of muscles within a compartment, and muscular weakness. However, because subfascial envenomation is uncommon, much of the impressive edema produced by envenomation does not occur in compartmentalized areas. Using noninvasive vascular arterial studies and skin temperature determinations in patients with rattlesnake envenomation, one report demonstrated that pulsatile arterial blood flow to an envenomated extremity actually increased after envenomation, even distal to the site of envenomation.[15] Compartment syndrome cannot be reliably diagnosed in envenomated extremities without directly measuring compartment pressures. Although there is little doubt that some crotaline bites may eventually require some surgical debridement or even skin grafting, the initial routine use of tissue excision or "exploration and debridement" is not recommended.[30,57] Fasciotomy is rarely needed and should be done only based on objective data of measured compartment pressures. Successful treatment of documented elevated compartment pressure after rattlesnake evenomation with antivenom

and mannitol alone has been reported.[26] Debridement of hemorrhagic blebs and blisters may be performed to evaluate underlying tissue and relieve discomfort. Some patients may require surgical debridement of necrotic tissue or even amputation of a digit 1 to 2 weeks after the bite. Referral to a hand surgeon is most appropriate for patients with evidence of extensive tissue necrosis. Physical therapy should be instituted early to ameliorate joint stiffness and decrease swelling.

Blood Products   Immeasurably low fibrinogen levels, prothrombin times greater than 100 seconds, and platelet counts lower than 20,000 are routinely encountered after rattlesnake envenomation, and such abnormal laboratory results alone should not prompt the clinician to treat with blood products in the absence of clinically significant bleeding. The circulating crotaline venom responsible for the initial bleeding diathesis is still present and will likely inactivate any component transfusions. For this reason, the mainstay of treatment for crotaline envenomation–induced coagulopathy is antivenom, not blood products. Correction of laboratory coagulation abnormalities and bleeding can frequently be achieved with antivenom alone. Monitoring trends in the coagulation profile is one objective way of assessing the seriousness of envenomation and the response to antivenom therapy.

Rarely, a patient will have active bleeding, and antivenom alone will not correct the coagulopathy. In such cases, fresh frozen plasma, cryoprecipitate, packed red blood cells, or platelet transfusions may be required. The criteria for the use of blood products appears to be quite arbitrary in clinical practice, but in general, blood products should be administered along with antivenom if the patient is actively bleeding.

Venom-induced thrombocytopenia that occurs after bites by many rattlesnake species is responsive to treatment with antivenom. The Timber rattlesnake, however, is known for producing thrombocytopenia resistant to antivenom. In some cases, thrombocytopenia may be difficult, or impossible, to totally correct with even large amounts of antivenom. The initial correction of platelet counts that occurs after treatment may be transient (lasting only 12–24 hours), with thrombocytopenia sometimes persisting for days to weeks after normalization of other coagulation parameters. In the absence of bleeding, thrombocytopenia is a benign, self-limiting disorder, resolving within 2 to 3 weeks of envenomations. It may be best to closely follow patients with resistant thrombocytopenia who are not bleeding clinically rather than attempt further platelet transfusions or antivenom administration.[13]

■ COPPERHEAD ENVENOMATIONS

Victims of proven copperhead bites should be observed for 4 to 6 hours and evaluated for signs of systemic involvement, the development of coagulation abnormalities, and progression of the local pathology. In the absence of progression of local symptoms and the lack of any systemic symptoms, this shorter observation period may be sufficient. In many instances, the entire care of a patient with a minimal copperhead envenomation can be accomplished in the emergency department, but a conservative approach is advised. Hospital admission for further observation is warranted for unreliable patients or if there are questions as to the identification of the snake or progression of symptoms.[50]

■ OTHER CONSIDERATIONS

Prophylactic antibiotics are not needed because studies show extremely low (0%–3%) rates of wound infections.[39] There is no rationale for the use of corticosteroids or antihistamines in the routine treatment of patients with snakebites, except for the rare case of anaphylaxis. Tetanus prophylaxis should be administered as clinically indicated.

Cardiovascular collapse is a life-threatening consequence of severe systemic crotaline envenomation and should be treated aggressively. It may

be prudent to use initial doses of eight to 10 vials of antivenom as opposed to the four to six vial doses indicated for mild to moderate envenomations, although this has not been studied. Blood pressure support with epinephrine may be required, and respiratory compromise should be anticipated in severe cases. Because of sudden and unpredictable respiratory paralysis associated with coral snake envenomation, tracheal intubation should be considered at the first sign of bulbar paralysis.

RECURRENCE PHENOMENA OF CROTALINE ENVENOMATION

In a significant proportion of patients treated with Crotalidae polyvalent immune Fab antivenom, a return of swelling, coagulopathy, or thrombocytopenia may be noted after initial successful resolution of the effect after antivenom initial treatment. This has been termed *recurrence of venom effect* and is attributed to the interrelated kinetics and dynamics of venom and antivenom.[4,54] Simply stated, Fab antivenom has a clinical half-life shorter than that of venom. Administration of "maintenance" doses of antivenom are used in an attempt to prevent development of recurrent effects. Anecdotally, this appears to be effective in preventing recurrence of local swelling in most cases, but many patients develop hematologic recurrence within 3 to 4 days of antivenom treatment despite administration of maintenance doses. Additionally, patients who never manifested thrombocytopenia or coagulopathy on their hospital presentation may later develop the effect, presumably because of initial "masking" of the effect by early antivenom. The exact clinical significance of these observations and the need for clinical intervention are uncertain. Currently, the most reasonable way to address possible recurrent hematologic effects of crotaline envenomation is careful outpatient follow-up after hospital discharge. The safest approach is to measure platelets and coagulation studies in all patients with rattlesnake envenomation 3 to 5 days after the last antivenom treatment. If values are abnormal or trending in the wrong direction, the studies should be repeated every few days until normalized. Patients should be advised to avoid surgical procedures and activities that place them at risk for injury. Opinions on when to retreat patients exhibiting recurrence with antivenom vary. Our general approach is to treat any patient with evidence of bleeding and recurrence, as well as patients with severe isolated thrombocytopenia (platelets <30,000/mm³) or moderate thrombocytopenia (platelets 30,000–50,000 /mm³) in combination with severe coagulopathy (fibrinogen <80 mg/dL). Many clinicians choose to cautiously observe patients with isolated coagulopathy as outpatients rather than to retreat them with antivenom.

SPECIAL CONSIDERATIONS FOR THE MANAGEMENT OF PREGNANT PATIENTS WITH SNAKEBITES

There is scant information available on the effects of poisonous snakebites during pregnancy. Case series show that although maternal death is rare, fetal demise may be as high as 43%.[18] Proposed mechanisms of injury to the fetus from envenomation include uterine artery hypotension with subsequent hypoxia, hemorrhagic complications such as abruptio placentae, and uterine contractions initiated by venom. As in each case of snakebite, it is prudent to evaluate the need for antivenom carefully during pregnancy. A single case report exists of a woman treated with CroFab in the third trimester of pregnancy without complications.[36] Given the relative safety of this antivenom and the high rate of fetal demise after envenomation, a low threshold for treatment should be considered. Fetal and maternal monitoring should be carried out throughout the patient's care.[19]

Repeated Exposure to Snake Venom.   Snake handlers and collectors are at risk for multiple bites over their careers, and questions have been raised

about possible immunity. No evidence was established that immunity develops as a result of repeated envenomation in one report of 14 patients with two or more bites.[46] Victims of repeat bites may actually be at greater risk for anaphylaxis because of prior sensitization and the development of IgE antibodies to venom.

TREATMENT OF CORAL SNAKE ENVENOMATION

The benign local effects of coral snake envenomation can be misleading and mistakenly equated with a dry bite.[44] Because it is difficult to judge initially which patients are envenomated, any patient with a confirmed coral snake exposure with fang marks or other evidence of skin penetration is recommended to receive antivenom therapy even in the absence of symptoms. This currently presents a problem because North American Coral Snake Antivenin, produced by Wyeth Pharmaceuticals, has been discontinued. Limited remaining supplies expired in October 2009. Until another antivenom becomes available, patients must be treated supportively with close observation and mechanical ventilation when indicated. Acetylcholinesterase inhibitors, neostigmine 0.5 mg, and edrophonium 10 mg have been successfully used to treat patients with South American coral snake bites, but their use should be considered experimental.[7]

A conservative approach is taken even for patients with less suspicion for envenomation. Any patient in whom coral snake bite cannot be excluded requires 24 hours of observation in a monitored unit where resuscitative measures, including endotracheal intubation, can be performed. Clinical deterioration may be totally unexpected and progress rapidly. In one series, 15% of patients required intubation and ventilation, but none died or suffered tissue loss or permanent neurologic sequelae.[37] Surgery is not a concern because no local tissue destruction is seen. Coral snake venom does not alter coagulation, so no bleeding diathesis is to be expected. Eastern coral snake envenomation can be fatal, but with supportive care and antivenom therapy, if available, patients usually recover completely.

EXOTIC SNAKEBITE

About 3% of poisonous snakebites reported in the United States are from nonnative species.[2,27] Many such snakes are owned by collectors, illegally imported, or stolen from zoos or pet stores. However, private individuals may easily purchase a plethora of vipers, cobras, and adders by mail or at reptile shows. Out of fear of legal retribution, some owners of exotic snakes can be quite vague about the circumstances of their envenomation. If they do not provide accurate identification, the local zoo, regional poison center, or herpetology society may be helpful in identification.

Bites from many nonnative Elapidae snakes, such as mambas, kraits, cobras, and several Australian species, are associated with high morbidity and mortality rates. Approximately one-third of bites from the king cobra are fatal.[27] Bites from these snakes may not display early local or systemic signs; therefore, the grading system developed for North American pit vipers is not helpful. Although local tissue destruction and edema may develop, classically, it is the neurologic signs, such as ptosis, dysphagia, muscular weakness, paresis, ophthalmoplegia, and respiratory failure that are noted. Cobra envenomation usually produces significant local toxicity, and these snakes are the only elapids whose venom possesses hemorrhagic activity.

Compression immobilization of an entire extremity with an elastic bandage (the Sutherland wrap) for the bite of some elapids (eg, sea snakes, kraits, cobras, and brown snakes) experimentally decreases the movement of elapid snake venom from the bite site to the systemic circulation and may be useful when antivenom is not available. This intervention, when it does not delay transport to medical care, has been recommended for bites from exotic elapids.[62] Local incision and suction should be avoided.

After the snake has been identified, attempts should be made to obtain appropriate antivenom. A good place to start is by contacting a regional poison center (800-222-1222) that has access to the Online Antivenom Index, a listing of available antivenoms for exotic snakes. Zoos may also stock exotic antivenoms and may be useful resources. Guidelines for the administration of antivenom for exotic snakes are vague and empiric. In addition, there is little standardization of the antivenoms for the same snake by different manufacturer. Because exotic snakes are generally quite poisonous, if fang marks are present, envenomation is strongly suspected, the snake has been identified, and the specific antivenom has been obtained, many physicians believe that it is logical to proceed with antivenom administration empirically. Antivenom is administered according to the package insert under the same monitoring guidelines as for crotaline antivenom. If the antivenom cannot be obtained then supportive care and close in-hospital observation, with prolonged mechanical ventilation in severe cases, may be all that is possible. Crotalidae polyvalent immune Fab (CroFab) may be effective in South American pit viper envenomations.[49]

One report documents rather dramatic reversal of the neurotoxic effects of a monocellate cobra (*Naja kaouthia*) bite after IV administration of the anticholinesterase neostigmine methyl sulfate (0.5 mg every 20 minutes for four doses).[24] The major neurotoxin from this snake is believed to resemble curare, causing a postsynaptic blockade of nicotinic neuromuscular receptor sites. The neurotoxicity from sea snakes and other elapids has been experimentally reversed with neostigmine.[53] Edrophonium chloride (10 mg administered IV with 0.5 mg of atropine) has also been suggested.

■ NONVENOMOUS SNAKEBITES

There are approximately 50,000 snakebites annually in the United States, and most (90%–95%) are from nonvenomous snakes.[25] Most snakes in the United States are nonvenomous, and the majority are of the Colubrid family, which are generally considered harmless to humans. However, several authors have reported toxic secretions from Duvernoy glands in many common species, including the hognose snake, garter snake, parrot snake, banded water snake, and ringneck snake.[28,43] Although no deaths have been reported, some victims developed coagulopathies and local edema and hemorrhage that could be confused with early crotaline envenomation.[41] There is no antivenom available to treat bites from these snakes, and serious complications from nonvenomous snakebites are extremely rare.

When there is no sign of envenomation after an appropriate period of observation after a suspected nonpoisonous snakebite, attention should be focused on the basic principles of wound care. Incision and suction, excision, and wide debridement are unnecessary in such bites. The wound should be treated as a contaminated puncture wound because it may contain foreign material, especially broken teeth. Any foreign material should be removed and an appropriate dressing applied. Certain large snakes of the Biodae family (not seen in the United States, except as pets or in zoologic gardens), including boas, pythons, and anacondas, may present a special problem because the force of contraction of their jaws may be great enough to cause severe tissue contusion or fractures and retained teeth. These reptiles also have numerous large, brittle teeth that commonly are broken off and lodged in the wound when the bitten part is forcibly extricated from the snake's mouth. Radiographs of the bitten area are needed to exclude fracture or foreign body.

Antibiotics are not recommended for routine use after nonvenomous snakebites. In one report, no infections occurred after snakebites in 72 patients bitten by a variety of nonpoisonous snakes indigenous to New England and imported boa constrictors and pythons.[59] Although *Clostridium tetani* has not been isolated from the mouths of snakes, the ubiquitous nature of this organism requires prophylaxis after the recommended approach for a contaminated wound. A cogent argument can be made for administering prophylactic antibiotics in nonvenomous snakebites if tooth fragments are retained or if there is significant soft tissue contusion. Outpatient therapy is appropriate; the patient should be instructed with regard to wound care and to seek medical care if signs of infection occur. Minor abrasions from nonvenomous snakes require only local wound care and tetanus prophylaxis. Delayed infection should prompt an investigation for a retained foreign body, especially a tooth fragment.[32]

■ OTHER POISONOUS REPTILES IN THE UNITED STATES

In North America, there are two indigenous species of venomous lizards that belong to the order Squamata, the same order as venomous snakes: the Gila monster (*Heloderma suspectum*) and the beaded lizard (*Heloderma horridum*). These lizards are found primarily in the desert areas of Arizona, southwestern Utah, southern Nevada, New Mexico, California, and Mexico. They are large, slow-moving, nocturnal, thick-bodied lizards that are prized by collectors and hobbyists. Adults are 30 to 40 cm long and are generally shy creatures, so bites are relatively rare and usually secondary to handling. Gila monsters are known for their forceful bites and propensity to hang on tenaciously during a bite, and they may be difficult to disengage. Some rather innovative anecdotal techniques have been developed to remove a Gila monster from an extremity, including the use of chisels, screwdrivers, and crowbars; pouring gasoline or ammonia into the lizard's mouth; or holding a flame to the animal's jaw. Teeth may break off in the wound.

Gila monster venom is complex, containing components similar to those of snake venoms, including numerous enzymes, hyaluronidase, phospholipase A, kallikrein, and serotonin.[31,52] Helothermine is the suspected toxin. Their venom delivery systems are not as efficient as those of poisonous snakes and consist of venom glands and grooved teeth rather than fangs. Dry bites often occur because of the ineffective mechanism of delivery. After skin puncture and venom release, the victim experiences local tenderness and soft tissue swelling, pain, and edema. There are occasional reports of anaphylactoid reactions; hypotension; angioedema of lip, tongue, and throat; respiratory depression; coagulopathy; and myocardial infarction.[47,48] Significant tissue destruction is unusual, but maceration may occur, and a cyanosis or blue discoloration is noted about the wound. There is no antivenom available against lizard venom. Treatment consists of avoiding over-aggressive local treatment and providing supportive care and wound care. Epinephrine, corticosteroids, and antihistamines may be indicated for the treatment of anaphylactoid reactions. Serious morbidity from lizard bites is unusual. The characteristics of the beaded lizard are similar, but their bites are less commonly confronted clinically.

SUMMARY

Clinicians face numerous critical decisions when treating patients with venomous snakebites. These patients should be rapidly assessed for signs and symptoms of envenomation through a careful history and examination along with judicious use of laboratory data. For significant envenomations, supportive care and early use of antivenom, when available, are the mainstays of treatment.

ANTIDOTES IN DEPTH (A36)

ANTIVENOM (CROTALINE)

Anthony F. Pizon, Bradley D. Riley,
and Anne-Michelle Ruha

For decades Wyeth-Ayerst (Marietta, PA) manufactured Antivenin Crotalidae Polyvalent (ACP) for treatment of crotaline snakebites in the United States. It was a poorly purified whole IgG product derived from horse serum with significant risk for acute and delayed allergic reactions.[10] ACP was formulated as a freeze-dried powder that required reconstitution before use. Wyeth has since stopped production of ACP, though expired supplies may still be available. Previous editions of this textbook contain details about Wyeth ACP.

In October 2000, the US Food and Drug Administration approved Crotalidae polyvalent immune Fab, manufactured by Protherics Inc (Savage Laboratories, Brentwood, TN). This antivenom is derived from sheep serum and formulated specifically to treat crotaline snakebites found in the United States. It is an effective and less allergenic alternative to the previously manufactured horse serum product and is currently the only crotaline antivenom available in the United States.[10,14]

A limited number of bites from exotic nonnative snakes, kept in zoos and by amateur collectors, occur in North America each year. Numerous antivenoms exist to treat bites from these exotic snakes, but they are of limited availability and difficult to obtain. Poison centers have access to the online Antivenom Index, which is useful when attempting to locate antivenom for a nonnative snake envenomation. Local zoos may also be useful resources when attempting to locate an exotic antivenom. Recommendations for these diverse antivenoms are difficult to make, but any available package instructions should be followed, and preparations should be made to treat life-threatening hypersensitivity reactions when using these unfamiliar products.

CROTALIDAE POLYVALENT IMMUNE Fab (OVINE)

Crotalidae polyvalent immune Fab (ovine), marketed under the brand name CroFab™, is produced by inoculating sheep with the venom of the eastern diamondback rattlesnake (*Crotalus adamanteus*), western diamondback rattlesnake (*Crotalus atrox*), cottonmouth (*Agkistrodon piscivorus*), and Mojave rattlesnake (*Crotalus scutulatus*). The refining process begins with papain digestion of isolated IgG antibodies to eliminate the Fc portion of the immunoglobulin, and then isolation of the antibody fragments [Fab and F(ab)$_2$]. This is followed by affinity purification and lyophilization. The resultant Fab fragments have a smaller molecular weight, are less immunogenic, and have increased tissue penetration compared with whole IgG antivenoms used previously.

■ CLINICAL USE

After an envenomation, the major indications for administration of antivenom are (1) hemodynamic compromise, (2) significant coagulopathy or thrombocytopenia, (3) neuromuscular toxicity, or (4) progression of swelling. These indications are vague and allow clinical interpretation of the need for antivenom under varying circumstances. Antivenom should not be given prophylactically to patients with minimal symptoms, or in the absence of evidence of envenomation. Patients with only minimal local tissue swelling that is not progressing should not be given antivenom.

When indicated, antivenom should be given as soon as possible to neutralize circulating venom. Animal studies report decreased mortality when antivenom is given immediately after envenomation.[5] Antivenom will not reverse swelling and tissue necrosis that has already occurred, and tissue necrosis may develop despite administration of antivenom. However, since antivenom will halt but will not reverse tissue injury, it makes sense that early administration is expected to reduce the pain and loss of function associated with a significant swelling of an extremity. A delay in treatment lessens the beneficial effects of antivenom in animal models,[7] and it is unknown how long antivenom remains effective following an envenomation. Anecdotally, antivenom may reverse venom-induced coagulopathy even if administered more than 24 hours after the bite.

In addition to halting the progression of local tissue swelling, antivenom can at least temporarily reverse systemic effects, including most coagulation and platelet defects.[2,8,9,11] While there are no studies comparing outcomes of envenomated patients treated with and without antivenom, it is generally agreed that antivenom reduces morbidity in patients with significant crotaline envenomation and in some situations may be a lifesaving therapy.[8]

■ TECHNIQUE OF ADMINISTRATION

A thorough history regarding asthma, atopy, use of β-adrenergic antagonists, food allergies, and previous use of antivenoms should be obtained. According to the manufacturer, the only absolute contraindication is an allergy to papaya or papain, which can still be present in residual amounts after the manufacturing process. A history of asthma, atopy, or use of β-adrenergic antagonists should be carefully considered when weighing the risks and benefits of antivenom. These conditions should not exclude the use of antivenom if the patient is suffering from a moderate to severe envenomation (see definitions below). Since antivenom is ovine derived, previous reactions to equine-derived antivenoms should not preclude its use. In cases of mild envenomation, the risk of allergic reaction to antivenom or difficulty in effectively treating an allergic reaction in a patient receiving β-adrenergic antagonists might outweigh any benefit of therapy. Antivenom should be administered in a monitored setting where resuscitation can be performed and airway supplies can be quickly accessed. Epinephrine, steroids, and antihistamines should be immediately available in the event a hypersensitivity reaction occurs.

Antivenom is packaged in vials as a lyophilized powder that must be reconstituted. Completely filling each vial with 25 mL of sterile water, rather than the 10 mL advised in the package insert, and then gently hand rolling the vials will result in dissolution times as rapid

as 1 minute. Adding the greater volume also reduces foaming of the product.[6,13]

The initial recommended dose is four to six vials, which is mixed in 250 mL 0.9% sodium chloride solution and administered over 1 hour. The exact concentration of antivenom is not critical. For children, the total volume of fluid in which the antivenom is diluted can be decreased when necessary.[12] No dosing adjustment is required for children or small adults because the amount of venom requiring neutralization is not dependent upon the patient's weight. On the other hand, there is no justification for partial doses or infusions of one or two vials in minor cases.

In order to avoid serious adverse reactions, the first dose of antivenom is administered cautiously in an escalating-rate fashion. No skin testing is suggested. The first dose of antivenom (four to six vials diluted in 250 mL 0.9% saline) is infused at an initial rate of 10 mL/h while the patient is observed carefully for evidence of hypersensitivity. If no adverse reactions are witnessed, then the rate is doubled every few minutes, as tolerated by the patient, with the goal of infusing the first dose over 1 hour. If the patient tolerates the initial dose without adverse effects, subsequent doses can be given at a rate of 250 mL/h without need for titration of rate.

The total dose of antivenom required to *control* an envenomation may vary widely, so additional doses may be needed to halt swelling and/or reverse coagulopathy or thrombocytopenia. With the introduction of Crotalidae polyvalent immune Fab (ovine), *control* was defined as arrest of local tissue manifestations and return of coagulation parameters, platelet counts, and systemic signs to normal. However, clinical experience demonstrated that some patients have venom-induced coagulopathy and thrombocytopenia that is resistant to antivenom treatment.[14] Therefore, we advocate *control* to mean clear improvement in hematologic parameters rather than complete normalization.[14] This definition may be more realistic, especially for patients with difficult-to-treat coagulopathy and thrombocytopenia. After each dose of four to six vials, prothrombin time, fibrinogen, and platelet counts are determined, and the patient's local injury is reexamined. Multiple doses are often required to achieve control. If repeat dosing is necessary to control swelling, but fibrinogen, prothrombin time and platelets remain normal, then these laboratory studies do not need to be repeated after each additional control dose. After achieving control, maintenance doses of two vials every 6 hours are given, for a total of three doses. Again, the two vials are added to 250 mL 0.9% sodium chloride solution and administered over 1 hour. Because the duration of action of antivenom is less than that of venom, the maintenance doses are given in an attempt to prevent recurrence of local manifestations, thrombocytopenia, and coagulopathy. An algorithm describing this approach is shown in Fig. A36–1.

Some patients will demonstrate recurrence of swelling during their maintenance infusions. For this reason close monitoring of extremity swelling should occur for 18 to 24 hours after apparent control has been achieved. If recurrent swelling occurs, additional control doses of four to six vials should be given until the swelling again becomes controlled. Likewise, despite successful completion of maintenance antivenom doses, patients may develop a recurrence of coagulopathy and/or thrombocytopenia, in which case additional antivenom should be considered.

■ ADVERSE REACTIONS

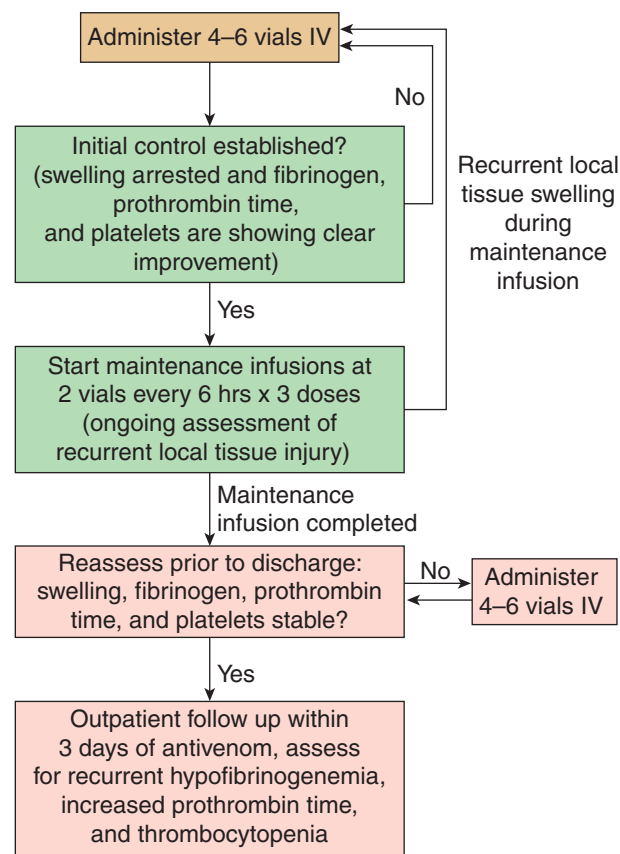
Despite reduced immunogenicity, acute and delayed hypersensitivity reactions to antivenom are well reported.[3,4] Urticaria, rash, bronchospasm, pruritus, angioedema, anaphylaxis, and delayed serum sickness all are associated with use of this product.[9,14] Acute reactions are


FIGURE A36–1. Algorithm for the administration of Crotalidae polyvalent immune Fab (ovine) antivenom for moderate to severe North American crotaline snake envenomation.

reported in 5.4% to 14.3% of patients, while delayed hypersensitivity reactions occur in 16% of patients.[3,8]

When antivenom is administered too rapidly, nonimmunogenically mediated anaphylactoid reactions may occur. In general, patients appear to tolerate four to six vials per hour without developing anaphylactoid reactions. If the patient requires rapid administration of antivenom because of the severity of the envenomation, H_1 and H_2 histamine receptor antagonists may be needed in addition to an epinephrine infusion. Clinically differentiating between anaphylactoid and anaphylactic reactions may be difficult, especially when antivenom is administered rapidly. Regardless, the treatment remains the same.

For acute anaphylactic reactions (which often occur shortly following initiation of even low doses of antivenom), the antivenom should be stopped and intravenous steroids, H_1 and H_2 histamine receptor antagonists, and epinephrine given. Epinephrine 2 to 4 µg/min (0.03–0.06 µg/kg/min for children) can be initiated and then titrated to effect. After the symptoms of hypersensitivity resolve, the antivenom should be restarted only in patients at high risk for significant morbidity or mortality from snake envenomation. In such cases, the antivenom infusion is restarted at 1 to 2 mL/h, while the epinephrine infusion is continued. The antivenom infusion rate can be slowly increased as tolerated. If anaphylaxis recurs, the antivenom should be stopped and the epinephrine infusion increased until symptoms resolve. Antivenom once again can be restarted while epinephrine is continued at the higher rate. With constant monitoring of patients at the bedside and titrating epinephrine and antivenom infusions, most patients with

life-threatening envenomation should tolerate the full antivenom dose. Patients have safely received subsequent doses of antivenom after an acute life-threatening reaction.[4]

In addition to acute allergic reactions, delayed hypersensitivity syndromes in the form of serum sickness may occur. Mild cases of serum sickness consist of urticaria, pruritus, and malaise. Occasionally arthritis, lymphadenopathy, and fever develop. Immune-complex glomerulonephritis, neuritis, vasculitis, and myocarditis occur rarely. The syndrome of serum sickness after antivenom use has not been well characterized or studied, but usually it is neither serious nor associated with chronic sequelae.[10] Most patients respond favorably to antihistamines and corticosteroids. Immediately after onset of symptoms, prednisone (2 mg/kg divided into twice daily oral dosing) is given and tapered over 2 to 3 weeks. Oral antihistamines can be used for symptomatic treatment as well. The vast majority of patients can be managed as outpatients.

At the time of discharge, the patient should be informed of the possibility of recurrent venom effects and told to refrain from activities associated with high risk for trauma and to avoid any surgical procedures for 3 weeks. The patient should receive instructions to watch for signs of bleeding, which may be associated with coagulopathy or thrombocytopenia. Recurrence occurs in approximately 25% to 50% of patients with rattlesnake envenomation who receive this antivenom.[1,14] Follow-up prothrombin time, fibrinogen concentration, and platelet count should be obtained within 3 to 5 days of antivenom completion in all patients. In most patients who develop recurrence, the decrease in platelets or increase in prothrombin time is evident within 3 days of the last antivenom therapy. Since early administration of antivenom may have masked the findings in patients who initially did not demonstrate coagulopathy or thrombocytopenia, and these patients still may develop these effects within days of completing antivenom treatment, follow-up coagulation studies are recommended in all cases.

Treatment recommendations vary for delayed recurrence of venom effects. Clinical experience demonstrates that delayed recurrence may be resistant to additional antivenom,[14] so the benefits of retreatment in the absence of active bleeding are unclear. No specific dosing regimen for retreatment is known at this time. In our practice, where we frequently encounter recurrence, our general approach is to only retreat patients who develop (1) severe isolated thrombocytopenia (platelet count less than 20,000–30,000/mm^3), (2) moderate thrombocytopenia (platelet count less than 30,000–50,000/mm^3) with severe coagulopathy (fibrinogen less than 80 mg/dL), or (3) active bleeding. A more conservative approach can be used for patients with additional risk factors for bleeding, such as increased risk for trauma or use of anticoagulants. Other patients with less severe recurrence, or isolated coagulopathy without thrombocytopenia, usually can be managed as outpatients with close follow-up and repeat laboratory tests every few days. Increased local tissue swelling at the time of follow-up usually is not an indication for redosing antivenom and most often is the result of dependent edema from inadequate extremity elevation. In the absence of any recurrence phenomenon, patients should have regular telephone follow-up for 3 weeks to check for signs of serum sickness.

ELAPID ANTIVENOM (EQUINE ORIGIN)

The production of North American Coral Snake Antivenin (Wyeth-Ayerst, Marietta, PA) for treatment of envenomation by the eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*Micrurus tener*) was recently discontinued. Limited supplies are still available with an

expiration date of October 2009. This equine-derived coral snake antivenom does not treat envenomation from coral snakes found in Mexico, Central America, or South America. Additionally, toxicity requiring treatment with antivenom has not been reported following bites from the less virulent Arizona (Sonoran, *Micruroides euryoxanthus*) coral snake.

In contrast to the recommendation to withhold crotaline polyvalent antivenom unless signs of significant envenomation are evident, prophylactic use of coral snake antivenom is recommended in any asymptomatic patient where a coral snake bite is assumed or proven.[11] For a number of hours following the bite of a coral snake, little objective evidence suggests envenomation, but systemic symptoms can develop insidiously. Therefore, at least three to five vials of coral snake antivenom are given initially and repeated on the basis of the clinical condition. The caveats for administration of crotaline antivenom discussed above (rate of infusion and treatment of allergic reactions) apply to coral snake antivenom, except less antivenom usually is required for coral snake bites. Up to 10 vials can be administered, but dosing recommendations are vague. Limited supplies of this antivenom may make adherence to this recommendation difficult.

If no antivenom is available, the mainstay of treatment will consist of aggressive supportive care. In particular, respiratory failure requiring intubation may ensue from muscle paralysis. This would require supporting the patient's respirations until recovery. With respiratory support, paralysis is completely reversible. However, it may take weeks to months to resolve completely.

SUMMARY

Antivenom, combined with good supportive care, is effective in the management of North American snake envenomations. All antivenoms are derived from foreign proteins and are capable of producing acute and delayed hypersensitivity reactions in humans. While crotaline polyvalent immune Fab appears to produce fewer hypersensitivity reactions than whole immunoglobulin antivenoms, the healthcare provider must be aware of the possibility of life-threatening reactions resulting from use of this product and be prepared to effectively treat a reaction should one occur.

M.
OCCUPATIONAL AND ENVIRONMENTAL TOXINS

CHAPTER 122

INDUSTRIAL POISONING: INFORMATION AND CONTROL

Peter H. Wald

Many important problems are associated with the diagnosis and treatment of occupational and environmentally caused diseases, including (1) the ability to establish correctly the diagnosis, (2) the ability to treat the condition correctly, and (3) the ability to act correctly on any public health issues related to the exposure. The following discussion instructs clinicians on how to assemble adequate information to achieve the appropriate diagnosis and treatment.

TAKING AN OCCUPATIONAL HISTORY

Because time spent at work is a large percentage of many people's day, the occupational health history should be a routine part of any medical history. This is especially true of patients who present to a physician with potential xenobiotic exposures at work or unusual symptoms. The history should include several brief survey questions. Positive responses then lead to a more detailed occupational and environmental history, which is composed of three elements: present work, past work, and nonoccupational exposures.

■ THE BRIEF OCCUPATIONAL SURVEY

The following three questions should be incorporated into the occupational survey:

Exactly what kind of work do you do?

Are you exposed to any physical (radiation, noise, extremes of temperature or pressure), chemical (liquids, fumes, vapors, dusts, or mists), or biologic hazards at work (Table 122–1)?

Are your symptoms related in any way to starting or being away from work? For example, do the symptoms start when you arrive at work at the beginning of the day or week or when you work at a specific location or during a specific process at work?

■ PRESENT WORK

Collected data on a person's present job reveal what his or her present exposures may be, which can help formulate the differential diagnosis

for the employee's complaints. These data can be systematically collected by focusing on four areas: specifics of the job, hazardous exposures, health effects, and control measures (Table 122–2).

Specifics of the Job It is not sufficient simply to inquire what the patient does for a living. Similar to healthcare professionals, workers in other industries have their own jargon. When asked for a job title, a patient may respond with a title that has meaning only in his or her trade. Even if the job title is recognizable, it may not provide any useful information and, in fact, may be misleading. A secretary working in a small plastics manufacturing plant may have occupational exposures that are quite different from a secretary who works for a law firm.

The important specific information requested should include the name of the employer, type of industry, duration and location of employment, hours and shift changes, process description (including unusual occasional activities), and adjacent processes. The employer may be able to provide information about materials used at the plant. However, clinicians should always obtain the patient's permission before calling the employer. A patient may be fired or otherwise discriminated against (despite legal protections) for suggesting that health problems are work related.

It is important to learn precisely what happens in the patient's immediate work environment because nearby work processes may contribute other exposures. If possible, the patient should be asked for a diagram of the work area. The patient also should be questioned about job process changes. A previously safe job may have been changed to a potentially dangerous job without a change in the patient's job title.

The patient should describe exactly what he or she does on any given day and for how long. Unusual and nonroutine tasks, such as those performed during overtime, maintenance, or in an emergency, should also be described. The primary job may not involve xenobiotics, but the patient may nevertheless perform tasks that entail unprotected exposure to a toxic xenobiotic.

Hazardous Exposures The names or types of all xenobiotic to which the patient may be exposed are important in determining potential adverse effects and any relationship to the patient's complaints. It is important to elicit any recent changes in suppliers of these products because even a slight change in the formulation of a xenobiotic may cause adverse effects in an individual who previously had no problems working with that compound. This information may be obtained from the material safety data sheet (MSDS), an important but not universally reliable source of information about the xenobiotic. In addition to adverse health effects, the MSDS contains information on chemical reactivity, safety precautions, and other data. As an initial step, the MSDS should be requested and reviewed; however, information provided on health effects should be confirmed using other resources. Four major concerns result from relying solely on the MSDS: (1) some MSDS forms are excellent, but others are incomplete and inadequate; (2) components of a product that are regarded as "trade secrets" do not

TABLE 122–1. Hazard Classes, Hazard Types, and Several Common Examples Found in the Workplace

Hazard Class	Hazard Type	Examples
Physical hazards	Human–machine interfaces	Repetitive motion
		Lifting
		Vibration
		Mechanical trauma, electric shock
	Physical environment	Temperature
		Pressure
		Long or rotating shifts
	Energy	Ionizing radiation: x-ray, ultraviolet
		Nonionizing radiation: infrared, microwave, magnetic fields
		Lasers
		Noise
Chemical hazards	Solvents	Aliphatics, aromatics, alcohols, ketones, ethers, aldehydes, acetates, peroxides, halogenated compounds
	Metals	Lead, mercury, cadmium
	Gases	Combustion products, irritants, simple and chemical asphyxiants, oxygen-deficient environments
	Dusts	Organic (wood) and inorganic (asbestos or silica)
	Pesticides	Organic chlorine, organic phosphorus, carbamate
	Epoxy resins and polymer systems	Toluene diisocyanate, phthalates
Biologic hazards	Bacteria	*Bacillus anthracis, Legionella pneumophila, Borrelia burgdorferi*
	Viruses	Hepatitis, HIV, Hantavirus
	Mycobacteria	*Mycobacterium tuberculosis*
	Rickettsia and *Chlamydia*	*Chlamydia psittaci, Coxiella burnetii*
	Fungi	*Histoplasma capsulatum, Coccidioides immitis*
	Parasites	*Echinococcus* spp, *Plasmodium* spp
	Envenomations	Arthropod, marine, snake
	Allergens	Enzymes, animals, dusts, insects, latex, plant pollen dusts

TABLE 122–2. Components of an Occupational Health History

Current work history
  Specifics of the job
    Employer's name
    Type of industry
    Duration of employment
    Employment location, hours, and shift changes
    Description of work process
    Unusual activities of the job that are occasional (eg, maintenance)
    Adjacent work processes
  Hazardous exposures (see Table 122–1)
  Possible health effects
    Suspicious health problems
    Temporality of symptoms
    Specific distribution of symptoms (rash, paresthesias)
    Affected coworkers
    Presence or absence of known risk factors (smoking, alcohol)
  Workplace sampling and monitoring

  Outdoor activities
  Residential exposures
  Community contamination
  Habits: tobacco, alcohol, other xenobiotics

have to be revealed; (3) components that have important health effects (eg, solvent or solid carriers of the "active ingredients") often may be grouped together under "inert ingredients" without being specifically named; and (4) process intermediates or unintended byproducts of a manufacturing process may not be identified. However, if a xenobiotic is believed to be related to a health effect, manufacturers are required to release to a physician all information, including trade secrets and inert components.

Exposures to physical and biologic xenobiotics can be elicited during the review of job processes. Most patients know what they are, or have been, exposed to, even if they do not know the exact name of the xenobiotics or its medical effects.

TABLE 122–3. Evidence Supporting Work-Relatedness of Occupational Disease

Known or documented exposure to a causative xenobiotic

Symptoms consistent with suspected workplace exposure

Suggestive or diagnostic physical signs

Similar problems in coworkers or workers in related occupations

Temporal relationship of complaints related to work

Confirmatory environmental or biologic monitoring data

Scientific biologic plausibility

Absence of a nonoccupational etiology

Resistance to maximum medical treatment because employee continues to be exposed at work

---

Health Effects Significant occupational exposures usually cause medical effects, although some do so only after a substantial latency period. Key areas of inquiry include suspicious health problems, temporality of symptoms, and affected coworkers. These data, combined with workplace monitoring and sampling data, may help in determining whether the patient is experiencing a work-related illness (Table 122–3). Patients may suspect that their illness or complaint is work related, especially when symptoms occur at the workplace and improve or disappear over the weekend or during a vacation. Specific distribution of findings, such as a rash in a bilateral glove pattern, is supportive of an occupational cause. Coworkers with similar complaints (not necessarily of the same severity) should raise suspicion that a workplace exposure is responsible for a particular symptom complex. Diseases such as lung cancer or hepatitis, which occur in the absence of known risk factors such as smoking and alcohol, must be epidemiologically investigated.

Workplace Sampling, Monitoring, and Control Control of workplace hazards begins with an industrial hygiene monitoring program. Employers are required to give results of both area and individual sampling to employees. A medical surveillance program that includes periodic spirometry and respiratory questionnaires usually indicates that the patient works with a potential respiratory toxin. A medical surveillance program that includes biologic monitoring for a specific xenobiotic may also provide an immediate clue to what may be causing the patient's complaints. Finally, if the patient knows exactly what he or she is working with, the physician can usually quickly determine whether any of the xenobiotics are compatible with the patient's complaints. Many companies do not perform routine industrial hygiene monitoring or medical surveillance. Individuals who become sick or ill at work are often sent to local emergency departments. In such situations, emergency physicians may need to perform the type of time-consuming, detailed occupational history outlined here or be able to consult or refer immediately to appropriate physicians or clinics.

Portions of Table 122–2 and the following section on Evaluation and Control of Workplace Hazards detail the types of controls typically used in workplaces. It is important to determine whether the workplace uses any control measures, engineering controls, work practice protocols, administrative controls, or personal protective equipment. The existence of control measures usually indicates that the employer recognizes and has attempted to deal with a hazardous exposure.

■ PAST WORK

It is important not to limit the occupational history to the patient's current workplace and job. Many occupational diseases have long latency periods between xenobiotic exposure and initial development of clinical symptoms. In addition, patients may have been exposed to xenobiotics at work that make them more sensitive to other environmental xenobiotics. For example, someone who developed asthma secondary to a previous workplace exposure may have asthma attacks upon exposure to simple irritants in the current workplace. When taking an in-depth occupational history, issues that may be relevant to the current work history as well as for each previous job should be explored.

■ NONOCCUPATIONAL EXPOSURES

Workers may be exposed to toxic xenobiotics in the course of pursuing secondary employment, hobbies, or outdoor activities in contaminated or industrial areas. Residential exposures, such as those from gas and wood stoves, chemically treated furniture and fabrics, and pest control, may be relevant. It is important to ask patients about these potential exposures before focusing entirely on exposures in their primary place of employment. This obviously includes relevant issues from the social history, such as tobacco, alcohol, and licit and illicit drug use.

EVALUATION AND CONTROL OF WORKPLACE HAZARDS

■ INITIAL WORKPLACE EVALUATION

The Occupational Safety and Health Act (OSHA) places legal responsibility for providing a safe and healthy workplace on the employer. The rationale for this placement of responsibility is that the employer is in the best position to make any modifications necessary to prevent additional work-related illness and injury. The physician may wish to initiate a dialogue with a patient's employer to promote preventive action but should do so only with the patient's informed consent. The initial treating physician may also refer the patient to an occupational medicine specialist, who is specifically trained to manage work-related exposures and diseases and initiate prevention programs.

Because the initial contact may influence subsequent events, it is important to identify an individual with an appropriate administrative role, such as someone in the company's medical department, the patient's supervisor, the plant's safety officer, or the shop manager. If management is willing to examine the hazardous conditions, a plant walk-through inspection can provide unique insight and information usually unavailable in an office setting. A walk-through by an occupational medicine specialist makes it easier to understand the work environment, identify safety and health hazards, assess control measures, and recognize opportunities for prevention. It also facilitates a good working relationship with key personnel in management and labor. The physician who cares for a number of patients who work in the plant or who provides health services to the workers through the company or labor union may wish to be involved in the walk-through. Assistance with plant inspections can be obtained from occupational health specialists, such as occupational physicians or industrial hygienists.

■ INDUSTRIAL HYGIENE SAMPLING AND MONITORING

Equipment is available to measure airborne concentrations of toxic xenobiotics, noise levels, radiation levels, temperature, and humidity. Employees can be fitted with pumps and other devices to measure individual exposure concentrations at the breathing zone, where, depending

on what controls are used, concentrations may vary from those in the general work area. These results then can be compared with OSHA standards and other available standards to help determine the extent of the hazard and to formulate a control plan. OSHA requires that employers monitor the concentrations of only a few specific hazards, including arsenic, asbestos, benzene, cadmium, chromium, cotton dust, ethylene oxide, formaldehyde, lead, noise, and vinyl chloride. A complete listing of all xenobiotics is available in the OSHA standard *29 CFR 1910 Part Z—Toxic and Hazardous Substances (*http://www.osha.gov/pls/oshaweb/owastand.display_standard_group?p_toc_level=1&p_part_number=1910). In addition, monitoring is required for certain operations such as hazardous waste operations or entering a confined space that may have an oxygen-deficient atmosphere. Ongoing sampling of the remaining estimated 60,000 xenobiotics used in the workplace is not required. Where industrial hygiene sampling is performed, OSHA's medical access standard gives any exposed worker or his or her representative the right to review and copy all sampling data.

■ CONTROL OF WORKPLACE HAZARDS

Workplace hazard control traditionally has relied on a hierarchy of methods to protect workers from exposure. The preferred solution is complete elimination of the hazard by *substitution*. When substitution is not possible, the next preferred method consists of shielding for workers to reduce their exposure. The least favored method is personal protective equipment, which requires a positive action from the worker.

Engineering Controls Health and safety professionals prefer and OSHA regulations require when feasible the use of engineering controls to reduce worker exposure to hazardous xenobiotics. These controls intercept hazards at their source or in the workplace atmosphere before they reach the worker. Engineering controls include redesign or modification of process or equipment to reduce hazardous emissions; isolation of a process through enclosure; automation of an operation; and installation of exhaust systems that remove hazardous dusts, fumes, and vapors. Local exhaust systems, such as hoods, are preferable to general dilution ventilation because the former removes contaminants closer to their source and at relatively high rates.

Engineering controls have several advantages over control measures focused on the worker. Properly installed and maintained engineering controls are reliable and consistent, and their effectiveness does not depend on human supervision or interaction. They can simultaneously limit exposure through several routes, such as inhalation and skin absorption. In addition, engineering controls do not place a burden on the worker or interfere with worker comfort or safety.

Work Practices Work practices are procedures that the worker can follow to limit exposure to hazardous xenobiotics. Examples are the use of high-powered vacuum cleaners instead of compressed air cleaning and pouring techniques that direct hazardous xenobiotics away from the worker. Although not as effective as engineering controls, work practice can be a useful component of an overall hazard control program.

■ ADMINISTRATIVE CONTROLS

Administrative controls reduce the duration of exposure for any individual worker or reduce the total number of workers exposed to a hazard. Examples are rotating workers into and out of hazardous areas so that no single worker is exposed full time and scheduling procedures likely to generate high levels of exposure, such as cleaning or maintenance activities, during nights or weekends. Administrative controls sometimes have the side effect of exposing more workers to a hazard, albeit at lower doses that are hoped do not cause health effects.

Personal Protective Equipment Personal protective equipment, such as respirators, earplugs, gloves, and hard hats, is the least effective but most commonly used control method. Personal protective equipment may be the only viable protection strategy when other controls are not practical but can also be used as an additional layer of protection in the presence of engineering controls. Some employers may favor personal protective equipment over the institution of more costly engineering and administrative controls.

Respirators and other forms of personal protective equipment often are hot, uncomfortable, and awkward to wear and may make it difficult for workers to breathe, speak, or hear, depending on the equipment involved. Consequently, workers often remove or refuse to wear the protection. Respirators place extra stress on the heart and the lungs. Both respirators and earplugs limit conversation and therefore present a safety hazard in themselves.

Because personal protective equipment does not stop a hazard from entering the environment, the worker is entirely vulnerable to exposure if the equipment fails. In addition, generally only one route of exposure is protected. For example, the commonly used half-mask respirator still leaves the skin and eyes exposed.

Choosing the right piece of personal protective equipment can be difficult and may depend on the nature and extent of the hazard. For example, each type of respirator is rated for the amount of protection it provides; as expected, the cost of a respirator increases with its protection factor. Use of the wrong type of respirator can leave the worker insufficiently protected.

Half-mask respirator cartridges are available in various colors that are coded to the xenobiotic filtered out of the breathing environment. If the wrong cartridge is used, the worker is essentially unprotected from the hazardous contaminant. To be effective, a respirator must be meticulously fit to the individual worker. Failure to achieve a proper seal negates the respirator's usefulness. High cheekbones, dentures, scars, perspiration, talking, head movements, and facial hair can prevent a proper seal. These factors often are ignored or overlooked by an employer who adopts a "one-size-fits-all" policy.

Even if each employee is provided the proper respirator, the respiratory protection program may not be effective. OSHA requires that employers institute a program of proper fit testing, cleaning, maintenance, and storage of respirators, which can be at least as costly as the institution of engineering controls.

In some instances, use of personal protective equipment may be unavoidable. An employer may need to control a hazardous exposure through a combination of measures, such as engineering controls and personal protective equipment. Ideally, the employer is using personal protective equipment as a control of last resort and in strict compliance with OSHA standards.

Worker Education and Training Regardless of the control measures used, workers and supervisors must be educated in the recognition and control of workplace hazards and the prevention of work-related illness and injury. The OSHA Hazard Communication Standard requires that employers train workers in ways to detect the presence or release of hazardous xenobiotics, their physical and health hazards, methods of protection against the hazards, and proper emergency procedures, as well as how to read the labeling system and how to read and use an MSDS.

With the passage of federal, state, and local right-to-know laws, many consulting companies now offer hazard communication training. These programs are of uneven quality. Those that tend to focus on acute hazards, ignore chronic effects, and emphasize personal protective equipment over other control measures may not be effective in training workers to recognize and control hazardous xenobiotics.

Medical Monitoring Together with worker education and industrial hygiene, a medical program can form the foundation of an effective

occupational disease prevention regimen. However, medical monitoring is fraught with technical and ethical pitfalls. Medical monitoring encompasses both medical screening and medical surveillance.

Medical screening refers to the cross-sectional testing of a population of workers for evidence of excessive exposure or early stages of disease that may or may not be related to work and that may or may not influence the ability to tolerate or perform work.

Preemployment and preplacement physical examinations are another type of medical screening that are often favored by employers. The Americans with Disabilities Act (ADA) and the new ADA Amendment Act of 2008 (ADAAA) regulate the timing, scope, content, and use of these examinations and the information gathered. Comprehensive resources for information on the ADA are available at http://www.adata.org. The ADA prohibits "preemployment" medical examinations and inquiries. After a job offer has been made, "preplacement" examinations and inquiries can be conducted to determine whether an applicant can perform a job safely and effectively. The physician evaluates the individual's medical history, current symptoms, and physical laboratory findings to determine whether he or she currently has the physical or mental abilities necessary to perform the essential functions of the job and whether the individual can do so without posing a "direct threat" to the health or safety of him- or herself or others. This threat must be more than theoretical and cannot be based on some future time; the threat must be concrete and relatively immediate.

Few tests and few conditions are good predictors of either the ability to perform a task or increased susceptibility to a particular exposure. Many workers and their advocates view preplacement examinations as a way for employers to choose the "fittest" worker and to avoid their legally mandated obligation to provide a safe and healthy workplace for all workers. This is not true for most employers. Physicians asked by an employer to perform preplacement examinations should be sure that each component of the examination relates to the actual job the individual is being hired to perform and the actual risks he or she will encounter on the job. Both the law and sound occupational medical practice dictate that the employer's attention and efforts be directed toward redesign of the job and its hazards so that it is safe and healthy for all workers to perform.

Medical surveillance refers to the ongoing evaluation, by means of periodic examinations, of high-risk individuals or potentially exposed workers to detect early pathophysiologic changes indicative of significant exposure. OSHA requires little in the way of medical surveillance, although several OSHA standards require employers to institute medical surveillance programs, for example, for workers exposed to asbestos, arsenic, cadmium, chromium, vinyl chloride, lead, and ethylene oxide. Depending on the potential exposure, medical surveillance may include a history and physical examination, chest radiography, pulmonary function tests, blood and urine tests, and other laboratory evaluations.

A medical surveillance program may also include biologic monitoring, the purpose of which is not to identify the occurrence of disease but to measure the uptake or presence of a particular xenobiotic or its metabolites in body fluids or organs. Ideally, this occurs before any pathophysiologic damage occurs. Consequently, biologic monitoring is potentially a primary preventive measure. For example, several volatile organic compounds, such as benzene and toluene, if inhaled or absorbed through the skin, produce metabolites that can be measured in urine.

Biologic monitoring can have some advantages over air monitoring because biologic monitoring measures the *actual* absorption of a xenobiotic by the body as opposed to ambient concentrations in the workplace. The amount of a chemical absorbed may not be closely correlated to ambient xenobiotics for several reasons, including differences in individual work habits, use and effectiveness of personal protective equipment, dermal absorption of xenobiotics unrelated to their concentration in the air, and nonoccupational exposures.

Biologic monitoring, however, has several significant limitations. For most xenobiotics, there are no standards of "normal" or "safe" concentrations against which results can be compared. The timing of specimen collection is critical because different xenobiotics have different biologic half-lives. The storage and handling of specimens and interpretation of results are vulnerable to error. Nevertheless, if carefully designed and implemented, biologic monitoring can be a useful complement to a comprehensive industrial hygiene program.

With the exception of biologic monitoring, medical monitoring programs identify disease processes already underway and therefore are, at best, a form of secondary prevention. Employers who use results to remove workers rather than remediating the hazard are abusing medical and biologic monitoring programs. To be an effective preventive measure, these programs must be coordinated with environmental monitoring programs that identify the nature, source, and extent of workplace hazards; implementation of engineering controls and other measures that control hazards as close as possible to the source; and worker education programs that, at a minimum, inform workers of exposures, their effects, and proper control measures.

Both medical monitoring programs and preplacement examinations raise issues of doctor–patient confidentiality. Employee medical records should be available only to the corporate medical or first-aid department and not to the personnel office and general management. Unless required by statute, employers should never be told the results of history, physical, or diagnostic examinations unless the patient gives his or her written consent. The examining physician need only inform the employer that an individual is or is not capable of performing a particular job with or without specified restrictions. The physician should not disclose diagnostic information about medical conditions.

INFORMATION RESOURCES

Healthcare professionals require information on industrial toxins in a number of situations, ranging from caring for an acutely ill patient in an emergency department, when information must be obtained quickly, to caring for a patient with chronic symptoms that may reflect an occupational disease. The American College of Occupational and Environmental Medicine publishes a Recommended Library and Electronic Resources (http://www.acoem.org) that provides reference sources for information on toxicology, acute and chronic health effects, diagnosis, and treatment; assists in screening and surveillance; and provides information on groups at risk, product uses, and sources of further information. However, use of these resources depends on the proper identification of the xenobiotic in question. If the xenobiotic, its generic name, and ingredients are not known, the research process becomes more difficult.

The practitioner should take a logical approach to seeking information about industrial xenobiotics. First, the xenobiotic must be identified by its generic name. This can be done by reviewing the MSDS or by contacting poison centers (PCs), the employer, manufacturer, unions, or government agencies. MSDSs also are available by searching online. A good starting point to find MSDSs on the Internet is http://www.ilpi.com/MSDS/index.html, but typing "MSDS" into any online search engine yields a number of sites offering data sheets.

POISON CENTERS

Regional PCs can provide assistance even when the exact chemical name is unknown because information on xenobiotics and their management may be cross-referenced by trade name and manufacturer. Moreover, PC personnel can usually suggest additional resources. Most PCs have computerized listings of poisons that are updated regularly. The best-known system is POISINDEX (Thompson Healthcare, Greenwood Village, CO). Subscribers to this system receive quarterly updates of an alphabetically organized listing of approximately 500,000 industrial and nonindustrial xenobiotics. The system includes trade names, the components, and the concentrations, when available, of each xenobiotic listed. These elements are then cross-referenced to management protocols. The name of the manufacturer is also listed.

EMPLOYERS AND MANUFACTURERS

Many state and federal laws require manufacturers to generate, retain, and disclose information that may help physicians care for persons with work-related health problems. Scientific information, exposure data, information on health effects, and collected medical data are included in the types of information that must be retained.

The Chemical Transportation Emergency Center (CHEMTREC; 800-262-8200; http://www.chemtrec.com), sponsored by the Chemical Manufacturers Association, has as its primary responsibility providing information to healthcare practitioners responding to hazardous spills. However, it also provides information on commercial products found in patients' workplaces. Employers are required to furnish this information to employees in the form of MSDSs.

WORKER'S COMPENSATION INSURANCE CARRIERS

Smaller companies often lack internal health and safety staffs. Worker's compensation or company risk insurance carriers may have valuable information about exposures and controls in the workplace. As a service to their clients, carriers often do walk-throughs and hazards evaluations for clients that lack these resources and suggest appropriate engineering controls. Healthcare professionals can contact the carrier directly to see what additional information is available.

REGULATORY AGENCIES

OSHA requires chemical manufacturers to create a MSDS for each chemical they produce, and employers who use chemicals must retain the MSDSs in the workplace. Required information includes xenobiotic and common names; physical, safety, and health hazard data; exposure limits; precautions for safe handling and use; generally applicable control measures; and emergency and first-aid procedures. The OSHA Hazardous Communication Standard requires individual employers to provide employees with information on the xenobiotics used in their workplaces. With the patient's permission, a call to the plant manager, foreperson, or safety officer may be all that is necessary to determine the name of the xenobiotic in question. Employers may be able to provide information on exposure concentrations in the patient's work environment. In addition, company medical departments (where they exist) may have results of medical testing done on the patient.

There is an important point to reiterate about MSDSs: healthcare providers should not rely on these sheets as the sole source of information. The MSDSs are created by the chemical manufacturers as they generate scientific and health data during the course of

seeking approval from the Environmental Protection Agency (EPA) to manufacture xenobiotics, and they are not a complete product evaluation. In addition, Section 8(c) of the Toxic Substances Control Act (TSCA) requires chemical manufacturers to report records of significant adverse reactions to human health or the environment. When contacting chemical manufacturers, physicians should ask to speak with a toxicologist, chemist, or someone in the products information department.

UNIONS

Labor unions, where they exist, can be excellent sources of information on xenobiotic exposures. At the local level, union officers, health and safety committee members, and shop stewards may be able to provide MSDSs, exposure data, medical and epidemiologic information, and reports of incidents or cases of interest in a particular plant. The health and safety department of the American Federation of Labor and Congress of Industrial Organizations (AFL-CIO), (http://www.aflcio.org) in Washington, DC, can provide information on occupational health and safety activities and advice on which member unions may be of specific help. At the international level, unions often have well-trained health and safety professionals who may provide or suggest sources of helpful information. In addition, some cities have a coalition of occupational safety and health groups that may provide information about other known exposed or affected workers.

GOVERNMENT AGENCIES

A myriad of agencies have some regulatory authority over manufacturing and services industries. These agencies and their important regulatory authority are listed in Table 122–4.

OSHA of the U.S. Department of Labor (http://www.osha.gov) is responsible for setting and enforcing workplace health and safety standards. It is empowered to investigate occupational health and safety complaints and can inspect work sites and levy fines for violations of its standards. In approximately half of the 50 states, the OSHA program is implemented by a state agency. Individual workers, their representatives (unions), or their physicians can file a complaint with the state or federal OSHA program and request an inspection. OSHA regulations protect workers from discrimination and punishment by their employer, who may be angered by their filing a complaint.

Some state OSHA agencies have separate enforcement and consultation arms. Thus, companies can request assistance from the occupational health specialists in the consultation branch without fear of reprisal from the enforcement branch. Healthcare workers should be familiar with the functions of their state agency and workers' rights under the law.

The National Institute for Occupational Safety and Health (NIOSH) of the U.S. Department of Health and Human Services is part of the Centers for Disease Control and Prevention (http://www.cdc.gov/niosh). NIOSH is not a regulatory agency and is responsible for researching the causes of occupational disease and injury and methods for their prevention and control, evaluating workplace conditions, recommending exposure limits to OSHA for standard setting, and training occupational health and safety professionals. It is empowered to conduct onsite evaluations of health hazards in response to requests from employee representatives or employers. After conducting these evaluations, NIOSH investigators immediately contact OSHA, the employees, and the employer if they find that the workers are in imminent danger.

TABLE 122–4. Government Agencies and Their Important Regulatory Authority of the Workplace—A Timeline

Regulation	Agency	Authority
Occupational Safety and Health Act (OSHA, 1970)	Department of Labor	Congress passed OSHA and created the Occupational Safety and Health Administration to ensure worker and workplace safety. The goal was to make sure employers provide their workers a place of employment free from recognized hazards to safety and health, such as exposure to toxic xenobiotics, excessive noise levels, mechanical dangers, heat or cold stress, and unsanitary conditions.
		To establish standards for workplace health and safety, the Act also created the National Institute for Occupational Safety and Health (NIOSH) as the research institution for the Occupational Safety and Health Administration. Part 1910.1200 of OSHA established the Hazardous Communication Standard (HazCom). The purpose of this section is to ensure that the hazards of all xenobiotics produced or imported are evaluated and that information concerning their hazards is transmitted to employers and employees. This transmittal of information is to be accomplished by means of comprehensive hazard communication programs, which are to include container labeling and other forms of warning, material safety data sheets, and employee training.
Resource Conservation and Recovery Act (RCRA, 1976)	Environmental Protection Agency (EPA)	RCRA (pronounced "rick-rah") gave the EPA the authority to control hazardous waste from "cradle to grave." This includes the generation, transportation, treatment, storage, and disposal of hazardous waste. RCRA also set forth a framework for the management of nonhazardous wastes. The 1986 amendments to RCRA enabled the EPA to address environmental problems that could result from underground tanks storing petroleum and other hazardous xenobiotics. RCRA focuses only on active and future facilities and does not address abandoned or historic sites (see CERCLA).
		HSWA (pronounced "hiss-wa"), the Federal Hazardous and Solid Waste Amendments, are the 1984 amendments to RCRA that required the phasing out of land disposal of hazardous waste. Some of the other mandates of this strict law include increased enforcement authority for the EPA, more stringent hazardous waste management standards, and a comprehensive underground storage tank program.
Toxic Substances Control Act (TSCA, 1976)	EPA	TSCA was enacted by Congress to give the EPA the ability to track the 75,000 industrial xenobiotics currently produced or imported into the United States. The EPA repeatedly screens these xenobiotics and can require reporting or testing of those that may pose an environmental or human health hazard. The EPA can ban the manufacture and import of xenobiotics that pose an unreasonable risk.
		Reporting requirements include (1) premanufacturing notification for new xenobiotics, (2) allegation of significant adverse reactions, (3) reporting of health and safety studies, and (4) notification of suspicion of substantial risk to health.
Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, 1980)	EPA	CERCLA, commonly known as the Superfund, was enacted by Congress on December 11, 1980. This law created a tax on the chemical and petroleum industries and provided broad federal authority to respond directly to releases or threatened releases of hazardous xenobiotics that may endanger public health or the environment. Over 5 years, $1.6 billion was collected, and the tax went to a trust fund for cleaning up abandoned or uncontrolled hazardous waste sites. CERCLA (1) established prohibitions and requirements concerning closed and abandoned hazardous waste sites, (2) provided for liability of persons responsible for releases of hazardous waste at these sites, and (3) established a trust fund to provide for cleanup when no responsible party could be identified.
		The law authorizes two types of response actions: (1) short-term removals, in which actions may be taken to address releases or threatened releases requiring prompt response, and (2) long-term remedial response actions that permanently and significantly reduce the dangers associated with releases or threats of releases of hazardous xenobiotics that are serious but not immediately life threatening. These actions can be conducted only at sites listed on the EPA's National Priorities List (NPL).
Superfund Amendments and Reauthorization Act (SARA, 1986)	EPA	SARA reflected the EPA's experience in administering the complex Superfund program during its first 6 years and made several important changes and additions to the program. SARA (1) stressed the importance of permanent remedies and innovative treatment technologies in cleaning up hazardous waste sites, (2) required Superfund actions to consider the standards and requirements found in other state and federal environmental

(Continued)

TABLE 122–4. Government Agencies and Their Important Regulatory Authority of the Workplace—A Timeline (*Continued*)

Regulation	Agency	Authority
		laws and regulations, (3) provided new enforcement authorities and settlement tools, (4) increased state involvement in every phase of the Superfund, (5) increased the focus on human health problems posed by hazardous waste sites, (6) encouraged greater citizen participation in making decisions on how sites should be cleaned up, and (7) increased the size of the trust fund to $8.5 billion. SARA also required the EPA to revise the Hazard Ranking System (HRS) to ensure that it accurately assessed the relative degree of risk to human health and the environment posed by uncontrolled hazardous waste sites that may be placed on the NPL. Emergency Planning and Community Right-to-Know Act (EPCRA), also known as Title III of SARA, was enacted by Congress as the national legislation on community safety. This law was designated to help local communities protect public health, safety, and the environment from xenobiotic hazards. The law requires manufacturers to report the amount of toxic xenobiotics released each year (Toxic Release Inventory [TRI]).
		To implement EPCRA, Congress required each state to appoint a State Emergency Response Commission (SERC). The SERCs were required to divide their states into Emergency Planning Districts and to name a Local Emergency Planning Committee (LEPC) for each district.
Americans with Disabilities Act (ADA, 1990) and the ADA Amendments Act of 2008 (ADAAA)	Department of Labor	The ADA was enacted by Congress to establish clear and comprehensive prohibition of discrimination on the basis of disability. The act specifically covers discrimination in the areas of (1) employment, (2) public services, (3) public accommodations and services operated by private entities, and (4) telecommunications. The ADAAA reaffirms Congress' initial intent of the 1990 law to (1) broadly define "disability," (2) use the definition of "handicapped individual" under the Rehabilitation Act of 1973 and (3) state that mitigating measures (eg, insulin for diabetes) shall not be a factor when determining whether an impairment substantially limits a major life activity

As part of the process of recommending exposure standards to OSHA, NIOSH develops comprehensive documents that critically evaluate all available scientific data on particular xenobiotics. These "criteria documents" review the chemical's properties, production methods, uses, and workers at risk as well as studies of exposure effects in humans and animals. Methods of screening, surveillance, and control are presented. The agency periodically issues technical reports and special occupational hazard reviews of specific occupations. In conjunction with OSHA, NIOSH develops and disseminates health hazard alerts to inform employers, employees, and healthcare professionals of serious health effects of particular xenobiotics.

The EPA (http://www.epa.gov) is charged with protecting the nation's land, air, and water. The agency administers a number of laws designed to preserve the public health and environment, one of which is the TSCA. This act authorizes the EPA to collect information on xenobiotic risks from manufacturers and processors and to review information on new xenobiotics and new uses of xenobiotics before they are manufactured. Unless designated a trade secret, this information is subject to disclosure and therefore is available. The TSCA assistance office may be most useful when resource materials and government documents contain no information about the xenobiotics or processes in question.

The National Toxicology Program (NTP; http://ntp-server.niehs.nih.gov) is a federal program established in 1978 to develop scientific information on exposure to xenobiotics.

The Agency for Toxic Substances and Disease Registry (ATSDR; http://www.atsdr.cdc.gov) was created by Congress in the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERLA; also known as Superfund Act) to implement the health-related sections of laws that protect the public from hazardous wastes and environmental spills of hazardous substances. In 1986, the Superfund Amendments and Reauthorization Act (SARA) made amendments to the initial enabling legislation of 1980 and broadened the ATSDR's responsibilities in the areas of health assessment, toxicologic databases, information dissemination, and medical education. One of its offices, the Division of Health Assessment and Consultation, provides emergency response for toxic and environmental disasters, consults in public health emergencies, assesses hazardous waste sites, provides technical assistance to agencies and organizations, and estimates health risks to humans from exposure to hazardous xenobiotics. The program areas in which ATSDR operates include health assessments, toxicologic profiles, emergency response, and exposure and disease registries.

■ ONLINE DATABASES

Printed material often is adequate for determining the adverse health effects of xenobiotic exposures, but some resources may be unavailable to physicians, and textbook publications usually lag 2 years or more behind new information. As a result, current findings and reports may be missed if the practitioner relies solely on printed material. The National Library of Medicine (http://www.nlm.nih.gov) now sponsors Internet searching of both Medline (PubMed: http://www.ncbi.nlm.nih.gov/pubmed/) and a number of databases in the Toxicology Data Network (TOXNET: http://www.toxnet.nlm.nih.gov) that are very

useful for finding information about industrial xenobiotics. Additional databases are available for searching on the OSHA, NIOSH, EPA, and ATSDR web sites.

■ OBLIGATIONS OF THE HEALTHCARE PROVIDER TO THE INDIVIDUAL PATIENT, COWORKERS, EMPLOYER, GOVERNMENT, AND COMMUNITY

Occupational diseases and injuries are, in principle, preventable. Physicians who diagnose a work-related disease or injury have an opportunity and an ethical obligation to participate in the identification and control of workplace hazards and the prevention of further occupational illness and injury. Physicians can choose from a range of possible follow-up measures, the goals of which are to prevent recurrence or worsening of the disease or injury in the patient and to prevent the development of disease or injury in other potentially exposed workers. Some of these activities may necessitate contact with occupational medicine physicians, toxicologists, industrial hygienists, lawyers, journalists, government officials, management personnel, and union officials.

■ OBLIGATIONS TO THE PATIENT

Inform the Patient that the Illness may be Work Related When the workplace is determined to be a factor in the etiology or aggravation of the patient's illness, this fact and its implications should be discussed with the patient. It should never be assumed that the patient is fully aware of the health risks associated with any workplace exposure. He or she should be provided information regarding the nature of workplace hazards, their health risks, preventive measures, and recommendations regarding continued exposure.

Suggest How the Patient Can Reduce the Exposure In some cases, the patient can take steps to reduce exposure. Adjustments in work habits that may be helpful include using a respirator or other personal protective equipment provided by the employer; using workplace shower and dressing rooms to avoid carrying xenobiotics from the workplace to the home; and avoiding ingestion of workplace xenobiotics by careful hand washing before eating or smoking and by taking lunch, coffee, and smoking breaks away from the work station. Obviously, these recommendations assume that the employer provides the appropriate equipment and facilities, which is not always the case. The most effective hazard control measures require significant commitment by, and cooperation from, the employer.

Suggest that the Patient Remove Him- or Herself from the Exposure The employer may be willing to transfer the patient to a location away from the offending hazard. This may result in a reduction in pay, seniority, or other benefits, which may be compensable under workers' compensation. The employment provisions of the ADA require employers to make "reasonable accommodations" for both work- and non–work-related disabilities. Nevertheless, the employer may not be able to accommodate the patient. The patient should be counseled carefully, and other options should be explored.

Advise the Patient to Notify the Employer Patients who are experiencing a work-related illness may be entitled to workers' compensation benefits, Social Security disability, or other government-sponsored benefit programs. In addition, they may have a valid claim against the manufacturer of a xenobiotic, a defective product, or another third party. The degree of disability necessary to bring a successful claim varies.

After a patient is informed that he or she has a work-related illness, strict time limits are set in motion, and failure to meet them can preclude the patient from successfully filing a claim or receiving

needed benefits. The patient should be advised to provide written notice immediately to his or her employer of a work-related illness (supported by a physician's letter) and to seek advice about statutes of limitations and other requirements. This information is generally available from the State Workers' Compensation Board and is usually required to be provided to the employee by the employer. If a union is available at the workplace, it may be able to advise and assist the patient.

■ OBLIGATIONS TO COWORKERS

A patient with a work-related illness should be advised to inform his or her coworkers about the condition. If the patient belongs to a union, he or she should inform the union representative. If there is no union, the patient may contact OSHA or discuss the situation with the employer.

If the patient is a union member and agrees, the physician can contact the union, which may assist in hazard investigation, identify and warn other workers potentially affected by the hazard, and pressure the employer to take corrective action if it is unwilling to do so. The union can help the patient obtain any available benefits. The patient may be able to identify appropriate contacts, such as shop stewards, members of the union's health and safety or workers' compensation committees, an occupational health specialist employed by the union at the local or national level, or an official of the union local.

Committees on Occupational Safety and Health (COSH); coalitions of labor, health, and legal professionals; and community and environmental activists working to prevent job-related illness and injury may be able to help with the diagnosis and follow-up of occupational diseases. These groups provide education and technical assistance nationwide on a range of topics, including the health effects of specific hazards, control measures, how to use government agencies, and the legal rights of disabled workers.

■ OBLIGATIONS TO NOTIFY THE GOVERNMENT

States may have laws that require direct physician reporting of occupational disease. If management is uncooperative despite notification of a hazardous situation, OSHA should be contacted, with the patient's consent. In addition to the federal agencies specifically empowered to protect worker health and safety, physicians may contact the state or local health department, which may initiate action or refer the problem to one of the federal agencies. Many states also require physicians to report any occupational injury or illness to the workers' compensation carrier.

■ OBLIGATION TO NOTIFY THE EMPLOYER

When treating a patient with an occupational injury or illness, healthcare providers often are required to report to government agencies, health departments, or insurance carriers. As part of that reporting process, the employer should also be notified. When there is imminent danger to coworkers or the public health, the employer should be contacted to correct the exposure situation.

■ OBLIGATION TO INFORM COLLEAGUES AND THE PUBLIC

On occasion, an individual primary care physician or specialist is the first person to suspect a link between a workplace exposure and a serious health problem. This is likely to recur in the future, especially if the physician practices in a small town or industrial area or provides healthcare to worker groups through a company or union. Armed with an increased index of suspicion and the occupational

history, the physician may be able to alert workers and companies and prevent the occurrence of a major health problem. Even if the physician chooses not to be involved in subsequent investigation or research, it is important that information about suspected problems and hazards be made available to workers and employers in similar industrial settings, government agencies, healthcare professionals, and perhaps the public at large. Case reports discussed in the medical literature, at medical meetings, or through the media can be helpful in this regard.

SUMMARY

Industrial, workplace, and environmental exposures represent a different kind of challenge to primary care and emergency physicians. Patients often present as a diagnostic dilemma or with common symptoms that do not respond to the usual medical treatment. The challenge for nonoccupational health professionals is to correctly establish and treat the condition. This chapter offers a basic approach to all patients that will aid in the diagnosis and treatment of occupational and environmental diseases. This approach uses additional questions applied to the medical history and access to printed and electronic information resources. Exposures to these materials have public health implications. Physicians who make the diagnosis of an occupationally or environmentally related disease have an obligation to prevent further injury. They should work with employee groups, employers, and government agencies to identify the toxic agent and prevent the development of disease in other potentially exposed individuals.

CHAPTER 123
NANOTOXICOLOGY

Silas W. Smith

HISTORY

Humanity has serendipitously used nanotechnology for hundreds of years. In the Greco-Roman period, the mixing of lead oxide and slaked lime with water resulted in the creation of lead sulfite nanocrystals (5 nm), which blackened hair when allowed to accumulate in the hair cuticle and cortex.[293] Gold nanoparticles produce the striking color of ruby glass present in the Roman Lycurgus cup and in later church stained glass windows.[107] Carbon nanotubes (CNTs) and cementite (Fe_3C) nanowires found in 17th century Damascus steel sword blades explain its high-quality mechanical properties.[240] In 1959, the physicist Richard Feynman proposed the theoretical framework for "manipulating and controlling things" all the way down to the atomic level in "There's Plenty of Room at the Bottom."[83] Norio Taniguchi is generally credited with coining the term "nano-technology"—"the processing of separation, consolidation and deformation of materials by one atom or one molecule"—in 1974.[270]

In practical terms, the invention of the scanning tunneling microscope (STM) in 1981 enabled the visualization of individual atoms and allowed the direct physical manipulation of atomic surfaces.[139] In 1985, Kroto and colleagues reported on a novel minute crystalline allotropic form of carbon, apparently conceived of some 15 years previously.[55,154,213] These now-familiar soccer ball–shaped carbon-60 structures were named "buckminsterfullerenes" after Buckminster Fuller. The discovery of CNTs followed in 1991.[123] The 2003 Congress enacted the "21st Century Nanotechnology Research and Development Act" to create a National Nanotechnology Program with a mandate to establish the goals, priorities, and metrics for evaluation of federal nanotechnology research, development, and other activities; to invest in federal research and development programs in nanotechnology and related sciences to achieve those goals; and to provide for federal interagency coordination.[196]

The health and safety impact of nanotoxicology came to fore during the first consumer recall of a purported nano-based invention.[301] In 2006, the bathroom cleaning product "Magic-Nano" was released in Germany. Within days, more than 110 cases of illness were reported, and several patients were hospitalized with severe respiratory complaints, including acute lung injury. No further episodes of illness occurred after product recall only 3 days after introduction.[135] Although it was ultimately determined that "Magic-Nano" contained no nanoparticles, the incident raised many questions about nanotechnology development, regulation, and health risks.[20,21] There are now more than 600 consumer xenobiotics incorporating nanotechnology, with approximately three to four new ones reaching the market weekly.[272] Exposure to nanoparticles is anticipated through a variety of mechanisms that must be considered from a toxicologic perspective.

PHYSIOCHEMICAL PRINCIPLES

Nanotechnology is defined as the "understanding, control, and use of matter at dimensions of roughly 1 to 100 nm, where unique characteristics enable novel applications."[238] The American Society for Testing and Materials (ASTM) International defines an *ultrafine particle* as a particle ranging in size from approximately 0.001 μm (1 nm; 10 Å) to 0.1 μm (100 nm; 1000 Å) and a *nanoparticle* as an ultrafine particle with lengths in two or three dimensions greater than 0.001 μm (1 nm; 1000 Å) and smaller than about 0.1 μm (100 nm; 1000 Å).[12]

For spherical nanoparticles, as particle diameter decreases, the percentage of molecules on the surface of the nanoparticle increases relative to the total number of molecules. This percentage increases quite steeply below 100 nm.[152] This provides a large area (high surface to volume ratio) for chemical reactions to occur and for contact and interaction with biologic systems. Furthermore, as particles reach sizes below 100 nm, quantum mechanical principles become manifest, and thus unique electrical, magnetic, optical, and solubility properties may emerge. Nanoparticles may exist as aggregations (individual particles held together by strong forces) and agglomerations (held together by weak forces such as van der Waals forces, electrostatic and surface tension). The extent of aggregations and agglomerations, particle dispersal, and electrical charge varies, depending on the primary particle constituents and on solvents or media.[304] This imparts additional properties to identical substances even at the nanoparticle level: whereas C_{60} fullerenes are intensely hydrophobic and essentially insoluble in water, colloidal C_{60} clusters remain mono-dispersed in water as long as electrostatic repulsions are not disrupted by salts.[31]

Nanomaterials and nanoparticles include a vast array of structures, such as composite nanodevices, dendrimers, fullerenes, liposomes, nanocrystals, nanogels, nanofibers, nanoshells, nanospheres, nanotubes, nanowires, polymeric micelles, quantum dots (QDs) and quantum rods, supermagnetic particles, and environmentally generated "ultrafine particles" (Fig. 123–1). They are composed of materials as diverse as their applications, including carbon, lipids, metals and metal oxides, nucleic acids, polymers, proteins, and combinations thereof.

CURRENT AND PROJECTED APPLICATIONS

Nanotechnologies are currently or anticipated to be incorporated into an ever-widening range of disciplines and industries, including agriculture; automobile parts; chemical and materials science (alloys, catalysts, ceramics, coatings, and thin films); electronics; energy capture and storage; environmental sensing and remediation; food processing; fuel additives; house-cleaning products; paints, varnishes, and sealants; textiles; and water purification.[238,246,257] Thousands of tons of engineered metal oxide nanoparticles and fullerenes are anticipated to be produced globally.[27] Ongoing areas of exploration and uses for human and biomedical applications include biomaterials, cancer treatments, diagnostics, drug and gene delivery systems, and imaging.[246,251,313]

◼ BIOMATERIALS

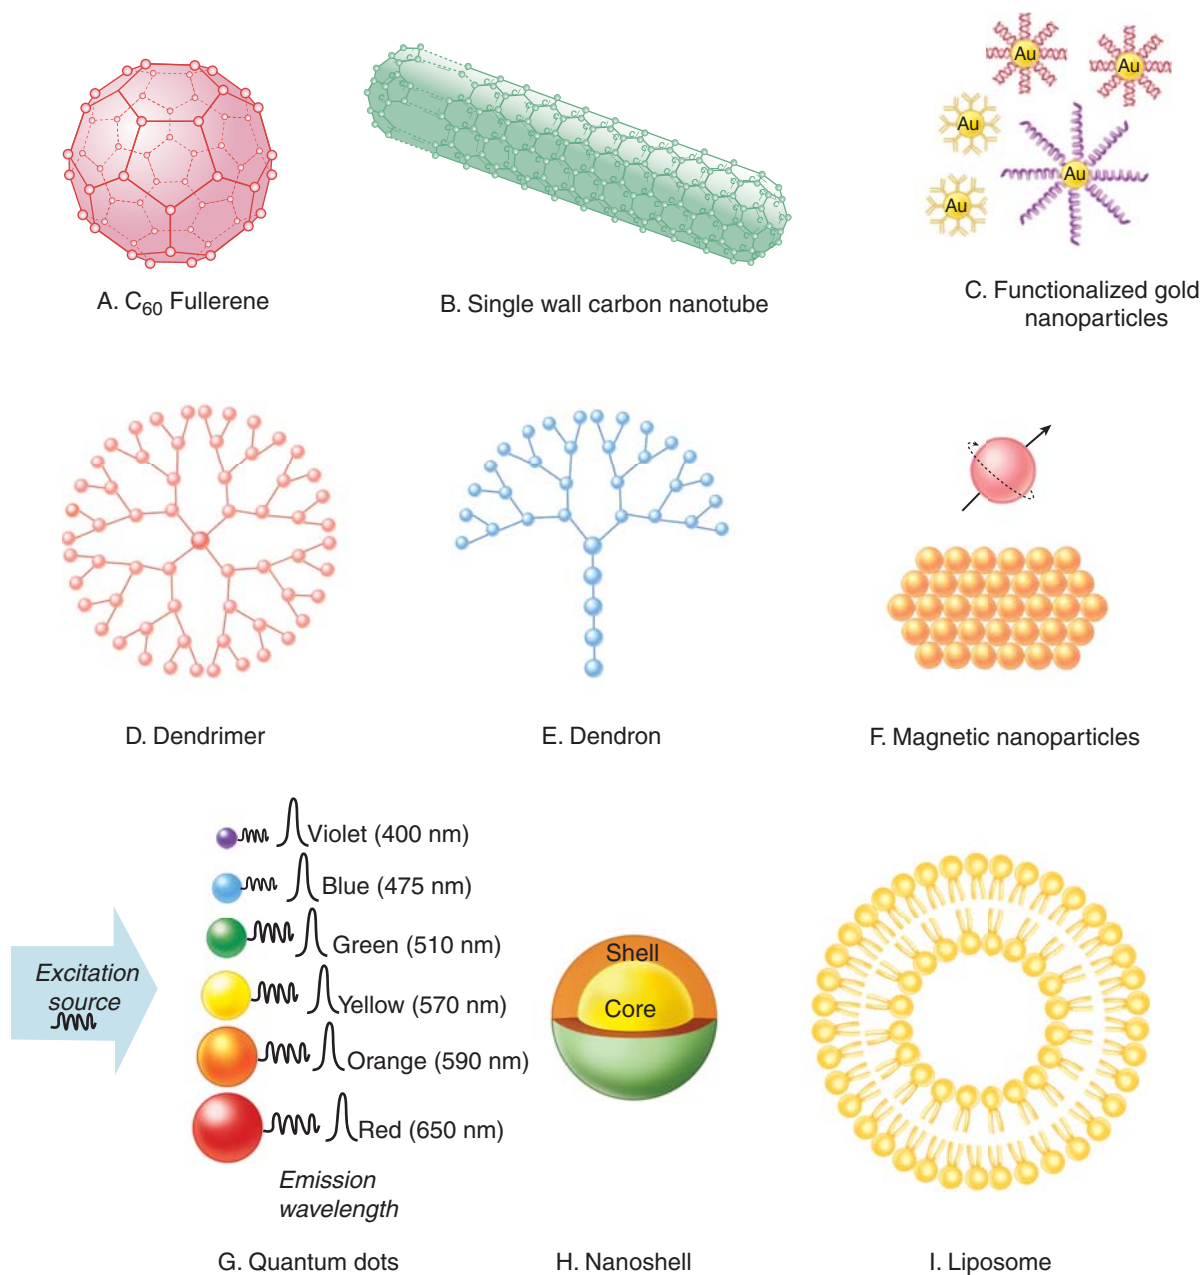
Applications include creation of scaffolds for in vivo or ex vivo growth as well as coatings to minimize immunogenicity, inhibit specific tissues or cell types, and allow macromolecular repair. Nanocrystalline hydroxyapatite and β-tricalcium phosphate have been approved for human use, as has a nanoparticle dental restorative. Multiple-walled CNTs (MWCNTs) can be molded into various scaffolds, which can support connective tissue and osteoblast adherence and growth.[54,87] Nanoscale systems have achieved selective human keratinocyte and fibroblast adhesion and stimulation.[247] Implanted self-assembled nanofiber scaffolds have been shown to span transected rat spinal cords and support angiogenesis and migration and differentiation of neural cells.[101] Such self-assembling peptide scaffold structures have allowed actual reconstitution of functional visual pathways after traumatic transection.[76] Neuronal growth and improved neuronal


FIGURE 123–1. Nanoparticles (not to scale). (**A**) C_{60} is a prototypical fullerene, or carbon cage, which may enclose additional atoms, ions, or molecular clusters. (**B**) Carbon nanotubes (CNTs) are single-walled (SWCNTs) or multiple-walled (MWCNTs) cylinders, which are capped at each end and can bundle together into longer and wider agglomerates. (**C**) Gold nanoparticles and other nanosized noble metals (eg, silver, copper, platinum) have unusual catalytic, optical, electronic, and (photo)thermal properties and can be conjugated to dyes, antibodies, peptides, and oligonucleotides. (**D**) Dendrimers are branched polymers consisting of a central core, an internal branching region, and surface terminal groups; drugs, genes, and imaging agents can be loaded into the inner protected cavities. (**E**) Dendrons are wedge-shaped sections of dendrimers with an accessible reactive group. (**F**) Magnetic nanoparticles include superparamagnetic iron oxide (SPIO) nanoparticles (Fe_2O_3, Fe_3O_4), pure metals (Fe and Co), and alloys ($CoPt_3$ and FePt). They are usually surrounded by a shell to minimize agglomeration and chemical reactivity. (**G**) Quantum dots (QDs) are semiconductor nanocrystals capable of size-dependent fluorescence with a "tunable" emission spectrum in the 400-nm to 2-μm range. (**H**) Nanoshells contain a dielectric silica core surrounded by thin metal gold shell. (**I**) Liposomes are globular vesicles with hydrophobic and hydrophilic zones composed of phospholipids, sphingolipids, and ceramides or other esters or polymers ranging in size from 25 nm to the micron range. Nanoparticles can be derivatized or bioengineered with a variety of detection, imaging, or targeting molecules.

electrical signaling on purified multiwall nanotubes,[166] and integration of neural tissues with free-standing vertically aligned carbon nanofiber platforms provides a basis for ultimately stable implantable neural devices.[203]

Bioactive coatings in prosthetics provide the opportunity to control fibrous tissue formation and biointegration. With the goal of increased osseointegration of implanted biomaterials, nano-engineered polymethylmethacrylate structures have been created to control cell adhesion, growth, spreading, cytoskeletal development, and production of the osteoblast marker proteins of human bone marrow cells.[57,195] Nanofilm layers (4 nm) containing dexamethasone can suppress immune response to implants.[51]

■ CANCER THERAPY

Several authors have reviewed nanocarrier-based cancer treatment modalities.[70,148,149,222,279,313] Examples of currently commercial products include albumin-bound paclitaxel nanoparticles, daunorubicin, doxorubicin, and vincristine liposomes; styrene maleic anhydride-neocarzinostatin; and PEG-L-asparaginase. New carriers include hyaluronic acid-PEG-poly(lactide-co-glycolide) nanoparticles copolymers for sustained release (15 days) of doxorubicin.[305]

Because of "leaky" tumor vasculature and poor lymphatic drainage compared with normal tissue, nanoparticles can nonselectively accumulate in tumor tissue. Tumor vascular pores range between 380 and 780 nm compared with normal vasculature (2–4 nm).[149] This can be used either diagnostically or therapeutically for imaging or drug delivery. However, a more selective approach is nanocarriers linked to specific proteins or antibodies targeting malignantly expressed receptors. Functionalized single-walled CNTs (SWCNTs) have targeted cells expressing specific integrins or overexpressing folate receptors.[163,309] Gold particles linked to vascular endothelial growth factor (VEGF) antibodies induced apoptosis in B-cell chronic lymphocytic leukemia.[190] Magnetic resonance imaging (MRI)–detectible magnetic nanoparticles labeled with near-infrared fluorescence dye and linked with short interfering RNA permitted both visualization and silencing of targeted genes in mice implanted with tumors.[178] Nanoparticles can achieve dual tumor imaging and thermal ablation through the ability to separately modify scattering, resonance shifts, and absorption spectrum.[129]

■ EXTERNAL PRODUCTS

Sunscreens (TiO_2, ZnO) and cosmetic lotions and conditioners are incorporating a range of nanotechnologies.[206] These provide both aesthetic (transparent sunscreen) and clinical (more efficient ultraviolet [UV] filtration) benefit.[238] The Food and Drug Administration (FDA) has permitted titanium dioxide and zinc oxide nanoparticles since 1999.[301] Nanotechnology is also advancing skin and wound care. FDA-approved wound dressings containing nanocrystalline silver delivery systems are currently commercially available. These silver nano-dressings improve wound healing through suppression of infection and inflammation and promotion of epithelialization via upregulation of micronutrients.[195,275,297]

■ DIAGNOSTICS AND DRUG DELIVERY

Nanotechnology is expected to accelerate medical diagnostic capability. Cancer diagnosis, biochemical monitoring, and pathogen sensing via a range of protein, nucleic acid, ion, and chemical detection techniques are rapidly advancing.[127] Tagged nanoparticles are currently used in commercial genotyping tests for coagulation disorders, folate metabolism, and warfarin metabolism.

Nanoengineering holds the promise of improved pharmacokinetics, delivery, and targeting of pharmaceuticals, proteins, and genes in a cell- or tissue-specific manner. Gram-positive antibacterial activity of rifampin increases when nanoencapsulated into a biodegradable polymer.[80] Encapsulation allows for more efficient drug delivery to intracellular pathogens such as *Mycobacterium tuberculosis*[6,260] and *Toxoplasma gondii*.[58] Gold nanoparticles conjugated with streptomycin and kanamycin showed greater heat stability and improved efficacy against *Escherichia coli, Micrococcus luteus,* and *Staphylococcus aureus*.[245] Antiretroviral drugs can be loaded into nanoparticles allow for improved organ uptake.[130]

In addition to the cancer modalities described above, aprepitant, fenofibrate, megestrol acetate, sirolimus, and topical estrogen preparations have been engineered for nanometer-sized particle delivery. A range of largely unregulated fat-soluble vitamins, carotenoids, phytosterols, minerals, and supplements are currently marketed as nano-based formulations.

■ IMAGING

Several reviews illuminate the expanding field of nanoparticle incorporation into both targeted and nontargeted approaches to imaging.[38,149,259] Intravenous (IV) superparamagnetic iron oxide (SPIO) and gadolinium chelate are nanotechnologies currently approved for MRI imaging. Specific organ, tumor, and sentinel lymph node imaging is now possible.[77,145,146,258] Iodinated nanoparticle contrast agents permit computed tomography detection of macrophages in atherosclerotic plaques.[122] Imaging at the cellular and molecular level includes differentiation of cellular subcompartments, uptake mechanisms, cell architecture, intracellular trafficking, and single proteins and receptors.[97,268,274]

■ IMMUNOLOGY

Nanotechnology is being applied to observe or suppress immune system functions to minimize the need for immunosuppressant medications. Thin coatings of cross-linked polyethylene glycol have been reduced to the 20-μm size to allow pancreatic islet cells thus encapsulated to excluded large immunostimulatory molecules while retaining the ability to secrete insulin in response to glucose in vitro.[303] Extending this work, intraperitoneal-delivered islet cells surrounded by a multicomponent capsule of 60 μm or smaller with nanometer-engineered pores maintained insulin independence in pancreatectomized dogs without requiring immunosuppressant drugs.[295] T-cell targeting with nanoparticles is being explored as a mechanisms of treating immune-mediated disease.[82,233]

EXPOSURE AND DISTRIBUTION

Exposure to nanoparticles is anticipated through a variety of mechanisms (Fig. 123–2). Exposure might occur through environmental discharge into air, water, or soil during the primary manufacturing process; disposition of industrial or research waste; engine combustion; or after biologic elimination from a primary target. Sanding, machining, wearing and weathering, or disposing of nanomaterial-containing products could also liberate nanoparticles. Several federal agencies involved in the National Nanotechnology Initiative are attempting to characterize actual exposure data and metrics.[238,267]

■ DERMAL EXPOSURE

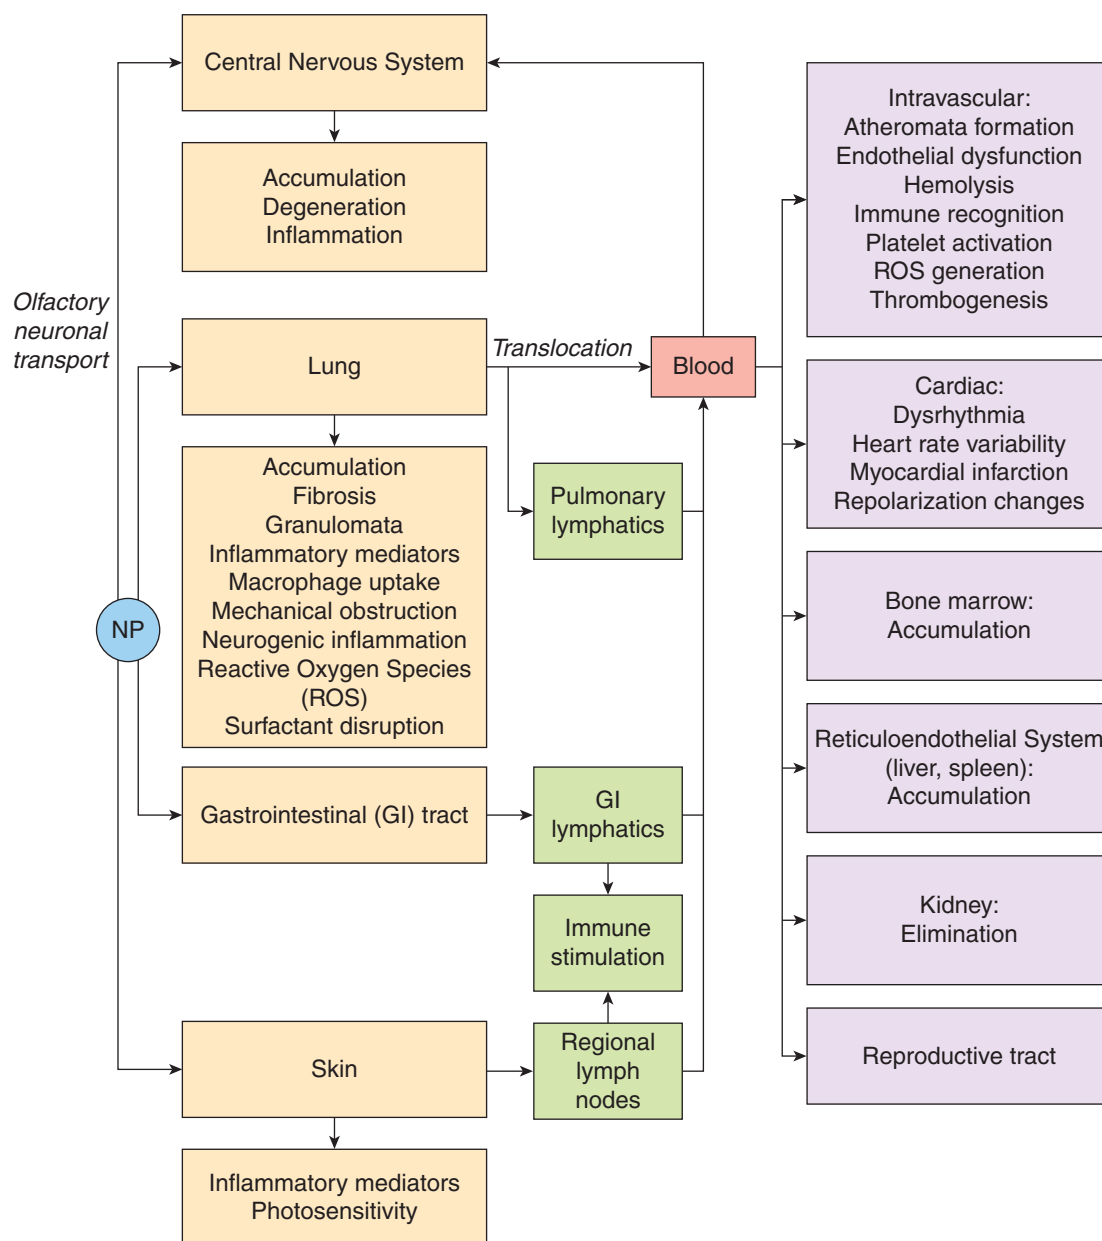
Nanosized liposomes and other formulations for transdermal drug delivery systems have already achieved dermal penetration for therapeutic intent. Various proprietary cosmetics also incorporate nanomaterials. The presumed etiology of podoconiosis (endemic nonfilarial elephantiasis, noninfectious geochemical elephantiasis) is absorption of various colloid-sized elemental particles in irritant clays (aluminum, silicon, magnesium, iron, and possibly beryllium and zirconium), which undergo macrophage phagocytosis to induce collagenization of afferent lymphatics and their ultimate obliteration.[60] A large review summarizing the available studies on dermal penetration of TiO_2 and ZnO nanoparticles found in sunscreens concluded that dermal penetration for those substances was unlikely[206]; however, abraded skin might increase dermal penetration.[243] Lymphatic drainage


FIGURE 123–2. Potential mechanisms of nanoparticle (NP) toxicity including exposure, distribution, and organ system effects. Accumulation may not be limited to the organ systems depicted.

to sentinel lymph nodes and systemic distribution are possible after the dermis is reached.[99,142]

■ INHALATION EXPOSURE

Inhalation is expected to be a major route of nanoparticle entry and toxicity. Nanoparticle aerosols may be generated in manufacturing or research environments. Non-engineered ultrafine products are encountered in welding, soldering, cooking fumes, and combustion products (pollution). As the iron-to-carbon (soot) ratio increases in diesel combustion, the number and size of self-nucleated metallic nanoparticles and larger agglomeration of metallic and carbon particles are observed.[159] Carbon fullerenes may be detected in flaming soot after combustion of various hydrocarbon fuels, including benzene, styrene, cyclohexane, cyclopentane, and rarely in charcoal.[262] Secondary

nanoparticles may form in the atmosphere via gas-to-particle conversions after nucleation and coagulation or condensation.[27] The tendency of intermediate particles (>80 nm and <200 nm) to remain suspended in air for prolonged periods of time (days to weeks) provides an additional exposure source.[284]

The pulmonary deposition of inhaled particles is affected by various factors, including diffusion and inertial impaction. Gravity contributes to greater particle deposition of fine particles in the central airways instead of the lung periphery.[59] Inhaled particles are transported from the airway duct to the alveoli by convective bulk flow combined with particle motion from sedimentation and diffusion. Alveolar deposition models support peak particle deposition at 30 nm and 4000 nm, with minimal particle deposition at 50 μm.[49] Consistent with diffusion motion theory, the total deposition fraction (TDF) of ultrafine aerosols in healthy young men and women *increased* as median particle diameter *decreased* from

100 nm (TDF, 26%) to 40 nm (TDF, 44%), as tidal volume increased, and as respiratory flow rate decreased (longer respiratory and retention time).[131] Deep breathing increased deposition of inhaled boluses of ^{99m}Tc–radiolabeled ultrafine carbon particles. After deposited, clearance may be affected by mucociliary movement, augmented by macrophages in at the alveolar level. Macrophages may either move particles toward ciliated epithelium, uptake and store particles, or contribute to transepithelial movement, where particles may deposit in the basement membrane or enter the lymphatics or bloodstream.[152,210] Inherently soluble compounds are generally rapidly absorbed. An additional concern is that nanoparticles may actually evade effective clearance. Macrophages inefficiently take up 15 to 80 nm particles (~20%), which are instead retained in epithelial cells or interstitium.[210] Prolonged pulmonary persistence (75% at 24 hours in healthy subjects) was seen in one human ultrafine particle inhalation study, even accounting for (minimal) translocation and urinary elimination.[184] In an animal study, at 60 days, 81% of MWCNTs and 36% of ground CNTs administered intratracheally (0.5 mg/rat) could be recovered.[191]

■ ORAL

Unintentional oral exposure is expected to be uncommon, although upper aerodigestive tract aerosol exposure could provide particulate matter for subsequent swallowing. Nanoparticles can enter bacteria and living cells, providing a mechanism for food chain bioaccumulation.[23] Therapeutically, multiple nanoparticulate systems are under evaluation for their ability to enhance solubility, permeability, bioadhesion, bioavailability, and efficacy of poorly absorbed drugs, proteins, and vaccines.[9,63,150] Direct uptake of nanoparticles has been observed via single enterocytes at villi and in Peyer's patch regions of the small intestine.[112] Similar to skin, inflamed or infected intestinal mucosa may increase permeability.[158] Macrophages in human gut–associated lymphoid tissue frequently contain multiple microparticles,[237] which correlate with chronic latent granulomatous inflammation in susceptible individuals.

■ CIRCULATORY ACCESS

Aside from intentional IV administration of nanoparticle pharmaceuticals, pulmonary translocation, intestinal absorption, dermal penetration, or draining lymphatics may provide circulatory access. In human volunteers, inhaled ^{99m}Tc-labeled ultrafine carbon particles (<100 nm) reached the blood within 1 minute, with a peak between 10 and 20 minutes, and persisted for up to 60 minutes.[200] Both hepatic accumulation and urinary excretion occurred. Gold nanomers (30 nm) can be recovered rapidly in blood platelets of the alveolar capillaries after rat intratracheal injection.[18] Aerosolized gold nanoparticles accumulated in more than 20 rat organs and tissues, particularly the lungs, esophagus, kidneys, aorta, spleen, and heart.[311]

■ ELIMINATION

Tight junctions (<2 nm) between endothelial cells preclude most nanoparticle exit from systemic circulation. However, organ-specific endothelial characteristics (hepatic fenestrations and splenic discontinuity), transcytosis, or leak-inducing disease conditions (inflammation and cancer) may allow exit of large particles.[86] Overall reticuloendothelial system (RES) and renal clearance are particle- and coating-specific.[1,3,161,241] Shielding nanoparticles with neutral compounds is also thought to impair opsonization and subsequent RES clearance.[214]

■ CELLULAR ENTRY

Applied research provides multiple examples of nanoparticle entry into cells. Although this can be taken advantage of therapeutically to deliver vaccines, genes, and chemotherapy, unwanted cellular introduction of nanoparticles might engender ensuing toxicity. Cellular uptake of nanoparticles involves multiple mechanisms, including phagocytic or endocytic mechanisms (clathrin mediated, scavenger receptor mediated, mannose receptor mediated, Fcγ receptor mediated, complement receptor mediated), potocytosis (caveolin dependent), macropinocytosis— and direct cytoplasmic entry.[41,56,68,86,198,220,263,274,286] CNTs have been observed to pierce and penetrate plasma membranes through largely energy independent mechanisms.[156] Various water-soluble C_{60} fullerene derivatives and native C_{60} are capable of easily penetrating biologic membranes, including those of human erythrocytes and platelets.[5] The mechanism of nanoparticle entry (free diffusion versus endosomal containment) may impact cellular effects.

DETECTION AND DOSE QUANTIFICATION

Development of effective nanomaterial detection methods is a national priority.[267] In the past, sampling of generated aerosols has focused on the average chemical composition and mass of all deposited particles, with the exception of asbestos, for which the number of fibers with a specific shape and composition is important.[176] Measurement approaches have been reviewed and include various devices to assess particle number (concentration), surface area, and mass.[4,88,176,197,204] Importantly, engineered nanoparticles are generally produced as a distribution of sizes as opposed to a uniform product. Dose assessment is further complicated by the multiple differences among nanoparticles and ongoing investigation as to the most appropriate metric: bulk amount (total particulate mass), particle burden (number of particles of a certain size), total surface area, or alternative metrics. In actual industrial settings, mass concentration measurements can vary significantly compared with particle number counts.[81,230]

TOXICITY

The diverse nature of the xenobiotics, compositions, structures, and physical properties involved in nanotechnology prohibits generalization regarding toxic effect. One review reported 428 studies documenting adverse effects of 965 unique nanoparticles.[104] Even reviews of a single "class" of nanoparticles (QDs,[106] fullerenes,[162] CNTs,[126] dendrimers,[71] and gold nanoparticles[162]) have found both adverse and neutral effects. The in vitro nature of many studies does not reliably predict or confirm systemic biologic effects in humans. Differences in experimental methodology, cell line, substance concentration, particle size and geometry, exposure parameters, duration of observation, and end points or surrogate markers have hindered comparison. There is a paucity of data addressing of long-term effects. Cell line–specific, organ-specific, and species-specific toxicities and effects in clinically or genetically susceptible populations are incompletely described. In addition to reported toxic effects, actual exposure assessments are required to appropriately characterize risk.

Several reviews have attempted to address the many real and theoretical issues surrounding nanoparticle toxicity,[27,33,66,67,115,152,162,198,210,212,219,286,299] and various schemes have been proposed to categorize nanoparticles.[104,176] Despite the many unknowns, experiences from previous work with particle toxicology have contributed to a large body of epidemiologic and experimental literature associating airborne particulate matter (PM) from pollution with mortality, cardiovascular, pulmonary, and neurological injury.[35,67,96,105,114,134,140,223,227,229,256] The strength of the association depends on the particle size and type and on the outcome of interest. Similarly, ultrafine particles in home-generated cooking fumes have been implicated in pulmonary disease, inflammation, and genotoxicity.[45,179,180,265,283,291,302]

Genetic or unique susceptibilities to nanoparticles are not well categorized. Preexisting acute or chronic disease (pulmonary disease, cardiac disease, malignancy, infection) or individual genetic variations (resistance to oxidative stress, immune composition, surface or serum proteins) may modify nanoparticle toxicity, specifically by altering deposition rates, clearance, or toxicity thresholds.[36,64,184] Although the following sections generally report "positive" studies in order to highlight nanotoxicity principles, it is important to acknowledge that many other studies have also produced negative results.[16,50,53,142,169,170,188,189,263,290,310]

■ FACTORS AFFECTING TOXICITY

Composition Ultrafine elemental carbon particles (90 nm) have been shown to be significantly more toxic to macrophages than diesel exhaust particles of comparable size.[183] Acid-functionalized SWCNTs and oxidized MWCNTs produced more murine pulmonary toxicity and human lymphocyte cytotoxicity than their "pristine" counterparts.[29,253] Decay of certain water-soluble fullerenes leads to daughter compounds with increased toxicity in vivo.[19] Gold nanoparticles, asbestos (chrysotile), Al_2O_3, Fe_2O_3, ZrO_2 (zirconia), and TiO_2 have different cytotoxicity in vitro.[266] Uncoated QD core materials (cadmium, lead, selenium) are toxic at relatively low concentrations, damaging the plasma membrane, mitochondrion, and nucleus, and resulting in cell death.[48,106,168]

Coating and Surfactant Materials Coating materials may have inherent toxicity or may shield toxicity of core compounds.[37,43,52] They also mediate the duration of circulation and cell- and organ-specific uptake.[244] Air exposure or photodecomposition can render initially benign coatings cytotoxic.[62] Hydrophilic compounds coating of QDs appear to mediate genotoxicity in human lymphoblast cells.[118] Organic solvents and surfactants used to maintain particle dispersion are frequently cytotoxic.[298] Exposure to protein-rich biologic fluids may change the tendency to agglomerate and therefore produce unique size-dependent effects. Using surfactants (eg, SWCNTs) may decrease protein adherence and therefore alter biological effect or fate.[72,92]

Contaminants Additional toxicity may occur in the presence of contaminants. "Doping" is the intentional process of introducing impurities in order to modify the behavior of materials such as the electrical properties of semiconductors. Similarly, doping may alter the electronic, optical, and magnetic properties of nanocrystals.[207] Doping may also be used to reduce toxicity. MWNTs doped with nitrogen improved biocompatibility and reduced lethality compared with unmodified MWNTs in mice exposed via intranasal, oral, intratracheal, and intraperitoneal routes.[40]

Contamination may unintentionally occur during the manufacturing process and may include atomic or molecular impurities in the nanomaterial structure itself, residual reagents, or byproducts of manufacturing in the final product. "Purified" SWNCTs may retain significant percentages of cobalt, mobolybdenum, iron, nickel, yttrium, and zinc.[157,173] Residual contaminants and impurities of substances used in surface modification of QDs are cytotoxic and genotoxic in vitro.[118] The near-total lethality of a preparation of citrate-, biotin-, cetyltrimethylammonium bromide–modified gold nanoparticles (18 nm) was eliminated by washing off the unbound cetyltrimethylammonium bromide.[53]

Size and Surface Area Size plays an important role in toxicity for certain compounds. Nanoparticles may have different toxicities than the sum of the particles despite a comparable exposure on a mass-for-mass basis. For example, cobalt–ferrite particles reduced in size to 6 nm showed significant increase in cytotoxicity and genotoxicity compared with 10- or 120-μm particles.[53] Ultrafine elemental carbon particles (5–10 nm) induced inflammatory mediators significantly

more compared with larger carbon black particles (14 or 51 nm).[17] CoCr nanoparticles generate more superoxide and hydroxyl free radicals and DNA damage than CoCr microparticles.[218] Independent of the concomitant increase in surface area, the small size allows access to protected sites such as the cell nucleus. Gold nanoparticles (1 nm) can penetrate cell and nuclear membranes.[282] QDs (2.1 nm) can rapidly enter the nucleus of human macrophages.[194] Small (2.2 nm) CdTe QDs induced cell death to a far greater extent than equally charged QDs of greater size (5.2 nm).[167]

Shape and Structure Shape and structure may affect toxicity and biologic interactions, even among nanoparticles of similar composition. SWCNTs produce pulmonary granulomata and inflammation, but nanoparticle carbon black does not.[157,173,264] Asbestos-like or mesothelioma-like pathology was seen for "long" MWCNTs (nanometer diameter, >15 μm length) in mice.[234] Compared with 220-nm structures, "long" (825 nm) CNTs increased the degree of inflammatory response in rats; macrophages more easily enveloped 220-nm CNTs.[252] Gold nanorods had significantly less cellular uptake than comparable spherical structures.[47] Toxicity varies with the type of crystalline structure of a given material. The particle shape of asbestos has been considered to constitute an important factor in genotoxicity, and inflammatory and mutagenic properties vary by silica type (crystalline or amorphous).[254] Amorphous TiO_2 crystals were found to generate significantly more reactive oxygen species (ROS) than anatase, mixed anatase and rutile, or rutile crystals, and material surface defects were important for ROS generation.[132]

In vivo, nanoparticles may be associated with layers of surrounding adsorbed biologic proteins or lipids, which may alter their effective size or shape. Curvature of the nanoparticle may affect the extent of this "corona" and influence interactions with bound proteins such as apolipoprotein and albumin, which may effect cells entry or receptor interactions.[171] Binding of albumin; fibrinogen; IgG; Ig light chain; and apolipoproteins A-I, A-IV, C-III and J to polymer nanoparticles was affected by particle hydrophobicity, charge, and functional groups.[89,90,92,249] Bioassociation may also alter nanomaterial properties. SWCNTs adsorbed with serum proteins (primarily albumin) gained an antiinflammatory effect.[72] In contrast, prevention of protein adsorption to amorphous silica particles reduced toxicity.

Charge Surface charge may alter the physical characteristics of the nanoparticle (dispersion, hydrophilicity) or biologic interaction and effect. Neutral SWCNTs aggregate in aqueous solution; introducing a strong negative charge induces dispersion.[253] Negatively charged nanoparticles permeated model pig skin, which excluded positively charged and neutral particles.[147] Increasing surface charge density alters protein absorption.[90] Charged nanoparticles are recognized as important in complement activation.[65] Strongly charged particles can mediate direct membrane damage (hole formation) in the lipid bilayer.[116,117] Positively charged polystyrene nanospheres induced oxidative stress; those with neutral charge did not.[304] Charge-dependent endocytosis was demonstrated in mouse peritoneal macrophages and a human hematopoietic monocytic cell line—the higher the negative or positive surface charge of albumin particles, the greater the uptake cells.[242] Nanoparticle charge and cytotoxicity were positively correlated in human colonic adenocarcinoma cells.[165]

Dose Depending on the xenobiotic, the observed "dose" (particle number or bulk amount) may or may not be relevant. Appropriate dose–response curves (linear, supralinear, biphasic, or threshold) are lacking for most nanoparticles.[210] Cytotoxicity of CdSe/CdS QDs was directly proportional to the number of intracellular particles.[43] Dose-dependent cytotoxicity occurred in human keratinocytes as SWCNT concentration increased from 0.11 to 10 μg/mL.[174] Dose- and time-dependent effects

were apparent in human peripheral blood lymphocytes exposed to oxidized or pristine MWCNTs.[29] SWCNT necrotic and apoptotic cytotoxicity to macrophages was dose-dependent starting at 2.5 μg/mL.[235] In zebrafish embryos, silver nanoparticles induced dose-dependent embryotoxicity and multiple developmental abnormalities.[160]

pH Nanoparticles have been engineered to be pH responsive. In the acidic environment of the endosome or lysosome (pH, 4.5), core-shell particles can swell by almost three times, disrupting these structures and allowing cytosolic entry.[120] Alternatively, at altered pH, certain functional groups can be cleaved, resulting in altered charge and improved QDs delivery.[182]

■ CELLULAR TOXICITY

Ultimately, after cellular–nanoparticle interaction occurs, toxicity may occur via a variety of different mechanisms (Fig. 123–3). Oxidative stress, membrane damage, cytoskeleton alteration, energy failure, cytoplasmic and nuclear protein alteration, photoxicity, and genotoxicity have all been described.

Oxidative Stress Oxidative stress with subsequent lipid peroxidation, DNA damage, and apoptotic or necrotic pathway induction is perceived as a major factor in nanoparticle toxicity. Interpretation of research is complicated by the finding that some particles induce ROS under abiotic conditions but not intracellularly.[304] The biological medium used may also alter ROS generation.[85] C_{60} fullerenes have shown conflicting results. Under visible light irradiation, C_{60} and C_{70} fullerenes induced $O_2^{.-}$ and $\cdot OH$, which could induce DNA cleavage.[307] In contrast, C_{60} fullerene and several derivatives have antioxidant activity, preventing radical-related toxicity of carbon tetrachloride in rats[93] and liposome lipid peroxidation induced by superoxide and hydroxyl radicals.[294] Unmodified CdTe QDs induced ROS formation, leading to multiple organelle damage and cell death.[48,168]

Cell Substructure Damage Independent of oxidative stress, nanoparticles may alter or damage multiple cellular substructural components. One of the most important functions that may be disrupted is energy production by mitochondria. Nanoparticles may exert significant toxic effects on mitochondria, including alterations in mitochondrial calcium levels, dissipation of the mitochondrial membrane potential, and lipid membrane destruction.[48,168,304] Gold nanoparticles (3 nm but not 6 nm) cross the mitochondrial membrane by accessing the voltage-dependent anion channel (porin).[248] In a rat liver–derived cell line, molybdenum (30 and 150 nm) and aluminum (30 and 103 nm)
FIGURE 123–3. Potential mechanisms of nanoparticle cellular toxicity. ΔΨm, mitochondrial membrane potential, DNA_{mt}, mitochondrial DNA; His, histone; MPTP, mitochondrial permeability transition pore; RNS, reactive nitrogen species; ROS, reactive oxygen species.

significantly impaired mitochondrial function at high levels of 100 to 250 μg/mL; silver (15 and 100 nm) did so at much lower levels of 5 to 50 μg/mL.[121] Evidence suggests that exposure to MWCNTs may result in mitochondrial DNA damage.[314]

Effects of nanoparticles on extracellular adherence are the subject of bioapplications research. Gold–citrate nanoparticles (13 nm) induced morphologic changes, including loss of adhesion and intracellular actin fiber changes in human dermal fibroblasts.[224] Calcium-mediated cytoskeletal function of murine macrophages was altered by ultrafine carbon particles but not by diesel exhaust or urban dust particles.[183] Superparamagnetic iron oxide nanoparticles rapidly disrupted actin distribution and microtubule structures within cells.[102] In a cell system, iron oxide nanoparticles reduced formation of actin microfilaments and microtubules extension, leading to an impaired ability to extend neurites.[232]

Protein function may also be altered by nanoparticles. Whereas clusters of copper nanoparticles selectively induced unfolding and precipitation of hemoglobin A0 and E, almost none occurred with hemoglobin A2.[22] C_{60} fullerene noncompetitively inhibited glutathione peroxidase in a substrate-specific manner.[125] Although relatively high concentrations were required (250 μM), C_{60} fullerene derivatives selectively inhibited P450 metabolism of progesterone.[84]

Phototoxicity One concern is that nanoparticles could be excited by ambient light to incidentally generate either oxygen radicals or direct thermal injury. One current clinical application uses liposomal verteporfin (benzoporphyrin derivative monoacid ring A) activated by low-intensity nonthermal laser light (689 nm) to efficiently generate singlet oxygen. This is believed to induce cell death and prevent the loss of visual acuity in patients with subfoveal choroidal neovascularization secondary to age-related macular degeneration, pathologic myopia, or presumed ocular histoplasmosis syndrome.[138] C_{60} fullerenes may generate ROS in the presence of visible light under physiologic conditions.[308] TiO_2-engineered nanoparticles produced significant DNA strand breaks and cytotoxicity only in the presence UV A irradiation.[289]

Gene Expression and Genotoxicity Nanoparticles may interfere with gene functioning on several different levels. Nanoparticles might aggregate within the nucleus, bind directly to DNA or chaperone proteins, induce nuclear membrane damage, or alter expression patterns. Secondary DNA damage might also occur through induction of ROS. Small QDs of 2.1 nm have been visualized to localize rapidly (<30 minutes) and preferentially in the nucleus of human macrophages, but 3.4-nm QDs were excluded.[194] These QDs apparently targeted histones. Nuclear effects of silica (SiO_2) nanoparticles included induction of nucleoplasmic clustering of topoisomerase I and aggregation of nuclear proteins away from their normal localization.[46] This inhibited replication, transcription, and cell proliferation. SWCNTs may accumulate in the cell nucleus by crossing the lipid bilayer and induced genotoxic effects.[143,235] Gold clusters (1.4 nm) may access and directly associate with the major grooves of DNA to induce cell death.[282] MWCNTs in human keratinocytes altered expression of proteins involved in the cytoskeleton, trafficking, protein degradation, metabolism, growth, detoxification, and stress response.[300] Nanoparticle presence within the nucleus is not required for alteration of protein expression.[215]

Cell Type Specificity Nanoparticles may target different cells or tissues differently. These may be the result of engineered properties such as antibody linkage, ferritin linkage, properties of nanomaterials themselves (size-dependent RES deposition), or biologic processes of target cells (phagocytosis ability, resistance to oxidative stress, cytoskeletal architecture). Although gold nanoparticles (33 nm) were cytotoxic (via apoptosis induction) to human lung carcinoma type II epithelial cells, human hepatocellular liver carcinoma and baby hamster kidney cells

were unaffected.[221] It is precisely because of this differential effect that multiple cell lines are advocated for toxicity testing.[261]

■ ORGAN SYSTEMS TOXICITY

Brain A significant concern is the ability of nanoparticles to translocate to normally protected spaces. This may be on both the macroscopic scale in organs such as the brain or on the microscopic level such as the ability to penetrate lipid bilayers protecting individual cells or nuclear space. Early studies of the poliomyelitis virus (25–30 nm) provided evidence that small particles could access the brain via the nose.[25,26,119,281] Therapeutically, engineered nanoparticle characteristics for intentional central nervous system (CNS) drug targeting have been reviewed by several authors.[24,128,280] Other compounds successfully transported into the brain using nanoparticles include loperamide, tubocurarine, dalargin (a hexapeptide), kytorphin (a dipeptide), MRZ 2/576 (N-methyl-D-aspartic acid receptor antagonist), and doxorubicin.[151] Children and dogs exposed to air pollution showed similar prefrontal white matter hyperintense lesions. These were associated with significant cognitive deficits in children; anatomic correlation in the dogs showed ultrafine particulate matter deposition, vascular pathology, and neuroinflammation.[39] Ultrafine elemental ^{13}C particles translocated into axons of the olfactory nerve in inhalation-exposed rats.[211] Rats exposed to poorly soluble manganese oxide ultrafine particles (30 nm) showed olfactory bulb uptake and CNS delivery to the striatum, frontal cortex, and cerebellum.[73] Cadmium, cobalt, manganese, mercury, nickel, and zinc reach the olfactory bulb when applied intranasally in animal models, and neuronal connections may carry cobalt, manganese, and zinc into deeper brain structures.[7,34,109,225,226,273,278] Entry of nanoparticles may result in CNS inflammatory changes, increase inflammatory gene expression and oxidative stress, upregulate excitatory neurotransmitters, and interfere with mitochondrial energy production.[73,144,164,228,277]

The blood–brain barrier may also be breached via the circulatory compartment. Polysorbate 80–coated peptides are capable of CNS entry and analgesic effect in mice.[150] CNS access from the circulation is also reported for certain water-soluble fullerenes.[306] Several studies provide evidence that nonspecific binding of apolipoproteins E may mediate nanoparticle transit across the blood–brain barrier.[91,151]

Lung Because the lungs are expected to be the major portal of entry, pulmonary toxicity of various engineered and ultrafine nanoparticles is being actively explored. Nanoparticle accumulation, acute and chronic inflammation, surfactant disruption, and neurogenic inflammation have been reported. In the bronchial airways, 24-hour retention depends on size fraction, which is negligible for particles greater than 6 μm and increases to 80% at 30 nm.[153] SWCNTs produced mortality caused by upper airway mechanical blockage and non–dose-dependent multifocal granulomata in rats and dose-dependent epithelioid granulomata, interstitial inflammation, peribronchial inflammation, and death in mice.[157,296] Ultrafine particles (5–10 nm) of elemental carbon were readily taken up by canine and human alveolar macrophages and induced lipid mediators in a dose-dependent fashion.[17] In human bronchial epithelial cells, nanoparticulate carbon black particles (14 nm) induced dose-dependent proliferation via EGF-R and β1-integrin membrane receptors, phosphoinositide 3-kinases, and the protein kinase B (Akt) signaling cascade.[287] Intratracheal instillation of ultrafine (<200 nm) particles from combusted coal induced a higher degree of neutrophil inflammation and cytokine levels than did the fine or coarse particles. Compared with control subjects, mice aspirating native and acid-functionalized SWCNTs had significantly higher bronchoalveolar lavage (BAL) cell counts, PMNs, and cytokines (IL-6, tumor necrosis factor-α, and macrophage-inflammatory protein-2 (MIP2)).[253] The severe toxicity of air-generated polytetrafluorethylene

(PTFE fumes) may be reduced by aging, filtering, and preexposure, suggesting nanoparticle upregulation of pulmonary inflammatory cytokines and antioxidants.[133]

Pulmonary surfactant is a mixture of lipids, phospholipids, and proteins that provides low surface tension and serves to bind and identify targets for phagocytosis. Independent of cellular effects, in vitro lung models suggest that nanoparticle deposition may cause pulmonary surfactant dysfunction during the breathing cycle.[136] Nanosized nickel, cobalt, and TiO_2 create more inflammation than larger metal particles of an equivalent mass concentration. Diesel exhaust particulate matter may be solubilized and dispersed in the major component of pulmonary surfactant (dipalmitoyl phosphatidyl choline) and induce genotoxicity in multiple different assays in bacteria and mammals.[250,292]

Hematological and Cardiovascular Effects Possible hematologic and vascular effects of concern include thrombogenesis, atherogenesis, endothelial dysfunction, hemolysis, and immune stimulation. Epidemiologic studies support an association between exposure to particulate matter of less than 10 μm (PM_{10}) and increased risk of deep venous thrombosis.[13] This is in contrast to larger particles (PM_{10}), which were not statistically associated with mortality from embolism and thrombosis.[113] Diesel exhaust particles (20–50 nm, 200–500 times smaller than PM_{10}) and positively charged polystyrene nanoparticles cause rapid activation of circulating blood platelets and microcirculatory thrombi.[199,201] Healthy volunteers exposed to concentrated ambient air particles had a linear increase in fibrinogen concentrations.[95]

Compared with larger particles, ultrafine particles produced larger atherosclerotic lesions, decreased the antiinflammatory effect of high-density lipoprotein, and induced oxidative stress in a susceptible animal model.[8] Human exposure to wood smoke increased the levels of serum amyloid A, a cardiovascular risk factor, as well as factor VIII in plasma and the factor VIII/von Willebrand factor ratio.[15] At doses that produced no significant pulmonary inflammatory changes, rats exposed to ultrafine TiO_2 aerosols displayed impaired endothelium-dependent arteriolar dilation or outright constriction.[208,209]

Multiple engineered and combustion-derived carbon nanoparticles stimulate human platelet aggregation, activate glycoprotein (GP) IIb/IIIa, and accelerate the rate of vascular thrombosis in rat carotid arteries.[239] Metal nanoparticles (iron, copper, gold, cadmium sulfide) induced dose-dependent platelet aggregation through the P2Y12 ADP receptor.[61] Nickel, cobalt, and titanium dioxide nanoparticles variably induce blood neutrophils to release ROS and reactive nitrogen species.[181] IV administration of ultrafine diesel exhaust particles induced monocyte proliferation, decreased hemoglobin concentrations, and increased pulmonary inflammation.[202]

Dendrimers may alter human erythrocyte shape, induce clustering, and cause significant hemolysis.[2,68,71,172] Polycationic water-soluble fullerene C_{60} derivatives and stabilized poly(lactide-co-glycolide) acid (PLGA) nanoparticles also induce significant hemolysis.[28,141]

The ability of ultrafine particles to alter intracardiac function (decrease heart rate variability and repolarization changes) has been reported by several investigators.[64,98,105,108,276,288,312] Heart rate variability provides a measure of cardiac autonomic control, and a decrease predicts mortality in patients with prior myocardial infarction.[276] Significant pulmonary inflammation is not a prerequisite for this independent effect. At levels that initiated only low-grade pulmonary inflammation but not increased blood coagulability, carbon ultrafine particles (38 nm) increased heart rate and decreased heart rate variability.[105] Autonomic reflexes from pulmonary nerve endings appeared to mediate these effects.[94]

Immune System Nanoparticles may interact with the immune system in complex ways. Depending on their biophysiochemical properties,

nanoparticles may stimulate, suppress, or elude the immune responses.[66] Induction of chronic inflammation is of concern because commercially and academically available MWCNTs induced asbestos-like, length-dependent pathology in the abdominal cavity of mice following intraperitoneal exposure in mice,[234] and work in murine macrophage cells lines demonstrates that MWCNTs have a cytotoxic response nearly identical to that of asbestos.[266] Particle specific interactions with macrophages may result in intracellular particle accumulation, antigen-mediated immune stimulation, inflammatory mediator release, or fibrous or granulomata formation. In fact, formation of mouse granulocyte-macrophage colonies is now a standard testing methodology for assessing nanoparticle toxicity.[11] Multiple examples of significant ultrafine and engineered nanoparticle interaction with macrophages and monocytes are detailed throughout this chapter. Other cell lines can be also induced to release inflammatory mediators. Human epidermal cells exposed to SWCNTs release interleukin-8.[185] MWCNTs introduced in human neonatal epidermal keratinocytes increased IL-8 and IL-1β release.[300]

Direct immune stimulation may also occur. Fullerenes may induce a direct IgG response, which is capable of cross-reaction with other fullerenes.[30,44] The degree of induced opsonization by various IgG and complement molecules is thought to explain part of the differences seen in blood clearance and tissue distribution of nanoparticles.[214] CNTs may also act as adjuvants to boost immune response even in the absence of direct immune stimulation.[217]

Antibodies are not the only responses involved. Volunteer exposure to concentrated ambient particles (<200 nm) increased inflammatory blood mediators (intercellular adhesion molecule 1).[98] Given that proteins are known to absorb to nanoparticles, expectedly, CNTs were found to activate human complement via both classical and alternative pathways, and C1q binds directly to CNTs.[249] Complement activation may underlie non–IgE-mediated immediate hypersensitivity reactions seen in PEGylated liposomal doxorubicin administration.[42] $MnFe_2O_4$ magnetic nanoparticles (diameter, 10 nm) induced severe inflammatory reactions in mice.[155] Last, nanoparticles may contribute to "neurogenic inflammation," the process of inflammation by airway nerves, which synthesize various inflammatory mediators (neurokinin A, substance P, calcitonin gene-related peptide, and others) in response to exogenous irritants and contribute to pathology.[75,100,187]

Reproduction and Embryologic Development Research into nanoparticle effects on the reproductive system is sparse. One review of eight articles concluded that nanoparticles are able to cross the blood–testis barrier and locate in the testes.[177] At least one study found dose-dependent mitochondrial impairment cytotoxicity in spermatogonia, particularly silver nanoparticles.[32] In the animal model of organogenesis, fish eggs (*Oryzias latipes*) easily took up 39.4-nm fluorescent particles and concentrated them in the yolk area and gallbladder during embryonic development.[137] More complex interactions, such as endocrine or androgen disruption from leaching or degradation of nanoparticles, are largely unexplored.[110,216,231]

Bioaccumulation and Persistence A final concern is nanoparticle accumulation in cells, tissues, or organs. Repeated exposure would then permit attainment of threshold toxicities. Alternatively, prolonged periods of persistence could allow leaching and toxicity of initially protected materials. Work in small-fiber toxicology (eg, asbestos) has demonstrated that biopersistent particle effects may not manifest for decades.[186] Among different fine particles (fiberglass, rock wool, slag wool, asbestos), biopersistent potential seems to underlie toxic effects.[111] Thus, the independent findings that MWCNTs may induce asbestos-like pathology and mesothelioma is worrisome.[234,269] Bone marrow deposition of nanoparticles[236] could allow for ongoing systemic exposure. Persistence in other compartments could also permit more extensive distribution (eg, translocation from lung tissue).

Dextran-coated ultrasmall superparamagnetic iron oxide particles currently used in clinical trials are retained by human monocyte–macrophages for days.[192,193] QDs persisted at least 4 months in mice, remaining at least 1 month in the liver, lymph nodes, and bone marrow.[14] At the cellular level, nanocrystals can be passed to daughter cells upon mammalian cell division.[103,175] In fact, retained fluorescing QDs have been used experimentally to trace *Xenopus* cells from the embryo to the tadpole stage.[69]

ADMINISTRATIVE, REGULATORY, AND RESEARCH ISSUES

The 21st Century Nanotechnology Research and Development Act guides U.S. nanotechnology policy.[196] Amendments to the National Nanotechnology Initiative (NNI) are currently under Congressional consideration.[271] Elements include establishment of national strategic plans for nanotechnology and triennial review by the National Research Council; establishment of a public database for funded EHS (environmental, health, and safety), educational and societal dimensions, and nanomanufacturing projects; fiscal support for a Nanotechnology Coordination Office; mandates for research in environmental, health, and safety; development of nomenclature and engineered nanoscale standard reference materials standards; development of standards for detection, measurement, monitoring, sampling, and testing of engineered nanoscale materials for environmental, health, and safety impacts; and nanotechnology education. The NNI comprises various federal agencies with funding, research, regulatory, and administrative roles, including the Department of Defense, National Science Foundation, Department of Education, National Institutes of Heath, National Institute for Occupational Safety and Health (NIOSH), FDA, National Institute of Standards and Technology, Environmental Protection Agency (EPA), United States Department of Agriculture, National Aeronautics and Space Administration, and others. In its congressionally mandated role to review federal nanotechnology research and development, the National Nanotechnology Advisory Panel has provided recommendations for continued development of infrastructure, standards, and EHS risk analysis concurrent with applications research.[238]

■ ENVIRONMENTAL, HEALTH, AND SAFETY

The detailed NNI strategy for EHS research recommends incorporation of many factors in concluding a nanotechnology risk assessment, including nanomaterials synthesis and use; nanomaterial lifecycle stage; transport, transformation, and abiotic effects; environmental concentration; exposure of environmental and biologic systems; internal dose; biologic response; and environmental effects.[267] Identified immediate priority needs included the development of nanomaterial detection methods, certified reference materials, and standardized physiochemical assessments; understanding generalizable toxicologic characteristics of nanomaterials in biologic systems; identification of environmental and occupational exposures; and evaluation of risk management approaches to nanomaterials.

■ OCCUPATIONAL HEALTH

NIOSH is the coordinating U.S. agency for nanotechnology human and environmental exposures assessment research.[267] At the time of writing, established U.S. government occupational exposure limits, action levels, or disclosure and surveillance guidelines specific for engineered nanoparticles were nonexistent.[255] The general federal statute limiting "particulates not otherwise regulated" (PNOR) (also known as "inert or nuisance dusts") to a respirable fraction of 15 millions of particles

per cubic foot of air (5 mg/m³) would include nanoparticles, although this may provide inadequate protection.[74,157,264] NIOSH has released two reports, "Approaches to Safe Nanotechnology"[204] and "Progress towards Safe Nanotechnology in the Workplace."[205] These identified potential health concerns (nanoparticle dose, deposition, reactivity, toxicity, and translocation) and safety issues (combustion and catalytic potential). Recommendations included epidemiology, surveillance and background nanoaerosol measurements, personnel exposure sampling, engineering controls, implementation of risk management programs, and use of filters and respirators when necessary.[204] NIOSH anticipates that properly fit NIOSH-certified respirators in conjunction with a respiratory control program will protect workers from most inhaled nanoparticles.[205] Other occupational professional guidance can be found in national and international guidelines and reviews.[10,88,124,197,255]

■ FOOD AND DRUG ADMINISTRATION

The FDA regulates food and color additives, drugs, biologics, devices, blood products, and cosmetics to ensure that they are "safe" and unadulterated. The FDA does not regulate "nanotechnology." Rather, marketing authorization occurs on a product-by-product basis. The FDA can require manufacturers to provide necessary information (eg, chemistry, manufacturing, active ingredients, pharmacologic and toxicologic results, and particle size) to support decisions regarding premarket approval; however, in evaluating the sponsor "claims," the FDA may be unaware that nanotechnology is being used. In general, the FDA has treated nanomaterial ingredients no differently than bulk material ingredients or products. An FDA task force recommended addressing nanotechnology labeling and environmental impact on a case-by-case basis.[285] Cosmetics and dietary supplement nanomaterials claims are largely unevaluated.

■ ENVIRONMENTAL PROTECTION AGENCY

The EPA is the coordinating agency for human nanomaterials environmental research.[267] Nanomaterial applications for environmental remediation are particularly attractive. Regulation of nanomaterials and the effects of nanotechnology may also come under the EPA's broad authorities under the Clean Air Act (CAA), Pollution Prevention Act (PPA), Clean Water Act (CWA), Safe Drinking Water Act (SDWA), Federal Insecticides and Rodenticides Act (FIFRA), Comprehensive Environmental Response Compensation and Liability Act (CERCLA), Resource Conservation and Recovery Act (RCRA), and Toxic Substances Control Act (TSCA). For example, the EPA determined that (nano) silver ion–generating washing machines marketed with bactericidal claims were subject to registration requirements under FIFRA,[79] and extended the requirement to copper- and zinc-emitting devices and ion generators in swimming pools. The EPA also launched a Nanoscale Materials Stewardship Program (NMSP) for reporting available information on the engineered nanoscale materials to complement its existing programs per TSCA, under which new nanomaterials might be regarded as "chemical substances."[78] The balance of nanotechnology to improve environmental conditions (e.g., improved fuel efficiency and decreased emissions via cerium oxide nanoparticle additives diesel fuel) will need to be carefully weighed against unintended consequences (eg, increased ambient cerium air concentrations and altered diesel emissions composition with increased benzene, 1,3-butadiene, and acetaldehyde concentrations).[284]

The rapid pace of development will mandate constant updating and assessment of available knowledge. A selected list of organizational resources is provided in Table 123–1.

SUMMARY

Nanotechnology and nanotoxicology represents new and expanding disciplines. Although the possible applications of nanotechnology are diverse and beneficial at this early stage in nanotoxicology, toxicologic profiles are incomplete. The special physiochemical properties of nanoparticles, which can yield non-intuitive biologic effects, complicate this assessment. Appropriate research methodologies, *in* vitro and in vivo models, risk assessment, and workplace and environmental standards await further exploration and consensus.

CHAPTER 124
SIMPLE ASPHYXIANTS AND PULMONARY IRRITANTS

Lewis S. Nelson and Oladapo A. Odujebe

The respiratory system is responsible for gas exchange, elimination of certain xenobiotics, insensible water loss, temperature regulation, and minor metabolic processes. The principle function of the respiratory system is gas exchange, which occurs in the greater than 300 million alveoli that make up approximately 90% of the human lung volume. The average resting adult is exposed to about 8 L/min of air (a tidal volume of about 500 mL) and averages 16 breaths per minute, and this volume can be increased exponentially by increasing the respiratory rate and tidal volume as occurs during exertion. In a 24-hour period, an average adult human at rest will have been exposed to 11,500 L of air. There are a number of protective systems within the respiratory system to prevent exposure to xenobiotics, but these systems can be overwhelmed. The principles of respiratory system function are covered extensively in Chapter 21.

The respiratory tract performs several important physiologic functions. Its most important role involves the transfer of oxygen to hemoglobin across the pulmonary endothelium. This transfer facilitates oxygen distribution throughout the body to permit effective cellular respiration. Diverse xenobiotics may act at unique points in this distribution pathway to limit or impair tissue oxygenation. For example, whereas opioids and neuromuscular blockers may induce hypoventilation, carbon monoxide and methemoglobin inducers prevent binding of oxygen to hemoglobin. Certain xenobiotics prevent adequate oxygenation of hemoglobin at the level of pulmonary gas exchange. Two mechanistically distinct groups of xenobiotics are capable of interfering with gas exchange: simple asphyxiants and pulmonary irritants. Impairment of transpulmonary oxygen diffusion, regardless of the etiology, reduces the oxygen content of the blood and may result in tissue hypoxia.

HISTORY AND EPIDEMIOLOGY

Unlike most xenobiotic exposures, simple asphyxiant and pulmonary irritant poisonings frequently occur on a mass scale because of the nature of the inhalational route. For example, the large-scale emission of carbon dioxide from Lake Nyos, a carbonated volcanic crater lake in Cameroon, West Africa, resulted in nearly 2000 human and many more livestock deaths (see Chap. 2).[15] In this disaster, simple asphyxiation was likely because medical evaluation of both survivors and fatalities demonstrated neither signs of cutaneous or pulmonary irritation nor toxicologic abnormalities.[201] The widespread use of compressed liquefied gases, which expands several hundredfold on depressurization or warming, account for a substantial number of workplace injuries.[123,183]

Irritant gases similarly may result in mass casualties. For this reason, chlorine and phosgene were used in battle during World War I, resulting in thousands of Allied deaths[83] (see Chap. 131). Atmospheric sulfur dioxide and oxides of nitrogen are the primary components of photochemical smog. During the London Fog incident in 1952, 4000 deaths occurred primarily from respiratory causes.[171] Similar smog incidents have occurred across the globe. Relatedly, the diverse irritants found in fire smoke are largely responsible for the development of acute lung injury (ALI) after smoke inhalation.[180]

Unexpected release of other irritant inhalants may lead to large-scale poisoning. In 1984, an inadvertent release of methylisocyanate in Bhopal, India, resulted in immediate and persistent respiratory symptoms in approximately 200,000 local inhabitants, with approximately 2500 deaths.[16,53]

Isolated exposures to individuals occur as well, often in workplaces, and more frequently in contained spaces (eg, indoors). Additionally, the use of simple asphyxiation as a painless and relatively undetectable method for committing suicide and, paradoxically, for euphoric experiences can be found in books, on the Internet, and in the medical literature.[67,75,77,162]

SIMPLE ASPHYXIANTS

Simple asphyxiants work primarily by displacing oxygen from ambient air, unlike chemical asphyxiants, which cause cellular hypoxia and are discussed in Chapters 125 and 126. Virtually every gas, excluding oxygen, is capable of acting as a simple asphyxiant.

◼ PATHOPHYSIOLOGY

Simple asphyxiants displace oxygen from ambient air, thereby reducing the fraction of inspired oxygen (FiO_2) in air to below 21%, and result in a decrease in the partial pressure of oxygen. The partial pressure is a measure of the contribution of oxygen to the total inspired air and is based on both FiO_2 and barometric pressure. For example, because the ambient pressure at sea level (less water vapor, 47 mm Hg) is 713 mm Hg and the percentage of oxygen is 21%, the partial pressure of oxygen in the lungs is 150 mm Hg. Under these typical conditions, the FiO_2 is a suitable surrogate for the partial pressure of oxygen. However, this relationship is not applicable at other barometric pressures. For example, at the summit of a mountain, the reduced barometric pressure results in a decrease in the partial pressure of oxygen despite a near-normal FiO_2. The barometric pressure decreases in a linear fashion with altitude (above sea level) and increases with decent below sea level. This reduced partial pressure may be insufficient to allow adequate oxygen saturation, and supplemental oxygen becomes necessary. As barometric pressure decreases, exposure to simple asphyxiant gases may further reduce the oxygen partial pressure to life-threatening levels. Conversely, underwater divers reduce their FiO_2 to below 21% by adding simple asphyxiant gases, such as helium, to their breathing mixture to avoid oxygen toxicity, yet they still maintain adequate oxygenation. This is because the elevated barometric pressure increases the partial pressure of oxygen to normal levels despite the addition of an asphyxiant gas. However, systemically poisonous gases that enter the breathing mixture would have a magnified effect, given their increased partial pressure at depth.

In general, simple asphyxiants have no pharmacologic activity. For this reason, exceedingly high ambient concentrations of these gases are necessary to produce asphyxia. Asphyxiation typically occurs in confined spaces or with rapid release of concentrated simple asphyxiants.

◼ CLINICAL MANIFESTATIONS

A patient exposed to any simple asphyxiant gas will develop characteristic clinical findings of hypoxia, or lack of oxygen at the cellular level (Table 124–1). These clinical findings are directly related to the

TABLE 124–1. Clinical Findings Associated with Reduction of Inspired Oxygen

FiO_2[a]	Signs and Symptoms
21	None
16–12	Tachypnea, hyperpnea, (resultant hypocapnia), tachycardia, reduced attention and alertness, euphoria, headache, mild incoordination
14–10	Altered judgment, incoordination, muscular fatigue, cyanosis
10–6	Nausea, vomiting, lethargy, air hunger, severe incoordination, coma
<6	Gasping respiration, seizure, coma, death

[a] At sea level, barometric pressure appropriate adjustments must be made for altitude and depth exposures.

FiO_2, fraction of inspired oxygen.

reduction in the partial pressure of oxygen in ambient air, which leads to hypoxemia, or low oxygen content of the blood.[123] Cardiovascular and central nervous system (CNS) complications of simple asphyxiants predominate because these organs have the greatest oxygen requirements. As hypoxemia becomes severe, multisystem organ failure and death from tissue hypoxia may occur.[50] Postmortem findings are generally minimal, hampering the cause of death determination without historical evidence or advanced laboratory testing.[10]

During simple asphyxiation, carbon dioxide exchange is not impaired, and hypercapnia does not occur. Because dyspnea develops more rapidly from hypercapnia than hypoxemia, the breathlessness associated with physical or simple chemical asphyxiation does not develop until severe hypoxemia intervenes.[92,111] In these circumstances, victims may succumb to hypoxemia without ever developing the expected warning symptoms. In the case of carbon dioxide inhalation, hypercapnia may occur very rapidly, which itself may produce acute cognitive impairment.

■ SPECIFIC AGENTS

Noble Gases: Helium, Neon, Argon, and Xenon Noble gases, which are stored almost exclusively in the compressed form, have numerous industrial and medical roles. Argon is predominantly used as a shielding gas during welding operations. Neon is used in the manufacture of decorative lighting. Xenon, in its radioactive gaseous form, has diagnostic medical applications in ventilation–perfusion scans. Helium has the lowest molecular weight and is the smallest member of the noble gas family of elements. Because of its lower lipid solubility, helium is used by divers to replace nitrogen to prevent nitrogen narcosis at depth (see Nitrogen). Even at diving gas mixtures of 50% helium, divers suffer no adverse effects as long as a normal partial pressure of oxygen is maintained by the mixture at depth. At depth, the quantity (molar quantity, not volume) of air inspired per breath is several-fold greater than that at sea level. The fact that helium has a lower density than nitrogen results in a lower viscosity, or a marked decrease in flow resistance. This property of helium is the basis for its use in patients with increased airway resistance, such as those with asthma.

Helium is also used in magnetic resonance imaging scanners to keep the coils super cooled. During emergency shutdown of a superconducting electromagnet, an operation known as "quenching," the liquid helium is rapidly boiled from the device and vented into the scanner room. This may displace oxygen from the environment and cause

asphyxia.[86] Helium is also used in lung imaging studies and pulmonary function tests. Similarly, helium's low viscosity has led to its use as an inflation gas for intraaortic balloons, for which rapid inflation and deflation are critical.

All noble gases, when compressed, form cryogenic liquids, which expand rapidly to their gas phase on decompression. Liberation of these gases in closed spaces may result in asphyxiation or freezing injuries[86] Xenon, unlike the other noble gases, has unique anesthetic properties because of its high lipid solubility and inhibition of N-methyl-D-aspartic acid (NMDA)receptors[86] The other noble gases have no known direct toxicity.

Short-Chain Aliphatic Hydrocarbon Gases: Methane, Ethane, Propane, and Butane The short-chain aliphatic hydrocarbon gases are primarily used in the compressed form as fuel. Methane (CH_4) has no known direct toxicity. Animals can breathe a mixture of 80% methane and 20% oxygen without manifesting hypoxic symptoms because their FiO_2, and thus their oxygen content, essentially is normal. Methane, also known as natural gas and "swamp gas," may be present in high ambient concentrations in bogs of decaying organic matter. In addition, compressed natural gas is now used as an alternative fuel for automotive use. Methane exposure is an occupational hazard for miners who historically carried canaries into their workplace as an "early warning" sign for the presence of toxic gases or oxygen deficiency. Theoretically, the higher metabolic and respiratory rates of small animals (and children) make them more rapidly susceptible to gas exposures. Methane is also an explosive risk.

Methane is odorless and undetectable without sophisticated equipment.[34] For this reason, natural gas is intentionally adulterated with a small concentration of ethyl mercaptan, a stenching agent, which is responsible for the well-recognized sulfur odor of natural gas. Cooking with natural gas may lead to increased respiratory symptoms and pulmonary dysfunction.[95] However, methane itself is unlikely to be the cause because its combustion is generally complete and ambient concentrations are negligible. It is likely that exposure to nitrogen dioxide (NO_2), one of the products of combustion of methane in air (70% nitrogen), is the explanation for these symptoms.

Ethane (C_2H_6) is an odorless gas that is a component of natural gas and is used as a refrigerant. It has characteristics similar to methane and has been occasionally implicated as a simple asphyxiant. Propane (C_3H_8) is widely used in compressed, liquefied form both as an industrial and domestic fuel and as an industrial solvent. Butane (C_4H_{10}) is a common fuel and solvent. Deliberate butane inhalation from cigarette lighters or air fresheners for recreational purposes predominantly in adolescents is associated with cardiovascular dysfunction and cerebral damage (see Chap. 81).[59,178]

Carbon Dioxide (CO_2) Although not a simple asphyxiant gas by definition because it produces physiologic effects, carbon dioxide closely resembles simple asphyxiants from a toxicologic viewpoint. Carbon dioxide gas has many practical industrial uses, such as production of carbonation in soft drinks and use as a shielding gas during welding. It is used in laboratories as a painless form of animal euthanasia and as a means of large-scale euthanasia of diseased livestock.[151] Carbon dioxide is widely used to extinguish fires because of its ability to safely displace oxygen from the local environment.[74] Dry ice, the frozen form of carbon dioxide, is an extremely cold substance (−141.3°F [−78.5°C]) that undergoes conversion from solid to gas without liquefaction, a process known as sublimation. Profound poisoning may occur when dry ice is allowed to sublimate in a closed space,[37] such as the cabin of a car or, as in the case above, in a cold storage room at 39.2°F (4°C).[74,57] Furthermore, inadvertent connection of respirable gas hoses to carbon dioxide and other nonrespirable sources has occurred in both industrial[92,184] and medical[96] settings, with resultant worker and

patient fatalities. This occurrence is uncommon because of the mandated use of engineering controls to prevent the incorrect connection of hose and source terminals.

Pharmacology and Pathophysiology. Carbon dioxide, an end product of normal human metabolism, dissolves in the plasma and is in equilibrium with carbonic acid (H_2CO_3). The pH at the central chemoreceptors, reflective of the dissolved carbon dioxide (PCO_2), is responsible for our respiratory drive, and PCO_2 is tightly controlled by the CNS through regulation of breathing.[111] For this reason, exogenous carbon dioxide, combined with oxygen, was at one time used medically as a respiratory stimulant in neonates. Under normal conditions, ambient air contains approximately 0.03% CO_2. When ambient concentrations increase above this level, uptake of carbon dioxide occurs, which further stimulates respiration,[148] increasing the uptake of ambient carbon dioxide. Accordingly, closed anesthesia systems use scrubbers containing sodium hydroxide to chemically eliminate exhaled carbon dioxide. Failure of the scrubber system results in increasing depth of anesthesia from hypercapnia-induced hyperventilation.

Clinical Manifestations. Carbon dioxide produces both acute and subacute poisoning syndromes. The latter occurs during hypoventilation when a patient fails to eliminate endogenous carbon dioxide, develops hypercapnia, and typically presents with gradual somnolence. This occurrence may be linked to respiratory failure, as in the case of emphysema or opioid poisoning, or it may be iatrogenic, as occurs during permissive hypercapnia.[133] Alternatively, intense carbon dioxide exposure may produce rapid and lethal poisoning. However, unlike other simple asphyxiants, experimental models of acute carbon dioxide poisoning in which FiO_2 is maintained at normal levels demonstrate that central nervous and respiratory system manifestations occur within seconds.[85,94] This finding suggests that CO_2 is not solely a simple asphyxiant but also possesses a potential for systemic effects.

Nitrogen (N_2) Gas Although nitrogen, like carbon dioxide, may produce clinical effects independently of hypoxemia, most poisonings are characterized by the manifestations of simple asphyxiants. Nitrogen gas is used as a carrier gas for chromatography, as a fertilizer, as a cryogenic gas for surgery, and extensively in manufacturing. Poisoning by nitrogen gas is uncommon but may occur after rapid evaporation of the liquid.[99,100]

Pharmacology and Pathophysiology. Nitrogen is a colorless, odorless, and tasteless gas that makes up 78% by volume of the atmospheric gas. Under standard conditions, it is an inert diatomic gas that has no direct physiologic toxicity.

Clinical Manifestations. Inadvertent connection of air-line respirator hoses to nitrogen and other inert gas sources results in acute asphyxiation, with unconsciousness occurring in approximately 12 seconds[92,123,183] and death shortly thereafter. More indolent inhalational poisoning by nitrogen is characterized by impairment of intellectual function and judgment, giddiness, and euphoria, which is qualitatively similar to ethanol intoxication.[126] More severely poisoned patients may manifest lethargy or coma.[66] Systemic absorption is not rapid, however, and prolonged, high-level exposure is required for poisoning. Nitrogen poisoning, also known as *nitrogen narcosis*, occurs in underwater divers while they are breathing air that contains 70% nitrogen. It has been called *rapture of the deep* (*l'ivresse des grandes profondeurs*) and has led to many deaths in the subaquatic environment. The underlying mechanism of nitrogen narcosis is unknown,[49] but the simple structure and relatively high lipophilicity of nitrogen suggest a mechanism similar to that of the anesthetic gases.[66] To avoid nitrogen narcosis, a less lipid-soluble inert gas such as helium is generally substituted for nitrogen. Substitution with oxygen, although intuitively logical, is inappropriate because of the risk of oxygen toxicity (see Oxygen).

Dermal exposure to liquid nitrogen produces frostbite because of liquid nitrogen's extremely cold temperature.[155] Ingestion of liquid nitrogen similarly produces a freezing injury of the gastrointestinal (GI) tract.[104,203] Rarely, bubbles introduced through the skin embolize through the vascular system and impair organ blood flow.[58]

■ TREATMENT

Treatment of all individuals poisoned by simple asphyxiants begins with immediate removal of the persons from exposure and provision of ventilatory assistance. Provision of supplemental oxygen is preferable, but room air usually suffices. Hyperbaric oxygen therapy has shown no benefit in the majority of cases. Restoration of oxygenation through spontaneous or mechanical ventilation occurs after only several breaths. Support of vital functions is the mainstay of therapy but is generally unnecessary after a brief exposure.

PULMONARY IRRITANTS

The irritant gases are a heterogeneous group of chemicals that produce toxic effects via a final common pathway: destruction of the integrity of the mucosal barrier of the respiratory tract (Table 124–2).

■ PATHOPHYSIOLOGY

In the lung, irritant chemicals damage both the more prevalent type I pneumocytes and the surfactant-producing type II pneumocytes.[106] Neutrophil influx, recruited in response to macrophage-derived inflammatory cytokines such as tumor necrosis factor (TNF)-α, releases toxic mediators that disrupt the integrity of the capillary endothelial cells.[116,153] This host defense response results in accumulation of cellular debris and plasma exudate in the alveolar sacs, producing the characteristic clinical findings of ALI. The specific mechanisms by which the irritant gases damage the pulmonary endothelial and epithelial cells vary. Many irritant gases require dissolution in lung water to liberate their ultimate toxicant, which often is an acid, as occurs when hydrogen chloride gas produces hydrochloric acid. The exact mechanism by which acids damage cells and induce an inflammatory response remains uncertain. Oxidation of intracellular proteins may result in rapid cytoskeletal shortening, creating spaces between endothelial cells and allowing fluid movement into the alveolar spaces.[189] Other gases, such as oxygen, induce pulmonary damage solely through free radical–mediated oxidative stress on the cellular membranes. NO_2 and chlorine are characteristic of a group of gases that produce both acid and free radical oxidants. Furthermore, other respirable xenobiotics, such as metals, injure the respiratory tract through oxidant stress and other mechanisms. Because the precise toxicologic and pathophysiologic effects vary widely depending on the physicochemical properties of the xenobiotic, these mechanisms are covered more completely in the following specific discussions.

By virtue of its use as a war agent, phosgene has received more investigation than the other irritant gases. Although the specific mechanisms of toxicity of the other irritants remain poorly defined, they likely cause injury through a similar process. The acids liberated upon dissolution in the mucosal water react with functional groups on epithelial and endothelial cell membranes and, via cellular messengers, result in a complex inflammatory response.[165,140] Phosgene stimulates the synthesis of lipoxygenase-derived leukotrienes and other cytokines such as TNF-α.[165] Leukotrienes are important chemotactic factors for neutrophils, which accumulate, liberate oxidants, and produce ALI.[93] ALI can be prevented in rabbits by tomelukast, a leukotriene receptor antagonist,[81] and by methylprednisolone, which blocks leukotriene

TABLE 124–2. Characteristics of Common Respiratory Irritants

Gas	Source or Exposure	Solubility (g%)[a]	Detection Threshold (ppm)	Regulatory Standard (ppm)[b]	IDLH[c] (ppm)	STEL[d] (ppm)
Ammonia	Fertilizer, refrigeration, synthetic fiber synthesis	90	5	50	300	35
Cadmium oxide fumes	Welding	I	Odorless	0.005 mg/m³	9 mg/m³ (as Cd)	NA
Carbon dioxide	Exhaust, dry ice sublimation	0.2	Odorless	5000	40,000	30,000
Chloramine	Bleach plus ammonia	M	NA	NR	NR	NR

[a] g% = grams of gas per 100 mL water; if applicable.

[b] Standards are either; Threshold Limit Value-Time-Weighted Average; (TLV-TWA) set by the American Conference of Governmental Industrial Hygienists (ACGIH); or permissible exposure limits (PELs) set by the Occupational Safety and Heath Administration (OSHA).

[c] Immediately dangerous to life and health: National Institute for Occupational Safety and Health (NIOSH), revised 1995. (Documentation for each IDLH (Immediately Dangerous to Life and Health limit) is available at http://www.cdc.gov/niosh/idlh/idlhintr.html.)

F, fluorine; I, insoluble; M, miscible; NR, no regulatory standard; NA, not available; P, poor; NIOSH and OSHA 15 minute or ceiling. STEL[d], short term exposure limit,

synthesis; both xenobiotics also offer postexposure benefit.[81] Ibuprofen, an inhibitor of the arachidonic acid cascade, and xenobiotics capable of reducing neutrophil influx, such as colchicine and cyclophosphamide, reduce lung injury and mortality in mice when they are administered shortly after phosgene exposure.[73,167] Intratracheal dibutyryl cyclic adenosine monophosphate (DBcAMP), a cAMP analog, and other cAMP amplifiers, such as terbutaline or aminophylline, inhibit the release of leukotrienes and reduce toxicity.[98,168] When administered 45 minutes after exposure to phosgene-poisoned rabbits, intratracheal *N*-acetylcysteine (NAC) decreases the formation of leukotrienes by an undefined means and limits the development of ALI.[169] Presumably, administration via nebulization would prove similarly effective. Intravenous administration of NAC to patients with mild to moderate ALI, none of whom had phosgene-induced pulmonary damage, improved systemic oxygenation and reduced their need for ventilatory support.[185] However, progression to pulmonary failure was not altered.

Free radicals are highly reactive molecular derivatives, typically from oxygen or nitrogen that bind to and destroy tissue near their site of generation. Through initiation of a lipid peroxidative cascade, free radicals destroy lipid membranes and inhibit energy production through the electron transport chain (see Chap. 12). Products of lipid peroxidation and cellular damage initiate neutrophilic influx, presumably in an immunologic attempt to combat a pathogen. Ironically, free radicals generated by the invading inflammatory cells contribute to pulmonary damage. Fortunately, the lung has antioxidant systems, both enzymatic (eg, superoxide dismutase, glutathione peroxidase, catalase) and nonenzymatic (eg, glutathione, ascorbate), which detoxify virtually all free radicals present in the lung.[149] However, the oxidant burden imposed by oxidant gases can preempt these detoxifying systems and produce cellular damage. For example, nebulization of manganese superoxide dismutase into the airway 1 hour after smoke inhalation, a form of oxidant lung injury, did not improve lung edema or pulmonary gas exchange.[114] However, the observed benefit of NAC may also be related to improved hemodynamic function (see Antidotes in Depth A4: *N*-Acetylcysteine).[87]

CLINICAL MANIFESTATIONS

Regardless of the mechanism by which the mucosa is damaged, the clinical presentations of patients exposed to irritant gases are similar. Those exposed to gases that result in irritation within seconds generally develop mucosal injury limited to the upper respiratory tract. The rapid onset of symptoms is usually a sufficient signal to the patient to escape the exposure. Patients may present with nasal or oropharyngeal pain in addition to drooling, mucosal edema, cough, or stridor.[188] Conjunctival irritation or chemosis, as well as skin irritation, is often noted because concomitant ocular and cutaneous exposure to the gases usually is unavoidable. Gases that are less rapidly irritating may not provide an adequate signal of their presence and may not prompt expeditious escape by the exposed individual. In this case, prolonged breathing allows entry of the toxic gas farther into the bronchopulmonary system, where delayed toxic effects may subsequently be noted. Tracheobronchitis, bronchiolitis, bronchospasm, and ALI are typical inflammatory responses of the airway and represent the spectrum of acute lower respiratory tract injury.

Experimental models assessing the water solubility of a gas to predict the location of its associated lesions have largely agreed with the clinical data.[101] However, exceptions to this relationship of a gas and its expected toxicity are common. For example, in situations in which escape from ongoing exposure is prevented, patients may develop lower respiratory tract injury after prolonged exposure to acutely irritating gases. Alternatively, rapid onset of upper respiratory irritation may be noted in patients after exposure to concentrated gases that are generally associated with delayed symptomatology. Exposure to exceedingly high concentrations of any gas may produce hypoxemia analogous to that resulting from exposure to a simple asphyxiant gas.

The most characteristic and serious clinical manifestation of irritant gas exposure is ALI.[11,18,157,158] ALI consists of the clinical, radiographic, and physiologic abnormalities caused by pulmonary inflammation and alveolar filling that must be both acute in onset and not attributable solely to pulmonary capillary hypertension as occurs in patients with congestive heart failure.[11,18,157,158] The most severe manifestation of ALI is the acute respiratory distress syndrome (ARDS). The criteria for diagnosis of ARDS is based on the ratio of the partial pressure of dissolved oxygen (PaO_2) to FiO_2, that is, patients with an appropriate history and clinical presentation for ALI with PaO_2/FiO_2 below 200 mm Hg meet the definition of ARDS. Importantly, positive end-expiratory pressure (PEEP) is not part of the oxygenation criteria (see Chap. 21). Both ALI and ARDS are nonspecific syndromes resulting from diverse physiologic insults such as sepsis or trauma. Patients with ALI may present with dyspnea, chest tightness, chest pain, cough, frothy sputum, wheezing or crackles, and arterial hypoxemia. Typical radiographic abnormalities include bilateral pulmonary infiltrates with an alveolar filling pattern and a normal cardiac silhouette that differentiate this syndrome from congestive heart failure.

SPECIFIC XENOBIOTICS

Acid- or Base-Forming Gases Highly Water-Soluble Xenobiotics *Ammonia (NH₃).* Ammonia is a common industrial and household chemical used in the synthesis of plastics and explosives and as a fertilizer, a refrigerant, and a cleaner. The odor is characteristic and may be an effective warning signal of exposure and stimulus to avoid further exposure. Dissolution of NH_3 in water to form the base ammonium hydroxide (NH_4OH) rapidly produces severe upper airway irritation. Patients with exposures to highly concentrated NH_3 or exposures for prolonged periods may develop tracheobronchial or pulmonary inflammation. Experimental inhalation of nebulized high-dose ammonia causes ALI that is manifested by a decrease in oxygen saturation and an increase in airway pressure within 2 minutes of exposure.[174] Ultrastructural study of the lungs from two individuals dying acutely of ammonia inhalation revealed marked swelling and edema of type I pneumocytes consistent with ALI.[33] Chronic inhalation of low concentrations of NH_3 or repetitive exposure to high concentrations of ammonia may cause pulmonary fibrosis.[29]

Chloramines. This series of chlorinated nitrogenous compounds (Fig. 124–1) includes monochloramine (NH_2Cl), dichloramine ($NHCl_2$), and trichloramine (NCl_3). The chloramines are most commonly generated by the admixture of ammonia with sodium hypochlorite (NaOCl) bleach, often in an effort to potentiate their individual cleaning powers.[68] Interestingly, the addition of bleach to septic systems may result in liberation of the chloramines after the reaction of bleach with urinary nitrogenous compounds.[124] On dissolution of the chloramines in the epithelial lining fluid, hypochlorous acid (HOCl), ammonia, and oxygen radicals are generated, all of which act as irritants. Although less water soluble than ammonia, the chloramines typically promptly result in symptoms. Because these initial symptoms are often mild, however, they may not prompt immediate escape, resulting in prolonged or recurrent exposure with pulmonary and ocular symptoms predominating.[38] Exposure to trichloramine occurs at indoor swimming pools[40] and is responsible for inducing permeability changes in the pulmonary epithelium, the consequences of which are not yet understood.[36]

$Cl_2 + H_2O \rightarrow HCl + HOCl$

FIGURE 124–2. Chlorine chemistry. (**A**) Formation of chlorine gas from the acidification of hypochlorous acid. (**B**) Dissolution of chlorine in mucosal water to generate both hydrochloric and hypochlorous acids (HCl and HOCl) and oxidants [O].

Hydrogen Chloride (HCl). The largest and most important use of hydrogen chloride gas is in the production of hydrochloric acid. Dissolution of hydrogen chloride gas in lung water after inhalation similarly produces hydrochloric acid.[32,147] Pyrolysis of polyvinyl chloride (PVC), a plastic commonly used in pipe fabrication, generates HCl and is an occupational hazard for firefighters.[136] By adsorbing to respirable carbonaceous particles generated in the fire, HCl may be deposited at the alveolar level and produce pulmonary toxicity.

Hydrogen Fluoride (HF). Hydrogen fluoride and its aqueous form, hydrofluoric acid, are used in the gasoline, glassware, building renovation, and semiconductor industries. Hydrogen fluoride gas dissolves in epithelial lining fluid to form the weak acid hydrofluoric acid. The intact HF molecule is the predominant form in solution, and few free hydronium ions are liberated. Low-dose inhalational exposures may result in irritant symptoms,[195,207] and large exposures may cause bronchial and pulmonary parenchymal destruction.[28,195] Death after inhalation may result from ALI but usually is related to systemic fluoride poisoning independent of the route of exposure because of the resultant calcium binding and subsequent hypocalcemia and hyperkalemia[24,55] (see Chap. 105).

Sulfur Dioxide and Sulfuric Acid (SO_2 and H_2SO_4). Sulfur dioxide has multiple industrial applications and is a byproduct found in the smelting and oil refinery industries. It may also be generated by the inadvertent mixing of chemicals, such as an acid with sodium bisulfite ($NaHSO_3$). Sulfur dioxide is highly water soluble and has a characteristic pungent odor that provides warning of its presence at concentrations well below those that are irritating. In the presence of catalytic metals (Fe, Mn), environmental sulfur dioxide is readily converted to sulfurous acid (H_2SO_3) within water droplets. Sulfurous acid is a major environmental concern and the cause of "acid rain." Exposure to atmospheric sulfur dioxide results in a roughly dose-related bronchospasm, which is most pronounced and difficult to treat in patients with asthma. Inhalation of sulfurous acid or dissolution of sulfur dioxide in epithelial lining fluid produces typical pathologic and clinical findings associated with ALI.[154] In addition to the effect of acid generation upon dissolution, sulfur dioxide may cause oxidative damage to the lungs.[122] Large acute exposure to either xenobiotic produces the expected acute irritant response of both the upper and lower respiratory tracts,[41] and pulmonary dysfunction (see Asthma and Reactive Airways Dysfunction Syndrome) may persist for several years.[144]

Intermediate Water-Soluble Xenobiotics *Chlorine (Cl_2).* Chlorine gas is a valuable oxidizing agent with various industrial uses, and occupational exposure is common. Chlorine gas was used as a chemical warfare agent by both the French and the Germans in World War I (see Chap. 131). Although chlorine gas is not generally available for use in the home, domestic exposure to chlorine gas is common. The admixture of an acid to bleach liberates chlorine gas (Fig. 124–2).[76,130] Because the anionic component of the acid is not involved in the reaction, combining hypochlorite with virtually any acid, such as phosphoric, hydrochloric, or sulfuric acid, may result in the release of chlorine gas. As such, inappropriate mixing of cleaning agents is the cause of
most nonoccupational exposures.[130] Rarely, patients have intentionally generated chlorine gas in this manner for purportedly "pleasurable" purposes.[150] Concentrated chlorine gas may be generated when aging swimming pool chlorination tablets, such as calcium hypochlorite [$Ca(OCl)_2$] or trichloro-*s*-triazinetrione (TST), decompose[113,208] or are inadvertently introduced to a swimming pool while swimmers are present.[13,200] Inadvertent mixture of $Ca(OCl)_2$ and TST results in excessive chlorine gas generation and may also be explosive.[113] Acute chlorine toxicity may occur when there is a failure of the system when compressed chlorine gas is used for direct chlorination of public swimming pools[13,199] or for drinking water systems. Occasional mass poisoning may occur during scientific, industrial, or transportation incidents.[39,193]

The odor threshold for chlorine is low, but distinguishing toxic from permissible air concentrations may be difficult until toxicity is manifest. The intermediate solubility characteristics of chlorine result in only mild initial symptoms after moderate exposure and permit a substantial time delay, typically several hours, before clinical symptoms develop. Chlorine dissolution in lung water generates HCl and hypochlorous (HOCl) acids. Hypochlorous acid rapidly decomposes into HCl and nascent oxygen (O^-). The unpaired nascent oxygen atom produces additional pulmonary damage by initiating a free radical oxidative cascade. Although the majority of life-threatening chlorine poisonings occur after acute, large exposures, patients with chronic, low-concentration exposure or recurrent, moderate concentration poisonings may manifest increased bronchial responsiveness.[5,65,72]

Hydrogen Sulfide (H_2S). Hydrogen sulfide exposures occur most frequently in the waste management, petroleum, and natural gas industries,[88] although poisoning occurs in asphalt, synthetic rubber, and nylon industry workers as well. It is also rarely seen in hospital workers using acid cleaners to unclog drains clogged with plaster of Paris sludge.[143] Hydrogen sulfide is present in natural sources such as volcanic emission, in caves, and in sulfur springs. It is a decay product of organic material found in sewers or manure pits. Hydrogen sulfide, hydrogen fluoride, and phosphine are differentiated from the other irritant gases by their ability to produce significant systemic toxicity. Hydrogen sulfide inhibits mitochondrial respiration in a fashion similar to that of cyanide (see Chap. 126).[60,152]

H_2S has the distinctive odor of "rotten eggs," which, although helpful in diagnosis, is not specific for the agent. Despite a sensitive odor threshold of several parts per billion,[152] rapid olfactory fatigue ensues, providing a misperception that the exposure and its attendant risk have diminished. At low and moderate concentrations (≤500 ppm), upper respiratory tract mucosal irritation occurs and is the principal toxicity.[187] The rapidity of death in patients exposed to high H_2S concentrations makes it likely that either simple asphyxiation or cytochrome oxidase inhibition is causal in most cases.

Phosgene (Carbonyl Chloride [$COCl_2$]). During World War I, phosgene was an important weapon of mass destruction that produced countless deaths (see Chap. 131). Currently, phosgene is used in the synthesis of various organic compounds, such as isocyanates, and it occasionally

produces poisoning. It is a byproduct of heating or combustion of various chlorinated organic compounds.[176]

Exposure to phosgene initially may produce limited manifestations but may result in acute mucosal irritation after intense exposure. In fact, the pleasant odor of fresh hay, rather than prompting escape, ironically may promote deep and prolonged breathing of the toxic gas. The most consequential clinical effect related to phosgene exposure is delayed ALI.[25,164] Because of the accumulation of a significant alveolar burden of phosgene, symptoms generally are severe after they occur. The delay in onset may be nearly 1 day, so prolonged observation of patients thought to be phosgene poisoned is warranted. The mechanism of phosgene toxicity is dependent on the dissolution of the gas into the fluid of the epithelial lining with resultant liberation of hydrochloric acid and reactive oxygen species (ROS).[164]

Oxidant Gases Rather than acidic or alkaline metabolites, free radicals mediate the pulmonary toxicity of certain irritant gases. Many of the chemicals discussed participate in both acid–base and oxidant types of injury. However, the clinical distinction between acid- or alkali-forming agents and oxidant gases is difficult but ultimately may prove therapeutically relevant.

Oxygen (O_2). Oxygen toxicity is uncommon in the workplace but, ironically, is common in hospitalized patients. Although O_2 may produce CNS and retinal toxicity, pulmonary damage is more common.[175] Several clinical studies indicate that humans can tolerate 100% O_2 at sea level for up to 48 hours without significant acute pulmonary damage.[35,52] Under hyperbaric conditions (2.0 atmospheres absolute), such as during compressed-air diving or while inside a pressurized hyperbaric chamber, oxygen toxicity may develop within 3 to 6 hours.[44] ALI occurs in approximately 5% of patients administered hyperbaric oxygen for therapeutic purposes.[175] Delayed pulmonary fibrosis, presumably from healing of subclinical injury, may develop in patients breathing lower concentrations of O_2 at sea level for shorter periods.

Although it appears paradoxical that O_2, an essential molecule, may be deleterious at elevated concentrations, it is not. In mitochondria, O_2 plays a critical role as the ultimate acceptor for electrons completing the electron transport chain. It is this same potent oxidizing activity that allows O_2 to remove electrons from other compounds generating the reactive oxygen intermediates.[159]

Generation of ROS, including superoxide (O_2^-), hydroxyl radical (OH·), hydrogen peroxide (HOOH), and singlet oxygen (O·), and nitric oxide (NO) produces cellular necrosis, increases pulmonary capillary permeability, and induces apoptosis.[137,159] NO, produced by inducible NO synthase in the setting of oxidative stress, is directly cytotoxic or may combine with superoxide anions to form the more reactive oxidant peroxynitrite.[89] Experimental prevention of these effects by administration of either parenteral NAC,[160,202] a chemical antioxidant, or superoxide dismutase, an enzymatic antioxidant,[35,194] suggests that the mechanism of toxicity relates to the oxidant, or electrophilic, effects of these ROS (see Chap. 11). Although several other therapies have shown promise in preventing oxygen-mediated toxicity, none has yet proven to be valuable for patients who already manifest pulmonary toxicity. Current techniques for preventing pulmonary oxygen toxicity emphasize reduction of the inspired oxygen concentration by use of PEEP ventilation, although this approach failed to prove beneficial in at least one clinical trial.[12] The potential role of liquid ventilation of the lung with perfluorocarbons to prevent or treat pulmonary oxygen toxicity remains under investigation.[12]

Oxides of Nitrogen (NO_x). Oxides of nitrogen are a series of variably oxidized nitrogenous compounds.[69] The most important substances included in this series are the stable free radicals nitrogen dioxide (NO_2) and nitric oxide (NO), as well as nitrogen tetroxide (dinitrogen tetroxide [N_2O_4]), nitrogen trioxide (N_2O_3), and nitrous oxide (N_2O). The oxides of nitrogen are of limited value in industrial operations, although they may be generated during welding and brazing. NO_2, in addition to hydrogen cyanide, is produced in the pyrolysis of nitrocellulose, which is a substantial component of radiographic film. For example, a fire in the radiology department of the Cleveland Clinic in 1929 resulted in 125 casualties, with virtually all deaths resulting from cyanide or NO_2 gas poisoning.[78] NO_2 toxicity may occur when propane-driven ice-cleaning machines are used in indoor ice skating rinks with poor ventilation, thereby allowing accumulation of the generated NO_2.[109] Military exposure to high NO_2 concentrations may occur during closed-space fires, such as in submarines.[115] NO_2 also causes silo filler's disease, in which the toxic gas generated during decomposition of silage accumulates within the silo shortly after grain storage, eliminating rodents that feast on the grains.[56,210] In the absence of ventilation, high concentrations of NO_2 may accumulate in the silo such that an individual entering the silo is rapidly asphyxiated from the depletion of oxygen.[79] Additionally, substantial quantities of NO_2 remaining after incomplete ventilation may produce the delayed-onset pulmonary toxicity characteristic of silo filler's disease. Chronic indoor exposure to NO_2, generated during cooking[95] or outdoor exposure to photochemical smog, of which the oxides of nitrogen are a component, may predispose individuals to the development or exacerbation of chronic lung diseases.

The various oxides of nitrogen may directly oxidize respiratory tract cellular membranes but more typically generate reactive nitrogen intermediates, or radicals, such as peroxynitrite (ONOO⁻), which subsequently damage the pulmonary epithelial cells.[141] In addition to generating oxidant cascades, dissolution in respiratory tract water generates nitric acid (HNO_3) and NO, which produce injury consistent with other inhaled acids. In fact, inhalation of HNO_3 produces the same clinical and pathologic syndrome.[82] Antioxidants afford significant protection to human endothelial cells exposed to NO_2, indicating an important role of free radicals in the toxicology of these xenobiotics.[196]

NO, an endogenous compound important as a neurotransmitter and vasorelaxant, is used clinically as exogenous inhalational therapy for pulmonary hypertension and ALI.[190] In patients with ALI not resulting from sepsis (although not specifically from inhalational injury), low concentrations of inhaled NO (5 ppm) did not improve the clinical outcome.[190] However, one patient with NO_2 pulmonary toxicity improved clinically after NO therapy, so further consideration is warranted.[107] Furthermore, its use in premature infants with respiratory distress syndrome is well accepted.[163] NO is less soluble in the fluid lining the epithelial surfaces than are the other oxides of nitrogen and produces irritant effects after large exposures.[84,206] Its pulmonary oxidative toxicity, the manifestations of which are typical of the oxidant gases, is substantially enhanced by conversion to reactive nitrogen intermediates such as ONOO⁻.[17] This radical selectively interacts with tyrosine to produce nitrotyrosine, which may subsequently serve as a marker for oxidant damage.[84] NO may be absorbed from the lung and is rapidly bound by hemoglobin to form nitrosylhemoglobin and methemoglobin.

Ozone (O_3). Ozone is abundant in the stratospheric region found between 5 and 31 miles above the planet. Ozone is formed by the action of ultraviolet light on oxygen molecules, thus reducing the amount of solar ultraviolet irradiation reaching earth. The ozone concentration in passenger aircrafts may at times be above regulatory limits,[177] although a specific relationship with the development of clinical effects in airline crew members is elusive.[131] Ozone is another important component of photochemical smog and, as such, contributes to chronic lung disease.[30,197] It is produced in significant quantities by welding

$$H-\overset{\displaystyle \overset{H}{|}}{\underset{\displaystyle \underset{H}{|}}{C}}-N=C=O$$
FIGURE 124–3. Methylisocyanate.

and high-voltage electrical equipment and in more moderate doses by photocopying machines and laser printers. Because of its high electronegativity (only fluorine is higher), ozone is one of the most potent oxidizing agents available. For this reason, it is used as a bleaching agent, particularly as an alternative to chlorine in water purification and sewage treatment.

The pulmonary toxicity associated with ozone primarily results from its high reactivity toward unsaturated fatty acids and amino acids with sulfhydryl functional groups.[19,97] Ozonation and free radical damage to the lipid component of the membrane initiate an inflammatory cascade, with resultant influx of inflammatory cells.[20,153] Reactive nitrogen species also are implicated, as NO synthase knockout mice are relatively protected from ozone-induced inflammation and tissue injury.[63] Increased permeability of the pulmonary epithelium results in alveolar filling from the transudation of proteins and fluids characteristic of ALI. Antioxidant agents (eg, vitamin E) that react preferentially with free radicals before membrane damage occurs prevent or limit the pulmonary toxicity of ozone.

Miscellaneous Pulmonary Irritants *Methylisocyanate.* Methylisocyanate (MIC; Figure 124–3) is one of a series of compounds sharing a similar isocyanate (N=C=O) moiety. Toluene diisocyanate (TDI) and diphenylmethane diisocyanate (MDI) are important chemicals in the polymer industry. In those exposed to MIC in Bhopal, ALI was evident both clinically and radiographically.[125] MIC is a significantly more potent respiratory irritant than the other regularly used isocyanate derivatives such as TDI.[6] Cyanide poisoning does not occur, and empiric antidotal therapy is not indicated.

Riot Control Agents: Capsaicin, Chlorobenzylidenemalononitrile, and Chloroacetophenone. Historically, riot control agents (see Fig. 131–5), commonly called Mace, consisted primarily of chloroacetophenone (CN) or chlorobenzylidenemalononitrile (CS).[22] Both are white solids that are dispersed as aerosols. The dispersion is generally accomplished through mixture with a pyrotechnic agent such as a grenade or with a volatile organic solvent in a personal protection canister. Because the delivery systems of these agents are of limited sophistication and are subject to prevailing environmental conditions, dosing is unpredictable, and unintended self-poisoning is common.[22] After low-concentration exposure, ocular discomfort and lacrimation alone are expected, accounting for the common appellation *tear gas.* The effects are transient, and complete recovery within 30 minutes is typical, although long-lasting pulmonary effects may occur (see Asthma and Reactive Airways Dysfunction Syndrome).[156] Closed-space or close-range exposure, as well as physical exertion during exposure, may produce significant ocular toxicity, dermal burns, laryngospasm, ALI,[191] or death[22]. Because of their high potential for severe toxicity, CN and CS were replaced for civilian use by oleoresin capsicum (OC), also known as *pepper spray* or *pepper mace.* Although capsaicin, its active component, is considerably less toxic, it is occasionally responsible for pneumonitis[21] and death.[181]

Capsaicin interacts with the vanilloid receptor-1 (VR1), which was recently renamed the transient receptor potential vanilloid-1 (TRPV1).[186] Stimulation of this receptor invokes the release of substance P, a neuropeptide involved with transmission of pain impulses.

Substance P also induces neurogenic inflammation, which, in the lung, results in ALI and bronchoconstriction (see Asthma and Reactive Airways Dysfunction Syndrome).[186] The severe pulmonary toxicity of CS and CN likely is related to their ability to alkylate tissues in a manner similar to mustard agents.[45]

Metal Pneumonitis. Acute inhalational exposures to certain metal compounds produce clinical effects identical to those of the chemical irritants. For example, zinc chloride ($ZnCl_2$) fume is used as artificial smoke because of the dense white character of the fume, and an aqueous solution is still used as a soldering flux. Exposure to zinc chloride fumes for just a few minutes is associated with ALI and death[62,90,91] (see Chap. 101). Cadmium oxide (CdO) is generated during the burning of cadmium metal in an oxygen-containing environment, as occurs during smelting or welding (see Chap. 90). The refining of nickel using carbon monoxide (Mond process) produces nickel carbonyl [$Ni(CO)_4$], a volatile pulmonary oxidant[170] (see Chap. 97). Inhalation of volatilized elemental mercury,[129] which occurs during the vacuuming of mercury spills or home extracting of precious metals, may be toxic. Although at sufficient concentrations, many of these metal exposures produce warning symptoms, severe toxicity may occur even in the absence of warning symptoms. The mechanism of toxicity may relate to overwhelming oxidant stress with a pronounced inflammatory response as measured by serum cytokines (eg, TNF-α) concentrations.[91] Experimental findings suggest a role for inactivation of natural antioxidant systems.[209] Patients with metal-induced pneumonitis present with chest tightness, cough, fever, and signs consistent with ALI. Metal pneumonitis is distinguishable from other causes of ALI only by history or, retrospectively, by elevated serum or urine metal concentrations.[8] In particular, metal pneumonitis should be differentiated from the more common and substantially less consequential metal fume fever, discussed later in this chapter. In addition to standard supportive measures, patients with acute metal-induced pneumonitis should be hospitalized and receive corticosteroids.[91] Chelation therapy has no documented benefit for treatment of patients with ALI but should be used based on conventional indications.

MANAGEMENT

■ STANDARD AND SUPPORTIVE MEASURES

Management of patients with acute respiratory tract injury begins with meticulous support of airway patency by limiting bronchial and pulmonary secretions and maintaining oxygenation. Although various theoretical and experimental treatment modalities have been proposed, supportive care remains the mainstay of therapy. Supplemental oxygen, bronchodilators, and airway suctioning should be used if clinically indicated. Nitrovasodilators, diuretics, and morphine have little role in the management of patients with ARDS, although low-dose morphine may prove beneficial as an anxiolytic agent.[3,145] Corticosteroid therapy, designed to reduce the inflammatory host defense response, frequently improves surrogate markers of pulmonary damage,[118,119] such as oxygenation status, but generally offers little outcome enhancement in patients with ARDS.[4,142] Importantly, most studies of ARDS involve predominantly septic or traumatized patients, with few patients suffering from inhalational poisoning. Because the inflammatory response initiated by bacterial endotoxin differs from that caused by irritant gases, the applicability of these studies to the treatment of poisoned individuals is limited. There is an interesting report of simultaneous, presumably equivalent chlorine exposure in two sisters, with improved outcome in the sister who received steroid treatment.[42] Most available research evaluates parenterally administered corticosteroids, although animal models demonstrate a beneficial effect of

nebulized beclomethasone[80] and nebulized budesonide[204] after acute chlorine poisoning. However, a human pretreatment model of inhaled budesonide fails to document a substantive alteration of the effects of ozone inhalation.[132] Ketoconazole, an antifungal agent with antiinflammatory effects,[1] and nonsteroidal antiinflammatory agents, such as ibuprofen,[166] variably improve experimental lung function or mortality in patients with ALI of various nontoxicologic etiologies and have little current role in the therapeutic armamentarium. Furthermore, most of the aforementioned studies assess acute outcome and not long-term effects in survivors. Because corticosteroids experimentally reduce the late fibroproliferative phase during lung recovery, they ultimately may prove beneficial. Overall, there is little reason to suspect any specific benefit of corticosteroids and other antiinflammatory drugs in most poisoned patients. However, because most studies demonstrate some benefit and little identifiable risk, corticosteroid use appropriately remains routine and based largely on local practices.

The clinical similarities among patients with irritant gas exposure and other etiologies of ALI suggest that similar management principles should be applied. Prone positioning during ventilation,[7,70] PEEP,[64] and inverse-ratio ventilation are successful in enhancing the oxygenation of patients with ALI of various causes but are not necessarily successful in improving outcome. Lower tidal volume mechanical ventilation using 6 mL/kg and plateau pressures 30 cm H_2O attenuated the inflammatory response[138] and resulted in lower mortality and less need for mechanical ventilation than traditional volume ventilation with 12 mL/kg.[2,127] Although not specifically evaluated in any of these studies, there are sound theoretical reasons to believe that all of these modalities should improve oxygenation in poisoned patients as well. Although it is always important to reduce the inspired concentration of oxygen to below 50% as rapidly as possible, patients poisoned by irritant gases may be even more susceptible to oxygen toxicity as a result of depletion of endogenous antioxidant barriers.[173]

■ NEUTRALIZATION THERAPY

A therapy unique to several of the acid-or base-forming irritant gases is chemical neutralization. Although contraindicated in acid or alkali injury of the GI tract, the large surface area of the lung and the relatively small amount of xenobiotic present allow dissipation of the heat and gas generated during neutralization. Case studies suggest that nebulized 2% sodium bicarbonate may be beneficial in patients poisoned by acid-forming irritant gases.[199] The vast majority of these cases involve chlorine gas exposure, and most patients received other symptomatic therapies as well.[26] Although there appears to be no specific benefit for patients exposed to chloramine, nebulized bicarbonate therapy appears to be safe.[139] A prospective evaluation of patients poisoned with chloramine and chlorine gas did not show any clinically significant difference between the group getting nebulized sodium bicarbonate and the control group, although there was a small but statistical improvement in forced expiratory volume in 1 second (FEV_1) at 120 and 240 minutes in the group that received nebulized sodium bicarbonate.[9] Any sodium bicarbonate solution used should be sufficiently diluted to prevent irritation. Typically, 1 mL of 7.5% or 8.4% sodium bicarbonate solution is added to 3 mL sterile water (resulting in an approximately 2% solution for nebulization).

Whether nebulized sodium bicarbonate therapy alters the natural course of irritant-induced pulmonary damage remains uncertain. The fact that many irritants produce concomitant oxidant injury suggests that it may not. Nebulized 4% sodium bicarbonate administered to chlorine-poisoned sheep improved oxygenation but failed to decrease mortality rates.[43] Therefore, patients receiving nebulized bicarbonate therapy require observation beyond the time of symptom resolution. Because administration of neutralizing acids for alkaline irritants,

such as ammonia, has not been attempted, their use cannot be recommended at this time (see Antidote in Depth A5: Sodium Bicarbonate).

■ ANTIOXIDANTS

Antioxidants include reducing agents such as ascorbic acid, NAC,[102] free radical scavengers such as vitamin E, and enzymes such as superoxide dismutase. Studies in humans have noted both increased[161] and decreased[27] endogenous antioxidant concentrations in bronchoalveolar lavage fluid in patients with ALI. Although the concept of treating pulmonary oxidant stress with antioxidants or free radical scavengers is intriguing, most currently available evidence suggests that these xenobiotics offer negligible benefit.[128,135] The rapid onset of the self-perpetuating destructive effects initiated by redox reactions may hinder any postexposure therapy. This interpretation is supported by pretreatment models in which antioxidants are effective at preventing or at least limiting the pathologic effects. Use of these and other newer therapies targeted against inflammatory mediators or the oxidative cascade are in the earliest investigative stages.

■ XENOBIOTIC-DIRECTED THERAPY

Patients with inhalational exposure to hydrogen fluoride should undergo frequent electrocardiographic evaluations and correction of serum electrolytes. Administration of nebulized 2.5% calcium gluconate, prepared as 1.5 mL 10% calcium gluconate plus 4.5 mL 0.9% sodium chloride solution or sterile water should be considered to limit systemic fluoride absorption.[103,108,195] By binding fluoride ion locally, nebulized calcium may prevent fluoride-induced cellular and systemic toxicity. Systemic calcium salts should be administered as needed to correct hypocalcemia (see Chap. 105 and Antidotes in Depth A30: Calcium).

Current therapy for inhalation of capsaicin, or of any tear gas, is primarily supportive. Extracorporeal membrane oxygenation has been used in children to maintain oxygenation in the presence of severe pulmonary toxicity resulting from capsaicin exposure.[21] Although no antidotes currently are available, the newly developing insight into the receptor mechanism of capsaicin suggests that a receptor active agent may hold future promise.

■ ADVANCED PHARMACOLOGIC THERAPY

Perfluorocarbon Partial Liquid Ventilation Partial liquid ventilation involves the intrapulmonary administration of perfluorocarbons, which are inert liquids with low surface tension and excellent oxygen-carrying capacity. Studies in patients with nonchemically induced ARDS suggest that exfoliated tissue, and presumably persistent xenobiotic, may be effectively lavaged from the bronchopulmonary tree with this method.[48] Perfluorocarbons improve oxygenation and may have an antiinflammatory effect, as demonstrated by reduced oxidant lung injury after liquid ventilation in animals.[47] Although this may prove to be a highly useful therapy in the future, their limited availability, high cost, and lack of demonstrated efficacy make them suitable only for academic and research settings.[48]

Exogenous Surfactant Several other recent developments may prove useful in the general management of patients with ARDS. Surfactant replacement therapy initially received attention as a treatment for patients with ARDS because of its beneficial effects in infant respiratory distress syndrome. Although several experimental and clinical studies suggested the safety and efficacy of surfactant therapy in patients with ARDS, large randomized, controlled clinical trials fail to show a benefit on survival.[179] Patients who received surfactant had a greater improvement in gas exchange during the 24-hour treatment period than patients who received standard therapy alone, suggesting the potential benefit

of a longer treatment course.[179] But because most studies involved patients with sepsis-related ARDS, the inability to show a beneficial effect may not adequately reflect the potential of surfactant in irritant gas-induced ARDS.[146] Many oxidant gases inactivate endogenous surfactant, although the specific effects on exogenous surfactant are not well understood.[146]

OTHER INHALATIONAL PULMONARY XENOBIOTICS

A particulate, or dust, is a solid dispersed in a gas. Dust is a substantial source of occupational particulate exposure and is an important cause of acute pulmonary toxic syndromes. A respirable particulate must have an appropriately small size (generally <10 μm) and aerodynamic properties to enter the terminal respiratory tree. Nonrespirable particulates, also called *nuisance dusts*, are trapped by the upper airways and are not generally thought to cause pulmonary damage. In distinction from the irritant gases, there is no unifying toxic mechanism among the respirable particulates. Many of the particulate diseases, such as asbestos exposure and its sequelae, are chronic in nature; only the acute or subacute syndromes are discussed here.

■ INORGANIC DUST EXPOSURE

Silicosis is a range of pulmonary diseases associated with inhalation of crystalline silica (SiO_2), or quartz. It typically occurs in workers involved in occupations in which rock or granite is pulverized, including mining, quarry work, and sandblasting. Although typically a chronic disease, intense subacute exposure may produce acute silicosis in a few weeks and death within 2 years. The mechanism of toxicity probably relates to the relentless inflammatory response generated by the pulmonary macrophages.[134] These cells engulf the indigestible particles and are destroyed, releasing their lytic enzymes and oxidative products locally within the pulmonary parenchyma. Patients present with dyspnea, cor pulmonale, restrictive lung findings, and classic radiographic findings. Treatment is limited and includes steroids and supportive care.

Silica combined with other minerals is referred to as *silicates*, the most important of which include asbestos and talc. Talc, or magnesium silicate $[(Mg_3Si_4)O_{10}(OH)_2]$, is widely used in industry, but its use in the home has been curtailed over the past two decades because of cases of severe pulmonary injury.[112] Much of the toxicity of talc is related to free silica or asbestos contamination. Improvement after acute massive exposure may be accompanied by progressive pulmonary fibrosis.

■ ORGANIC DUSTS

Inhalation of dusts from cotton or similar natural fibers, usually during the refinement of cotton fibers (byssinosis), produces chest tightness, dyspnea, and fever that typically begin within 3 to 4 hours of exposure. Similar reactions may occur after inhalation of hay, silage, grain, hemp, or compost dust. Symptoms often resolve during the work week but return after a weekend hiatus. Byssinosis is probably caused by an endotoxin present on the cotton and is not immunologic in nature.[205] "Grain fever" is caused by a respirable compound associated with grain dust, as occurs during harvesting, milling, and transporting.

■ HYPERSENSITIVITY PNEUMONITIS

Hypersensitivity pneumonitis, also known as extrinsic allergic alveolitis, is the final common pathway for many different organic dust exposures.[182] The name attached to the individual syndrome typically identifies the associated occupation or substrate. For example, *bagassosis* is the term associated with sugar cane (bagasse), and *farmer's lung* is the term associated with moldy hay, although both conditions are caused by thermophilic *Actinomycetes* spp. When associated with puffball mushroom spores (*Lycoperdon* spp), the syndrome is called *lycoperdonosis* (see Chap. 117); when caused by bird droppings, it is called *bird fancier's lung*. The implicated allergen is capable of depositing in the pulmonary parenchyma and eliciting a cell-mediated (type IV) immunologic response. Clinical findings include fever, chills, and dyspnea beginning 4 to 8 hours after exposure. The chest radiograph usually is normal but may reveal diffuse or discrete infiltrates. Progressive disease is associated with a honeycombing pattern on the radiograph and a restrictive lung disease pattern on formal pulmonary function testing. Treatment includes corticosteroids and avoidance of the antigen.

■ METAL FUME FEVER AND POLYMER FUME FEVER

Metal fume fever is a recurrent influenza-like syndrome that develops several hours after exposure to metal oxide fumes generated during welding, galvanizing, or smelting. Although most symptoms of metal fume fever are similar to those expected with irritant gas exposures (dyspnea, cough, chest pain), the presence of fever, typically 100.4°F to 102.2°F (38°C–39°C), distinguishes the syndromes.[23] In addition, patients may experience headache, metallic taste, myalgias, and chills. Direct pulmonary toxicity probably does not occur, and patients with metal fume fever generally have normal chest radiographs. Interestingly, acute tolerance develops, so repeat daily exposures produce progressively milder symptoms. However, the tolerance disappears rapidly, and after a short work hiatus such as a weekend, the original intensity resumes, thus accounting for the designation "Monday morning fever." Many metal oxides are capable of eliciting this syndrome, but it is noted most frequently in patients who have welded galvanized steel, which contains zinc. Metal fume fever also occurs commonly after the high-temperature welding of copper-containing compounds, thus accounting for the historical appellation "brass foundry workers ague." There is a strong association between welding-related metal fume fever and welding-related respiratory symptoms suggestive of occupational asthma.[61] Serum and urine metal concentrations typically are not elevated after the acute event, although they may be chronically elevated from daily occupational exposure. The etiology of metal fume fever is debated, but the syndrome has features suggestive of both an immunologic and a toxic etiology.[23] Antigen release with immunologic response appears to be responsible for the induction of symptoms. On subsequent exposure, proinflammatory cytokines, such as TNF-α, and various interleukins can be detected in bronchoalveolar lavage fluid.[105] However, because symptoms may occur with the patient's first exposure to fumes, a direct toxic effect on the respiratory mucosa presumably exists.[117] Exposure to certain metal fumes, such as cadmium oxide or other zinc compounds, may produce direct toxic effects on the pulmonary parenchyma.[117]

The management of patients with metal fume fever is supportive and includes analgesics and antipyretics. There is no specific antidote, and chelation therapy should not be instituted unless otherwise indicated; patients with ALI probably have metal toxicity (eg, cadmium pneumonitis). The natural course of metal fume fever involves spontaneous resolution within 48 hours. Persistent symptoms are rare and should prompt investigation for metal toxicity.

A remarkably similar syndrome occurs subsequent to inhaling pyrolysis products of fluorinated polymers (eg, Teflon), which is aptly termed *polymer fume fever*.[172] Patients develop self-limited viral illness-type symptoms several hours after exposure to the fumes. As with metal fumes, very large exposures to polymer fumes may result in direct pulmonary toxicity. Supportive care is the therapy of choice.

■ ASTHMA AND REACTIVE AIRWAYS DYSFUNCTION SYNDROME

Asthma, or *reversible airways disease*, is a clinical syndrome that includes intermittent episodes of dyspnea, cough, chest pain or tightness, wheezes on auscultation, and measurable variations in expiratory airflow. Episodes typically are triggered by a xenobiotic or physical stimulus and resolve over several hours with appropriate therapy. The underlying process is immunologic in most cases, with allergen-triggered release of inflammatory mediators causing bronchiolar smooth muscle contraction and subsequent inflammation. Because asthma affects 5% to 10% of the world's population and the triggers often are nonspecific, it is not surprising that work-aggravated asthma is extremely common. The patients are previously sensitized, and the initial irritant exposure causes bronchospasm or similar symptoms. Thus, work-aggravated asthma is discovered early in the worker's employment, and a more appropriate workplace or occupation can be pursued.

Occupational asthma, or asthma occasioned by a workplace exposure to a sensitizing xenobiotic, accounts for perhaps 10% to 17% of all newly diagnosed asthma in adults.[110,192] Casual exposure to one of the 250 or more known sensitizers (Table 124–3) is usually associated with a latency period of weeks or months of exposure before symptom onset. After symptoms begin, however, they recur consistently after reexposure to the inciting trigger agent. Occupational asthma with latency may be IgE dependent, in which case it is identical to allergic asthma, or is IgE independent.[198] The IgE-dependent form is most commonly associated with high-molecular-weight compounds (>5000 daltons) or with certain haptenic low-molecular-weight agents (eg, acetic anhydride). The low-molecular-weight agents (eg, nickel, isocyanates) more typically cause IgE-independent disease, which manifests as the delayed reaction pattern of cell-mediated, or type IV, hypersensitivity. Because contact with a trigger may be difficult to avoid in either case, reassignment or an outright occupational change may be required. Treatment for exacerbations is comparable to standard asthma therapy and includes bronchodilators and corticosteroids.

Acute exposure to irritant gas may result in the development of a persistent asthma-like syndrome also termed *reactive airways dysfunction syndrome* (RADS), *irritant-induced asthma*, or *occupational asthma without latency*. Virtually every irritative xenobiotic is reported to cause this syndrome, and those not yet described probably are simply unrecognized. Although asthma typically is associated with massive inhalational exposure, as occurred after the World Trade Center collapse,[14] occasional patients are susceptible to low-level exposure.[31] RADS is often compared to occupational asthma because both disorders are chemically induced and most frequently occur after chemical exposure in the workplace.[46] However, in comparison with those who develop occupational asthma, patients who develop RADS have a lower incidence of atopy and are exposed to agents not typically considered to be immunologically sensitizing.[31] In addition, the airflow improvement with β_2-adrenergic agonist therapy is significantly better in patients with occupational asthma.[71] Bronchial biopsy performed in patients with RADS generally reveals a chronic inflammatory response.[71] RADS may have a neurogenic etiology[120] as opposed to an immunologic origin, as in patients with occupational asthma, which may differentiate these clinically similar diseases on a mechanistic basis. Neurogenic inflammation results from increased vascular permeability, presumably secondary to release of substance P from unmyelinated sensory neurons (C fibers).[54] Neurogenic inflammation is inhibited by substance P depletors such as capsaicin and enhanced by substances that inhibit neutral endopeptidase, the enzyme responsible for degradation of substance P.[121] The role of corticosteroids is undefined, but animal models suggest an antiinflammatory benefit.[51] Recovery may take months, with the delay related to either ongoing low-level exposures to endopeptidase inhibitors or persistent irritation of impaired tissue by environmental irritants such as pollution.

SUMMARY

The overall quality of the air we breathe continues to deteriorate, and fluctuations in environmental pollutants periodically cause epidemic disease. Although the spectrum of xenobiotics capable of causing pulmonary toxicity is large, the pathologic changes are rather limited. Gases that have little or no irritant potential or systemic toxicity cause simple asphyxiation, in which the ambient atmosphere has a diminished oxygen concentration. Parenchymal irritation and ALI occur after exposure to acid-forming or free radical–generating gases and may progress to severe toxicity manifesting as ARDS. RADS is described in patients after exposure to virtually all of the irritant gases. Treatment of all such exposures centers on symptomatic and supportive care.

TABLE 124–3. Common Xenobiotic Sensitizers Producing Occupational Asthma

Molecular Weight	Example	Primary Risk Occupations
High		
Proteins	Crab shell protein	Seafood processors
Low		
Acrylate	–	Adhesives, plastics
Glutaraldehyde	–	Healthcare workers
Isocyanates	Toluene diisocyanate	Polyurethane foam, automobile painters
Metals	Nickel sulfate	Nickel platers
Trimellitic anhydride	–	Chemical workers
Wood dust	Western red cedar (*Thuja plicata*)	Foresters, carpenters

CHAPTER 125
CARBON MONOXIDE

Christian Tomaszewski

Carbon Monoxide (CO)

MW	=	28.01 daltons
Gas density	=	0.968 (air = 1.0)
Blood carboxyhemoglobin level		
Nonsmokers	=	1–2%
Smokers	=	5–10%
Action level	>	10%
TLV–TWA	=	50 ppm

Carbon monoxide (CO) is a leading cause of poisoning morbidity and mortality in the United States. It is formed during the incomplete combustion of virtually any carbon-containing compound. Because it is an odorless, colorless, and tasteless gas, it is remarkably difficult to detect in the environment even when present at high ambient concentrations. The clinical findings are protean, making diagnosis difficult, and even objective data, such as elevated carboxyhemoglobin (COHb) concentrations, are not highly prognostic unless at one of the extremes. Hyperbaric oxygen (HBO) therapy, if practical to perform, remains the treatment of choice. However, the necessity for HBO therapy remains controversial, in large part related to the controversy over the incidence and significance of the long-term clinical effects of CO exposure.

HISTORY AND EPIDEMIOLOGY

Based on U.S. national death certificate data, there were 439 annual deaths from unintentional non-fire exposure to CO from 1999 to 2004.[20,107] The groups with the highest risk were male gender and elderly age, possibly because of occupational exposure and inability to discern CO symptoms, respectively. CO-related mortality remained essentially unchanged in 2002 despite increased CO detector use.[21,22,23] In that time period, 2001 to 2003, there were 15,200 patients treated annually in emergency departments (EDs) for nonfatal, unintentional, non–fire-related CO exposure. More than half of these cases (64%) occurred in homes with faulty furnaces, usually in the fall or winter months. Despite increased awareness for CO poisoning, in 2004 to 2006, there were still an average of 20,636 nonfatal, unintentional, non–fire-related CO exposures treated annually in the United States.[22] More than 40% of cases occurred in the winter, with almost 75% occurring in residences. However, exclusion of intentional and fire-related cases severely underestimates the extent of the problem. Based on firsthand hospital data, a minimum of 50,000 CO cases present to U.S. EDs each year.[67]

The more significant problem with CO poisoning may be the morbidity rather than mortality. The most serious complication is persistent or delayed neurologic or neurocognitive sequelae, which occurs in up to 50% of patients with symptomatic acute poisonings.[58,128,171] To date, there is still no completely reliable method of predicting who will have a poor outcome, suggesting that the threshold for HBO therapy for CO poisoning should be appropriately low.

Potential sources of CO abound in our society, often resulting in unintentional poisoning[22] (Table 125–1). Although CO is found naturally in

the body as a byproduct of hemoglobin degradation by heme oxygenase found in the liver and spleen,[32] it is readily available for inhalation from the incomplete combustion of virtually any carbonaceous fuel. Alternatively, absorption—dermal, ingestion, or inhalation—of methylene chloride may result in CO toxicity after hepatic metabolism[112] (see Chap. 106). Despite catalytic converters and other emission controls, more than 50% of unintentional CO deaths are still caused by motor vehicle exhaust.[31,107] Occupants of motor vehicles are not the only victims of exhaust gases; CO poisoning is also reported in occupants of the beds of pickup trucks and on boats.[19,66] Workers can become symptomatic from use of propane-powered equipment indoors such as ice skating rink resurfacers[16] and forklifts.[45] For optimal performance, propane-powered forklifts are typically adjusted to produce no less than 10,000 ppm of CO in exhaust and in fact average more than 30,000 ppm.[46] In an enclosed warehouse with poor ventilation, even with proper emission control, CO levels could exceed safe concentration within 1 hour.

In the past 10 years, non-vehicular sources of CO have increasingly accounted for most unintentional poisonings.[107] Predominantly, these have involved the burning of charcoal, wood, or natural gas for heating and cooking.[63] Propane burning furnaces for heating are often implicated, especially when the flue is blocked.[70,71] Gas kitchen stoves are also an important source of CO in indigent populations with marginal heating systems.[71] In fact, the use of gas stoves for supplemental heat is predictive of CO poisoning in patients who present to the ED with headache and dizziness.[71] During ice storms and other natural disasters, the indoor use of gasoline-powered generators and charcoal burning grills, the latter particularly in immigrant populations, has resulted in epidemic CO poisoning outbreaks.[18,21,179]

Fires are another important source of CO exposure, contributing substantially to the approximate 5613 smoke inhalation deaths each year.[31] CO is considered to be the most common hazard to smoke inhalation victims.[51,138]

TOXICOKINETICS

CO is readily absorbed after inhalation. The Coburn-Forster-Kane (CFK) model allows the prediction of COHb concentrations based on exposure history.[33] This model has been simplified to allow estimation of the equilibrium based on the ambient concentration of CO in ppm: COHb (%) = $100/[1 + (643/\text{ppm CO})]$.[163] This assumes that the individual weighs 70 kg and is not anemic. With exponential uptake, it may take more than 4 hours for equilibrium to be attained. Therefore, within minutes of high CO exposures, the arterial COHb concentration may actually overshoot predicted estimates before equilibration.[7,12] Endogenous production of CO is not factored in because its contribution to COHb is only 2%.

After it has been absorbed, CO is carried in the blood, primarily bound to hemoglobin. The Haldane ratio states that hemoglobin has approximately a 200 to 250 times greater affinity for CO than for oxygen. Therefore, CO is primarily confined to the blood compartment, but eventually up to 15% of total CO body content is taken up by tissue, primarily bound to myoglobin.[33] Therefore, the dissolved CO concentration in the serum may better reflect the ultimate potential for poisoning because it is available for diffusion into all tissue compartments, including the muscle and brain.[92]

Elimination of CO, like absorption, from the blood can be modeled mathematically using the CFK model. The equation predicts a half-life of 252 minutes. In actual volunteer studies, means of 249 and 320 minutes breathing room air are reported.[124] With 100% oxygen, these half-lives can be reduced significantly to means of 47, 78, and 80 minutes in studies of volunteers who attain COHb concentrations of 10% to 12%.[124,146] Patients poisoned with CO showed actual mean half-lives of 74 and 131 minutes when treated with 100% oxygen.

TABLE 125–1. Sources of Carbon Monoxide Implicated in Poisonings[168]
Anesthetic absorbents[82]
Banked blood
Boats[19]
Camp stoves and lanterns
Charcoal grills[50]
Coffee roasting[114]
Gasoline-powered equipment (eg, generators, power washers)[17,18]
Ice resurfacing machines[16]
Methylene bromide
Methylene chloride
Natural gas combustion furnaces (water heaters, ranges and ovens)
Propane-powered forklifts[46]
Underground mine explosions[98]
Wood pellet storage

Methylene chloride, a paint stripper, is another source of CO. It is readily absorbed through the skin or by ingestion or inhalation and is metabolized in the liver to CO.[141] Reaching peak COHb concentrations may take 8 hours or longer and may range from 10% to 50%.[91,131] Because of ongoing production of CO, the apparent COHb half-life is prolonged to 13 hours in these patients.[129] COHb concentrations after methylene chloride exposure appear to be proportional to the concentration and duration of exposure.[129]

PATHOPHYSIOLOGY

The most obvious deleterious effect of CO is binding to hemoglobin, rendering it incapable of delivering oxygen to the cells. Therefore, despite adequate partial pressures of oxygen in blood (PO_2), there is decreased arterial oxygen content. Further insult occurs because CO causes a leftward shift of the oxyhemoglobin dissociation curve, thus decreasing the offloading of oxygen from hemoglobin to tissue[133] (see Fig. 21–2). This may result in part from a decrease in erythrocyte 2,3-bisphosphoglycerate (2,3-BPG) concentration. The net effect of all these processes is the decreased ability of oxygen to be delivered to tissue.

CO toxicity cannot be attributed solely to COHb-mediated hypoxia. Neither clinical effects nor the phenomena of delayed neurologic deficits can be completely predicted by the extent of binding between hemoglobin and CO.[159] Furthermore, such a model fails to explain why even minimal levels of COHb (4%–5%) may result in cognitive impairment. An early study showed that dogs breathing 13% CO died within 1 hour and had COHb levels of 54% to 90%. However, exchange transfusion of this same blood into healthy dogs to reach similar COHb levels caused no untoward effects.[52] Hemorrhaging the dogs to comparable degrees of anemia also produced no adverse effects. The appropriate conclusion was that inherent to CO toxicity is its delivery to target organs such as the brain and heart and that although COHb is easily measured, it rarely has a significant contribution to clinical toxicity. For CO to reach tissue, it had to be dissolved in the plasma rather than bound to hemoglobin.[56,57]

CO interferes with cellular respiration by binding to mitochondrial cytochrome oxidase. Initial studies show that this binding is especially exaggerated under conditions of hypoxia and hypotension. In vitro rat models demonstrate that this oxidative stress causes mitochondrial damage with protein oxidation and lipid peroxidation, particularly in the hippocampus and corpus striatum.[147] In vivo models reveal that CO poisoning causes cell loss in the frontal cortex, which is associated with decrements in learning and memory.[125] Although no comparable brain studies exist in humans, the peripheral lymphocytes of CO-poisoned patients show cytochrome oxidase inhibition accompanied by increased lipid peroxidation.[103] In a small clinical series of CO-poisoned patients, normalization of this cytochrome activity lagged behind and seemed to agree better with symptom severity than COHb concentrations.[104]

Inactivation of cytochrome oxidase may be only an initial part of the cascade of inflammatory events that results in ischemic reperfusion injury to the brain after CO poisoning (see Fig. A37–1). During recovery from the initial poisoning, white blood cells are attracted to and adhere to the damaged brain microvasculature.[152,153,154] This attraction may be partly attributable to endothelial changes from initial cytochrome oxidase dysfunction, mediated primarily through the free radical nitric oxide (NO).[152,157] CO displaces NO from platelets that in turn form peroxynitrites, which are even stronger inactivators of cytochrome oxidase.[157] Multiple animal studies demonstrate that NO is ultimately responsible for much of the endothelial damage from CO and that NO synthase inhibitors can prevent toxicity.[156,157] The NO formation promotes platelet–neutrophil aggregates that in turn leads to neutrophil adhesion to the brain microvasculature.[153] Myelin peroxidase activation in the area may further promote neutrophil adhesion with degranulation and release of proteases that convert xanthine dehydrogenase to xanthine oxidase, an enzyme that promotes formation of oxygen free radicals.[151] The end result of this process is delayed lipid peroxidation of the neurons, and the extent of destruction may be correlated with decrements in learning in rodents.[151] Rats depleted of xanthine oxidase through a tungsten modified diet show no changes in myelin basic protein and cognitive function after CO poisoning.[69]

Simultaneously, with all this perivascular oxidative stress in the brain, there is activation of excitatory amino acids, which ultimately may be responsible for the subsequent neuronal cell loss.[157] In fact, in rat brains, glutamate concentrations increase after CO poisoning. Glutamate is an excitatory amino acid that can bind at N-methyl-D-aspartate (NMDA) receptors and cause intracellular calcium release, resulting in delayed neuronal cell death (see Chap. 18). Blockade of NMDA receptors may prevent the neuronal death and learning deficits that accompany serious CO poisoning in mice.[77] Increases in the glutamate concentrations in rat brain in the first hour after severe CO poisoning are followed by a later increase in hydroxyl radicals.[125] Ultimately, at 1 to 3 weeks, the animals show histologic evidence of both neuronal necrosis and apoptosis in the frontal cortex, globus pallidus, and cerebellum that are accompanied by deficits in learning and memory.

Ultimately, CO neuronal cell death may be caused by apoptosis, and this has been confirmed in various models. In bovine pulmonary artery cells, CO exposure is accompanied by activation of caspase-1, a protease implicated in delayed cell death.[155] Confirmatory evidence was provided in the same study because both caspase-1 and NO synthase inhibitors blocked apoptosis. The end result of all these cellular processes is brain injury, particularly in the basal ganglia and hippocampus, resulting in learning impairment. Thus, animal models correlate well with what ultimately occurs in victims of serious CO poisoning, namely, persistent or delayed deficits in learning and memory associated with structural changes in the brain.

Myoglobin, another heme protein, binds CO with an affinity about 60 times greater than it binds oxygen.[34] About 10% to 15% of the total body store of CO is extravascular, primarily binding to myoglobin.[12,33] A dog model demonstrates that this binding is enhanced under hypoxic conditions.[34] This binding may partially explain the myocardial

impairment that occurs in both animal studies and low-level exposures in patients with ischemic heart disease. The combination of COHb formation, which decreases oxygen-carrying capacity, and the production of reduced myoglobin in the heart, which decreases oxygen extraction, may explain the preterminal dysrhythmias that occur in animals.

Several studies suggest that CO effects on the cardiovascular system are necessary for ischemic reperfusion injury of the brain. Hypotension is an essential component and results from a combination of myocardial depression and vasodilation. CO, perhaps because of its similarity to NO, activates guanylate cyclase, which in turn relaxes vascular smooth muscle. Also, CO may further displace NO from platelets, resulting in additional vasodilation.[156] These factors contribute to the hypotension that occurs in animal experiments with exposure to high concentrations of CO.[52] Such an episode of hypotension may present clinically as syncope, and this finding portends a worse clinical outcome.[28] In rhesus monkeys, cerebral white matter lesions correlate better with decreases in blood pressure than with COHb level.[55] Lipid peroxidation of the brain in rats develops 1 hour after a CO exposure that has produced syncope and hypotension.[150] This delay is comparable to the time that is necessary to produce mitochondrial destruction from oxidative stress in rats exposed to CO. In a feline model, central nervous system (CNS) damage from CO can be reproduced only when hypoxia is accompanied by one interval of ischemia, confirming the ischemic-reperfusion model.[116]

Endogenous CO behaves like NO, binding to guanylate cyclase and thereby increasing cGMP concentrations.[78] Although low endogenous concentrations are physiologic, excessive concentrations of CO from exogenous sources may be problematic because CO persists much longer than NO. CO appears to be a neuronal messenger by virtue of the fact that as a gas, it can diffuse and signal adjacent cells.[97]

CLINICAL MANIFESTATIONS

■ EFFECTS OF ACUTE EXPOSURE

The earliest symptoms associated with CO poisoning are often nonspecific and readily confused with other illnesses, typically a viral syndrome[175] (Table 125–2). The initial symptom reported by volunteers within 4 hours of exposure to 200 ppm COHb levels (15%–20%) is headache; shorter exposures at 500 ppm also produces nausea.[143] The incidence of CO poisoning in symptomatic patients presenting to EDs in the winter with an influenzalike illness ranges from 3% to 24% in some series.[41,71] The typical presenting complaints include headache, dizziness, and nausea, and the most frequent exposures occur during the winter, explaining why influenza is the most common misdiagnosis.[41] The most common symptom, headache, is usually described as dull, frontal, and continuous. CO poisoning is also frequently misdiagnosed

as food poisoning, gastroenteritis, and even colic in infants. Similar to adults, children tend to develop nonspecific symptoms, complicating identification of the diagnosis.

Continued exposure to CO may lead to symptoms attributable to oxygen deficiency in the heart. Low-level exposures, leading to COHb levels of 2% to 4%, in volunteers with stable angina results in decreased exercise tolerance as well as signs and symptoms of myocardial ischemia.[2] At higher levels (COHb 6%), there is a greater frequency of premature ventricular contractions during exercise. Myocardial infarction and dysrhythmias are described in victims of CO poisoning, and acute mortality from CO is usually a result of ventricular dysrhythmias.[1,2] Prolonged exposure to CO or high levels of COHb is associated with temporary myocardial stunning, lasting usually less than 24 hours and reflected by a decrease in left ventricular ejection fraction (LVEF).[80] This stunning is reflected by a decrease in LVEF and is correlated with increased B-type natriuretic peptide. Troponin may be elevated as well in the absence of any coronary artery disease. These patients have an increased propensity for cardiac mortality, with almost one-third dying within 8 years after serious CO poisoning.[72]

The CNS is the organ system that is most sensitive to CO poisoning. Acutely, otherwise healthy patients may manifest headache, dizziness, and ataxia at COHb levels as low as 15% to 20%; with higher levels or longer exposures, syncope, seizures, or coma may result.[175] Patients may present with focal neurologic symptoms suggestive of a cerebrovascular accident. The electroencephalogram (EEG) may show diffuse frontal slow-wave activity. Within 1 day of exposures that result in coma, computed tomography (CT) and magnetic resonance imaging (MRI) may show decreased density in the central white matter and globus pallidus (Fig. 125–1).[93] Autopsies show involvement of other areas, including the cerebral cortex, hippocampus, cerebellum, and substantia nigra.[89]

Metabolic changes may reflect CO's toxic effects better than any particular COHb concentration. Patients with mild CO poisoning

TABLE 125–2. Clinical Manifestations of CO Poisoning	
Ataxia	Myocardial ischemia
Cardiac dysrhythmias	Nausea
Chest pain	Syncope
Confusion	Tachypnea
Dizziness	Visual blurring
Dyspnea	Vomiting
Headache	Weakness

may develop respiratory alkalosis in an attempt to compensate for the reduction in oxygen-carrying capacity and delivery. More substantial exposures result in metabolic acidosis with lactate production that accompanies tissue hypoxia.[140] The importance of metabolic acidosis is highlighted by the findings of a retrospective series of 48 CO-poisoned patients, in which hydrogen ion concentration was a better predictor of poor recovery during initial hospitalization than was COHb concentration.[167]

Although the brain and heart are the most sensitive, other organs may also manifest the effects of CO poisoning. One-fifth to one-third of patients with severe CO poisoning—those who required endotracheal intubation—develop pulmonary edema.[59] This does not appear to be a direct effect of CO on lung tissue because sheep with prolonged exposure to CO, resulting in COHb levels greater than 50%, showed no anatomic or physiologic changes in lung function.[137] Although myonecrosis and even compartment syndromes occur, patients rarely develop renal failure. Retinal hemorrhages may develop with exposures greater than 12 hours.[81] Cherry-red skin coloration occurs only after excessive exposure (2%–3% of cases referred to one hyperbaric center) and may represent a combination of CO-induced vasodilation, concomitant tissue ischemia, and failure to extract oxygen from arterial blood.[132] Another classic but uncommon phenomenon is the development of cutaneous bullae after severe exposures. These bullae are thought to be caused by a combination of pressure necrosis and possibly direct CO effects in the epidermis.

■ DELAYED NEUROCOGNITIVE SEQUELAE

The persistent or delayed effects of CO poisoning are varied and include dementia, amnestic syndromes, psychosis, parkinsonism, paralysis, chorea, cortical blindness, apraxia and agnosia, peripheral neuropathy, and incontinence.[90] Neurologic deterioration is typically preceded by a lucid period of 2 to 40 days after the initial poisoning.[28] In patients admitted to an intensive care unit for severe CO poisoning and treated with 100% oxygen, 14% of survivors had permanent neurologic impairment.[85] In a Korean series of 2360 CO-poisoned patients, 3% continued to show memory failure or parkinsonian features 1 year after exposure.[28] Another series of 63 seriously poisoned patients showed memory impairment in 43% and deterioration of personality in 33% at 3 year follow-up.[140] Children also develop behavioral and educational difficulties after severe poisoning.[88] However, patients older than 30 years of age appear to be more susceptible to the development of delayed sequelae.[28,173] Most cases of delayed neurocognitive sequelae are associated with loss of consciousness in the acute phase of toxicity.[28]

Delayed or persistent neurocognitive sequelae probably involve lesions of the cerebral white matter.[53] Weeks after exposure, autopsies show necrosis of the white matter, globus pallidus, cerebellum, and hippocampus. MRI studies confirm the damage to the white matter and hippocampus.[48,93,175] Animal studies show that having a markedly elevated COHb concentration alone cannot cause similar white matter lesions but that there must also be an episode of hypotension.[55,116] The fact that the areas permanently damaged in serious CO poisoning cases are the areas with the poorest vascular supply in the brain is consistent with these findings.

■ EFFECTS OF CHRONIC EXPOSURE

Often, patients complain of persistent headaches and cognitive problems after long-term exposure to low concentrations of CO. Unfortunately, to date, there have been no controlled studies demonstrating that in the absence of a severe acute poisoning episode, this type of exposure results in any long-term sequelae. Warehouse workers who are chronically exposed to CO from propane combustion have intermittent problems with headache, nausea, and lightheadedness.[45] Fortunately, unless there has been an episode of severe poisoning with acute deterioration, most workers go on to have resolution of their symptoms.[46] One series of chronic CO poisoning demonstrates a high incidence of headache and memory complaints along with motor slowing and memory problems on neuropsychologic testing.[109] Although many of the objective deficits improved with elimination of the exposure and HBO treatment, many continued to have posttraumatic stress and conversion disorders. Although it is unclear that chronic exposure to low concentrations of CO can cause permanent damage, healthcare providers still should be vigilant for symptomatic individuals to prevent continued or catastrophic outcomes.

DIAGNOSTIC TESTING

The most useful diagnostic test obtainable in a suspected CO poisoning is a COHb level. Normal levels of COHb range from 0% to 5%. Levels at the high end of this range occur in neonates and patients with hemolytic anemia because CO is a natural byproduct of the breakdown of protoporphyrin to bilirubin.[33] COHb levels average 6% in one-pack-per-day smokers but may range as high as 10%.[142] Although high COHb levels confirm exposure to CO, particular levels are not necessarily predictive of symptoms or outcome.

The usual method for measuring COHb is with a co-oximeter, a device that spectrophotometrically reads the percentage of total hemoglobin saturated with CO. Traditionally, arterial blood is used for this determination; however, venous blood levels are accurate.[166] Refrigerated heparinized samples yield accurate COHb levels for months and at room temperature for 28 days, making retrospective clinical and postmortem evaluations possible.[62,87]

Bedside tests using ammonia or sodium hydroxide are unable to differentiate reliably various levels of COHb versus control subjects.[118] Because of the similarities in extinction coefficients, COHb is misinterpreted as oxyhemoglobin on most types of pulse oximetry (see Chap. 21).[6] Thus, the pulse oximetry reading is usually normal in the setting of even severe CO poisoning.[61] Some newer pulse oximeters, called pulse co-oximeters, have the ability to measure COHb noninvasively.[4] A study in 10 healthy volunteers who inhaled CO at 500 ppm until they reached a peak COHb level of 15% found good agreement between pulse co-oximetry and cooximetry.[5] Because the test is noninvasive, it may be useful in screening ED patients who present with nonspecific symptoms for occult CO poisoning.[26] In addition, it may be used in the field for screening fire victims, patients with potential CO exposure, and rescuers.

Breath-sampling methods may be used for screening patients.[35,37,43] A cutoff of 53 ppm in patients breathing air and 43 ppm in those breathing oxygen has an approximate reliability of approximately 80% in predicting COHb concentrations above 10%.[47] Breath sampling for CO has been advocated as quick screening device for detecting recent exposure to CO in ED patients.

Some clinical laboratories measure CO directly in blood samples rather than COHb. This technique involves assaying CO directly with infrared spectrophotometry after it is extracted from the blood sample with a manometer. Based on calculations rather than true experimental data, the assumption has been made that for a patient with a normal hemoglobin, a CO concentration of 1 mmol/L corresponds to an 11% COHb concentration. A simpler method to measure serum CO content is to add a known solution of hemoglobin followed by sodium dithionite to form COHb. The resulting COHb is measured spectrophotometrically with the assumption that 1 mole of hemoglobin binds 4 moles of CO. Interestingly, in one study, serum CO ranged 0.14 to 0.6 mg/L but was the same in smokers (average,

4.6% COHb) and nonsmokers (average, 1% COHb).[177] At this time, further research is required to determine the clinical importance of serum CO content.

Additional laboratory tests may be useful in severe poisoning cases. An arterial or venous blood gas analysis will confirm the presence of metabolic acidosis, and a measurement of serum lactate concentration should be performed simultaneously. Metabolic acidosis with elevated lactate concentration may serve as a more reliable index of severity than a measurement of the COHb concentration.[140] Unfortunately, arterial pH does not correlate well with either initial neurologic examination or the COHb level, making it a poor criterion for deciding the need for HBO treatment.[108]

Cardiac monitoring and a 12-lead electrocardiography (ECG) are essential to identify ischemia or dysrhythmias in symptomatic patients with preexisting coronary artery disease or severe exposure. Mild elevations of creatine phosphokinase are common (ranging 20–1315 IU/L in one series of 65 cases), usually because of rhabdomyolysis rather than cardiac sources.[136] However, because CO may cause myocardial infarction in the presence of normal coronaries,[80] it is not surprising to see nonspecific increases in troponin concentrations, which may reflect diffuse cardiac myonecrosis rather than focal coronary artery disease.[24] Congestive heart failure or hypotension can be evaluated with a B-type natriuretic peptide or echocardiography (or both), looking for evidence of myocardial stunning.[80] Because of the potential for increased cardiovascular mortality,[72] patients with ECG changes or elevated cardiac enzymes may benefit from further cardiac testing, a stress test, or angiography.

The problem with using COHb levels to base treatment is that there is a wide variation in clinical manifestations with identical COHb levels. Furthermore, particular COHb levels are not predictive of symptoms or final outcome.[99,115,140] In a large prospective study of CO poisoning, COHb levels did not correlate with loss of consciousness and were not predictive of delayed neurologic sequelae.[128] The admission COHb levels are inaccurate predictors of peak levels, and the use of nomograms to extrapolate to earlier levels has not been validated. Their credibility is also suspect because of the great variability in COHb half-lives and differences in treatment with oxygen.

Because of the inherent unreliability of COHb levels in predicting outcome, researchers have been searching for other surrogate markers. Rats have early increases in glutathione released from erythrocytes, a potential marker for CO oxidative stress that could ultimately lead to brain injury.[158] Another promising marker is serum S100B, a structural protein in astroglia that is released from the brain after hypoxic stress. A series of 38 consecutive patients poisoned with CO showed that those who presented with normal neurologic findings and no loss of consciousness had normal S100B concentrations.[14] Patients who presented with loss of consciousness and neurologic deficits all had elevated concentrations. CO-poisoned rats treated with HBO did not develop elevated S100B concentrations unlike those treated with ambient oxygen therapy.[13] However, other studies have failed to find a difference between CO-poisoned patients and control subjects with respect to such markers as the S-100B protein and neuron-specific enolase.[130]

■ NEUROPSYCHOLOGIC TESTING

The extent of neurologic insult from CO can be assessed with a variety of tests. The most basic is documentation of the normal neurologic examination with a quick mini mental status examination. A more sensitive indicator of the acute effects of CO on cortical function is a detailed neuropsychologic test battery developed specifically for CO patients.[102] The advantages of such testing, which usually takes about 30 minutes, are that it can reliably distinguish 79% of the time between

CO-poisoned patients and control subjects, and it shows improvement with appropriate HBO treatment.[102] Unfortunately, such testing shows a sensitivity of only 77% and specificity of 80% for CO poisoning. There may be practice effects as well if repeated testing is performed. Another study suggested that the degree of impairment CO patients had on a test of short-term rote and context-aided verbal memory correlated well with the number of HBO treatments needed.[100] The biggest problem with such neuropsychiatric testing is that it is unclear if deficits in the test during the acute CO poisoning phase are at all predictive of the development of neurologic sequelae and therefore the necessity of HBO treatment.

■ NEUROIMAGING

Acute changes on CT scans of the brain occur within 12 hours of CO exposure that resulted in loss of consciousness.[93,105] Symmetric low-density areas in the region of the globus pallidus, putamen, and caudate nuclei are frequently noted.[75] Changes in the globus pallidus and subcortical white matter early within the first day after poisoning are associated with poor outcomes[120] (see Fig. 125–1). Alternatively, in one series of 18 patients, a negative CT within a week of admission was associated with favorable outcome.[164] The use of contrast may enhance early isodense changes not visible on initial CT scan[182] but is not routinely performed.

MRI appears to be superior in detecting basal ganglia lesions after CO poisoning.[93] One study found a much higher incidence of periventricular white matter changes on MRIs done within the first day after exposure. However, such changes had no correlation with COHb level or cognitive sequelae.[120] These periventricular changes are more common and probably more sensitive than globus pallidus lesions. However, globus pallidus lesions were present on MRI in only one patient (1.4%) in a prospective study of CO-poisoned patients, half of whom had loss of consciousness.[75] Diffusion-weighted MRI may have more promise in detecting changes in subcortical white matter within hours of serious CO poisoning.[148] Regardless, neuroimaging usually does not influence patient management and can be reserved for patients who show poor response or have an equivocal diagnosis.

The most promising area of neuroimaging after CO poisoning is in assessing regional cerebral perfusion.[30,119] Single-photon emission CT (SPECT) gauges regional blood flow noninvasively using an iodine or technetium tracer. In one series of 13 patients with delayed neurologic sequelae, all cases showed patchy hypoperfusion throughout the cerebral cortex within 11 days of poisoning.[29] These changes in perfusion may occur as early as 1 day after poisoning and primarily involve watershed regions such as the temporoparietooccipital area.[40] Perfusion defects on SPECT scanning appear to be associated with neuropsychological impairment months after serious CO poisoning.[48] Unfortunately, because of the scant availability of the procedure and the lack of comprehensive studies, SPECT scanning is not the definitive tool at this time for determining prognosis or need for HBO.

Positron emission tomography (PET) can also be used to evaluate regional blood flow as well as oxygen metabolism in the brain after CO exposure. In one series of severely CO-poisoned patients, PET examination after HBO treatment showed increased oxygen extraction and decreased blood flow in the frontal and temporal cortices.[38] Of note, patients with permanent deficits persisted in showing these abnormalities on PET scanning. One delayed PET study demonstrated that increases in dopamine D2 receptor binding in the caudate and putamen after CO poisoning were improved with bromocriptine, at which time neuropsychiatric symptoms resolved.[181] Although PET scanning cannot be used to predict outcome, abnormalities that

persist on the scan may be indicative of patients with permanent neurologic sequelae.

To complement perfusion studies, EEG mapping has also been performed on CO-poisoned patients. Although initial studies demonstrate that many patients have regional EEG abnormalities after poisoning, it is unknown if these are predictive of persistent or delayed neurologic problems. EEG mapping may be discrepant relative to SPECT scanning because EEG preferentially demonstrates subcortical lesions.

MANAGEMENT

The mainstay of treatment is initial attention to the airway. One hundred percent oxygen should be provided as soon as possible by either non-rebreather face mask or endotracheal tube. It is important to remember that a non-rebreathing mask only delivers 70% to 90% oxygen; a positive pressure mask or an endotracheal tube is necessary to achieve higher oxygen concentrations. The immediate effect of oxygen is to enhance the dissociation of COHb.[133] In volunteers, the half-life of COHb is reduced from a mean of 5 hours (range, 2–7 hours) when breathing room air (21% oxygen) to approximately 1 hour (range, 36–137 minutes) when breathing 100% oxygen at normal atmospheric pressure.[124] Actual poisonings show a range in half-lives of 36 to 137 minutes (mean, 85 minutes) when breathing 100% oxygen; the longer elimination half-lives appear to be most often associated with long, low-level exposures.[110,172] With oxygenation and intensive care treatment, hospital mortality rates for serious exposures range from 1.0 to 30%. The duration of treatment is unclear, with a valid end point being the resolution of symptoms, usually accompanied by a COHb below 5%.

Cardiac monitoring and intravenous (IV) access are necessary in any patient with systemic toxicity from CO poisoning. Hypotension can initially be treated with IV fluids; inotropes may also be necessary to treat myocardial depression. An evaluation for cardiac ischemia, including ECG and cardiac enzymes, should be considered in symptomatic patients at risk. Standard advanced cardiac life support protocols can be followed for the treatment of patients with life-threatening dysrhythmias. Patients with a depressed mental status should have a rapid blood glucose checked. Animal studies of CO poisoning suggest that hypoglycemia can be deleterious.[122] Correction of any acidemia with bicarbonate is controversial and may result in further cellular injury secondary to a left shift of the oxyhemoglobin dissociation curve.

■ HYPERBARIC OXYGEN

HBO therapy appears to be the treatment of choice for patients with significant CO exposures.[160] One hundred percent oxygen at ambient pressure reduces the half-life of COHb to 40 minutes; at 2.5 atmospheres absolute (ATA), it is reduced to 20 minutes.[124] Actual CO-poisoned victims treated with HBO have half-lives ranging from 4 to 86 minutes.[110] HBO also increases the amount of dissolved oxygen by about 10 times, which is sufficient alone to supply metabolic needs in the absence of hemoglobin.[9] This is rarely an important clinical issue because most patients have already been stabilized and have appreciably decreased COHb with ambient oxygen alone and the time required for transport to an HBO facility.

HBO is more than just a modality to clear COHb more quickly than ambient oxygen (see Antidotes in Depth A37: Hyperbaric Oxygen for more details). More importantly, in rats after loss of consciousness from CO exposure, hyperbaric, but not normobaric, oxygen therapy prevents brain lipid peroxidation.[149] HBO appears to prevent ischemic reperfusion injury by a variety of mechanisms. First, in animal models, HBO accelerates regeneration of inactivated cytochrome oxidase, which may be the initiating site for CO neuronal damage.[11] Second, HBO also prevents β integrin mediated neutrophil adhesion to brain microvascular endothelium, a process essential for amplification of CNS damage from CO.[160] This may explain why HBO, but not 100% oxygen at atmospheric pressure, prevented delayed deficits in a learning and memory maze model.[153]

Clinical studies of the effectiveness of HBO in preventing neurologic damage from CO are not as convincing as basic science studies would suggest. In uncontrolled human clinical series, the incidence of persistent neuropsychiatric symptoms, including memory impairment,

TABLE 125–3. Favorable Cognitive Outcome at 4 to 6 Weeks After Exposure to Carbon Monoxide in Randomized Clinical Trials of Hyperbaric Oxygen

Study	Design	Max HBO Pressure	Time to Treatment	Syncope (%)	Suicide (%)	Treatment	Control	Odds Ratio (95% CI)

ranged from 12% to 43% in patients treated with 100% oxygen and was as low as 0% to 4% in patients treated with HBO.[59,99,111,115]

More recently, several controlled clinical trials have evaluated the efficacy of HBO in CO poisoning (Table 125–3). The first randomized study of CO poisoning included more than 300 patients and failed to show a benefit from HBO in patients who had no initial loss of consciousness.[128] Unfortunately, seriously ill patients were not randomized to surface pressure oxygen; they received either one or three treatments of HBO. Flaws in the study included significant delays to treatment and the use of suboptimal pressure of 2.0 ATA. A smaller ($n = 60$) controlled study avoided some of these flaws and showed that HBO was able to decrease delayed neurologic sequelae from 23% to 0% in CO-poisoned patients without loss of consciousness.[162] However, all patients with syncope, a marker of serious poisoning, were excluded. A very small study ($n = 26$) of patients presenting with Glasgow Coma Scores (GCS) above 12 after CO poisoning included almost half with loss of consciousness.[42] Randomization to HBO versus 100% normobaric oxygen resulted in decreased EEG abnormalities and less reduction in blood flow reactivity to acetazolamide at 3 weeks. Unfortunately, all of these studies failed to definitively study all CO-poisoned patients, including those with syncope or coma.

The first randomized trial to directly address the issue of HBO efficacy in seriously CO-poisoned patients evaluated 191 CO-poisoned patients referred for HBO treatment.[135] Patients were randomized to a minimum of three daily treatments of HBO (2.8 ATA for 60 minutes) or 100% oxygen at 1.0 ATA for 3 days. Although the HBO group had a higher incidence of persistent neurologic sequelae at 1 month, there was no significant difference between the two groups; more than two-thirds of each group had persistent problems. This study, although the largest controlled, randomized study to date, suffered from several flaws. Fewer than half of the patients had follow-up at 1 month. Disproportionate numbers of suicide cases (about two-thirds) and drug toxicity (44%), with accompanying neuropsychologic defects, could have confounded any beneficial effect from HBO. Finally, HBO treatment was delayed for 6 hours, making it much less likely to be effective.[59,128]

A more recent randomized, double-blind, placebo-controlled study identified a beneficial effect of HBO in CO-poisoned patients.[171] Most of these patients were ill, with a mean initial COHb level of 25% and a 50% incidence of loss of consciousness. Patients were all treated within a 24-hour window after exposure, but the success of the study might be partially attributable to the rapid mean time to treatment of less than 2 hours. Patients received HBO three times at intervals of 6 to 12 hours, each at 2.0 ATA, except for the first hour of the first treatment, which was at 3.0 ATA. Control patients received sham treatments in the HBO chamber with 100% oxygen at 1.0 ATA. At 6 weeks, the HBO group had a 24% incidence of cognitive sequelae versus 46% in the control group. Based on these data, the number of patients needed to treat to prevent one case of cognitive impairment is only five. Critics of this study point out that the neuropsychiatric tests were not significantly different between the groups except for digit spam and trail making, and there was no difference in activities of daily living. However, untreated patients had increased self-reported memory problems at 6 weeks (28% versus 51%), and the beneficial effect on cognitive sequelae lasted well into 12 months.

Based on the above studies, it is not surprising that the Underwater and Hyperbaric Medical Society (UHMS) recommends HBO treatment for all CO patients with signs of serious toxicity.[49] With the low risk of this procedure,[134,139] almost 1500 patients are treated with HBO for CO poisoning in the United States each year.[61] Therefore, HBO has become the standard of care for serious CO poisoning, even though that there is substantial disagreement in the interpretation of the existing evidence.[70,94,178]

TABLE 125–4. Suggested Indications for Hyperbaric Oxygen[a]
Syncope (loss of consciousness)
Coma
Seizure
Altered mental status (GCS<15) or confusion
Carboxyhemoglobin >25%
Abnormal cerebellar function
Age ≥36 years
Prolonged CO exposure (≥24 hours)
Fetal distress in pregnancy

[a] These are criteria that are potential risk factors for cognitive sequelae, suggesting that such patients have the most to benefit from HBO treatment)[174] GCS, Glasgow Coma Score.

Indications for Hyperbaric Oxygen Therapy Although specific indications for HBO after acute CO poisoning are listed (Table 125–4), they have not been prospectively evaluated. The patients most likely to benefit are those most at risk for persistent or delayed neurologic sequelae, such as those presenting in coma or with a history of syncope.[173] These may be clinical markers for the episode of hypotension that are necessary for causing neuronal damage from CO-induced ischemic–reperfusion injury in animal models.[55,117] However, syncope is neither particularly sensitive nor specific marker for cognitive sequelae. Patients with long exposures, or "soaking" periods, are also at greater risk for neurologic sequelae.[10] The presence of a significant metabolic acidosis may be a surrogate marker.[140,167] Some authors advocate ongoing myocardial ischemia as an indication for HBO; however, in our experience, these patients usually already meet neurologic criteria for treatment, such as loss of consciousness or ongoing mental status changes. Isolated cardiac ischemia, more importantly, deserves immediate proven myocardial salvaging therapy rather than delayed treatment with an unproven therapy such as HBO.

Some authors advocate treating all patients with COHb levels of 40% or greater with HBO. Many HBO centers arbitrarily use a more conservative level of 25% as an indication for HBO.[65] More important than the actual level are patient history and examination. Further analysis of data from the most recent controlled trial demonstrates that in patients not treated with HBO, there were no reliable factors—COHb level, loss of consciousness, or base excess—for predicting who progressed to cognitive sequelae.[173] This recent multivariate analysis showed that of all factors—loss of consciousness, age, exposure time, and COHb levels—only age of 36 years or older and CO exposure duration of 24 hours or longer predicted risk factor for cognitive dysfunction at 6 week follow-up. More problematic is the incidence of cognitive sequelae in patients without those risk factors: 32% in those younger than age 36 years and 36% in those with less than 24 hours of exposure. In conclusion, it appears that there are no reliable predictors for screening out patients who will do well and not develop cognitive sequelae, thereby avoiding HBO treatment in patients with mild CO poisoning.

Therefore, at this time, it is prudent to refer for HBO patients with the most serious neurologic symptoms, regardless of their COHb concentration. Such symptoms include coma, seizures, focal neurologic deficits, altered mental status (GCS <15), and although controversial, loss of consciousness. Patients who have had cardiac arrest from CO poisoning and had the return of spontaneous circulation may be poor candidates for HBO therapy because all of these cases have been fatal.[68]

Excluding patients with milder symptoms after CO poisoning may be problematic because they are susceptible to neurocognitive sequelae. One series of 55 patients with mild poisoning as defined by no LOC and highest reported COHb level below 15% found that even one-third of these individuals had neurocognitive sequelae up to 12 months after exposure.[25] This was no different than that occurring in the severely poisoned group, although the milder group had a much longer duration of exposure as well as a greater delay to COHb level drawn. Brain imaging studies have confirmed that mild exposures, marked by no LOC and COHb levels lower than 15%, may result in visible changes.[48,126] Taken to its logical but impractical conclusion, because even apparently mild cases of CO poisoning may have poor neurocognitive outcomes, HBO treatment of every CO-exposed patient, regardless of severity, could be justified.

It is still unclear if mild neurologic symptoms, such as confusion, headache, dizziness, visual blurring, or abnormal mental status testing on initial presentation after CO poisoning, are prognostic for cognitive sequelae. These symptoms simply represent CO poisoning, which, at COHb levels approaching 10% in volunteers, may cause temporary impairment of learning and memory.[3] In a recent prospective clinical trial of CO poisoning, the incidence of cerebellar dysfunction portended a higher incidence of cognitive sequelae (odds ratio, 5.7 [95% confidence interval, 1.7–19.3]).[171] Therefore, difficulty with finger-to-nose, heel-to-shin, rapid alternating hand movements, or even ataxia, should be considered indications for HBO. Patients with other mild neurologic findings, such as headache, warrant at least several hours of oxygen by non-rebreather face mask until symptoms resolve. If symptoms do not resolve, HBO may be considered; however, any delay in HBO may decrease its efficacy.

A more promising track to try to discern patients who may respond to HBO may be the genotype, apolipoprotein E, specifically the isoform ε4.[76] This particular polymorphism allele is present in up to one quarter of the population and its presence is associated with worse neurologic outcome from trauma and stroke. In the presence of CO poisoning, it is associated with lack of response to HBO for the prevention of neurocognitive sequelae. Further studies may support not treating patients with this particular allele, focusing on those with the potential for response to HBO therapy.

Because of the confusion in determining which CO poisoned patients really need HBO treatment, several professional societies have developed evidence-based guidelines. As alluded to previously, the American College of Emergency Physicians has noted that no clinical variable can be used to predict patients at risk of cognitive sequelae and therefore most likely to benefit from HBO.[178] Similarly, the Cochrane Collaboration review on the use of HBO in CO poisoning concluded that because of so much conflicting data, there is really no ability to recommend HBO for CO poisoning at this time.[79] The most recent guidelines from the UHMS states that CO-poisoned patients should be referred for HBO if they have serious poisoning, such as unconsciousness, whether it is transient or persistent; age 36 years or older; or CO exposure duration of 24 hours or longer, even if intermittent.[174] This is all consistent with the prior studies discussed earlier. The UHMS guidelines also state that many physicians treat when neuropsychologic testing is abnormal or COHb levels are greater than 25% to 30%.

Some authors recommend selective use of HBO because of cost and difficulties in transport if the primary facility lacks a chamber. However, complications that may make such transfers and treatment unsafe are rare.[139] Although HBO cannot be recommended for every patient with CO poisoning, it is a relatively safe treatment that should be considered in all patients with significant findings by history or clinical examination. Fortunately, even without HBO, anywhere from one-third to three-quarters of cases with persistent cognitive sequelae resolve over the subsequent year.[28,171]

Delayed Administration of Hyperbaric Oxygen The optimal timing and number of HBO treatments for CO poisoning is unclear. Patients treated later than 6 hours after exposure tend to have worse outcomes in terms of delayed sequelae (30% versus 19%) and mortality (30% versus 14%).[59] This may explain the failure of one of the first randomized trials on HBO in CO, which had a mean time to treatment of over 6 hours after poisoning.[135] Meanwhile, HBO treatments delivered within 6 hours after poisoning in patients with loss of consciousness after CO seem to be almost completely preventive of neurologic sequelae.[183] However, patients may benefit if they are treated even later. In the most recent randomized clinical trial showing beneficial effects of HBO, although all patients were treated within 24 hours of exposure, 38% of patients were treated later than 6 hours after exposure. Therefore, it is not unreasonable to consider HBO, contingent on transport limitations, within 24 hours of presentation for symptomatic acute poisoning.

One case series suggests beneficial effects for HBO used up to 21 days after exposure, even after patients have developed neuropsychologic sequelae.[111] The problem with studies showing HBO benefits days after an acute poisoning or after chronic poisoning is that these cases are all anecdotal and lack control subjects. In fact, delayed neurocognitive sequelae frequently resolve within 2 months in patients with mild CO poisoning[162] and in those with serious CO poisoning who survive to HBO treatment, one-third resolve within 1 year.[171] It is possible that these delayed or chronic cases may simply represent the beneficial effects of HBO.

Repeat Treatment with Hyperbaric Oxygen A randomized clinical trial demonstrated that three HBO treatments within the first 24 hours improves cognitive outcome.[171] Unfortunately, there was no group treated with only one or two HBO sessions. Regardless, multiple treatments are advocated for patients who have persistent symptoms, particularly coma, and do not clear after their first HBO session. In a nonrandomized retrospective study, CO-poisoned patients who received a second HBO treatment had a reduction in delayed neurologic sequelae from 55% to 18% compared with control subjects who had only one treatment.[58] Prospective studies comparing single versus multiple courses of HBO therapy have failed to confirm any benefit from repeated HBO treatment, so multiple treatments cannot be recommended routine at this time. The most recent clinical guidelines from the UHMS state that the optimal number of HBO treatments for CO poisoning is unknown at this time and that one should consider reserving multiple treatments for patients who fail to fully recover after one treatment.[49]

■ **TREATMENT OF PREGNANT PATIENTS**

The management of CO exposure in the pregnant patient is difficult because of the potential adverse effects of both CO and HBO. A literature review of all CO exposures during pregnancy revealed a high incidence of fetal CNS damage and stillbirth after severe maternal poisonings.[169] A series of three severely symptomatic patients who did not receive HBO had adverse fetal outcomes: two stillbirths and one case of cerebral palsy.[84] There have even been cases of limb malformations, cranial deformities, and a variety of mental disabilities in children poisoned in utero.[15,95,96]

Traditionally, it was thought that fetal hemoglobin had a high affinity for CO. Pregnant ewe studies show a delayed but substantive increase in COHb levels in fetuses, exceeding the level and duration of those in the mothers.[96] Thus, it appeared that fetuses are a sink for CO and could be poisoned at levels lower than mothers. However, such data may not apply to humans because in vitro work shows that as opposed to sheep, human fetal hemoglobin actually has less affinity for CO than maternal hemoglobin, at a ratio of 0.8. Under conditions of low

oxygenation and high 2,3-BPG, as in serious CO poisoning, the affinity of human fetal hemoglobin starts to approach that of maternal.[176] The more important issue with maternal CO exposure is the precipitous decrease in fetal arterial oxygen content that occurs within minutes at CO concentrations of 3000 ppm.[54] Therefore, the ensuing hypoxia of the fetus, rather than increase in fetal COHb, is of more concern.

Maternal COHb levels do not accurately reflect fetal hemoglobin or tissue levels.[36] In primate studies, a single CO exposure insufficient to cause clinical disease in the mother led to intrauterine hypoxia, fetal brain injury, and increased rate of fetal death.[54,55] In humans, there are a few cases of fetal demise with maternal levels of COHb less than 10%.[15] However, in that series, some mothers were treated with oxygen before obtaining their COHb levels. Another issue with some of these data is that often the mother has been chronically "soaked" with CO, making levels difficult to interpret. Rodent studies show that chronic low level CO exposure in pregnant mothers may result in permanent cognitive deficits in the subsequent progeny.[39]

Because maternal COHb does not necessarily predict fetal demise, clinicians must direct their attention to maternal symptoms of CO toxicity. Multiple case series demonstrate that pregnant women who present with normal mental status and no loss of consciousness have excellent outcomes in terms of normal deliveries.[15,84] These infants have no subsequent delay in attaining their developmental milestones. Therefore, it appears that mothers who appear well after acute CO poisoning will have good outcomes with respect to their pregnancies.

The bigger dilemma for clinicians is the approach to treatment of seriously symptomatic CO-poisoned pregnant patients. All patients should receive 100% oxygen by face mask, at least until the mother is asymptomatic. However, CO absorption and elimination are slower in the fetal circulation than in the maternal circulation.[96] A mathematical model predicts that elimination of CO from fetuses takes 3.5 times longer than maternal CO elimination.[73] However, based on the fact that some of these data are based on sheep fetal hemoglobin kinetics, the optimum time for treatment of the mother cannot be recommended at this time.

For exposed pregnant women with a loss of consciousness or high COHb levels, HBO might be considered. Unfortunately, pregnant patients were excluded from all prospective trials documenting efficacy of HBO. However, treatment of pregnant patients with HBO is not without theoretical risk. Animal studies show conflicting results on the effects of HBO on fetal development. Some studies have shown that HBO causes developmental abnormalities in the central nervous, cardiovascular, and pulmonary systems of rodent fetuses. This is in marked contrast to the extensive Russian experience, in which hundreds of pregnant women were treated with HBO, apparently without significant perinatal complications and with improvement in fetal and maternal status for their underlying conditions of toxemia, anemia, and diabetes.[106] Cases in the United States have been published in which HBO used for mild CO poisoning resulted in infants who were normal at birth. However, less than optimal outcomes have occurred in cases of sicker patients in which the mother has had loss of consciousness or presented comatose.[44] Thus, it appears that HBO should be safe and have the same efficacy for pregnant patients as in nonpregnant patients. However, its effect in preventing adverse fetal outcomes is unclear.

There currently is no scientific validation for an absolute level at which to provide HBO therapy for a pregnant patient with CO exposure. Arbitrarily, COHb levels greater than 20% are recommended as an indication in a pregnant patient regardless of symptoms. Pregnant patients should not be treated any differently if they meet criteria for HBO that have already been mentioned (see Table 125–4). Additional criteria include any signs of fetal distress, such as abnormal fetal heart rate.

■ TREATMENT OF CHILDREN

It has been suggested that children are more sensitive to the effects of CO because of their increased metabolic rate.[27] Epidemiologic studies suggest that children can become symptomatic at COHb levels less that 10%, which is lower than commonly expected in adults.[83] The other problem is that these patients may have unusual presentations. Most children manifest nausea, headache, or lethargy. But an isolated seizure or vomiting may be the only manifestation of CO toxicity in an infant or child.

In drawing COHb levels in infants, clinicians must be aware of two confounding factors. First, many co-oximeters give falsely elevated COHb levels in proportion to the amount of fetal hemoglobin present.[170] Second, CO is produced during breakdown of protoporphyrin to bilirubin. Therefore, infants normally have higher levels of COHb, which are even higher in the presence of kernicterus. Thus, before it is assumed that an elevated COHb level implies CO poisoning in an infant, the contribution of jaundice and fetal hemoglobin must be considered in the final analysis.

Although children may be more susceptible to acute toxicity with CO, their long-term outcomes appear to be more favorable than adults. In a series of 2360 serious CO cases, all incidences of delayed neurologic sequelae were in adults older than age 30 years.[28] Pediatric series of CO poisoning demonstrated an incidence of delayed neurologic sequelae of 10% to 20% of children after severe CO poisoning.[27] This low incidence, in patients treated only with 100% oxygen at 1.0 ATA, has been used as an argument to avoid HBO. However, there still is a real risk of such sequelae, and HBO has been used successfully to prevent it.[180] If the use of surface-pressure oxygen is selected to treat a child, it is comforting to know that the COHb half-life is approximately 44 minutes, which is comparable to that in adults.[83]

■ NOVEL NEUROPROTECTIVE TREATMENTS

A variety of neuroprotective agents have been tested in animal models. They are targeted primarily at preventing the delayed neurologic sequelae associated with serious CO poisoning. One of the simplest treatments tested is insulin. Hyperglycemia has been shown to exacerbate neuronal injury from stroke as well as in arrest situations. In CO poisoning of rodents, it is associated with worse neurologic outcome.[122] However, insulin, independent of its glucose-lowering effect, may be the protective agent after ischemia. In rodent studies, improved neurologic outcome, as measured by locomotor activity, occurs after those with CO poisoning treated with insulin. In light of these findings, it is reasonable to aggressively treat documented hyperglycemia with insulin in serious CO poisoning.

Many neuroprotective agents involve blockage of excitatory amino acids that are implicated in neuronal cell death after CO poisoning. Pretreatment of mice with dizocilpine (MK-801), which blocks the action of glutamate at N-methyl-D-aspartate receptors, ameliorates learning, memory, and hippocampal deficits with CO poisoning.[77] Ketamine, another glutamate antagonist, decreases the mortality rate of rats poisoned with CO after carotid ligation.[123] Treatment of mice with various glutamate antagonists prevents learning and memory deficits in a model of CO poisoning.[52] Blockage earlier in the immunologic cascade, with a neuronal NO synthase inhibitor also prevented NMDA receptor activation, thus protecting mice from learning deficits after CO poisoning.[157] One exciting approach is the use of antioxidants, such as dimethyl sulfoxide and disulfiram, that prevent learning and memory deficits when given after CO poisoning in mice.[52] Use of these or related therapeutics, although promising, awaits further animal testing because of potential adverse effects.

Other modalities have been tested in preventing neuronal damage from CO without much success. Hypothermia, rather than being beneficial, actually increases mortality in animals.[145] Allopurinol has been shown to prevent formation of free radicals through xanthine oxidase. This xenobiotic, when given prior to exposure, inhibits lipid peroxidation in CO poisoning.[151] This strategy has not been promising because of the necessity for pretreatment.

PREVENTION

Early diagnosis prevents much of the morbidity and mortality associated with CO poisoning, especially in unintentional exposures. The increased quality of home CO-detecting devices allows personal intervention in the prevention of exposure.[86] If a patient presents complaining that his or her CO alarm sounded, it is important to realize that the threshold limit for the alarm is set roughly to approximate a COHb level of 10% at worst. Therefore, manufacturers must have their alarms activate within 189 minutes at 70 ppm CO, 50 minutes at 150 ppm, and 15 minutes at 400 ppm (Underwriters Laboratories, UL2034). Alarms are not to activate for prolonged exposures below 30 ppm to prevent epidemic alarms during winter inversions in large cities.[8] Government ordinances for obligatory CO alarms could potentially prevent many poisonings, particularly during winter storms.[21,60]

Routine laboratory screening of ED patients during the winter is not very efficacious in diagnosing unsuspected CO poisoning; the yield is less than 1% when patients are tested in whom the diagnosis of CO exposure was already excluded by history. Instead, selecting patients with CO-related complaints, such as headache, dizziness, or nausea, increases the yield to 5% to 11%.[43,144] During the winter, risk factors such as gas heating or symptomatic cohabitants in patients with influenzalike symptoms such as headache, dizziness, or nausea, particularly in the absence of fever, is the most useful method for deciding when to obtain COHb levels for potential patient.

The issue of symptomatic cohabitants is especially important from a preventive standpoint. Alerting other cohabitants to this danger and effecting evacuation may prevent needless morbidity and mortality. Most communities have multiple resources for onsite evaluation. Usually the local fire department or utility company can either check home appliances or measure ambient CO concentrations with portable monitoring equipment. Current workplace standard for ambient CO exposures is 35 ppm averaged over 8 hours with a ceiling limit of 200 ppm (measured over a 15-minute period).[113] Just a 4-hour exposure to 100 ppm of CO may result in COHb level greater than 10% with symptoms.

SUMMARY

Unintentional exposures to CO may easily be missed or misdiagnosed. Patients with a suspected influenzalike illness should be screened for potential home sources of CO, and symptomatic cohabitants should be alerted. CO should also be considered in patients with unexplained coma, acidosis, or signs of cardiac ischemia, especially if attempted suicide is suspected. Fire victims, in addition to airway problems and potential cyanide toxicity, may succumb to CO toxicity. The mainstay of treatment in all these cases is good supportive care with early oxygenation to increase the elimination of CO. Because of the overwhelming clinical successes with HBO and its limited risks, early use of this treatment modality in severe exposures is encouraged. Discussion with a regional poison center or hyperbaric facility will help in identifying patients who are most likely to benefit from such treatment.

ANTIDOTES IN DEPTH (A37)

HYPERBARIC OXYGEN

Stephen R. Thom

Hyperbaric oxygen (HBO) therapy is a treatment modality whereby a person breathes 100% O_2 while exposed to increased atmospheric pressure. Treatments are performed in either a monoplace (single patient) or a multiplace (typically two to 14 patients) chamber. Pressures applied while patients are in the chamber usually are two to three atmospheres absolute (ATA). Treatments vary from 1.5 to 8 hours, depending on the indication, and may be performed one to three times daily. Monoplace chambers usually are compressed with pure oxygen. Multiplace chambers are pressurized with air, and patients breathe pure oxygen through a tight-fitting face mask, a head tent, or endotracheal tube.

Therapeutic mechanisms of action for HBO are based on elevation of both hydrostatic pressure and the partial pressure of oxygen. Elevation of the hydrostatic pressure causes a reduction in the volume of gas according to Boyle's law. This action has direct relevance to pathologic conditions in which gas bubbles are present in the body, such as arterial gas embolism and decompression sickness. During treatment, the arterial oxygen tension typically exceeds 1500 mm Hg, and tissue oxygen tensions of 200 to 400 mm Hg.[153] Under normal environmental conditions, hemoglobin is virtually saturated with oxygen on passage through the pulmonary microvasculature, so the primary effect of HBO is to increase the dissolved oxygen content of plasma. Application of each additional atmosphere of pressure while breathing 100% oxygen increases the dissolved oxygen concentration in the plasma by 2.2 mL O_2/dL (vol%) (Chap. 21).

Mechanisms of HBO relevant to its use as an antidote are its ability to diminish hypoxic stress by increasing tissue oxygen tension and decreasing the production of reactive oxygen species (ROS) and reactive nitrogen species (RNS).[74,130,142,150,151] Reactive species are recognized to serve as signaling molecules in transduction cascades.[2,25,166] Reactive species have positive and negative effects depending on their concentration and intracellular localization. Hence, with regard to HBO as with any xenobiotic, one must contend with a dosing issue in order to achieve benefit versus injury. Because exposure to hyperoxia in typical clinical HBO protocols is rather brief, studies show that antioxidant defenses are adequate so that tissue injuries can be avoided.[44,45,123,164]

Although elevating tissue O_2 tension is a primary effect of HBO, lasting benefits are related to abatement of the underlying pathophysiological processes. In the context of an antidote, HBO is most commonly used for treatment of carbon monoxide (CO) poisoning. Experience using HBO for life-threatening poisonings from cyanide (CN), hydrogen sulfide (H_2S), or carbon tetrachloride (CCl_4) and in patients with high methemoglobin levels is limited. HBO has been suggested for management of diverse poisonings, but discussion of these applications is beyond the scope of this Antidotes in Depth because supporting clinical and experimental evidence is sparse.[161]

CARBON MONOXIDE

Administration of supplemental oxygen is the cornerstone for treatment of CO poisoning. Historically, its use was based on the affinity of CO for heme proteins and formation of carboxyhemoglobin (COHb). Elevated COHb can result in tissue hypoxia, and exogenous oxygen both hastens dissociation of CO from hemoglobin and provides enhanced tissue oxygenation directly through the increased Po_2. HBO causes COHb dissociation to occur at a rate greater than that achievable by breathing 100% O_2 at sea-level pressure.[113] Additionally, HBO accelerates restoration of mitochondrial oxidative processes.[20] CO poisoning causes perivascular inflammatory injuries, especially in the brain, and animal studies have shown that HBO ameliorates this process by impeding neutrophil adherence to the vasculature.[28,76,82,152,157]

Survivors of CO poisoning are faced with potential impairments to cardiac and neurological function. CO poisoning can cause acute cardiac compromise and survivors exhibit an increased risk for cardiovascular-related death in the subsequent 10 years.[65,126] With regard to neurological impairments, there is a historical precedence for dividing disorders into "acute/persistent" and "delayed" forms. Some patients exhibit acute abnormalities wherein they have an abnormal level of consciousness and/or focal neurological findings from the time of initial presentation and never recover.[4,34,37,54] Other patients seemingly recover from acute poisoning but then manifest neurological or neuropsychiatric abnormalities from 2 days to about 5 weeks after poisoning.[29,46,56,68,92,98,101,108,119,133,136,158,175] Events occurring after a clear or "lucid" interval have been termed "delayed" neurological sequelae.

Results from animal studies do not provide a clear distinction between mechanisms responsible for "acute/persistent" and "delayed" sequelae. Several animal studies indicate that "acute/persistent" sequelae arise because of neuronal necrotic or apoptotic death, but this does not mean that injuries are mediated solely by hypoxia/ischemia versus processes such as excitotoxicity and perivascular oxidative stress that have been linked to more slowly evolving "delayed" brain disorders.[53,71,99,109,149,155,156] Because the different pathological processes occur in close proximity and in some cases concurrently, one can expect that pathological insults for "acute/persistent" and "delayed" sequelae overlap. Thus, there may be more of a continuum of clinical disorders as opposed to distinctly different syndromes.

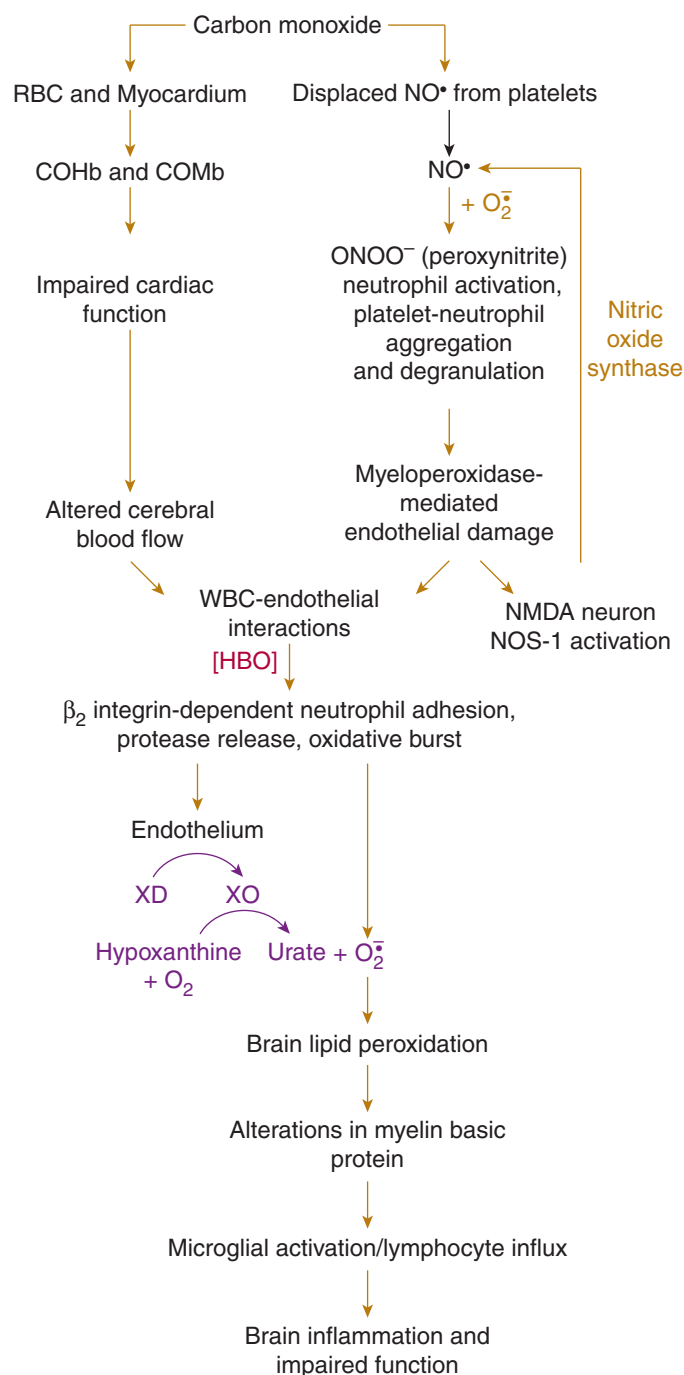
Vascular abnormalities occur in animal models of CO poisoning. Among the earliest events that occur in both animal models and humans is platelet-neutrophil adherence that mediates intravascular neutrophil activation. These changes precipitate neutrophil adherence that initiates a cascade of events that ultimately causes neurological dysfunction (Fig. A37–1).[70,155,156] Animals poisoned with CO then treated with HBO have more rapid improvement in cardiovascular status,[47] lower mortality,[115] and lower incidence of neurological sequelae.[154] Benefits are likely based on both improved oxygenation and secondary effects pertaining to inhibition of neutrophil adhesion. The ability of HBO to inhibit function of neutrophil β_2-integrin adhesion molecules in animal models forms the basis for amelioration of encephalopathy resulting from CO poisoning and decompression sickness, smoke-induced lung injury, as well as reperfusion injuries of brain, heart, lung, liver, and skeletal muscle.[7,79,95,146,147,152,160,165,169,178–180]


FIGURE A37–1. This figure demonstrates concurrent events leading to vascular injury with CO poisoning and the sequence of events leading to neurological injuries. RBC, erythrocyte; ONOO-, peroxynitrite; ·NO, nitric oxide; O_2, superoxide radical; COHb, carboxyhemoglobin; COMb, carboxymyoglobin; NMDA, N-methyl-D-aspartate; NOS-1, neuronal nitric oxide synthase; NO_2, nitrite (major oxidation product of ·NO); WBC, leukocytes; XD, xanthine dehydrogenase; XO, xanthine oxidase.

Exposure to 2.8 to 3.0 ATA O_2 for 45 minutes temporarily inhibits neutrophil adherence mediated by the activation-dependent β_2-integrins on the neutrophil membrane in both rodents and humans.[28,76,82,152,157] Exposure to HBO *inhibits* β_2-integrins of neutrophils, but not other circulating leukocytes, because hyperoxia increases synthesis of RNS derived from type-2 nitric oxide synthase and myeloperoxidase

(see A37–1). This leads to excessive S-nitrosylation of cytoskeletal β actin, which in turn impedes the function of β_2 integrins.[150] HBO does not reduce neutrophil viability, and functions such as degranulation and oxidative burst, in response to chemoattractants, remain intact.[152,157] Inhibiting β_2-integrins with monoclonal antibodies will also ameliorate ischemia-reperfusion injuries, but in contrast to HBO, antibody therapy causes profound immunocompromise.[102,103]

Since 1960, HBO has been used with increasing frequency for severe CO poisoning because clinical recovery appeared to improve beyond that expected with ambient-pressure oxygen therapy. Support for HBO use comes from this experience.[56,57,69,83,97,108,111,122] The clinical efficacy of HBO for acute CO poisoning has been assessed in five prospective, randomized trials published in peer-reviewed journals. Only one clinical trial satisfies all items deemed to be necessary for the highest quality of randomized, controlled trials.[175] This double-blind, placebo-controlled clinical trial involved 152 patients. All patients received treatment with either three sessions of HBO therapy or normobaric O_2 (NBO) with sham pressurization to maintain blinding. Critically ill patients were included, with half of enrolled patients having lost consciousness and 8% requiring intubation. The follow-up rate was 95%. The definition of neurological sequelae, defined a priori, was fulfilled in symptomatic patients by an aggregate performance on six neuropsychological tests. The pretreatment characteristics of the 152 patients enrolled in the trial were similar except that cerebellar dysfunction was more frequent in the NBO treatment group. The group treated with HBO had a lower incidence of cognitive sequelae than the group treated with NBO after adjustment for pretreatment cerebellar dysfunction and stratification (odds ratio 0.45, 95% confidence interval 0.22–0.92, $p = 0.03$). Post hoc subgroup analysis incorporating risk factors showed that HBO reduced cognitive sequelae in patients with any of the following: unconsciousness, COHb greater than or equal to 25%, age greater than or equal to 50 years, or base excess less than or equal to 2 mEq/L. HBO did not improve outcome in patients with none of these criteria.

The only other blinded, prospective, randomized trial was published in 1999 and it involved 191 patients of different severity treated with either daily HBO (3.0 ATA for 60 minutes) with intervening high-flow oxygen for 3 or 6 days versus high-flow NBO for 3 or 6 days.[128] Additional HBO treatments (up to six daily) were performed in patients without neurological recovery. The primary outcome measure for this trial was testing performed at completion of treatment (3–6 days) and not from long-term follow-up. This study had a high rate of adverse neurological outcomes in all patients, regardless of treatment assignment. Neurological sequelae were reported in 74% in HBO-treated patients and 68% in controls. No other clinical trial has described this magnitude of neurological dysfunction. The high incidence is likely to be related to the assessment tool, which could not discern true neurological impairments from poor test-taking related to depression.[129] Suicide attempts with CO represented 69% of cases in this trial. Moreover, 54% of subjects were lost to follow-up. Outcomes at 1 month were not reported, but were stated to show no difference. Multiple statistical comparisons were reported without apparent planning or the requisite statistical correction. Both treatment arms received continuous supplemental mask O_2 for 3 days between their hyperbaric treatments (both true HBO and "sham"), resulting in greater overall O_2 doses than conventional therapy. Multiple flaws in the design and execution of this study are discussed in the literature, so it is impossible to draw meaningful conclusions from the data.[60,106] Despite these issues, conclusions from the trial have been accepted by some as a negative outcome for HBO therapy.[75]

The first prospective clinical trial involving HBO therapy did not demonstrate therapeutic benefits.[119] This study has been criticized

because the authors used a low oxygen partial pressure (2 ATA) versus the more usual protocols with 2.5 to 3 ATA and because nearly half of the patients received hyperbaric treatments more than 6 hours after they were discovered.[19] In 1969, a retrospective study indicated that HBO reduced mortality and morbidity only if HBO was administered within 6 hours of CO poisoning.[57] HBO was effective in several other prospective investigations. In a trial involving mildly to moderately poisoned patients, 23% of patients (seven of 30) treated with ambient-pressure oxygen developed neurologic sequelae, whereas no patients (zero of 30; $p < 0.05$) treated with HBO (2.8 ATA) developed sequelae.[158] In another prospective, randomized trial, 26 patients were hospitalized within 2 hours of discovery and were equally divided between two treatment groups: ambient-pressure oxygen or 2.5 ATA O_2.[46] Three weeks later, patients treated with HBO had significantly fewer abnormalities on electroencephalogram, and single-photon emission computed tomography (SPECT) scans showed that cerebral vessels had nearly normal reactivity to carbon dioxide, in contrast to diminished reactivity in patients treated with ambient-pressure oxygen.

In conclusion, published clinical trials span a broad range in quality. Efficacy of HBO for acute CO poisoning is well supported in animal trials and studies provide a mechanistic basis for treatment. In this era of evidence-based medicine a great deal of emphasis has been placed on systematic reviews, although flaws in this approach are increasingly recognized. Treatment of CO poisoning has undergone a number of systematic reviews, but the analytical fidelity has been poor. For example, profound flaws in two successive Cochrane Library Reviews have been identified but, to date, are not corrected.[88]

Several recent reports have provided additional insight into risks for neurological sequelae post-CO poisoning and the benefit of HBO. One such study reported on a cohort of 238 patients and found that independent risk factors for developing neurological sequelae include age greater than or equal to 36 years, exposure for 24 hours or longer (with or without intermittent CO exposures), and acute complaints of memory abnormalities.[174] The only risk factor where HBO demonstrated a reduction in incidence of sequelae was for the group greater than or equal to 36 years. The trial was underpowered to reliably assess the benefit of HBO in those with long-duration CO exposure, but none of five patients exposed for 24 hours or longer manifested neurological sequelae.

Another study has shown that HBO is only beneficial in reducing neurological sequelae among patients who do not possess the apolipoprotein ε4 allele.[66] Because genotype is typically unknown this report does not provide treatment guidelines, but it will become important for future research. Although the basic mechanisms are unknown, it is well established that the apolipoprotein genotype can have profound effects on risk for a variety of neuropathological events.[1,50,100,127] Whether apolipoprotein ε4 modifies the primary pathophysiological insults of CO or mechanisms of HBO is currently unknown. As yet no objective method is available for staging the severity of CO poisoning, although preliminary reports suggest plasma markers may be used in the future.[149] Psychometric screening tests have not proved reliable because abnormalities during the initial screening do not correlate with development of delayed sequelae.[158] The optimal dose of HBO, the number of treatments, treatment pressure, and the time after which it is no longer effective therapy are not clearly defined. Randomized trials have treated patients as soon as possible after CO poisoning based on work suggesting the existence of a 6-hour window of greatest opportunity.[57] However, it is possible that the time of potential benefit goes beyond what has been investigated for some patients. The requisite number of treatments also remains unclear. Clinical indications for HBO in CO poisoning are reviewed in greater detail in Chap. 125 and specifically in Table 125-4.

METHYLENE CHLORIDE

Methylene chloride (CH_2Cl_2) is an organic solvent used commercially in aerosol sprays as a solvent in plastics manufacturing, photographic film production, and food processing; as a degreaser; and as a paint stripper. It is readily absorbed through the skin or by inhalation. It is metabolized by the cytochrome P450 oxidase system to yield CO.[144] This process is slow, and peak COHb levels of 10% to 50% may not be reached for 8 hours or more.[27,48,77,84,93,135,144] Methylene chloride toxicity can have many of the same acute manifestations as CO poisoning.[144] Acute signs and symptoms are attributable to the direct effects of this solvent on the central nervous system (CNS) and to concomitant hypoxia. Effects that are present after 1 hour or more, particularly if the COHb level is elevated, may be partially caused by CO toxicity. There are anecdotal reports of treatment with HBO.[67,121,124,125]

COMBINED CARBON MONOXIDE AND CYANIDE

CO and CN poisonings can occur concomitantly in victims of smoke inhalation.[5,6,10–12,15,30,36,81,89,91,104,134,137,171,176] Experimental evidence suggests that they can produce synergistic toxicity.[9,107,112,113,116] Animal studies demonstrate that ambient-pressure 100% O_2 can enhance protection from CN toxicity[132] and can also enhance CN metabolism to thiocyanate when thiosulfate is used concomitantly.[17] HBO may have either direct effects on reducing CN toxicity[35,72,73,138,148] or augment other antidote treatments.[24,132,173] However, not all animal studies have found that HBO improved outcome,[172] and clinical experience regarding CN treatment with HBO is sparse.[4,55,131] In a series of smoke-inhalation victims with both toxic CO and CN concentrations who received both HBO and treatment for CN involving sodium nitrite and sodium thiosulfate, four of five patients survived without apparent neurologic damage.[63] Clinical case reports where HBO was used along with standard antidote treatment (sodium nitrite plus sodium thiosulfate) for isolated CN poisonings are equivocal.[55,87,131,162] One case showed dramatic improvement,[162] but another showed no response.[87] Methemoglobin formation with the standard antidote treatment involving nitrite is not thought to generate seriously high methemoglobin concentrations, but in the face of concomitant COHb the additional reduction of oxygen carrying capacity may pose a risk. In this regard, there is a report of a patient with 75% methemoglobin due to isobutyl nitrite poisoning who was successfully treated with toluidine-blue and HBO.[86] Further research in this area is necessary. Because CN is among the most lethal poisons and toxicity is rapid, standard antidotal therapy for isolated CN poisoning is of primary importance. Hyperbaric oxygen may be an adjunct for consideration in refractory cases. Consideration for possible use of HBO therapy may also change as the role of hydroxocobalamin alters the use of nitrites (see Chaps 126 and 127).

HYDROGEN SULFIDE

Hydrogen sulfide (H_2S) binds to cytochrome a-a$_3$ and hence it is similar to CN, although it is more readily dissociated by O_2.[145] Clinical manifestations of toxicity are also similar to those with CO and CN.[145] Management of patients with serious H_2S poisoning principally involves oxygenation and cardiovascular support, as well as consideration of sodium nitrite.[51,59,110] HBO may be more effective than sodium nitrite in preventing mortality in animals.[16] In several instances, HBO appeared to be beneficial.[13,23,58,140,177] Relatively late treatment with HBO (eg, over 10 hours after poisoning) is reported to be beneficial

in some[168] but not all cases.[3,141] No definitive data regarding use of HBO for H_2S poisoning are available, but HBO should be considered in refractory cases.

CARBON TETRACHLORIDE

Carbon tetrachloride (CCl_4) hepatotoxicity may be diminished by HBO. Mortality was decreased in a number of animal studies,[14,22,105,120] and there are several case reports of patients surviving potentially lethal ingestions with HBO therapy.[85,143,163,181] HBO appears to inhibit the cytochrome P450 oxidase system responsible for conversion of CCl_4 to hepatotoxic free radicals.[21,96] Because there are no proven antidotes for CCl_4 poisoning, HBO should be considered for potentially severe CCl_4 exposures. However, there may be a delicate balance between oxidative processes that are therapeutic and those that mediate hepatotoxicity.[18] Therefore, when HBO is being considered, it should be instituted before the onset of liver function abnormalities.

PATIENT MANAGEMENT

A fundamental aspect to emergency patient management and treatment is the knowledge and training of the healthcare team. HBO treatment centers typically have the ability to manage patients who require critical care support. Plans for treatment begin while the patient is still in the emergency department, before transport to the hyperbaric chamber is initiated. Issues to be addressed include informed consent, determination that all intravenous/arterial lines and nasogastric tubes/Foley catheters are secured, capping all unnecessary intravenous catheters, placing chest tubes to suction venting apparatus or one-way Heimlich valves, replacing air in endotracheal tube cuffs with water to prevent excessive air leakage at pressure, and adequately sedating or paralyzing the patient as clinically indicated. Substantial clinical experience demonstrates that patients can be transported without adverse events.[94,139]

HBO therapy should never be considered unless proper supportive medical care can be delivered. Most chamber facilities today have equipment and treatment protocols analogous to an intensive care unit. Intensive care support for pediatric cases also can be achieved.[78,170] The inherent toxicity of O_2 and potential for injury resulting from elevations of ambient pressure must be addressed whenever HBO is used therapeutically. Preexisting conditions that require evaluation for possible management before initiation of HBO include claustrophobia, sinus congestion, and patients with scarred or noncompliant structures in the middle ear, such as otosclerosis.[80]

Middle ear barotrauma is the most common adverse effect of HBO treatment.[26] As the ambient pressure within the hyperbaric chamber increases, the patient must be able to equalize the pressure within the middle ear by autoinsufflation. When autoinsufflation fails, tympanostomies can be performed. The incidence of aural barotrauma has been reported to be between 1.2% and 7%.[33,117,164] Pulmonary barotrauma during HBO treatment is rare but should be suspected if any chest or hemodynamic alterations occur during or shortly after decompression. If pneumothorax is suspected, placement of a chest tube is appropriate. Preexisting pneumothorax should be treated with chest tube insertion prior to initiating therapy.

Toxicity resulting from O_2 can be manifested by injuries to the CNS, lungs, and eyes. CNS O_2 toxicity is manifested as a grand mal seizure and occurs at an incidence of approximately one to four per 10,000 patient treatments.[39,62,117] The complex pathophysiology of CNS oxygen toxicity involves production of ROS, RNS, and an imbalance of excitatory and inhibitory neurotransmitters.[8,41,43] The risk of CNS oxygen

toxicity is higher in hypercapnic patients and possibly in those who are acidotic or have compromise resulting from sepsis, as an incidence of 7% (23 of 322 patients) was reported in case series of HBO treatment of gas gangrene.[38,61] Pulmonary oxygen toxicity involves local free radical production as well as a neurogenic mechanism involving adrenergic/cholinergic pathways.[40,42] Pulmonary insults can impair mechanics (elasticity), vital capacity, and gas exchange (reviewed in reference[31]). These conditions typically do not arise when standard treatment protocols are followed.[32,49,64,118] There is one report of reversible small airways changes in four of 21 patients treated daily for 90 minutes at 2.4 ATA for 21 days.[159] Progressive myopia may occur in patients undergoing prolonged daily therapy but typically reverses within 6 weeks after treatments are terminated.[90] Nuclear cataracts can form with excessive treatments, exceeding a total of 150 to 200 hours, and they may rarely develop with standard treatment protocols.[52,114] Although there is a theoretical risk for retrolental fibroplasia in neonates, experimental and clinical evidence does not indicate that typical HBO therapy protocols have detrimental effects on neonates or the unborn fetus.[167]

SUMMARY

In conclusion, the mechanisms of action and efficacy of HBO in toxicology continue to be investigated. Some research findings are provocative because they highlight the fact that traditional assessments of mechanisms for toxicity of some agents are incomplete. Questions persist on many issues. Further investigation is required to discern those cases where clear benefit arises with HBO treatment and to define the constraints that may limit its efficacious use.

CHAPTER 126
CYANIDE AND HYDROGEN SULFIDE

Christopher P. Holstege, Gary E. Isom, and Mark A. Kirk

Cyanide (CN)

MW	=	26.02 daltons
Whole blood	<	1 µg/mL (38.5 µmol/L)

Concentrations: Airborne

Immediately fatal	=	270 ppm
Life threatening	=	110 ppm (>30 min)

Hydrogen Sulfide (H₂S)

MW	=	34.08 daltons

Concentrations: Airborne

Odor threshold	=	0.02–0.13 ppm
Olfactory fatigue	=	100–150 ppm
Immediately fatal	=	700 ppm

CYANIDE POISONING

An emergency involving the diagnosis and management of patients exposed to cyanide is a potential scenario for any healthcare facility. Cyanide exposure is associated with smoke inhalation, laboratory mishaps, industrial incidents, suicide attempts, and criminal activity. Cyanide is a chemical group that consists of one atom of carbon bound to one atom of nitrogen by three molecular bonds (C≡N). Inorganic cyanides (also know as cyanide salts) contain cyanide in the anion form (CN⁻) and are used in numerous industries, such as metallurgy, photographic developing, plastic manufacturing, fumigation, and mining. Common cyanide salts include sodium cyanide (NaCN) and potassium cyanide (KCN). Sodium salts react readily with water to form hydrogen cyanide. Organic compounds that have a cyano group bonded to an alkyl residue are called nitriles. For example, methyl cyanide is also known as acetonitrile (CH_3CN). Hydrogen cyanide (HCN) is a colorless gas at standard temperature and pressure with a reported bitter odor. Cyanogen gas, a dimer of cyanide, reacts with water and breaks down into the cyanide anion.

Many plants, such as *Manihot* spp, *Linum* spp, *Lotus* spp, *Prunus* spp, *Sorghum* spp, and *Phaseolus* spp, contain cyanogenic glycosides.[112] The *Prunus* species consisting of apricots, bitter almond, cherry, and peaches have pitted fruits containing the glucoside amygdalin. When ingested, amygdalin is biotransformed by intestinal β-*d*-glucosidase to glucose, aldehyde, and cyanide (Fig. 126–1). Laetrile, which contains amygdalin, has been inappropriately suggested to have antineoplastic properties. When laetrile is administered by intravenous (IV) infusion, amygdalin bypasses the necessary enzymes in the gastrointestinal (GI) tract to liberate cyanide and does not cause toxicity. However, when ingested, laetrile may cause cyanide poisoning.[48] Despite data demonstrating its lack of utility in the treatment of cancer, laetrile is still available via the Internet.

Cassava (*Manihot esculenta*) root is a major source of food for millions of people in the tropics. It is a hardy plant that can remain in the ground for up to 2 years and needs relatively little water to survive. Because the shelf life of a cassava root is very short after it is removed from the stem, cassava root must be processed and sent to market as soon as it is harvested. However, proper processing must occur to ensure the food's safety. Processed cassava is called *Gari*. Linamarin (2-hydroxyixo-butynitrite-β-D-glycoside) is the major cyanogenic glycoside in cassava roots. It is hydrolyzed to hydrogen cyanide and acetone in two steps during the processing of cassava roots.[126] Whereas soaking peeled cassava in water for a single day releases approximately 45% of the cyanogens, soaking for 5 days causes 90% loss. If processing is inefficient, linamarin and cyanohydrin, the immediate product of hydrolysis of linamarin, remain in the food.[87,88] Consumed linamarin is hydrolyzed to cyanohydrins by β-glucosidases of the microorganisms in the intestines. Cyanohydrins present in the food and formed from linamarin then dissociate spontaneously to cyanide in the alkaline pH of the small intestines.

Iatrogenic cyanide poisoning may occur during use of nitroprusside as a vasodilator given to reduce blood pressure and afterload. Each nitroprusside molecule contains five cyanide molecules, which are slowly released in vivo. If endogenous sulfate stores are depleted, as in a malnourished or postoperative patient, cyanide may accumulate even with therapeutic nitroprusside infusion rates (2–10 µg/kg/min).

■ HISTORY AND EPIDEMIOLOGY

In 1782, the Swedish chemist Carl Wilhelm Scheele first isolated hydrogen cyanide. He reportedly died from the adverse health effects of cyanide poisoning in 1786. Napoleon III was the first to use hydrogen cyanide in chemical warfare, and it was subsequently used on World War I battlefields. During World War II, cyanide (Zyklon B) caused more than 1 million deaths in Nazi gas chambers at Auschwitz, Buchenwald, and Majdanek. In 1978, KCN was used in a mass suicide led by Jim Jones of the People's Temple in Guyana, resulting in 913 deaths. Other notorious suicide cases include Wallace Carothers, Herman Goring, Heinrich Himmler, and Ramon Sampedro. In 1982, seven deaths resulted from consumption of cyanide-tainted acetaminophen in Chicago that subsequently led to the requirement of tamper-resistant pharmaceutical packaging.[30,38] Cyanide has also been used for illicit euthanasia.[18]

Cyanide poisoning accounted for 242 of the more than 2 million exposures reported to the American Association of Poison Control Centers (AAPCC) in 2007.[23] The majority of reported cyanide exposures are unintentional. These events frequently involve chemists or technicians working in laboratories where cyanide salts are common reagents.[17] The potential for cyanide poisoning also exists after smoke inhalation.[6,31,107] The combustion of materials such as wool, silk, synthetic rubber, and polyurethane releases cyanide. Ingestion of cyanogenic chemicals (ie, acetonitrile, acrylonitrile, and propionitrile) is another source of cyanide poisoning.[116] Acetonitrile (C_2H_3N) and acrylonitrile (C_3H_3N) are themselves nontoxic, but biotransformation via cytochrome P450 liberates cyanide (see Fig. 126–1).[128]

■ PHARMACOLOGY

The dose of cyanide required to produce toxicity is dependent on the form of cyanide (ie, gas or salt), the duration, and the route of exposure. However, cyanide is an extremely potent toxin with even small exposures lead to symptoms. For example, an adult oral lethal dose of KCN is approximately 200 mg. An airborne concentration of 270 ppm (µg/mL) of hydrogen cyanide (HCN) may be immediately fatal, and exposures above 110 ppm for more than 30 minutes are generally considered life threatening. The current Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for both hydrogen cyanide and cyanogen is 10 ppm as an 8-hour time-weighted average (TWA) concentration. The American Conference of
FIGURE 126–1. Biotransformation of cyanogens (**A**) acetonitrile and (**B**) amygdalin to cyanide.

Governmental Industrial Hygienists has assigned a ceiling limit value of 4.7 ppm, which should not be exceeded during any part of the working exposure.

Acute toxicity occurs through a variety of routes, including inhalation, ingestion, dermal, and parenteral. Hydrogen cyanide readily crosses membranes because it has a low molecular weight (27 daltons) and is nonionized. After absorption and dissolution in blood, cyanide exists in equilibrium as the cyanide anion (CN^-) and undissociated HCN. Hydrogen cyanide is a weak acid with a pK_a of 9.21. Therefore, at physiologic pH 7.4, it exists primarily as HCN. Rapid diffusion across alveolar membranes followed by direct distribution to target organs accounts for the rapid lethality associated with HCN inhalation.

PHARMACOKINETICS AND TOXICOKINETICS

Cyanide is eliminated from the body by multiple pathways. The major route for detoxification of cyanide is the enzymatic conversion to thiocyanate. Two sulfur transferase enzymes, rhodanese (thiosulfate-cyanide sulfurtransferase) and β-mercaptopyruvate-cyanide sulfurtransferase, catalyze this reaction. The primary pathway for metabolism is rhodanese, which is widely distributed throughout the body and has the highest concentration in the liver. This enzyme catalyzes the transfer of a sulfane sulfur from a sulfur donor, such as thiosulfate, to cyanide to form thiocyanate. In acute poisoning, the limiting factor in cyanide detoxification by rhodanese is the availability of adequate quantities of

sulfur donors. The endogenous stores of sulfur are rapidly depleted, and cyanide metabolism slows. Hence, the efficacy of sodium thiosulfate as an antidote stems from its normalization of the metabolic inactivation of cyanide. The sulfation of cyanide is essentially irreversible, and the sulfation product thiocyanate has relatively little inherent toxicity. Thiocyanate is eliminated in urine. A number of minor pathways of metabolism (<15% of total) account for cyanide elimination, including conversion to 2-aminothiazoline-4-carboxylic acid, incorporation into the one-carbon metabolic pool, or in combination with hydroxocobalamin to form cyanocobalamin.

Limited human data regarding the cyanide elimination half-life are available. Elimination appears to follow first-order kinetics,[69] although it varies widely in reports (range, 1.2–66 hours).[6,47,69] Disparity in values may result from the number of samples used to perform calculations and the effects of antidotal treatment. The volume of distribution of the cyanide anion varies according to species and investigator, with 0.075 L/kg reported in rats.[35]

PATHOPHYSIOLOGY

Cyanide is an inhibitor of multiple enzymes, including succinic acid dehydrogenase, superoxide dismutase, carbonic anhydrase, and cytochrome oxidase.[130] Cytochrome oxidase is an iron-containing metalloenzyme essential for oxidative phosphorylation and hence aerobic energy production. It functions in the electron transport chain within mitochondria, converting catabolic products of glucose into adenosine triphosphate (ATP). Cyanide induces cellular hypoxia by inhibiting cytochrome oxidase at the cytochrome a_3 portion of the electron transport chain (Fig. 126–2).[93,130] Hydrogen ions that normally would have combined with oxygen at the terminal end of the chain are no longer incorporated. Thus, despite sufficient oxygen supply, oxygen cannot be used, and ATP molecules are no longer formed.[72] Unincorporated hydrogen ions accumulate, contributing to acidemia.

Hyperlactemia occurs after cyanide poisoning because of failure of aerobic energy metabolism. During aerobic conditions, when the electron transport chain is functional, lactate is converted to pyruvate by mitochondrial lactate dehydrogenase. In this process, lactate donates hydrogen moieties that reduce nicotinamide adenine dinucleotide (NAD^+) to nicotinamide adenine dinucleotide (NADH). Pyruvate then enters the tricarboxylic acid cycle, with resulting ATP formation. When cytochrome a_3 within the electron transport chain is inhibited by cyanide, there is a relative paucity of NAD^+ and predominance of NADH, favoring the reverse reaction, in which pyruvate is converted to lactate.[108]

Cyanide is a potent neurotoxin. It exhibits a particular affinity for regions of the brain with high metabolic activity.[96,135] Central nervous system (CNS) injury occurs via several mechanisms, including impaired oxygen utilization, oxidant stress, and enhanced release of excitatory
FIGURE 126–2. Pathway of cyanide and hydrogen sulfide toxicity and detoxification. * = hydroxocobalamin.

neurotransmitters. Cranial imaging of survivors of cyanide poisoning reveals that injury occurs in the most oxygen-sensitive areas of the brain, such as the basal ganglia, cerebellum, and sensorimotor cortex.[104]

Cyanide enhances *N*-methyl-D-aspartate (NMDA) receptor activity and directly activates the NMDA receptor,[3,91] which increases release of glutamate[90] and inhibits voltage-dependent magnesium blockade of the NMDA receptor.[136] This NMDA receptor stimulation results in Ca^{2+} entry into the cytosol of neurons. Cyanide also activates voltage-sensitive calcium channels[59] and mobilizes Ca^{2+} from intracellular stores.[73,97] As a result, cytosolic Ca^{2+} increases and activates a series of biochemical reactions that lead to the generation of reactive oxygen species (ROS) and nitrous oxide.[66,77,105] These ROS initiate peroxidation of cellular lipids, which together with cyanide-induced inhibition of the respiratory chain adversely affect mitochondrial function, initiating cytochrome c release and execution of apoptosis, necrosis, and subsequent neurodegeneration.[5,59,95,106] Experimental studies demonstrate that NMDA inhibitors such as dextrorphan and dizocilpine, antioxidants, and cyclooxygenase inhibitors protect neurons against cyanide-induced damage.[56,71,127]

Sulfurtransferase metabolism via rhodanese is crucial for detoxification. However, the aforementioned cyanide-induced metabolic derangement may decrease enzyme detoxification. Decreased ATP and ROS and increased cytosolic calcium stimulate protein kinase C activity, which in turn inactivates rhodanese.[2]

■ CLINICAL MANIFESTATIONS

Acute Exposure to Cyanide The amount, duration of exposure, route of exposure, and premorbid condition of the individual influence the time to onset and severity of illness. A critical combination of these factors overwhelms endogenous detoxification pathways, allowing cyanide to diffusely affect cellular function within the body. No reliable pathognomonic symptom or toxic syndrome is associated with acute cyanide poisoning.[45] Clinical manifestations reflect rapid dysfunction of oxygen-sensitive organs, with CNS and cardiovascular findings predominating. The time to onset of symptoms typically is seconds with inhalation of gaseous HCN or IV injection of a water-soluble cyanide salt and several minutes after ingestion of an inorganic cyanide salt. The clinical effects of cyanogenic chemicals often are delayed, and the time course varies among individuals (range, 3–24 hours), depending on their rate of biotransformation.[116] Clinically apparent cyanide toxicity may occur within hours to days of initiating nitroprusside infusion, although concurrent administration of thiosulfate or hydroxocobalamin may prevent toxicity (see Chap. 62).[102]

CNS signs and symptoms are typical of progressive hypoxia and include headache, anxiety, agitation, confusion, lethargy, seizures, and coma. A centrally mediated tachypnea occurs initially followed by bradypnea.

Cardiovascular responses to cyanide are complex. Studies of isolated heart preparations and intact animal models show that the principal cardiac insult is slowing of rate and loss of contractile force. Several reflex mechanisms, including catecholamine release and central vasomotor activity, may modulate myocardial performance and vascular response in patients with cyanide poisoning. In laboratory investigations, a brief period of increased inotropy caused by reflex compensatory mechanisms occurs before myocardial depression. Clinically, an initial period of bradycardia and hypertension may occur followed by hypotension with reflex tachycardia, but the terminal event is consistently bradycardia and hypotension. Ventricular dysrhythmias do not appear to be an important factor.

Pulmonary edema is found at necropsy.[45] In cyanide poisoning, acute lung injury (ALI) may be neurogenic in origin or result from membrane leak from direct pneumocyte toxicity. Inhalation of HCN may be associated with mild corrosive injury to the respiratory tract mucosa.

GI toxicity may occur after ingestion of inorganic cyanide and cyanogens and includes abdominal pain, nausea, and vomiting. These symptoms are caused by hemorrhagic gastritis, which is frequently identified on necropsy, and are thought to be secondary to the corrosive nature of cyanide salts. However, if death occurs rapidly, this gastritis may not be present at autopsy because development of inflammation occurs over time.[45]

Cutaneous manifestations may vary. Traditionally, a cherry-red skin color is described as a result of increased venous hemoglobin oxygen saturation, which results from decreased utilization of oxygen at the tissue level.[108] This phenomenon may be more evident on funduscopic examination, where veins and arteries may appear similar in color. Despite the inference in the name, cyanide does not directly cause cyanosis. The occurrence of cyanosis in some cases likely is secondary to shock.[123]

Delayed Clinical Manifestations of Acute Exposure Survivors of serious, acute poisoning may develop delayed neurologic sequelae.[75,104] Parkinsonian symptoms, including dystonia, dysarthria, rigidity, and bradykinesia, are most common. Symptoms typically develop over weeks to months, but subtle findings may be present within a few days. Head computed tomography (CT) and magnetic resonance imaging (MRI) consistently reveal basal ganglia damage to the globus pallidus, putamen, and hippocampus, with radiologic changes appearing several weeks after onset of symptoms. Whether delayed manifestations result from direct cellular injury or secondary hypoxia is unclear. Extrapyramidal manifestations may progress or resolve. Response to pharmacotherapy with antiparkinsonian medications is generally disappointing.

Chronic Exposure to Cyanide Chronic exposure to cyanide may result in insidious syndromes, including tobacco amblyopia, tropical ataxic neuropathy, and Leber hereditary optic neuropathy. Tobacco amblyopia is a progressive loss of visual function that occurs almost exclusively in men who smoke cigarettes. Affected smokers have lower serum cyanocobalamin and thiocyanate concentrations than unaffected smoking counterparts, suggesting a reduced ability to detoxify cyanide. Cessation of smoking and administration of hydroxocobalamin often reverse symptoms.

Tropical ataxic neuropathy is a demyelinating disease associated with improperly processed cassava consumption.[86,113] Neurologic manifestations include Parkinson's disease, spastic paraparesis, sensory ataxia, optic atrophy, and sensorineural hearing loss.[124] Concomitant dermatitis and glossitis suggest an association of high dietary cassava with low vitamin B_{12} intake. Elevated thiocyanate concentrations in affected individuals further implicate cyanide as the cause. Removal of dietary cassava and institution of vitamin B_{12} therapy alleviates symptoms. Leber hereditary optic atrophy, a condition of subacute visual failure affecting men, is thought to be caused by rhodanese deficiency.[41]

Chronic exposure to cyanide is associated with thyroid disorders.[1] Thiocyanate is a competitive inhibitor of iodide entry into the thyroid, thereby causing the formation of goiters and the development of hypothyroidism.[65] Chronic exposure to cyanide in animals is associated with hydropic degeneration in hepatocytes and epithelial cells of the renal proximal tubules; however, these morphologic lesions are not linked to functional alternations.[112]

■ DIAGNOSTIC TESTING

Because of nonspecific symptoms and delay in laboratory cyanide confirmation, clinicians must rely on historical circumstances and some initial findings to raise suspicion of cyanide poisoning and institute therapy (Table 126–1).

TABLE 126–1. Cyanide Poisoning: Emergency Management Guidelines

When to suspect cyanide poisoning

Sudden collapse of a laboratory or industrial worker

Fire victim with coma or metabolic acidosis

Suicide attempt with unexplained coma or metabolic acidosis

Ingestion of artificial nail remover

Ingestion of seeds or pits from *Prunus* spp.

Patient with altered mental status, metabolic acidosis, and tachyphylaxis to nitroprusside

Supportive care

Control airway, ventilate, and give 100% oxygen

Crystalloids and vasopressors for hypotension

Administer $NaHCO_3$; titrate according to blood gas analysis and serum HCO_3^-

Antidotes

1. *Hydroxycobalamin*

   Initial adult dose: 5 g IV over 15 minutes

2. *Cyanide antidote kit*

   Amyl nitrite pearls are included in the kit for prehospital use; for hospital management, sodium nitrite is the preferred methemoglobin inducer and is given in lieu of the pearls

   Give sodium nitrite ($NaNO_2$) as a 3% solution over 2–4 minutes IV:

   Adult dose: 10 mL (300 mg)

   Pediatric dose: See Table 126-2; if hemoglobin is unknown, presume 12-g dosing

Caution: Monitor blood pressure frequently and treat hypotension by slowing the infusion rate and giving crystalloids and vasopressors. Obtain methemoglobin level 30 minutes after dose and consider possible excessive methemoglobin formation if the patient deteriorates during therapy.

Give sodium thiosulfate (NaS_2O_3) as a 25% solution IV: Adult dose: 50 mL (12.5 g) Pediatric dose: 1.65 mL/kg

Decontamination

Protect healthcare providers from contamination

Cutaneous: Carefully remove all clothing and flush the skin

Ingestion: Lavage with an orogastric tube and instill 1 g/kg of activated charcoal

Laboratory

Arterial blood gas

Electrolytes and glucose concentrations

Blood lactate concentrations

Whole-blood cyanide concentration (for later confirmation only)

Consider a central venous blood gas for AV O_2 difference

ABG, arterial blood gas; AV, arteriovenous; IV, intravenous.

Laboratory findings suggestive of cyanide poisoning reflect the known metabolic abnormalities, which include metabolic acidosis, elevated lactate concentration, and increased anion gap. Elevated venous oxygen saturation results from reduced tissue extraction.[60] A venous oxygen saturation above 90% from superior vena cava or pulmonary artery blood indicates decreased oxygen utilization. This finding is not specific for cyanide and may represent cellular poisoning from other xenobiotics such as carbon monoxide, clenbuterol, hydrogen sulfide, and sodium azide or medical conditions such as sepsis, high-output cardiac syndromes, and left-to-right intracardiac shunts.

Lactic acidosis is found in numerous critical illnesses and typically is a nonspecific finding. However, a significant association exists between blood cyanide and serum lactate concentrations.[11] In a small group of patients in whom the diagnosis of cyanide poisoning was strongly suspected clinically, a serum lactate concentration above 72 mg/dL (8 mmol/L) was associated with sensitivity of 94%, specificity of 70%, positive predictive value of 64%, and negative predictive value of 98% for a blood cyanide concentration above 1.0 µg/mL. Arterial blood gas (ABG) analysis of whole blood may provide additional information. Arterial pH correlates inversely with cyanide concentration.[7] The finding of a narrow arterial–venous oxygen difference also may suggest cyanide toxicity.

Cyanide results in nonspecific electrocardiographic findings. Bradycardia, tachycardia, myocardial injury pattern, or atrioventricular conduction block may occur.

Blood cyanide determination can confirm toxicity, but this determination is not available in a sufficiently rapid manner to affect initial treatment. Whole blood or serum usually is analyzed. In mammals, including primates, whole-blood concentrations are twice serum concentrations[9] as a result of cyanide sequestration in red blood cells. Background whole-blood concentrations in nonsmokers range between 0.02 and 0.5 µg/mL.[49,54] Higher blood concentrations suggest toxicity. Coma and respiratory depression are associated with concentrations above 2.5 µg/mL, and death is associated with concentrations above 3 µg/mL. Detecting urinary cyanide is difficult, and urinary thiocyanate is a more readily detectable and useful marker of cyanide exposure. Serum thiocyanate concentrations are of little value in assessing patients with acute poisoning because of little correlation with symptoms but are useful in confirming exposure.

A semiquantitative assay that uses calorimetric paper test strips may immediately detect cyanide. Cyantesmo test strips currently are used by water treatment facilities to detect cyanide. An investigation of the utility of these strips in clinical practice found that the test strips incrementally increased to a deep blue color over a progressively longer portion of the test strip with increasing concentrations of cyanide.[100] These strips accurately and rapidly detected CN concentrations above 1 µg/mL in a semiquantifiable manner.

■ MANAGEMENT

Because cyanide poisoning is rare, it is easy to overlook the diagnosis unless there is an obvious history of exposure. Thus, the most critical step in treatment is considering the diagnosis in high-risk situations (see Table 126-1) and initiating empiric therapy with 100% oxygen and either hydroxocobalamin or the cyanide antidote kit. The initial care (see Table 126-1) of a cyanide-poisoned patient begins by directing attention to airway patency, ventilatory support, and oxygenation. Acidemia should be treated with adequate ventilation and sodium bicarbonate administration.[26]

IV access should be rapidly obtained and blood samples sent for renal function, glucose, and electrolyte determinations. A whole-blood cyanide concentration can be obtained for later confirmation of exposure. ABG analysis and serum lactate concentration will help assess the patient's acid–base status. Initiation of crystalloid and infusion of vasopressor for hypotension are warranted.

First responders should exercise extreme caution when entering potentially hazardous areas such as chemical plants and laboratories where a previously healthy person is "found down." Exposure to cyanide may occur by multiple routes, including ingestion, inhalation, dermal, and parenteral. For patients with inhalation exposure, removal from the area of exposure is critical. Further decontamination is generally unnecessary. Decontamination of the cyanide-poisoned

patient occurs concurrently with initial resuscitation. The healthcare provider should always be protected from potential dermal contamination by using personal protective devices such as water-impervious gowns, gloves, and eyewear. For patients with cutaneous exposure, the healthcare provider should remove the patient's clothing, brush off any powder from the skin, and flush the skin with water. Particular attention should be given to open wounds because CN^- or HCN is readily absorbed through abraded skin.

Instillation of activated charcoal often is considered ineffective because of low binding of cyanide (1 g of activated charcoal only adsorbs 35 mg of cyanide). However, a potentially lethal oral dose of cyanide (ie, a few hundred milligrams) is within the adsorptive capacity of a 1-g/kg dose of activated charcoal. Prophylactic activated charcoal administration improved survival in animals given an LD_{100} dose of KCN.[70] Based on the potential benefits and minimal risks, activated charcoal may be considered in the patient with an intact protected airway.

Either hydroxocobalamin or the cyanide antidote kit should be administered as soon as cyanide poisoning is suspected. Hydroxocobalamin, a vitamin B_{12} precursor, is now available in multiple countries for cyanide poisoning.[16] In 2006, it was approved by the U.S. Food and Drug Administration (FDA). Hydroxocobalamin is a metalloprotein with a central cobalt atom that complexes cyanide, forming cyanocobalamin (vitamin B_{12}). Cyanocobalamin is eliminated in the urine or releases the cyanide moiety at a rate sufficient to allow detoxification by rhodanese. One molecule of hydroxocobalamin binds one molecule of cyanide, yielding a molecular weight binding ratio of 50:1. The adult starting dose is 5 g administered by IV infusion over 15 minutes. Depending on the severity of the poisoning and the clinical response, a second dose of 5 g may be administered by IV infusion for a total dose of 10 g. Hydroxocobalamin has few adverse effects, which include allergic reaction and a transient reddish discoloration of the skin, mucous membranes, and urine.[19,24,50] No hemodynamic adverse effects other than a potential transient increase in blood pressure are observed[10,103] (see Antidotes in Depth A40: Hydroxocobalamin).

The cyanide antidote kit contains amyl nitrite, sodium nitrite, and sodium thiosulfate. Both thiosulfate and nitrite individually have antidotal efficacy when given alone in animal models of cyanide poisoning, but they have even greater benefit when they are given in combination.[31a] Thiosulfate donates the sulfur atoms necessary for rhodanese-mediated cyanide biotransformation to thiocyanate. The mechanism of nitrite is less clear. The traditional rationale relies on the ability of nitrite to generate methemoglobin. Because cyanide has a higher affinity for methemoglobin than for cytochrome a_3, cytochrome oxidase function is restored. However, improved hepatic blood flow and nitric oxide formation are alternate explanations (Antidotes in Depth A38: Sodium and Amyl Nitrites, A39: Sodium Thiosulfate, and A40: Hydroxocobalamin). Amyl nitrite is contained within glass pearls that are crushed and intermittently inhaled or intermittently introduced into the ventilator system to initiate methemoglobin formation. The amyl nitrite pearls are reserved for cases in which IV access is delayed or not possible. IV sodium nitrite is preferred and is supplied as a 10-mL volume of 3% solution (300 mg). The outdated goal of IV nitrite therapy is to achieve a methemoglobin concentration of 20% to 30%. This concentration is not based on cyanide treatment data but represents the maximum tolerated concentration without adverse symptoms from methemoglobinemia in a healthy individual. Clinical response is reported at lower methemoglobin concentrations of 3.6% to 9.2%. These reports are not conclusive because levels typically are not drawn serially, and peak concentrations may be misrepresented. Also, methemoglobin concentrations do not include cyanmethemoglobin. Therefore, lower-than-expected methemoglobin concentrations may represent indirect evidence of cyanide poisoning. Adverse effects of nitrites include excessive methemoglobin formation and, because of potent vasodilation, hypotension

TABLE 126–2. Cyanide Management: Pediatric Sodium Nitrite Guidelines[a]

Hemoglobin (g)	NaNO$_2$ (mg/kg)	3% NaNO$_2$ solution (mL/kg)
7.0	5.8	0.19
8.0	6.6	0.22
9.0	7.5	0.25
10.0	8.3	0.27
11.0	9.1	0.30
12.0	10.0	0.33
13.0	10.8	0.36
14.0	11.6	0.39

[a] Pediatric thiosulfate dose: 1.65 mL/kg of 25% solution.

and tachycardia. Avoiding rapid infusion, monitoring blood pressure, and adhering to dosing guidelines limit adverse effects. Because of the potential for excessive methemoglobinemia during nitrite treatment, pediatric dosing guidelines are available.[11] Based on the premise that nitrite oxidizes hemoglobin on a mole-for-mole basis, doses were calculated for various hemoglobin concentrations (Table 126–2). These values are useful if the patient is known to be anemic. However, when giving nitrite empirically, treatment is based on a presumed 12-g hemoglobin concentration. The practitioner should not delay treatment while awaiting a hemoglobin measurement. Sodium thiosulfate is the second component of the cyanide antidote kit. It is supplied as 50 mL of 25% solution (12.5 g). It is a substrate for the reaction catalyzed by rhodanese that is essentially irreversible, converting a highly toxic entity to a relatively harmless compound. However, thiocyanate does have its own toxicity in the presence of renal failure, including abdominal pain, vomiting, rash, and CNS dysfunction.[34] Thiosulfate itself is not associated with significant adverse reactions. The pediatric dose of thiosulfate is adjusted for weight.

In Europe, 4-dimethylaminophenol (4-DMAP), rather than sodium nitrite, is the methemoglobin-inducer of choice. It generates methemoglobin more rapidly than sodium nitrite, with peak methemoglobin concentrations at 5 minutes after 4-DMAP rather than 30 minutes after sodium nitrite. The dose of 4-DMAP is 3 mg/kg and is coadministered with thiosulfate. As with sodium nitrite, its major adverse effect is excessive methemoglobin formation and the potential for hypotension. Cobalt in the form of dicobalt edetate has been used as a cyanide chelator, but its usefulness is limited by serious adverse effects such as hypotension, cardiac dysrhythmias, decreased cerebral blood flow, and angioedema.[21,79] Stroma-free methemoglobin, oxidized hemoglobin from which the cell membrane has been removed, is an investigational therapy. It attenuates lethality and prevents hemodynamic changes in animal models.[20,115] The advantage of this treatment lies in providing exogenous methemoglobin to bind cyanide without compromising the oxygen-carrying capacity of native hemoglobin, and removal of the cell membrane eliminates antigenicity. Dihydroxyacetone (DHA) is an investigational antidote that restores mitochondrial respiration inhibited by cyanide in isolated rat hepatocytes.[81] It also diminishes cyanide lethality in animal models and has synergistic effects with thiosulfate.[80,82] DHA binds readily to cyanide to form a cyanohydrin, but this binding is reversible, and cyanide's clinical effects reappear between 1 and 24 hours without readministration.[80] α-Ketoglutarate is another investigational antidote.[14,52] It rapidly complexes cyanide to form a cyanohydrin.[103] Pretreatment with α-ketoglutarate reduced lethality and increased sodium thiosulfate efficacy in animal studies.[15,37,58,83]

The advantage of α-ketoglutarate is direct binding of cyanide without generation of methemoglobin. Preliminary evidence demonstrates that α-ketoglutarate at a dose offering maximum antidotal efficacy is nontoxic and potentially safe for treatment of patients with cyanide poisoning.[13] Cobalamin has been used both prophylactically and therapeutically to treat experimental cyanide toxicity, and when given at high enough doses, it has rescued animals from cyanide-induced apnea and coma.[22] Cobalamin has been used in France to treat human cyanide exposure, either alone or combined with sodium thiosulfate. Cobinamide has a much greater affinity for cyanide ion than cobalamin.[80]

In animal models, the antioxidant vitamins A, C, and E diminish the extent of tissue damage caused by subacute cyanide intoxication.[85] This is especially important in the tropics, where the majority of dietary staples are cyanophoric crops such as cassava.

Patients who do not survive cyanide poisoning are suitable organ donors. The heart, liver, kidneys, pancreas, cornea, skin, and bone have been successfully transplanted after cyanide poisoning.[40]

HYDROGEN SULFIDE POISONING

■ HISTORY AND EPIDEMIOLOGY

Hydrogen sulfide (H_2S) exposures are often dramatic and can be fatal. The AAPCC's National Poison Data System reported only 1229 exposures in 2007 (see Chap. 135). Only 317 of these exposures required evaluation at a healthcare facility, 77 reported moderate or major effects, and 13 deaths occurred.[23] Over a 10-year period from 1983 to 1992, 5563 exposures and 29 deaths attributed to hydrogen sulfide were reported in the national poison center database.[111] Most often, serious consequences of hydrogen sulfide exposures occur through workplace exposures but are also implicated in environmental disasters and most recently in suicides.

Hydrogen sulfide is produced naturally by bacterial decomposition of proteins and is used or produced in many industrial activities. Industrial sources of hydrogen sulfide include pulp paper mills, heavy-water production, the leather industry, roofing asphalt tanks, vulcanizing of rubber, viscose rayon production, and coke manufacturing from coal.[32] Hydrogen sulfide is a major industrial hazard in oil and gas production, particularly in sour gas fields (natural gas containing sulfur). Decay of sulfur-containing products such as fish, sewage, and manure also produces hydrogen sulfide. Several farm workers and rescuers have died from exposure to hydrogen sulfide generated in liquid manure pits. OSHA records show 80 occupationally related fatalities between 1984 and 1994.[42] Between 1990 and 1999, hydrogen sulfide poisoning was associated with the deaths of 18% of U.S. construction workers killed by toxic inhalation.[36] Many died while working in confined spaces. Poisoned workers are "knocked down," which prompts coworkers to attempt a rescue. Numerous case reports describe multiple victims because the would-be rescuers often themselves become victims when they attempt a rescue in an environment having high concentrations of hydrogen sulfide.[36,84,111] Studies report that up to 25% of fatalities involve rescuers.[36,42,53] OSHA and a variety of occupational organizations, such as the American Industrial Hygiene Association, National Institute of Occupational Safety and Health, American Shipbuilding Association, and U.S. Chemical Safety Board, recognize the serious dangers of hydrogen sulfide exposures in the workplace and continue to promote safety alerts and educational programs.[89]

Natural sources of hydrogen sulfide are volcanoes, caves, sulfur springs, and underground deposits of natural gas,[32,99] and it has been implicated in several environmental disasters. In 1950, 22 people died and 320 were hospitalized in Poza Rica, Mexico, when a local natural gas facility inadvertently released hydrogen sulfide into the air.[74]

Hydrogen sulfide claimed nine lives when a sour gas well failed, releasing a cloud of the poisonous gas into the Denver City, Texas, community in 1975.[78] In 2003, a gas drilling incident in southwest China released natural gas and a cloud of hydrogen sulfide into a populated area. More than 200 people died, 9000 were treated for injuries, and more than 40,000 were evacuated.[131]

Recently, a large number of suicides have been attributed to mixing common household chemicals such as fungicides and toilet bowl cleaners to create hydrogen sulfide gas.[117,120] In Japan, it is reported that more than 500 people killed themselves in the first half of 2008 by this means.[133] Information resources on the Internet are implicated for the widespread practice and prompted police to request purging the suicide recipes from Internet sites.[51] One suicidal incident in Japan caused 90 people to become ill from the toxic gas as it permeated an apartment building.[120] Also in 2008, the Pasadena hazmat team evacuated an area surrounding the scene of a man found dead in his car and a note on the vehicle warning first responders of the hazardous chemicals he used.[117]

■ PHARMACOLOGY AND TOXICOKINETICS

Hydrogen sulfide is a colorless gas, more dense than air, with an irritating odor of "rotten eggs." It is highly lipid soluble, a property that allows easy penetration of biologic membranes. Systemic absorption usually occurs through inhalation, and it is rapidly distributed to tissues.[99]

The tissues most sensitive to hydrogen sulfide are those with high oxygen demand. The systemic toxicity of hydrogen sulfide results from its potent inhibition of cytochrome oxidase, thereby interrupting oxidative phosphorylation.[32,67] Hydrogen sulfide binds to the ferric (Fe^{3+}) moiety of cytochrome a_3 oxidase complex with a higher affinity than does cyanide (see Fig. 126-2). The resulting inhibition of oxidative phosphorylation produces cellular hypoxia and anaerobic metabolism.[32,134]

Cytochrome oxidase inhibition is not the sole mechanism of toxicity. Other enzymes, such as carbonic anhydrase and monoamine oxidase, are inhibited by hydrogen sulfide and may contribute to its toxic effects.[99] Besides producing cellular hypoxia, hydrogen sulfide alters brain neurotransmitter release and transmission through potassium channel–mediated hyperpolarization of neurons and other neuronal inhibitory mechanisms.[99] A proposed mechanism of death is poisoning of the brainstem respiratory center through selective uptake by lipophilic white matter in this region.[129] The olfactory nerve is a specific target of great interest. Not only does the toxic gas cause olfactory nerve paralysis but it is also thought to be a portal of entry into the CNS because of its direct contact with the brain.[134] It is also cytotoxic through formation of reactive sulfur and oxygen species. It may also react with iron to fuel the Fenton reaction, causing free radical injury[118] (see Chaps. 11 and 12).

In addition to systemic effects, hydrogen sulfide reacts with the moisture on the surface of mucous membranes to produce intense irritation and corrosive injury. The eyes and nasal and respiratory mucous membranes are the tissues most susceptible to direct injury.[70,134] Despite skin irritation, it has little dermal absorption.

Inhaled hydrogen sulfide enters the systemic circulation, where it dissociates into hydrosulfide ions (HS^-), sulfide (S^{-2}), and sulfate (SO_2^{-4}). After it has been absorbed, hydrogen sulfide and dissociation products are metabolized by oxidation, methylation, and binding to metalloproteins. The major pathway of detoxification is enzymatic and nonenzymatic oxidation of sulfides and sulfur to thiosulfate and polysulfides.[134] Other pathways, such as methylation to dimethyl sulfide and conversion to sulfite or sulfate by oxidized glutathione, may also play a role in detoxification and elimination.[32,134] Hydrosulfide ions interact with metalloproteins, disulfide-containing enzymes, and thio dimethyl S transferase.[33] Sulfhemoglobin is not found in significant concentrations in the blood of animals or fatally poisoned humans.[94]

■ CLINICAL MANIFESTATIONS

Acute Manifestations Hydrogen sulfide poisoning should be suspected whenever a person is found unconscious in an enclosed space, especially if the odor of rotten eggs is noted. The primary target organs of hydrogen sulfide poisoning are those of the CNS and respiratory system. The clinical findings reported in two large series are listed in Table 126–3.[4,25]

The intensity of exposure likely accounts for the diverse clinical findings in the reports. A distinct dose response to hydrogen sulfide is identified. The odor threshold is between 0.02 and 0.13 ppm, and a strong, intense odor is noted at 20 to 30 ppm. Mild mucous membrane irritation occurs at 50 to 100 ppm, and olfactory fatigue occurs at 100 to 150 ppm. The ability to perceive the odor is rapidly extinguished at higher concentrations because of olfactory nerve paralysis. Prolonged exposure may occur when the extinction of odor recognition is misinterpreted as dissipation of the gas. Strong irritation of the upper respiratory tract and eyes and ALI occur at 200 to 300 ppm. At above 500 ppm, H_2S produces systemic effects. Rapid unconsciousness and cardiopulmonary arrest occur at concentrations above 700 ppm.[8,99]

Hydrogen sulfide reacts with the moisture on the surface of mucous membranes to produce intense irritation and corrosive injury. Mucous membrane irritation of the eye produces keratoconjunctivitis. If exposure persists, damage to the epithelial cells produces reversible corneal ulcerations ("gas eye") and, rarely, irreversible corneal scarring.[70,125] The irritant effects on the respiratory tract include rhinitis, bronchitis, and ALI.[4,25,134]

Neurologic manifestations are common and may be severe. Hydrogen sulfide's rapid and deadly onset of clinical effects have been termed the *slaughterhouse sledgehammer effect*. In a series, 75% of 221 patients with acute hydrogen sulfide exposure lost consciousness at the time of exposure.[25] In acute, massive exposures, rapid loss of consciousness ("knockdown") results from loss of central respiratory drive.[76] If the patient is rapidly removed from the exposure, recovery may be prompt and complete. Hypoxia from respiratory compromise may cause secondary neurologic effects.[8,32,134] Neurologic outcomes are quite variable, ranging from no neurologic impairment to permanent sequelae. Delayed neuropsychiatric sequelae may occur after acute exposures.[27] Most evidence suggests that whereas the early rapid CNS effects are direct neurotoxic effects of hydrogen sulfide, the permanent neurologic sequelae result from hypoxia secondary to respiratory insufficiency.[8,134] Reported neuropsychiatric changes include memory failure (amnestic

TABLE 126–3. Hydrogen Sulfide Poisoning

When to suspect hydrogen sulfide poisoning

Person rapidly loses consciousness ("knocked down")

Rotten eggs odor

Rescue from enclosed space, such as sewer or manure pit

Multiple victims with sudden death syndrome

Collapse of a previously healthy worker at work site

Clinical Manifestations

System	Signs and Symptoms
Cardiovascular	Chest pain, bradycardia
Central nervous	Headache, weakness, dysequilibrium, convulsions, coma
Gastrointestinal	Pharyngitis, nausea, vomiting
Ophthalmic	Conjunctivitis
Pulmonary	Dyspnea, cyanosis, hemoptysis, crackles

---

syndrome), lack of insight, disorientation, delirium, and dementia.[32,134] Neurosensory abnormalities include transient hearing impairment, vision loss, and anosmia. Motor symptoms are likely caused by injury to the basal ganglia and result in ataxia, position or intention tremor, and muscle rigidity.[121] Common neuropathologic findings observed on neuroimaging and at autopsy are subcortical white matter demyelination and globus pallidus degeneration.[27,122]

Acute exposures affect other organ systems. Myocardial hypoxia or direct toxic effects of hydrogen sulfide on cardiac tissue may cause cardiac dysrhythmias, myocardial ischemia, or myocardial infarction.[46] Because unresponsiveness is rapid, trauma from falls should not be overlooked.[4,43] In a report, 7% of patients experiencing a "knockdown" had associated traumatic injuries.[4]

Chronic Manifestations Most data about chronic, low-level exposures to hydrogen sulfide come from oil and gas industry workers. Mucous membrane irritation seems to be the most prominent problem in patients with low-concentration exposures. Workers report nasal, pharyngeal, and eye irritation; fatigue; headache; dizziness; and poor memory with low-concentration, chronic exposures. The chronic irritating effects of hydrogen sulfide were thought to be the cause of reduced lung volumes observed in sewer workers.[101] Volunteer studies have not demonstrated significant cardiovascular effects after long-term exposure to concentrations less than 10 ppm.[12] The liver, kidneys, and endocrine system are unaffected. No studies demonstrate increased incidences of cancer with low-level exposures.[32]

Rapid loss of consciousness from hydrogen sulfide exposure was a well-known and, amazingly, accepted part of the workplace in the gas and oil industry for many years.[55] Some workers experienced repeated "knockdowns," and these workers reported an increased incidence of respiratory diseases and cognitive deficits. Single or repeated high-concentration exposures resulting in unconsciousness may cause serious cognitive dysfunction. The acute effects of rapid loss of consciousness are most likely caused by hydrogen sulfide neurotoxicity. Although a clear association exists between knockdown and chronic neurologic sequelae, many of the case reports are complicated by associated apnea or hypoxemia from respiratory failure, asphyxia or exposure to other xenobiotics in a confined space, head injury from a fall, or near drowning in liquid manure or sludge.[134] The association of neurotoxic sequelae is less clear with protracted low-concentration exposures. Case series suggest that low-concentration exposures may cause subtle changes that can be measured by only the most sensitive neuropsychiatric tests.[68]

Epidemiologic data regarding the effects of low-concentration environmental exposures to hydrogen sulfide are clouded in populations exposed to complex mixtures of pollutants. Other malodorous sulfur compounds (eg, methyl mercaptan and methyl sulfide) are generated as byproducts of pulp mills. Study populations exposed to this complex mixture of pollutants demonstrate a dose-related increase in nasal symptoms, cough, nausea, and vomiting.[32]

These changes are nonspecific, and many of the patients have a poorly documented exposure assessment. Currently, the association of protracted and low-concentration hydrogen sulfide exposure with chronic neurologic sequelae remains controversial and needs further study.[134]

The strong odor of low concentrations of hydrogen sulfide can magnify irritant effects by triggering a strong psychological response.[134] Hydrogen sulfide has been the alleged source of mass psychogenic illness cases.[44] Clinical, epidemiologic, and toxicologic analyses suggested that 943 cases of illness in Jerusalem were caused by the odor of low concentrations of hydrogen sulfide gas. The most frequent associated symptoms are headaches; faintness; dizziness; nausea; chest tightness; dyspnea and tachypnea; eye, nose, and throat irritation; weakness; and extremity numbness.[29] Low-concentration exposure to hydrogen sulfide may produce nonspecific signs and symptoms that could closely

mimic psychogenic illness. Attempting to identify true toxicity from a powerful emotional reaction can be extremely difficult.[44] Therefore, symptomatic patients must be assessed for toxicity even when mass psychogenic illness is suspected.

■ DIAGNOSTIC TESTING

In hydrogen sulfide poisoning, diagnostic testing is of limited value for clinical decision making after acute exposures, confirmation of acute exposures, occupational monitoring, and forensic analysis after fatal accidents.

Because no available rapid method of detection is of clinical diagnostic use, management decisions must be made based on the patient's history, clinical presentation, and diagnostic tests that infer the presence of hydrogen sulfide. Circumstances surrounding the patient's illness often provide the best evidence for hydrogen sulfide poisoning (see Table 126-3). At the bedside, the smell of rotten eggs on clothing or emanating from the blood, exhaled air, or gastric secretions suggests hydrogen sulfide exposure. In addition, darkening of silver jewelry is a clue to exposure. Paper impregnated with lead acetate changes color when exposed to hydrogen sulfide and is used to detect its presence in the patient's exhaled air but is not rapidly available.[32]

Specific tests for confirming hydrogen sulfide exposure are not readily available in clinical laboratories. Therefore, the presence of hydrogen sulfide is best confirmed by directly measuring the gas in the environment. It can be detected in atmospheric air samples by monitoring devices such as colorimetric tubes or xenobiotic-specific air sampling devices. Many emergency response teams investigate the toxic environment of a hazardous materials incident with detection devices that measure hydrogen sulfide with electrochemical sensors.

In acute poisoning, readily available diagnostic tests that are biomarkers of hydrogen sulfide poisoning may be useful but are nonspecific. ABG analysis demonstrating metabolic acidosis with an associated elevated serum lactate concentration is expected, and oxygen saturation should be normal unless ALI is present. Hydrogen sulfide, similar to cyanide, decreases oxygen consumption and is reflected as an elevated mixed venous oxygen measurement. Because sulfhemoglobin typically is not generated in patients with hydrogen sulfide poisoning, an oxygen saturation gap is not expected.[94]

After serious injury from hydrogen sulfide, diagnostic testing for neurologic structure and function may show abnormalities for weeks or months. Brain MRI and head CT studies demonstrate structural changes such as globus pallidus degeneration and subcortical white matter demyelination. Neuropsychologic testing after serious hydrogen sulfide poisoning demonstrates specific abnormalities in cortical functions, such as concentration, attention, verbal abstraction, and short-term retention. Single-photon emission CT (SPECT) or positron emission tomography brain scans define neurotoxin-induced lesions that correlate well with clinical neuropsychologic testing.[28]

Whole-blood sulfide concentrations above 0.05 mg/L are considered abnormal. Reliable measurements are ensured only if the concentration is obtained within 2 hours after the exposure and analyzed immediately.[99]

In acute exposures, blood and urine thiosulfate concentrations may be reflective of exposure.[64] Urinary thiosulfate excretion is used to monitor chronic low-concentration exposure in the workplace.

One study attempted to establish background concentrations of urinary thiosulfate in an occupational environment with low-level and short-term hydrogen sulfide exposure with a reported mean increase from preexposure concentrations of 4.6 μm/L to postexposure concentrations of 11.5 μm/L.[39] These concentrations provide a comparison for concentrations obtained from fatal and nonfatal victims after exposure. However, the study could not demonstrate a correlation between the degree of exposure and change in urine thiosulfate. Another study

analyzed the value of blood and urine thiosulfate from data collected in case series of fatal and nonfatal hydrogen sulfide victims.[61,63] Because thiosulfate was detected in the urine but sulfide and thiosulfate were not detected in the blood of nonfatal exposures, this report concluded that thiosulfate in the urine is the only indicator to prove hydrogen sulfide poisoning in nonfatal cases. In addition, measuring sulfide and thiosulfate in the blood are helpful in forensic investigations.

Sulfide concentrations obtained in postmortem investigations may be useful, but their use requires rapid sample collection because sulfide concentrations increase with tissue decomposition.[99] In addition to blood sulfide concentrations, sulfide and thiosulfate concentrations are at their highest in the lung and brain.[62] If death is rapid, urinary thiosulfate concentrations may be nondetectable despite blood sulfide and thiosulfate concentrations 10-fold or greater than normal concentrations.[61] During the autopsy, a greenish discoloration of the gray matter, viscera, and bronchial secretions may be noted.[62,84]

MANAGEMENT

The initial treatment (Table 126–4) is immediate removal of the victim from the contaminated area into a fresh air environment. High-flow oxygen should be administered as soon as possible. Optimal supportive care has the greatest influence on the patient's outcome. Because death from inhalation of hydrogen sulfide is rapid, limited patients reaching the hospital for treatment are reported in the literature. Most patients experience significant delays before receiving treatment. Therefore, specific treatments and antidotal therapies do not show definitive improvement in patient outcome.

TABLE 126–4. Hydrogen Sulfide Poisoning: Emergency Management

Supportive care
  Prehospital
    Attempt rescue only if using SCBA
    Move victim to fresh air
    Administer 100% oxygen
    During extrication, consider traumatic injuries from falls
    Apply ACLS protocols as indicated
  Emergency department
    Maximize ventilation and oxygenation
    Consider PEEP for ALI
    Treat metabolic acidosis based on arterial pH and serum
      bicarbonate analysis
    Administer crystalloid and vasopressors for hypotension
Antidote
  Give sodium nitrite (3% NaNO$_2$) IV over 2–4 minutes
    Adult dose: 10 mL (300 mg)
    Pediatric dose: See Table 126-2; if hemoglobin is unknown,
      presume 12 g dosing
  Caution:
    Monitor blood pressure frequently
    Obtain methemoglobin level 30 minutes after dose
  Consider HBO if immediately available

ACLS, advanced cardiac life support; ALI, acute lung injury; HBO, hyperbaric oxygen; IV, intravenous; PEEP, positive end-expiratory pressure; SCBA, self-contained breathing apparatus.

The proposed toxic mechanisms, animal studies, and human case reports suggest that oxygen therapy is beneficial for hydrogen sulfide poisoning.[32,98,134] Proposed mechanisms for the beneficial effects of oxygen are competitive reactivation of oxidative phosphorylation by inhibiting hydrogen sulfide–cytochrome binding, enhanced detoxification by catalyzing oxidation of sulfides and sulfur, and improved oxygenation in the presence of ALI. All patients suspected of hydrogen sulfide poisoning should receive supplemental oxygen. In case reports, poisoned patients receiving hyperbaric oxygen (HBO) had favorable clinical outcomes.[57,109] However, no clinical data are available to suggest HBO is superior to normobaric oxygen for acute poisoning or preventing delayed neurologic sequelae.

The similarities in the toxic mechanism between hydrogen sulfide and cyanide created an interest in the use of nitrite-induced methemoglobin as an antidote. Methemoglobin protects animals from toxicity of hydrogen sulfide poisoning in both pretreatment and postexposure models.[110] Nitrite-generated methemoglobin acts as a scavenger of sulfide. The affinity of hydrogen sulfide for methemoglobin is greater than that for cytochrome oxidase. When hydrogen sulfide binds to methemoglobin, it forms sulfmethemoglobin.[9] Because hydrogen sulfide poisoning is rare, no studies have evaluated the clinical outcomes of patients treated with sodium nitrite. Animal studies suggest that nitrite must be given within minutes of exposure to ensure effectiveness.[9] However, several human case reports showed a rapid return of normal sensorium when nitrites were administered soon after exposure.[57,92,114] Patients with suspected hydrogen sulfide poisoning who have altered mental status, coma, hypotension, or dysrhythmias should receive sodium nitrite by slow infusion at the same dose given for cyanide poisoning. Sodium thiosulfate is of no benefit in the treatment of patients with hydrogen sulfide poisoning. In addition, only a single in vivo mouse model is published to suggest a beneficial effect of hydroxocobalamin as an antidote for hydrogen sulfide poisoning.[119] Additional research is warranted to determine its usefulness for hydrogen sulfide poisoning.

Treatment of patients with hydrogen sulfide poisoning requires optimal supportive care. Treatments and antidotes beyond supportive care are not of proven clinical benefit. Because hydrogen sulfide toxicity is severe and research studies suggest potential benefits of nitrite therapy, it should be considered for seriously ill patients exposed to hydrogen sulfide. This therapy should be initiated after optimum supportive care has been ensured.

Only a few inhalation risks are similar to that of hydrogen sulfide in their ability to rapidly "knock down" victims. Some examples include low oxygen environments in an enclosed space, hydrogen cyanide, volatile nerve agents, and carbon monoxide. The cause may be unclear early in the patient's emergency care, requiring clinicians to make treatment decisions without confirmatory evidence of poisoning. Clinicians faced with victims of knockdown syndrome should search for clues such as a victim's activities such as working at a manure pit, reports of chemicals detected at the scene by first responders, or suggestive clinical signs. The critical decision is whether to empirically administer specific antidotes. Vapor exposure to volatile nerve agents would likely result in miosis and require antidotes such as atropine, pralidoxime, and benzodiazepines. Which, if any, cyanide antidotes to administer in a "knockdown" situation is most difficult. The basic aims are to gather as many facts and suggestive clues as possible, weigh the risk benefits for treatment or not, and treat early in the course. Again, meticulous attention to optimal supportive care is required.

SUMMARY

Both cyanide and hydrogen sulfide are highly toxic xenobiotics. Cyanide is of great concern with regard to homicide and suicide. There are particular metabolic risks and concerns with regard to exposure to

both xenobiotics because they bind specifically to the ferric moiety of the cytochrome a_3 oxidase complex. Odor recognition is unreliable and is not a definitive approach to diagnosis. The laboratory evaluation usually is not timely for diagnostic purposes. Decontamination, removal from the site of exposure, and oxygen are essential. The controversies over the ideal therapeutic modalities for these agents are substantial, and extensive research continues.

ANTIDOTES IN DEPTH (A38)

SODIUM AND AMYL NITRITE

Mary Ann Howland

Amyl and sodium nitrite are effective cyanide antidotes when they are administered in a timely fashion. Amyl nitrite is volatile and available in ampules that can be broken and administered by inhalation while sodium nitrite is being prepared to administer intravenously. Although the exact mechanism of action of the nitrites is unclear, the production of methemoglobin is both therapeutic in cyanide poisoning and potentially life threatening if nitrites are administered to a patient with impaired oxygen-carrying capacity, from smoke inhalation or elevated concentrations of carboxyhemoglobin or methemoglobin from any cause. In the latter cases, sodium thiosulfate and/or hydroxocobalamin can still be administered intravenously without causing harm.

HISTORY

Expanding on earlier work that demonstrated the limited role of methylene blue and the efficacy of sodium nitrite in cyanide-poisoned animals, inhaled amyl nitrite prevented and protected against cyanide-induced seizures and muscular rigidity in dogs.[3] Amyl nitrite administered by inhalation protected dogs from up to four minimum lethal doses of sodium cyanide (a total of 24 mg/kg subcutaneously). In the regimen used, therapy started within 5 to 7 minutes of exposure and continued for several hours. The frequency of inhalations was based on clinical response. These experimental results led to the use of inhaled amyl nitrite for patients poisoned by cyanide. The same authors discovered that intravenous (IV) use of sodium thiosulfate alone protected against three minimum lethal doses of cyanide in dogs and that the combination of sodium thiosulfate with either inhaled amyl nitrite or IV sodium nitrite protected against 10 and 13 to 18 minimum lethal doses, respectively.[2,4]

CHEMISTRY

The chemical formula for sodium nitrite is $NaNO_2$ and for amyl nitrite is $C_5H_{11}NO_2$. Sodium nitrite has a molecular weight of 69 daltons and amyl nitrite 117 Da. Amyl nitrite is volatile even at low temperatures, and is highly flammable.

Cyanide quickly and reversibly binds to the ferric iron in cytochrome oxidase, inhibiting effective energy production throughout the body. The ferric iron in methemoglobin preferentially combines with cyanide, producing cyanomethemoglobin. This drives the reaction toward cyanomethemoglobin and liberates cyanide from cytochrome oxidase. Stroma-free methemoglobin is effective against four minimum lethal doses of cyanide in rats.[17] Nitrites oxidize the iron in hemoglobin to produce methemoglobin. Because nitrites are accepted antidotes for cyanide poisoning, for many years methemoglobin formation was assumed to be their sole antidotal mechanism of action.[13,21] Other, faster methemoglobin inducers, such as 4-dimethyaminophenol and hydroxylamine, also are effective as cyanide antidotes.[13,19] The production of methemoglobin by nitrite is slow, but when methylene blue is administered to prevent methemoglobin formation, nitrite still is an effective antidote.[13,21] Reasoning that nitrite-induced vasodilation might be part of the mechanism of action, investigators considered the antidotal actions of other vasodilators. Only the α-adrenergic antagonists and ganglionic blockers demonstrate antidotal activity, and only when they are administered with sodium thiosulfate.[21] It is possible that the benefits of nitrites given shortly after cyanide result from reversal of cyanide-induced circulatory effects rather than reversal of the effects of cyanide on cytochrome oxidase.[18] Experimental evidence in organ damage induced by hypoxia or hypotension suggest that the benefits of nitrite may be related to its ability to be converted to nitric oxide, a potent vasodilator. The conversion to nitric oxide appears to occur only in tissues or blood with the lowest oxygen concentrations.[5,14]

PHARMACOKINETICS AND PHARMACODYNAMICS

The pharmacokinetics of sodium nitrite are not established. Most studies have been directed at measuring methemoglobin levels rather than nitrite concentrations.[19]

Sodium nitrite administered intramuscularly to dogs is not effective as a cyanide antidote unless atropine is given as pretreatment.[20] Most likely the rapid reversal of cyanide-induced bradycardia by atropine allows sufficiently rapid absorption of sodium nitrite, which then can be effective.[20] In healthy adults, 300 mg IV sodium nitrite can produce peak methemoglobin concentrations of 10% to 18%.[2] Inhalation of crushed amyl nitrite ampules in human volunteers produces insignificant amounts of methemoglobin but does cause headache, fatigue, dizziness, and hypotension.[12]

CLINICAL USE

Maximal benefits of sodium nitrite are realized experimentally when sodium nitrite is given prophylactically, but benefits are still evident even when sodium nitrite is administered following cyanide poisoning. Regardless of the exact mechanism of action, amyl and sodium nitrite clearly are effective soon after administration, even when methemoglobin concentrations are low. Thus a target methemoglobin concentration should not be used to determine the correct dose of sodium nitrite, although care must be taken to avoid excessive methemoglobinemia.[11] Administration of sodium nitrite should always be followed by sodium thiosulfate. Sodium thiosulfate donates a sulfur, which, with the help of rhodanese (cyanide sulfur transferase) and mercaptopyruvate sulfurtransferase, carries sulfane sulfur to bind to cyanide, producing thiocyanate. Thiocyanate is a much less toxic substance than cyanide and is renally eliminated.[3]

As early as 1952, the literature reported 16 cyanide-poisoned patients who survived with administration of nitrites and sodium thiosulfate.[2]

Even patients who were unconscious or apneic have survived when given timely cardiopulmonary resuscitation and antidotal therapy.[2] Case reports attest to the ability of amyl nitrite, sodium nitrite, and sodium thiosulfate to reverse the effects of cyanide if they are administered in a timely fashion.[8,22] A 34-year-old man who ingested 1 g potassium cyanide became comatose within 45 minutes. One hour after ingestion, he arrived in the emergency department, became apneic, and was intubated. His blood pressure was 134/84 mm Hg and pulse 84 beats/min; his pupils were dilated. Seizure activity that began just prior to sodium nitrite infusion resolved rapidly, and by the time the sodium thiosulfate had finished infusing, his pupils were reactive and spontaneous respirations had returned.[8] At 1 hour 15 minutes, he was given 300 mg sodium nitrite intravenously over 20 minutes, followed by 12.5 g sodium thiosulfate.

In another case, a 4-year-old boy ingested twelve 50-mg tablets of laetrile (amygdalin), became unresponsive, and developed seizures within 90 minutes.[10] Upon arrival at a second hospital, the patient required intubation, had no blood pressure, and had dilated pupils that were minimally responsive. Arterial blood gas analysis revealed pH, 6.85; P_{CO_2}, 15 mm Hg; P_{O_2}, 169 mm Hg on 100% oxygen. The anion gap was 26 mEq/L. The patient's vital signs improved with intermittent inhalation of amyl nitrite pearls. Six hours after ingestion (and 1 hour 45 minutes after amyl nitrite administration), sodium nitrite and sodium thiosulfate obtained from another hospital were administered. Within 30 minutes of completion of 5 mL (0.33 mL/kg) 3% sodium nitrite solution by IV infusion, spontaneous respirations returned, and his blood pressure and pulse normalized. Over the next 3 hours, the patient's mental status and acid–base balance improved. By 15 hours after ingestion, he was alert, oriented, and extubated. Elevated whole blood cyanide concentrations verified the ingestion.

ADVERSE EFFECTS

Amyl nitrite and sodium nitrite work by inducing methemoglobinemia, but excessive methemoglobinemia is potentially lethal. Therefore, nitrite dosages must be carefully calculated and nitrites administered to avoid excessive methemoglobinemia, especially in cases where other coexisting conditions, such as carboxyhemoglobin, sulfhemoglobin, and anemia, might compromise hemoglobin oxygen saturation.[9,15] Children are particularly at risk for medication errors because of dosage miscalculations. A reported death from methemoglobinemia was caused by the administration of an adult dose of sodium nitrite to a 17-month-old child suspected of ingesting a toxic amount of cyanide.[1]

Nitrites are potent vasodilators, so transient hypotension may occur. Other adverse effects include headache, nausea and vomiting.[2]

ADMINISTRATION AND DOSING

■ CYANIDE

Adults   Amyl nitrite can be used prior to IV administration of sodium nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Break one amyl nitrite ampule and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off.[7,16] Inhalation of amyl nitrite should be discontinued prior to sodium nitrite administration. The healthcare provider should be extremely careful not to inhale the amyl nitrite to prevent light-headedness and syncope. Sodium nitrite 300 mg (10 mL of 3% solution) should be injected intravenously at a rate of 2.5 to 5 mL/min. The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[6,16]

Immediately following the completion of the sodium nitrite infusion, 12.5 g (50 mL of 25% solution) sodium thiosulfate should be infused intravenously. The same needle and vein can be used and the dose of the thiosulfate can be repeated at half the initial dose whenever manifestations of cyanide toxicity reappear or at 2-hour intervals as prophylaxis.[6,16]

In situations where additional methemoglobin formation would be harmful, as in patients with smoke inhalation from a fire, it may be safer to withhold the nitrite and only administer the sodium thiosulfate and/or IV hydroxocobalamin. Sodium thiosulfate can be administered through a separate IV line following the hydroxocobalamin. The initial dose of hydroxocobalamin in adults is 5 g (2×2.5 g vials) IV over 15 minutes (7.5 min/vial) with a second dose administered if warranted.[7]

Children   As for adults, amyl nitrite can be used prior to IV administration of sodium nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Break one amyl nitrite ampule and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off.[6,16] Inhalation of amyl nitrite should be discontinued prior to sodium nitrite administration.

Intravenously inject 6 to 8 mL/m² (approximately 0.2 mL/kg) of 3% sodium nitrite solution, not to exceed 10 mL or 300 mg.[6,16] A 0.2-mL/kg dose of 3% sodium nitrite solution is 6 mg/kg sodium nitrite. Based on an in vitro calculation, this dose would be safe for a child with a hemoglobin of 7 g/dL in the absence of other factors that could compromise hemoglobin oxygen saturation, such as carboxyhemoglobin or sulfhemoglobin.[1] The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours after the first dose as prophylaxis (see Table 126–2).[16]

Immediately following sodium nitrite infusion, 7 g/m² or 0.5 g/kg (2 mL/kg) of 25% solution of sodium thiosulfate, not to exceed the adult dose of 12.5 g (50 mL of 25% solution) sodium thiosulfate, should be infused intravenously. The same needle and vein can be used. The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[6,16]

In situations where additional formation of methemoglobin would be harmful, as in patients with smoke inhalation from a fire in which other toxic gases may coexist, the nitrite can be withheld and only the sodium thiosulfate administered. Since hydroxocobalamin is now available in the United States, combined therapy with hydroxocobalamin and sodium thiosulfate would be synergistic and ideal. Although there is no approved US pediatric dose of hydroxocobalamin, 70 mg/kg has been used outside of the United States.[7] Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate through the same IV line since a physical incompatibility occurs, inactivating the hydroxocobalamin.

AVAILABILITY

Sodium nitrite is available in ampules containing 300 mg in 10 mL (3% concentration) water for injection (USP). It contains no additives or preservatives. It is also available in a kit containing two ampules of sodium nitrite (300 mg in 10 mL) with 12 ampules of amyl nitrite inhalants (0.3 mL) and two vials of sodium thiosulfate 12.5 g in 50 mL water for injection (USP), with boric acid or sodium hydroxide added to adjust the pH.[6]

ANTIDOTES IN DEPTH (A39)

SODIUM THIOSULFATE

Mary Ann Howland

Sodium thiosulfate is a safe and effective antidote that detoxifies cyanide by donating a sulfur moiety to form thiocyanate. Thiocyanate is much less toxic than cyanide and is renally eliminated. Sodium thiosulfate works synergistically with nitrites and hydroxocobalamin in the detoxification of cyanide. Because sodium thiosulfate does not compromise hemoglobin oxygen saturation, it can be used without nitrites in circumstances where the formation of methemoglobin would be detrimental, as in patients who have elevated concentrations of carboxyhemoglobin or preexistent methemoglobinemia from smoke inhalation from fires. Sodium thiosulfate is used prophylactically with nitroprusside to prevent cyanide toxicity. Sodium thiosulfate is also used to treat calciphylaxis (calcific uremic arteriolopathy) by forming the very water-soluble calcium thiosulfate.[4,21]

HISTORY

In 1933 Chen et al.[6] noted that preexposure treatment with intravenous (IV) sodium thiosulfate protected dogs against three minimum lethal doses of sodium cyanide, and even more remarkable was the synergistic effects obtained by combining sodium thiosulfate with either inhaled amyl nitrite or IV sodium nitrite, which protected the dogs against 10 to 18 minimum lethal doses of cyanide.[5,6]

CHEMISTRY

The chemical formula of sodium thiosulfate is $Na_2S_2O_3$. The molecular weight of sodium thiosulfate is 248 Da including the pentahydrate. It is a pentahydrate that is highly water soluble. Sodium hyposulfite is a synonym.

MECHANISM OF ACTION

The sulfur provided by sodium thiosulfate binds to cyanide with the help of rhodanese (cyanide sulfur transferase) and mercaptopyruvate sulfur transferase.[6,27,29] This sulfur, a sulfane sulfur (a divalent sulfur bound to one other sulfur), is the only type of sulfur that reacts with cyanide to produce thiocyanate, which is minimally toxic and renally eliminated. In many different animal models, sodium thiosulfate protects against several minimum lethal doses of cyanide.[14,17] The addition of rhodanese increases the efficacy of sodium thiosulfate, but the use of rhodanese is impractical in the clinical setting.[17,28] The cationic site on rhodanese is crucial to cleaving the sulfur–sulfur bond of thiosulfate and forming a sulfur–rhodanese complex that readily reacts with cyanide.[29]

Rhodanese is probably not solely responsible for sulfur–sulfur bond cleavage, as rhodanese is largely a mitochondrial enzyme found in the liver and skeletal muscle, and sodium thiosulfate is a divalent ion that poorly crosses membranes.[11,17,22,27,29] An additional theory proposes that both mercaptopyruvate sulfurtransferase and rhodanese are involved in the formation of sulfane sulfur in the liver from sodium thiosulfate, and that serum albumin then carries the sulfane sulfur from the liver to other organs. When cyanide is present, albumin delivers this sulfur to cyanide, forming thiocyanate.[15,27–29]

PHARMACOKINETICS AND PHARMACODYNAMICS

■ ANIMAL STUDIES

Sodium thiosulfate is a large divalent anion. Canine studies suggest that sodium thiosulfate rapidly distributes into the extracellular space and then slowly into the cell, perhaps with a carrier facilitating entry into the mitochondria.[13,22] When administered prior to cyanide, thiosulfate converted more than 50% of the cyanide to thiocyanate within 3 minutes and increased the endogenous conversion rate more than 30 times.[26] One study in canines, using a continuous IV infusion model of cyanide toxicity to induce a respiratory arrest, demonstrated that the IV administration of 500 mg/kg of sodium thiosulfate brought the serum cyanide concentration down and with it restored respiration within 3 minutes.[8] Thiosulfate is filtered and secreted in the kidney. At low serum concentrations, thiosulfate is largely reabsorbed. At high serum concentrations, filtration and secretion predominate.[12,22]

■ HUMAN VOLUNTEERS

A volunteer study examined the pharmacokinetics of sodium thiosulfate and the fate of thiosulfate.[14,22] After injection of 150 mg/kg, volume of distribution (Vd) was 0.15 L/kg, distribution half-life was 23 minutes, and elimination half-life was 3 hours. The peak serum thiosulfate concentration rose 100-fold. Approximately 50% of the drug was eliminated in 18 hours, most of it within 3 hours. Baseline thiosulfate concentrations were higher in starved patients and children, presumably because of their higher protein utilization and metabolism to thiosulfate.[14] Normally, the kidney actively reabsorbs thiosulfate, but this study found that with exogenous administration, thiosulfate clearance equaled creatinine clearance.[14]

Another report researching the effects of thiosulfate as a cisplatin neutralizer found that thiosulfate had a half-life of 80 minutes, and that renal clearance accounted for only 30% of the total clearance.[25] Oral sodium thiosulfate is poorly absorbed and acts as a laxative.[22]

CLINICAL USE

■ CYANIDE TOXICITY

In 1952, 16 cyanide-poisoned patients survived with administration of nitrites and sodium thiosulfate.[5] Even patients who were unconscious or apneic survived when given timely cardiopulmonary resuscitation and antidotal therapy.[5]

Case reports attest to the ability of sodium nitrite and sodium thiosulfate to reverse the effects of cyanide with timely administration.[7,20,22]

In the few reported cases of cyanide ingestion treated with sodium thiosulfate alone all patients had favorable outcomes.[22] Prior to sodium thiosulfate administration, we advocate the use of amyl or sodium nitrite, or hydroxocobalamin if available. As noted, nitrites would be relatively contraindicated for patients who have elevated carboxyhemoglobin or methemoglobin concentrations from smoke inhalation from a fire.

■ CALCIFIC UREMIC ARTERIOLOPATHY (CALCIPHYLAXIS)

Case reports attest to sodium thiosulfate ameliorating calcification of the medial layer of arteries leading to subcutaneous nodules that progress to necrotic skin ulcers, a rare manifestation of vascular disease in chronic renal failure patients.[1,2,4,21] The dose of sodium thiosulfate is usually 5 to 25 g IV in adults after or during hemodialysis.[21] Thiosulfate is always used in concert with other therapies for this condition since the mechanism of action is unclear, although the increased water solubility of calcium thiosulfate is proposed.[23] In a uremic rat model, sodium thiosulfate was able to prevent vascular calcifications but also induced a metabolic acidosis and reduced bone strength.[24]

ADVERSE EFFECTS

The toxicity of sodium thiosulfate is low. The LD_{50} (median lethal dose in 50% of test subjects) for animals is approximately 3 to 4 g/kg, with death attributed to metabolic acidosis, elevated sodium concentration, and decreased blood pressure and Po_2.[17] Sodium thiosulfate delivers a significant sodium load and is hyperosmolar. Administering the infusion over 10 to 30 minutes attenuates some of these adverse effects.[22]

Adverse effects associated with therapeutic dosing include hypotension, nausea, and vomiting. The osmotic and diuretic effects presumably result from both the formation of thiocyanate and the intrinsic osmotic properties of the drug.[22]

ADMINISTRATION AND DOSING

■ CYANIDE TOXICITY

Adults   In a patient with presumed cyanide poisoning, the adult dose of sodium thiosulfate is 12.5 g (50 mL of 25% solution) administered intravenously either as a bolus injection or infused over 10 to 30 minutes, depending on the severity of the situation.[9] The dose of sodium thiosulfate can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[9]

In situations where the formation of methemoglobin by a nitrite would not be harmful, intravenously inject 300 mg sodium nitrite (10 mL of 3% solution) at a rate of 2.5 to 5 mL/min prior to administration of sodium thiosulfate. The same needle and vein can be used. The dose of sodium nitrite can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[9]

Amyl nitrite can be used prior to IV administration of sodium nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Break one amyl nitrite ampule and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off.[9] Inhalation of amyl nitrite should be discontinued prior to administration of sodium nitrite.

In situations where the additional formation of methemoglobin would be harmful, as in patients in whom carboxyhemoglobin or methemoglobin may be present from smoke inhalation from a fire, the nitrite can be withheld and only the sodium thiosulfate administered.

Since hydroxocobalamin is now available in the United States, combined therapy of hydroxocobalamin with sodium thiosulfate, which is synergistic, would be ideal. The initial dose of hydroxocobalamin in adults is 5 g (2×2.5 g vials) IV over 15 minutes with a second dose administered if warranted.[10] Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate through the same IV line since a physical incompatibility occurs, inactivating the hydroxocobalamin.

Children   The dose of sodium thiosulfate in children is 7 g/m² up to the adult dose[9] or 0.5 g/kg (2 mL/kg of 25% solution) up to the adult dose of 12.5 g (50 mL of 25% solution).[22] The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[9]

In situations where the formation of methemoglobin by a nitrite would not be harmful, intravenously inject 3% sodium nitrite solution at 6 to 8 mL/m² (approximately 0.2 mL/kg), not to exceed 10 mL or 300 mg, prior to administration of sodium thiosulfate.[9] The same needle and vein can be used. A 0.2-mL/kg dose of 3% sodium nitrite solution is approximately 6 mg/kg sodium nitrite. Based on an in vitro calculation, this dose would be safe for a child with a hemoglobin of 7 g/dL in the absence of other factors that could compromise hemoglobin oxygen saturation, such as carboxyhemoglobin, methemoglobin, or sulfhemoglobinemia.[3] The dose of sodium nitrite can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours after the first dose as prophylaxis.[9]

Amyl nitrite can be used prior to IV administration of sodium nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Break one amyl nitrite ampule and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off. Amyl nitrite inhalation should be discontinued prior to administration of sodium nitrite. The healthcare provider must not inhale the amyl nitrite.

In situations where additional formation of methemoglobin would be harmful, as in patients with smoke inhalation from a fire, the nitrite can be withheld and only the sodium thiosulfate administered. Since hydroxocobalamin is now available in the United States, combined therapy of hydroxocobalamin with sodium thiosulfate, which is synergistic, would be ideal. Although there is no approved US pediatric dose, 70 mg/kg of hydroxocobalamin has been used outside of the United States.[10] Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate through the same IV line since a physical incompatibility occurs, inactivating the hydroxocobalamin.

■ NITROPRUSSIDE-INDUCED CYANIDE TOXICITY

Nitroprusside   Canine experiments reveal that when the nitroprusside infusion rate is greater than 0.5 mg/kg/h, cyanide concentrations in the blood begin to rise. Coadministration of sodium thiosulfate with sodium nitroprusside in a 5:1 molar ratio (because nitroprusside contains five cyanide ions) prevents the rise in cyanide concentration.[22] The usual dosage of sodium nitroprusside is 3 μg/kg/min (range 0.25–10 μg/kg/min).[18] Each mole of nitroprusside has a molecular weight of 298 Da including the sodium dehydrate and contains five cyanide ions. A 70-kg person administered 3 μg/kg/min would receive 12.6 mg/h of nitroprusside. This would require 52.4 mg of sodium thiosulfate per hour to detoxify the five cyanide ions liberated from nitroprusside. Prolonged infusion or doses in excess of the body's detoxifying capability may lead to thiocyanate or cyanide toxicity. Some authors recommend adding 0.5 g sodium thiosulfate to each 50 mg of nitroprusside.[19] This dose of sodium thiosulfate usually is sufficient to prevent cyanide toxicity from nitroprusside; however, thiocyanate may accumulate, especially in patients with renal insufficiency. Although thiocyanate is relatively nontoxic compared to

cyanide it may produce dose-dependent tinnitus, miosis, hyperreflexia, and hypothyroidism, especially at serum concentrations greater than 60 μg/mL,[18] and thiocyanate is hemodialyzable. Nitroprusside-induced cyanide toxicity should be treated like cyanide toxicity from any other cause: stop the nitroprusside dosage and administer sodium thiosulfate, sodium nitrite, or hydroxocobalamin (if available) according to the doses and precautions listed.

AVAILABILITY

Sodium thiosulfate is available in 50-mL vials containing 12.5 g in water for injection (USP), with boric acid or sodium hydroxide added to adjust the pH. It is also available in a kit containing two ampules of sodium nitrite (300 mg in 10 mL water for injection) with 12 ampules of amyl nitrite inhalants (0.3 mL) and two vials of sodium thiosulfate 12.5 g in 50 mL water for injection, with boric acid or sodium hydroxide added to adjust the pH.[9]

HYDROXOCOBALAMIN

Mary Ann Howland
Hydroxocobalamin is a relatively new antidote for cyanide toxicity in the United States. Cyanocobalamin, vitamin B_{12}, is formed when hydroxocobalamin combines with cyanide. Nitrites and sodium thiosulfate have traditionally been used to treat patients with cyanide toxicity. Nitrites have the disadvantage of producing methemoglobin, which is dangerous in a patient with coexistent elevated carboxyhemoglobin concentrations, such as would be found in fire victims suspected of having cyanide toxicity. Unfortunately, there are no controlled studies comparing sodium thiosulfate with hydroxocobalamin in these circumstances.

HISTORY

The antidotal actions of cobalt as a chelator of cyanide were recognized as early as 1894.[12,35] Hydroxocobalamin has been used as a cyanide antidote in France for many years, first as a sole agent and then in combination with sodium thiosulfate.[19] In the United States, hydroxocobalamin was finally approved by the Food and Drug Administration (FDA) in December 2006 and is available under the trade name Cyanokit.[11,13]

Hydroxocobalamin subsequently was shown to be successful in protecting against several minimum lethal doses of cyanide as long as an equimolar ratio of hydroxocobalamin to cyanide was used.[1,7,28,33]

CHEMISTRY

The molecule is porphyrinlike in structure and has a cobalt ion at its core. The only difference between cyanocobalamin (vitamin B_{12}) and hydroxocobalamin (referred to as vitamin B_{12a}) is the replacement of the CN group with an OH group at the active site in the latter.[24,30]

MECHANISM OF ACTION

The cobalt ion in hydroxocobalamin combines with cyanide to form the nontoxic cyanocobalamin.[27,28] One mole of hydroxocobalamin binds 1 mole of CN. Given the molecular weights of each, 52 g of hydroxocobalamin are needed to bind 1 g of cyanide.[19] An ex vivo study using human skin fibroblasts demonstrates that hydroxocobalamin penetrates intracellularly to form cyanocobalamin.[2] In the setting of cyanide poisoning, hydroxocobalamin removes cyanide from the mitochondrial electron transport chain, allowing oxidative metabolism to proceed. Hydroxocobalamin also binds nitric oxide, a vasodilator, causing vasoconstriction, particularly in the absence of cyanide. This same property potentially contributes to its beneficial effects by increasing systolic and diastolic blood pressure and improving the hemodynamic status of cyanide-poisoned patients.[7,16] Other cobalt chelators, such as dicobalt ethylenediaminetetraacetic acid (EDTA), have been used both experimentally and clinically in other countries, but their therapeutic index is narrow, especially in the absence of cyanide. Additionally, idiosyncratic adverse effects make these compounds less advantageous.[27,35] Use of hydroxocobalamin with sodium thiosulfate is synergistic and comparable to the sequential use of sodium nitrite with sodium thiosulfate.[19,33]

PHARMACOKINETICS AND PHARMACODYNAMICS

Under an FDA Investigational New Drug permit, the first pharmacokinetic study of intravenous (IV) hydroxocobalamin was performed in the United States and published in 1993.[13,14] Adult volunteers who were heavy smokers were given 5 g hydroxocobalamin (5%) intravenously, obtained from a French manufacturer. The first four patients received the dose undiluted over 20 minutes.[14] They then received 12.5 g (50 mL of 25% solution) of sodium thiosulfate intravenously infused over 20 minutes. The next 11 patients received the same dose of hydroxocobalamin but diluted with 100 mL water for injection (USP) and infused over 30 minutes. The serum and urine sampling of hydroxocobalamin differed in the two patient groups, yielding somewhat different half-lives (4 hours versus 1.27 hours). The α distribution half-life was 0.52 hours in the group 1 patients. Peak hydroxocobalamin concentration averaged 813 μg/mL (604 μmol/L), and volume of distribution (Vd) averaged 0.38 L/kg. A mean dose of 62% was recovered in the urine in 24 hours. Whole-blood cyanide concentrations significantly decreased in all subjects following hydroxocobalamin. A problem with this study was the short collection time for serum hydroxocobalamin concentrations of only 6 hours, making the pharmacokinetic analysis imprecise.[20,21]

A pharmacokinetic study performed in adult victims of smoke inhalation in France[19] was conducted with very different patients given hydroxocobalamin 5 g (5%) by IV infusion over 30 minutes, starting within 30 minutes of their removal from the fire.[20,21] The α distribution half-life of hydroxocobalamin was 1.86 hours, elimination half-life was 26.2 hours based on sampling up to 6 days, and Vd was 0.45 L/kg. The peak serum cyanocobalamin concentration was 287 μg/mL (212 μmol/L). In the one patient who was subsequently determined not exposed to cyanide, the hydroxocobalamin elimination half-life was 13.6 hours and Vd was 0.23 L/kg. Renal clearance of hydroxocobalamin was 37% in the cyanide-exposed patients compared with 62% in the unexposed patient.

In a study of 12 fire victims in France who were suspected of having cyanide poisoning, the patients received IV hydroxocobalamin 5 g in 100 mL sterile water (USP) over 30 minutes.[23] Pretreatment and posttreatment cyanide concentrations and cyanocobalamin concentrations were analyzed. In patients with cyanide concentrations less than 1.04 μg/mL (less than 40 μmol/L), a linear relationship existed between the blood cyanide concentration and the formation of cyanocobalamin. In the three patients with blood cyanide concentration greater than 1.04 μg/mL (greater than 40 μmol/L), the formation of cyanocobalamin reached a plateau, implying that all of the hydroxocobalamin was consumed. In the one patient with a blood cyanide concentration greater than 1.04 μg/mL (greater than 40 μmol/L) who received a second 5-g dose of hydroxocobalamin, the cyanocobalamin concentration subsequently rose.[3,23]

The protein binding and tissue distribution of cyanide, hydroxocobalamin, and cyanocobalamin likely are different.[22] In addition, hydroxocobalamin probably causes redistribution of cyanide from the intracellular to the intravascular space.[22]

CLINICAL USE

Many case reports and studies in France document the efficacy of hydroxocobalamin combined with sodium thiosulfate for treatment of cyanide toxicity.[6,8,18] An observational case series reviewed 69 adult smoke inhalation victims suspected of cyanide poisoning who were treated either at the scene of the fire or in the intensive care unit (ICU). They received a median dose of 5 g of hydroxocobalamin, up to a maximum of 15 g, infused as a 5% solution in sterile water for injection over 15 to 30 minutes. Cardiopulmonary arrest occurred in 15 patients, with a mean blood cyanide concentration of 123 μmol/L (greater than 100 μmol/L = greater than 2.7 μg/mL and potentially fatal), and a mean carboxyhemoglobin of 30%. Two of these patients survived with normal neurologic function. Of 42 patients with confirmed cyanide concentrations greater than 39 μmol/L (1 μg/mL), 28 (67%) survived. The contribution to toxicity of carboxyhemoglobin is difficult to sort out in this study. Of the 69 patients in this study, 57 also received hyperbaric oxygen, complicating the interpretation of the outcome results.[7]

An 8-year retrospective analysis of the use of hydroxocobalamin in the prehospital setting concluded that the risk-benefit ratio favors its use in smoke inhalation victims suspected of cyanide poisoning.[15] Of 72 patients in whom survival status could be determined, 30 (42%) survived. Cyanide blood concentrations were not measured in these patients. Of 38 patients found in cardiac arrest, 21 had hemodynamic improvement; however, survival was dismal with only two patients ultimately surviving. The neurologic function of those two patients was not revealed.

Hydroxocobalamin also prevented the rise in cyanide concentration following nitroprusside infusion compared with patients who just received nitroprusside.[9] When nitroprusside is administered, use of concomitant hydroxocobalamin prevents cyanide accumulation and toxicity in both animal models and in humans.[8,9,36] Sodium thiosulfate

also prevents nitroprusside-induced cyanide toxicity (see Antidotes in Depth A39: Sodium Thiosulfate).

There are currently no studies comparing the nitrite plus sodium thiosulfate regimen with hydroxocobalamin in patients with cyanide poisoning. There are no studies comparing hydroxocobalamin with or without sodium thiosulfate to sodium thiosulfate alone in smoke inhalation victims presumed cyanide toxic. Most animal studies demonstrate a synergistic effect of hydroxocobalamin and thiosulfate on the elimination of cyanide.[18]

ADVERSE EFFECTS

Hydroxocobalamin has a wide therapeutic index.[7,15,34] Large doses have been administered to animals with no adverse effects.[27,31,32] The LD$_{50}$ (median lethal dose in 50% of test subjects) in mice is 2 g/kg.

Red discoloration of mucous membranes, serum, and urine may occur and last from 12 hours to days after therapy.[7,15] Allergic reactions including anaphylaxis and angioedema are reported, but serious allergic reactions are rare.[5,6,8,30] Prior chronic exposure to hydroxocobalamin or cyanocobalamin for treatment of vitamin B$_{12}$ deficiency is associated rarely with development of anaphylaxis.[19] A study in 102 healthy volunteers demonstrated that chromaturia is universal, and as the dose increases from 2.5 g to 10 g, the incidence of skin erythema, pustular rash, headache, injection site reaction, nausea, pruritus, chest discomfort, dysphagia, and papular rash increases.[34] Two patients developed allergic reactions that required therapy. Skin rash lasted up to 9 days, while the pustular rash appeared most often on the face and neck after a delay of 1 to 3 weeks and lasted 1 to 4 weeks. Of 102 volunteers randomized to receive hydroxocobalamin, 24 experienced a clinically significant rise in diastolic blood pressures, up to 124 mm Hg. However, only three of them also had a clinically significant rise in systolic blood pressure up to 188 mm Hg. These elevations in blood pressure resolved within 4 hours of the end of the infusion.

The hydroxocobalamin solution should not be administered through the same infusion site or at the same time as the thiosulfate solution because sodium thiosulfate binds to hydroxocobalamin and renders it inactive.[29]

An in vitro study found statistically significant alterations in serum concentrations of aspartate aminotransferase (AST), total bilirubin, creatinine, magnesium, and iron after hydroxocobalamin administration.[10] Colorimetric assays are most likely to be adversely affected because both hydroxocobalamin and cyanocobalamin have an intensely red color. Although an in vitro study demonstrated a considerable false increase in carboxyhemoglobin concentrations by hydroxocobalamin when measured by cooximetry, other authors suggest that the interference is minimal and results in slight overestimates depending on the instrument and the concentration of hydroxocobalamin.[4,17,25] Inconsequential increases of 1% to 5.7% in the carboxyhemoglobin concentration occurred in another study.[17]

ADMINISTRATION AND DOSING

■ CYANIDE TOXICITY

The starting dose of hydroxocobalamin in adults is 5 g (two 2.5-g vials). Each vial is reconstituted with 100 mL of 0.9% sodium chloride and administered intravenously over 15 minutes (7.5 min/vial). Each vial should be inverted or rocked (not shaken) for 30 seconds prior to administration. The reconstituted solution should be dark red and free of particulate matter, and should be used within 6 hours of reconstitution.[11] A second dose of 5 g can be repeated as clinically necessary and infused over 15 minutes to 2 hours depending on patient status.[11]

In children, a dose of 70 mg/kg of hydroxocobalamin up to the adult dose has been used in places outside of the United States.[11]

Sodium thiosulfate can be administered in addition to hydroxocobalamin. It is expected to be synergistic and has been used extensively in conjunction with hydroxocobalamin.[26] Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate simultaneously through the same IV line since this may inactivate the hydroxocobalamin. The adult dose of sodium thiosulfate is 12.5 g (50 mL of 25% solution) and should be administered intravenously as either a bolus injection or infused over 10 to 30 minutes, depending on the severity of the situation. The dose of sodium thiosulfate in children is 7 g/m² up to the adult dose, or 0.5 g/kg (2 mL/kg of 25% solution) up to the adult dose of 12.5 g. The dose of sodium thiosulfate can be repeated at half the initial dose if manifestations of cyanide toxicity persist or reappear, or empirically at 2 hours as prophylaxis.

■ NITROPRUSSIDE INDUCED CYANIDE TOXICITY

The dose of hydroxocobalamin to prevent cyanide toxicity from the IV infusion of nitroprusside is not precisely known, but a dose of hydroxocobalamin of 25 mg/h in one study was sufficient to decrease the red cell and serum cyanide concentrations and to prevent the development of a metabolic acidosis while the nitroprusside continued to be administered.[36] These authors recommend possibly continuing the hydroxocobalamin for 10 hours after the discontinuation of the nitroprusside. Hydroxocobalamin could also be used as rescue therapy in the typical dosage, as could sodium thiosulfate (see Antidotes in Depth A39: Sodium Thiosulfate).

AVAILABILITY

Each Cyanokit contains two 250 mL glass vials, each containing 2.5 g of lyophilized dark red, hydroxocobalamin crystalline powder for injection.[11] The kit also contains two sterile transfer spikes, one sterile IV infusion set, one quick reference guide and one package insert, but no diluent.

CHAPTER 127
METHEMOGLOBIN INDUCERS

Dennis P. Price

Methemoglobin occurs when the iron atom in hemoglobin loses one electron to an oxidant, and the ferrous (Fe^{2+}) or oxidized state of iron is transformed into the ferric (Fe^{3+}) state. Although methemoglobin is always present at low concentrations in the body, methemoglobinemia is defined herein as an abnormal elevation of the methemoglobin level above 1%.

The widespread utilization of pulse oximetry in clinical medicine has made it easier to recognize low oxygen saturation, consequently increasing our recognition of methemoglobinemia. The ubiquity of oxidants both in the environment and in the hospital has increased the number of case reports associated with methemoglobin. It is also evident that host factors play a crucial role in the development of methemoglobinemia in many individuals.

Biologic systems have protective cell membrane and intracellular mechanisms that are protective with regard to oxidant stresses. Some are enzyme systems that involved electron transport mechanisms, and others are simple reducers such as ascorbic acid and reduced glutathione. When fully functional, these systems maintain methemoglobin levels under 1%, but with acute and/or chronic stress, they may be overwhelmed, allowing methemoglobin level to increase.

The cellular systems that protect the individual from oxidant stress involve cytochrome b reductase, flavin, nicotinamide adenine dinucleotide (NADH)methemoglobin reductase, nicotinamide adenine dinucleotide phosphate (NADPH) methemoglobin reductase, reduced glutathione and ascorbic acid are interrelated and incompletely understood. Depletion of the reducing power of these systems leads to methemoglobinemia and other disorders of oxidant stress such as hemolysis.

Underlying illnesses,[47,57,72,74] the treatment with xenobiotics for these illnesses,[3,17,58,73] and the therapeutic and diagnostic modalities involved[47,72] in patient care all predispose patients to methemoglobinemia. For many individuals, methemoglobinemia is not caused by one oxidant stressor but rather a series of stressors that makes methemoglobinemia clinically apparent and potentially predictable.

Reduced hemoglobin functions reliably as an oxygen transporter because in its protected heme pocket, it shares an outer valence electron with the oxygen it transports. Normally reduced hemoglobin releases this oxygen without giving up an electron, but occasionally, this electron is lost to the departing oxygen in the process of auto-oxidation. Oxidation is increased in the presence of some hereditary conditions such as hemoglobin M disease. However, oxidizing xenobiotics may produce methemoglobin by direct interaction with the Fe^{2+} moiety. These exogenous products are a major source of oxidant stress to the individual and the most frequent cause of methemoglobinemia. Although typically not life threatening, methemoglobinemia may produce symptoms of cellular hypoxia and should be considered in the differential diagnosis of cyanotic patients who do not have an apparent cardiovascular cause. In the cases of methemoglobinemia, cyanosis is not caused by deoxyhemoglobin but rather by the color imparted to the skin as a result of oxidized hemoglobin.

HISTORY AND EPIDEMIOLOGY

Methemoglobin was first described by Felix Hoppe-Seyler in 1864.[29] Subsequently, in 1891, a case of transient drug-induced methemoglobinemia was described.[65] In the late 1930s, methemoglobinemia was recognized as a predictable adverse effect of sulfanilamide use, and methylene blue was recommended for treatment of the ensuing cyanosis.[39] Some authors even recommended concurrent use of methylene blue when sulfanilamides were used.[93] Methylene blue has been used prophylactically during general surgery to treat an individual with congenital methemoglobinemia.[6] In 1948, an enzyme defect was reported in twin brothers. The defect caused cyanosis in the absence of cardiopulmonary disease and responded to ascorbic acid. [31]

Methemoglobinemia may be hereditary or acquired. The hereditary types are rare, with only several hundred cases reported.[40,89] Although the frequency with which xenobiotic-induced methemoglobinemia occurs is unknown, the American Association of Poison Control Centers' annual data show approximately 100 uses of methylene blue as an antidote. These data substantially underestimate the incidence of this poisoning because poison centers are not notified in most cases (see Chap. 135).

Methemoglobinemia is relatively common and generally produces no clinical findings. Co-oximetry data collected at two teaching hospitals noted a significant number of elevated methemoglobin levels.[4] Of a total of 5248 co-oximetry tests over 28 months on 1267 patients, 660 tests revealed methemoglobin levels above 1.5% in 414 patients (some patients had more than one test). Thus, 12.5% of all tests and 19.1% of all patients who had co-oximetry performed had an abnormal methemoglobin level. A total of 138 patients with peak methemoglobin levels greater than 2% were identified. The mean peak methemoglobin level was 8.4% (range, 2.1%–60.1%), and the ages of the patients ranged from 4 days to 86 years old.

Benzocaine spray accounted for the most seriously poisoned patients ($n = 5$), with a mean peak methemoglobin level of 43.8% (range, 19.1–60.1%). Dapsone accounted for the largest number of cases ($n = 58$), with a mean peak of 7.6% (range, 2.1–34.1%). Of the 33 of 35 patients who had elevated methemoglobin levels, 8% had symptomatic methemoglobinemia, and 12 received methylene blue. One fatality and three near fatalities were directly attributed to methemoglobinemia. These data likely represent an underestimation of the true number of cases of methemoglobinemia at these institutions because co-oximetry was performed only upon physician orders for suspected dyshemoglobinemia, and 25% of cases with levels above 2% were found incidentally when co-oximetry was performed in the catheterization laboratory to provide data on oxyhemoglobin and deoxyhemoglobin. Also, not all patients taking dapsone were tested.[4] Extrapolating these data throughout the country would suggest underreporting and substantial under recognition of this entity with its potential danger.

The incidence of induced methemoglobinemia in the workplace is poorly documented. A number of reports document several hundred such cases of methemoglobinemia and several more workplace exposures.[15,61,86] Underreporting and underrecognition occur because of the limited symptoms associated with low concentrations of methemoglobin in most cases.

HEMOGLOBIN PHYSIOLOGY

Hemoglobin consists of four polypeptide chains noncovalently attracted to each other. Each of these subunits carries one heme molecule deep within the structure. The polypeptide chain protects the iron moiety of the heme molecule from inappropriate oxidation (Fig. 127–1).
FIGURE 127–1. Hemoglobin molecule symbolically represented with its heme center surrounded by the globin portion of the molecule. his = histidine.

The iron is held in position by six coordination bonds. Four of these bonds are between iron and the nitrogen atoms of the protoporphyrin ring with the fifth and sixth bond sites lying above and below the protoporphyrin plane. The fifth site is occupied by histidine of the polypeptide chain. A variety of hemoglobin mutations are attributable to changes in the amino acid sequence of the polypeptide chain, as occur in the hemoglobin M diseases. This influences this protective "pocket," allowing easier iron oxidation (Fig. 127–2), or hemoglobin auto-oxidation. The sixth coordination site is where most of the activity within hemoglobin occurs. Oxygen transport occurs here, and this site is involved with the formation of methemoglobin or carboxyhemoglobin (Fig. 127–3). It is at this site that an electron is lost to oxidant xenobiotics, transforming iron from its ferrous (Fe^{2+}) to its ferric (Fe^{3+}) state.

Hemoglobin transports an oxygen molecule only when its iron atom is in the reduced ferrous state (Fe^{2+}). During oxygen transport, the iron atom actually transfers an electron to oxygen, thus transporting oxygen as a superoxide charged particle $Fe^{3+}O^{2-}$. When oxygen is released, the ferrous state is restored, and hemoglobin is ready to accept another oxygen molecule. Interestingly, a small percentage of oxygen is released from hemoglobin with its shared electron (forming superoxide O^{2-}),
FIGURE 127–2. Hemoglobin M occurs when histidine is replaced by tyrosine in the amino acid sequence of the polypeptide chain. Hemoglobin M is more easily auto-oxidized (as shown) to methemoglobin.
FIGURE 127–3. Heme molecule depicted with its bonding sites. Oxyhemoglobin, carboxyhemoglobin, and methemoglobin all involve the sixth coordination bonding site of iron.

leaving iron oxidized (Fe^{3+}). This sixth coordination site becomes occupied by a water molecule. This abnormal unloading of oxygen contributes to the steady-state level of approximately 1% methemoglobin found in normal individuals.

METHEMOGLOBIN PHYSIOLOGY AND KINETICS

Because of the spontaneous and xenobiotic-induced oxidation of iron, the erythrocyte has developed multiple mechanisms to maintain a normal concentration of methemoglobin.[12] All of these systems donate an electron to the oxidized iron atom. Because of these effective reducing mechanisms, the half-life of methemoglobin acutely formed as a result of exposure to oxidants is between 1 and 3 hours.[44,64] With continuous exposure to the oxidant, the apparent half-life of methemoglobin is prolonged.

Quantitatively the most important reductive system requires NADH, which is generated in the Embden-Meyerhof glycolytic pathway (Fig. 127–4). NADH serves as an electron donor, and along with the enzyme NADH methemoglobin reductase, reduces Fe^{3+} to Fe^{2+}. There are numerous cases of hereditary deficiencies of the enzyme NADH methemoglobin reductase.[40] Individuals who are homozygotes for this enzyme deficiency usually have methemoglobin levels of 10% to 50% under normal conditions without any clinical or xenobiotic stressors. Individuals who are heterozygotes do not ordinarily demonstrate methemoglobinemia except when they are subject to oxidant stress. Additionally, because this enzyme system lacks full activity until approximately 4 months of age, even genetically normal infants are more susceptible than adults to oxidant stress.[69,95]

Oxidized iron can be reduced nonenzymatically using either ascorbic acid or reduced glutathione as electron donors, but this method is slow and quantitatively less important under normal circumstances.

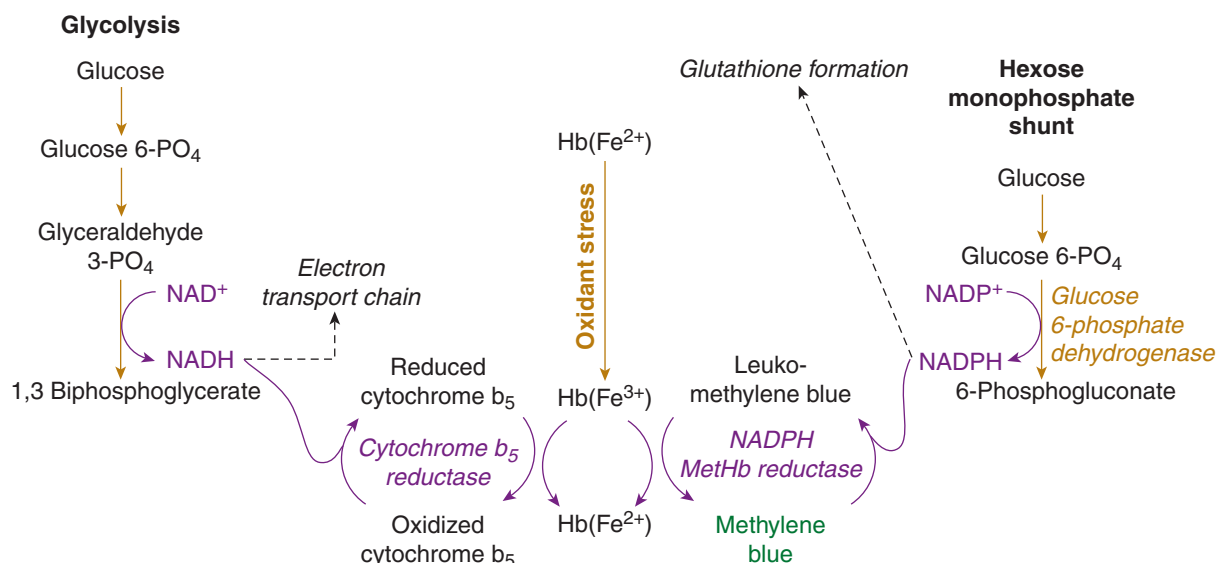
Within the red cell is another enzyme system for reducing oxidized iron that is dependent on the NADPH generated in the hexose monophosphate shunt pathway (see Fig. 127–4). Although it is generally accepted that this NADPH-dependent system reduces only a small percentage of methemoglobin under normal circumstances, it may play a more prominent role in maintaining oxidant balance in the cell.[53] Patients with an isolated deficiency of NADPH methemoglobin reductase do not exhibit methemoglobinemia under normal circumstances,[85] perhaps because of the prominence of other cellular protective mechanisms.


FIGURE 127–4. Role of glycolysis in the Embden-Meyerhof pathway and the role of methylene blue in the reduction of methemoglobin using NADPH generated by the hexose monophospate shunt. $Hb(Fe^{3+})$ is methemoglobin.

However, when the NADPH methemoglobin reductase system is provided with an exogenous electron carrier, such as methylene blue, this system is accelerated and may assist in the reduction of oxidized hemoglobin (see Antidotes in Depth A41: Methylene Blue).

XENOBIOTIC INDUCED METHEMOGLOBINEMIA

Nitrates and nitrites are powerful oxidizing agents that are two of the most common methemoglobin-forming compounds. Sources of nitrates and nitrites include well water, food, industrial compounds, and pharmaceuticals. Nitrogen-based fertilizers and nitrogenous waste from animal and human sources may contaminate shallow rural wells. The contamination of drinking water occurs mainly with nitrates because nitrites are easily oxidized to the highly soluble nitrates in the environment. Furthermore, foods such as cauliflower, carrots, spinach, and broccoli have high nitrate content, as do preservatives in meat products such as hot dogs and sausage.[5] Dietary nitrates are generally converted by intestinal bacteria to nitrates before absorption.

The reactions of nitrates that occur both in vivo and in vitro are complex and poorly understood. Ingested nitrates are reduced to nitrites by bacteria in the gastrointestinal (GI) tract (especially in infants) and then can be absorbed, ultimately leading to methemoglobin production. This conversion is not essential, however, because nitrates themselves can oxidize hemoglobin.[27,38,88] Some question whether well water consumption alone can cause serious methemoglobinemia in the absence of comorbid disease.[24]

In the past, nitrate-contaminated well water was associated with infant fatalities because of methemoglobinemia.[55,63] A number of reports from the Midwest United States demonstrated the problems of poorly constructed shallow wells that permit contamination by surface waters containing chemicals, pesticides, fertilizers, and microorganisms.[66] In several South Dakota studies, 20% to 50% of wells contained both coliform bacteria and water that exceeded the Environmental Protection Agency standards for permissible quantities of nitrogen as nitrates (10 ppm or 10 mg/L).[46] In New York State, 419 wells from rural farms demonstrated elevated concentrations of nitrogen compounds, and 15.7% were found to have well water nitrate concentrations >10 mg/L.[30]

Nitroglycerin (glyceryl trinitrate) and organic nitrates are more effectively absorbed through mucous membranes and intact skin than from the GI tract. Their onset of action is more rapid, and the total effect is much greater, when mucous membrane or cutaneous absorption occurs.[20,43,75] Aromatic amino and nitro compounds indirectly produce methemoglobin.[49] These xenobiotics do not form methemoglobin in vitro; therefore, they are assumed to do so by in vivo metabolic chemical conversion to some active intermediates.[14,51]

Elevated methemoglobin and carboxyhemoglobin level are found in victims of fires and automobile exhaust fume poisoning.[11,43,48,59] Heat-induced hemoglobin denaturation in burn patients and the inhalation of oxides of nitrogen from combustion are suggested to be causative factors for methemoglobin formation.

Topical anesthetics are widely used to facilitate multiple procedures and are implicated in the most serious of toxic methemoglobin cases.[1,36] Cetacaine spray (14% benzocaine, 2% tetracaine, 2% butylaminobenzoate) and 20% benzocaine sprays commonly produce of methemoglobinemia. The dosing recommendations are difficult to comprehend (eg, 0.5-second spray repeat once) and are often ignored. One study showed that the dose is dependent on the residual volume in the canister and the physical orientation of the canister as the spray is being applied.[52]

A review of 52 months of data from the Food and Drug Administration (FDA) Adverse Event Reporting System demonstrated 132 cases of benzocaine-induced methemoglobinemia. Benzocaine spray was implicated in 107 severe adverse events and two deaths. In 123 cases, the product was a spray. In 69 cases in which the dose was specified, 37 patients received a single spray.[67]

This FDA effort is exclusively based on self-reporting and probably greatly underestimates the extent of the problem.[34] The FDA itself has estimated that approximately 10% of serious events are reported and that some studies show 1% or less serious event reporting.[67]

In one institution, the incidence of benzocaine-induced methemoglobinemia occurring during transesophageal echocardiograms was determined in 28,478 patients over a 90-month period. The incidence was low at 0.067% (one case per 1499 patient), with sepsis, anemia, and hospitalization suggested as predisposing factors.[47] During a 32-months period at another institution, an incidence of 0.115% (five of 4336) of benzocaine-induced methemoglobinemia was observed.[72] There were no cases of methemoglobinemia in a study of 154 patients receiving

Malnutrition

Renal insufficiency[33]

Sepsis[47,57,72,74]

lidocaine for bronchoscopy at doses as high as 15 mg/kg. Lidocaine is a much weaker oxidant than benzocaine and is a reasonable substitute in susceptible individuals.

Nitric oxide (NO) delivered by inhalation is used to treat persistent pulmonary hypertension of newborns and other cardiopulmonary diseases associated with pulmonary hypertension because it is a potent vasodilator.[82] Despite being a potent oxidant, if NO is used in doses of less than 40 ppm, most patients will maintain methemoglobin levels under 4%.[41,92] Some cases of serious toxicity have occurred because of intentional and unintentional overdoses.

Dapsone has been implicated as a cause of methemoglobinemia and is used in patients with AIDS. Cases of prolonged methemoglobinemia from dapsone ingestion are related to the long half-life of dapsone and the slow conversion to its methemoglobin-forming hydroxylamine metabolites.[23] Patients receiving dapsone should be carefully monitored for methemoglobinemia.[94] The bladder anesthetic phenazopyridine is a commonly reported causes of methemoglobinemia.[19,26,30,68] For this reason, its use should be limited to short periods of time and at the lowest dose to improve symptoms. This approach is particularly pertinent in the presence of renal failure. Predispositions for methemoglobinemia are listed in Table 127–1.

Infants who are bottled fed with well water may be exposed to nitrates and nitrites. Additionally, infants have a relatively large body surface area, making dermal and mucosal absorption of oxidants more of a threat to them than adults.

Methemoglobinemia of unknown origin is often reported in infants.[77,84,96] These patients are usually ill for other reasons such as dehydration, acidosis, or diarrhea.[37] These infants may have methemoglobin levels in the 20% to 67% range with severe consequences.[42] As noted above, young children are relatively deficient in the enzyme glucose-6-phosphate dehydrogenase (G-6-PD), accounting for their high incidence of methemoglobinemia.

METHEMOGLOBINEMIA AND HEMOLYSIS

The enzyme defect responsible for most instances of oxidant-induced hemolysis is G-6-PD deficiency. Reviews of hemolysis addressed the confusion regarding the relationship between hemolysis and methemoglobinemia.[9,10,28]

Both hemolysis and methemoglobinemia are caused by oxidant stress, and hemolysis may occur after episodes of methemoglobinemia.[10] Certain protective mechanisms involving NADPH and reduced glutathione nonspecifically reduce the oxidant burden and prevent

the development of both disorders. Another source of confusion concerning hemolysis and methemoglobinemia is that reduced glutathione is required to protect against both toxic manifestations. Erythrocytes are able to withstand hemolytic oxidant damage as long as they can maintain adequate concentrations of reduced glutathione, the principal cellular antioxidant. Glutathione is maintained in its reduced form by using NADPH as its reducing agent. Cells with reduced capacity to produce NADPH (ie, erythrocytes of patients with G-6-PD deficiency or cells with depleted reduced glutathione or NADPH) are thus susceptible to hemolysis. In the presence of methemoglobinemia, reduced glutathione plays a minor role as a reducing agent, but NADPH is necessary for successful antidotal therapy with methylene blue. This codependence on the reducing power of NADPH links the two disorders. Competition for NADPH by oxidized glutathione and exogenously administered methylene blue is postulated to be the cause of methylene blue-induced hemolysis (ie, competitive inhibition of glutathione reduction). Methylene blue itself is an oxidant, but in an assessment of the hemolytic potency of varied drugs, methylene blue in doses of 390 to 780 mg proved to be only a moderate hemolytic agent.[50] The clinical importance of this phenomenon is uncertain. It may be easier to consider hemolysis and methemoglobin formation as subclasses of disorders of oxidant stress. They should be considered separate clinical entities sharing limited characteristics.

However, oxidative damage to erythrocytes occurs at different locations in the two disorders. Hemolysis occurs when oxidants damage the hemoglobin chain acting directly as electron acceptors or through the formation of hydrogen peroxide or other oxidizing free radicals. This results in oxidants forming irreversible bonds with sulfhydryl group of hemoglobin cause denaturation and precipitation of the globin protein to form Heinz bodies within the erythrocyte (Figure 127–5). Cells with large numbers of Heinz bodies are removed by the reticuloendothelial system, producing hemolysis. Alternatively, a limited number of oxidants can destroy the erythrocyte membrane directly, causing non–Heinz body hemolysis. Methemoglobinemia does not necessarily progress to hemolysis, even if untreated (Table 127–2).
FIGURE 127–5. Heinz bodies are particles of denatured hemoglobin, usually attached to the inner surface of the red cell membrane. Xenobiotics that result in the oxidative denaturation of hemoglobin in normal (eg, phenylhydrazine) or glucose-6-phosphate dehydrogenase–deficient (primaquine) individuals and unstable hemoglobin mutants are prone to develop these bodies. The Heinz bodies can be identified when blood is mixed with a supravital stain, notably crystal violet. The Heinz bodies appear as purple inclusions. (Reproduced with permission from Lichtman MA, Shafer MS, Felgar RE, Wang N. *Lichtman's Atlas of Hematology*, 1st ed. New York: McGraw-Hill, Inc; 2007.)

Numerous cases describe the occurrence of hemolysis after methemoglobinemia. The combined occurrence is reported with dapsone,[23] phenazopyridine,[19,26,32,68] amyl nitrite,[16] and aniline.[46,49] These instances of combined syndromes may represent the incidental toxicity of an oxidizing agent at both locations or may represent the depletion of all cellular defenses against oxidants. Currently, it is not possible to predict when hemolysis will occur after methemoglobinemia with any degree of certainty.

CLINICAL MANIFESTATIONS

The clinical manifestations of methemoglobinemia are related to impaired oxygen-carrying capacity and delivery to the tissue. The clinical manifestations of acquired methemoglobinemia are usually more severe than those produced by a corresponding degree of anemia. This discordance occurs because methemoglobin not only decreases the available oxygen-carrying capacity but also increases the affinity of the unaltered hemoglobin for oxygen. This shifts the oxygen hemoglobin dissociation curve to the left, which further impairs oxygen delivery[22] (see Chap. 21). This effect is attributed to the formation of heme compounds intermediate between normal reduced hemoglobin (all four iron atoms are ferrous) and methemoglobin, in which one or more of the iron moieties are in the ferric state.[22] The degree to which this high oxygen affinity hemoglobin reduces oxygen delivery to the tissue from arterial blood is unclear but is clinically significant.[18]

Because the symptoms associated with methemoglobinemia are related to impaired oxygen delivery to the tissues, concurrent diseases such as anemia, congestive heart failure, chronic obstructive pulmonary disease, and pneumonia may greatly increase the clinical effects of methemoglobinemia (Fig. 127–6). Predictions of symptoms and recommendations for therapy are based on methemoglobin percentage in previously healthy individuals with normal total hemoglobin concentrations.

Cyanosis is a consistent physical finding in patients with substantial methemoglobinemia and is caused by the deeply pigmented color of methemoglobin. Cyanosis typically occurs when just 1.5 g/dL of methemoglobin is present. This represents only 10% conversion of hemoglobin to methemoglobin if the baseline hemoglobin is 15 g/dL. In contrast, 5 g/dL of deoxyhemoglobin (which represents 33% of hemoglobin) is needed to produce the same degree of cyanosis from hypoxia.

In previously healthy individuals, methemoglobin levels of 10% to 20% usually result in cyanosis without apparent adverse clinical manifestations. At 20% to 50% methemoglobin levels, dizziness, fatigue, headache, and exertional dyspnea may develop. At about 50% methemoglobin, lethargy and stupor usually appear. The lethal percent probably is greater than 70% (Table 127–3).

The cyanosis associated with methemoglobinemia is both peripheral and central. Patients often appear in less distress or less ill than patients with cyanosis secondary to cardiopulmonary causes.

The symptoms of methemoglobinemia are determined not only by the absolute percent of methemoglobin but also by its rates of formation and elimination. A percentage of methemoglobin that may be clinically benign when caused by hereditary defects or maintained chronically likely will produce more severe signs when acutely acquired. Healthy subjects lack the compensatory mechanisms that develop over a lifetime in individuals with hereditary compromise, such as erythrocytosis and increased 2,3-bisphosphoglyceric acid (2,3 BPG).
FIGURE 127–6. Clinical manifestations of methemoglobinemia depend on the level of methemoglobin and on host factors such as preexisting disease, anemia, and hypoxemia. Five examples of arterial blood gas and co-oximeter analyses are presented. (**A**) Blood gas from a normal individual with 14 g/dL of hemoglobin. Almost all hemoglobin is saturated with oxygen. (**B**) Blood gas from a patient with cardiopulmonary disease producing cyanosis in which only 9 g/dL of hemoglobin is capable of oxygen transport. (**C**) Methemoglobin level of 28% in an otherwise normal individual will reduce hemoglobin available for oxygen transport to less than 9 g/dL (~4 g/dL of methemoglobin and 1.3 g/dL of high oxygen affinity hemoglobin because of the left shift of the oxyhemoglobin dissociation curve). (**D**) Same degree of methemoglobin as in C but in a patient with a hemoglobin of 10 g/dL. Only 6 g/dL of hemoglobin would be capable of oxygen transport. (**E**) Methemoglobinemia and anemia to the same degree as D but in a hypoxic patient.

TABLE 127–2. Common Causes of Methemoglobinemia

Hereditary

Hemoglobin M

Cytochrome b_5 reductase deficiency (homozygote and heterozygote)

Acquired

A. Medications

Amyl nitrite

Benzocaine

Dapsone

Lidocaine

Nitric oxide

Nitroglycerin

Nitroprusside

Phenazopyridine

Prilocaine

Quinones (chloroquine, primaquine)

Sulfonamides (sulfanilamide, sulfathiazide, sulfapyridine, sulfamethoxazole)

B. Other xenobiotics

Aniline dye derivatives (shoe dyes, marking inks)

Chlorobenzene

Fires (heat-induced denaturation)

Organic nitrites (eg, Isobutyl nitrite, butyl nitrite)

Naphthalene

Nitrates (eg, well water)

Nitrites (eg, foods)

Nitrophenol

Nitrous gases (seen in arc welders)

Silver nitrate

Trinitrotoluene

Pediatric

Reduced NADH methemoglobin reductase activity in infants (<4 months)

Associated with low birth weight, prematurity, dehydration, acidosis, diarrhea, and hyperchloremia

DIAGNOSTIC TESTING

For an individual in whom methemoglobinemia is suspected, a source for the oxidant stress should be sought. Arterial blood gas sampling may reveal blood with a characteristic chocolate brown color. However, in patients who are clinically stable and not in need of an arterial puncture, a venous blood gas will be accurate in demonstrating the methemoglobin level. The arterial PO_2 should be normal, reflecting the adequacy of pulmonary function to deliver dissolved oxygen to the blood. However, arterial PO_2 does not directly measure the hemoglobin oxygen saturation (SaO_2) or oxygen content of the blood. When the partial pressure of oxygen is known and oxyhemoglobin and deoxyhemoglobin are the only species of hemoglobin, oxygen saturation can be calculated accurately from the arterial blood gas. If, however, other hemoglobins are present, such as methemoglobin, sulfhemoglobin, or carboxyhemoglobin, then the fractional saturation of the different hemoglobin species must be determined by co-oximetry.

The co-oximeter is a spectrophotometer that identifies the absorptive characteristics of several hemoglobin species at different wavelengths. Because oxyhemoglobin, deoxyhemoglobin, methemoglobin, and carboxyhemoglobin all have different absorptions at the different measuring points of the co-oximeter, their proportions and concentrations can be determined. Some newer co-oximeters have an expanded spectrum at which they read and are also able to read fetal hemoglobin and sulfhemoglobin.[97]

The pulse oximeter applied to a patient's finger at the bedside was developed to estimate oxygen saturation trends in critically ill patients. The device takes advantage of the unique absorptive characteristics of oxyhemoglobin and deoxyhemoglobin and the different concentrations of these two hemoglobin species during different phases of the pulse. Each manufacturer has calibrated its oximeter using volunteers breathing progressively increasing hypoxic gas mixtures in the absence of a dyshemoglobinemia.[78,87,91] In other words, the oxygen saturation values displayed on the pulse oximeter are derived independently by each manufacturer, which develops a formula using their own hardware and sensor. The manufacturer then compares this value with a set of validation data derived from an experimental population.

Most pulse oximeters in use today use two different wavelengths to determine O_2, saturation and the manufactures do not provide validation data for situation where any dyshemoglobin is present. These manufactures disclaim accuracy under such circumstances. Similar to co-oximetry, the dual-wavelength pulse oximeter reads absorbance of light at wavelengths of 660 and 940 nm, which are selected to efficiently separate oxyhemoglobin and deoxyhemoglobin. However, methemoglobin absorption at these wavelengths is greater than that of either oxyhemoglobin or deoxyhemoglobin.[8,70] Therefore, when methemoglobin is present, the readings become inaccurate. The degree of inaccuracy is unique for each brand of instrument and may be influenced by signal quality, skin temperature, refractive error induced by blood cells, and other factors (eg, finger thickness and perfusion).[80]

In the dog model, the pulse oximeter oxygen saturation (SpO_2) values decrease with increasing methemoglobin levels. This decrease in SpO_2 is not exactly proportional to the percentage of methemoglobin. However, the pulse oximeter overestimates the level of actual oxygen saturation. For example, in a case in which the methemoglobin level measured in the blood using a co-oximeter was 20%, the pulse oximeter indicated an SpO_2 of 90%.[8,90] However, as the methemoglobin concentration approached 30%, the pulse oximeter saturation values decreased to about 85% and then leveled off, regardless of how much higher the methemoglobin level became.[8,90]

From our experience and that of others,[35,79] in humans, much lower levels of oxygen saturation (SpO_2) than 85% can occur by pulse oximetry when methemoglobin levels increase above 30%.[45] These differences result from variations in the way different model pulse oximeters deal with methemoglobin interference.[78,79] The clinician, therefore, must understand how the particular pulse oximeter measures oxygen saturation when methemoglobin levels are elevated and recognize that co-oximetry determination is needed when methemoglobinemia is suspected.

Although the pulse oximeter reading in patients with methemoglobinemia may not be as accurate as desired, it may be helpful when it is compared with that of the arterial blood gas: if there is a difference between the *measured* oxyhemoglobin saturation of the pulse oximeter (SaO_2) and the *calculated* oxyhemoglobin saturation of the arterial blood gas (SpO_2), then a "saturation gap" exists. The calculated SaO_2 of the blood gas will be greater than the measured SpO_2 if methemoglobin is present (Table 127–4).

Recently, a pulse oximeter has been developed that reads at eight different wavelengths. This pulse oximeter displays methemoglobin and carboxyhemoglogin. Validation experiments were performed using volunteers with varying degrees of methemoglobinemia.[7]

TABLE 127–3. Signs and Symptoms Typically Associated with Methemoglobin Levels in Healthy Patients with Normal Hemoglobin Concentrations

Methemoglobin Level (%)	Signs and Symptoms
1–3 (normal)	None
3–15	Possibly none
	Slate gray cutaneous coloration
	Pulse oximeter reads low SaO_2
15–20	Cyanosis
	Chocolate brown blood
20–50	Dyspnea
	Exercise intolerance
	Headache
	Fatigue
	Dizziness, syncope
	Weakness
50–70	Tachypnea
	Metabolic acidosis
	Dysrhythmias
	Seizures
	CNS depression
	Coma
>70	Grave hypoxic symptoms
	Death

MANAGEMENT

For most patients with mild methemoglobinemia of approximately 10%, no therapy is necessary other than withdrawal of the offending xenobiotic because reduction of the methemoglobin will occur by normal reconversion mechanisms (NADH methemoglobin reductase). However, in some patients, even small elevations of methemoglobin should be considered problematic because they suggest the individual is at a point where further oxidant stress may cause methemoglobin levels to increase. An individual receiving dapsone with a small elevation of methemoglobin level may be more susceptible to clinically significant methemoglobinemia if challenged with a benzocaine-containing anesthetic or an increase in dapsone dose. In the clinical setting, continued absorption, prolonged half-life, and toxic intermediate metabolites may prolong methemoglobinemia. Patients should be examined carefully for signs of physiologic stress related to decreased oxygen delivery to the tissue (Fig. 127–7). Obviously, changes in mental status or ischemic chest pain necessitate immediate treatment, but subtle changes in behavior or inattentiveness may be signs of global hypoxia and should be treated. Patients with abnormal vital signs tachycardia and tachypnea or an elevated lactate concentration thought to be caused by tissue hypoxia or the functional anemia of methemoglobinemia should be treated aggressively. An elevated methemoglobin level alone generally is not an adequate indication of need for therapy.

The most widely accepted treatment of methemoglobinemia is administration of one to two mg/kg body weight of methylene blue infused intravenously (IV) over 5 minutes. This is 0.1 to 0.2 mL/kg of 1% solution. The use of a slow 5-minute infusion helps prevent painful local responses

from rapid infusion. When a painful reaction occurs, it can be minimized by flushing the IV rapidly with a bolus of at least 15 to 30 mL of fluid after the infusion. Clinical improvement should be noted within minutes of methylene blue administration. If cyanosis has not disappeared within 1 hour of the infusion, a second dose should be given and other factors considered (see Fig. 127–7). Methylene blue causes a transient decrease in the pulse oximetry reading because its blue color has excellent absorbance at 660 mm.[54,60]

The use of methylene blue in patients with G-6-PD deficiency is controversial. Deficiency of this enzyme is an estimated 200 million people worldwide. Its incidence in the United States is highest among African Americans (11%),[9] among whom the disease has different degrees of severity. For this reason, G-6-PD–deficient patients have been excluded from most treatment protocols because methylene blue is a mild oxidant and case reports have suggested methylene blue's toxicity. However, because of the lack of immediate availability of G-6-PD testing, most patients who need treatment receive methylene blue therapy before their G-6-PD status is known. Although many patients with G-6-PD deficiency undoubtedly have been treated unknowingly, few case reports of toxicity have been described.

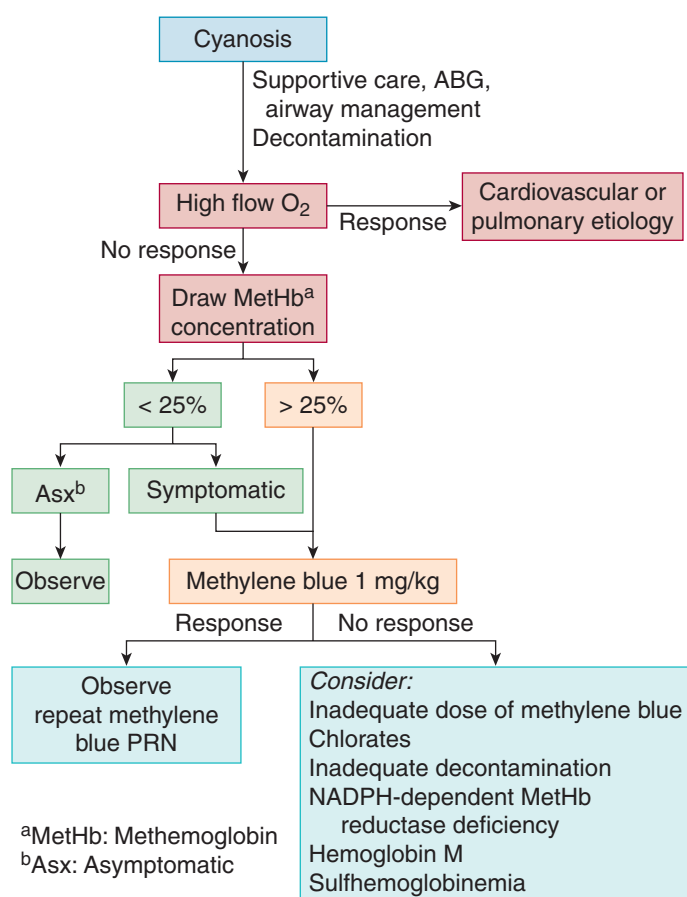
Even the authors of the review most frequently cited as a rationale for withholding methylene blue treatment were unsure whether the methylene blue given to their G-6-PD–deficient patient produced hemolysis[83]; the dose of methylene blue given to the patient was small, and the patient had taken other xenobiotics capable of producing hemolysis. Patients with G-6-PD deficiency have variable activity of the enzyme and manifest different degrees of disease in response to oxidant stress. For all of these reasons, the judicious use of methylene blue is warranted in most patients with G-6-PD deficiency and symptomatic methemoglobinemia.


FIGURE 127–7. Toxicologic assessment of a cyanotic patient.

aMetHb: Methemoglobin
bAsx: Asymptomatic

If methylene blue treatment fails to significantly relieve the methemoglobinemia, a number of possibilities should be considered. The cause of the oxidant stress may not have been identified and adequately removed, allowing for continuing oxidation. In such situations, decontamination of the gut and skin cleansing must be assured. Additional doses of methylene blue are also indicated. Patients who have sulfhemoglobinemia, or are deficient in NADPH methemoglobin reductase, may not improve after methylene blue therapy (see Antidotes in Depth A41: Methylene Blue).

Theoretically, exchange transfusion or hyperbaric oxygen (HBO) may be beneficial when methylene blue is ineffective. Both interventions are time consuming and costly, but HBO allows the dissolved oxygen time to protect the patient while endogenous methemoglobin reduction occurs. Ascorbic acid is not indicated in the management of acquired methemoglobinemia if methylene blue is unavailable because the rate at which ascorbic acid reduces methemoglobin is considerably slower than the rate of normal intrinsic mechanisms.[13] Methylene blue has no therapeutic benefit in the presence of sulfhemoglobinemia.[76]

Treatment with dapsone deserves special consideration because of its tendency to produce prolonged methemoglobinemia. *N*-hydroxylation of dapsone to its hydroxylamine metabolite by a cytochrome P450–mediated reaction is partly responsible for methemoglobin formation in both therapeutic and overdose situations. Both the parent compound and its metabolites are oxidants with long half-lives. Cimetidine is a competitive inhibitor in the cytochrome p450 metabolic pathway and reduces methemoglobin concentrations during therapeutic dosing because less dapsone will be metabolized by the route.[81] In overdose situations, cimetidine may exert some protective effects and should be used with methylene blue. When dapsone is therapeutically indicated but low levels of methemoglobin are found, cimetidine should be considered as a method for reducing oxidant stress.

SULFHEMOGLOBIN

Sulfhemoglobin is a hemoglobin variant in which a sulfur atom is incorporated into the heme molecule but is not attached to iron. The exact location of the sulfur atom in the porphyrin ring is unclear. Sulfhemoglobin is a darker pigment than methemoglobin, producing cyanosis when only 0.5 g/dL of blood is affected. The cyanosis produced is similar to that produced by methemoglobinemia. Sulfhemoglobin also reduces the oxygen saturation determined by the pulse oximeter[2,71] and is characterized in the laboratory by its spectrophotometric appearance and its lack of reaction when cyanide is added to the mixture. Cyanide does not react with sulfhemoglobin but does react with methemoglobin, forming cyanomethemoglobin, which has no adsorption at the spectrums tested. In contrast, the methemoglobin absorption peak will no longer be present after the addition of cyanide. Using conventional co-oximetry, sulfhemoglobin is misidentified as methemoglobin. However, the addition of cyanide to the blood sample eliminates the methemoglobin peak (through conversion to cyanomethemoglobin) but not the methemoglobin peak caused by sulfhemoglobin. This technique is not routinely done in the clinical laboratory, and the diagnosis often is made based on the patient's failure to improve with methylene blue.[2,56,62,71] In the laboratory, isoelectric focusing techniques further define sulfhemoglobin.

Sulfhemoglobin is an extremely stable compound that is eliminated only when red blood cells are removed naturally from circulation. Although the oxygen-carrying capacity of hemoglobin is reduced by sulfhemoglobinemia, unlike methemoglobinemia there is a decreased affinity for oxygen in the remaining "unaltered" hemoglobin. The oxyhemoglobin dissociation curve is shifted to the right (see Fig. 21-2). This makes oxygen more available to the tissues. This phenomenon reduces the clinical effect of sulfhemoglobin in the tissues.

Sulfhemoglobin can be produced experimentally in vitro by the action of hydrogen sulfide on hemoglobin and was produced in dogs fed elemental sulfur.[76] A number of xenobiotics induce sulfhemoglobin in humans, including acetanilid, phenacetin, nitrates, trinitrotoluene, and sulfur compounds. Most of the xenobiotics that produce methemoglobinemia have been reported in various degrees to produce sulfhemoglobinemia. Sulfhemoglobinemia is also recognized in individuals with chronic constipation and in those who abuse laxatives.[76]

Sulfhemoglobinemia usually requires no therapy other than withdrawal of the offending xenobiotic. It appears that patients come to the

TABLE 127–4. Hemoglobin Oxygenation Analysis

Measuring Device	Source	What is Measured?	How Are Data Expressed?	Benefits	Pitfalls	Insight
Blood gas analyzer	Blood	Partial pressure of dissolved oxygen in whole blood	PO_2	Also gives information about pH and PCO_2	Calculates SaO_2 from the partial pressure of oxygen in blood; inaccurate if forms of Hb other than OxyHb and DeoxyHb are present	An abnormal Hb form may exist if gap exists between ABG and pulse oximeter
Co-oximeter	Blood	Directly measures absorptive characteristics of oxyhemoglobin, deoxyhemoglobin, methemoglobin, and carboxyhemoglobin at different wavelength bands in whole blood	SaO_2, %MethHb, %CoHb, %OxyHb, %DeoxyHb	Directly measures hemoglobin species	Provides data on hemoglobin only; most instruments will not measure sulfhemoglobin, HbM, and some other forms of Hb	Most accurate method of determining the oxygen content of blood
Pulse oximeter	Monitor sensor on patient	Absorptive characteristics of oxyhemoglobin in pulsatile blood assuming the presence of only OxyHb and DeoxyHb in vivo	SpO_2	Moment-to-moment bedside data	Inaccurate data if interfering substances are present (methemoglobin, sulfhemoglobin, carboxyhemoglobin, methylene blue)	Maximum depression, 75%–85% regardless of how much methemoglobin is present

ABG, arterial blood gas; Hb, hemoglobin; HbM, hemoglobin M; SaO_2, hemoglobin oxygen saturation; SpO_2, pulse oximeter oxygen saturation.

attention of clinicians earlier because sulfhemoglobinemia produces more cyanosis than does methemoglobinemia. There is no antidote for sulfhemoglobinemia because it results from an irreversible chemical bond that occurs within the hemoglobin molecule. Exchange transfusion would lower the sulfhemoglobin concentration, but this approach usually is unnecessary.

SUMMARY

Oxidation of hemoglobin is a less common but rapidly treatable cause of cyanosis. In the absence of findings of cardiopulmonary disease, methemoglobinemia is likely the cause of cyanosis. The diagnosis is confirmed by evaluation of blood by co-oximetry. When treatment is clinically indicated, methylene blue is the treatment of choice. The source of oxidant stress should be sought and eliminated. Patients with low methemoglobin levels should be considered to be under oxidant stress and at risk for more serious methemoglobinemia if oxidant stressors persist or increase in their environment. Methemoglobinemia should be considered to be a disease state sometimes caused by an acute, overwhelming oxidant protective mechanism of the host by an oxidant or more commonly and importantly, as a final clinical manifestation of multiple oxidant stressors.

METHYLENE BLUE

Mary Ann Howland

Methylene blue is an extremely effective antidote for acquired methemoglobinemia. Methylene blue also has other actions, including inhibition of nitric oxide synthase and guanylyl cyclase, and inhibition of the generation of oxygen free radicals. These effects are offered as explanations of the beneficial effects of methylene blue in the hepatopulmonary syndrome, treatment of priapism, modulation of streptozocin-induced insulin deficiency, prevention and treatment of ifosfamide-induced encephalopathy, use in sepsis, treatment of refractory hypotension, and reduction of development of postsurgical peritoneal adhesions.[14,15,19,22,28,34,42,50]

HISTORY

Methylene blue was initially recommended as an intestinal and urinary antiseptic and subsequently recognized as a weak antimalarial.[18] In 1933, Williams and Challis successfully used methylene blue for treatment of aniline-induced methemoglobinemia.[54]

PHARMACOLOGY

Methylene blue is tetramethylthionine chloride,[18] a basic thiazin dye. Methylene blue is an oxidizing agent, which, in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) and NADPH methemoglobin reductase, is reduced to leukomethylene blue (see Fig. 127–4). Leukomethylene blue then becomes available to reduce methemoglobin to hemoglobin.[10,18,51] Reduction of methemoglobin via this NADPH pathway is limited under normal circumstances. However, in the presence of methylene blue, the role of the NADPH pathway is dramatically increased (four to five times in dogs) and becomes the most efficient means of methemoglobin reduction. This property makes methylene blue the treatment of choice for methemoglobinemia.

PHARMACOKINETICS

The pharmacokinetics of methylene blue were studied in animals and human volunteers following intravenous (IV) and oral administration of 100 mg.[10–12,35] Methylene blue exhibits complex pharmacokinetics consistent with extensive distribution into deep compartments, followed by a slower terminal elimination with a half-life of 5.25 hours. Peak concentrations after oral administration were reached in 1 to 2 hours, but were approximately 80 to 90 nmol/L, as opposed to 8000 to 9000 nmol/L following IV administration. The substantial differences in whole-blood concentrations achieved by these routes of administration can be attributed to extensive first-pass organ distribution into the intestinal wall and liver, following oral administration.[35] Total

urinary excretion at 24 hours accounts for 28.6% of the drug following IV administration versus 18.5% after oral administration. In both cases, one-third was in the leukomethylene blue form.

ADVERSE EFFECTS

Reports of the paradoxical induction of methemoglobinemia by methylene blue suggest an equilibrium between the direct oxidization of hemoglobin to methemoglobin by methylene blue and its ability (through the NADPH and NADPH-methemoglobin-reductase pathway, and leukomethylene blue production) to reduce methemoglobin to hemoglobin.[5,6] Methylene blue does not produce methemoglobin at doses of 1 to 2 mg/kg. The equilibrium seems to favor the reducing properties of methylene blue, unless excessively large doses of methylene blue are administered[4,17,53] or the NADPH methemoglobin reductase system is abnormal. This equilibrium constant may vary substantially, as 20 mg/kg IV in dogs and 65 mg/kg intraperitoneally in rats failed to produce methemoglobinemia.[45] In the earliest studies, 50 to 100 mL of a 1% concentration (500–1000 mg) of methylene blue was used intravenously in volunteers[30] and to treat patients with aniline dye-induced methemoglobinemia.[54] In these studies, methemoglobin levels, measured when symptoms were most pronounced, were approximately 1.0 g/dL (0.4%–8.3% of total hemoglobin), and unlikely to be solely responsible for the adverse effects demonstrated. Other consequential adverse effects included shortness of breath, tachypnea, chest discomfort, burning sensation of the mouth and stomach, initial bluish-tinged skin and mucous membranes, paresthesias, restlessness, apprehension, tremors, nausea and vomiting, dysuria, and excitation. Urine and vomitus make take on a blue color. These studies with limited evidence led to the recommendation to avoid doses greater than 7 mg/kg.

In high doses, methylene blue can induce an acute hemolytic anemia independent of the presence of methemoglobinemia.[17,27] In dose–response studies in glucose-6-phosphate dehydrogenase (G6PD)-deficient homozygous African American men, daily doses of 390 to 780 mg (5.5–11 mg/kg) of methylene blue produced hemolysis,[26] which was comparable with the results following exposure to 15 mg of primaquine base.[26] Because of the sensitivity of neonates (hemoglobin F [HbF] and diminished NADH reductase) to these risks, the smallest effective dose of methylene blue should be used.[21,25] Because oxidizing agents can independently induce Heinz body hemolytic anemia, the specific contribution of methylene blue often is difficult to elucidate.[25]

Since methylene blue is a dye it will alter pulse oximeter readings.[7] Large doses may interfere with the ability to detect a clinical decrease in cyanosis; therefore, repeat cooximeter measurements and arterial blood gas analysis should be used in conjunction with clinical findings to evaluate improvement.

Intraamniotic injection of methylene blue may result in a number of adverse effects, including infants born with skin dyed blue (with resultant inaccurate pulse oximetry readings),[43] methemoglobinemia, hemolysis, phototoxic skin reactions,[36] or intestinal obstruction.[7,9,24,27,29,32,38,48] One infant exposed in utero at 5.5 weeks was normal at birth.[24] An excessive dose of enterally administered methylene blue that subsequently leaked into the peritoneum of a premature neonate most likely was responsible for a hemolytic anemia appearing 3 days later.[1]

Methylene blue leads to a bluish-green discoloration of the urine and may cause dysuria.[37] Intravenous methylene blue is irritating and exceedingly painful. It may cause local tissue damage even in the absence of extravasation.[38] Subcutaneous and intrathecal administrations are contraindicated.[38]

Two recent reviews reveal an association between an encephalopathy and the use of methylene blue for localization of parathyroid tumors in women on serotonin reuptake inhibitors.[31,47] Five out of 132 patients in the first review developed one or more of the following: confusion, expressive aphasia, lethargy, and vertigo which lasted from 2 to 3 days. The second review detailed seven patients with signs and symptoms consistent with serotonin toxicity. It should be noted that these patients usually received 3 to 5 mg/kg of methylene blue as a continuous infusion over 1 hour. A subsequent in vitro study documented the ability of methylene blue to competitively bind to monoamine oxidase A (MAO_A), raising the possibility that methylene blue might interact with serotonergic xenobiotics by acting as a monamine oxidase inhibitor (MAOI).[39]

XENOBIOTIC-INDUCED METHEMOGLOBINEMIA

Sulfanilamide-induced methemoglobinemia was reversed by methylene blue doses of 1 to 2 mg/kg intravenously or 65 to 130 mg orally every 4 hours.[20,52] With these regimens, a very rapid fall in methemoglobin was accompanied by disappearance of cyanosis. Subsequent investigations confirmed the effectiveness and safety of IV doses of 1 to 2 mg/kg methylene blue in reversing the methemoglobinemia produced by sulfanilamide,[52] aniline dye,[13] silver nitrate, benzocaine, nitrites, phenazopyridine and among other xenobiotics.[46,49]

USE IN PATIENTS WITH GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Methylene blue is frequently hypothesized to be ineffective in reversing methemoglobinemia in patients with G6PD deficiency[41] because G6PD is essential for generation of NADPH (Chap. 24) and without NADPH, methylene blue cannot reduce methemoglobin. However, G6PD deficiency is an X-linked hereditary deficiency with more than 400 variants. The red cells containing the more common G6PD A⁻ variant found in 11% of African Americans retain 10% residual activity, mostly in younger erythrocytes and reticulocytes. In contrast, the enzyme is barely detectable in those of Mediterranean descent who have inherited the defect. Therefore, it is impossible to predict before the use of methylene blue who will or will not respond, and to what extent. Currently, it appears that most individuals have adequate G6PD and express deficiency states in relative terms. This variable expression of their deficiency allows an effective response to most oxidant stresses. In addition, in theory, normal cells might convert methylene blue to leukomethylene blue, which might diffuse into G6PD-deficient cells and effectively reduce methemoglobin to hemoglobin.[3]

Before it is assumed that G6PD deficiency is responsible for a continued elevation of methemoglobin levels despite administration of methylene blue, ongoing xenobiotic absorption and/or continued methemoglobin production must be excluded. On the other hand, when therapeutic doses of methylene blue fail to have an impact on the methemoglobin concentration, the possibility of G6PD deficiency should be considered, and further doses of methylene blue should not be administered because of the risk of methylene blue–induced hemolysis. In these cases, exchange transfusion and hyperbaric oxygen are potential alternatives for treating methemoglobinemia (Chap. 127).

DOSING

Methylene blue is indicated in patients with symptomatic methemoglobinemia. This usually occurs at methemoglobin levels greater than 20%, but may occur at lower levels in anemic patients or those with cardiovascular, pulmonary, or central nervous system compromise.

In most cases, doses of 1 to 2 mg/kg given intravenously over 5 minutes, followed immediately by a fluid flush of 15 to 30 mL to minimize local pain, is both effective and relatively safe. In neonates, 0.3 to 1 mg/kg doses often are effective.[16,23] The onset of action is rapid, and maximal effects usually occur within 30 minutes.

Repetitive dosing of methylene blue may be required in conjunction with efforts to decontaminate the gastrointestinal (GI) tract when there is continued absorption or slow elimination of the xenobiotic producing the methemoglobinemia, such as with dapsone.[44] Additionally, cimetidine is indicated to prevent further formation of the methemoglobin-inducing metabolite of dapsone.[8,40]

A continuous IV infusion of methylene blue at 0.1 mg/kg/h or 3 to 7 mg/h (in a concentration of 0.05% in 0.9% sodium chloride solution) also has been used.[2,44] However, this method of administration is not adequately studied.

Intraosseous administration of 0.3 mL of 1% solution (1 mg/kg) of methylene blue over 3 to 5 minutes into the anterior tibia of a 6-week-old infant was well tolerated.[21,33] Methylene blue is ineffective in treating sulfhemoglobinemia (Chap. 127).

AVAILABILITY

Methylene blue is available in 10-mL 1% ampules containing 10 mg/mL.

SUMMARY

Methylene blue is an effective reducing agent for patients with acquired induced methemoglobinemia. When used in the proper dose, its onset of action is rapid and adverse reactions are limited. Repeat doses often are required when methemoglobin-producing drugs with a long duration of effect such as dapsone are ingested.

CHAPTER 128
SMOKE INHALATION

Nathan Phillip Charlton and Mark A. Kirk

Smoke is generated as a result of thermal degradation of a material; it is a complex mixture of heated air, suspended solid and liquid particles (aerosols), gases, fumes, and vapors. Particulates and aerosols typically make these thermal degradation products visible to the naked eye, resulting in the black, acrid substance so often thought of as "smoke;" however, thermal decomposition also results in generation of gaseous substances that are invisible to the naked eye. The ever-growing variety of materials used in our environment contributes to the broad spectrum of products present in typical smoke.[30] The chemical composition of the parent materials, oxygen availability, and temperature at the time of decomposition determine the combustion products found in smoke (Table 128–1).[11,29,30,44,54,66,112,122,132,133,156] As a result of these variabilities, specific thermal degradation products resulting from a fire are difficult to predict; in fact, even the composition of smoke is quite variable within the same fire environment.[11,38,122]

Smoke inhalation is a complex medical syndrome involving diverse toxicologic injuries, making care of smoke-injured patients very challenging. Victims of smoke inhalation exhibit a spectrum of illness induced by tissue hypoxia. Importantly, smoke inhalation, not burns, is the leading cause of death from fires. However, cutaneous burns found concurrently with smoke inhalation complicate airway management and fluid resuscitation and increase infection risk. Consequently, burn victims with smoke inhalation injury have higher morbidity and mortality than those with burns alone.[41,148,154,158,171] Treatment of smoke inhalation should be aimed at correcting tissue hypoxia by maximizing oxygen delivery while avoiding unnecessary therapies that delay or hinder oxygenation.

HISTORY AND EPIDEMIOLOGY

Disastrous fires are frequent reminders of the role of inhalation injuries in fire deaths.[38,86] Throughout the United States, a fire department responds to a fire every 20 seconds.[79] In 2007, the National Fire Protection Agency reported 1,557,500 fire incidents in the United States, with 3430 fire deaths and 17,675 fire injuries.[79] A civilian fire death occurred every 153 minutes on average in 2007.[79] Compared with other countries, the United States has one of the highest fire death rates in the world.[99] An estimated 50% to 80% of these fire deaths result from smoke inhalation injuries rather than dermal burns or trauma.[17,67,112,173] More than 30% of patients hospitalized in burn units develop concomitant pulmonary complications, and 75% of these patients die.[70,155] World Health Organization data show that in developing countries, indoor smoke from heating and cooking fuel is one of the four most common causes of death and disease.[16]

Fire injuries may result from an array of inhaled toxic xenobiotics or thermal burns. Before 1942, toxic inhalation from dwelling fires was not considered in the pathophysiology of morbidity and mortality in fire victims. However, in that year, a fire at the Cocoanut Grove Night Club in Boston resulted in a number of fatalities in which victims had no cutaneous burns. This led to the observation that toxic gases are generated in typical structure fires and may result in significant pathology.[121] From 1955 to 1972, death from smoke inhalation injury

increased threefold and was attributed to abundant use of newer synthetic materials for building and furnishings.[17] Despite improved firefighting resources, mass casualties from smoke inhalation continue. On November 11, 2000, 170 deaths occurred when a cable train carrying skiers caught fire in a tunnel in Austria. Most of the victims apparently managed to escape the burning train but were killed by "acrid smoke" as they tried to flee.[3] A fire in a crowded Rhode Island nightclub on February 20, 2003, killed 100 people and injured more than 200 people, with the majority suffering from smoke inhalation.[37] On December 31, 2004, a fire at an Argentina night club killed 175 people and injured more than 700. Most of the victims died of smoke inhalation.[4] Forty-five women died in a fire on December 9, 2006, at a state-sponsored drug treatment facility in Moscow, Russia. The majority of these women were patients and were unable to escape the building because the windows had been barred. Most died from smoke inhalation.[5]

PATHOPHYSIOLOGY

Toxic combustion products are classified into three categories: simple asphyxiants, irritant toxins, and chemical asphyxiants (Table 124–2). Simple asphyxiants such as carbon dioxide exert a space-occupying effect; they simply displace oxygen.[38,44,151,171] In addition, combustion uses oxygen, potentially resulting in an oxygen-deprived environment (see Chap. 124).[38]

Irritant gases are chemically reactive compounds that exert a local effect on the respiratory tract, primarily through the production of any combination of acids, alkalis, or reactive oxygen species (ROS) (see Chap. 124). For example, high concentrations of acrolein are measured in air samples from fire environments and in the blood of fire victims.[2,95,163] Acrolein penetrates cell membranes easily because it is lipid soluble, injuring cells by denaturing intracellular proteins and nucleic acids.[55,173] Ammonia is generated when wool, silk, nylon, or synthetic resins are burned. It reacts with the mucosal moisture to produce the alkaline agent ammonium hydroxide.[31,90] Sulfur dioxide, an oxidation product of sulfur-containing material, is found in more than 50% of air samples from fires.[24] Sulfurous acid forms when sulfur dioxide reacts with the water of the respiratory mucosa. Hydrogen chloride, chlorine, and phosgene are formed from the thermal degradation of polyvinyl chloride (PVC), a plastic widely used in home and office furnishings, floor coverings, and electrical insulation.[18,20,38,44,97] In the presence of mucosal water, these combustion products generate damaging hydrogen chloride and ROS.[39] Phosgene produces delayed alveolar injury.[21] Isocyanates, combustion products generated from burning foam furniture padding, cause intense irritation of the upper and lower respiratory tracts.[128]

Thermal degradation of organic material produces finely divided carbonaceous particulate matter (soot) suspended in hot air and gases. These particles are not just composed of carbon; organic acids, aldehydes, heavy metals, and reactive chemicals such as sulfur dioxide, hydrogen chloride, chlorine, and phosgene are adsorbed to their surfaces.[24,44,71,97,151,171] Soot adheres to the mucosa of the airways, allowing adsorbed irritant xenobiotics to react with the mucosal surface moisture and often enhancing and prolonging exposure to irritants in a fire environment. The deposition of these particles in the respiratory tract depends on their size, with particles of 1 to 3 μm reaching the alveoli.[105] Experimental animals have markedly decreased lung injury when they are exposed to toxic gas from smoke that was filtered to remove particulates.[83] Irritant gases can also "piggyback" on aerosol droplets and alter the site of gas deposition.[68]

Water solubility is the most important chemical characteristic in determining the timing and anatomic level of respiratory tract injury. Highly water-soluble xenobiotics primarily injure the upper airway

TABLE 128–1. Common Materials and Their Thermal Degradation Xenobiotics

Material	Thermal Degradation Xenobiotics
Wool	Carbon monoxide, hydrogen chloride, phosgene, chlorine, cyanide, ammonia
Silk	Sulfur dioxide, hydrogen sulfide, ammonia, cyanide
Nylon	Ammonia, cyanide
Wood, cotton, paper	Carbon monoxide, acrolein, acetaldehyde, formaldehyde, acetic acid, formic acid, methane
Petroleum products	Carbon monoxide, acrolein, acetic acid, formic acid
Polystyrene	Styrene
Acrylic	Acrolein, hydrogen chloride, carbon monoxide
Plastics	Cyanide, hydrogen chloride, aldehydes, ammonia, nitrogen oxides, phosgene, chlorine
Polyvinyl chloride	Carbon monoxide, hydrogen chloride, phosgene, chlorine
Polyurethane	Cyanide, isocyanates
Melamine resins	Ammonia, cyanide
Rubber	Hydrogen sulfide, sulfur dioxide
Sulfur-containing material	Sulfur dioxide
Nitrogen-containing material	Cyanide, isocyanates, oxides of nitrogen
Fluorinated resins	Hydrogen fluoride
Fire-retardant materials	Hydrogen chloride, hydrogen bromide

by damaging mucosal cells, which subsequently release mediators of inflammation or ROS.[22,91,107,132] These xenobiotics deposit rapidly in the upper airway by combining with mucosal water and leaving little of the parent compound to travel farther down the airway. The rapidity with which these xenobiotics exert their effects provides a warning that the environment is unsafe and prompts escape. After more than

TABLE 128–2. Toxic Thermal Degradation Xenobiotics

Asphyxiants	Irritants
Simple	**High water solubility** (upper airway injury)
Carbon dioxide	Ammonia
Chemical	Hydrogen chloride
Carbon monoxide	Sulfur dioxide

a trivial exposure, the intense inflammatory response increases microvascular permeability and allows movement of fluid from the intravascular space into the tissues of the upper airway. The loosely attached underlying tissue of the supraglottic larynx may become markedly edematous, causing upper airway obstruction within minutes to hours.[74] The obstruction may progress such that the upper airway is completely occluded.[140] Xenobiotics with low water solubility react with the upper respiratory mucosa very slowly and do not elicit an escape response. These xenobiotics reach the distal lung parenchyma, where they react slowly to create a delayed toxic effect. Xenobiotics, such as chlorine, with intermediate water solubility are more likely to result in damage to both the upper and lower respiratory tracts. Other factors, such as concentration of the substance inhaled, duration of exposure, particle size, respiratory rate, absence of protective reflexes, and preexisting disease, influence the region of respiratory tract injury. For example, as the concentration of a highly water-soluble irritant gas increases, more chemical is presented to the lower airway, possibly leading to damage of the lower respiratory tract. In addition, patients with loss of consciousness may increase their exposure secondary to their loss of protective reflexes.

Damage to the tracheobronchial tree is mediated by many of the same mechanisms as those of the pharynx and hypopharynx. Inhaled particulates and toxic gases result in deposition of acids, alkalis, and oxidative agents. Direct thermal injury is less likely to occur secondary to the efficient cooling ability of the upper airways.[107] Injury to the tracheobronchial tree leads to an increase in airway resistance from mucosal edema, bronchoconstriction, and accumulation of intraluminal debris and airway secretions.[28,96,159] Increased tracheobronchial vascular permeability contributes to interstitial edema of the airways and increased airway resistance. Bronchoconstriction and subsequent wheezing are caused by a reflex response to toxic mucosal injury and a response to mediators of inflammation.[63,161] Damaged cells release chemotactic factors that stimulate production of an exudate rich in protein, including fibrin and inflammatory cells.[46,165] This injury eventually results in sloughing of the mucosa; sloughed epithelial cells and inflammatory cells combined with the exudate to create casts of the airways.[46] In victims of smoke inhalation, casts block both the small and large airways, increasing airway resistance and mechanically preventing passage of oxygen to the alveoli.[28,34,110,159,165]

Irritant xenobiotics that reach the alveoli injure the lung parenchyma.[116] Caustics, proteolytic enzymes, reactive free radicals, and mediators of inflammation all contribute to acute lung injury (ALI).[82,85,127,161,171] Pathophysiologic changes of ALI decrease lung compliance and bacterial defenses and lead to ventilation–perfusion mismatch with intrapulmonary shunting, increased extravascular lung water, and microvascular permeability.[28,56,161,165,169] Lung compliance is further decreased from atelectasis when toxic chemicals deactivate pulmonary surfactant.[28,116,124,165] In animals, patchy atelectasis occurs rapidly after smoke is inspired.[28,116,165] In addition, ventilation–perfusion mismatch occurs when pulmonary blood flow is diverted by hypoxia and vasoactive mediators of inflammation.[92,93,115,161] Xenobiotics cause additional injury by impairing mucociliary clearance, altering alveolar macrophage function, and impairing phagocytosis of bacteria, which all contribute to development of pulmonary infections and sepsis.[13,14,51,69,139] The combination of delayed toxic effects of some inhaled xenobiotics and slowly developing inflammatory response may explain the limited initial manifestations of parenchymal injury during the first 24 hours after smoke exposure.

Nitric oxide plays a significant role in the pathogenesis of smoke inhalation induced lung injury.[49,102,166] Combined smoke inhalation and burn injury results in an upregulation of inducible nitric oxide synthase (iNOS) mRNA synthesis in animal models and subsequently results

in increased activity of iNOS.[47,48,50,102,149] Elevation of nitric oxide may result in myocardial contractile dysfunction with subsequent hypotension.[149] It also appears to play a role in increased vascular permeability and resultant edema.[102] A possible mechanism is the formation of the highly reactive peroxynitrite ($ONOO^-$) radical from the combination of nitric oxide and ROS, which may lead to alveolar capillary membrane damage and subsequent ALI.[47,102] Inhibition of iNOS reduced lung injury in combined smoke inhalation and burn injury in an ovine model.[49]

Chemical asphyxiants exert their toxic effects at extrapulmonary sites. Incomplete combustion of organic materials generates carbon monoxide, which is considered the most common serious acute hazard to victims of smoke inhalation injury (see Chap. 124).[1,15,38,163,173] Carbon monoxide prevents oxygen from binding to hemoglobin, creating a functional anemia. It also hinders the release of oxygen at the tissues by shifting the oxyhemoglobin dissociation curve to the left. In addition, CO binds myoglobin in cardiac and skeletal muscle[25] and cytochrome oxidase in all tissues.[75] The combination of these features impairs oxygen utilization by the myocardium and contributes to myocardial dysfunction. Other mechanisms of toxicity include induction of oxidative stress and lipid peroxidation (see Chap. 124).[157] Cyanide is produced from combustion of organic nitrogen-containing products such as plastics, melamine resins, polyurethanes, wool, silk, nylon, nitrocellulose, polyacrylonitriles, synthetic rubber, and paper.[122] High concentrations of cyanide are measured in air samples from fires, and elevated blood cyanide concentrations occur in both fire survivors as well as those who die in fires.[6,10,11,28,38,65,78,146,147,153,167] Cyanide has at least an additive, if not synergistic, effect with carbon monoxide in smoke inhalation toxicity (see Chaps. 125 and 126).[10,104,119,130,133] Combustion of nitrogen-containing materials generate oxides of nitrogen, which are irritants and methemoglobin inducers (see Chap. 127).

Depending on the fuel, other combustion products are aerosolized and act by local irritation or systemic toxicity. Metal oxides, hydrocarbons, hydrogen fluoride, and hydrogen bromide may contribute to toxicity. Antimony, bromine, cadmium, chromium, cobalt, gold, iron, lead, and zinc often are recovered from air samples taken during fires and from soot removed from the surface of the trachea and bronchi of fire victims.[15,38] Fires at industrial sites, clandestine drug laboratories, transportation incidents, and natural disasters such as erupting volcanoes produce additional unique toxic inhalants.

CLINICAL MANIFESTATIONS

The primary clinical problem in smoke inhalation victims is respiratory compromise; therefore, clinical evaluation should specifically address this issue. Initially, patients may complain of mucous membrane, ocular, and pharyngeal irritation. They may have voice changes, and their speech may progressively worsen as the airway becomes increasingly edematous. Cough, chest tightness, and dyspnea are common. Stridor and acute respiratory arrest may develop. Patients may have difficulty managing their airway secretions, with expectoration of copious quantities of soot containing sputum. The oropharynx and nares may be erythematous, coated with soot, or have progressing edema. Visualization of the vocal cords by direct laryngoscopy is sometimes difficult secondary to soot accumulation, secretions, or edema. Conjunctival injection, corneal ulcerations, marked lacrimation, and blepharospasm may be noted on ophthalmologic examination.

Auscultation of the chest may reveal rhonchi, rales, and wheezing suggestive of ALI.[61] Bronchospasm may occur, particularly in patients with underlying reactive airway disease. Breath sounds, including wheezing, may become virtually inaudible in patients with severe bronchospasm. ALI is a common complication and is defined as diffuse alveolar filling of acute onset with hypoxemia but without left atrial hypertension.[12] The most severe manifestation of ALI is the acute respiratory distress syndrome (ARDS), which is defined based on the patient's ability to oxygenate at a given FiO_2 (see Chaps. 21 and 124).

Tachycardia and tachypnea may be pronounced, and hypotension may occur, with faint or no peripheral pulses noted.[149] Smoke inhalation victims may develop an altered mental status, including agitation, confusion, or coma. This is most likely attributable to hypoxia from either pulmonary compromise or cellular hypoxia.

DIAGNOSTIC TESTING

Because smoke inhalation injury causes pulmonary and airway damage, diagnostic studies should focus on assessing oxygenation and ventilation. Therefore, arterial blood gas (ABG) analysis, carboxyhemoglobin and methemoglobin concentrations, and chest radiography are the most important tests to obtain.

ABG analysis assesses both pulmonary function and blood pH. The presence of metabolic acidosis may be an early clue to tissue hypoxia or cyanide poisoning. Serial measurements of arterial oxygenation and alveolar ventilation are helpful in identifying hypoxemia or ventilatory failure. The accuracy of oxygen saturation measurement depends on the method used. Oxygen saturation calculated from ABG analysis may be unreliable in the setting of an elevated blood carbon monoxide concentration, but measured oxygen saturation determined by co-oximeter accurately reflects the percent saturation of hemoglobin. Transcutaneous measurement of oxygen saturation by pulse oximetry is unreliable in patients with smoke inhalation because the test overestimates oxygen saturation in the presence of carboxyhemoglobin.[8,45,118,164]

A carboxyhemoglobin concentration should be obtained for all smoke inhalation victims.[27,172] When using blood sampling, either arterial or venous samples can be used to accurately measure carboxyhemoglobin concentrations.[94,160] Noninvasive bedside pulse co-oximetry may be a rapid screening tool for the detection of carbon monoxide, and its use is becoming more prevalent in clinical practice.[131,152] The carboxyhemoglobin concentration alone is a poor predictor of the severity of smoke inhalation because a low or nondetectable concentration does not exclude the possibility of developing inhalation injury.[101,150] Rarely, elevated methemoglobin levels are reported in fire victims. Because methemoglobin can further reduce oxygen-carrying capacity and is part of standard co-oximetry measurement, methemoglobin concentrations, along with carboxyhemoglobin concentrations, should also be obtained in the initial laboratory evaluation.[72,144] Blood cyanide analysis is of little clinical use because results of analysis are not available for hours, and therapy should never await laboratory confirmation of the presence of cyanide. Accurate measurement depends on acquiring the sample soon after exposure because cyanide is rapidly eliminated from the blood.[10,80] A plasma lactate level greater than 10 mmol/L in the setting of smoke inhalation suggests cyanide poisoning and should be enough evidence to support empiric antidotal treatment of critically ill patients.[10,108]

A chest radiograph obtained early in the course of smoke inhalation is an insensitive indicator of pulmonary injury.[27,61,129,170] The most frequent abnormal findings on initial chest radiography are diffuse alveolar and interstitial changes, found in up to 34% of patients admitted to the intensive care unit (ICU) with smoke inhalation after dwelling fires followed by focal abnormalities
FIGURE 128–1. (**A**) to (**D**) Progression over 72 hours of diffuse alveolar and interstitial infiltrates representative of inhalation induced acute lung injury. *(Images contributed by the University of Virginia Medical Toxicology Fellowship Program.)*

in 12% of patients.[61] In one series, no significant differences in the duration of either ventilation or duration in the ICU stay were observed between smoke inhalation victims who exhibited abnormal findings on the first chest radiographic examination and those without any abnormalities.[61] Subtle findings within 24 hours of exposure include perivascular haziness, peribronchial cuffing, bronchial wall thickening, and subglottic edema.[87,155] Serial chest radiographs (Fig. 128–1) done after a baseline study are helpful in detecting pulmonary injury after smoke inhalation.[63] Widespread airway disease usually occurs more than 24 hours after inhalation injury and may represent ALI, aspiration, volume overload, infection, or cardiogenic pulmonary edema.[155] Computed tomography (CT) of the lungs appears to be a more sensitive modality than plain radiography for detecting early pulmonary injury after smoke inhalation.[81,126,137] However, no data are available to support improved patient outcomes when using this radiographic modality.

MANAGEMENT

From oxygen acquisition to cellular utilization, the final common pathophysiologic effect resulting from smoke's injury is hypoxia. Basic critical care strategies that optimize oxygen delivery and oxygen utilization take priority over other treatments. High-flow oxygen, preferably humidified, should accompany initial resuscitation and will begin to correct hypoxia induced by smoke inhalation. To aid in oxygen

delivery, hypotensive patients should have two large-bore intravenous (IV) lines placed and receive aggressive fluid resuscitation. Because smoke is a complex mixture of xenobiotics, it is recommended that treatments beyond basic critical care are focused on symptom-based therapy based on recognized toxidromes. Specific antidotes available for common xenobiotics found in smoke should be considered if they are relatively safe and their antidotal effects comply with this strategy. Because many of these treatments are empiric, the risks of treatment must be weighed against the potential benefits.

Critical airway compromise may be present upon the patient's arrival at the hospital, or it may develop subsequently.[35,62,140] A major pitfall in managing a patient with smoke inhalation is failing to appreciate the possibility of rapid deterioration. The history and physical findings help to determine significant smoke exposure and the potential for clinical deterioration. The clinical effects of smoke exposure and their appropriate treatment are described in Figure 128–2 .Upper airway patency must be rapidly established. When obvious oropharyngeal burns are observed, upper airway injury almost certainly is present, even if overt injuries are not visualized, and distal injury may be present and underestimated.[62] Direct evaluation of the upper airway, preferably with fiberoptic endoscopy, is essential for assessing patients at high risk for inhalation airway injury.[35,62,63,74] When evidence of upper airway injury exists, early endotracheal intubation should be performed under controlled circumstances. Other indications for early intubation include coma, stridor, and full-thickness circumferential neck burns.[9,62,63,140] Edema of injured tissue, including that of the airway, is worsened with massive fluid resuscitation in burned patients.[62,63,111,140] Therefore, early intubation may be necessary for patients with dermal burns undergoing aggressive fluid management.[62]

Pathophysiologic changes in the lung may cause progressive hypoxia over hours to days. Treatment of progressive respiratory failure includes mechanical ventilation, continuous positive airway pressure, positive end-expiratory pressure (PEEP), and vigorous clearing of pulmonary secretions.[113] Decreased lung compliance is common secondary to cast formation, tissue damage, and atelectasis.[46,103,113] Recommendations for limiting barotrauma in mechanically ventilated patients include using a low tidal volume (6–8 mL/kg), PEEP, and allowing permissive hypercapnia as necessary.[103] FiO_2 should be weaned to below 0.4 as rapidly as tolerated to limit oxygen toxicity.[103] Frequent airway suctioning, chest physiotherapy, and therapeutic bronchoscopy can clear inspissated secretions, plugs, and casts.[34,103,110] High-frequency percussive ventilation (HFPV) may be considered as an alternative to conventional forms of ventilation in patients with inhalational injury. Several studies have investigated the use of HFPV in ventilated patients with inhalational injury. Although limited, some evidence suggests that HFPV may decrease peak pulmonary pressures, limit barotrauma, decrease the incidence of pneumonia, and improve mortality.[32,58,103,136,143] Experimental treatment has examined percutaneous arteriovenous carbon dioxide removal, perfluorocarbons, inhaled nitric oxide, extracorporeal membrane oxygenation, instillation of natural surfactant into the lung, and deferoxamine–hetastarch complex for improving inhalation injury.[26,33,40,64,76,84,109,117,120,123,134,135] However, none of these modalities has been definitively proven to improve outcome.

The initial treatment of carbon monoxide poisoning consists of supplemental oxygen therapy. Oxygen can be administered by a high-flow tight-fitting mask, endotracheal tube, or hyperbaric oxygen therapy. Hyperbaric oxygen has been recommended as a modality for treatment in certain situations involving carbon monoxide exposure; however, smoke inhalation injury is much more complex than poisoning with carbon monoxide alone (eg, a furnace leak).[60] In victims of smoke inhalation, other clinical requirements, such as maintaining a secure airway and the need for additional resuscitative measures, should be taken to account when determining the appropriate therapy (see Chap. 125 and Antidotes in Depth A37: Hyperbaric Oxygen).

Cyanide poisoning should be suspected in seriously ill patients with smoke inhalation and metabolic acidosis with an elevated lactic acid level, particularly if the carboxyhemoglobin concentration is low.[53,138] Serum lactate concentrations at the time of hospital admission correlate closely with blood cyanide concentrations, with serum lactate concentrations of 10 mmol/L reported to be a sensitive indicator of cyanide toxicity.[10] Treatment of cyanide toxicity should be considered while other life support measures, including 100% oxygen therapy, are instituted.[10,104,119,130,132,147] Treatment options include supportive care alone, administration of all or part of the traditional cyanide antidote kit, or administration of hydroxocobalamin. The risks of antidote administration should be weighed against the benefits because patients have survived potentially lethal cyanide concentrations with simply oxygen therapy and supportive care[19,142] (see Chap. 126 and Antidotes in Depth A38: Sodium and Amyl Nitrite and A40: Hydroxocobalamin).

The amyl nitrite and sodium nitrite components of the classic cyanide antidote kit should be used with caution in victims of smoke inhalation. Amyl nitrite and sodium nitrite produce methemoglobinemia, which binds cyanide to form cyanmethemoglobin (see Chap. 126 and Antidotes in Depth A38: Sodium and Amyl Nitrite). Unfortunately, methemoglobin is a dysfunctional hemoglobin that is unable to carry oxygen. In addition, its presence increases the affinity of the remaining hemoglobin for oxygen, which prevents its release to the tissues.[36] Impairing oxygen-carrying capacity and oxygen delivery to tissues with nitrite-induced methemoglobinemia is a valid concern in the presence of tissue hypoxia from carboxyhemoglobinemia, lung injury, or other factors. Furthermore, rapid infusion of sodium nitrite may cause hypotension secondary to vasodilation.[57]

Inhaled β_2-adrenergic agonists are effective and considered first-line therapy for acute reversible bronchoconstriction resulting from asthma or chronic obstructive pulmonary disease. Pathophysiologic changes induced by irritant toxins in smoke are partially reversible, suggesting that β_2-adrenergic agonists improve airflow obstruction.[77,100] β_2-adrenergic agonists also possess antiinflammatory properties, partially through interaction with β receptors on immune cells.[98,168] β_2-adrenergic agonists may also enhance resolution of alveolar edema by modulating the flow of sodium and potassium across cell membranes.[98,168] Limited data in an ovine model suggest that nebulized albuterol may improve pulmonary function after smoke inhalation and burn injury.[125] Although human data on the efficacy of β_2-adrenergic agonists specifically in smoke inhalation injury are lacking, their role is well established in conditions with reversible brochoconstriction; animal studies[125,168] lend support for their use and the potential benefits greatly outweigh any risks.

Corticosteroids have been used after smoke inhalation in an attempt to limit inflammation and improve outcome. One argument for the use of corticosteroids is for the treatment of lung injury induced by oxides of nitrogen. Pulmonary sequelae, including bronchiolitis obliterans, are known to occur after significant exposure to oxides of nitrogen, which may be a prominent composition of smoke.[52,73,88] Although data regarding efficacy are limited, corticosteroids are often used in treatment of nitrogen oxide exposure in relation to industrial exposure and silo filler's disease to prevent bronchiolitis obliterans.[73,145] The mixed xenobiotic exposure from smoke inhalation appears to further complicate the outcome. One early rat study showed a trend toward reduced mortality in animals given supraphysiologic doses (25–100 mg/kg) of methylprednisolone; however, other tested steroids (hydrocortisone, dexamethasone, cortisone) failed to demonstrate similar improvement. Consequently, this study failed to effectively prove that steroids reduce mortality after rat exposure to white pine smoke.[43] Subsequent human studies have been quite limited in size and design. The results of these human studies have also failed to show an improvement in
Pathophysiology	Signs and symptoms	Management
A) Direct CNS toxic effects	Coma Hypoventilation	Oxygen; secure unprotected airway
B) Upper airway edema	Hypoxemia; respiratory distress Stridor Hoarse voice	Oxygen Direct visualization of vocal cords Endotracheal intubation
C) Bronchiolar airway obstruction Mucosal edema Intraluminal debris and casts Inspissated secretions Bronchospasm	Respiratory distress Hypoxemia Wheezes Cough Increased peak airway pressures	Oxygen Removal of debris and secretions Chest physiotherapy Frequent airway suctioning Therapeutic bronchoscopy Inhaled β-adrenergic agonists
D) Atelectasis Surfactant destruction Acute lung injury (ALI)	Respiratory distress Hypoxemia Crackles Chest radiographic changes	Oxygen Continuous positive airway pressure Mechanical ventilation Positive end−expiratory pressure
E) Impaired oxygen−carrying capacity (carbon monoxide or methemoglobinemia)	CNS depression or seizures Myocardial ischemia Dysrhythmias Metabolic acidosis	Oxygen Consider hyperbaric oxygen Consider methylene blue
F) Impaired oxygen use at tissues (cyanide, hydrogen sulfide, or carbon monoxide)	CNS depression or seizures Myocardial ischemia Dysrhythmias Metabolic acidosis	Oxygen Assure adequate tissue perfusion Consider treating suspected cyanide toxicity with cyanide antidote Consider hyperbaric oxygen

FIGURE 128–2. The final common pathway from all pathophysiologic changes that occur in smoke inhalation is hypoxia. All treatments should be focused on improving oxygen delivery and oxygen utilization.

clinical outcome and may trend toward worsening outcome.[23,89,114,141] Consequently, limited available literature does not support the use of corticosteroids for treatment of patients with smoke inhalation.

A significant amount of pulmonary injury after smoke inhalation is attributable to free radical damage. Smoke inhalation decreases systemic levels of the antioxidant vitamin E in sheep models.[162] Two animal models demonstrate a decrease in smoke inhalation induced pulmonary injury after treatment with nebulized vitamin E (α- and γ-tocopherol).[59,106] Nebulized heparin and *N*-acetylcysteine (NAC) are used by some centers to limit pulmonary toxicity. Heparin is a glycosaminoglycan with anticoagulant and antiinflammatory properties also occasionally used both topically and IV in burn treatment. Nebulized heparin combined with NAC appeared to attenuate lung injury in pediatric patients.[42] In an ovine model of combined cutaneous burn and smoke inhalation, nebulized heparin combined with recombinant human antithrombin reduced airway obstruction and improved gas exchange.[46] The mechanism is likely attributable to deceased airway inflammation and decreased fibrin deposition and, consequently, decreased cast formation in the airway.[46] Although limiting free radical damage appears to be a promising area of future research, human data are currently limited regarding each of these modalities, and all are considered experimental at this time. Victims from fires may have respiratory compromise and other pathology not directly related to smoke inhalation but rather from trauma or underlying medical problems. Trauma from falls or explosions must be suspected and treatment started simultaneously with treatment of burns and inhalation injury. Comatose patients should be considered to have other causes for their injuries and should receive naloxone, thiamine, and hypertonic dextrose as indicated. Inhaled xenobiotics, such as carbon monoxide, may directly cause altered mental status, but drug and ethanol intoxication contribute significantly to fire fatalities and injuries. Blood ethanol concentrations correlate with elevated concentrations of carbon monoxide and cyanide, implying that intoxication impairs escape and prolongs toxic smoke exposure.[7,15,112] Intracranial pathology should be considered and CT scans obtained as indicated.

Xenobiotics may injure the skin or mucous membranes in addition to the respiratory mucosa.[31] The duration of contact of a xenobiotic with tissue is an important factor in determining the extent of chemical injury to the skin and eyes. Rapid removal of soot from the skin or eyes may prevent continued injury. The eyes should be evaluated for corneal burns caused by thermal or irritant chemical injury. Patients with signs of ocular irritation should have their eyes irrigated. Dermal decontamination should be considered to prevent burns from toxin-laden soot adherent to the skin.

SUMMARY

Smoke inhalation continues to contribute significantly to the morbidity and mortality of fire victims. Clinicians caring for these patients must have a basic knowledge of the pathophysiology of smoke inhalation injury. Smoke inhalation is a complex syndrome involving diverse toxicologic injury. A spectrum of damage may occur, ranging from rapid upper airway occlusion to delayed ALI and ARDS. The end result of toxicity is tissue hypoxia. Goals of treatment should focus on maximizing oxygen delivery while avoiding unnecessary therapies that may hinder oxygenation. Early airway management should be implemented for patients with airway compromise. High-flow oxygen will help reverse tissue hypoxia, and fluid resuscitation should be instituted to improve cardiovascular status. Definitive therapies are available and should be considered in appropriate cases to help stabilize the patient. There are still many controversies regarding the care of these patients. Treatments are still evolving, and further research is warranted.

DISASTER PREPAREDNESS

CHAPTER 129

RISK ASSESSMENT AND RISK COMMUNICATION

Charles A. McKay

Certified Specialists in Poison Information (CSPIs) and clinical and medical toxicologists are confronted by a range of patient presentations daily. The spectrum ranges from an anxious parent with questions about a child's potentially toxic exposure, an urgent consultation for a critically ill patient in the emergency department or intensive care unit and media requests for information about environmental public health issues, and biopreparedness education. Toxicologists and CSPIs must establish rapport and provide information; instructions; and when appropriate, reassurance, typically by telephone or in short face-to-face interactions. For CSPIs, attribution of the patient's complaints to one or more potential exposures and ascertaining the true reason or concern behind a call are also difficult given the limited information and time and lack of visual clues that are usually available during a clinical evaluation. All of these situations require a knowledgeable, compassionate, and well-reasoned response. This chapter focuses on two particular components of this response: risk assessment and risk communication. These principles apply to both individual calls to poison control centers as well as interactions with the public and medical professionals in educational outreaches, occupational and environmental exposure evaluations, and supportive roles with other public health agencies, as in bioterrorism preparedness, environmental public health tracking programs, and research.

RISK ASSESSMENT

Risk assessment is the process of determining the likelihood of toxicity for an individual or group after a perceived exposure to some substance, generally referred to as a xenobiotic. It involves determining the nature and extent of the exposure (ie, xenobiotic, dose, duration, route) and its specific clinical effects, defining an exposure pathway, and assessing the likelihood of effects from a given situation. A published body of knowledge can be applied to some components of risk characterization or assessment. An overview and a number of tools can be accessed through the websites of the Environmental Protection Agency (EPA) and the Agency for Toxic Substance and Disease Registry (ATSDR) of the Centers for Disease Control and Prevention (CDC).[1,9] However, any given risk assessment is often based on incomplete information. This may include such features as uncertainty regarding the exposure xenobiotic or mixture, whether there has been an actual exposure or just proximity to the xenobiotic (completion of an exposure pathway), lack of the exact dose, or unpredictable features such as host factors (underlying medical conditions or genetic polymorphisms) that could modify the response to a potential exposure. Unfortunately, those conducting a risk assessment are affected by their own biases and assumptions in the interpretation of their results, as are the people to whom a risk assessment is communicated. The emotional response to being "poisoned" makes this process even more difficult.

A good example of the practical difficulties involved in a risk assessment is evident from a published description of mass psychogenic illness.[17] In this incident, many individuals at a school complained of odor-triggered symptoms that spread in a so-called "line of sight" transmission with no evident dose–response pattern. Extensive testing demonstrated the possibility of potential sources of exposure, such as dry floor drain traps, but identified no actual release. The extent of investigation of these events can be profound, highlighting the difficulty in appropriately applying potentially unlimited laboratory technology to a situation. Also, our ability to assess a "no-risk" situation is limited, as can be noted in the letters to the editor to this publication criticizing the methods or conclusions in this event and "subsequent and comparable" outbreaks.[4,15,22]

The response of individuals to uncertainty correlates with their affinity for one component of the negative data paradigm—"the absence of evidence of harm" versus "evidence of absence of harm." Both of these positions have at their core the continued evaluation of evidence as it becomes available, with subsequent refinement of a resulting risk assessment. Unfortunately, these potentially converging points on a spectrum of knowledge and research have been polarized in debate and policy as two opposing principles: the *Kehoe principle* and the *precautionary principle*. The Kehoe principle is best summarized as "prove something is harmful before excluding a product with known benefits because of concern about potential, unproven future adverse effects." A common example of the use of this principle is the continued marketing of a xenobiotic after another member of the class has been removed because of safety issues. More intense scrutiny may be indicated, but a class-wide medication recall without evidence of some level of harm by an individual therapeutic drug is very rare. This principle has been misused in the past to minimize known risks attributable to environmental lead pollution to delay removal of lead additives from gasoline.[24] Critics of the Kehoe principle have suggested that waiting for evidence of harm from a substance results in costly or irreparable damage.

The alternative position of the precautionary principle is often summarized as "where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason to postpone cost-effective measures to prevent environmental degradation."[20,28] Critics of the precautionary principle often cite the lack of attention paid to the "cost" component of the principle, complaining that devotees stifle economic growth and prosperity with unfounded fears rather than reasoned consideration of known data. This principle is commonly extended to potentially harmful situations other than the

---

TABLE 129–1. Components of Risk Assessment

Hazard Identification
Name and amount of suspected xenobiotic (or general use category if the xenobiotic is unknown)

Exposure Pathway
Proposed route of exposure
Consistency with the nature of the xenobiotic (eg, water-soluble liquid)

Modifying Factors
Environmental factors that would influence systemic availability of the xenobiotic
Patient characteristics (susceptibility or resistance factors), such as:
   Chronic medical conditions
   Possible xenobiotic–drug or other interactions
   Genetic polymorphisms in hepatic or other metabolic pathways

Toxicity Assessment
Compare and contrast organ effects expected from the particular xenobiotic with existing symptoms

---

environment. A common criticism of the precautionary principle is the degree to which alternative actions have been evaluated for safety. As an example, concern about thimerosal safety (as a vaccine preservative and source of ethylmercury exposure) in young children led many parents to forego childhood vaccinations. Vaccine manufacturers have removed the thimerosal preservative from most routine childhood vaccines. Although this process was accelerated by the theoretical—and ultimately unfounded—concerns regarding this source of mercury exposure in young children, the cost of delayed or omitted vaccination was a number of real and preventable infectious diseases, including hepatitis B.[5,6]

Although the Kehoe and precautionary principles originated as policy approaches to public health issues, they underlie the automatic or subconscious biases that each individual brings to his or her own personal risk assessment or tolerance. The response to uncertain situations is derived from one's framing of belief systems and assumptions about life, justice, and eternity.[3,10,13] These underlying world views should be explicitly recognized and addressed in a formal risk assessment. Table 129–1 lists components of a risk assessment.

DIFFERENTIATING PUBLIC HEALTH FROM INDIVIDUAL RISK ASSESSMENT

It is difficult to translate public health risk assessment done for populations by entities such as the EPA to the individual level. Simplistically, the iterative process of adjusting known noncancer adverse exposure outcome limits in an animal model (eg, lowest observed adverse effect level [LOAEL] or no observed effect level [NOEL]) to a safe level of exposure for all humans (including so-called "sensitive subpopulations") has been arbitrarily set at repetitive multiplicative factors of 10 for each of these extrapolations. These are called "uncertainty factors" and are used in the absence of specific information about human exposure to identify a conservative human "safe dose." This would be set at 0.001 times the animal model LOAEL, reflecting a 10-fold reduction in dose for extrapolation from LOAEL to NOEL, another 10-fold reduction for extrapolation from animal to human, and another 10-fold reduction for potentially "sensitive" human populations. These "uncertainty factors" are actually safety factors for the adverse effect of

interest. When individuals exceed these limits, they remain protected by very robust safety factors, and are not—as it is often portrayed—exposing themselves to a defined harm. An example of this is the dietary guidelines (also known as "fish health advisories") for fish consumption based on concern about exposure to methylmercury and polychlorinated biphenyls (PCBs). These dietary recommendations are based on epidemiologic studies that suggest subtle neuropsychiatric abnormalities in maternal–fetal pairs (in at least some populations) from levels of consumption 10 to 100 times that of the "usual" American diet. Clinical mercury toxicity requires still higher levels of consumption. Although it seems reasonable for pregnant women to limit their intake of certain high mercury-containing fish species, it is inappropriate to avoid fish and the nutrients contained therein because of a misplaced fear of mercury exposure. Furthermore, these risk assessments do not apply to nonpregnant women, children, or men, although they are often generalized to all humans.[2]

The public health modeling concept for cancer health effects risk assessment is even more complex and often misunderstood. In this setting, modeling assumes a linear, no-threshold carcinogenic effect from exposure to a given xenobiotic. Cancer risk from small exposures is extrapolated from data in cancer-prone animal models with exposures so large that they are only likely in the experimental setting. This experimental construct ignores incremental dosing of small amounts over a protracted period of time, and potential metabolic and self-repair mechanisms in the human. The "acceptable risk" in this setting is then taken as "one excess cancer in a population of 1,000,000 exposed individuals." Although a limitation of this model is explicit in the statement that this represents "a plausible upper bound estimate of risk at low dose where true risk may be lower, including zero,"[11] this important caveat is rarely communicated, resulting in the common response by individuals that "an extra cancer may be acceptable for you, but not when it is my child."

As this brief review of the principles of regulatory approaches to noncancer and cancer effects demonstrates, risk assessment is often imprecise. Risk characterization for the individual should avoid unfamiliar statistical concepts, aiming instead to communicate the likelihood of significant risk for the exposure actually experienced. The CDC has codified this approach for a community using such escalating terms as "no public health concern," "public health concern," "public health threat," and "immediate risk." Although there is debate about the general use of these terms in isolation (without explicit explanations), a similar approach with an individual could summarize the risk assessment using the terms "safe"; "don't expect any adverse effects"; "may be of concern—we will need to do some follow-up testing"; and "this might be (or is) a problem—let's do the following studies or treatments."

RISK COMMUNICATION

Risk communication is an exchange of facts and opinions to allow an individual or a group of individuals to make an informed decision regarding a course of action or treatment. Practically, risk communication is a way of translating incomplete knowledge in a manner such that individuals can achieve informed decision making. During a one-on-one interaction with a poisoned individual and his or her family or a caller to the poison center, there is a need to gain the fullest attention or cooperation of the individual. After this has occurred, the discussion is usually focused on the risks and benefits of various treatment options (eg, gastrointestinal decontamination) or possible diagnostic modalities (eg, observation versus neuroimaging versus antidote administration). The group dynamics of environmental exposure risk communication at a public meeting are very different.

TABLE 129–2. Principles of Risk Communication[7] and Applicability to the Poison Center

Principle	Applications
Accept and involve the individual as a partner.	The caller must be involved to obtain the best information possible.
Plan carefully and evaluate your efforts.	There is a very short time to establish rapport with the caller; do not increase the caller's anxiety by asking irrelevant questions or arguing.
	Monitor your tone; ask for repetition of key information or recommendations.
Listen to the individual's specific concerns.	Why did the person call? Was it for information, treatment recommendations, or reassurance? Make sure the underlying reason has been addressed.
Be honest, frank, and open.	If there is uncertainty or there are unknowns, indicate that uncertainty while providing a workable plan.
Work with other credible sources.	Involve medical toxicology backup and other consultants, particularly for questions regarding chronic exposure or effects.
Meet the needs of the media.	If calls involve media notification or contact, make sure the critical information is stated frequently, provide a human context, and avoid sensationalism.
Speak clearly and compassionately.	Remember that the caller was concerned enough to initiate the contact; make sure the call is completed with a clear plan; provide follow-up appropriate to the situation.

Federal agencies that interact with communities in "Superfund" sites (eg, the EPA and the ATSDR) have promulgated principles and practical recommendations for risk communication in this setting. Table 129–2 summarizes general principles of risk communication.

Although some of these recommendations are more applicable to longer-term deliberations and interactions, much of the individual communication done by the poison center and medical toxicologists succeeds or fails based on these same principles (see Table 129–2). Lacking the opportunity for repeated interactions over time to identify and discuss assumptions and biases, toxicologists need to establish credibility, listen to concerns and respond empathetically, admit areas of insufficient knowledge, and commit to follow-up interactions to effectively convey a risk characterization for an individual based on the available knowledge and experience. The scientific terms, rationale, and any extrapolation from modeling (eg, animal data or case series) should be conveyed in an understandable manner to show that appropriate safety factors are incorporated into areas of uncertainty as a risk-diminishing step. The patient or audience should leave the interaction with a clear understanding of the difference between a short-term risk of symptoms that will resolve or result in serious illness and the degree of certainty about the potential for a long-term consequence.

An example of poor risk communication can be found in the immediate aftermath of the World Trade Center disaster in September 2001. The mass rescue and recovery response was largely voluntary and heroic; however, inadequate attention was paid to the importance of respiratory protection against the heavy particulate and alkaline dust in the early hours after the towers collapsed. The high incidence and persistence of cough and other respiratory symptoms in responders has been attributed to this exposure. Communication of the real risk of respiratory symptoms to early responders would have emphasized the critical importance of appropriate use of personal protective equipment. This would have been balanced against the time-limited possibility of saving lives of those potentially trapped in largely inaccessible locations. Since 2001, a proliferation of other associations to World Trade Center dust exposure (including low birthweight) are reported, which are of doubtful validity.[29] Appropriate risk communication to people concerned about these reports should emphasize the important role of confounders, the investigational nature of the study hypothesis, and the lack of relevant risk to any given individual.

Effective risk communication must therefore address several questions. After the best information has been obtained about the identification of the xenobiotic and the nature of the exposure, the following must be conveyed:

- The likely **magnitude** of the risk. This includes information on the process by which the person would be exposed (ie, the exposure pathway), such as airborne inhalation or drinking water delivery via a contaminated plume in the ground water and dose–response, such as: "Does the reported exposure to a particular xenobiotic (amount and duration) approach the exposure amounts reported to cause symptoms?"

- The **urgency** of the risk must also be conveyed along with practical recommendations for simple actions consistent with the level of urgency.

- The **applicability** of a risk characterization might also need to be addressed. Are the animal data applicable to humans? Is the exposure something of concern for an individual?

- The **uncertainties** of the risk assessment. This could include a "worst-case scenario" approach to unknown exposures or uncertainties in the quantity of an absorbed dose. The need for continued observation or follow-up for clinical changes would be expressed here. Individual risk tolerance may vary greatly. The same information may be interpreted differently by risk-averse versus risk-tolerant people. A variety of comparisons or communication techniques may be used to provide an adequate characterization of risk.

- **Management options.** In addition to follow-up and repeated evaluations by a medical toxicologist, the range of choices, associated with their relative benefits or risks, would be presented to the individual or group of individuals. A summary recommendation or opinion from the presenter should emphasize specific steps people can take to decrease exposure or potential toxicity if indicated by the level of risk. This last step is important because uncertainty significantly impacts the ability of an individual to take appropriate action. People should not leave the meeting with the impression that "no one knows what is going on or what we should do."

APPLICATION OF RISK ASSESSMENT AND COMMUNICATION PRINCIPLES TO TOXICOLOGY

Although it has long been recognized that many home-initiated poison center calls concern nontoxic or minimally toxic xenobiotics ingested by children,[23] the frequent lack of documented ingestion raises the possibility of under-triage based on misplaced confidence

based on prior experience. It is generally assumed that the sheer volume of calls provides some reassurance regarding the accuracy of our risk assessment of these xenobiotics, but we should remain cautious in our interpretation of poison center data[5,16,25] (see Chap. 135). Moreover, even calls about nontoxic xenobiotics require communication between the caller and CSPI beyond simple substance identification. The importance of risk assessment and communication principles can be seen in the joint Position Statement on the Prehospital Management of "Minimally Toxic Substances" crafted by the American Association of Poison Control Centers (AAPCC), American Academy of Clinical Toxicology (AACT), and American College of Medical Toxicology (ACMT).[21] According to the position statement, for a CSPI to make a risk assessment that an exposure is benign or minimally toxic, the following characteristics must be true:

- "The information specialist has confidence in the accuracy of the history obtained and the ability to communicate effectively with the caller.
- "The information specialist has confidence in the identity of the product(s) or substance(s) and a reasonable estimation of the maximum amount involved in the exposure.
- "The risks of adverse reactions or expected effects are acceptable to both the information specialist and the caller based on available medical literature and clinical experience.
- "The exposure does not require a healthcare referral because the worst potential effects are benign and self-limited."[21]

The position statement further notes that patient disposition decisions can be altered by many additional factors, including intent, environment, presence of symptoms (possibly unrelated to the xenobiotic in question), and ongoing review of current recommendations in the face of more data. These points emphasize both the dependence of the CSPI on information derived from the caller and his or her confidence in the level of comprehension of the caller. The caller should understand that his or her exposed child is safe; the conversation with the toxicology experts should alleviate concern as the nature of the assessment process is explained to whatever degree is necessitated by the caller's risk tolerance.

In the case of a symptomatic patient or a hospital- or physician-initiated contact to a poison center or medical toxicologist, the caller should expect more than just xenobiotic-related information; he or she also expects knowledge and expertise that will provide reassurance or direction for improving the patient's health status. However, merely relaying information regarding the diagnosis, course, and predicted outcome is insufficient. There is often another underlying reason for the call. This could be anxiety, uncertainty, or misinformation established by an individual's previous experiences or knowledge base. A sense of guilt may underlie a parent's call for an inadvertent exposure occurring when a child was unsupervised. A physician may have had significant difficulties previously in the management of a poisoned patient. If these issues are not addressed, the caller may continue seeking reassurance by repeated calls to the poison control center or by seeking additional input from other sources, such as family, friends, primary physicians, other healthcare providers. Any variance in the information obtained from these sources may be construed as inconsistencies between supposed experts rather than differences in emphasis with regard to the same information, leading to further uncertainty for the caller. Of further concern, the Internet has become a common source of second opinion for healthcare. Although many sites are useful, there is no quality control or filter to sort good information from bad or even harmful advice.[12] Table 129–3 lists some barriers to effective risk assessment and communication.

TABLE 129–3. Factors That Affect Appropriate Risk Assessment and Effective Risk Communication

Nature of previous encounters with poison center or healthcare field

Lack of prior patient–healthcare provider relationship

Incomplete or inadequate response to a prior question

The provision of information contrary to "popular understanding" or media representation

Loss of credibility

Lack of appreciation of individual or cultural differences in the perception of risk or the applicability of data

Incomplete or limited comprehension of scientific or statistical principles

---

INTERPRETING PUBLIC HEALTH CONCERNS FOR THE INDIVIDUAL

CSPIs and medical toxicologists frequently encounter callers or individuals at community events or interact with the media regarding public health–related issues, such as heavy metal exposures involving mercury, lead, or arsenic or concerns about "toxic mold" and other environmental xenobiotics. Often these people are concerned that their symptoms or future health or family health may be adversely impacted by such exposures. Such supposed exposures are usually poorly documented, sometimes also driven by popular media descriptions or litigation, and the risk is virtually impossible to ascertain during a short telephone or personal interaction. In these situations, the individual is best served by referral to a primary care physician with toxicology consultation or directly to a medical toxicology clinic. In such a setting, the data and perceptions can be reviewed completely and a more appropriate risk assessment communicated. These interactions are very difficult because they are often emotionally and politically charged.

In general, the communication of and response to information depend on a preexisting world view and prevailing circumstances. The same possible outcome will be perceived as more or less severe depending on several factors other than the nature of the outcome itself. Several authors have characterized the perceived tolerance to different risks, stratified by features such as familiarity and personal control[10,27] (Table 129–4). The emotional response of individuals confronted with these risks is sometimes characterized as "outrage." One communications specialist has posited that "Risk = Hazard + Outrage."[26]

TABLE 129–4. Factors That Alter the Acceptability of Perceived Risk[10]

More Acceptable	Less Acceptable
Natural	Human-made
Associated with a trusted source	Not associated with a trusted source
Familiar	Unfamiliar
Voluntary	Involuntary
Potentially beneficial	Limited or absent potential benefit
Statistical (low harm likelihood)	Catastrophic (high harm likelihood)
Fairly distributed or shared by all	Unfairly distributed ("injustice")
Affects adults	Affects children

He characterizes situations in which there is a significant hazard but little outrage as requiring "precaution advocacy," essentially informing the relevant parties of the need for more action or involvement to reduce risk. On the other end of the spectrum is a situation with little hazard but significant outrage, which requires "outrage management" to address fear or anger that is dissociated from the actual hazard posed by the situation. Although not necessarily applicable to the initial "fight-or-flight" response to an emergency, these concepts are certainly applicable to the aftermath of these events. The greater the degree of familiarity with the particular exposure situation and the greater the voluntary nature of the exposure, the less fear or outrage will be expressed for a given adverse outcome, whether this is an appropriate response or not. Of note, although risk communicators use analogies to place exposures into a context familiar to their audience, one must be careful to avoid equating voluntary and involuntary risk assumption or equating those exposures or risks assumed by one segment of the population unequally. An example of this is the use of a smoking risk analogy for a nonsmoker versus for a smoker.

Risk communication has become very important in the setting of preparedness for terrorism. Although a great deal of attention and money have been directed to improvement of public health infrastructure, reporting and surveillance mechanisms, and response to perceived and actual terrorist acts, less attention has been directed to the process of communicating risk to the individual.[8,19] Although some countries practice public health emergency drills regularly, the United States has concentrated on development of organizational structures and lines of authority, with attention to the importance of outcome-based exercises only recently emphasized.

Maintaining a readiness for catastrophic terrorist events (or natural occurrences such as pandemic influenza) should use the same risk assessment and communication techniques that are appropriate for other urgent public health matters. Unfortunately, many factors affect the characterization of risk other than the facts. The importance of presentation or the role of the communicator's own biases are exemplified by these two composite articles describing the same events:

1. Unknown assailants have infiltrated the mail delivery system, resulting in severe illness and death of children, healthy adults, and elderly people throughout the country. The initial symptoms can be nonspecific but rapidly progress to death if treatment is not begun early. The medical community routinely fails to diagnose the conditions early, and the government has no system in place to detect this threat after it occurs. The long-ignored public health system is not prepared to deal with the huge burden of preventing illness in those who may have been or will be exposed. Anyone who receives regular mail may be at risk. Tens of thousands of our citizens are taking prophylactic antibiotics "just in case." If you receive any unusual packages or see collections of powder that do not have an obvious explanation, call the police. If you develop a fever, cough, chest pain, or unusual rash, which may not be painful, seek medical attention at once. Tune in to your local news station for more information on this burgeoning threat to our nation's security.

2. A small number of individuals in isolated exposure settings have developed illnesses after bioterrorism events. Most people have survived these exposures, particularly with early and proper medical care. The government has developed a case definition, and medical experts have disseminated information to assist the medical community and public in the early recognition of symptoms and signs that are consistent with this exposure. Prophylactic treatment within days of exposure of those in high-risk professions, such as mail handlers at major postal sorting facilities, prevents illness. Unfortunately, there have been a large number of hoaxes and false alarms about possible terrorist events and a lot of understandable

fear in the community about nonspecific symptoms. For more information, contact your local health department or use the CDC website: http://www.bt.cdc.gov/agent/anthrax/needtoknow.asp.

Both of these paragraphs describe the 2001 anthrax bioterrorism events within the United States during which a total of 22 people become ill of whom five died from anthrax exposure. The first communication suggests that everyone is at risk and the situation is dire; the communication in the second paragraph is that the risk is isolated (a single individual died who was not in what was recognized as an at-risk setting from the seven identified mailings) and there is a plan and process being developed to respond to the threat. Whereas the first is sensationalistic, imparting a helpless victim role to the reader, the second provides a framework in which to assess one's personal risk and access to sources of reliable information. Both types of reports were prevalent after the 2001 anthrax attacks. Which report seems more complete, accurate, or useful is determined by the assumptions and perspectives of the reader in addition to the message the author wishes to deliver or response desired. Some would say that communicating a high degree of risk is important to gain the attention of the reader and to ensure that no one ignores a warning. However, the lack of a risk perspective prevents the reader from placing this information in context with the myriad other risk communication messages conveyed on a daily basis. In general, risk communication messages that do not provide a context or comparison to generally familiar activities or risks are more prone to misinterpretation or misapplication. As biopreparedness moves from public health infrastructure development and surveillance improvement to planning and response drills, appropriate message development and risk communication to the public become increasingly important.

SUMMARY

High-quality risk assessment and effective risk communication are the hallmarks of a successful interaction between the public and poison centers and between a toxicologist and an individual patient, the media, or the public health community. Adherence to general principles include obtaining the best information possible regarding potential exposures and conveying in an understandable fashion as complete as possible a risk characterization of the hazard, likelihood of a completed exposure pathway (thus, the likelihood of an actual exposure), possible health effects, and treatment options. It is important to clarify the difference between public health standards and individual exposure risks, with an understanding of the many psychosocial issues that influence perception. Information should be provided in a context that allows the individual to prioritize his or her response based on a factual and balanced presentation with respect to his or her health literacy and health numeracy (ie, the ability of the listener to understand quantitative concepts and interpret data that relies on numbers).[14]

CHAPTER 130
HAZMAT INCIDENT RESPONSE

Bradley J. Kaufman

A hazardous material (hazmat) can be any xenobiotic (solid, liquid, or gas) with the potential to harm. Typically, we are most concerned about xenobiotics that can harm people, although a hazmat may only harm other living organisms, the environment, or property. Outside of the United States, hazardous materials are often referred to as *dangerous goods*.

A "hazmat incident" implies that there was an unplanned or uncontrolled release of or exposure to a hazardous material. Although there are no specific requirements for an event to be considered a hazmat incident, typically there will be the potential for many people or a large area to be affected; otherwise, all toxicologic exposures would fall into this category. Therefore, a hazmat incident falls within the larger disaster management framework within a community.

Hazardous materials include chemical, biologic, and radiologic xenobiotics. In fact, a single event could provide exposure to multiple xenobiotics. Complicating matters, the incident response required for chemical, biologic, or radiologic xenobiotics may differ substantially depending on many factors. For instance, an envelope containing a white powder suspicious for containing anthrax spores that is opened in an office might require decontamination of the exposed people and environment. However, the release of the same anthrax spores surreptitiously at multiple sites may not be recognized until days later because of the delayed onset of symptoms. Certainly, a very different emergency response would be required. Emergency managers and healthcare providers must consider all possibilities and adjust the incident response based on the specific xenobiotics involved. This chapter discusses the basic principles used for a confined and quickly identifiable hazmat incident.

In general, a hazmat incident response focuses on the care of patients exposed to xenobiotics in the prehospital setting, prepares for multiple casualties, and emphasizes patient decontamination while at the same time trying to prevent exposure and contamination of healthcare providers.

DISASTER MANAGEMENT AND RESPONSE

Disaster management has four phases: mitigation, planning, response, and recovery. *Mitigation* measures are plans and efforts that attempt to prevent or reduce the effects of a potential hazard from becoming a disaster or minimizing the effects of a disaster if it has already occurred. One example of a mitigation measure is to use a secure container to prevent leakage of a chemical that is to be stored. *Preparedness* requires the planning of actions to be taken when a disaster occurs, as well as the practicing with mock exercises of these actions. Pre-planning is critical to limit damage from an event, and numerous such hazmat incident response plans exist. The *recovery* phase occurs after the immediate needs and threats to human life are addressed in the response phase and entail the restoration of property, infrastructure, and the environment.

The *response* phase includes the mobilization of appropriate resources and the coordinated management of the incident. Hazmat incident response must include the containment of the xenobiotic followed by neutralization, removal, or both. Typically, such a response includes multiple trained professionals from various agencies, often including the emergency medical services (EMS), fire departments, police departments, environmental protection agencies, and other first responder emergency services personnel. In fact, major hazmat events, especially those considered purposeful or terrorist related, may have responders from multiple federal, state, and local agencies, each with equipment and vehicles, and hundreds of personnel at the scene. These events can be chaotic until control and coordination are achieved.

Initial disaster management is provided by local resources and agencies with progressive escalation to county, state, and federal agencies as necessary. The Federal Emergency Management Agency (FEMA) within the Department of Homeland Security is the lead federal agency for emergency management in the United States.

Medical providers are a necessary part of all hazmat incident responses because patient assessment and treatment are typically the highest priority. However, as with all mass casualty events, physicians and other healthcare providers, even those highly trained in emergency medicine, toxicology, or hazmat response, must not respond to the location of the event unless they are part of a planned response team that has been requested to respond to the incident. Unsolicited medical personnel at the scene of a hazmat incident, although well intentioned, may actually harm the coordinated response and lifesaving efforts.

Limiting the loss of life is dependent on all responding agencies and personnel working efficiently and effectively together. The coordination of federal, state, and local governments is mandated by a National Incident Management System (NIMS).[9] Interoperability and compatibility among on-scene assets is dictated by the Incident Command System (ICS), which consists of an organizational hierarchy and defines the necessary management components of the overall incident, including mechanisms necessary for controlling personnel, operations, communications, and so on.

The request for mobilization, management, and utilization of volunteer medical personnel at the scene of a disaster should be planned for in advance for those events that might benefit from these resources.[29] Unsolicited medical providers lack the communications equipment necessary to work within a multi-agency coordinated operation. They often function outside the organized ICS. They may lack or be unaware of the necessary personal protective equipment (PPE). The medical treatments they provide may lack the oversight and protections required for the provision of medical care. These environments are, by definition, hazardous, and freelance medical personnel may in turn become patients themselves, thereby adding to the burden of on-scene rescuers. Furthermore, although a patient affected by a specific hazardous material may have the same physical findings and treatment indications whether at the hazmat scene or at the hospital and although the same toxicologic principles apply, these differences in location often require variation to the medical decisions made and care provided. Typically, disaster plans incorporate the utilization of local medical assets such as hospitals and clinics. Therefore, communities are best served if medical providers respond to their respective institutions during an incident.

RESPONSE COMPONENTS

After the release of a hazardous material, there must be a notification to emergency response personnel. Typically, someone witnesses the incident itself, such as a motor vehicle collision in which a road trailer is breached, or some resultant effects of the release, such as a fire, and the individual then activates the emergency response system by calling 911. Alternatively, an established detector may activate an

emergency response to a hazmat incident even before there are easily observable results of the release.

The first responders may not be aware that an incident is hazmat related when responding. For instance, they may be assigned to respond to an unconscious patient, unaware that the cause of the medical emergency was a chemical exposure. Although every emergency response cannot be assumed to have a hazmat etiology, emergency responders must always remain vigilant for such situations.

Extensive knowledge, training, and judgment are required for all emergency personnel who respond to hazmat incidents. There are some basic paradigms followed for a hazmat response. Personnel should approach the scene from uphill and upwind if possible. They should not rush in to try to help patients because the rescuer may become an additional victim if exposed. It is important to establish a perimeter to secure the scene while evacuating those not contaminated, thereby preventing additional people from being exposed or contaminated. The identification of material, establishment of zones, wearing of PPE, decontamination, and medical management of patients are discussed later. Other considerations include hazmat resources available, the need for escalation to other emergency response agencies, weather conditions, terrain, whether the release is confined to a specific area or has potential for further dissemination, whether the release was intentional or unintentional, and the need for rapid rescue and evacuation of casualties.

■ IDENTIFICATION OF THE HAZMAT

If the identity of the xenobiotic(s) is known before arrival at the scene, research can begin while the responders are still en route with reviews of the physical, chemical, and toxicologic properties of the xenobiotic. If the xenobiotic is not known before arrival at the scene, efforts to obtain this information should begin as soon as safely possible.

The identification of the specific xenobiotic(s) involved is of highest priority because many of the response components depend on the properties and potential health effects of the xenobiotic itself. Whether the incident involves a transportation element such as a rail car or road trailer or is at a fixed location such as a factory or medical facility, all available information must be used toward material identification, including placards, container labels, shipping documents, material safety data sheets (MSDS), detector devices, knowledgeable persons at the scene, patient symptomatology, and even odors at the scene such as the rotten egg smell of hydrogen sulfide.

Because many hazardous materials are transported via rail car or road trailer, emergency response personnel must always maintain a high index of suspicion when responding to a transportation incident. In the United States, first responders are required to be familiar with the use of the *Emergency Response Guidebook*, which is an aid for quickly identifying the hazards of the material(s) involved in a transportation incident.[43]

Hazardous materials may be categorized in various ways, often grouped by their harm-causing property. For instance, hazmats may be radioactive, flammable, explosive, asphyxiating, pathogenic and biohazardous.

The substances most commonly encountered at hazmat incidents vary from one locale to another and are predominately determined by the major industries in a particular area.[46,47] For example, pesticides are the most commonly encountered class of hazardous materials in Fresno County, California, whose major industry is agribusiness.[47] Although most hazmat incidents involve only one hazardous material, more than one hazardous material may be encountered at a given incident. One study described 107 hazmat incidents involving a total of 156 materials.[47]

The vast majority of consequential hazmat incidents are caused by gases, vapors, or aerosols. In one study, four of the five most commonly encountered individual chemicals were ammonia, phosphine, sulfur oxides, and hydrogen sulfide.[8] The important implication for decontamination is that gases do not usually contaminate people secondarily because they do not adhere to patients. Therefore, patients exposed only to gases generally do not require skin decontamination to prevent secondary contamination, and much greater efficiency is possible in patient care at gas, vapor, and aerosol hazmat incidents. Inhalation is the most common route of exposure at hazmat incidents and was the route of exposure at 73% of the hazmat incidents, accounting for 76% of the exposed patients described in one study.[7,8]

Because the number of hazardous materials is so large, it is efficient to group hazardous materials according to their toxicological characteristics. Various classification systems have been devised. The International Hazard Classification System (IHCS) is the most commonly used system (Table 130–1).[43,46] Individual hazmat studies commonly use their own classification systems, emphasizing the toxicodynamic effects of hazardous materials such as systemic asphyxiants or highlighting individual chemicals such as ammonia or chlorine or general classes of chemicals such as acids, bases, or volatile organic compounds.[7,8]

TABLE 130–1. International Hazard Classification System

Class 1: Explosives
    Division 1.1: Mass explosion hazard
    Division 1.2: Projection hazard
    Division 1.3: Predominantly a fire hazard
    Division 1.4: No significant blast hazard
    Division 1.5: Very insensitive explosives
    Division 1.6: Extremely insensitive detonating articles

Class 2: Gases
    Division 2.1: Flammable gases
    Division 2.2: Nonflammable compressed gases
    Division 2.3: Poisonous gases
    Division 2.4: Corrosive gases (Canada)

Class 3: Flammable/combustible liquids

Class 4: Flammable solids
    Division 4.1: Flammable solid
    Division 4.2: Spontaneously combustible materials
    Division 4.3: Dangerous when wet materials

Class 5: Oxidizers and organic peroxides
    Division 5.1: Oxidizers
    Division 5.2: Organic peroxides

Class 6: Poisonous materials and infectious substances
    Division 6.1: Poison materials
    Division 6.2: Infectious substances

Class 7: Radioactive substances

Class 8: Corrosive materials

Class 9: Miscellaneous hazardous materials

Chemical Names and Numbers Chemical compounds may be known by several names, including the chemical, common, generic, or brand (proprietary) name.[4,5] A chemical may be the sole substance in a given hazardous material or one of several compounds in a mixture.

The Chemical Abstracts Service (CAS) of the American Chemical Society (ACS) numbers chemicals to overcome the confusion regarding multiple names for a single chemical. The CAS assigns a unique CAS registry number (CAS#) to atoms, molecules, and mixtures. For example, the CAS# of methanol is 67–56–1.[34,35] These numbers provide a unique identification for chemicals and a means for crosschecking chemical names. Identifying a chemical by name and CAS# is critical because one must be as specific as possible about the hazardous material in question. Trade or brand names can be misleading. The MSDS describing a product usually lists the chemical name, the CAS#, and the brand name.[28]

Vehicular Placarding: UN Numbers, NA Numbers, and PIN Substances in each hazard class of the IHCS (see Table 130-1) are assigned four-digit identification numbers, which are known as United Nations (UN), North American (NA), or Product Identification Numbers (PINs) and are displayed on characteristic vehicular placards. This system is used by the U.S. Department of Transportation in the *Emergency Response Guidebook*.[43] The IHCS assigns a chemical to a hazard class based on its most dangerous physical characteristic, such as explosiveness or flammability. Other potential hazards of an agent, such as its ability to cause cancer or birth defects, are not considered. This system provides very little guidance in treating poisonings caused by hazardous materials.

National Fire Protection Association 704 System for Fixed Facility Placarding Fixed facilities, such as hospitals and laboratories, use a placarding system that is different from the vehicular placarding system. The National Fire Protection Association (NFPA) 704 system is used at most fixed facilities.[30] The NFPA system uses a diamond-shaped sign that is divided into four color-coded quadrants; red, yellow, white, and blue. This system gives hazmat responders information about the flammability, reactivity, and health effects, as well as other information, such as the water reactivity, oxidizing activity, or radioactivity.

The red quadrant on top indicates flammability; the blue quadrant on the left indicates health hazard; the yellow quadrant on the right indicates reactivity; and the white quadrant on the bottom is for other information, such as OXY for an oxidizing product, W for a product that has unusual reactivity with water, and the standard radioactive symbol for radioactive substances.

Numbers in the red, blue, and yellow quadrants indicate the degree of hazard: numbers range from 0, which is minimal, to 4, which is severe, and indicate specific levels of hazard.

Similar to all placarding systems, this one also has limitations. It does not name the specific hazardous substances in the facility and gives no information about the quantities or locations of the materials.

United Nations Recognizing that the transport of chemicals often occurs internationally and that the labels and MSDS often have different information in different countries, the United Nations developed a chemical classification system in an attempt to harmonize an approach to classification and labeling. The Globally Harmonized System of Classification and Labelling of Chemicals (GHS) classifies substances and mixtures by their health, environmental, and physical hazards.

CHEMTREC is a service of the Chemical Manufacturers Association with regard to shippers, products, and manufacturers and CHEMTREC is available at 800–424–9300 or at http://www.chemtrec.org at no charge, 24 hours a day. Details of an incident are relayed to the shipper's or manufacturer's 24-hour emergency contact, and they, in turn, are linked to hazmat incident responders. Technical data are available on handling the substance(s) involved, including the physical characteristics, transportation, and disposal.

A regional poison center is another valuable source of information. Other information sources include local and state health departments, the American Conference of Governmental and Industrial Hygienists (ACGIH), Occupational Safety and Health Administration (OSHA), National Institutes of Occupational Safety and Health (NIOSH), Agency for Toxic Substances and Disease Registry (ASTDR), and Centers for Disease Control and Prevention (CDC).[1,2,3,34,35,37]

Exact identification is desirable but not always possible. Hazmat responders may be able to classify the hazardous material into one of several major toxicologic classes by identifying a hazmat toxidrome that allows them to reasonably treat the patients and protect themselves and others. For example, do patients have irritation of the mucous membranes and upper airway caused by a highly water-soluble irritant gas? Do the patients exhibit signs of asphyxia with major central nervous system (CNS) or cardiopulmonary signs and symptoms? Do patients exhibit signs of cholinergic excess caused by organic phosphorus compounds or carbamate poisoning? Do patients exhibit chemical burns compatible with corrosives? Do patients have the odor of solvents with signs of CNS depression and cardiac irritability compatible with exposure to hydrocarbons or halogenated hydrocarbons?

Also, even when the exact identity of the hazardous material is not known, what is usually known is the physical state of the material, that is, solid, liquid, or gas. Airborne xenobiotics potentially mean many more victims. Airborne xenobiotics include not only gases and vapors but also the liquid suspensions (fog and mists) and the solid suspensions (smoke, fumes, and dusts).

■ EXPOSURE AND CONTAMINATION

A person may have received an external *exposure* to a hazmat and may be at risk for the resultant health consequences even though he or she may not to be contaminated by the hazmat. For instance, a person may be temporarily irradiated by an exposure to a radioactive source. After exposure, a hazardous material may remain on a victim (external) or within a victim (internal). For instance, if radioactive materials (usually in the form of dust particles) are on the body surface or clothing (ie, contamination has occurred), then the person will continue to have exposure until decontamination occurs.

Primary contamination is contamination of people or equipment caused by direct contact with the initial release of a hazardous material by direct contact at its source of release. Primary contamination may occur whether the hazardous material is a solid, a liquid, or a gas. *Secondary contamination* is contamination of healthcare personnel or equipment caused by direct contact with a patient or equipment covered with adherent solids or liquids that have been removed from the source of the hazardous material spill.

The state of matter will help healthcare providers determine whether the hazardous material presents a significant risk of secondary contamination and whether decontamination of the skin and mucous membranes is necessary. Secondary contamination generally occurs only with solids or liquids. In general, patients or equipment covered with adherent solid or liquid hazardous materials, including chemical, biologic, or radiologic agents, should be decontaminated before transportation to prevent downstream contamination of healthcare providers and equipment. An exception to the principles of limited need for cutaneous decontamination for those exposed to gas is a patient whose sweaty skin was exposed to a highly water-soluble irritant gas such as ammonia that dissolves in sweat to produce corrosive ammonium hydroxide. In this case, the primary purpose of decontamination is to prevent or treat the patient's chemical burns caused by the caustic action of aqueous ammonium hydroxide on perspiring skin rather than

to prevent secondary contamination of rescuers. Aerosols are airborne xenobiotics that are not gases. Aerosols are suspensions of solids or liquids in air, such as solid dusts or liquid mists, that can cover victims with these adherent solids or liquids, which can effect secondary contamination. These patients do require decontamination to prevent secondary contamination.

Emergency personnel and equipment can become contaminated at hazmat incidents.[11,19,20,21,46,47,50] For example, in one study, contamination occurred to one ambulance that drove through a puddle of liquid organic phosphorus pesticides that had spilled from a crashed exterminator truck. This ambulance was responding to a call for a "motor vehicle crash."[47]

■ HAZMAT SITE OPERATIONS

Limiting dispersion of the hazardous material is critical to prevent further ill consequences. The physical state of a material determines how it will spread through the environment and gives clues to the potential route(s) of exposure for the material. Unless moved by physical means such as wind, ventilation systems, or people, solids will usually stay in one area. Solids can cause exposures by inhalation of dusts, by ingestion, or rarely by absorption through skin and mucous membranes. Solids that undergo sublimation, changing directly from a solid into a gas without passing through the liquid state, can give off vapors that may cause airborne exposure. Only two commonly encountered solids sublime, dry ice (CO_2) and naphthalene. A vapor is defined as a gaseous dispersion of the molecules of a substance that is normally a liquid or a solid at standard temperature and pressure (STP), that is, 32°F (0°C = 273°K) and 1 atm (760 torr = 760 mm Hg = 14.7 psi). Uncontained liquids will spread over surfaces and flow downhill. Liquids may evaporate, creating a vapor hazard.

The vapor pressure (VP) is useful to estimate whether enough of a solid or liquid will be released in the gaseous state to pose an inhalation risk. VP is defined essentially as the quantity of the gaseous state overlying an evaporating liquid or a subliming solid. The lower the VP, the less likely the xenobiotics will volatilize and generate a respirable gas. Conversely, the higher the VP of a chemical, the more likely it will volatilize or generate a respirable gas. Water has a VP of approximately 20 mm Hg at 70°F (21°C), and acetone has a VP of 250 mm Hg at the same temperature. Therefore, acetone evaporates more rapidly than water and poses more of an inhalation risk. Standard reference texts (eg, *NIOSH Pocket Guide to Chemical Hazards Merck Index*) list VPs for commonly encountered chemicals.[34,35,43]

Hazmat Scene Control Zones   Scene management is a fundamental feature at a hazmat incident. It is almost always necessary to isolate the scene, deny access to the public and the media, and limit access to emergency response personnel to prevent needless contamination. Three control zones are established around a scene and are described by "temperature," "color," or "explanatory terminology" (Table 130–2 and Fig. 130–1). NIOSH, the U.S. Environmental Protection Agency (EPA), and most U.S. prehospital and hospital healthcare professionals use the temperature terminology system.[35]

The hot zone is the area immediately surrounding a hazardous materials incident. It extends far enough to prevent the primary contamination of people and materials outside this zone. Primary contamination may occur to those who enter this zone. In general, evacuation—but no decontamination or patient care—is carried out in this zone, except for opening the airway and placing the patient on a backboard with spine precautions. This is because rescuers are generally hazmat technicians who wear level A or B suits that severely limit their visibility and dexterity. In specific situations, antidotes may be administered via autoinjectors (eg, nerve agent antidotes).

TABLE 130–2. The Nomenclatures of the Hazmat Control Zones

Temperature Terminology System[a]	Color Terminology System	Explanatory Terminology System
Hot zone	Red zone	Exclusion or restricted zone
Warm zone	Yellow zone	Decontamination or contamination reduction zone
Cold zone	Green zone	Support zone

[a]From the National Institutes of Occupational Safety and Health and the Environmental Protection Agency.

The warm zone is the area surrounding the hot zone and contains the decontamination or access corridor, where victims and the hazmat entry team members and their equipment are decontaminated. It includes two control points for the access corridor. Many consider initiating therapy at this stage, particularly for chemical weapons, events where multiple casualties are involved.

The cold zone is the area beyond the warm zone. Contaminated victims and hazmat responders should be decontaminated before entering this area from the warm zone. Equipment and personnel are not expected to become contaminated in this zone. This is the area in which resources are assembled to support the hazmat emergency response. The incident command center is usually located in the cold zone, and there is greater ability to provide patient care there. Care provided in this zone includes the primary survey and resuscitation with management of airway (with cervical spine control), breathing, circulation, disability, and exposure with evaluation for toxicity and trauma (ABCDE). Definitive care also includes antidotal treatment for specific poisonings.

■ PERSONAL PROTECTIVE EQUIPMENT

A critical goal of hazmat emergency responders is protecting themselves and the public. Safeguarding hazmat responders includes wearing appropriate PPE to prevent exposure to the hazard and prevent injury to the wearer from incorrect use of or malfunction of the PPE equipment.[25,36]

PPE can create significant health hazards, including loss of cooling by evaporation, heat stress, physical stress, psychological stress, impaired vision, impaired mobility, and impaired communication. Because of these risks, individuals involved in hazmat emergency response must be trained regarding the appropriate use, decontamination, maintenance, and storage of PPE. This training includes instruction regarding the risk of permeation, penetration, and degradation of PPE. PPE with a self-contained breathing apparatus (SCBA) has a fixed supply of air that significantly limits the amount of time the wearer can operate in the hot zone, usually about 20 minutes.

Levels of Protection   The EPA defines four levels of protection for PPE: levels A (highest) through D (lowest). The different levels of PPE are designed to provide a choice of PPE, depending on the hazards at a specific hazmat incident (Table 130–3).

Level A provides the highest level of both respiratory and skin (clothing) protection and provides vapor protection to the respiratory tract, mucous membranes, and skin. This level of PPE is airtight, fully encapsulating and the breathing apparatus must be worn under the suit.

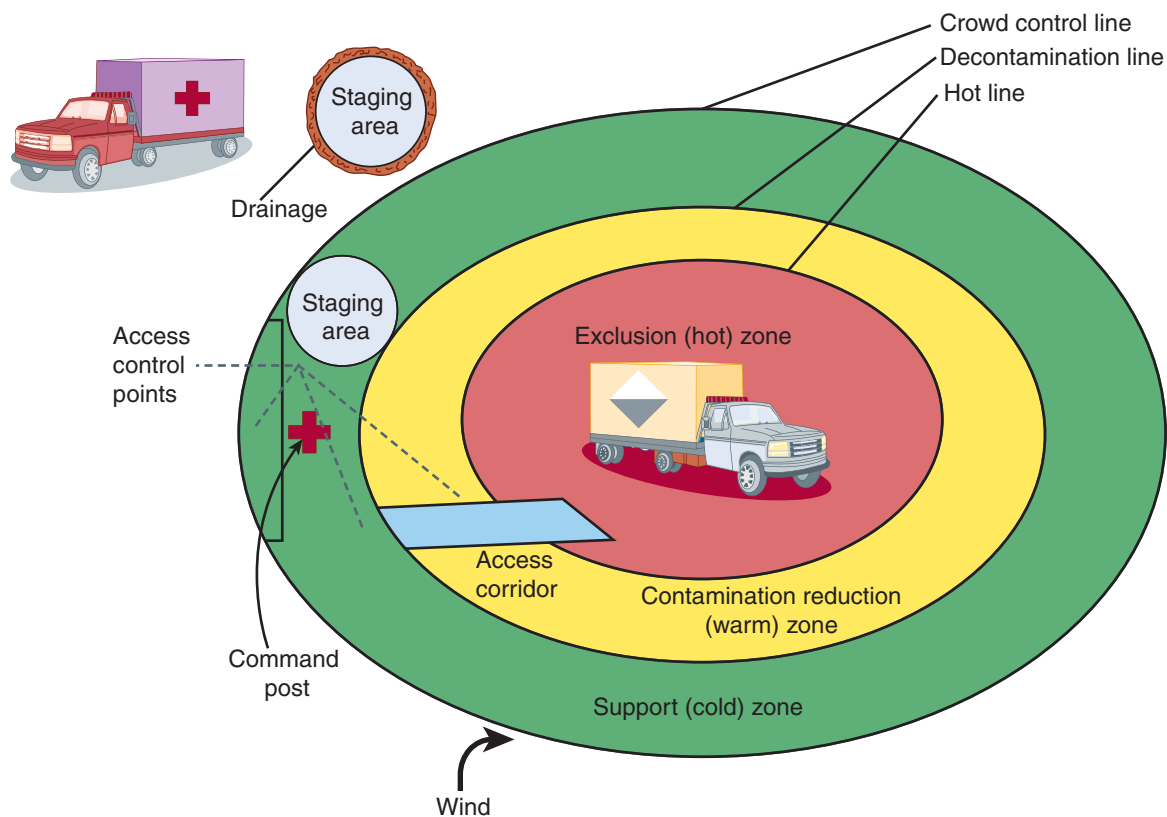
Level B provides the highest level of respiratory protection and skin splash protection by using chemical-resistant clothing. It does not


FIGURE 130–1. NIOSH/OSHA recommended control zones.

provide skin vapor protection but does provide respiratory tract vapor protection. Some hospitals have specially trained healthcare professionals who wear level B PPE when decontaminating patients presenting to the hospital. However, the majority of hospitals are training their frontline emergency department (ED) healthcare professionals to wear level C PPE when decontaminating contaminated patients who present to the hospital.

Level C protection should be used when the type of airborne substance is known, its concentration can be measured, the criteria for using air-purifying respirators are met, and skin and eye exposures are unlikely. Level C provides skin splash protection, the same as level B; however, level C has a lower level of respiratory protection than levels A and B.

Level D is basically a regular work uniform. It should not be worn when significant chemical respiratory or skin hazards exist. It provides no respiratory protection and minimal skin protection. Level D was specifically developed to show *what not to wear* for chemical protection.

Personal Protective Equipment Respiratory Protection Personnel must be fit tested before using any respirator. A tiny space between the edge of the respirator and the face of the hazmat responder could permit exposure to an airborne hazard. Contact lenses cannot be worn with any respiratory protective equipment. Corrective eyeglass lenses must be mounted inside the face mask of the PPE. The only exception to these general rules are the use of hooded level C powered air purifying respirators (PAPRs) that do not require fit testing and allow individuals to wear their own eyeglasses within the hooded PAPR. This is the reason that the majority of U.S. hospitals prefer hooded PAPRs for their ED personnel who must decontaminate patients.

Level A PPE mandates the use of a SCBA. An SCBA is composed of a face piece connected by a hose to a compressed air source. An open-circuit, positive-pressure SCBA is used most often in emergency response and provides clean air from a cylinder to the face piece of the wearer, who exhales into the atmosphere. Thus, a higher air pressure is maintained inside the face piece than outside. This affords the SCBA wearer the highest level of protection against airborne hazards because any leakage will force air out of the face piece and not allow airborne hazards to enter against the higher pressure within the face piece. Disadvantages of the SCBA include its bulkiness and heaviness and

TABLE 130–3. Personal Protective Equipment

Level[a]	Protects Skin and Eyes from:			Protects Respiratory System from:	
	Select Vapors and Aerosols	Gases, Vapors, and Aerosols	Oxygen-Deficient Atmospheres	Liquids and Solids	Gases and Vapors
D					
C	+			+	
B	+		+	+	+
A	+	+	+	+	+

[a]Level A is a self-contained breathing apparatus (SCBA) worn under a vapor-protective, fully encapsulated, airtight, chemical-resistant suit. Level B is a positive-pressure supplied-air respirator with an escape SCBA worn under a hooded, splash-protective, chemical-resistant suit. Level C is an air-purifying respirator worn with a hooded, splash-protective, chemical-resistant suit. Level D is regular work clothing (offers no protection).

a limited time period of respiratory protection because of the limited amount of air in the tank.

A supplied-air respirator (SAR) may be used in level B PPE and differs from SCBA in that air is supplied through a line that is connected to a source located away from the contaminated area. Only positive-pressure SARs are recommended for hazmat use. One major advantage of SARs over SCBA is that they allow an individual to work for a longer period. However, a hazmat worker must stay connected to the SAR and cannot leave the contaminated area by a different exit.

An air-purifying respirator (APR) may be used in level C PPE and allows breathing of ambient air after inhalation through a specific purifying canister or filter. There are three basic types of APRs: chemical cartridge, disposable, and powered air (PAPR). Although APRs afford the wearer increased mobility, they may be used only where there is sufficient oxygen in the ambient air. The chemical cartridges or canisters purify the air by filtration, adsorption, or absorption. Filters may also be used in combination with cartridges to provide increased protection from particulates such as asbestos.

■ DECONTAMINATION

A major goal of the initial hazmat response is the decontamination of contaminated victims. Not only might this reduce the health consequences for the victim (by reducing absorption or exposure time) but also prevents secondary contamination. Decontamination of equipment, the environment, and the entire area (ie, hot zone) may also be necessary but is secondary to the decontamination of victims.

An estimated 75% to 90% of contaminants may be removed simply by removing the victim's clothing and garments. Subsequent decontamination is most commonly accomplished by using water to copiously irrigate the skin of a victim, thereby physically washing off, diluting, or hydrolyzing the agent. However, the water solubility of a hazardous material must be considered to determine whether water alone is sufficient for skin decontamination or whether a detergent must also be used. The general rule regarding solubility is that "like dissolves like." In other words, a polar solvent, such as water, will dissolve polar substances such as salts. For example, the herbicide paraquat is actually a salt, paraquat dichloride, that is miscible in water. Therefore, if a patient's skin is contaminated with paraquat, copious water irrigation is sufficient for skin decontamination. A mild liquid detergent is acceptable but is not necessary. On the other hand, a nonpolar solvent, such as toluene, is not water soluble and is immiscible.[34,35] Therefore, if a patient's skin is contaminated with toluene, water irrigation alone may be insufficient for decontamination, and a mild liquid detergent is also necessary.[34,35] Furthermore, copious water may not be available at the site, thereby requiring rescuers to ration the supply and minimize irrigation using the least amount of water necessary. Some solid chemical contaminants may react with water and thereby cause an increased hazard if water used for decontamination. Such xenobiotics may be better removed mechanically by physically wiping it from the skin while avoiding smearing the agent or abrading the skin. Some contaminants may be chemically 'inactivated' by applying another chemical, such as a 0.5% hypochlorite solution.

When performing decontamination, close attention should be paid to all exposed skin, particularly, the skin folds, axillae, genital area, and feet. Lukewarm water should be used with gentle water pressure to reduce the risk of hypothermia. Water should be applied systematically from head to toe while the patient's airway is protected.

Exposed, symptomatic eyes should be continuously irrigated with water throughout the patient contact, including transport, if possible. Remember to check for and remove contact lenses.

Removal of internal contamination is often much more problematic. In some cases, specific medications may be administered to enhance elimination or inactivate the hazardous material. For instance, Prussian blue can trap radioactive cesium in the intestine so that it can be eliminated from the body in the stool rather than be reabsorbed.

HAZMAT INCIDENT RESPONSE RULES AND STANDARDS

OSHA and the NFPA have developed rules and guidelines, respectively, regarding hazmat incident response.[23,30,31,32,33,39,44] OSHA's rules are mandated as law and must be followed.[23,39,44] Meeting NFPA guidelines will ensure OSHA compliance.[23,30,31,33,36,39]

The Superfund Amendments and Reauthorization Act of 1986, known as SARA, required OSHA to develop and implement standards to protect employees responding to hazardous materials emergencies. This resulted in the *Hazardous Waste Operations and Emergency Response* standard, 29 CFR 1910.120, or HAZWOPER.[44]

NFPA 471, *Recommended Practice for Responding to Hazardous Materials Incidents*, outlines the following tactical objectives: incident response planning, communication procedures, response levels, site safety, control zones, PPE, incident mitigation, decontamination, and medical monitoring.[31]

NFPA 472, *Standard on Professional Competence of Responders to Hazardous Materials Incidents*, helps define the minimum skills, knowledge, and standards for training outlined in HAZWOPER for three types of responders.[32]

■ PREHOSPITAL HAZMAT EMERGENCY RESPONSE TEAM COMPOSITION, ORGANIZATION, AND RESPONSIBILITIES

First Responder at the Awareness Level   First responders at the awareness level could be first on the scene at an emergency incident involving hazardous material. They are expected to recognize the presence of hazardous materials, protect themselves, secure the area, and call for better trained personnel. They must take a safe position and keep other people from entering the area. They must recognize that the level of mitigation exceeds their training and call for a hazmat response team. Most basic curricula of emergency medical technicians (EMTs) include this level of first responder training.

First Responder at the Operational Level   These individuals are trained in all competencies of the awareness level and are additionally trained to protect nearby persons, the environment, and exposed property from the effects of hazmat releases. Operational-level certified individuals are expected to assume a defensive posture, control the release from a safe distance, and keep the hazardous material from spreading. Operational-level individuals are trained to perform absorption of liquids, containment of the spill, vapor suppression, and vapor dispersion. They do not operate within the hot zone.

Hazardous Materials Technician   Hazardous materials technicians respond to hazmat releases, or potential releases, for the purpose of controlling the release. They are trained in the use of chemical-resistant suits, air-monitoring equipment, mitigation techniques, and the interpretation of physical properties of hazardous materials. Technicians are capable of containing an incident, making safe entry into a hazardous environment, determining the appropriate course of action, victim rescue, and cleaning up or neutralizing the incident to return the property to a safe and usable status, if possible. These individuals are trained to operate within the hot zone to mitigate the incident. This certification level includes knowledge of hazardous material chemistry, air-monitoring equipment, tools used within the hot zone, and more.

■ ADVANCED HAZMAT COMPONENTS

Advanced Hazmat Providers Paramedics should be trained in the recognition of signs and symptoms caused by exposure to hazardous materials and the delivery of antidotal therapy to victims of hazmat poisonings.[23]

The inclusion of such training into a department's hazmat response team is beneficial, not only for the needs of the public but also to protect hazmat technicians who make entry into hazardous atmospheres.[23] Ideally, hazmat technicians' entry into hazardous atmospheres should not be performed until appropriately trained paramedics are on the scene with resuscitative equipment in place, including a drug box containing essential antidotes for specific hazardous materials.[23]

Patient Care Responsibilities of the Prehospital Decontamination Team and the Hazmat Entry Team Hazmat responders should identify the entry and exit areas by controlling points for the access corridor (decontamination corridor) from the hot zone, through the warm zone, to the cold zone (see Fig. 130–1). This corridor should be upwind, uphill, and upstream from the hot zone, if possible. Hazmat technician entry team members should remove victims from the contaminated hot zone and deliver patients to the inner control point of the access (decontamination) corridor. Hazmat decontamination team members decontaminate patients in the decontamination (access) corridor of the contamination reduction (warm) zone.[10,13,17,18,23,26,27,41]

The primary responsibility of the prehospital hazmat medical sector is the protection of the hazmat entry team personnel. This is accomplished by researching and recording clinically pertinent information about the hazardous material, remaining available on scene for medical treatment, and assessing individuals before entry into and on exit from a hazardous environment.[23] Documentation of each assessment should be recorded on a prepared form and compared with the exclusion criteria defined by NFPA 471.[23,31]

In some systems, the hazmat entry team may include specialized providers who have the ability to provide lifesaving patient care within the hot zone. The ability to perform triage or cardiopulmonary resuscitation or to provide any medical care is greatly limited by the PPE being worn. Therefore, only immediately lifesaving procedures should be considered, such as intubation/ventilation or antidote administration using an autoinjector.

Patient Care Responsibilities of Emergency Medical Services Providers at Hazmat Incidents EMS providers who are not part of the hazmat team should report to the incident staging area and await direction from the incident commander. They should approach the site from upwind, uphill, and upstream, if possible.

EMS providers should remain in the cold zone until properly protected hazmat incident responders arrive, decontaminate, and deliver patients to them for further triage and treatment. Then EMS providers should evaluate each patient, triage as appropriate, and move the patient to the appropriate casualty collection point or rapidly transport to the hospital as resources allow. Exposed victims who are initially asymptomatic should continue to be observed and reassessed for the delayed development of symptoms, and the EMS provider should be prepared to upgrade the triage category for the patient. All EMS systems should have protocols in place that direct operations at hazmat scenes. Ideally, the EMS response matrix for such events includes the response of an EMS physician or contact with online medical control, who will coordinate appropriate care with the regional poison center, toxicologists, and hospitals.

Transportation of patients from the hazmat incident is ultimately under the control of the incident commander but is usually delegated to the prehospital hazmat medical sector and EMS providers. In general, no victim with skin contamination should be transported from the hazmat site without being properly decontaminated. Before transportation, EMS should notify the receiving hospital of the number of victims being transported and their toxicologic history, patient assessments, and treatment rendered.

■ HOSPITAL RESPONSIBILITIES FOR HAZMAT VICTIMS

Ideally, the local or regional ED physicians and personnel will receive advanced notification about a hazmat incident before any victims arrive at the hospital. This notification to the hospital should occur as early in the event as possible to allow for maximum "ramp-up" time. The notification should include, if known, information regarding the event, hazmat involved, number and condition of casualties to be transported to the hospital, as well as information regarding the decontamination completed.

Victims may leave an incident scene on their own and subsequently present to a hospital. The hospital must have a preestablished protocol by which hospital response teams will decontaminate patients who arrive at the hospital if they have not been previously decontaminated or if field decontamination is believed to be insufficient.[6,14,15,16,22,24,38,40,42,45,48,49] Hazmat patients who require skin decontamination should be denied entry to the ED until they are decontaminated by an appropriately trained and equipped hazmat response team. The emergency physician will determine when the patient is safe to enter the ED after carefully assessing the risks and benefits to the decontaminated patient, the other patients in the ED, and the ED healthcare personnel.

SUMMARY

Hazmat incident response is an integrated, interdisciplinary approach involving prehospital, hospital, poison center, and public health professionals. Most patients at hazmat incidents are exposed through inhalation of a gas, a solid, or a liquid aerosol. Prehospital and hospital healthcare professionals must use appropriate PPE when caring for patients who have not been decontaminated. Decontamination is critical to alter absorption for patients and to prevent secondary contamination of downstream healthcare providers and equipment.

The general principles of toxicology apply regardless of whether a patient is at a hazmat incident in a prehospital or hospital setting. Although patient care resources vary among these treatment settings, the fundamental principles of patient care remain the same. All patients should receive a primary survey and resuscitation, emphasizing airway, breathing, and circulation.

CHAPTER 131
CHEMICAL WEAPONS

Jeffrey R. Suchard

Recent years have witnessed an enormous resurgence of interest in chemical and biological weapons (CBW). Although "unconventional" warfare with chemical and biological agents has been practiced since antiquity, it was not until the 20th century that such weapons were manufactured and used on a mass scale. In addition to battlefield use, chemical weapons may appeal to terrorist groups, in that the technology and financial outlay required to produce them is much less than for nuclear weapons, although the potential morbidity, mortality, and societal impact remain high (Table 131–1).

Chemical weapons clearly fall within the purview of medical toxicology. Indeed, unlike the many drugs and chemicals widely studied by toxicologists that may incidentally cause poisonings, these compounds were specifically designed to kill, injure, or incapacitate. Some compounds generally considered nonlethal, such as tear gas and pepper spray, are therefore also considered chemical weapons. Biological warfare agents share some characteristics with chemical agents (Table 131–2) and are covered in Chap. 132, although the issues common to both chemical and biological weapons are discussed in this chapter.

This chapter focuses on the acute and long-term clinical effects of exposure to chemical weapons, their mechanisms of toxicity, and the medical treatment of individual casualties, based on published human case experience. There are many other potential subtopics related to chemical (and biological) weapons that are not specifically reviewed here, including disaster incident command (see Hazmat Incident Response, Chap. 130), CBW agent detection, provision of medical care in a chemically contaminated environment, and the ever-growing body of evidence accumulated from in vitro and ex vivo models of chemical warfare agent poisoning.

HISTORY

The first well-documented intentional use of chemicals as weapons occurred in 423 B.C. when Spartans besieging Athenian cities burned pitch-soaked wood and brimstone to produce sulfurous clouds.[88] Chemical weapons were sporadically used, or their use considered, up through the 19th century.[49]

Large-scale chemical warfare began in World War I when the Germans released chlorine near Ypres, Belgium killing hundreds and forcing 15,000 troops to retreat.[20,49] Both sides rapidly escalated the use of toxic gases, released from cylinders or by artillery shells that included various pulmonary irritants, lacrimators, arsenicals, and cyanides.

The Germans first used sulfur mustard in 1917, again near Ypres, and caused over 20,000 deaths or injuries.[49] Unlike prior war gases, mustard was persistent in the environment and vesicated the skin in addition to injuring the lungs and mucous membranes. The Allies soon responded in kind. Sulfur mustard was unequaled in its ability to incapacitate opponents.[9] Injuries far outweighed fatalities, tying up manpower and resources to care for the wounded. By the end of the war, chemical weapons had caused over 1.3 million casualties and approximately 90,000 deaths.[20]

Only one major chemical weapon event occurred during World War II when German planes bombed American ships carrying chemical munitions in Bari, Italy releasing the contents of 2000 mustard bombs and causing over 600 Allied military and an unknown number of civilian casualties.[9,49]

Germany began producing nerve agents just before World War II. Tabun was developed in 1936 by Gerhard Schrader when conducting insecticide research for IG Farbenindustrie,[30,77] but was abandoned as an insecticide because of its overwhelming human toxicity. Sarin was synthesized in 1938, and named after its developers: *S*chrader, *A*mbrose, *R*udringer, and Van der L*in*de.[30] Between 10,000 and 30,000 tons of tabun and 5–10 tons of sarin were produced during World War II. Soman was synthesized in 1944, but no large-scale production facilities were developed. When the Allies discovered these nerve agents at the end of the war, code names were designated based on the order of their development. Tabun was called GA (the letter G standing for German), sarin was GB, and soman was GD.[30]

In 1952, the British synthesized an even more potent nerve agent while searching for a dichlorodiphenyltrichloroethane (DDT) replacement. This substance was given to the United States for military development, and was named VX. A VX leak killed 6000 sheep near a military base in Skull Valley, Utah in 1968.[30,44,77] The Russians developed a similar nerve agent, variably referred to as VR or "Russian VX."[40] The United States used defoliants and riot-control agents in Vietnam and Laos. Iraq used sulfur mustard, tabun, and soman during its war with Iran in the 1980s, and may have also used cyanide against the Kurds.[49]

More recently, terrorist groups have begun to employ chemical weapons. Sarin was released twice by the Aum Shinrikyo cult in Japan. The first release occurred in Matsumoto in 1994, killing 7 and injuring over 600.[51] A more highly publicized sarin attack occurred in the Tokyo subway system in 1995, killing 12 and resulting in over 5000 persons seeking medical attention.[74] Cult members have also used VX in assassinations.[50]

GENERAL CONSIDERATIONS

■ PHYSICAL PROPERTIES

The term *war gas* is generally a misnomer. Sulfur mustard and nerve agents are liquids at normal temperatures and pressures, and many riot-control agents are solids. These weapons are most efficiently dispersed as aerosols, which probably leads to the confusion with gases. Some chemical weapons (eg, chlorine, phosgene, hydrogen cyanide) are truly gases, and although they are generally considered obsolete for battlefield use, they might still be used as improvisational agents, especially in terrorist attacks.

Liquid chemical weapons have a certain degree of volatility and may evaporate into poisonous vapors. Volatility is inversely related to persistence, the tendency to remain in the environment. Persistent agents, such as mustard or VX, can contaminate an area for prolonged periods, denying the enemy free movement and use of contaminated material. The toxic hazard from semipersistent agents like sarin or nonpersistent agents like hydrogen cyanide dissipates more rapidly.

Aerosols, gases, and vapors are highly subject to local atmospheric conditions. Less dispersion occurs with atmospheric inversion layers and in the absence of wind, as typically occurs at night or in the early morning. Enclosed spaces also prevent wind dispersion and even simple dilution. Except for hydrogen cyanide, CW gases and vapors are all denser than air and will pool in low-lying areas.

An example was the use of sarin in the Tokyo subway where the number of fatalities could have been much higher had the nerve agent

TABLE 131–1. Unconventional Weapons: Definitions and Acronyms

Chemical warfare	Intentional use of weapons designed to kill, injure, or incapacitate on the basis of toxic or noxious chemical properties
Biological warfare	Intentional use of microorganisms or xenobiotics derived from living organisms to cause death, disability, or damage in humans, animals, or plants
Terrorism	The unlawful use of force against persons or property to intimidate or coerce a government, the civilian population, or any segment thereof, in furtherance of political or social objectives
CW	Chemical warfare, or chemical weapon
BW	Biological warfare, or biological weapon
CBW	Chemical and/or biological warfare, or weapons
NBC	Nuclear, biological and/or chemical; usually in reference to weapons
CBRNE	Chemical, biological, radiological, nuclear, and explosive; usually in reference to weapons
WMD	Weapon of mass destruction; nuclear, radiologic, chemical, or biological weapon intended to produce mass casualties

been effectively aerosolized instead of simply allowed to evaporate. Photos from the attack show severely affected or deceased victims in very close proximity to mildly affected, ambulatory individuals. Presumably, sarin concentrations decreased so rapidly with distance from the source, that few victims, if any, were actually contaminated. After removal from high-concentration areas, the victims' bodies posed less threat to bystanders because of dilution and improved ventilation. Even so, some healthcare providers were secondarily exposed, as the victims were not disrobed prior to entering the hospitals. Up to 46% of hospital staff in areas with poor ventilation reported symptoms consistent with mild acute poisoning, although cholinesterase levels were not reported.[55,56,59] About one-third of rescue workers in the 1994 Matsumoto sarin incident also developed mild toxicity. Rescuers arriving at the scene later were less likely to develop symptoms,[52] suggesting that the vapor had dissipated over time.

■ PREPARATION FOR CBW INCIDENTS

A rational medical response to CBW events differs from the common response to isolated toxicologic incidents. Healthcare providers must learn about these unconventional weapons and the expected "toxidromes" that may occur.[1] In addition, healthcare providers must protect themselves and their facilities first, or ultimately no one will receive care. New medicolegal and ethical considerations will arise in CBW mass-casualty events that are otherwise infrequently seen. The greatest good for the greatest number of victims may preclude heroic

TABLE 131–2. Chemical versus Biological Weapons: Comparison and Contrast[27]

Similarities

Xenobiotics most effectively dispersed in aerosol or vapor forms
Delivery systems frequently similar
Movement of xenobiotics highly subject to wind and weather conditions
Appropriate personal protective equipment prevents illness

Differences	Chemical Weapons (CW)	Biological Weapons (BW)
Rate at which attack results in illness	Rapid, usually minutes to hours	Delayed, usually days to weeks
Identifying release	*Easier*:	*Harder*:
	Rapid clinical effects	Delayed effects
	Possible chemical odor	Lack of color, odor, or taste
	Commercially available chemical detectors	Limited development of real-time detectors
Xenobiotic persistence	Variable	Generally nonpersistent most BW agents degraded by sunlight, heat, desiccation (exception: anthrax spores)
	Liquids semipersistent to persistent	
	Gases nonpersistent	
Victim distribution	Near and downwind from release point	Victims may be widely dispersed by time disease is apparent
First responders	EMTs, Hazmat teams, firefighters, law enforcement officers	Emergency physicians and nurses, primary care practitioners, infectious disease physicians, epidemiologists, public health officials (but may be same as CW if release is identified immediately)
Decontamination	Critically important in most cases	Not needed in delayed presentations; less important for acute exposures
Medical treatment	Chemical antidotes, supportive care	Vaccines, antibiotics, supportive care
Patient isolation	Unnecessary after adequate decontamination	Crucial for easily communicable diseases (eg, smallpox, pneumonic plague); however, many BW agents are not easily transmissible

interventions in a few critical patients. Charges of negligence may later arise regarding delays in treatment or failure to diagnose subtle signs of disease, even if such actions were unavoidable at the time. Even if physicians become well versed in the appropriate response to CBW incidents, the question remains of how many will be willing to continue working in case of an actual public health disaster.[31]

The responses to chemical and biological agents will also differ.[27] Chemical weapons, like conventional explosives, generally produce clinical effects within seconds to hours, making a "scene" or "hot zone" evident. The first responders for a chemical event will be fire and police authorities, hazmat teams, and emergency medical services. Patients will be brought to local healthcare facilities and the disease process, although perhaps not the specific diagnosis, will be recognized rapidly. With biological agents, the victims will not all present for care at the same time in the same place. First responders will be local and distant emergency departments and primary care offices, highlighting the need for training in these specialties.

Recommendations for sustained healthcare facility domestic preparedness include improved training to promptly recognize CBW mass casualty events, efforts to protect healthcare providers, and establishing decontamination and triage protocols.[43] Table 131–3 lists some specific recommendations. Several facets of the response to a CBW event are still being refined, such as the optimal choice of personal protective equipment, determining who needs decontamination and by what means, and what is to be done with wastewater produced by mass decontamination.[39,43] On a tactical level, communication can be severely impaired by personal protective gear, which points out the need for loudspeakers or some other form of public address.[43,87]

Individual clinicians and hospitals caring for victims of known or suspected CBW incidents should contact their local department of

health, who may in turn report the incident to outside agencies such as the Federal Bureau of Investigation (FBI) and the Centers for Disease Control and Prevention (CDC) (Table 131–4).

■ DECONTAMINATION

Decontamination serves two functions: (1) to prevent further absorption and spread of a noxious substance on a given casualty, and (2) to prevent spread to other persons. Decontamination is critical for some chemical weapons exposures, but is less crucial for biologic agents. Victims of an occult biological weapon agent release will not present for medical care until they become symptomatic, usually several days later when decontamination will be futile. Also, chemical weapon agents can be dispersed as liquids, which are more amenable to decontamination than gases or aerosols, and are more likely to spread on a person or between persons. Decontamination issues specific to biological weapon agents are discussed in the following chapter.

Chemical weapons that are exclusively gases at normal temperatures and pressures such as chlorine, phosgene, or hydrogen cyanide require as decontamination only removing the victim from the area of exposure. Isolated vapor exposures, as from volatilized nerve agents or sulfur mustard, are also terminated by leaving the area and may require no skin decontamination of the victims.[49,75] Japanese experience with sarin suggests that clothing should be removed from victims of nerve agent vapor exposure and placed in airtight receptacles, such as sealed plastic bags. Some of the secondary exposures to sarin were thought to have occurred as nerve agent that had condensed on the victims' clothing revaporized into the ambient air, and this caution probably holds true also for sulfur mustard vapor exposures.

Chemical weapons dispersed as liquids present the greatest need for decontamination. Because nerve agents are highly potent and have rapid onset of effects, some victims with significant dermal contamination may not survive to reach medical care.[75] Liquid-contaminated clothing must be removed, and if able, victims should remove their own clothing to prevent cross-contamination.

Decontamination should be done as soon as practicable, to prevent progression of disease, and should occur outside of healthcare facilities to prevent contamination of the working environment and secondary casualties. Decontamination near the incident scene would be ideal in terms of timeliness, although logistically this will not be possible in many situations. Evidence supports the likelihood that contaminated victims will present at healthcare facilities on their own, or be transported for care without decontamination.[39] In mass-casualty incidents,

---

TABLE 131–3. Recommendations for Healthcare Facility Response to CBW Incidents

- Immediate access to personal protective equipment (PPE) for healthcare providers
- Decontamination facilities that can be made operational within minimal delay 2 to 3 minutes (Rational? Realistic?)
- Triage of victims into those able to decontaminate themselves (decreasing the workload for healthcare providers) and those requiring assistance
- Decontamination facilities permitting simultaneous use by multiple persons and providing some measure of visual privacy
- A brief sign-in process where patients are assigned numbers and given identically numbered plastic bags to contain and identify their clothing and valuables
- Provision of food, water, and psychological support for staff, who may be required to perform for extended periods
- Secondary triage to separate persons requiring immediate medical treatment from those with minor or no apparent injuries who are sent to a holding area for observation
- Providing victims with written information regarding the agent involved, potential short- and long-term effects, recommended treatment, stress reactions, and possible avenues for further assistance
- Careful handling of information released to the media to prevent conflicting or erroneous reports
- Instituting postexposure surveillance

decontamination efforts may benefit from separating victims into those who can remove their own clothing and shower themselves with minimal direction and assistance, and the more seriously affected who will require full assistance. The degree of protective gear required by the decontamination personnel cannot be predicted in advance, and may not be easy to objectively determine at the time of the incident. Level C personal protective equipment may be sufficient for most hospital settings when the source is defined (eg, receiving and decontamination areas); however, if healthcare workers begin to develop symptoms, level B gear with supplied air would become necessary[57] (see Chap. 130). When the source of the contamination is not yet known, level B gear should be used. Chemically contaminated victims presenting to a healthcare facility should, if possible, be denied entrance until decontaminated. Patients who have already entered a healthcare facility and are only later determined to be a contamination hazard present a more difficult problem. If the situation allows, such patients should be taken outside for decontamination before returning, and the previous care area cordoned off until any remaining safety hazard has been assessed and eliminated. In a mass-casualty disaster, however, such efforts at remediation may not be practical.

Nerve agents are hydrolyzed and inactivated by solutions that release chlorine, such as household bleach or solutions that are sufficiently alkaline. To avoid potential dermal and mucous membrane injury, a 1:10 dilution of household bleach in water (producing a 0.5% sodium hypochlorite solution) has been recommended, not only for nerve agents, but also for sulfur mustard and many biological agents.[43,47,77] Alternatives include regular soap and water or copious water alone. Rapid washing is more important than the choice of cleaning solution because 15–20 minutes is necessary for hypochlorite solutions to inactivate chemical agents.[43] Care should be taken to clean the hair, intertriginous areas, axillae, and groin.[77]

Decontamination after sulfur mustard exposure is more problematic than for nerve agents. First, it is more likely that significantly contaminated victims will survive to reach medical care, and they may remain asymptomatic for several hours. Also, the biochemical damage becomes irreversible long before symptoms develop. Decontamination within 1–2 minutes is the only effective means of limiting tissue damage from mustard.[79] The actual means of mustard decontamination, however, are identical to those for nerve agents. Victims must be disrobed and thoroughly showered. Dilute hypochlorite solutions (eg, 0.5% sodium hypochlorite, a 1:10 dilution of household bleach) have been advocated to inactivate mustard, but copious water irrigation will also suffice.[49] Symptomatic victims of mustard exposure should still be decontaminated, even though it is unlikely to benefit that particular casualty, to prevent the spread of agent to others.[79] Lewisite and phosgene oxime must also be decontaminated quickly, although they produce immediate symptoms, making it more likely that victims will present promptly when decontamination is most effective.

Water irrigation is generally recommended for riot control agent exposures because hypochlorite solutions may exacerbate skin lesions.[49] Inadequately decontaminated patients exposed to lacrimator agents can produce secondary cases among healthcare providers, so any contaminated clothing should be removed and bagged.

Significant issues remain regarding decontamination measures. The number of people potentially requiring decontamination may easily outstrip capacity. Incidents with hundreds or thousands of victims may necessitate communal showers and/or selective decontamination. Decontamination wastewater should ideally be contained and treated, but few facilities have the capability or funds to do this. Wastewater may, however, be a minor issue. In biological weapon incidents there is only a temporary risk because of rapid environmental degradation, and in large–scale chemical weapon events the wastewater poses only a small percentage of the total environmental impact.[43]

■ RISK OF EXPOSURE

The actual release of CBW agents can be characterized as a low-probability, high-consequence event. Potential sources for civilian exposure include terrorist attacks, inadvertent releases from domestic stockpiles, direct military attacks, and industrial events. Terrorists may sabotage military or industrial stockpiles or directly attack the populace. Experience has shown that physicians are much more likely to encounter hoaxes,[12] isolated cases,[66] or limited incidents with a modest number of casualties.[86] Riot control agents are exceptions, in that treating riot control agent and pepper spray victims is a routine occurrence in many urban emergency departments (EDs).

Technical and organizational obstacles decrease the chance of major CBW terrorist events. Obtaining or producing chemical or biological weapons, although simpler than for nuclear weapons, is only part of the process. Effective dissemination is difficult if the goal is to maximize casualties. Proper milling of biologic agents to produce stable, respirable aerosols requires technical sophistication probably only attainable with governmental research support.[81] Illustrating this point is the ineffectiveness of the Aum Shinrikyo's biological weapon releases and the limited number of sarin fatalities, despite large amounts of funds available to support these attacks.[61] Low-technology attacks such as food contamination, poisoning of livestock, and enclosed-space weapons dispersal appear more likely to occur than attacks resulting in hundreds, thousands, or millions of casualties.[81] Smaller attacks, or merely threatening use of CBW agents, may be equally consequential from a terrorist's perspective if they exert the same political influence.

Nevertheless, even inefficiently dispersed agents of sufficient toxicity can produce multiple casualties and terrorize the populace, as occurred in the Matsumoto and Tokyo sarin attacks. Impact estimates of efficiently dispersed biological weapons are alarming. Fifty kilograms of anthrax spores disseminated along a 2-km line upwind of 500,000 people would be expected to kill 95,000 and incapacitate another 125,000 people—nearly a 50% casualty rate.[18] The societal economic impact of bioterrorist attacks ranges from $477.7 million per 100,000 persons exposed for brucellosis to $26.2 billion per 100,000 exposed for anthrax.[35]

The chemicals most likely to be used militarily appear to be sulfur mustard and the nerve agents. A "low-tech" terrorist attack could involve the release of industrial chemicals, such as chlorine, phosgene, or ammonia gas. Although the list of potential biological weapon agents is long, only a handful of pathogens have credible risk of producing public health disasters by overwhelming healthcare resources and causing high mortality, widespread panic, and massive disruption of commerce.[13] Topping this list are anthrax, smallpox, and plague, followed by botulinum toxin, hemorrhagic fever viruses, and tularemia.

■ PSYCHOLOGICAL EFFECTS

Either the threat or the actual use of CBW agents presents unique psychologic stressors. Even among trained persons, a CBW-contaminated environment will produce high stress through the necessity of wearing protective gear, potential exposure to agents, high workload intensity, and interactions with the dead and dying. Disorders of mood, cognition, and behavior will be common among exposed or potentially exposed victims as a result of the uncertainty, fear, and panic that may accompany a CBW incident, even a hoax. The psychological casualties will probably outnumber victims requiring medical treatment. Civilians without training, including some healthcare providers, are likely to confuse somatic symptoms with true exposure. Medical resources may easily be overwhelmed unless triage can identify those who will benefit most from appropriate counseling, education, and psychologic support. Psychiatrists should be enlisted in plans to manage CBW incidents for their expertise in treating anxiety, fear, panic, somatization, and grief.[15]

In Israel during the Gulf War, anxiety-related somatic reactions to missile attacks were reported in 18%–38% of persons surveyed,[10] and over 500 people sought medical attention in emergency departments for anxiety.[63] Among 5510 people seeking medical attention after the Tokyo subway sarin release, only about 25% were hospitalized.[74] Some of the "victims" presented days or even weeks after the incident, apparently feeling unwell and thinking they had been exposed.[56,60] Civilian survivors of chemical attacks in the 1980–1988 Iran–Iraq war report increased symptoms of depression, anxiety, and posttraumatic stress disorder compared to those exposed to low-intensity conventional warfare.[24] In one longitudinal study of American Persian Gulf War veterans, 4.6% reported their belief that they were exposed to CBW agents, despite the lack of any convincing evidence of deliberate exposures, nor of unintended exposure to any significant levels of chemical agents. Greater combat stress was associated with a higher incidence in belief in such exposures.[82] Another study reported a 64% incidence in belief of CBW agent exposure among Gulf War veterans.[8] Reported indicators supporting these beliefs included receiving an alert, having physical symptoms, and being told to use protective gear. Belief in exposure to biological agents correlated with having received an alert about chemical agents, suggesting that CW alerts can spread misinformation and confusion among recipients.

Uncontrolled release of information may compound terror and increase psychologic casualties. Imagine the influx of patients resulting from a news report suggesting that anyone with dizziness or nausea be checked for nerve agent toxicity, or that fever and cough indicate infection with anthrax.

■ THE ISRAELI EXPERIENCE DURING THE GULF WAR

Israel as a country is probably best prepared for CBW disasters. In late 1990, the civilian population was supplied with rubber gas masks, atropine syringes, and Fuller's earth decontamination powder.[63] Major Israeli hospitals conduct chemical practice drills every 3–5 years.[87] These drills identify several key lessons, including designating specific hospitals for chemical casualties, blocking hospital access to a single guarded entrance to prevent internal contamination, and extending nurses' authority to initiate treatment by established protocols. The Israeli plan provides two tiers of triage. The first triage occurs outside of the hospital by protected medical personnel who perform only life-saving interventions, such as intubation, hemorrhage control, and antidotal therapy. Patients are then decontaminated and enter the hospital. Afterward, patients are triaged again according to severity of illness into separate areas in which dedicated healthcare teams provide the appropriate interventions.[68,87]

Thirty-nine ballistic missiles with conventional warheads were launched against Israel from Iraq in early 1991, with only six missiles causing direct casualties. Many more "injuries" resulted from CBW defensive measures and psychologic stress than from physical trauma. Out of 1060 injuries reported from EDs during this time period, 234 persons were directly wounded in explosions (most injuries were minor), and there were only 2 fatalities from trauma.[34,63] Over 200 people presented for medical evaluation after self-injection of atropine, a few requiring admission to the hospital.[3,34,63] About 540 people sought care for acute anxiety reactions. Some suffocated from improperly used gas masks, fell and injured themselves when rushing to rooms sealed against CBW agents, or were poisoned by carbon monoxide in these airtight rooms.[34,63] Increased rates of myocardial infarction and cerebrovascular accidents were also observed.[63] A survey of hospital staff members found that only 42% would report for duty following a chemical weapon attack.[69]

■ SPECIAL POPULATIONS

Pregnancy does not appear to be a significant factor in the treatment of women victims of chemical weapons. In the Tokyo subway sarin attack, five victims were identified at one hospital as being pregnant. These women were only mildly affected and were admitted for observation. All had healthy babies, the first one born 3 weeks after the incident.[56,58,60] In Israel, no obstetric complications occurred among women wearing gas masks during labor and delivery.[19,63]

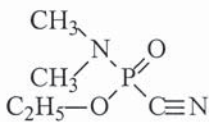
Children have important differences from adults regarding chemical weapon effects and decontamination efforts. Children breathe at a lower elevation above the ground and at a higher rate than adults. Because nearly all chemical weapon gases and vapors are heavier than air, children will be exposed to higher concentrations than adults in the same exposure setting, and will likely exhibit symptoms earlier.[4,65,92] Children may also be more susceptible to vesicants and nerve agents than adults with equivalent exposures.[64,92] Children have thinner and more delicate skin, allowing for more systemic absorption and more rapid onset of injury with sulfur mustard. The pediatric blood–brain barrier may also be less resistant than in adults and the activity of endogenous detoxifying enzymes, such as paraoxonase, is less, allowing for greater toxicity with nerve agents. Additionally, children with organic phosphorus compound poisoning less frequently exhibit a muscarinic toxic syndrome than adults, and often present with isolated CNS depression.[64]

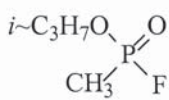
The decontamination of children is another feature that requires an age-adjusted approach. Children have a larger surface area-to-mass ratio and may be more likely to carry a toxic or fatal dose of a chemical weapon on their skin. Most children will need assistance and supervision during decontamination procedures; keeping a mother or other adult guardian with a child should help with both decontamination and thermoregulation.[65]

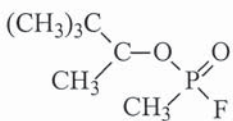
■ NERVE AGENTS

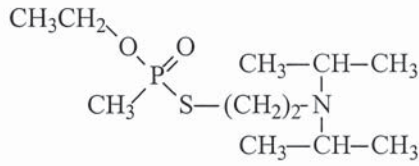
Physical Characteristics and Toxicity Nerve agents (Fig. 131–1) are extremely potent organic phosphorus compound cholinesterase inhibitors, and are the most toxic of the known chemical weapons.[49] For example, sarin is 1000-fold more potent in vitro than the pesticide parathion.[75] Aerosol doses of nerve agents causing 50% human mortality (LD_{50}) range from 400 mg-min/m^3 for tabun down to 10 mg-min/m^3 for VX, compared to 2500–5000 mg-min/m^3 for hydrogen cyanide. Dermal exposure LD_{50}s for nerve agents range from 1700 mg for sarin down to only 6–10 mg for VX.[49,75] Pure nerve agents are clear and colorless. Tabun has a faint fruity odor, and soman has been variably described as smelling sweet, musty, fruity, spicy, nutty, or like camphor. Most subjects exposed to sarin and VX have been unable to describe the odor.[44,75] The G-agents tabun (GA), sarin (GB), and soman (GD) are volatile and present a significant vapor hazard. Sarin is the most volatile, only slightly less so than water. VX is an oily liquid with low volatility and higher environmental persistence.[44,49,75] Other G- and V-agents have been developed, including cyclosarin (GF) and Russian VX (VR).

Pathophysiology The pathophysiology of nerve agents is essentially identical to that from organic phosphorus compound insecticides (see Chap. 113), differing only in terms of potency and physical characteristics of the toxins. The resultant toxic syndrome includes muscarinic (salivation, lacrimation, urination, defecation, GI cramping, emesis, or SLUDGE syndrome) and nicotinic (muscle fasciculation, weakness, paralysis) signs, and central effects (loss of consciousness, seizures, respiratory depression).[30,73,77]

Clinical Effects Nerve agent vapor exposures produce rapid effects, within seconds to minutes, whereas the effects from liquid exposure may be delayed as the agent is absorbed through the skin.[47,75] Vapor








Military Designation	Common Name	Proper Name	Chemical Formula
GA	Tabun	Ethyl-*N,N*-dimethylphosphoramidocyanidate	
GB	Sarin	Isopropyl-methylphosphonofluoridate	
GD	Soman	Pinacolyl-methylphoshonofluoridate	
VX	-	*O*-Ethyl-*S*-[2-(diisopropylamino)ethyl]-methylphosphonothiolate	

FIGURE 131–1. Nerve agents.

or aerosol exposures have historically been more common, whether through experiments or from unintentional releases in the laboratory[73] or in terrorist attacks.[51,60] Aerosol or vapor exposure initially affects the eyes, nose, and respiratory tract. Miosis is common, resulting from direct contact of nerve agent with the eye, and may persist for several weeks.[73,77] Other ocular effects include conjunctival injection and blurring and dimming of the vision. Dim vision is often ascribed to pupillary constriction, but central neural mechanisms also play a role.[75] Ciliary spasm produces ocular pain, headache, nausea, and vomiting, often exacerbated by near-vision accommodation.[30] Rhinorrhea, airway secretions, bronchoconstriction, and dyspnea occur with increasing exposures. With a large vapor exposure, one or two breaths may produce loss of consciousness within seconds, followed by seizures, paralysis, and apnea within minutes.[47]

In the 1995 Tokyo subway sarin incident, ocular effects were most common after sarin vapor exposure, with miosis (89%–99% of symptomatic victims), eye pain, dim vision, and decreased visual acuity.[30,60] Other common complaints were cough, throat tightness, nausea, headache, dizziness, chest discomfort, and abdominal cramping.[46,84] Among 111 patients admitted to one hospital, the most common presenting signs and symptoms were miosis (99%), headache (74.8%), dyspnea (63.1%), nausea (60.4%), eye pain (45%), blurred vision (39.6%), dim vision (37.8%), and weakness (36.9%).[56,60] Excessive secretions were less common, with rhinorrhea seen in about one-quarter of patients admitted at one hospital,[60] and in none of 58 patients at another.[84] Secondary exposures occurred among emergency medical technicians (EMTs) and hospital personnel in both the Tokyo[46,55,56] and Matsumoto[51,52] terrorist sarin releases, apparently from evaporation of nerve agent that had condensed on the primary victims' clothing.

Liquid nerve agents can permeate ordinary clothing, allowing for percutaneous absorption and rendering patients as potential hazards to healthcare personnel prior to proper decontamination. Mild dermal exposure produces localized sweating and muscle fasciculations

after an asymptomatic period lasting up to 18 hours. Moderate skin exposure produces systemic effects with nausea, vomiting, diarrhea, and generalized weakness. Substantial dermal contamination will produce earlier and more severe symptoms, often with abrupt onset. Severe toxicity from any route of exposure causes loss of consciousness, seizures, generalized fasciculations, flaccid paralysis, apnea, and/or incontinence.[49,75,77] Cardiovascular effects are less predictable, as either bradycardia (muscarinic) or tachycardia (nicotinic) may occur.[47] In the Tokyo sarin event, tachycardia and hypertension were more common than bradycardia.[54,84] Subtle CNS effects may continue for weeks, but typically resolve if no anoxic brain injury occurred.

Long-term effects from nerve agent exposure have mostly been limited to psychologic sequelae.[71] Neither delayed peripheral neuropathy nor the intermediate syndrome has been reliably described in humans exposed to nerve agents.[77,78] Followup studies from the Japanese sarin incidents show that neuropathy and ataxia, when initially present, resolved within 3 days to 3 months.[91] The main persistent sequela is posttraumatic stress disorder, found in up to 8% of victims.[29,91]

■ TREATMENT OF NERVE AGENT EXPOSURE

Decontamination   In critically ill patients, antidotal treatment may be necessary before or during the decontamination process; but generally, decontamination should occur before other treatment is instituted.

Atropine   Atropine is the standard anticholinergic antidote for the muscarinic effects of nerve agents.[17] Atropine does not reverse nicotinic effects but does have some central effects and may thus assist in halting seizure activity.[30,44,75]

Atropine is administered parenterally, either by the intravenous (IV) or intramuscular (IM) route, and the dose is determined by titration to effect. The standard adult dose determined by the American military is 2 mg, an amount expected to produce substantial benefit in reversing nerve agent toxicity but one that should be tolerated by a

healthy unexposed adult unintentionally receiving the drug.[75] Current recommendations place the minimum initial dose of atropine in adults at 2 mg; dosing in children begins at 0.05 mg/kg for mild to moderate symptoms and 0.1 mg/kg for severe symptoms.[4] Severely poisoned adult patients receive an initial dose of 5–6 mg.[30,75] Repeat doses are given every 2–5 minutes until resolution of muscarinic signs of toxicity. Therapeutic endpoints are, drying of respiratory secretions and resolution of bronchoconstriction, bradycardia, and/or seizures (if initially present). Neither reversal of miosis nor development of tachycardia is a reliable marker to guide atropine therapy.[30] The total amount of atropine necessary to treat nerve agent poisoning is often much less than required for organic phosphorus insecticide toxicity of a similar degree. Typically, less than 20 mg is required in the first 24 hours, even in severe cases.[30,75,77] Fewer than 20% of moderately ill patients admitted to one hospital for sarin poisoning in Tokyo required more than 2 mg atropine.[60]

American troops in the Gulf War were issued 3 MARK I kits for immediate field treatment of nerve agent poisoning. Each kit contains two autoinjectors: an AtroPen containing 2 mg of atropine in 0.7 mL diluent, and a ComboPen containing 600 mg of pralidoxime chloride (pyridine-2-aldoxime, 2-PAM) in 2 mL diluent (Survival Technology, Rockville, MD).[75] These autoinjectors permit rapid IM injections of antidote through protective clothing and are given in the lateral thigh.[17] Treatment algorithms guided the number of MARK I kits to administer. In general, conscious casualties not in severe distress self-administer one kit (2 mg atropine), moderate to severe cases receive three kits (6 mg atropine) initially, and all receive additional doses as necessary, every 5–10 minutes[17,49,75] (Antidotes in Depth A34: Atropine).

In a nerve agent mass casualty incident, a hospital's intravenous atropine supplies may be rapidly depleted. Alternative sources include atropine from ambulances, ophthalmic and veterinary preparations, or substituting an antimuscarinic such as glycopyrrolate.[30] Atropine might also be stored as a bulk powder formulation and rapidly reconstituted for injection when needed.[21]

Oximes Oximes are nucleophilic compounds that reactivate organic phosphorus compound-inhibited cholinesterase enzymes by removing the dialkylphosphoryl moiety. The only oxime approved in the United States by the FDA is 2-PAM, a monopyridinium compound. Other pralidoxime salts are used elsewhere, such as the methanesulfonate salt of pralidoxime (P2S) in the United Kingdom and 2-PAM methiodide in Japan. Other oximes include the bispyridinium compounds trimedoxime (TMB4) and obidoxime (toxogonin) used in other European countries.[44,60,75] Oximes should be given in conjunction with atropine, as they are not particularly effective in reversing muscarinic effects when given alone. Oximes are the only available nerve agent antidotes that can reverse the neuromuscular nicotinic effects of fasciculations, weakness, and flaccid paralysis (see Antidotes in Depth A33: Pralidoxime).

Oximes are effective only if administered before irreversible dealkylation, or "aging," of the organic phosphorus compound-cholinesterase complex occurs. Soman has an aging half-life of 2–6 minutes in humans.[16] It is unlikely that soman-poisoned victims will reach medical care early enough for oxime therapy to be of great benefit. For comparison, tabun has an aging half-life of about 14 hours, sarin 3–5 hours, and VX 48 hours.[16,80] Pralidoxime is effective against sarin and VX in animal studies but not against tabun because of ineffective nucleophilic attack against that particular agent, and not because of aging issues. Obidoxime also is effective against sarin but not against tabun.[44]

The bispyridinium Hagedorn (H-series) oximes, particularly HI-6 and HLö-7, have also been studied in the context of nerve agent toxicity.[44] HI-6 appears beneficial against soman poisoning (possibly through direct pharmacological action and/or reactivation of aged

soman-inhibited ChE) but is not very effective against tabun. HLö-7 has reactivating activity for both soman- and tabun-inhibited ChE and may thus represent a universal oxime antidote for nerve agents. Administration of HI-6 and HLö-7 by autoinjector is difficult because they are not stable in aqueous solution.

For more details about pralidoxime administration, dosing, and side effects, see Antidotes in Depth A33: Pralidoxime. The ComboPen autoinjector in MARK I kits contains 600 mg pralidoxime, which produces a therapeutic maximal serum concentration of 6.5 μg/mL in average human subjects.[75] When possible, however, pralidoxime is optimally administered IV. Repeat pralidoxime dosing or continuous infusions are less likely to be needed for nerve agents than for organic phosphorus compound insecticides because severe effects are shorter-lived in properly decontaminated patients.[30]

Anticonvulsants Severe human nerve agent toxicity rapidly induces convulsions, which persist for a few minutes until the onset of flaccid paralysis. Diazepam is more beneficial than other anticonvulsants and simple γ-aminobutyric acid (GABA) channel agonists due to its effects on choline transport across the blood–brain barrier and acetylcholine turnover.[44] Current American military doctrine is to administer 10 mg diazepam IM by autoinjector at the onset of severe toxicity whether seizures are present or not. Thus, whenever 3 MARK I kits are used, a victim is given diazepam as well. Additional autoinjectors are given by medical personnel as necessary for seizures.[49] The reason for the IM route of diazepam suggested above is related to timely administration under field conditions. If intravenous access is feasible, IV diazepam in 5-mg doses IV every 15 minutes (up to 15 mg) is recommended[44] (see Antidote in Depth A24: Benzodiazepines)

Although diazepam is the most well-studied benzodiazepine in the treatment of nerve agent toxicity, other medications in the same class such as lorazepam and midazolam should have similar beneficial effects. Armed service personnel of the United Kingdom are supplied with ComboPens containing atropine sulfate (2 mg), pralidoxime mesylate (P2S; 30 mg), and avizafone (10 mg), a water-soluble prodrug of diazepam.[90]

Pyridostigmine Pretreatment The first large-scale use of pyridostigmine as a pretreatment for nerve agent toxicity occurred during Operation Desert Storm.[36] Pyridostigmine is a carbamate acetylcholinesterase inhibitor that is freely and spontaneously reversible, whereas nerve agent inhibition is permanent once "aging" occurs. Toxicity from rapidly aging nerve agents such as soman (GD) can probably not be reversed by standard oxime therapy in realistic clinical situations. Almost paradoxically, then, a carbamate can occupy cholinesterase, blocking access of nerve agent to the active site, and thereby protect the enzyme from permanent inhibition. Following nerve agent exposure, pyridostigmine is rapidly hydrolyzed from acetylcholinesterase and can also be easily displaced by oximes, regenerating functional enzyme. Between 20% and 40% cholinesterase inhibition is desired to protect against nerve agents.[17] Sixty-milligram doses of pyridostigmine bromide reduces cholinesterase activity by 28.4% in healthy individuals. Asthmatics taking 30 mg doses had a mean 24.3% reduction in cholinesterase activity without significant reductions in respiratory function or in response to inhaled atropine.[62] In animal studies, pyridostigmine confers a benefit against soman and tabun, but not against sarin or VX.[17] Also, it must be recognized that pyridostigmine is not an antidote, but is instead a pretreatment adjunct that greatly enhances the efficacy of atropine and oxime therapy.[77]

American troops in the Gulf War took 30 mg pyridostigmine bromide orally every 8 hours when under threat of nerve agent attack. Cholinergic side effects, mostly gastrointestinal, were common but rarely required treatment or discontinuing therapy.[36] Israeli soldiers taking the same dose also reported a range of mostly cholinergic symptoms but also a high incidence (71.4%) of dry mouth, which

may be more related to environmental and psychological stressors.[70] Nine Israeli patients were hospitalized during the Gulf War for acute intentional pyridostigmine overdoses.[2] All patients recovered fully, including one patient who self-treated with atropine autoinjectors and presented with anticholinergic toxicity and another who suffered cardiac arrest, apparently from co-ingesting 4000 mg propranolol.

■ VESICANTS

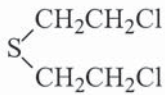
Vesicants are agents that cause blistering of skin and mucous membranes (Fig. 131–2).

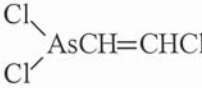
Sulfur Mustard   Sulfur mustard is bis(2-chloroethyl) sulfide, a vesicant alkylating compound similar to nitrogen mustards used in chemotherapy. Nineteenth-century scientists described the compound as smelling like mustard, tasting like garlic, and causing blistering of the skin on contact. The Allies of World War I called it Hun Stoffe (German Stuff), abbreviated as HS and later as just H. Distilled, nearly pure mustard is designated HD. The French called it Yperite, after the site where it was first used, and the Germans called it LOST after the two chemists who suggested its use as a chemical weapon, **Lo**mmel and **St**einkopf. It was also called "yellow cross" after the markings on German artillery shells filled with mustard.[9,14,79] Sulfur mustard caused over one million casualties in World War I,[22] and has since been use by the Italians and Japanese in the 1930s, by Egypt in the 1960s, and by Iraq in the 1980s.[49] About 100,000 Iranians from both military and civilian backgrounds were exposed to chemical warfare agents during the latter years of the Iran–Iraq war (1984–1988), many of whom are still suffering long-term effects.[23] Nonbattlefield exposures have also occurred among Baltic Sea fishermen while recovering corroding shells dumped after WWII, and to persons unearthing or handling old chemical warfare ordinance.[22,53,66,79]

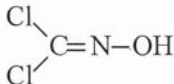
Physical Characteristics   Sulfur mustard is a yellow to brown oily liquid with an odor resembling mustard, garlic, or horseradish. Mustard has relatively low volatility and high environmental persistence. Nonetheless, most historical mustard injuries occurred from vapor exposure, a danger that increases in warmer climates. Mustard vapor is 5.4 times denser than air. Mustard freezes at 57°F (13.9°C), so it is sometimes mixed with other substances, including chemical weapon agents like chloropicrin or Lewisite, to lower the freezing point and permit dispersion as a liquid.[14,49,79]

Pathophysiology   Sulfur mustard toxicity occurs through several mechanisms. First, mustard is an alkylating agent. Mustard spontaneously undergoes intramolecular cyclization to form a highly reactive sulfonium ion that alkylates sulfhydryl ($-SH$) and amino ($-NH_2$) groups.[9,14,49,79] The most important acute manifestation is indirect inhibition of glycolysis. Sulfur mustard rapidly alkylates and crosslinks purine bases in nucleic acids (see Fig. 131–3). DNA repair mechanisms are activated, including the activation of the enzyme poly(ADP-ribose) polymerase,[45] depleting NAD^+, which in turn inhibits glycolysis, and ultimately leads to cellular necrosis from adenosine triphosphate (ATP) depletion.[9] Other mechanisms are probably involved, since the inhibition of glycolysis only partially correlates with the depletion of NAD^+; sulfur mustard may also inhibit glycolysis directly through undetermined mechanisms.[45] Mustard also depletes glutathione, leading to loss of protection against oxidant stress, dysregulation of calcium homeostasis, and further inactivation of sulfhydryl-containing enzymes.[79] Sulfur mustard is also a weak cholinergic agonist.[49,79]

Clinical Effects   The organs most commonly affected by mustard are the eyes, skin, and respiratory tract. During WWI, 80%–90% of American mustard casualties had cutaneous lesions, 86% had ocular involvement, and 75% had airway injury. Iranian soldiers had more airway (95%) and ocular injuries (92%), and 83% had cutaneous lesions, probably because of the more extensive vaporization occurring in the warmer environment.[9,79] Incapacitation may be severe in terms of number of lost man-days, time for lesions to heal, and increased risk of infection. In contrast, mortality is rather low. In WWI, only 2%–3% of British mustard casualties and fewer than 2% of American casualties died. Fatality rates of 3%–4% were reported from the Iran–Iraq War.[9] Most deaths occur several days after exposure, either from respiratory failure, secondary bacterial pneumonia, or bone marrow suppression.

Dermal exposure produces dose-related injury. After a latent period of 4–12 hours, victims develop erythema that may progress to vesicles and/or bullae formation and skin necrosis. Warm, moist, and thin skin is at increased risk of mustard injury, in particular the perineum, scrotum, axillae, antecubital fossae, and neck. The vesicle fluid does not contain mustard because all chemical reactions are complete within a few minutes. If decontamination is not performed immediately after exposure, injury cannot be prevented. Later decontamination may, however, limit the severity of lesions and further spread of the agent.






Military Designation	Common Name	Proper Name	Chemical Formula

Cross-linked guanine molecules
FIGURE 131–3. Mechanism of sulfur mustard toxicity: alkylation and DNA cross-linking.

Skin exposure to vapor typically results in first- or second-degree burns, although liquid exposure may result in full-thickness burns.[79] Mustard easily penetrates normal clothing and uniforms, and many soldiers received gluteal, perineal, and scrotal burns from sitting on contaminated objects.

Latency of several hours also occurs following ocular and respiratory tract exposures. Ocular effects include pain, miosis, photophobia, lacrimation, blurred vision, blepharospasm, and corneal damage. Permanent blindness is rare, with recovery generally occurring within a few weeks. Inhalation of mustard results in a chemical tracheobronchitis. Hoarseness, cough, sore throat, and chest pressure are common initial complaints. Bronchospasm and obstruction from sloughed membranes occur in more serious cases, but lung parenchymal damage occurs only in the most severe inhalational exposures. Productive cough associated with fever and leukocytosis is common 12–24 hours after exposure, and represents a sterile bronchitis or pneumonitis. Nausea and vomiting are common within the first few hours. High-dose exposures may also cause bone marrow suppression.[9,10,49,79]

Various long-term sequelae have been associated with sulfur mustard. Factory workers chronically exposed to mustard have increased risk of respiratory tract carcinomas, although the carcinogenic risk from battlefield exposures is more controversial.[22,23,78] Respiratory sequelae include chronic bronchitis, emphysema, tracheobronchomalacia, and bronchiolitis obliterans.[23] Mustard victims may also develop a delayed and often recurrent keratitis.[22,72] Chronic dermatologic complications include scarring, pigmentation changes, and chronic,

neuropathic pain and pruritus.[22,72] Among approximately 34,000 Iranians with confirmed exposure to sulfur mustard during the war with Iraq, chronic pulmonary sequelae were noted in 42.5%, ocular lesions in 39.3%, and dermatologic lesions in 24.5%.[38]

Treatment Decontamination is essential in treating the sulfur mustard exposures, even among asymptomatic victims. Further treatment is largely supportive and symptomatic.[9,49,79] Victims may become blinded because of a combination of blepharospasm and corneal edema, which completely resolves in most cases; patients should be informed that this condition is very likely temporary.[32]

Several xenobiotics have been investigated as treatments for sulfur mustard injury. Antiinflammatory and sulfhydryl-scavenging agents have shown benefit in animals as prophylactic therapy or if given immediately after exposure.[79] N-acetyl cysteine appears to be a promising therapeutic agent in cell culture and animal studies, although most of the evidence for its use relates to inhalational aerosol exposures to mustard.[7] Neutropenia can be treated with granulocyte colony–stimulating factor.[48]

Lewisite Lewisite (2-chlorovinyldichloroarsine) was developed as a less persistent alternative to avoid some shortcomings in the use of sulfur mustard in World War I. Lewisite was never used in combat because the first shipment was en route to Europe when the war ended, and it was intentionally destroyed at sea. British anti-Lewisite (BAL, dimercaprol) was developed as a specific antidotal agent and remains in use for chelation of arsenic and other heavy metals.[44,79]

Pure Lewisite is an oily, colorless liquid. Impure preparations are colored from amber to blue-black to black and have the odor of geraniums. Lewisite is more volatile than mustard and is easily hydrolyzed by water and by alkaline aqueous solutions such as sodium hypochlorite. These properties increase safety for offensive battlefield use, but make maintaining a potent vapor concentration difficult.

Lewisite toxicity is similar to that of sulfur mustard, resulting in dermal and mucous membrane damage, with conjunctivitis, airway injury, and vesiculation. An important clinical distinction is that Lewisite is immediately painful, whereas initial contact with mustard is not. Other differences are faster onset of inflammatory response and healing of lesions from Lewisite, less secondary infection of Lewisite lesions, and less subsequent pigmentation changes.[79] The mechanisms of Lewisite toxicity are not completely known, but appear to involve glutathione depletion and arsenical interaction with enzyme sulfhydryl groups. Nevertheless, Lewisite toxicity is qualitatively and quantitatively different from the arsenic it contains. Treatment consists of decontamination with copious water and/or dilute hypochlorite solution, supportive care, and BAL. BAL is given parenterally for systemic toxicity and is also used topically for dermal or ophthalmic injuries. Alternative heavy metal chelators that may be used as Lewisite antidotes include dimercaptopropane sulfonate (DMPS) and succimer (2,3-dimercaptosuccinic acid).[44]

Phosgene Oxime Although classified as a vesicant, phosgene oxime (dichloroformoxime, or CX) does not cause vesiculation of the skin. CX is more properly an urticant or "nettle" agent, in that it produces erythema, wheals, and urticaria likened to stinging nettles. Phosgene oxime produces immediate irritation of the skin and mucous membranes. CX has never been used in battle, and little is known about its mechanism or effects on humans.[49,79]

■ CYANIDES (BLOOD AGENTS)

Several cyanides have been used as chemical weapons. During World War I, the French used hydrogen cyanide (HCN) and cyanogen chloride (CNCl), designated as agents AC and CK, respectively, without great success; the Austrians introduced cyanogen bromide (CNBr).

Cyanide weapons are relatively ineffective because of rapid dispersion and their "all or nothing" biological activity. An exposed individual either rapidly succumbs to cyanide toxicity, or will rapidly recover with minimal sequelae. Mass casualty events from cyanide CW agents have been reported during the Iran–Iraq War and from Iraq's suppression of the Kurds.[5,49]

The clinical effects and treatment of cyanide toxicity are covered elsewhere (Chap. 126) and do not differ significantly if used as a weapon. Hydrocyanic acid gas persists for only a few minutes in the atmosphere, because it is lighter than air and rapidly disperses. Cyanogen chloride additionally causes ophthalmic and respiratory tract irritation and can produce delayed acute lung injury in victims who are not rapidly killed.[5,49]

■ PULMONARY AGENTS

Both chlorine and phosgene were used as war gases in World War I. Chlorine, phosgene, various organohalides, and nitrogen oxides belong to a group of toxic chemicals designated "pulmonary agents" because they can all induce delayed pulmonary edema from increased alveolar-capillary membrane permeability.[44,49,88] Although pulmonary agents have not been used militarily since 1918, the risk of chlorine and phosgene exposure remains because of their extensive use in industry, or possibly as a terrorist weapon. (See Chap. 124 for clinical details, as the remainder of this section highlights mass-casualty issues regarding these agents.)

When released on the battlefield, chlorine forms a yellow-green cloud with a distinct pungent odor detectable at levels that are not immediately dangerous. Phosgene is either colorless or seen as a white cloud as a result of atmospheric hydrolysis. Phosgene, which is reported to smell like grass, sweet newly mown hay, corn, or like moldy hay, accounted for about 85% of all WWI deaths attributed to chemical weapons.[9,44] Phosgene produces injury by hydrolysis in the lungs to hydrochloric acid and by forming diamides that cross-link cell components (Fig. 131–4). Similar cross-linking reactions may occur with hydroxyl and thiol groups. Battlefield exposure triggers cough, chest discomfort, dyspnea, lacrimation, and the peculiar complaint that smoking tobacco produces an objectionable taste. WWI phosgene fatalities were noted to develop a mushroom-shaped efflux of pink foam at their mouths from pulmonary edema fluid. Prolonged observation after phosgene exposure is the rule, as some casualties have initially appeared well and have been discharged, only to return in severe respiratory distress a few hours later.[44,49,88] Exercise appeared to precipitate pulmonary edema in phosgene casualties.[67] For American soldiers in WWI, the average time spent recovering away from the front was 60 days for chlorine and 45.5 days for phosgene.[20]
FIGURE 131–4. Proposed mechanism of phosgene toxicity. **A.** Phosgene reacts with amine group to form an amide, releasing hydrochloric acid. **B.** A second reaction cross-links two amine equivalents, forming a diamide.

■ RIOT CONTROL AGENTS

Riot control agents (Fig. 131–5) are intentionally nonlethal chemicals that temporarily disable exposed individuals through intense irritation of exposed mucous membranes and skin. These agents are also known as lacrimators, irritants, harassing agents, human repellents, and tear gas. They are solids at normal temperatures and pressures, but are typically dispersed as aerosols or as small solid particles in liquid sprays. Common characteristics include rapid onset of effects within seconds to minutes, relatively brief duration once exposure has ceased and the victim is decontaminated, and a high safety ratio (lethal dose vs. effective dose).[44,49,76]

Chloroacetophenone (CN) is the active ingredient in the Chemical Mace brand nonlethal weapon.[83] o-Chlorobenzilidene malononitrile (CS) has largely replaced CN because of its higher potency, lower toxicity, and improved chemical stability.[41,76] When used for crowd control, both CN and CS are disseminated as aerosols or as smoke from incendiary devices. Exposed persons develop burning irritation of the eyes, progressing to conjunctival injection, lacrimation, photophobia, and blepharospasm. Mucous membranes of the upper aerodigestive tracts can also be involved. Inhalation causes chest tightness, cough, sneezing, and increased secretions. Dermal exposure may cause a burning sensation, erythema, or vesiculation, depending on the dose. Victims generally remove themselves from the offensive environment and recover within 15–30 minutes. Deaths are rare from riot control agents, and typically occur from respiratory tract complications in closed-space exposures where exiting the area is impossible.[44,49,76]

The biological mechanism whereby riot-control agents exert their effects is less well described than for other chemical weapons. CS and CN are SN_2 alkylating agents (versus sulfur mustard, an SN_1 alkylator) and react with sulfhydryl-containing compounds and enzymes. For instance, CS reacts rapidly with the disulfhydryl form of lipoic acid, a coenzyme for pyruvate decarboxylase. Tissue *injury* may be related to inactivation of certain enzyme systems. Pain in the absence of tissue injury may be bradykinin mediated.[49]

Personal protective devices dispensing lacrimator substances also cause chemical injuries in the absence of war or civil unrest. Law enforcement agencies and private citizens may have access to products containing CS, CN, and/or OC (oleoresin capsicum, or pepper spray). OC is the essential oil derived from pepper plants (*Capsicum anuum* species) which contains capsaicin (trans-8-methyl-*N*-vanillyl-6-noneamide), a naturally occurring lacrimator. Capsaicin activates heat–dependent nociceptors, explaining why exposures are experienced as "hot."[11] Severe respiratory tract injuries and fatalities are occasionally reported from exposures to these devices, typically only with prolonged or highly concentrated exposures. A new capsaicin-containing riot control device called Pepperball Tactical Powder has caused severe localized skin injuries.[26] This device is a pellet of powdered capsaicin (and carrier substances) pressurized within a thin plastic shell fired as a munition.

Chloropicrin (trichloronitromethane, or nitrochloroform) is another lacrimator that occasionally causes human toxicity through its use as a fumigant and soil insecticide.[85] DM (10-chloro-5,10-dihydrodiphenarsazine, or diphenylaminearsine) is a vomiting agent. Clinical effects are delayed for several minutes after exposure, by which time the victim may have absorbed a significant amount. In addition to upper respiratory and ocular irritation, diphenylaminearsine causes more prolonged systemic effects with headache, malaise, nausea, and vomiting.[49,76]

The primary treatment for all riot-control agents is removal from exposure. Contaminated clothing should be removed and placed in airtight bags to prevent secondary exposures.[41] Skin irrigation with copious cold water is used for significant dermal exposures.[6,41,42]

Military Designation	Common Name	Proper Name	Chemical Formula
CN	Chemical mace	1-Chloroacetophenone 2-Chloroacetophenone 2-Chloro-1-phenylethanone	
CS	Tear gas	O-Chlorobenzylidene malonitrile 2-Chlorobenzalmalonitrile	
DM	Adamsite	10-Chloro-5,10-dihydrophenarsazine Diphenylaminechlorarsine	
OC	Pepper spray, capsaicin	*trans*-8-Methyl-*N*-vanillyl-6-noneamide Oleoresin capsicum	

FIGURE 131–5. Riot control agents.

Symptomatic treatments, such as with topical ophthalmic anesthetics, nebulized bronchodilators, or oral antihistamines and corticosteroids, are indicated as appropriate in more severely affected victims.[6] Capsaicin-induced dermatitis has been treated variably with immersion in water or oil, vinegar, bleach, lidocaine gel, and topical antacid suspensions.[28,33,83] Cold water produces earlier symptomatic relief, but oil immersion has longer-lasting benefit.[33]

■ INCAPACITATING AGENTS

3-Quinuclidinyl benzilate (BZ or QNB; Fig. 131–6) is an antimuscarinic compound that has been developed as an incapacitating CW agent. BZ is 25-fold more potent centrally than atropine, with an ID_{50} (dose that incapacitates 50% of those exposed) of about 0.5 mg. Clinical effects are characteristic for anticholinergics, with drowsiness, poor coordination, and slowing of thought processes progressing to delirium. BZ takes at least an hour to produce initial manifestations, peaks at 8 hours, continues to incapacitate for 24 hours, and takes 2–3 days to fully resolve.[37] During the recent Balkan wars, allegations were made that Bosnian Serbs used BZ against civilians, who reported hallucinations associated with attacks by artillery shells emitting smoke.[25]

Ultrapotent opioids may also be used as incapacitating CW agents. In 2002, Russian security forces used a fentanyl derivative (possibly carfentanil or remifentanil) to end a 3-day standoff with terrorists in a Moscow theater in which Chechen rebels held more than 800 hostages.[89] A "gas" was introduced into the theater ventilation system, which quickly subdued the occupants. Over 650 of the hostages were hospitalized, and 128 died. Initial news reports suggested the use of BZ, although the clinical findings were more consistent with a CNS depressant. Within a few days, Russian officials stated that the agent used was a fentanyl derivative and was not expected to cause fatalities. The relatively high case fatality rate could be because of multiple factors, including variability in dose, displacement of oxygen by rapid introduction of gas into the building, failure to adequately notify healthcare teams and supply them with antidotes, and poor physical condition of the hostages.

Lysergic acid diethylamide (LSD) has also been investigated as an incapacitating agent.[37] Although effective at very low doses, battlefield use of LSD is impractical since intoxication will not reliably prevent a soldier from participation in combat.

Table 131–5 describes the various toxic syndromes that may be seen from use of CW agents.
FIGURE 131–6. Incapacitating agent BZ (3-quinuclidinyl benzilate, QNB).

TABLE 131–5. Chemical Weapons Toxic Syndromes

| Chemical Weapon | Onset | Organ System | | | | | | |
		Eyes	Upper Airways and Mucous Membranes	Lungs	Skin	CNS	GI Tract	Other
Nerve Agents								
Tabun (GA), Sarin (GB) Soman(GD), VX Aerosol/vapor (Mild/moderate exposure)	Rapid (sec-mins)	Miosis, eye pain, dim or blurred vision	Rhinorrhea, ↑ secretions	Dyspnea, cough, wheezing, bronchorrhea	–	Headache	Nausea, vomiting, abdominal cramps	–
Dermal exposure (Mild/moderate exposure)	Delayed (min-hrs)	–	–	–	Localized sweating	–	Nausea, vomiting, diarrhea, cramping Incontinence	Subjective weakness local muscle fasciculations
Severe exposure (Any route)	As above (by route)	Miosis	↑ Secretions	Apnea	–	Sudden collapse, seizures	Incontinence	generalized fasciculations, weakness, flaccid paralysis
Vesicants								
Sulfur Mustard (H, HD)	Delayed (hrs)	Conjunctivitis, eye pain, blurred vision, blindness (temporary)	Irritation, hoarseness barky cough, sinus tenderness tracheobronchitis	(More severe exposures) Productive cough, pseudomembrane formation, airway obstruction	Erythema, vesicles, bullae, necrosis	–	Nausea, vomiting	Bone marrow suppression (in severe exposures)
Lewisite (L)	Immediate irritation Delayed vesication	Pain, blepharo-spasm conjunctivitis, lid edema	(Same as Sulfur Mustard)	(Same as Sulfur Mustard)	Erythema, vesicles	–	–	Shock (in severe exposures)
Phosgene Oxime (CX)	Immediate irritation Delayed urtication	Pain, corneal damage	Irritation	Acute lung injury	Pain blanching, erythema, urticaria Necrosis	–	–	–

Pulmonary Agents								
Phosgene (CG), Chlorine (CL)	Immediate Irritation Delayed ALI	Irritation	Irritation stridor (Chlorine)	Dyspnea, cough Acute lung injury	–	–	–	Chlorine effects more rapid than phosgene
Cyanides								
Hydrogen Cyanide (AC)	Rapid (sec-mins)	–	–	Hyperpnea then apnea	–	Anxiety, agitation, sudden collapse, seizures	–	–
Cyanogen Chloride (CK)	Rapid (sec-mins)	Irritation	Irritation	Hyperpnea then apnea	–	Anxiety, agitation, sudden collapse, seizures	–	–
Riot Control Agents								
Lacrimators (CN, CS) Capsaicin (OC)	Immediate	Pain, lacrimation, blepharospasm conjunctivitis	Irritation	Cough, chest pain	Burning pain, erythema Vesiculation severe exposures	–	Nausea, retching (may occur with CN/CS)	–
Adamsite (DM)	Rapid (min)	Irritation	Irritation, sneezing	Cough, chest pain	–	Headache	Nausea, vomiting, abdominal cramps	–
Incapacitating Agent								
3-quinuclidinyl benzilate (BZ)	Delayed (hrs)	Mydriasis	Dry mouth	–	–	Anticholinergic delirium	–	–
Ultra-potent opioids	Rapid (sec-min)	Miosis	–	Hypoven-tilation	–	CNS depression	–	–

SUMMARY

Unconventional weapons of mass destruction continue to pose a threat to public safety. Chemical and biologic weapons releases are considered more likely to occur than thermonuclear weapons incidents, as CBW agents use resources subject to less governmental control and require less sophisticated technology and financial outlay than nuclear weapons. CBW agents are appealing to terrorist groups because the impact in terms of death, disability, economic losses, and panic remains high. The psychological impact of CBW terrorism may well exceed that for conventional or nuclear weapons. Although the probability of incidents resulting in widespread public health disasters appears low, the consequences are high, and substantial preparations must be made in advance. Smaller CBW incidents, unintentional releases, and hoaxes have occurred and will probably continue to occur. Toxicologists and associated healthcare professionals occupy a unique position to impact preparedness and response through familiarity with chemical hazards and biologic toxins.

CHAPTER 132
BIOLOGICAL WEAPONS

Jeffrey R. Suchard

Expertise in dealing with biological weapons requires specific knowledge from the fields of infectious disease, epidemiology, toxicology, and public health. Biological and chemical warfare agents share many characteristics in common, including intent of use, some dispersion methods, and initial defense based on adequate personal protective equipment and decontamination (see Tables 131–2 and 131–3). Key differences between biological and chemical weapons, however, involve a greater delay in onset of clinical symptoms after exposure to biological weapons; that is, the incubation period for most biological warfare (BW) agents is greater than the latent period for most chemical warfare (CW) agents. Decontamination is less crucial for victims exposed to BW agents than to CW agents. Additionally, a few BW agents can reproduce in the human host and cause secondary casualties, and disease following exposure to several of these agents can be prevented by the timely administration of prophylactic medications.

Biological weapons may be bacteria, fungi, viruses, or toxins derived from microorganisms. Some fungi are listed as potential BW agents, although to date, none are known to have been developed into weapons.[84] Because toxin weapons do not contain living organisms, some authorities classify them as chemical, rather than biological, weapons. For the purposes of discussion in this chapter, toxin weapons derived from microorganisms will be considered biological weapons. Most of the bacterial BW agents exert their effects by elaborating protein toxins.

A majority of the diseases caused by biological weapons are either infrequently encountered in modern clinical medicine, such as anthrax and plague, or no longer occur naturally, such as smallpox. Healthcare personnel therefore require specific training in the recognition and management of biological warfare victims. Potential BW agents have been categorized by the risk of mass-casualty outbreaks resulting from deployment and exposure.[17] The high-risk agents are easily disseminated or transmitted and may cause high mortality and potentially a public health disaster; these agents include smallpox, anthrax, plague, botulism, tularemia, and several hemorrhagic fever viruses. The moderate-risk agents include Q fever, brucellosis, the equine encephalitis viruses, ricin, and staphylococcal enterotoxin B, all of which are briefly discussed in this chapter.

HISTORY

Biological warfare has ancient roots. Missile-type weapons poisoned with natural toxins were used as early as 18,000 years ago (Chap. 1). Excavation of an Egyptian tomb, from about 2100 B.C., yielded arrows coated with cardioactive steroids and paralytic toxins.[62] The first recorded intentional spread of infectious disease in warfare occurred in the Anatolian war of 1320–1318 B.C. and appears to have involved tularemia.[81] Around 600 B.C., the Athenians used hellebore, and the Assyrians used ergot alkaloids, to poison enemy water supplies. In 200 B.C., the Carthaginian general Maharbal tainted wine consumed

by African rebel forces with the anticholinergic herb mandragora and then ambushed the intoxicated troops. In 184 B.C., Hannibal ordered earthen pots filled with "serpents of every kind" hurled onto enemy ships, thereby winning the naval battle of Eurymedon against King Eumenes of Pergamon.[32] In 67 B.C., King Mithridates VI of Pontus was retreating from the Roman General Pompey near Trebizond, modern northeast Turkey. At the advice of a physician-counselor, Mithridates maneuvered Pompey's troops into a region where the honey was contaminated with grayanotoxins from rhododendron nectar. The Romans ate the poisoned honey and were effectively ambushed.[52]

From 1344 to 1346 A.D., the Tartars besieged the Genoan trade city of Kaffa on the Black Sea coast. When the Tartars began to die of bubonic plague, the dead bodies were hurled over the battlements. Within the city, plague forced the Genoans to flee, and they then disseminated the disease to other trade ports and eventually to the rest of Europe, causing the Black Death.[86] In 1763, Sir Jeffrey Amherst, the commander of British forces during the French and Indian War, instituted a policy of spreading smallpox to Native Americans by giving them contaminated blankets and handkerchiefs.[26]

During World War I, Germany was the only combatant nation with an active BW program. German agents infected Allied livestock with anthrax and glanders.[85] Eighty years after the capture of a German device used to disseminate anthrax, viable spores were recovered.[70]

Shiro Ishii, a Japanese army doctor, headed an active BW program throughout Japan's war with China and World War II.[41] Several centers were founded, the most famous being Unit 731 in Manchuria, where human experiments on prisoners of war and imprisoned civilians occurred. Several field trials with bubonic plague were performed on Chinese civilians and Russian troops. The Soviet Union, Germany, France, Britain, and Canada all started BW research facilities in the period between the World Wars.

BW research program in the United States was founded at Camp Detrick, Maryland in 1942. Fort Detrick, as it is now known, remains the home of the United States Army Medical Research Institute of Infectious Diseases (USAMRIID). Anthrax and botulinum toxin were the foci of weapons development during WWII; it is estimated that the United States could have manufactured 1,000,000 anthrax bombs and 275,000 botulinum bombs by 1945 had full-scale production been implemented.[7]

In 1940 the British BW program was established at Porton Down, but most of the field testing of anthrax occurred on Gruinard Island off the northern coast of Scotland. In 1979, the soil was still found to be contaminated with viable anthrax spores.[53] The island was decontaminated with 5% formaldehyde in sea water, and was deemed safe by the British government in 1988.[1]

During the Cold War, the US military maintained active research into biological weapons, including field trials with bacterial simulants. In 1950, ships in San Francisco harbor released aerosols of *Serratia marcesans* and other simulants, which resulted in a minor outbreak of Serratia sepsis. In 1966, light bulbs filled with *Bacillus subtilis* var *globigii* were shattered in the New York City subway system, confirming the hypothesis that the piston-like action of the subway trains could rapidly disperse the bacterial aerosol throughout the city.[26,73]

In London, in 1978, the Bulgarian exile Georgi Markov was assassinated by a tiny metal pellet fired from a gun designed to appear like an umbrella. He was thought to have died from sepsis until the pellet was found at autopsy.[27] After the fall of the Soviet Union, government officials confirmed that the KGB used umbrella guns firing ricin pellets to assassinate Markov and others.

In 1979, an outbreak of human anthrax caused at least 66 fatalities in the Russian city of Sverdlovsk. Autopsies revealed that the deaths were

from inhalational anthrax, and epidemiologic investigation demonstrated that almost all of the cases occurred downwind from a military facility. These data are consistent only with a release of aerosolized anthrax, which has since been confirmed by Russian authorities.[59]

In the late 1970s and early 1980s, many reports came from Southeast Asia and Afghanistan that Soviet-supported troops were using a biological weapon known as Yellow Rain.[83] Some samples of Yellow Rain were found to contain trichothecene mycotoxins, although controversy remains regarding whether this finding represents intentional biological warfare or a naturally occurring phenomenon.[74]

During the 1990s there was a great deal of concern about the use and possible stockpiling of weapons of mass destruction (WMD) by Saddam Hussein in Iraq.[51] As part of the WMD program, Iraq had a very active BW research program, investigating at least five bacteria, one fungus, five viruses, four toxins, simulants, and a variety of dispersion methods.[75,88] Thousands of liters of anthrax spores, botulinum toxin, and aflatoxin were produced and weaponized into bombs and as payloads for SCUD missiles.

Biological terrorism and the threat of bioterrorism are now recognized as worldwide, growing public health concerns.[42] In the United States in 1984, a large outbreak of salmonellosis was traced to intentional contamination of restaurant salad bars by the Rajneeshee cult in Oregon.[80] The Aum Shinrikyo cult based in Japan investigated the use of cholera and Q fever, unsuccessfully released anthrax spores and botulinum toxin, and even sent members to Africa to obtain the Ebola virus.[64,78] The mere threat of biologic agent release can terrorize a city. At the end of the 1990s, there was a huge increase in false anthrax threats, which paralyzed Los Angeles and cities in Indiana, Kentucky, and Tennessee among many others.[15] Because of heightened concern for bioterrorism, even naturally occurring disease outbreaks have raised suspicion of biological terrorism. In 1999, an outbreak of West Nile-like virus encephalitis in New York and a case of brucellosis in New Hampshire acquired under suspicious circumstances were investigated as potential BW agent releases.[16,71] Similarly, a 1999–2000 epidemic of tularemia in war-torn Kosovo was scrutinized as the potential result of an intentional BW agent release.[40]

GENERAL CONSIDERATIONS

■ DIFFERENCES BETWEEN BW INCIDENTS AND NATURALLY OCCURRING OUTBREAKS

Because the clinical effects of bioweapons are often delayed for several days after exposure to the agents, it may be difficult to differentiate occult BW releases from naturally occurring disease outbreaks. Several epidemiologic criteria are proposed to aid in such determinations,[63] many of which should be identifiable in a BW incident (Table 132–1).

To avoid early detection, terrorists might choose to release an agent causing endemic infection, or a disease that mimics an endemic infection, during its season of peak incidence. In some areas of the United States, for example, a few cases of bubonic plague would not attract notice; that is, until dozens or hundreds of cases were identified. An outbreak of inhalational anthrax during the influenza season may similarly be hidden among patients with similar early symptoms until an unusually high mortality was evident.[22] By the time the BW outbreak was recognized, the perpetrators could dispose of any physical evidence and flee the area. On the other hand, even a single case of smallpox (anywhere in the world), Ebola virus infection, or Congo-Crimean hemorrhagic fever (in nonendemic areas) should immediately raise suspicion of a BW attack.

TABLE 132–1. Epidemiologic Clues Suggesting Biological Weapon Release

- Large epidemic with unusually high morbidity and/or mortality
- Epidemic curve (number of cases versus time) showing an "explosion" of cases, reflecting a point source in time rather than insidious onset
- Tight geographic localization of cases, especially downwind of potential release site
- Predominance of respiratory tract symptoms because most BW agents are transmitted by aerosol inhalation
- Simultaneous outbreaks of multiple unusual diseases
- Immunosuppressed and elderly persons more susceptible
- Nonendemic infection ("impossible epidemiology")
- Nonseasonal time for endemic infection
- Organisms with unusual antimicrobial resistance patterns, reflecting BW genetic engineering
- Animal casualties from same disease outbreak
- Absence of normal zoonotic disease host
- Low attack rates among persons incidentally working in areas with filtered air supplies or closed ventilation systems, using HEPA masks, or remaining indoors during outdoor exposures
- Delivery vehicle or munitions discovered
- Law enforcement or military intelligence information
- Claim of BW release by belligerent force

■ PREPAREDNESS

Many BW agents initially produce nonspecific symptoms, and diseases that are rarely, if ever, seen in clinical practice. Inhalational anthrax and pneumonic plague, for example, could easily be misdiagnosed as influenza or acute bronchitis. Providers in emergency departments (EDs) and primary care medicine must be educated to recognize the signs, symptoms, and clinical progression of diseases caused by BW agents.[72] Clear identification, isolation, and aggressive treatment early after exposure within the first 24–48 hours are the best and only means of reducing mortality and, in the case of smallpox or plague, preventing secondary or tertiary cases.[31] However, even with increasing awareness and educational efforts, many physicians remain inadequately prepared.

■ DECONTAMINATION

Biological warfare agents are most effective when dispersed by aerosol. Shortly after a known or suspected release of bioaerosols, decontamination is a relatively minor concern, because aerosols sized to reach the lower respiratory tract (<5-μm particles) produce little surface contamination. However, simple removal of clothing will eliminate a high proportion of deposited particles, and subsequent showering with soap and water will probably remove 99.99% of any remaining organisms on the skin.[50] Thus, decontamination after BW aerosol exposure, when needed, is achieved through disrobing and showering with soap and water. This can be done onsite or in the victims' homes and away from healthcare facilities, thereby reducing strain on disaster response manpower and material in multiple-victim exposures.[31,42,50,72] When there is gross, visible evidence of skin exposure to biological agents, the patient should be decontaminated by thorough irrigation, and, if available,

sterilizing the skin with a sporicidal/bactericidal solution (eg, 0.5% sodium hypochlorite), and a final water rinse.[50,72] After occult bioweapons releases, victims are identified late after exposure; decontamination will obviously not be helpful and may only serve to delay care.

BIOLOGICAL WARFARE AGENTS

■ BACTERIA

Anthrax Anthrax is caused by *Bacillus anthracis*, a Gram-positive spore-forming bacillus found in soil worldwide. *B. anthracis* causes disease primarily in herbivorous animals. Human anthrax cases generally occur in farmers, ranchers, and among workers handling contaminated animal carcasses, hides, wool, hair, and bones.[37]

Clinical Manifestations. A few clinically distinct forms of anthrax may occur, depending on the route of exposure. Cutaneous anthrax results from direct inoculation of spores into the skin via abrasions or other wounds and accounts for about 95% of endemic (naturally occurring) human cases. Patients develop a painless red macule that vesiculates, ulcerates, and forms a 1- to 5-cm brown-black eschar surrounded by edema.[56] The eschar color gave rise to the name anthrax, from the Greek *anthrakos* meaning "coal." Most skin lesions heal spontaneously, although 10%–20% of untreated patients progress to septicemia and death. Cutaneous anthrax when treated with antibiotic therapy rarely results in fatalities. Anthrax is not transmissible among humans.

Gastrointestinal anthrax results from ingesting insufficiently cooked meat from infected animals. Patients develop nausea, vomiting, fever, abdominal pain, and mucosal ulcers, which can cause GI hemorrhage, perforation, and sepsis. Mortality from gastrointestinal anthrax is at least 50%, even with antibiotic treatment.[37]

Inhalational anthrax results from exposure to aerosolized *B. anthracis* spores. Although this form of anthrax is very rare, it is so closely associated with occupational exposures that it has been called "woolsorter's disease." Inhalational anthrax is also likely to be the form that occurs in a BW attack, because the anthrax spores would be most effectively disseminated by aerosol. After an incubation period of 1–6 days, the patient develops fever, malaise, fatigue, nonproductive cough, and mild chest discomfort, which may be easily mistaken for community acquired pneumonia.[22] The initial symptoms may briefly improve for 2–3 days or the patient may abruptly progress to severe respiratory distress with dyspnea, diaphoresis, stridor, and cyanosis. Bacteremia, shock, metastatic infection such as meningitis, which occurs in about 50% of cases, and death may follow within 24–36 hours. Prior to the 2001 bioterrorist outbreak, mortality from inhalational anthrax was expected to be nearly 100%, even with antibiotics, once symptoms develop.[35,37] With appropriate antibiotic therapy and supportive care, 5 of 11 patients with inhalational anthrax in 2001 died, and although this is still a high mortality rate, it is less than that previously predicted.[46]

Pathophysiology. Inhalational anthrax causes a mediastinitis. Diagnostic imaging typically shows mediastinal widening from enlarged hilar lymph nodes and pleural effusions, although pulmonary parenchymal infiltrates may also be seen.[46] Inhaled spores are taken up into the lymphatic system where they germinate and the bacteria reproduce. *B. anthracis* produces three toxins: protective antigen, edema factor, and lethal factor. Protective antigen (PA) is so named because antibodies against it protect the subject from the effects of the other two toxins. PA forms a heptamer that inserts into plasma membranes, facilitating endocytosis of the other two toxins into target cells (see Figure 132–1). Edema factor is a calmodulin-dependent adenylate cyclase. Increased intracellular cyclic adenosine monophosphate (AMP) upsets water homeostasis, leading to massive edema and impaired neutrophil function. Lethal factor is a zinc metalloprotease
FIGURE 132–1. Model of action of anthrax toxins. PA = protective antigen; EF = edema factor; LF = lethal factor; PK = Protein Kinase. EF and LF are unable to enter cells until they complex with a PA heptamer, forming edema toxin and lethal toxin respectively. Once intracellular, release from PA allows EF and LF to exert their intracellular effects. Antibodies against PA confer resistance to the toxic effects of anthrax.

that stimulates macrophages to release tumor necrosis factor α and interleukin-1β, contributing to death in systemic anthrax infections.[29] The combination of PA plus edema factor is called *edema toxin*, while PA plus lethal factor is *lethal toxin*.[39]

Treatment. The primary antibiotics recommended to treat anthrax are ciprofloxacin and doxycycline. Although other fluoroquinolones would be expected to have similar activity against anthrax, only the manufacturer of ciprofloxacin applied for and received a Food and Drug Administration (FDA)-approved indication for use in this infection. In a mass-casualty setting or for postexposure prophylaxis, adults should be treated with ciprofloxacin 500 mg PO every 12 hours. Alternate therapies are doxycycline 100 mg PO every 12 hours, or amoxicillin 500 mg PO every 8 hours, if the anthrax strain is proven susceptible.[46] The recommended duration of therapy is 60 days, stemming from case experience in Sverdlovsk where some patients developed disease several (6–7) weeks after the spore release.[59] Children can also be treated with ciprofloxacin (15 mg/kg; maximum 500 mg/dose) or amoxicillin (80 mg/kg/d divided every 8 hours; maximum 500 mg/dose). The relative pediatric contraindication to fluoroquinolones is outweighed by the risk of potentially fatal disease. Cutaneous anthrax is treated with the same drugs and doses as for postexposure prophylaxis.

Inhalational anthrax should be treated initially with intravenous antibiotics. Adults should receive ciprofloxacin 400 mg IV or doxycycline 100 mg IV every 12 hours, along with one or two additional antibiotics with in vitro activity against anthrax (eg, rifampin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, clarithromycin). Children should be given ciprofloxacin 10 mg/kg IV (max. 400 mg/dose), or doxycycline 2.2 mg/kg IV (max. 100 mg/dose), and additional antibiotics as above.[46] In a true mass-casualty event, however, when resources are strained and inpatient care is not available for every victim, oral therapy, as described above, may be instituted. When clinically appropriate, oral antibiotic therapy can be substituted for IV, with a total treatment duration of 60 days. Some patients in the 2001 outbreak were specifically treated with additional antibiotics that inhibit protein synthesis in attempts to reduce bacterial production of toxins.

Anthrax Vaccine. An effective vaccine against anthrax is available.[38,58,89] In the United States, the Bioport Corporation (formerly Michigan Biologic Products Institute) is licensed by the FDA to produce anthrax vaccine adsorbed (AVA). The vaccine consists of a membrane-sterilized culture filtrate of *B. anthracis* V770-NP1-R, an avirulent, nonencapsulated strain that produces protective antigen, adsorbed to aluminum hydroxide, formulated with benzethonium chloride (preservative) and

formaldehyde (stabilizer).[89] In human and animal experiments, the vaccine is highly effective in preventing all forms of anthrax (including inhalational), and the vaccine is recommended for workers in high-risk occupations. As in the case of any vaccine, local reactions to AVA occur in some recipients (up to 20% with mild, local reactions), and self-limited systemic reactions occur more rarely (<1.5%). Women have been noted to have more frequent injection-site reactions and other adverse events, although this sex difference is also noted with other common vaccines.[39] Serious adverse events are very rare, with only 22 potentially related cases of serious adverse events from over 1 million doses administered to US armed forces.[38] The dosage schedule for AVA is 0.5 mL subcutaneously at 0, 2, and 4 weeks and 6, 12, and 18 months, followed by yearly boosters.

The 2001 Bioterrorist Anthrax Outbreak. Starting on September 27, 2001 a 63-year-old Florida man developed malaise, fatigue, fever, chills, anorexia, and diaphoresis. He was admitted to a local hospital on October 2, after presenting with additional complaints of nausea, vomiting, and confusion. Chest radiography showed cardiomegaly, a left perihilar infiltrate, small left pleural effusion, and a prominent superior mediastinum. Lumbar puncture revealed hemorrhagic meningitis with many Gram-positive bacilli. *Bacillus anthracis* was isolated from the cerebrospinal fluid after only a 7-hour incubation and from blood cultures within 24 hours. The patient had progressive clinical deterioration and died on hospital day four.[12,48]

On October 4, the Centers for Disease Control and Prevention (CDC) released a public health message regarding this case, which initially appeared to be an isolated, perhaps naturally occurring sporadic event; another case of anthrax was reported in Texas earlier the same year.[18] Nevertheless, the rarity of inhalational anthrax especially outside of a high-risk occupation, combined with increased suspicion in the wake of events on September 11, 2001, led to intense investigation of a potential bioterrorist event. Within days, epidemiologic investigation suggested workplace exposure to anthrax spores, and personnel working in the same building were started on prophylactic ciprofloxacin.[19] On October 12, a case of cutaneous anthrax was reported in New York City associated with a suspicious letter opened on September 25.[20] Anthrax cases and environmental contamination were also soon detected in Washington DC and in a New Jersey postal facility. The public response to the reports of these serious and fatal cases included misuse and hoarding of antibiotics, purchasing gas masks (often with inappropriate filtering mechanisms for biological weapons), reporting numerous miscellaneous powdery substances, and perpetrating or reporting copycat hoaxes.

By November 7, 2001, a total of 22 cases of anthrax were reported: 10 inhalational and 12 cutaneous.[21] One additional death from inhalational anthrax occurred on November 21, 2001,[5] and a case of cutaneous anthrax also occurred in a laboratory worker analyzing samples obtained during the investigation.[23] In two of the fatal cases, no contact with contaminated letters could be established.[5,61] One infant hospitalized in New York City with cutaneous anthrax was initially misdiagnosed as suffering from a brown recluse spider envenomation.[36] The total number of medical victims of anthrax by the Spring of 2002 was 23: 11 cases of inhalational anthrax (with 5 fatalities), and 12 cases of cutaneous anthrax (8 confirmed and 4 suspected).[23]

Although the overall morbidity and mortality from this bioterrorist event were relatively low, the psychosocial-economic impact was high. Several hundred postal and other facilities were tested for *B. anthracis* spore contamination, and public health authorities recommended antibiotic prophylaxis be initiated for approximately 32,000 persons.[21] Additional indirect costs and effects are more difficult to quantify, including the number of persons self-initiating antibiotic treatment without an evident indication, lost production and wages, environmental

and biologic sample testing, decontamination efforts, and an international sense of unease.

Published estimates of tens of thousands of deaths from a military-style anthrax attack[49] depend on efficient BW agent dispersion. The technically easier anthrax letter has clearly proven itself to be a "weapon of mass disruption." As predicted, the psychological impact far exceeded the actual medical emergency, and events with a modest number of medical patients are probably more likely than true mass-casualty BW incidents. On the other hand, prior assumptions regarding the clinical aspects of anthrax were not as reliable. The mortality rate among the 11 cases of inhalational anthrax was 45%, considerably lower than expected and probably because of earlier diagnosis, improved supportive care measures, and a wider choice of antibiotics, compared to historical controls. Presentation with fulminant illness, such as sepsis, still appears to be predictive of a fatal outcome, yet the initial phase of illness does not necessarily lead to death, if treated with appropriate antibiotics.[8,48,54] Pleural effusions were the most common radiographic abnormality, rather than a widened mediastinum, and pulmonary parenchymal infiltrates were seen in seven patients, whereas earlier teaching had been that pneumonia does not commonly occur with inhalation anthrax.[37,48]

Plague *Yersinia pestis* is a Gram-negative bacillus responsible for over 200 million human deaths and 3 major pandemics in recorded history.[56,57] Naturally occurring plague is transmitted by flea vectors from rodent hosts, or by respiratory droplets from infected animals or humans. Bubonic plague could result from an intentional release of plague-infested fleas. Plague is a particularly frightening BW agent because it can be released as an aerosol to cause a fulminant communicable form of the disease for which no effective vaccine exists. Antibiotics must be initiated early after exposure because once symptoms develop, mortality is extremely high.

Clinical Presentation. Plague occurs in three clinical forms: bubonic, septicemic, and pneumonic. Bubonic plague has an incubation period of 2–10 days followed by fever, malaise, and painful, enlarged regional lymph nodes called buboes. The inguinal nodes are most commonly affected, presumably because the legs are more prone to flea bites, although cervical or axillary buboes are more common in children.[69] In the United States, 85%–90% of human plague patients have the bubonic form, 10%–15% have a primary septicemic form without lymphadenopathy, and about 1% present with pneumonic plague. Secondary septicemia occurs in 23% of patients presenting with bubonic plague.[57] Various skin lesions at the site of inoculation (pustules, vesicles, eschars, or papules) occur in some patients, although the petechiae and ecchymoses that occur in advanced cases may resemble meningococcemia.[56] Distal gangrene may occur from small artery thrombosis, explaining why plague pandemics are sometimes called "The Black Death." If left untreated, bubonic plague carries a 60% mortality rate.[56]

Pneumonic plague is an infection of the lungs with *Y. pestis*. Between 5% and 15% of bubonic plague patients develop secondary pneumonic plague through septicemic spread of the organism.[57] Primary pneumonic plague occurs from inhalation of infected respiratory droplets or an intentionally disseminated BW aerosol. The incubation period of pneumonic plague after inhalation is 2–3 days. The onset of disease is acute and often fulminant. Patients develop fever, malaise, and cough productive of bloody sputum, rapidly progressing to dyspnea, stridor, cyanosis, and cardiorespiratory collapse. Plague pneumonia is almost always fatal unless treatment is begun with 24 hours of symptom onset.[35]

Diagnosis and Treatment. Plague can be diagnosed by various staining techniques, immunologic studies, or by culturing the organism

from blood, sputum, or lymph node aspirates. When gram stained, *Y. pestis* appears as a Gram-positive safety pin–shaped bipolar coccobacillus.[35,69] Chest radiographs in pneumonic plague reveal patchy or consolidated bronchopneumonia. Leukocytosis with a left shift is common, as are markers of low-grade disseminated intravascular coagulation (DIC) and elevations of unconjugated bilirubin and hepatic aminotransferases.[35]

Antibiotic treatment options are similar to those for anthrax. In a mass-casualty setting or for postexposure prophylaxis, adults are treated with doxycycline 100 mg PO twice daily or ciprofloxacin 500 mg orally twice daily. Children receive doxycycline 2.2 mg/kg or ciprofloxacin 20 mg/kg, up to a maximum of the adult doses. Chloramphenicol 25 mg/kg orally four times daily is an alternative. The duration of treatment is 7 days for postexposure prophylaxis, and 10 days for mass-casualty incidents.[45] Patients with pneumonic plague need to be isolated to prevent secondary cases. Respiratory droplet precautions are necessary in pneumonic plague until the patient has received antibiotics for 3 days.[35] In a contained-casualty setting, pneumonic plague is treated with parenteral streptomycin or gentamicin; alternative antibiotics include doxycycline, ciprofloxacin, and chloramphenicol.[45] A killed whole-cell vaccine effective against bubonic plague is available, but does not reliably protect against pneumonic plague in animal studies.[56,58]

Tularemia *Francisella tularensis* is a small, aerobic, Gram-negative coccobacillus weaponized by the United States and probably other countries as well. Tularemia occurs naturally as a zoonotic disease spread by bloodsucking arthropods or by direct contact with infected animal material. Tularemia in humans may occur in ulceroglandular or typhoidal forms, depending on the route of exposure. Ulceroglandular tularemia is more common, occurring after skin or mucous membrane exposure to infected animal blood or tissues. Patients develop a local ulcer with associated lymphadenopathy, fever, chills, headache, and malaise. Typhoidal tularemia presents with fever, prostration, and weight loss without adenopathy. Exposure to aerosolized bacteria, as employed in BW, will most likely result in typhoidal tularemia with prominent respiratory symptoms such as a nonproductive cough and substernal chest discomfort. Diagnosing tularemia is often difficult, as the organism is hard to isolate by culture and the symptoms are nonspecific. Chest radiography may demonstrate infiltrates, mediastinal lymphadenopathy, or pleural effusions.[28,33,35,58]

Antibiotic treatment options are again similar to those for anthrax and plague. In mass-casualty settings, or for postexposure prophylaxis, adults are treated with doxycycline 100 mg twice daily or ciprofloxacin 500 mg orally twice daily for 14 days; pediatric dosing for doxycycline is 2.2 mg/kg or ciprofloxacin 15 mg/kg (maximum = adult dose) twice daily. When dealing with a limited number of casualties, the preferred antibiotics are streptomycin 1 g IM twice daily, or gentamicin 5 mg/kg IM/IV once daily. Alternatives include parenteral doxycycline, chloramphenicol, and ciprofloxacin.[28]

Brucellosis Brucellosis could potentially be used as an incapacitating BW agent, because it causes disease with low mortality but significant morbidity. Indeed, the initial attraction of brucellosis as a weapon was its ability to induce chronic disease.[65] Brucellae (*Brucella melitensis*, *abortus*, *suis*, and *canis*) are small, aerobic, Gram-negative coccobacilli that generally cause disease in ruminant livestock. Humans develop brucellosis by ingesting contaminated meat and dairy products or by aerosol transmission from infected animals. The United States weaponized *B. suis* and other countries are also believed to have developed *Brucella* bioweapons. Brucellosis commonly presents with nonspecific symptoms such as fever, chills, and malaise, with either an acute or insidious onset. Because brucellae are facultative intracellular parasites that localize in the lung, spleen, liver, CNS, bone marrow, and

synovium, organ-specific signs and symptoms may occur. Diagnosis is made by serologic methods or culture. Because single-drug treatment often results in relapse, combined therapy is indicated. Treatments of choice (adult doses) are doxycycline 200 mg/d orally, plus rifampin 600–900 mg/d orally for 6 weeks, or doxycycline 200 mg/d orally for 6 weeks with either streptomycin 15 mg/kg twice daily IM or gentamicin 1.5 mg/kg IM q8h for the first 10 days.[35,44,58]

Rickettsiae Features of rickettsiae favoring their use as BW agents include environmental stability, aerosol transmission, persistence in infected hosts, low infectious dose, and high associated morbidity and mortality. Rickettsiae that have been weaponized include *Coxiella burnetti*, the causative organism of Q Fever, and *Rickettsia prowazekii*, the causative organism of louseborne typhus. Release of *R. prowazekii* into a crowded louse-infested population might induce a typhus outbreak with rapid transmission and high mortality.[4]

Q Fever Q fever was first described in 1937, and was given its name—Q for "query"—because the causative organism was not then known. Q fever occurs naturally as a self-limited febrile, zoonotic disease contracted from domestic livestock. Q fever is now known to be caused by *Coxiella burnetti*, a unique rickettsia-like organism that can persist on inanimate objects for weeks to months and can cause clinical disease with the inhalation of only a single organism. These features are of obvious benefit for use as a potential BW agent. After a 10- to 40-day incubation period, Q fever manifests as an undifferentiated febrile illness, with headache, fatigue, and myalgias. Patchy pulmonary infiltrates on chest radiography that resemble viral or atypical bacterial pneumonia occur in 50% of cases, although only half of patients have cough and even fewer have pleuritic chest pain. Uncommon complications include hepatitis, endocarditis, meningitis, encephalitis, and osteomyelitis. Patients are generally not critically ill, and the disease can last as long as 2 weeks. Treatment with antibiotics will shorten the course of acute Q fever and can prevent clinically evident disease when given during the incubation period. Tetracyclines are the mainstay of therapy, and either tetracycline 500 mg PO q6h or doxycycline 100 mg PO q12h should be given for 5–7 days.[13,35]

■ VIRUSES

Smallpox Smallpox is caused by the variola virus, a large DNA orthopoxvirus with a host range limited to humans. Prior to global World Health Organization (WHO) efforts to eradicate naturally occurring smallpox by immunization, recurrent epidemics were common and the disease carried roughly a 30% fatality rate in unvaccinated populations.[43,55] Smallpox is highly contagious. Outbreaks during the 1960s and 1970s in Europe often resulted in 10–20 secondary cases per index case. One German smallpox patient with a cough, isolated in a single room, infected persons on three floors of a hospital.[43] The overwhelming majority of secondary infections, however, occur among close family contacts, especially those sleeping in the same room or even in the same bed.[30]

In 1980, the United Nations' WHO certified that smallpox had been eradicated from the world, and recommended ceasing vaccinations and either destroying or transferring remaining stocks of variola virus to one of two designated biosafety level 4 facilities: the CDC in Atlanta, or the Russian State Research Center of Virology and Biotechnology.[11] All remaining known variola stocks were scheduled for destruction in 1999; however, before this was done, a WHO resolution called for a delay based on an Institute of Medicine report concluding that live virus should be retained to develop new antiviral agents or vaccines to protect against any potential future release of smallpox.[76] The Soviet Union is known to have weaponized smallpox, and other countries are believed to maintain stocks of variola virus. In addition to the known stockpiles of smallpox vaccine, several types of new vaccines are being

produced.[66,87] Smallpox vaccination for military personnel was reinstated in 2002 and was made available for some civilians in 2003.[24,25]

Pathophysiology. Transmission of smallpox typically occurs through inhalation of droplets or aerosols, but may also occur through contaminated fomites. The infectious dose is not known, but is probably only a few virions. After a 12- to 14-day incubation period, the patient develops fever, malaise, and prostration with headache and backache. Oropharyngeal lesions appear, shedding virus into the saliva. Two to three days after the onset of fever, a papular rash develops on the face and spreads to the extremities. The fever continues while the rash becomes vesicular and then pustular. Scabs form from the pustules and eventually separate, leaving pitted and hypopigmented scars. Deaths usually occur during the second week of the illness. Vaccination before exposure, or within 2–3 days after exposure, provides almost complete protection against smallpox. The disease most likely to be confused with smallpox is chickenpox (varicella). Although the individual lesions of smallpox and varicella are physically indistinguishable, the person infected with smallpox may still be differentiated clinically. The lesions of smallpox should all appear at the same stage of development (synchronous), whereas chickenpox lesions occur at varying stages (asynchronous). Smallpox lesions tend to be found in a centrifugal distribution (face and distal extremities), whereas chickenpox lesions are more centripetal and tend to appear first on the trunk.

Two antiviral drugs commercially available in the United States, cidofovir and ribavirin, are effective in vitro against variola.[58] Current evidence suggests, however, that although cidofovir may prevent smallpox when given within 1 or 2 days of exposure, it is unlikely to be effective once symptoms develop.[43] Even a single case of smallpox should be considered a potential international health emergency and immediately reported to the appropriate public health authorities.

Smallpox Vaccination. Rapid postexposure vaccination confers excellent protection against smallpox. The smallpox vaccine employs a live vaccinia virus (derived from cowpox vaccine) rather than the actual variola virus that causes smallpox. Although contracting smallpox from the vaccine is therefore impossible, other adverse reactions may occur. The two most serious reactions are postvaccinal encephalitis and progressive vaccinia. Postvaccinal encephalitis occurs in about three cases per million primary vaccinees. Forty percent of cases are fatal, and some survivors are left with permanent neurologic sequelae. Progressive vaccinia can occur in immunosuppressed individuals and is treated with vaccinia immune globulin (VIG).[87] Another historically common complication of smallpox vaccination was ocular vaccinia, which typically occurred among healthcare personnel administering vaccine when it was inadvertently placed in the eye. Ocular vaccinia is also treated with VIG. Because smallpox was eradicated before the emergence of HIV, there is limited clinical experience with smallpox vaccination in AIDS patients, who theoretically are at increased risk of progressive vaccinia.[43,55] However, among 10 individuals with undiagnosed HIV at the time of recent smallpox vaccination, none developed complications.[79] Routine vaccination is contraindicated in the immunosuppressed, persons with a history or evidence of eczema and other chronic dermatitis, close household or sexual contacts of patients with these contraindications, and during pregnancy. Because the vaccine is a live virus, it can be transmitted from the vaccinee to close contacts. Thirty secondary and tertiary cases of vaccinia were reported resulting from recent US military vaccinations.[24] The number of serious adverse events from modern smallpox vaccination is very low;[25] however, rare cardiac complications not reported in previous decades were noted with the recent re-institution of smallpox vaccination in the early 2000s. More than one million military vaccinations by 2006 resulted in 120 cases of myopericarditis, while 21 cases of myopericarditis occurred among nearly 40,000 civilian vaccine recipients between 2002

and 2003.[66] The number of cardiac ischemic events among vaccinees was not significantly higher than age-matched controls. After a true exposure to variola, most authorities would agree that the only absolute contraindication to smallpox vaccination is significant impairment of systemic immunity. Concomitant administration of VIG would be recommended for pregnant women and persons with eczema.[55]

Viral Hemorrhagic Fevers Several taxonomically diverse RNA viruses produce acute febrile illnesses characterized by malaise, prostration, and increased vascular permeability that can result in bleeding manifestations in the more severely affected patients. Viral hemorrhagic fevers (VHF) are all highly infectious by the aerosol route, making them candidates for use as BW agents. These agents include the viruses causing Lassa fever, dengue, yellow fever, Crimean-Congo hemorrhagic fever, and the Marburg, Ebola, and Hanta viruses. Clinical features, such as the extent of renal, hepatic, and hematologic involvement, vary according to the infectious agent, but they all carry the risk of secondary infection through droplet aerosols. Ribavirin has been used for some VHFs, but supportive care is the mainstay of therapy.[9,35,47]

Viral Encephalitides Three antigenically related alpha viruses of the *Togaviridae* family pose risks as BW agents: western equine encephalitis (WEE), eastern equine encephalitis (EEE), and Venezuelan equine encephalitis (VEE). Birds are the natural reservoir of these viruses, and natural outbreaks occur among equines and humans by mosquito transmission. Eastern equine encephalitis infections are the most severe in humans, with a 50%–70% fatality rate and high incidence of neurologic sequelae among survivors. WEE is less neurologically invasive, and severe encephalitis from VEE is rare, except in children. Adults infected with VEE usually develop an acute, febrile, incapacitating disease with prolonged recovery. The equine encephalitides have many properties helpful for weaponization, in that they can be produced in large quantities, they are relatively stable and highly infectious to humans as aerosols, and a choice is available between lethal or incapacitating infections.[77]

Venezuelan equine encephalitis is considered the most likely BW threat among the viral encephalitides. After a 1- to 5-day incubation period, victims experience the sudden onset of malaise, myalgias, prostration, spiking fevers, rigors, severe headache, and photophobia. Nausea, vomiting, cough, sore throat, and diarrhea may follow. This acute phase lasts 24–72 hours. Between 0.5% and 4% of cases develop overt encephalitis, with meningismus, seizures, coma, and paralysis, which carries up to a 20% fatality rate. The diagnosis is usually established clinically, although the virus can sometimes be isolated from serum or from throat swabs, and serologic tests are available. The white blood cell count often shows a striking leukopenia and lymphopenia. Treatment is supportive. Person-to-person transmission can theoretically occur from droplet nuclei. Recovery takes 1–2 weeks.[35,77]

■ TOXINS

Several toxins derived from bacteria, plants, fungi, and algae could theoretically be used as BW agents, if produced in sufficient quantities. Because of their high potency, only small amounts of these agents would be needed to kill or incapacitate exposed victims. Fortunately, obstacles in manufacturing weaponizable amounts limit the number of toxins that are practical for use as biological weapons. Discussion here is limited to those toxins known or highly suspected to have been weaponized. Toxins themselves are not living organisms and therefore can not reproduce; for this reason, they are arguably equivalent to chemical weapons. But because toxin weapons are derived from living organisms, they are categorized here as biological weapons.

Botulinum Toxin Botulinum toxin has been developed as a biological weapon in the United States and other countries.[2,64,75,88] The two most

likely means of employing botulism as a BW agent are by food contamination or by aerosol. Either method would result in the clinical syndrome of botulism (Chap. 46), characterized by multiple bulbar nerve palsies and a symmetric descending paralysis, ending in death from respiratory failure. Inhalation botulism from laboratory incidents has occurred rarely in humans and has also been investigated in animal experiments.[60]

Ricin Ricin is derived from the castor bean plant (*Ricinus communis*) and is the only biological toxin to exist naturally in macroscopic quantities, comprising 1%–5% of the beans by weight.[10] Its easy accessability, relative ease of preparation, and low cost may make ricin an attractive biological weapon for terrorists or poor countries.[68] Although ricin has never been used in battle, it has attracted the attention of domestic extremists and terrorists and has been used in politically motivated assassinations.[3,27,34] Ricin is a glycoprotein lectin (or toxalbumin) composed of two protein chains linked by a disulfide bond. The B chain facilitates cell binding and entry of the A chain into cells. The A chain inhibits protein synthesis, inactivating eukaryotic ribosomes by removing an adenine residue from ribosomal RNA.[3]

Clinical toxicity from ricin will vary depending on the dose and route of exposure. Inhalation of aerosolized ricin results in increased alveolar-capillary permeability and airway necrosis following a latent phase of 4–8 hours. Ingestion causes gastrointestinal hemorrhage with necrosis of the liver, spleen, and kidney. Intramuscular administration produces severe local necrosis with extension into the lymphatics. In the absence of specific immunologic testing, differentiating ricin poisoning from sepsis may be difficult, because of the presence of leukocytosis and fever. Vaccination of laboratory animals with an investigational toxoid is protective.[34]

Staphylococcal Enterotoxin B Staphylococcal enterotoxin B (SEB) is one of seven enterotoxins produced by *Staphylococcus aureus*. SEB is recognized as a "superantigen," because of its profound activation of the immune system on exposure to even minute quantities. As a BW agent, SEB could be ingested through contaminated food or water, resulting in acute gastroenteritis identical to classic staphylococcal food poisoning. If inhaled as an aerosol, SEB produces fever, myalgias, and a pneumonitis after a 3- to 12-hour latent period. SEB inhalation can be fatal, but more often would simply be incapacitating for several days to weeks. Treatment is supportive.[82]

Trichothecene Mycotoxins The trichothecene mycotoxins are low-molecular-weight (250–500 Da) nonvolatile compounds produced by filamentous fungi (molds) of various genera, including *Fusarium*, *Myrothecium*, *Phomopsis*, *Trichoderma*, *Tricothecium*, and *Stachybotrys*.[6,83] Tricothecene mycotoxins are unusual among potential BW agents in that toxicity can occur with exposure to intact skin. Naturally occurring trichothecene toxicity results from ingesting contaminated grains or by inhaling toxin aerosolized from contaminated hay or cotton. Outbreaks of ingested trichothecene toxins result in a clinical syndrome called alimentary toxic aleukia, characterized by gastroenteritis, fevers, chills, bone marrow suppression with granulocytopenia, and secondary sepsis—a syndrome similar to acute radiation poisoning. Survival beyond this stage is characterized by the development of GI and upper airway ulceration, and intradermal and mucosal hemorrhage. Trichothecene toxins are potent inhibitors of protein synthesis in eukaryotic cells, producing widespread cytotoxicity, particularly in rapidly proliferating tissues; different trichothecene toxins interfere with initiation, elongation, and termination stages of protein synthesis.[6] Exposure to any mucosal surface results in severe irritation. Dermal exposure can produce inflammatory lesions lasting for 1–2 weeks, vesiculation, and, in higher doses, death.[83]

Several reports from the 1970s and 1980s suggested that Soviet-supported forces were using trichothecene mycotoxins, particularly
FIGURE 132–2. Trichothecene mycotoxins. (**A**) Tetracyclic trichothecene nucleus (**B**) T-2 toxin.

the toxin T-2 (Fig. 132–2), as BW agents. Aerosol and droplet clouds called Yellow Rain were associated with mass casualty incidents in southeast Asia.[83] Such incidents would involve multiple routes of exposure, with skin deposition likely being the major site. Early symptoms included nausea, vomiting, weakness, dizziness, and ataxia. Diarrhea would then ensue, at first watery and then becoming bloody. Within 3–12 hours victims would develop dyspnea, cough, chest pain, sore mouths, bleeding gums, epistaxis, and hematemesis. Exposed skin areas would become intensely inflamed, with the appearance of vesicles, bullae, petechiae, ecchymoses, and frank necrosis.[83]

Nonetheless, evidence that trichothecene mycotoxins were used as BW agents was mostly circumstantial. Although T-2 toxin was found in victims' blood and urine, it was also found in samples from unexposed individuals, probably from baseline ingestion of contaminated foods. Environmental samples containing Yellow Rain droplets were inconsistently found to contain mycotoxins. Eyewitness accounts of Yellow Rain attacks varied widely (including various descriptions of the alleged agent's color), and, despite the large number of such attacks, no contaminated ordinance or dispersal device was ever recovered.[74] It was also discovered that Yellow Rain droplets were composed mostly of pollen grains. Supporters of the Yellow Rain as BW theory retorted that pollen grains would be an ideal carrier for biotoxins, given that their size is ideal for aerosolization. However, the pollen in Yellow Rain samples did not contain protein, similar to pollen that has been digested by bees. Further, the distribution of pollen species found in Yellow Rain was indistinguishable from the contents of feces of the Asian honeybee, and mass bee defecation resulting in showers of yellow droplets has been observed.[74] The Yellow Rain as bee feces theory assumes that any mass-casualty incidents were from endemic disease outbreaks, other CBW agents not yet identified, or a combination of both.

■ FUNGI AND OTHER FUNGAL TOXINS

Fungi may at first appear to be ideal BW agents, given their relative ease of handling, dissemination, and resistance of spores to physical stressors.[14] The only fungi to be included on lists of microbes with potential use as biological weapons are *Coccidioides* species, probably based on the high incidence of symptomatic infection in endemic areas. Nevertheless, the risk of serious disease is low, limiting the utility of *Coccidioides* as an effective weapon.[14,67]

Fungal toxins considered to have potential use as biological weapons include trichothecene mycotoxins (above), aflatoxins, and amanita toxins. Although α-amanitin is extremely potent, water soluble, and heat stable, its use as a weapon would be limited by difficulties in mass production.[67] Aflatoxin would be ineffective on the battlefield,

since its acute toxicity is uncertain and the carcinogenetic potential is too delayed.[6] Both of these agents may, however, still be effective as terror agents.

SUMMARY

Although biological weapons have been used intermittently for centuries, only recently has their danger in potentially causing mass casualties been commonly recognized. Even with multinational bans against their development and use, the threat of biological weapons remains because the financial outlay in developing biological weapons is low compared to other weapons of mass destruction, and because even the threat of their use may aid some parties in furthering their political goals. Currently, the risk of a medical catastrophe from BW agents producing thousands or millions of victims appears low, with inhalational anthrax or smallpox being the most likely agents in such a scenario. Nevertheless, incidents with limited numbers of casualties, or just threats of employing BW agents, can have significant social impact.

CHAPTER 133
RADIATION

Joseph G. Rella

Over the last century, radiation injuries and the nature of radiation itself have been vigorously studied as a result of its expanding role in our society. Today, radionuclides are used for a wide variety of medical and nonmedical purposes ranging from detecting smoke to diagnostic testing to powering spacecraft. Although useful, radionuclides can present a danger to humans both through their metallic nature and through the process of radioactive decay. This ionizing radiation may cause injury to multiple cellular structures and critical molecules, such as DNA, resulting in mutations, neoplasms, or cell death. The particles of radiation, their sources, and the mechanisms by which they pose a health risk are the subjects of the following discussion.

HISTORICAL EXPOSURES

Radiation became a concern for scientists as a toxin only a year following the discovery of x-rays by Wilhelm Roentgen in 1895.[91] Soon after, Thomas Edison reported corneal injuries in several of his workers conducting experiments using his newly invented x-ray generator. Eight years later, Clarence Dally, one of Edison's most dependable assistants, became the first radiation-related death in the United States.[32] Fortunately, the medical community recognized the utility of Edison's fluoroscope and began to use x-ray machines to help diagnose various illnesses. For example, the British army developed and used mobile x-ray machines to find bullets and shrapnel in wounded soldiers in Sudan in the early 1900s.

Over the next 10–15 years, radioactive substances also found their way into society as objects of fascination and as a means of alternative medical therapies. Aggressively marketed as "cure-alls," advertisements for products such as the Revigator and Radithor enticed people to drink water "charged" with radon or radium. These products ushered in 20 years of "health" products containing radioactive materials.[60,61]

In 1915, the British Roentgen Society, recognizing the potential hazards of radiation, proposed standards for radiation protection of workers, which included shielding, restricted work hours, and medical examinations. Unfortunately, no dose limits were implemented because dose quantitation was unavailable.

The opening of the Radium Luminous Materials Corporation in Orange, New Jersey, in 1917 represented the first of several companies to profit from the novelty and popularity of the bluish glow of radium. In an industry that employed over 4000 workers at its peak, nearly all of whom were women, the radium was hand-painted onto watch and instrument dials. These young women were instructed to obtain a fine tip on their paintbrushes using a technique called "lip pointing," which meant using their lips and tongues to shape their paintbrushes. Unaware of the danger, some of these women also painted their nails, lips, and eyelids with the radioactive paint. By 1927, about 100 of them died from osteosarcoma of the jaw, brain tumors, and developed other noncancerous lesions of the mouth, all related to radium exposure.[63,74]

The only occasions nuclear bombs were used against humans occurred in August 1945 when the United States dropped bombs on Hiroshima and Nagasaki, Japan.[30] One contained a uranium core and liberated energy equivalent to 12,500 tons of TNT. The other contained a plutonium core and liberated an energy equivalent to 20,000 tons of TNT. Estimates of dead and injured for both cities are well over 200,000.[38] Most of the deaths were from the bomb blast, but many thousands died from acute radiation syndrome (ARS) and subsequently from radiation-induced cancers. In addition to the people of those cities who were victims of the bombs, at least 20,000 men and women from Britain, Australia, New Zealand, and India who formed the British Commonwealth Occupation Forces (BCOF) were also exposed to residual radiation as they were involved in security and clean-up tasks. Published memoirs even include photographs of Australian soldiers playing football on the flattened hypocenter of Hiroshima. Data concerning the health effects of the BCOF in postwar Japan are less well known than those reported by the British Nuclear Tests Veterans Association (BNTVA). The BNTVA is a group of 20,000 men who were required to attend United Kingdom nuclear weapons tests in Australia and at Christmas Island between 1952 and 1963. Over two thirds of this cohort died of neoplasms at ages of 50–65 years, irrespective of the individual's age at the time of the witnessed explosion.[83,84] Since that time there have been thousands of nuclear bomb tests around the world in the atmosphere, underground, and underwater.

With the beginning of the nuclear age also came unintentional criticality events of varying kinds in which individuals were exposed to large amounts of radiation. Criticality refers to the chain reaction of fissionable atoms that results in the release of energy. It is the basic operating principle behind fission bombs and nuclear reactors and is an efficient means of generating energy. Two criticality events occurred in Los Alamos in the 1940s during experiments in which scientists performed what was called "tickling the dragon." In that era, determining the amount of fissionable material necessary to precipitate a chain reaction was not precisely defined mathematically. Harry Daghlian and Louis Slotin, two scientists involved in the development of the first atomic bomb, were to bring subcritical amounts of fissionable material together to see if a reaction would occur. Both men died of acute radiation sickness (ARS) following exposure to high levels of radiation released during these experiments. Since 1945 numerous criticality events have occurred, the most recent in Tokaimura, Japan in 1999. In that instance, workers making fuel for nuclear reactors allowed excess uranium to enter the reaction container. The criticality event that resulted killed one worker and caused the evacuation of all the people living within 350 meters of the manufacturing plant.

During the late 1920s, radiologists used a thorium-containing contrast agent called Thorotrast. During that time when imaging modalities were limited, this opacifying xenobiotic, given intravascularly in a colloidal suspension, provided essential medical information during the early development of angiography. Unfortunately, physicians did not appreciate the dangers and only later discovered its very slow elimination rate and propensity to accumulate in hepatic tissue. Because of emission of α particles, cases of thorium-induced hepatic carcinomas and angiosarcomas led to its eventual discontinuance in 1952.

Although many nuclear reactor incidents have occurred around the world, the most serious occurred at Chernobyl in the Ukraine in 1986. In this instance, a series of errors led to a fire at the reactor core, several explosions, and a meltdown of the reactor. Over the first 10 days following the incident, a cloud carrying radioactive material (predominantly ^{131}I and ^{137}Cs) spread to the Baltic States, Scandinavia, and Europe. In addition to the 31 people who died of ARS in the first few weeks following the event, nearly 250 others in the surrounding area were hospitalized, and an unknown number suffered other long-term sequelae.[31,37,48]

Not all radiation events occur at nuclear facilities. In September 1987 in Goiânia, Brazil, two men scavenged the contents of an abandoned

medical clinic and unwittingly handled a source of ^{137}Cs. As in the early part of the century with radium, the fascinating bluish glow contributed to many radiation exposures, some of them quite extensive. In the end, the government monitored approximately 113,000 individuals and found nearly 250 contaminated individuals. Forty-six patients were treated with a chelating agent, 19 were found to have localized radiation burns, and 4 died in the month following the initial exposure with another dying several years afterward from radiation-induced injuries.[69]

Perhaps one of the most notorious deaths from radiation was that of Alexander Litvinenko, a former Soviet KGB operative who was living in London. On November 1, 2006, shortly after meeting with several men in a public restaurant, Litvinenko experienced nausea and vomiting prompting a visit to the emergency department. He was treated and released only to return 3 days later for continued vomiting and worsening abdominal pain. Physicians were puzzled by his rapid deterioration, including weight loss, alopecia, hypotension, kidney failure, and leukopenia. He was initially thought to have been poisoned by thallium, and later by radioactive thallium. Litvinenko died on November 23; it was only after his death that ^{210}Po was discovered to be the cause, heralding what some consider to be a new era of nuclear terrorism.

THE PRINCIPLES OF RADIOACTIVITY

Dating from the 15th century, *radiation* is defined as energy sent out in the form of waves or particles. Although considered by physicists as incomplete, the particle-wave theory remains a useful model by which to understand the toxic aspects of radiation. Despite the strong nuclear force that holds the basic building blocks of atoms together, many isotopes are unstable. Several other forces, most notably the weak nuclear force, may tip the balance toward instability and an isotope will transform. This process may be intentional, as with the criticality events in a nuclear reactor or nuclear bomb, but mainly occurs spontaneously in nature as the process called radioactive decay.

■ RADIOACTIVE DECAY

In 1900, Marie Curie discovered that unstable nuclei decay or transform into more stable nuclei (daughters) via the emission of various particles or energy. Radioactive decay occurs through five mechanisms: emission of γ-rays, α-particles, β-particles, positrons, or by capture of an electron. The emission of these various particles makes radioactive decay dangerous because these particles form ionizing radiation. These emitted particles are released with specific decay energies depending on the isotope undergoing the process.

The half-life ($t_{1/2}$), a term first used by Ernest Rutherford in 1904, is the period of time it takes for a radioisotope to lose half of its radioactivity. Every radioisotope has a characteristic half-life. Some isotopes exist for only millionths of a second, whereas others last billions of years. In every case, the activities of radioactive isotopes diminish exponentially with time. The equation $R = R_0 e^{-\lambda t}$ describes radioactive decay, in which R is the activity, R_0 is initial activity, t is time, and λ is the decay constant. Each radioisotope has its own decay constant (Table 133–1).

Photons are massless particles that travel at the speed of light and mediate electromagnetic radiation. Depending on the energy of the particles, and therefore their wavelength, they are given (or have) different names. Radiation having the lowest energy and the longest wavelength are called radio waves. As photons become more energetic and have shorter wavelengths, they are called, sequentially, microwaves, heat or infrared, visible light, and ultraviolet rays. X-rays and γ-rays have greater energy than ultraviolet rays and can penetrate deeply into the body, which makes them both deadly and beneficial as radiation therapy.

TABLE 133–1. Physical Properties of Common Radioisotopes

Isotope	Half-Life	Mode of Decay	Decay Energy (MeV)[a]
^{14}C	5730 y	β$^-$	0.156
^{47}Ca	4.53 d	β$^-$	1.979
^{57}Co	270 d	electron capture	0.837
^{51}Cr	27.8 d	electron capture	0.752
^{137}Cs	30.23 y	β$^-$	1.176
^{67}Cu	61.8 h	β$^-$	0.576
^{3}H	12.26 y	β$^-$	0.02
^{123}I	13.3 h	electron capture	1.4
^{131}I	8 d	β$^-$	0.970
^{40}K	1.28×10^9 y	β$^-$/β$^+$ electron Capture	1.35/1.505
^{32}P	14.3 d	β$^-$	1.710
^{210}Po	138 d	α	5.297
^{222}Rn	3.8 d	α	5.587
^{85}Sr	64 d	electron capture	1.11
^{201}Tl	73 h	electron capture	0.41
^{238}U	4.51×10^9 y	α	4.268
^{133}Xe	5.27 d	β$^-$	0.427

[a]MeV = mega-electron volts.

X-rays and γ-rays are essentially the same and are only distinguishable by their source. γ-radiation is emitted by unstable atomic nuclei in the process of radioactive decay. A given γ-ray will have a fixed wavelength depending on the energy that formed it; the greater the energy of the decay, the smaller the wavelength of the γ-radiation. X-rays come from atomic processes outside the nucleus. For example, an x-ray machine generates x-rays by accelerating electrons through a large voltage and colliding them into a heavy metal target. The rapid deceleration of electrons in the target generates x-rays. This process is also known as *bremsstrahlung* or braking radiation. In general, the higher the voltage, the greater the energy of the x-rays generated along a spectrum of wavelengths. X-rays and γ-rays may have the same energy. Once an x-ray and γ-ray of the same energy leave their respective sources they cannot be distinguished from one another. They behave in exactly the same way, including the types of biological effects they may cause. Because of their nature, high-energy γ- and x-rays can penetrate several feet of insulating concrete.

β-particles are also called electrons. They are emitted during β-decay from an unstable radionuclide, which is an atom that disintegrates by emitting a particle, electromagnetic radiation, or both. Positrons, positively charged electrons, may also be emitted during decay processes. Because of their mass, electrons have less penetration than γ-radiation but may still pass several centimeters into human skin.[90] For this reason, β-particles cause health problems chiefly through incorporation into living organisms, which occurs when a radionuclide is inhaled, ingested, or deposited on a wound.[6]

α-particles are helium nuclei (two protons and two neutrons) stripped of their electrons. These relatively massive particles are emitted during α-decay. They are the most easily shielded of the emitted particles and are stopped by a piece of paper, skin, or clothing. Like β-particles, α-particles principally cause health effects only when they are incorporated.

Neutrons are primarily released from nuclear fission, although high-energy photon beams used in radiotherapy may also produce them. The natural decay of radionuclides does not include emission of neutrons. This is mainly a health hazard for workers in a nuclear power facility or victims of a nuclear explosion. Unique among the particles of radioactivity, when neutrons are stopped or captured they can cause a previously stable atom to become radioactive.

Cosmic rays complete the group of various kinds of radiation to which an individual may be exposed. Cosmic rays are streams of electrons, protons, and α-particles thought to emanate from stars and supernovas. They rain down on the earth from all directions only to give up their energy as they strike the nuclei of oxygen and nitrogen in the upper reaches of the earth's atmosphere. By the time it reaches the earth, the energy of cosmic radiation is reduced by several orders of magnitude. Traveling or living at altitude where the atmosphere shields relatively less cosmic radiation naturally means greater exposure to cosmic rays but in general is not considered a toxic threat to humans.

Isotope, nuclide, radioisotope, and radionuclide atoms that have the same number of protons but different numbers of neutrons, contributing to a different atomic mass, are isotopes (eg, 123^I, 125^I, 127^I, 131^I). A nuclide is a species of atom that is characterized by the number of protons, neutrons, and the energy state of the nucleus. (eg, 99_{mTc} vs. 99_{Tc}) The term nuclide is not synonymous with isotope, which is any member of a set of nuclides having the same atomic number but a different atomic mass. Radioisotopes are isotopes that are radioactive, that is, they spontaneously decay and emit energy. Of the iodine isotopes listed previously, 123^I , 125^I, and 131^I are radioisotopes. The isotope 127^I is stable. Finally, radionuclides are simply nuclides that are radioactive.

IONIZING RADIATION VERSUS NONIONIZING RADIATION

Ionizing radiation refers to any radiation with sufficient energy to disrupt an atom or molecule with which it impacts. In this interaction, an electron is removed or some other decay process occurs, leaving behind a changed atom. Depending on the specifics of the interaction, these atoms may now be ionized or highly reactive free radicals. Hydroxyl free radicals, formed by ionizing water, are responsible for biochemical lesions that are the foundation of radiation toxicity.

The space between collisions of ionizing radiation and their target molecules varies with the particle type and its energy. A heavy charged particle, such as an α-particle, loses kinetic energy through a series of small energy transfers to other atomic electrons in the target medium, such as tissues. Most of the energy deposition occurs in the "infratrack," a narrow region around the particle track extending about 10 atomic distances. The energy loss per unit length of particle track is called the linear energy transfer (LET), which is expressed in kiloelectron volts per micrometer (keV/μm; see Table 133–1). Heavy charged particles, such as α-particles, are referred to as high-LET radiation, whereas x-rays, γ-rays, and fast electrons are low-LET radiation.

Because of its large size, collisions along the path of an α-particle are clustered together, limiting its ability to penetrate tissue. By comparison, collisions along the path of γ-rays are spread out, increasing their ability to penetrate tissue. It is this ability to penetrate tissue and transfer energy that accounts for the relative dangers of the forms of radiation and tissue susceptibility.

For a source of radiation to pose a threat to tissue, the ionizing particle must be placed in close proximity to vital components of tissue that can sustain damage. High-energy photons penetrate deeply and so pose a similar risk whether they come from an external source or from an incorporated source. As noted previously, α- and β-particles have much more limited tissue penetration and thus radionuclides that radiate these particles must first be incorporated to pose a threat to tissue.

Nonionizing radiation spans a wide spectrum of electromagnetic radiation frequencies. Generally, nonionizing radiation consists of relatively low-energy photons and is used safely in cell phone and television signal transmission, radar, microwaves, and magnetic fields that emanate from high-voltage electricity and metal detectors. Although these are all considered radiation in that they are all energies released from a source, these photons lack the necessary energy required to cause ionization and cellular damage.

RADIATION UNITS OF MEASURE

The amount of radiation to which an object is exposed, that is, the amount emitted from a source that falls on an object, is given in units called roentgens (R). A roentgen is a unit for measuring the quantity of γ- or x-radiation by measuring the amount of ionization produced in air. It may be loosely defined as the amount of x-radiation that produces 1 electrostatic unit of charge in 1 cubic centimeter of air at standard temperature and pressure. As an example, an individual standing at a given distance from the x-ray–generating tube of a particular x-ray machine is exposed, on the skin, to a particular number of roentgens of x-rays (Fig. 133–1).

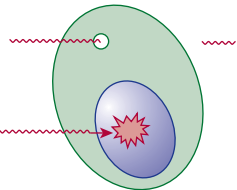
Not all roentgens to which an individual is exposed pose a risk for cellular damage. Much of the radiation passes through the body and does not cause harm. Only the fraction that is absorbed by the tissue has a probability of causing cellular damage. The unit that describes absorbed radiation is the rad (radiation-absorbed dose), which corresponds to an absorption of energy in any medium of 100 ergs/g. The units of the International System (SI), first introduced in the 1970s, have largely replaced the older units. The gray (Gy) is the corresponding SI unit to the rad and is equivalent to 100 rads.

To measure the risk of biological damage regardless of the type of radiation, the effective dose is given in rem (roentgen equivalent man) and Sv (sievert, in SI). This calculation is an overall indicator that enables all types of exposures (external or internal, partial or total) to be measured on the same scale. These units are also useful for comparing the effects of different radiations or evaluating the danger of a mixture of radiations, such as in radioactive decay, in which some isotopes emit more than one kind of radiation at a time (eg, β and γ). In defining rem, x-rays are the standard radiation for comparison. One rem may be defined as the dose of radiation that produces damage equivalent to one rad of x-rays (or 0.01 Sv). Thus, for x-rays, one Sv is equivalent to 100 rem. The effective dose is calculated according to the following equation:

$$E = D \times W_R \times W_T$$

E is the dose in sieverts, D is the absorbed dose in grays, W_R is the radiation weighting factor, also called Q, and W_T is the tissue weighting factor indicating the radiosensitivity of each organ.

To perform the normalization, the dose in grays is multiplied by a relative biologic effectiveness-dependent quality factor (Q). This factor Q multiplies the amount of radiation by 1 for x-rays, γ-rays, and β-particles, 2 for α-particles, and by 5 or more for neutron radiation. Thus, 1 Sv is equivalent to 1 Gy of x-rays. As a very coarse reference point, a regular chest radiograph imparts about 20 to 40 mrem or 0.2 to 0.4 mSv to an individual, but it must be remembered that this radiation dose is delivered very quickly to a limited portion of the body and is quite different from a similar amount delivered over a longer period of time to a worker through an occupational exposure.

In 1910, the curie (Ci) became the unit defining the activity of radioactive decay, although it does not give information regarding what is released or the risk of exposure. One curie equals 3.7×10^{10} disintegrations per second, based on the decay of 1 g of radium. The SI unit is the becquerel (Bq), named for Antoine Henri Becquerel, who in 1896 first reported invisible emanations from naturally occurring minerals that


Ci / Bq	Roentgens	Rad / Gy	Rem / Sv
The amount of radioactivity in a radionuclide can be described either by the number of disintegrations per second, the becquerel (Bq), or by comparing the number of disintegration to that of radium, the curie (Ci).	Particles released during radioactive decay travel in all directions. When gamma or X-rays ionize the air surrounding a source, an electrostatic charge is produced. This ionization is quantified by the roentgen (R), which is an indirect measure of the amount of radiation.	Most of these particles pass through tissue without being absorbed. Only the fraction of particles that contacts and is absorbed by tissue can cause cellular damage. This fraction is measured in rads or gray (Gy).	For a given energy, larger particles cause more damage when absorbed by tissue than smaller particles. To predict the degree of damage that a given particle will cause, the dose in Gy or rad is multiplied by the particle-specific biological effectiveness coefficient (Q) to calculate rem or Sv.

FIGURE 133–1. The definitions associated with radiation. Both curie and bequerel describe a quantity of radionuclide in terms of the number of disintegrations rather than mass. Roentgens describes the amount of air ionized by either gamma (γ) or x-rays, which indirectly quantifies the amount of radiation in the air around a source. Rad and gray (Gy) describe the fraction of radiation that actually interacts with cellular material and potentially causes injury. Roentgen equivalent man (Rem) and sievert (Sv) calculate the effective dose taking into account the different particles. For example, a 100 keV alpha (α) particle causes more damage to cellular material than a 100 keV beta (β) particle.

fogged photographic plates. One becquerel is equivalent to 1 disintegration per second. Thus, 1 Ci is equivalent to 3.7×10^{10} Bq. This number corresponds to an amount of radioactivity in a source. For example, following the Chernobyl incident, 1.2×10^7 TBq (terabecquerel) or 1.2×10^{19} disintegrations per second of radioactive material was released into the atmosphere. By comparison, the men who removed the source of ^{137}Cs in Goiânia found 50.9 TBq (50.9×10^{12} Bq or 13.7×10^5 mCi) of cesium. A thallium stress test uses 111×10^6 Bq (3 mCi) of ^{201}Tl, and the average indoor concentration of ^{222}Rn in the United States is 55 Bq/m^3 (14.8×10^{-6} mCi). To illustrate further, a stress test's dose of ^{201}Tl provides a dose of 0.018 Gy (1.8 rad) and 0.018 Sv (1.8 rem).

■ PROTECTION FROM RADIATION

Shielding refers to the process by which one may limit the amount of unwanted ionizing radiation in a given setting. Placing a specific material between a radiation source and a target will limit the amount of ionizing radiation that will interact with the target and possibly cause harm. When a particle of ionizing radiation is incident on a material, there exists some probability that it will interact with the material and be attenuated. What happens as a result of this interaction is dependent upon several factors, including the type of particle, its energy, and the atomic number of the target material. The photoelectric effect for photons, Bremsstrahlung for β-particles, and elastic scattering for neutrons are several examples of specific interactions. The shielding equation below allows calculation of the efficacy of shielding.

$$I = I_0 e^{-\mu x}$$

I is the radiation intensity after shielding; I_0 is the radiation intensity before shielding; μ is the linear attenuation coefficient; *x* is the thickness material in centimeters. The linear attenuation coefficient is defined as the fraction of photons removed from the radiation field per

centimeter of absorber through which it passes. Examples of shielding materials are Lucite, lead, and concrete.

Distance is an important safety factor in limiting radiation exposure. Because of their greater interaction with the atmosphere particle radiation, such as α- and β-particles, do not travel more than a few centimeters through air. Generally, moving a few feet from the source of this kind of radiation is enough protection by distance. X-rays and γ-rays, however, have an unlimited range in space and their intensity is only reduced by interactions with matter. Photon radiation that is emitted from a point source diverges from that source to cover an increasingly wider area. The intensity of this radiation follows the inverse square law:

$$\frac{I_1}{I_2} = \frac{(r_2)^2}{(r_1)^2}$$

where I_1 is the initial intensity; I_2 is the final intensity; r_1 is the initial distance from the source; r_2 is the final distance from the source. For example, if the intensity of radiation one meter from a source is 1 Gy, its intensity would be 0.11 Gy at 3 meters from the source.

Time of exposure is another important safety factor in limiting radiation exposure. Obviously the longer a person is exposed to radiation the greater the exposure. Federal and state regulations based on National Council on Radiation Protection and Measurement and FDA recommendations specify the limits of occupational exposure as well as exposure to patients designed to limit the potentially damaging effects of radiation.

■ IRRADIATION, CONTAMINATION, AND INCORPORATION

An object that is irradiated is exposed to ionizing radiation. This type of exposure includes handling radioactive isotopes, medical diagnostic imaging modalities such as x-ray machines and CT scanners, and rare

exposures to criticality events. These sources of ionizing radiation can generate high-energy photons, which penetrate tissue well and cause tissue damage. A whole-body irradiation is one in which the entire body is exposed at once, whereas more commonly shielding devices, such as lead aprons, and collimation techniques used in radiotherapy limit the amount of exposed tissue to the intended target. The risk of tissue damage depends on the total amount of radiation and the tissue type because different tissue types have their own intrinsic resistance to radiation damage. An irradiated object does not become radioactive itself, unless exposed to neutrons.

The Food and Drug Administration (FDA) approved irradiation of wheat and flour in 1963. They have concluded from 40 years of study that irradiation is a safe and effective process for many foods to control bacteria such as *Escherichia coli*, *Salmonella spp*, and *Campylobacter spp*. Irradiation does not make food radioactive, compromise nutritional quality, or noticeably change the taste, texture, or appearance of food, as long as it is applied properly to a suitable product. Organizations that support irradiation of food include the American Medical Association (AMA), the Centers for Disease Control and Prevention (CDC), and the World Health Organization (WHO).

Contamination occurs when a radioactive substance covers an object completely or in part. Several examples include a laboratory or industrial worker who unintentionally spills a radionuclide on clothing or skin or a victim of a radiologic dispersing device, a "dirty bomb," in which a radionuclide is packaged with a conventional explosive and the resultant explosion disperses the radionuclide. In these similar cases, the source of radiation is the nuclide undergoing its normal decay process, and the individual is exposed to particles such as those mentioned in Table 133–1. The risk for tissue damage from the radiation particles is usually quite low, assuming that the contamination is detected and appropriate measures for decontamination are instituted.

Incorporation occurs when a radionuclide assimilates into a patient's body tissue. It generally follows exposure via the inhalational, enteral, or parenteral route, but may occur via any route that permits a radionuclide to enter the body. This principle is used in many diagnostic and therapeutic procedures such as a thallium stress test, bone scan, gallium scan, liver and spleen scan, and strontium therapy.[93] Depending on the dose and type of radionuclide, incorporation may lead to tissue damage, as was the situation for many people following the event at Chernobyl. In this instance, inhalation and subsequent absorption of ^{131}I allowed this radionuclide access to the thyroid, resulting in an increase in thyroid cancer among children and adolescents in the most contaminated regions of Ukraine and Belarus.[11,46,96]

REGULATION AND REPORTING

The use of ionizing radiation, radiation sources, and the byproducts of nuclear energy are among the most heavily regulated processes worldwide. Regulations for medical use of radiation derive from six international organizations and three national organizations. Among the international groups are: United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), International Commission on Radiological Protection (ICRP), Biological Effects of Ionizing Radiation Committee (BEIR), International Commission on Radiological Units and Measurements (ICRU), Radiation Effects Research Foundation (RERF), and International Radiation Protection Association (IRPA). Since international organizations do not have the authority to enforce their recommendations worldwide, most countries have their own regulatory groups that cooperate internationally. The agencies in the United States are the National Council on Radiation Protection and Measurement (NCRP), Nuclear Regulatory Commission (NRC), and the Food and Drug Administration (FDA).

The NCRP issues reports called the Biological Effects of Ionizing Radiation (BEIR reports), which have direct standards for ionizing radiation use. For medical imaging standards, recommendations from the NCRP are considered to be guidelines with which all radiology departments must comply. The goal is to foster a radiation protection program that prevents deterministic effects (see below)

The Nuclear Regulatory Commission (NRC), the Environmental Protection Agency (EPA), and many state governments share the responsibility of licensing and regulating radionuclides in the United States. The Oak Ridge Institute for Science and Education's (ORISE) supports the NRC by maintaining the NRC's website for Radiation Exposure Information and Reporting System (REIRS) and the database of radiation exposure from NRC licensees. http://www.reirs.com/ Individual states regulate radioactive substances that occur naturally or are produced by machines, such as linear accelerators or cyclotrons. The FDA regulates the manufacture and use of linear accelerators, but the individual states regulate their operation. The NRC regulates medical, academic, and industrial uses of nuclear materials generated by or from a nuclear reactor.

ORISE's Radiation Emergency Assistance Center/Training Site (REAC/TS) and the International Atomic Energy Agency (IAEA) both maintain radiation incident registries that track US and foreign radiation incidents. However, recognizing that both these registries are limited in their data collection regarding individual patient's clinical conditions and their therapy, the Moscow Ulm Radiation Accident Clinical History Database (MURAD) was formed in 1990. The International Computer Database for Radiation Exposure Case Histories (ICDREC) succeeded MURAD and seeks to gather as many cases of ARS as possible to develop research and management strategies for the scientific community.[18]

Exposures to man-made sources of radiation are not required to be reported to poison centers and in general do not result in significant morbidity. However, the American Association of Poison Control Centers Toxic Exposure Surveillance System (AAPCC-TESS) reported a total of 2950 exposures to radioactive isotopes over the last 14 years, increasing from 166 in 1993 to 314 in 2007. This increase in reported exposures was commensurate with the overall increase in reports to poison centers. Of the 2007 reported cases, 219 (69%) were unintentional, and 24 (7%) involved children younger than 6 years of age. There were no deaths reported to poison centers from exposure to radioisotopes over the last 14 years[12] (see Chap. 135).

EPIDEMIOLOGY

Everyone is exposed to radiation in one form or another each day (Table 133–2). There are naturally occurring sources of radiation in the earth's crust that make the largest annual contribution to radiation exposure, and man-made sources of radiation that make a relatively smaller contribution to our average annual exposure.

■ NATURAL SOURCES OF RADIATION

A wide variety of natural sources expose humans on a daily basis to ionizing radiation. In the United States, the estimated annual dose equivalent of radiation is 3.6 mSv, and natural sources contribute about 80% of that annual dose.[15,32] Terrestrial sources of radiation originate from radionuclides in the earth's crust that move into the air and water. These primordial radionuclides, so named because their physical half-lives are comparable to the age of the earth, include uranium, actinium, and thorium. Geographic areas vary regarding the content of these radionuclides.

Radon, a radioactive noble gas, accounts for most of the human exposure to radiation from natural sources. This gas, a natural decay product of uranium and thorium, enters homes and other buildings from the building materials themselves or through microscopic cracks

TABLE 133–2. Average Effective Annual Ionizing Radiation Dose Equivalent in the United States

Source	Dose[a]	
	mSv[b]	% of Total
Natural		
Cosmic	0.27	8
Internal	0.39	11
Radon[c]	2.0	55
Terrestrial	0.28	8
Subtotal	**2.94**	**82**
Man-made		
Consumer products	0.10	3
Nuclear medicine	0.14	4
Occupational	<0.01	<0.3
X-ray diagnostic imaging	0.39	11
Subtotal	**0.63**	**18**
Total	**3.6**	**100**

in the building's structures. With a relatively short half-life of 3.82 days, ^{222}Rn poses a health risk if decay occurs while in the respiratory space and deposits on respiratory tissue as one of its daughter isotopes, which are solids. These radon daughters emit α-particles as they decay and are the principle causes in the associated increased incidence of lung cancer in those exposed to radon[76] (Table 133–2).

Additionally, radon daughters are charged and can attach to larger aerosols to be inhaled primarily. Radon daughters can also remain unattached to aerosols and form smaller-sized aggregates, enabling them to penetrate to smaller airspaces. There is a complex relationship between exposure to radon progeny and dose to target cells. Influencing physiologic factors include tidal volume, minute ventilation, mucus thickness, and mucociliary clearance. The risk of lung cancer is increased in heavy smokers who additionally expose their lungs to 200 mSv from ^{210}Po (a radon daughter) that is naturally found in tobacco smoke.

Areas of New York, New Jersey, and Pennsylvania, called the Reading Prong, have particularly high concentrations of radon as a result of a richer concentration in the earth's crust of primordial radionuclides that liberate radon. The EPA has recommended household level intervention when ambient radon concentrations exceed 147 Bq/m³ (4 pCi/L). Individuals can test their own homes for radon with either short-term (less than 90 days) or long-term (greater than 90 days) commercially available measurement devices.

The second largest natural source of radiation originates from ingested radionuclides, of which ^{40}K, a naturally occurring isotope, is the most abundant. Potassium is the seventh most abundant element in the earth's crust and ^{40}K represents about 0.012% of this naturally occurring element. With a half-life of 1.3 billion years, ^{40}K decays via beta emission and electron capture. Since it is part of the environment, the average amount of ^{40}K in the body is about 3700 Bq, delivering about 1.8×10^{-4} Sv and 1.4×10^{-4} Sv to soft tissue and bone, respectively. The lifetime cancer mortality risk has been calculated for ^{40}K to be 5.9×10^{-6} per Bq ingested or 4 in 100,000 from external exposure (compared

to 1 in 5 from the group predicted to die of cancer from all other causes per US average.) Together with other primordial radionuclides in our diet, this source of internal radiation accounts for about 12% of the annual dose of absorbed radiation.

■ **MAN-MADE SOURCES**

As mentioned earlier, man-made sources of radiation can be found in many consumer products and in many different types of industry (Table 133–3). The National Council on Radiation Protection and

TABLE 133–3. Uses of Radioisotopes

Radioisotope	Use
^{241}Americium	Smoke detectors, to measure lead concentrations in paint, steel, and paper production
^{109}Cadmium	Analyze metal alloys
^{47}Calcium	Biomedical research of cell function and bone formation
^{252}Californium	Inspect luggage for explosives, gauge moisture content of soil and silo materials
^{14}Carbon	Pharmaceutical research, radiometric dating
^{137}Cesium	Measure dosages of radioactive pharmaceuticals, oil industry to measure flow in pipelines
^{51}Chromium	Red blood cell survival studies
^{57}Cobalt	Nuclear medicine
^{67}Copper	Chemotherapy
^{244}Curium	Mining industry
^{123}Iodine	Diagnosis of thyroid disorders
^{129}Iodine	Check some radioactivity counters in vitro diagnostic testing
^{131}Iodine	Treatment of thyroid disorders
^{192}Iridium	Test the integrity of pipeline welds, boilers, and aircraft parts
^{55}Iron	Analyze electroplating solutions
^{85}Krypton	Indicator lights, textile industry
^{63}Nickel	Detect explosives, voltage regulators, surge protectors
^{32}Phosphorus	Molecular biology and genetics research
^{238}Plutonium	Power source for NASA spacecraft
^{210}Polonium	Photographic film production
^{147}Promethium	Thermostats, textile industry
^{226}Radium	Lightning rods
^{75}Selenium	Protein studies
^{24}Sodium	Industrial pipelines integrity
^{85}Strontium	Study bone formation and metabolism
^{99}Technetium	Nuclear medicine
^{201}Thallium	Cardiac imaging
^{229}Thorium	Fluorescent lights
^{230}Thorium	Coloring and fluorescence in colored glazes and glassware
^{232}Thoriated Tungsten	Electric arc welding
^{3H}Tritium	Basic science and pharmaceutical studies, for self-luminous signs, luminous dials, gauges and wrist watches, luminous paint
^{234}Uranium	Dental fixtures, military projectiles
^{235}Uranium	Fuel for nuclear power plants and naval nuclear propulsion systems, fluorescent glassware, colored glazes, and wall tiles
^{133}Xenon	Nuclear medicine

Measurements estimates the annual number of workers occupationally exposed to radiation to be nearly a million, although worldwide this number is several million.[32,82] On average, those occupations with the highest exposures (about 4 mSv/yr) are uranium miners and millers, nuclear power operators, and sailors in close proximity to nuclear reactors. Those with lesser additional exposures (about 0.5–1 mSv/yr) include physicians, x-ray technologists, nuclear fuel processing workers, and workers in other industries that use radionuclides.

Medical occupational exposure principally includes physicians, nurses, and x-ray technologists, who receive an additional annual effective dose of about 1 mSv. This dose can range up to 17 mSv with certain techniques such as fluoroscopy but are only partial body exposures because of the appropriate use of lead aprons and other protective barriers. Medical procedures also account for substantial annual exposure to man-made radiation for patients. In 1989, the NCRP estimated the annual number of various diagnostic procedures involving radiation in the United States to exceed 250 million, although the number has increased quite rapidly over the last decade. Medical sources of exposure to patients account for about 0.5 mSv or 15% of the average annual exposure.

Exposures have been studied in emergency physicians, orthopedists, and interventional cardiologists.[33,45,99,105] Each of these fields uses different modalities of radiation, which pose different risks to the individual performing the procedure. Two studies examining exposure to physicians assisting in cervical spine radiographs found the calculated whole-body exposure ranged up to 0.027 mSv per procedure, or 0.75% of the estimated annual dose equivalent of radiation in the United States.[45,105] This exposure annualized over a year neared the NCRP upper limits of safety, but this exposure should decrease as these studies have decreased with the increased use of CT of the cervical spine for diagnostic purposes. Two other studies examined physician exposure to radiation by fluoroscopy used in interventional cardiology and orthopedic procedures. These doses ranged from 0.05 to 0.3 mSv per procedure. In each of these four studies, appropriate shielding was used, and dosimeters measured individual areas of exposed body parts such as extremities and the head. Radiation was undetectable beneath a lead apron. Estimated whole-body exposures to these procedures were considered not to exceed the limits established by OSHA of 50 mSv per year. Although the likelihood of exceeding established radiation limits is low regardless of the procedure, and even assuming a reasonable increase in the number of procedures performed, appropriate shielding and safety training are emphasized to minimize the risk of exposure.

Various medical scans use radionuclides to study various disease processes (Table 133–4). Other radionuclides used in medical diagnostics include ^{111}In, ^{67}Ga, and ^{51}Cr. Other scientific research uses tritium (3H) and ^{32}P. These radionuclides decay through β-particle capture or emission. In general, unintentional topical exposure to these radionuclides in this setting is not considered hazardous because skin and clothing provide adequate barriers against the poorly penetrating particles emitted. In the case of unintentional incorporation, it is highly unlikely that the amount infused will be sufficient to cause a serious health risk.

Depleted uranium (DU) is used by the US military and by several other governments as an armor-piercing alloy ammunition. Munitions made of this material are favored because it is pyrophoric, sharpens on impact, has a high density (about 1.7 times that of lead), and is less expensive than tungsten, which was used for this purpose until 1973. DU can be obtained from the enrichment process of natural uranium in the development of nuclear fuel, the reprocessing of spent nuclear fuel, or developed directly for military purposes. DU is mainly ^{238}U, but contains approximately 0.2% of other isotopes of uranium and

TABLE 133–4. Diagnostic Imaging Procedures: Type and Amount of Radionuclide or Radiation

Test	Radionuclide	Amount
Whole body bone scan	^{99}Tc	25mCi(9.25×10^8 Bq)
Radionuclide cerebral angiogram	^{99}Tc-DTPA	15mCi(5.55×10^8 Bq)
Cardiac ejection scan (MUGA)	^{99}TcO$_4$	20mCi(7.4×10^8 Bq)
DISIDA/Hepatobiliary scan	^{99}Tc-DISIDA	5mCi(18.5×10^7 Bq)
Ventilation/Perfusion scan	^{133}Xe	10mCi(37×10^7 Bq)
	^{99}Tc	4mCi(14.8×10^7 Bq)
Thyroid scan	^{123}I	0.2mCi(0.74×10^7 Bq)
Myocardial perfusion scan (exercise)	^{201}Tl	3mCi(11.1×10^7 Bq)
	^{99}Tc	20mCi(7.4×10^8 Bq)
Strontium therapy	^{89}Sr	4mCi(14.8×10^7 Bq)
Venogram	^{99}Tc	20mCi(7.4×10^8 Bq)
Chest radiograph	60 mrad or 0.06 mGy in a collimated field[a]	
Abdominal radiograph	100–1500 mrad or 1–5 mGy in a collimated field	
CT-head	1–2 rads or 0.01–0.02 Gy per slice[b]	
CT-body	1 rad or 0.01 Gy per slice[2b]	

[a] Collimation is the act of restricting the size of the useful x-ray field to the region of clinical interest. These skin-entry doses are approximations dependent on equipment and technique.

[b] The dose per each examination is about the same as the dose per slice and not the sum of the slices.

several other transuranic elements as well depending on its origin. Consequently, DU's α- and β-activity is about 40% less radioactive than naturally occurring uranium. When DU munitions strike a hard target, it is dispersed as an aerosol and contaminates a limited area. Radiation exposure is derived from incorporation of the aerosolized material as well as from retained shrapnel.[34] Thus, as a radiation hazard, external exposure to solid ^{238}U is considered to be negligible although currently many studies are investigating the potential link between DU and the incidence of leukemias, other cancers, and birth defects.[5,14,21,27,44,66,67,71,72,75] One study examined a cohort of over 50,000 service personnel from the United Kingdom who served in Gulf War I but found no increase in the incidence of any cancers over 6 years following the end of the war.[59] Another study examining a cohort of Gulf War I veterans over 16 years found only subtle bone differences and few clinically significant uranium-related health effects despite ongoing exposure from embedded DU fragments.[65]

EXPOSURE LIMITS

The various agencies involved in regulating radiation exposures to both workers and the public include OSHA, the NRC, and the Department of Transportation (DOT). The NRC has established "Standards for

Protection against Radiation," which regulates radiation exposures using a 2-fold system of dose limitation: doses to individuals shall not exceed limits established by the NRC, and all exposures shall be kept *as low as reasonably achievable* (ALARA). The total effective dose equivalent may not exceed 50 mSv/yr to reduce the risk of stochastic effects (see Stochastic Versus Deterministic Effects of Radiation later in the chapter). The dose to the fetus of a pregnant radiation worker may not exceed 5 mSv over 9 months and should not substantially exceed 0.5 mSv in any 1 month, although this amount is not carefully defined.[43,86]

PATHOPHYSIOLOGY

Ionizing radiation causes damage to tissue by several mechanisms depending on its energy. Radiation with high LET predominantly causes direct damage, which is when incoming radiation impacts a target molecule directly. This occurs because high LET radiation, such as an α particle, has a high statistical probability of impacting an important molecule, such as DNA.[32] If this occurs, a mutation may arise, which may then result in alteration of a germ line, development of a neoplasm, or cell death. The risk of these consequences overall, however, is low because of the relative paucity of DNA within a cell and the even smaller percentage of active DNA within a given cell.

Low LET radiation, x-rays, γ-rays, and fast electrons, predominantly cause indirect damage. The likelihood that radiation will cause cell damage is a function of its LET and reaches a peak at about 100 keV/μm. At this energy, the average separation between ionization events coincides with the diameter of the DNA helix and allows for the greatest probability of double-strand breaks, which is the basis for most biologic effects. Greater or lesser energies correlate to a lower probability of DNA impacts, and so the rest of the cell media becomes the energy absorber.[40]

Indirectly, radiation impacts a molecule and creates a reactive species, which then chemically reacts with organic molecules in cells, altering their structure or function. These radiation-induced ions are quite unstable, however, and usually convert to free radicals. Most importantly, radiation may impact a water molecule, which is in great abundance, to generate a hydroxyl radical (OH·).[32] The hydroxyl radical diffuses only a short distance through the cell because of its highly reactive nature and itself causes molecular damage.

The bystander effect refers to cellular damage in unirradiated cells that neighbor irradiated cells. As early as the 1940s, there were reports of inactivation of cells by ionization of the surrounding medium. Recently, the use of a single-particle microbeam (a device that can fire a predefined exact number of α-particles through a particular cell nucleus) demonstrated that cultured cells that were not hit by radiation showed increased chromosome damage, rearrangement, and rate of death. The bystander effect is demonstrated using proton beams and x-rays, and in cells cultured with DU.[68,77] Communication from cell to cell via gap junctions is an important factor in cell death and mutations, which are observed in these experiments. In one experiment, when 10% of cells on a dish were exposed to two or more α-particles, the resulting frequency of induced oncogenic transformation was indistinguishable from that when all the cells on the dish were exposed to the same number of α-particles.[88]

Genomic instability is when a gene responsible for the stability of the genome and the consistency of replication is altered, resulting in a cascade of other mutations and the subsequent development of a neoplasm. Several studies demonstrate that, in addition to direct radiation damage to genetic material, radiation causes perturbations in intracellular oxidation-reduction reactions and far outlast radiation-generated hydroxyl radicals, which exist only for fractions of a second. These changes in oxidation–reduction reactions, in turn, cause other

changes in signaling pathways leading to apoptosis, transformation, and other bystander effects that manifest as delayed or lethal mutations and chromosomal instability. Studies are ongoing that investigate specific causes of cellular injury and the precise mechanisms that may be responsible.[40,58]

Although any molecule may be damaged in a variety of ways that may lead to cell injury of varying severity, double-stranded breaks in DNA are the type of damage most likely to cause chromosomal aberrations or cell death. The radiosensitivity of the cell is directly related to its rate of proliferation and inversely related to its degree of differentiation.[47,80] Thousands of these types of lesions occur daily in the human body from natural environmental radiation.

For this reason, there are several mechanisms that protect and repair damage that may result from either direct or indirect means of radiation damage. Estimates are that up to 90% of all chromosomal breaks heal by adhesion in a process known as "restitution." All that is required for DNA to heal is oxygen and time, which forms the basis for fractionated radiation therapy. This therapy takes advantage of the inefficient repair mechanisms of cancerous cells compared to normal cells. Thus, by giving the radiation dose over several sessions, radiation damage will accumulate in cancer cells during radiation therapy, and more cancer cells are killed. Sulfhydryl-containing molecules, such as glutathione, and other scavengers provide protection against free radicals. These molecules react with free radicals and inactivate them quickly, thus limiting the potential damage. Following a large radiation exposure, however, both restitution and the protection provided by free-radical scavengers may be overwhelmed, and damage may occur.

STOCHASTIC VERSUS DETERMINISTIC EFFECTS OF RADIATION

The radiation damage just described has two consequential results: it kills cells or it alters cells and causes cancer. Injuries that do not require a threshold limit to be exceeded include mutagenic and carcinogenic changes to individual cells where DNA is the critical and ultimate target. This is the stochastic effect of radiation. Theoretically, there is no dose of radiation too small to have the potential of causing cancer in an exposed individual.[16] Theories suggesting that a single dose of radiation can cause a change in the genome that potentially alters the structure of a protoon-cogene, control of an oncogene, or activates oncogenic viruses in hosts are supported by a growing body of work investigating bystander effects and genomic instability.[40] These effects may take several months to years to manifest, as happened with Japanese survivors of the nuclear bombs who suffered a spectrum of malignancies many years after the event.

Whereas the stochastic effects of radiation may follow less severe exposures, such as prolonged exposure to low-concentrations of radon gas, the deterministic effects of radiation usually follow a large whole-body exposure, such as a Chernobyl- or Tokaimura-type event. In terms of cell death, a relatively large number of cells of an organ system must be killed before an effect becomes clinically evident. This number of killed cells constitutes a threshold limit that must be exceeded, and this is what is known as the deterministic or nonstochastic effects of radiation.

To illustrate the differences between stochastic and nonstochastic effects, consider a single alpha particle from [210]Po incorporated in a radon-contaminated household may impact an active segment of DNA in a patient's respiratory tract, ultimately giving rise to a cancer—the stochastic effect. In Tokaimura, the most severely injured worker received 17 Sv of neutron- and γ-radiation and experienced so much cell death across so many systems in his body that he died well before any injured yet surviving cells could develop into a cancer—the deterministic effect.

ACUTE RADIATION SYNDROME

The Army Medical Corps first described ARS in 1946 when victims of the explosions at Hiroshima and Nagasaki were admitted for treatment at Osaka University Hospital.[50] Understanding the features of ARS is essential for managing a patient who is exposed to massive whole-body irradiation, generally considered to be 1 Gy (250 times the average annual exposure) or more. In many cases, a reliable estimate of the radiation dose is difficult, thus making it more practical to focus on the clinical features of radiation injury and their prognostic utility.

The acute radiation syndrome involves a sequence of events that varies with the severity of the exposure.[29,97,104] Generally, more severe exposures lead to more rapid onset of symptoms and more severe clinical features. Four classic clinical stages are described, which begin with the early prodromal stage of nausea and vomiting. These symptoms begin anywhere from hours to days postexposure. Although the time to onset postexposure is inversely proportional to the dose received, the duration of the prodromal phase is directly proportional to the dose. That is, the greater the dose received, the more rapid the onset of symptoms, and the longer their duration, except in cases in which death follows rapidly.[80] The latent period follows next as an apparent improvement of symptoms, during which time the patient appears to have recovered and has no clinically apparent difficulties. The duration of this stage is inversely related to dose and may last from several days to several weeks. The third stage usually begins in the third to fifth week after exposure and consists of manifest illness described in subsequent paragraphs. If the person survives this stage, recovery, the fourth stage, is likely, but may take weeks to months before it is completed. Those exposed to supralethal amounts of radiation may experience all the phases in a few hours prior to a rapid death.

These four stages describe the clinical manifestations that may be observed as a result of massive exposure, but the various systems of the body manifest their own injuries, which constitute several subsyndromes.[29,104] These subsyndromes are not mutually exclusive of one another and may overlap as cell death or damage progresses.

The cerebrovascular syndrome describes the manifestations of injury to the central nervous system following massive irradiation. This syndrome, following exposure to doses of about 15 to 20 Gy or greater, is characterized by rapid or immediate onset of hyperthermia, ataxia, loss of motor control, apathy, lethargy, cardiovascular shock, and seizures. The mechanism of this injury may be a combination of radiation-induced vascular lesions and free radical–induced neuronal death and cerebral edema.

Despite autopsy evidence of some radiation-induced inflammatory changes to the heart, animal experiments demonstrate that the heart is relatively resistant to high doses of radiation. Cardiovascular shock is more likely because of systemic vascular damage, which may later compound shock resulting from other subsyndromes should the patient survive to that point. A "vascular radiation subsyndrome" might be considered to help explain the hemodynamic changes a patient experiences following a massive dose of radiation. Once these subsyndromes are manifest, they may be irreversible.[23,29,80,87]

The gastrointestinal syndrome begins following an exposure to about 6 Gy or more when gastrointestinal mucosal cell injury and death occur. Symptoms include anorexia, nausea, vomiting, and diarrhea. As the mucosal lining is sloughed, there is persistent bloody diarrhea, hypersecretion of cellular fluids into the lumen, and a loss of peristalsis, which may progress to abdominal distension and dehydration. Destruction of the mucosal lining allows for colonization by enteric organisms with ensuing sepsis.

The hematologic changes that occur following an exposure to about 1 Gy or greater are called the hematopoietic syndrome. Hematopoietic stem cells are highly radiosensitive, in contrast to the more mature erythrocytes and platelets. Lymphocytes are also radiosensitive and can die quickly from cell lysis following an exposure. This contrasts with granulocytes, which endure radiation better. In addition to stem cell death and white cell depletion with immunodeficiency, platelets are consumed in gingival and gastrointestinal microhemorrhages. The main effect of radiation-induced hematopoietic syndrome is pancytopenia leading to death from sepsis complicated by hemorrhage. A lymphocyte nadir typically occurs 8–30 days postexposure, with higher doses achieving earlier nadir.[17,28]

The pulmonary system is not spared injury from irradiation. Pneumonitis may occur within 1–3 months following a dose of 6–10 Gy. This may lead to respiratory failure, pulmonary fibrosis, or cor pulmonale months to years later.

DOSE ESTIMATION

Determining the dose received by an individual who was irradiated is important in providing appropriate therapy and establishing a prognosis. However, estimating the dose received is difficult for a number of reasons, such as the absence of a radiation-monitoring device, exposure to radiation of mixed form (such as γ and neutron radiation), and partial shielding of various body parts.[87]

In cases of whole-body irradiation, it is the ARS itself that allows for an estimate of the radiation dose received. The Biological Assessment Tool available at the Armed Forces Radiobiology Research Institute's web site, and guidelines from the International Atomic Energy Agency (IAEA), use clinical signs and symptoms, including the time to onset of vomiting after an exposure to radiation, to calculate the exposure dose and may be the clinician's best dosimeter.[80] Use of this kind of timing may be limited, however, because most exposures cannot be perceived by human senses.

As previously mentioned, lymphopenia is common following an exposure to 1 Gy or more. The observed predictability of lymphopenia has led to the development of several models for biodosimetry. It is important to note that dosimetry models have been validated and already take into account other potential modifiers of lymphocyte count, such as trauma or burns. However, discrepancies between the models suggest that more than one element of dosimetry be used whenever possible.[104]

The broad ranges of radiation doses that correlate with lymphocyte count are described in the classic Andrews nomogram of 1965 (Fig. 133–2). Using historical data from exposed patients, a lymphocyte depletion constant was calculated using the equation:

$$L(t) = L_0 e^{-K(D)\,t}$$

in which $L(t)$ is the lymphocyte count at time t, L_0 is the lymphocyte count prior to the exposure—the population mean taken as 2.45×10^9 cells/L, K is the rate constant for a given dose of radiation, and D is the dose of radiation. Solving for $K(D)$ will allow for an accurate estimate of a rapidly delivered, whole body exposure[35] (Table 133–5).

The currently accepted standard criteria for biodosimetry are chromosome aberration bioassays. Introduced in 1966, this technique analyzes the number of dicentric chromosomes that occur following an exposure to radiation. An exposure to radiation can cause breakage of the DNA molecule in two nonhomologous chromosomes and produce "sticky ends" that recombine end-to-end. In metaphase, these appear as a single chromosome with two centromeres and are called dicentric. The number of dicentrics in lymphocytes correlates reliably with a given dose of radiation. Additionally, if the number of dicentric chromosomes follows a Poisson distribution, a uniform exposure can be assumed (see Table 133–5).[2,53,78]
FIGURE 133–2. Classic Andrews lymphocyte depletion curves with accompanying clinical severity curves. Curves 1–4 correspond to whole body exposures of 3.1, 4.4, 5.6, and 7.1 Gy, respectively. (Adapted from Goans RE, Holloway EC, Berger ME, Ricks RC. Early dose assessment following severe radiation accidents. *Health Phys.* 1997:72:513–518.)

Even though there is no currently accepted standard for performance, analysis of dicentric chromosomes in peripheral blood lymphocytes is the only method routinely used in biodosimetry. Unfortunately, because proliferative death of cells containing aberrant chromosomes reduces the number of such cells available for analysis over time, and the migration of lymphocytes into tissue and the lymphatic system, a limited period is available to use this test to perform dose calculations retrospectively.[49,52] A recent development in molecular biology, the fluorescence *in situ* hybridization (FISH) chromosome-painting technique, has opened the possibility for accurate recognition of translocations and thus retrospective determination of dose. Unlike dicentrics, complete translocations persist in cell division and enable dose estimation over years following exposure.[51] In fact, this technique was

TABLE 133–5. Biodosimetry Tools[104]

Dose Estimate (Gy)	Time to Onset of Vomiting (Hours)	Rate Constant for Lymphocyte Depletion	Dicentric Chromosomes in Human Peripheral Blood Lymphocytes (per 1000 Cells)
0	n/a	—	1–2
1	>24	0.126	88
2	4.5	0.252	234
3	2.5	0.378	439
4	1.75	0.5	703
5	1.25	0.63	1024

employed to evaluate the radiation dose experienced by clean-up workers at Chernobyl. These authors concluded that it is likely that recorded doses for these cleanup workers overestimate their average bone marrow doses, perhaps substantially.[55] Unfortunately, these techniques are not widely available, require incubation times of 48–72 hours, and cannot assess for doses greater than 5 Gy, although new methods for high-exposure assessments are being developed.

PROGNOSIS

The prognosis of those exposed to radiation varies with the amount of the exposure, the type of medical care received, and the number of casualties in a given exposure scenario. Survival is inversely proportional to the radiation dose absorbed, and even the relatively radioresistant cell types can be killed by high amounts of radiation. For these reasons, an acute dose of 20 Gy or more is considered supralethal.[90] Historically, those who were exposed to greater than 10 Gy died despite care. This includes one worker at Tokaimura who was exposed to 17 Gy who died 3 months postexposure, and 20 of 21 workers who were exposed to radiation in the 6- to16-Gy range at Chernobyl. Some authors suggest that those exposed to 10 Gy or greater be given supportive and comfort care only because their survival is considered to be unlikely.[104]

Within the group exposed to 5–10 Gy, depending on the dose received, there may be milder forms of CNS and cardiovascular syndromes that last for prolonged periods of time. A severe GI syndrome in which high fever and persistent hematochezia are present suggests a poor prognosis. This syndrome may overlap with a severe form of the hematopoietic syndrome in which damage to bone marrow stem cells is so severe that bone marrow function may not recover for weeks or months. These patients will likely require bone marrow transplantation and multiple transfusions of platelets and red blood cells, optimal supportive care, and infection control to survive.

Patients exposed to radiation in the range of 2–5 Gy will likely survive with medical care. Although the median lethal dose of radiation for humans is estimated to be 4.5 Gy, the manifestations of ARS will be similar to those noted previously but will likely be delayed and less severe. Many patients will survive without bone marrow transplantation if supportive care optimizes fluid and electrolyte replacement and controls bleeding and infection.

Survival is expected for those patients acutely exposed to less than 2 Gy with little medical intervention necessary. Mild forms of GI and hematopoietic syndromes may occur in delayed fashion compared to more severe exposures.

CARCINOGENESIS

Radiation increases the incidence of specific cancers in humans. One of the most important evidentiary sources is life-span studies of atomic bomb survivors in Japan.[22] This group of people is extensively studied over the last half-century, and although the relative risks assigned to specific cancers are modified over the years and subject to interpretation, there is a general agreement that the incidences of leukemia (except chronic lymphocytic leukemia, CLL), female breast carcinoma, and thyroid cancer increase following a sufficient exposure. This risk is largely extrapolated from models of high-dose exposures, but is also supported by data for persons exposed to radon.[22] These cancers usually do not appear until many years after the exposure. Because of technical and logistical difficulties in performing appropriate epidemiological studies, quantifying the cancer risk from exposure to low-dose (less than 10 mSv) radiation is difficult, leading some to question the validity of the linear–no threshold theory.[9,16] For those exposed while

they are young, the excess incidence of cancer occurs only when they are at the age when those cancers otherwise appear in the unirradiated population, as was discussed earlier with the BNTVA group.[32,83]

Pulmonary exposure to radon has been studied extensively in the last few years. Both uranium miners and household residents in areas with high ambient radon concentrations, such as New Jersey and Sweden are at increased risk for developing lung cancer from exposure to radon gas. A cohort of nonsmoking uranium miners showed a 12-fold increased risk of lung cancer over controls, which is similar to the estimates of the increased risk of lung cancer caused by radiation exposure in atomic bomb survivors.[15,85] The increased risk of lung cancer from exposure to radon gas is modified by concurrent cigarette smoking, which may have a multiplicative effect rather than an additive effect.[73]

COMMONLY ENCOUNTERED RADIONUCLIDES

Most exposures that come to medical attention are not large, whole-body irradiations but are rather small spills in the laboratory or inadvertent exposures from one of many products that are commercially available. With the notable exception of a well-known case of massive americium contamination in Oak Ridge, Tennessee, and the cesium exposure in Goiânia, Brazil, the vast majority of these types of cases are not reported in the medical literature.[28,95]

Americium (symbol Am, atomic number 95, and atomic weight 243) was discovered in 1944 in Chicago during the Manhattan Project. Its most stable isotope, [241]Am, has a half-life of over 7500 years, although [241]Am, with a half-life of 470 years, was the first americium isotope to be isolated. It decays by α-activity and γ-emissions and will accumulate in bone if incorporated.[53] It is used to test machinery integrity, glass thickness, and in smoke detectors (about 0.26 μg per detector), where it ionizes the air between 2 electrodes and generates an electric current that soot may impede. α-Particles from these detectors are easily absorbed within a few centimeters of the surrounding air and pose little risk. One g of americium dioxide provides enough americium for more than 5000 smoke detectors. In 1976, a worker at the Hanford Plutonium Finishing Plant, suffered a large [241]Am contamination in an explosion at the site. One hundred grams (500,000 smoke detectors' worth) of [241]Am was involved, contaminating the victim's face with 70 MBq, but there was likely some inhalational exposure as well. He was treated with long-term diethylenetriaminepentaacetic acid (DTPA), and despite some leukopenia from the radiation, he survived for 11 years before dying from unrelated cardiac disease.[95]

Cesium (symbol Cs, atomic number 55, and atomic weight 132): Bunsen discovered Cs spectroscopically in 1860. It decays by β activity and γ emissions and tends to follow the potassium cycle in nature, providing a whole-body dose if incorporated. It is used as a radiation source in radiation therapy and as a radionuclide source for atomic clocks. Cesium, the radionuclide of the Goiânia incident, comes in the form of a powder, which would make dispersal relatively easy if used in a dirty bomb. Insoluble Prussian blue is the FDA-approved chelator for patients contaminated with cesium (see Antidotes in Depth A29: Prussian Blue).[20,54]

Cobalt (symbol Co, atomic number 27, and atomic weight 58.9) was discovered in 1735 by Brandt. [60]Co is an artificially made isotope and is an important source of γ-rays for radiotherapy, and detecting weld seam integrity. [60]Co was the source of a significant radiation incident that took place in North America in 1983.[62] A radiotherapy source containing 16.65×10^{12} Bq (450 Ci) of ^{60}Co in the form of thousands of millimeter-sized pellets was opened and spilled onto a truck in a junk yard in Juarez, Mexico. At least 200 people were exposed to the contaminated truck and the materials subsequently made from the contaminated scrap metal in the junk yard.

Iodine (symbol I, atomic number 53, and atomic weight 126.9): Courtois discovered iodine in 1811. There are 23 isotopes of iodine; [127]I is the only one that is stable. [125]I is used in thyroid studies and decays by γ emissions. [131]I is used in metastatic thyroid surveys and decays by β activity and γ emissions. [129]I and ^{131}I are also products of fission in nuclear reactors that may be released into the environment during an event. These isotopes will accumulate in thyroid tissue if incorporated and can cause local damage to thyroid tissue. It is this potential for incorporation that prophylaxis with potassium iodide (KI) is indicated in the event of a large exposure.

Phosphorus (symbol P, atomic number 15, and atomic weight 30) was discovered in 1669 by Brand. [32]P has a half-life of 14 days and decays by β-activity. The maximum range of decay particles in air is 20 feet, and in tissue, one-third of an inch. For soluble ^{32}P compounds, bone receives approximately 20% of the dose following ingestion or inhalation. Shielding for ^{32}P and other β-emitters should be made of material with atomic numbers of less than 13 (aluminum) to reduce the generation of x-rays, electromagnetic radiation produced by the rapid change of velocity of a fast-moving particle as it approaches an atomic nucleus and is deflected. This is best accomplished by Lucite or other plastics and not by lead or even glass. Pharmacodynamics of sodium [^{32}P] phosphate, given to patients with polycythemia vera include whole body distribution within the phosphate pool. Five percent to 10% is excreted in the urine within the first 24 hours and about 20% during the first week. After 3 days, ^{32}P is deposited primarily in bone marrow, liver, and spleen. Whole body retention curves show a mean biological half-life of 39.2 days.

Polonium (symbol Po, atomic number 84, and atomic weights range from 192 to 218) was discovered by Marie Curie while searching for the cause of radioactivity of pitchblende (uranium ore). It was named after her native country, Poland. Po has 27 isotopes; the most isotopes of all the elements and all are radioactive. Po is a very rarely occurring natural element where only 100 mcg is found in a ton of uranium ore. Po is chiefly manufactured by bombarding [210]Bi with neutrons in nuclear reactors, but can also be extracted from commercially produced devices that are used to remove dust and control static charge by a chemical process.[1] [210]Po exhibits several properties that make it extremely dangerous. The short half-life of [210]Po and high specific activity of 4490 Ci/g means it emits a great deal of high energy alpha particles (5.3 MeV) that produce 140 W/g. A capsule containing 500 mg of [210]Po reaches a temperature of 500°C. It also demonstrates a high volatility where 50% vaporizes in 45 hours at 55°C and can contaminate a relatively large area even when left alone. Although only a small fraction of absorbed [210]Po accumulates in tissue, cumulative doses of radiation can lead to organ systems failure and death. Animal data estimate an LD_{50} of 1.3MBq/kg, and that various mammalian species die within 20 days following in ingestion of 1–3 GBq. Because of the extreme specific activity of [210]Po this corresponds to a dose of about 0.01 μg/kg. Currently there are no specific chelating agents for [210]Po although development of new agents continues.[7,81,102] While there are limited data regarding the effects of [210]Po on humans, Alexander Litvinenko's death within 22 days of his poisoning is similar to animal survival data.

Radon (symbol Rn, atomic number 86, and atomic weights range from 204 to 224) was discovered in 1900 by Dorn, and was first called *radium emanation*, then *niton*, and finally radon in 1923. Radon is the heaviest noble gas. Radon is also a decay product of radium and a decay product of thorium and actinium, where it is also called thoron and actinon, respectively. [222]Rn decays by α-activity and γ-emissions. Exposure of radon gas to the pulmonary epithelium is associated with an increased incidence of lung cancer in both uranium miners and in those who dwell in residences with increased concentrations of radon. Damage to bronchial epithelium results from the α emissions of radon and radiation from radon daughters that precipitate as solids and

remain in the lungs. Good enclosed space ventilation, abstinence from cigarette smoking, and monitoring of radon concentrations will help to minimize this risk.

Technetium (symbol Tc, atomic number 43, and atomic weight 98.9) was discovered in 1937, and was the first element to be produced artificially. Unusual among the lighter elements, Tc has no stable isotopes and is therefore rarely found on earth as a product of spontaneous uranium fission. The majority of technetium is extracted from nuclear fuel rods and is a byproduct of fission of ^{235}U. ^{99m}Tc is used in nuclear medicine for imaging and immunoscintigraphy because of several favorable attributes. ^{99m}Tc (the *m* is for metastable referring to an intermediate energy state), emits γ;-rays of similar energy to diagnostic x-rays for easy detection, and has a brief half-life of 6 hours. The daughter isotope, ^{99}Tc, has a half-life of 2.1×10^5 years and allows the isotope to be eliminated before it decays. Most human contact with Tc is in medical scans where Tc has a biological half-life of about a day. There are no reports of adverse effects resulting from overdose with Tc, and no specific therapy is recommended in that event. Chelation with DTPA may be effective.

Thallium (symbol Tl, atomic number 81, and atomic weight 204): Crookes discovered thallium spectroscopically in 1861. ^{201}Tl is used for cardiac imaging, has a half-life of 73 hours, and decays by electron capture and γ emission. Pharmaceutical ^{201}Tl comes as thallous chloride and is created in a cyclotron by bombarding thallium with protons creating ^{201}Pb. It is shipped in this form, which decays into ^{201}Tl. Since the radioactive decay process is continual, it is recommended to administer the ^{201}Tl close to its calibration time to minimize the presence and effects of other radionuclidic contaminants. Chelation can be accomplished with Prussian blue (see Antidotes in Depth A29: Prussian Blue).

Tritium is an isotope of hydrogen whose nucleus contains 1 proton and 2 neutrons, and its symbol is ^{3}H.[103] Tritium decays by β activity and is used in basic science research as a radioactive label, for luminous dials, and self-powered exit signs, which may contain as much as 9.3×10^{11} Bq (25Ci). Tritium has a half-life of 12.3 years. Tritium emits very weak radiation in the form of 18.6 KeV beta particles, which are very easily stopped by thin layers of material and is safe for glow-in-the-dark watches. Tritium is not absorbed as a hydrogen gas, although in contact with oxygen forms tritiated water, which can be absorbed via inhalation or transdermally. The estimated LD_{50} is 3.7×10^{11} Bq (10 Ci) given its extreme specific activity of 9649 Ci/g. When absorbed as tritiated water, tritium tends to follow the water cycle in humans, providing a whole-body dose if incorporated. However, its biological half-life is 10–12 days, which can be decreased by increasing urine output, greatly limiting its potential toxicity.

MANAGEMENT

■ INITIAL ASSESSMENT

The initial management of patients exposed to radiation will obviously depend on a number of different factors, including the amount of radiation in the exposure and the number of casualties in the event. These important factors will describe to a great extent the amount of resources, such as hospital beds or relatively rarely used medications, which will be required in managing those who were exposed. In a mass-casualty event, established prehospital plans should be followed to provide the best management for the large numbers of variously injured given that the radiation exposure may also be accompanied by an explosion of potentially catastrophic size.

Each patient should have stabilization of the airway, breathing, and circulation. Field triage protocols, according to the kind of event, will designate patients as minor, delayed, immediate, or deceased depending on their burns or physical trauma and will not be altered because of their radiation exposure. Decontamination should proceed in the field taking care not to contaminate prehospital providers or equipment. Prehospital personnel should use personal protective equipment appropriate to the situation, although most events will only require C- or D-level protection, and Geiger counters.

■ INITIAL EMERGENCY DEPARTMENT MANAGEMENT

When one or more patients who have been exposed to massive irradiation present to the emergency department (ED), attention must first be paid to the more conventional injuries that may also be present.[80,97,104] Many times radiation exposures occur with fires or explosions, and patients may have burns, smoke inhalation injuries, or traumatic injuries. This scenario would be the same for the explosion of the "dirty bomb," a conventional explosive designed to disperse a radionuclide. Most survivable radiation injuries require prompt treatment but are not life-threatening in the first few hours post-event. Thus, there is time to determine if the nature of the exposure was an irradiation or contamination by a radionuclide. Routine considerations of airway, breathing, and circulation take priority for these patients as with all others. If a patient should require surgery, the Armed Forces Radiobiology Research Institute (AFRRI) recommends that surgery proceed immediately because of the delayed and impaired wound healing associated with irradiated tissue.

For large-scale radiation incidents, it is likely that a number of individuals will be involved in developing the best management plan for the casualties. Locally, the radiation safety officer, the medical toxicologist, and the medical oncologist will lend their expertise to the emergency physician to determine the risk of the contaminant, begin appropriate testing to determine the biological effect, and to initiate medical therapy if warranted. Additionally, the local or regional Department of Health should be notified. Larger or complex exposures may require the expertise of the Radiation Emergency Assistance Center based in Oak Ridge, Tennessee (865-576-3131 Monday–Friday 8 am–4:30 pm EST, after hours call 865-576-1005), which can provide valuable support.

Smaller-scale exposures to radiation still require at least a brief evaluation for burns and trauma, depending on the circumstances surrounding the nature of the exposure. Calls to the poison center from a residence require referral to emergency services for an expert evaluation of the extent of the contamination of the site and appropriate decontamination measures. Exposures in the laboratory or nuclear medicine suites require referral to the radiation safety officer in the building for a similar evaluation.

■ DECONTAMINATION

Patients exposed to radionuclides may be contaminated either externally or internally or both. Historically no medical personnel have ever developed ARS through exposure to a contaminated patient, although caution must be exercised when performing decontamination to minimize exposure to care providers. Unless there is active ongoing radiation, many authors recommend decontamination at the site of exposure to minimize the spread of radioactive materials.[80] All clothing should be removed, and patients should be thoroughly washed with soap and water. In the past, green soap, phosphate-based detergents, and chelating agents such as ethylenediaminetetraacetic acid (EDTA) and DTPA were used.[87] This approach can remove up to 95% of radioactive material from the patient. Open wounds should be carefully scrubbed to minimize the risk of internal contamination. A portable dosimeter may assist in external decontamination. If the patient was exposed to neutron radiation such as from a nuclear reactor, blood samples testing for induced ^{24}Na by γ-spectrophotometric analysis may help as an

additional indicator of total dose received. Collected emesis and feces may also be analyzed to help estimate total body dose. All clothing and liquid used to decontaminate must be collected and be clearly marked as radioactive waste. Obviously, there should be no eating, drinking, or smoking at the scene of decontamination.

For patients with smaller exposures to radionuclides, such as laboratory workers, decontamination is often the only management technique required to limit injury. Portable dosimeters will identify contaminated areas, which may be sealed off to limit spread of exposure, especially if the radionuclide is in gaseous form. As with larger exposures, contaminated clothing must be removed and collected. Contaminated skin must be washed with lukewarm soap and water, repeatedly if needed, with care taken not to abrade intact skin and risk inadvertent incorporation. Washing may also be guided by a portable dosimeter. The cesium-exposed patients in Goiânia received repeated baths in warm water and neutral soap over the first 2 days of their hospitalization, as did the patient exposed to americium at Hanford.[95] If the patient is still contaminated after repeated washing, it is recommended to use a cream hand cleaner that contains no abrasives. Some of the Goiânia patients habitually walked barefoot and had developed hyperkeratosis. The palms and soles that were heavily contaminated were treated with titanium dioxide mixed with hydrated lanolin. The paste was rubbed into the contaminated area and then gently abraded to try to remove more cesium.[69]

In evaluating an area in which a spill of radioactive material has occurred, a judgment must be made regarding the severity of the incident so that appropriate steps are taken. If a major incident has occurred involving large amounts of radioactive material, a large contaminated area, airborne radioactivity, or spread of radiation outside an authorized area, evacuation, notification of the radiation safety officer in an institutional setting, and calling local or regional emergency response personnel are recommended. Minor incidents involve small amounts of radioactive material where the individual knows how to clean the site, has appropriate decontamination material on hand, and can clean the area in a reasonably short time. Several different decontaminating agents are commercially available from general stores and many scientific suppliers. These agents come in the form of concentrated detergents or foaming sprays where a small spill is quickly wiped clean and disposed of in an appropriate container.

■ TRIAGE

It is critical for patients exposed to a large dose of radiation to be triaged according to the dose so that a management plan can be created for them. There are many proposed stages of the various subsyndromes of ARS to help with this dosimetry, but in general we may consider three groups: exposure to less than 2 Gy, exposure to 2–4 Gy, and exposure greater than 4 Gy. Those exposed to less than 2 Gy may experience some of the hematopoietic syndrome, but may be followed as outpatients with or without cytokine therapy. Between 2 and 4 Gy, the hematopoietic syndrome is likely and may be severe, but at this dose the GI syndrome is not likely to be a major complication. Hospitalization is recommended at least initially for more accurate dosimetry and supportive care, including the early initiation of cytokine therapy. Exposure to greater than 4 Gy will mean a severe hematopoietic syndrome and likely a severe GI syndrome as well. These patients will likely require an intensive care setting and substantial supportive care for their survival.

■ MEDICAL MANAGEMENT

In the ED, after airway and breathing have been managed appropriately, intravenous access should be established. As in the case of patients with thermal burns, peripheral IVs are more prone to infection, and central venous access is recommended. Fluid replacement may begin with crystalloid solution where the rate will be modified by recorded inputs and outputs and assessment of surface area burns if any.

Emergency management of emesis and pain may be difficult in those patients who received a high dose of radiation. Many types of antiemetics are used to control an irradiated patient's vomiting. The 5-HT$_3$ antagonists are particularly effective in this setting. Mild pain may be managed with acetaminophen, but nonsteroidal antiinflammatory medications are not recommended as they may exacerbate gastric bleeding in a patient for whom bleeding may soon become difficult to control. Morphine is recommended for the management of more severe pain, which may develop within a few hours after the injury from burns, mucositis, and other complications. Prophylactic use of antibiotics is not recommended as is the case with burned patients.

In the ED, it is important to obtain a complete blood count as soon as possible after exposure to begin biodosimetry estimation, and for blood typing. The timing of prodromal signs, such as vomiting, and calculation of the rate constant for lymphocyte depletion help to estimate the dose of radiation to which the patient was exposed. Ideally, a CBC is obtained every 4–6 hours on the first day and then daily following exposure.[36] Some authors recommend initiation of cytokine therapy as soon as possible if the estimated exposure dose is 3 Gy or greater. A threshold of 2 Gy may be used for children younger than 12 years and adults older than 60 years because these patients may be relatively more sensitive to the toxic effects of radiation. Blood typing early is important because the patient may require transfusions of red blood cells and platelets. Use of irradiated cells is recommended to avoid graft-versus-host disease.

For patients who survive the acute period, sepsis is the leading cause of death. To maximize survival, patients with a severe radiation exposure should be treated as other severely burned or immunocompromised patients regarding their risk of infection. Rigorous attention must be paid to the proper use of H$_2$ antagonists, antibiotics, antifungals, antivirals, and cultures of body fluids.

■ SPECIAL MANAGEMENT TECHNIQUES

Some patients may require supportive measures to boost their immune system and decrease the risk of infection.[80,104] The colony-stimulating factors, granulocyte colony-stimulating factor, and granulocyte macrophage colony-stimulating factor prime neutrophil microbicidal activity and accelerate neutrophil recovery. Spared hematopoietic stem cells in patients with significant whole body or partial radiation exposures can be stimulated to proliferate in this manner. Although these cytokines only have approval by the FDA for treatment of myelosuppression resulting from cancer treatments, the rationale for their use in the setting of radiation-induced myelosuppression is based on positive results obtained in treating cancer patients and a small number of radiation incident victims and experiments with nonhuman primates.[24,25,104] Colony-stimulating factors were used successfully at Goiânia and decreased the period of leukocyte depression while raising the nadir. Although there is no conclusive evidence that early administration is critical for best outcome for these patients, colony-stimulating-factor therapy should be initiated as early as possible following the diagnosis of a 3-Gy exposure or greater. These factors should be continued until the absolute neutrophil count exceeds 1000 cells/mm^3. However, in the setting of a mass casualty event, it may be prudent to withhold these resources from those with large dose exposures or those with significant concurrent traumatic injuries.

Following Chernobyl, 13 patients received bone marrow transplantation for hematopoietic support until their irradiated bone marrow could recover.[2,80] Unlike patients who undergo bone marrow suppression for clinical reasons, patients involved in a radiation exposure may

have incomplete exposure and are usually partially shielded, which may allow for survival of some stem cells. Eleven of these bone marrow transplantation patients at Chernobyl died, complicating the interpretation of the efficacy of transplantation. Bone marrow transplantation does not change the mortality risk from the other subsyndromes of ARS. The ability of bone marrow transplantation to improve the clinical course of an irradiated patient depends on how likely the patient was to die from hematopoietic syndrome alone. Some authors consider that there is limited indication for stem cell transplantation when there is also severe radiation injury to organ systems other than the hematopoietic system.[18] This remains a controversial mode of treatment for irradiated patients.

Probiotics is the introduction of selective nonpathogenic strains of *Lactobacillus* and *Bifidobacteria* into the gastrointestinal tract to suppress the number of pathogens.[80,98] Experimentally, this technique increases survival in canine and rodent models. Probiotics was also used in Chernobyl on three men whose survival time was prolonged, although it was not statistically significant when compared, respectively, to case controls.

Incorporation of radionuclides presents a challenge to the treating physicians in which the goal is removing an internal store of the radioactive material. Beginning in 1966, experiments with beagle dogs treated with DTPA showed decreased incidences of bone cancer when exposed to ^{241}Am.[56,57] Both Ca-DTPA and Zn-DTPA were approved in August 2004 by the FDA for human use for decontamination of plutonium, americium, and curium (see Antidotes in Depth A43: DTPA) Currently, Oak Ridge Associated Universities (ORAU) distributes DTPA under contract with the US Department of Energy (DOE). Additionally, rat experiments with LIHOPO demonstrate decreased retention of plutonium and uranium even after incorporation into bone.[21,101]

Prussian blue, ferric hexacyanoferrate, has been used for many years to treat thallium poisoning. Because it absorbs cesium ions, it is used in fission product recovery and is therefore useful in chelation therapy for patients contaminated with cesium. The two forms of Prussian blue, soluble and insoluble, have been used somewhat interchangeably as antidotes for thallium. However, it is the insoluble form that has the advantage when increasing elimination of cesium from the body (see Antidotes in Depth A29: Prussian Blue).[20,94,100]

As was mentioned earlier, ^{131}I is one of the key fission products that may be released from a nuclear power facility in an accident such as happened at Chernobyl. Additionally, much discussion is currently devoted to the potential for a terrorist attack either on a nuclear power facility or using a radiological dispersal device (ie, "dirty bomb") in which there could be environmental dispersal of radioactive iodine, although the 8-day half-life of ^{131}I theoretically limits its effectiveness as an environmental contaminant. The increase of thyroid cancer observed in atomic bomb survivors and in those contaminated from the Chernobyl event prompted the International Atomic Energy Agency (IAEA) to establish intervention criteria for a radiation emergency of an effective dose equivalent of 100 mSv. The detrimental effects of radioactive iodine can be limited through the use of supplemental potassium iodide (see Antidotes in Depth A42: Potassium Iodide).

PREGNANCY AND RADIATION

In the normal course of events, uncertainty exists regarding the normal viability of the fertilized ovum, and there is a naturally high rate of embryo loss during the early weeks of pregnancy. When exposure to radiation via medical examination is possible, pregnant women and physicians have exhibited extreme concern over its potential teratogenic effects, even though maternal exposures to less than 0.05 Gy (5 rad) is not considered to be teratogenic.[4,39,79] Additionally, risk of direct harm to the fetus from cosmic radiation during casual airline travel is thought to be negligible.[3] Unfortunately, there is little direct information concerning the effects of radiation in early human pregnancy. Experimental data using rats and mice show increased mortality rates both in vitro and in vivo following irradiation and a dose-response curve that depicts incremental increases in radiation dose corresponding to increasingly greater effects in causing malformations.[92] Experimental human data from the 1930s show increased lethality and induction of abortion when pregnant women were exposed to 3.6 Gy and 5 Gy for a therapeutic abortion by x-ray.[42,64]

The most important sources of information concerning the teratogenic effects of fetal irradiation are the survivors of the nuclear bomb blasts of World War II. The three principal risks to a fetus following radiation exposure are congenital abnormalities, severe mental retardation, and the late development of a neoplasm. The embryo is at particular risk because of its rapid development, and there are several periods of particular sensitivity so that irradiation at specific times is associated with increased risk of specific problems. Roughly speaking, uterine absorption of 0.1–0.15 Sv during the first 2 weeks postconception risks fetal lethality. During the third to seventh weeks postconception, uterine doses of 0.05–0.5 Sv risks congenital abnormalities, growth retardation, and small head size that may be accompanied by mental retardation. During the time between weeks 8 and 25 postconception, the risk is severe mental retardation, though that risk decreases at the 16th week.[26,89,92]

Accurate specification of the risks from fetal doses is difficult especially at doses less than 0.2 Sv. Different models consider dose-response relationships for developmental complications and cancer development as linear or linear-quadratic, and with or without a threshold limit. A risk of congenital abnormalities of 5% following exposure to 0.2 Sv compares to a widely accepted average incidence for congenital abnormality of 6% for newborns throughout the world.[92] Patients receiving various diagnostic procedures in the hospital may be exposed to these doses.[41] Clearly, pregnant women who are exposed to radiation are at some risk for a fetal complication, although that risk may be difficult to quantify at the low doses expected with routine radiologic procedures.[13] That low-level intrauterine exposure to radiation increases subsequent cancer risk is not the question, but rather the etiologic significance of the radiation. For many years, studies have been plagued with incomplete data, biological implausibility, and other problems that confound an explanation.[8] Consideration should always be given to the potential maternal benefit of the radiologic procedure and the potential risk to the fetus.[86] However, the vast majority of routine diagnostic imaging procedures imparts less than 0.05 Sv to the fetus and so is considered to be of negligible risk.

PEDIATRICS AND RADIATION

The use of CT scanning in children has markedly increased over the last 20 years. One hospital survey showed a 92% increase in abdominal and pelvic CT examinations from 1996 to 1999 for children younger than 15 years old. Although it is difficult to estimate the increased incidence of cancer rates because of LET radiation, there are reports that attribute a greater lifetime risk for cancer mortality resulting from CT examination in children. This risk is compounded by the tendency not to adjust the radiation dose given to a child during a CT examination from the amount given to adults. Together, these trends may mean increased radiation-induced mortality over the lifetime of the patient resulting from medical evaluation.[10,19,70]

SUMMARY

The danger of ionizing radiation to humans is through the disruption of cellular structure and function. Cell death and mutagenesis are the destructive consequences of an exposure to radiation. Fortunately, large exposures of radiation to the general population are rare outside of the setting of an armed conflict, and most contaminations that occur are small and easily controlled.

In general, recognition of the exposure and thorough decontamination are the critical steps to minimizing the potential toxicity of an exposure. Careful attention to storage of radioactive waste and contaminated materials and good supportive care are usually all that are required to care for most patients.

POTASSIUM IODIDE

Joseph G. Rella

When a nuclear reactor experiences a catastrophic failure, an uncontrolled release of nuclear fission products such as radioactive iodine (eg, ^{131}I) may occur (Fig. A42–1). Monitoring of the exposed population of Belarus, Russia, following the Chernobyl meltdown of the reactor in 1986 revealed almost a 100-fold increase in the incidence of thyroid cancer among children, echoing similar long-term effects of the nuclear destruction of Hiroshima and Nagasaki in 1945.[4] Iodine is a solid, bimolecular halogen that sublimates under standard conditions. Potassium iodide (KI), the most commonly available iodide salt, has been "generally recognized as safe" by the Food and Drug Administration (FDA) for nearly 40 years. Potassium iodide is recommended to prevent the uptake of radioactive iodine into the thyroid in order to reduce the future risk of thyroid cancer.

IODINE PHYSIOLOGY

Iodine, or its ionic form iodide (I^-), is an essential nutrient present in humans in minute amounts of 15 to 25 mg. Iodine is required for the synthesis of the thyroid hormones l-triiodothyronine (T_3) and l-thyroxine (T_4), which in turn regulate metabolic processes and determine early growth of most organs, especially the brain. Radioactive tracer iodine is distributed in the neck only 3 minutes after ingestion in a fasting subject. Iodide is actively transported with sodium into thyroid follicular cells where it is concentrated 20- to 40-fold compared with its serum concentration. It is then transported into the follicular lumen where it iodinates thyroglobulin to form T_3 and T_4 (see Chap. 49). Thyroid hormones are metabolized in hepatic and other peripheral, extrathyroid tissues by sequential deiodination. Iodide is then excreted in sweat, feces, and urine, and the presence of iodine in the urine is considered a reliable indicator of adequate iodine intake.

PATHOPHYSIOLOGY OF INADEQUATE OR EXCESS IODINE CONCENTRATIONS

Iodine deficiency is a worldwide health problem with large geographic areas deficient in iodine in the foods; this occurs predominantly in mountainous areas and regions far from the world's oceans. In 2003 the World Health Organization (WHO) estimated there were 1.9 billion people with insufficient iodine intake despite universal salt iodization.[22] Iodine deficiency disorders include spontaneous abortions, congenital anomalies, endemic cretinism, goiter, subclinical or overt hypothyroidism, mental retardation, retarded physical development, decreased fertility, and increased susceptibility of the thyroid gland to radiation.

During the critical, immediate postnatal period and the prepubertal and pubertal growth periods, there is a progressive growth of the thyroid gland as well as an increase in thyroglobulin and iodothyronine stores. Insufficient iodine supply in the diet results in increased iodine trapping by the thyroid gland. That is, the thyroid gland accumulates a larger percentage of exogenous ingested iodide and more efficiently reuses iodine that is released by the thyroid or generated by degraded thyroid hormones. These periods of increased iodine uptake explain why children are at greater risk than adults for developing thyroid cancer following exposure to radioactive iodine, especially in endemic areas or areas of relative iodine deficiency.

■ IODINE EXCESS

Because the effect of iodine on the thyroid is complex, problems may arise as a result of iodine excess as well. The Wolff-Chaikoff effect is a well-known phenomenon where high concentrations of iodine or iodide inhibit the synthesis of thyroid hormones. While this phenomenon is transient and adults generally tolerate it well, its effect may be devastating to a fetus or neonate as it progresses through critical stages of its development. Both the prevalence of goiter and subclinical hypothyroidism can increase when iodine intake is chronically high.[17] Historically, the introduction of iodized salt to iodide-deficient areas increased the incidence of thyrotoxicosis from three to seven per 100,000 in one study,[19] and from 25 to 125 per 100,000 in another study.[5] The majority of these patients were over 40 years old and had autonomous thyroid nodules. The incidences of thyroid autoantibodies and thyroiditis are increased in populations that are iodine replete rather than iodine deficient.[2] One study where subjects began a daily intake of 50 mg of iodide, which was continued for 32 weeks, reported sharply increased thyroid antibody levels in 14% of the studied population.[12]

PATHOPHYSIOLOGY OF RADIOACTIVE IODINE

Exposure via inhalation of gaseous molecular iodine, gaseous organic iodine, and particulate iodine (iodine adherent to suspended particles) may occur when a plume of radioactive material passes overhead. Deposition of radioactive iodine either in the upper respiratory tissue or the digestive tract leads to rapid absorption. The major pathway to toxicity following the Chernobyl incident was ingestion of food contaminated by radioactive iodine, specifically via milk from cows grazing on contaminated grass.[11] For reasons mentioned above, patients with relative iodine deficiency and all children are at increased risk of radioactive iodine uptake. Once incorporated into the thyroid gland, ^{131}I exposes tissue to relatively low energy β and γ emissions, potentially leading to genetic alterations and cancer. This is the stochastic effect of radiation. Although there is some controversy regarding whether the increased number of post-Chernobyl patients with thyroid cancer were due to increased screening[7,8] several reports bear out the increased risk of thyroid cancer,[1,9,11] and it is notable that genetic analysis can distinguish radiation-induced cancers from sporadic papillary cancers.[13,14]

$$^{235}U + {}^{1}n \longrightarrow {}^{131}In \xrightarrow{0.28\ s} {}^{131}Sn \xrightarrow{56\ s} {}^{131}Sb \xrightarrow{23\ m} {}^{131}Te \xrightarrow{25\ m} \boxed{^{131}I} \xrightarrow{8.02\ d} \boxed{^{131}Xe}$$

FIGURE A42–1. The decay pathway that describes how ^{131}I derives from nuclear fuel, whether in a bomb or a reactor, ultimately decaying to stable xenon.

BENEFITS AND RISKS OF POTASSIUM IODIDE FOR RADIOACTIVE IODINE EXPOSURE

■ BENEFITS

The principle behind prophylaxis with KI is isotopic dilution where KI competes with radioactive iodine for the active iodine transport system. Similar to the Wolff-Chaikoff effect where excess iodine decreases the synthesis of thyroid hormone, KI prophylaxis blocks thyroid uptake of radioactive iodine by direct competition, although potentially putting some vulnerable populations at risk for hypothyroidism. In nuclear radiology, administration of iodine-containing contrast media can contain up to 45 times the recommended daily intake of free iodine and delay the uptake of therapeutic ^{131}I for several weeks.[10,15,20] Limitation of radioactive iodine incorporation in this situation reduces the risk of developing thyroid cancer. Although radioactive iodine may still be incorporated into thyroid tissue by diffusion from blood (to a much smaller degree), administration of KI limits the recycling of radioactive iodine, diminishes its chemical half-life, and increases its rate of excretion.

■ RISKS

Adverse reactions can be described in terms of thyroidal and extrathyroidal effects. The thyroidal effects, both hyper- and hypothyroidism, including the Wolff-Chaikoff effect, are described above. Pregnant women with hyperthyroidism must not take KI because of the same effect. Many extrathyroidal effects of KI have been described. Sialadenitis, or iodide mumps, is an inflammation of the salivary glands and appears to be unpredictable. Ioderma is a rare and reversible acneiform eruption related to iodine ingestion that may result from nonspecific immune stimulation.[16] Other reactions reported in association with KI use include gastrointestinal disturbances, fever, and shortness of breath.

Although some reports use imprecise definitions when attributing adverse reactions to iodine or iodide-containing medications, *allergy* refers to a specific immune response to target proteins via an IgE-triggered release of cell mediators, such as histamine. There are no studies that demonstrate IgE antibodies to small molecules such as iodine or iodide.

"Allergy" to radiocontrast media is actually an anaphylactoid response to the high osmolarity of the xenobiotics. Anaphylactoid responses manifest by release of similar mediators to anaphylactic response but via non–IgE-mediated pathways. An anaphylactoid response to iodine-containing medications or iodinated contrast materials may be predicted in patients with asthma, allergic rhinitis, and food allergies to chocolate, eggs, and milk. While seafood may contain iodine, allergy to fish or shellfish is due to specific marine proteins and not sensitivity to iodine. Patients manifesting allergic contact dermatitis resulting from iodine-containing cleaning preparations, such as povidone-iodine, do not react to patch testing with KI. Therefore, when physicians consider the safety of KI dosing in the event of radioactive iodine exposure, reactions to radiocontrast media, seafood, and povidone-iodine should not be interpreted as an allergy to KI. Physicians must also consider that there are inactive ingredients or diluents of the KI formulation.[17]

RECOMMENDATIONS FOR DOSING POTASSIUM IODIDE

■ CONSIDERATION FOR DIFFERENT EXPOSED GROUPS[6,23]

Adults over 40 years face a near-zero risk of developing thyroid cancer from exposure to radioactive iodine. For this group, the complications from iodide supplementation, including nodular goiter, Grave disease, and autoimmune thyroiditis, outweigh any benefit. Therefore, iodide prophylaxis is not indicated for this age group unless the risk from inhalation rises to 5 Gy or greater, which is unlikely at a substantial distance from the site of nuclear origin. The exact safe distance regarding the likelihood of an exposure greater than 5 Gy is uncertain but is probably about 10 miles from the release site. Beyond this distance, dispersal of the radioactive material in the environment should decrease any exposure to less than 5 Gy.

Adults 18 to 40 years of age have risk of developing thyroid cancer that is approximately equal to the risks of side effects of a single dose of iodide supplementation, although it should be understood that both risks are very small. The decision to treat should be based upon the threshold criteria used as well as the risks of iodine supplementation, such as iodine allergy or a history of past thyroid disease. Repeat administration of KI is not indicated in this group because of increased risk of side effects. Control of food intake should be used to limit any further exposure to radioactive iodine.

Lactating mothers pass as much as 25% of absorbed iodine to their milk within 24 hours. Iodide supplementation will limit this to some extent, but there are several potential complications. Repeat dosing of lactating mothers carries the same risk of repeat doses for other adults 18 to 40 years. Additionally, while stable iodine will be delivered to the nursing newborn, it is possible to cause functional blocking of iodine uptake by an overload of iodine via the Wolff-Chaikoff effect. Therefore, the FDA recommends that lactating mothers not receive repeated doses except during continuing, severe contamination, which would generally be defined by health officials.

Pregnant women have increased thyroid uptake of iodine, especially in the first trimester, compared with other adults. The developing fetus also has increased iodine uptake during the second and third trimesters. Since iodine passes across the placenta, the fetus potentially may be exposed to radioactive iodine. Thus supplementation with KI is recommended at appropriate thresholds. At this critical point in the fetus' development there is a risk of blocking fetal thyroid function by repeat dosing, and the principle of using the minimum effective dose should be followed. While there is no need to vary dosing between pregnant women in different trimesters, if KI is given late in pregnancy, thyroid function should be monitored in the newborn. Repeat dosing of pregnant women is generally not recommended.

Children 1 month to 18 years are at high risk of thyroid cancer from exposure to radioactive iodine and are at low risk of side effects from supplementation with KI. Supplementation for children in this age group should therefore begin promptly following official notification of a potential radioactive iodine release and may continue daily if continued risk warrants it.

Neonates are at significantly increased risk from exposure to radioactive iodine because of a marked increase in uptake of iodine

resulting from neonatal body cooling in the immediate postdelivery period. At the same time, neonates are susceptible to functional blocking by overloading with stable iodine. Therefore, when supplementation is indicated, KI should promptly be given to neonates paying critical attention to dosing. The WHO recommends the KI solution be available for maternity wards in the precise dosing for newborns. Since the most critical time period for thyroid blockage is within the first postpartum week, dosing neonates who are older than 1 week may be performed at home via dividing, crushing, or suspending tablets in milk, formula, or water. Repeat dosing of neonates is not recommended. Neonates who are treated with KI in the first weeks of life should be monitored for thyroid-stimulating hormone and free T_4.

■ DIFFERENCES BETWEEN WHO AND FDA RECOMMENDATIONS

There are several differences between the FDA and the WHO recommendations for dosing adolescents, and also regarding radiation intervention levels. For adolescents 12 to 18 years old, the WHO recommends 130-mg doses based on their perception of this age group's high risk of cancer from exposure instead of the FDA recommended dose of 65 mg. The FDA does allow for a 130-mg dose in adolescents in this age range who approach adult size. Treatment recommendations made by the FDA and the WHO are shown in Table A42–1.

For those exposed in childhood and for lactating women, the WHO additionally recommends a lower intervention threshold of 0.01 Gy rather than the 0.05 Gy threshold used by the FDA. This recommendation is derived from a basic safety standard generic intervention level of 0.1 Gy regardless of age and an estimated incidence of thyroid cancer following a severe event resulting in 20 to 50 new patients with thyroid cancer per million children per year. To decrease this estimate of additional thyroid cancer patients from 20 to 50 to two to five new patients per million per year, compared with an estimated one case per million per year background risk, the WHO recommends decreasing the intervention threshold to 0.01 Gy.

TABLE A42–1. Food and Drug Administration and World Health Organization Guidance for Threshold Thyroid Radioactive Exposures and Recommended Doses of KI for Different Risk Groups

	Predicted Thyroid Exposure (Gy)		KI dose (mg)		No of 130-mg Tablets
	FDA	WHO	FDA	WHO	
Adults > 40 years	≥5	≥5	130	130	1
Adults 18–40 years	≥0.1	≥0.1	130	130	1
Pregnant or lactating women	0.05	0.01	130	130	1
Adolescents 12–18 years			65	130	1/2-1
Children 3–12 years			65	65	1/2
Children 1 month to 3 years			32	32	1/4
Birth to 1 month			16	16	1/8

FORMULATION

Potassium iodide is preferred over potassium iodate (KIO_3) since KI produces less gastrointestinal irritation. When stored in a cool, dry place, tablets packed in their foil should remain fresh for 5 years. These tablets are nonprescription and may be purchased online from multiple vendors. They are sold under such trade names as KI4U, Iosat, Nuke pills, Rad-block, and others, and are available in 65-mg and 130-mg tablets. A liquid formulation also exists with a concentration of 65 mg KI per mL.

TIMING OF ADMINISTRATION

For full blocking effect, KI should be administered shortly before exposure or as soon as possible afterwards. Some models describe the blockade of only 50% of iodine uptake when there is a delay of several hours following an exposure.[23] Depending on the duration and type of risk, administration of KI months after an exposure may also partially reduce thyroid cancer risk.[7] One study from Poland shows that following the Chernobyl disaster the incidence of thyroid cancers increased with the degree of radioactive contamination as well as the degree of iodine deficiency. Young people aged 19 years old or younger accounted for only 1.6% of the new cancers compared with women over 40 years old who comprised nearly 80% of the new cancers in this group. No mention was made regarding KI prophylaxis for patients in this group.[18]

AVAILABILITY, DISTRIBUTION, AND OTHER PROTECTIVE MEASURES

The degree of regulation of KI by the government has changed several times over the last few years. Although the US government began stockpiling iodine for defense purposes following the end of World War II, it reduced its KI stockpile from 3700 to 1629 metric tons by 2001. Following the incident at Three Mile Island in 1979, the federal government established the Federal Radiological Preparedness Coordinating Committee (FRPCC) to ensure a consolidated federal position on preparedness, which recommended KI only be stockpiled for emergency workers and institutionalized persons within a 10-mile *plume exposure pathway emergency planning zone* (EPZ) for emergencies near nuclear power plants. In 2001, the FRPCC supported a Nuclear Regulatory Commission (NRC) rule change extending KI to the general public within a 10-mile EPZ as a prudent adjunct to sheltering and evacuation. Section 127 of the Public Health Security and Bioterrorism Preparedness and Response Act of 2002 stated the federal government would make KI available to state and local governments for populations within 20 miles of a nuclear power plant. As of October 2006, 21 of 34 states with commercial nuclear power facilities requested and/or received KI tablets, and 11 also requested or received liquid preparations. These supplies are made available through the Strategic National Stockpile to local governments that may distribute KI from various distribution centers. A waiver of Section 127 of the Public Health Security and Bioterrorism Preparedness and Response Act of 2002 was invoked in July 2007 reducing the radius of federally supported KI to 10 miles, favoring evacuation and food interdiction for those living outside that area.[3]

The perception of the nature of the threat is varied. The FRPCC considers a significant exposure to radioactive iodine a very low risk and has determined that state and local governments should decide on stockpiling and distribution plans for themselves. One survey of public

health officials in New York State reported that 65% of those surveyed were not in favor of taking any steps to plan or act to protect the public's health against the potential dangers from local nuclear plant even though 62% of the same group considered a Chernobyl-type event could occur in the United States.[21]

Despite an experience in Poland following the Chernobyl event where a single age-appropriate dose was given to more than 18 million people over a period of 3 days, drills to distribute KI to homes within five miles of a nuclear power plant in the United States were considered too slow to provide adequate protection, supporting the argument of having KI distributed prior to any potential event. In 2002, the New Jersey Department of Health and Senior Services (NJDHSS) distributed KI to interested persons living within 10 miles of two nuclear reactors and surveyed the recipients regarding indications and usage of KI. Whereas the study demonstrated the need for a significant education and outreach program, 40% of respondents indicated they might use KI regardless of an announcement from a government agency, which may herald an epidemic of inappropriate use of KI. Additionally, the study found that emergency departments and primary care physicians would likely receive large volumes of patients seeking KI pills during a nuclear event.[3]

■ EVACUATION AND FOOD INTERDICTION

KI is not a panacea for radiation exposure. Even if appropriately used during a release of ^{131}I, KI will not protect against direct radiation exposure or against other radioactive elements that may be included in fallout. Depending on radiation levels, communities may be evacuated from areas immediately surrounding a nuclear power plant experiencing a release of radioactive material. Evacuation is most effective if implemented before the passage of a radioactive plume, but this should be guided by realistic dose estimates.

The FDA and WHO both recommend food interdiction and food control as the principle means to limit public exposure to contamination. Exposed canned food from affected areas may ultimately pose no risk to the population if they are stored for weeks to months, which would allow the radioactive iodine to decay completely. The WHO considers food control to be preferable to iodine prophylaxis and removal of milk from the diet of some populations to be merely inconvenient.[6,23]

SUMMARY

KI is a safe and effective means of blocking the uptake of ^{131}I following a nuclear catastrophe. Firm reliance on health officials' evaluation of the risk of exposure is vital since the overall likelihood of exposure to the critical radiation threshold is very low except for those living within 10 miles of a nuclear reactor. Exposed persons should strictly adhere to dosing guidelines to minimize the potential risks of KI dosing, especially in pregnant women and newborn children. It should be recognized that food interdiction and evacuation or avoidance of the radioactive plume are preferable to KI prophylaxis in the event of a potential exposure and may obviate the need for KI completely.

ANTIDOTES IN DEPTH (A43)

DTPA [PENTETIC ACID OR PENTETATE (ZINC OR CALCIUM) TRISODIUM]

Joseph G. Rella

Pentetate zinc trisodium and pentetate calcium trisodium (zinc or calcium diethylenetriaminepentaacetate), Zn-DTPA and Ca-DTPA, are chelators approved for the treatment of internal contamination with plutonium (Pu), americium (Am), and curium (Cm). Both xenobiotics were first used investigationally in 1955 to enhance elimination of these transuranic elements.[3] DTPA has also been used for the extraction of metals from soil,[20] as a treatment for iron overload and lead toxicity,[2,9] and as a chelator for Food and Drug Administration (FDA)-approved nuclear medical studies to prevent incorporation of injected radioisotopes.

CHEMISTRY

DTPA is a synthetic polyamino polycarboxylic acid with a molecular weight of 522 daltons. It is water soluble and bonds stoichiometrically with a central metal ion through the formal donation of one or more of its electrons. In addition to the use of DTPA to chelate the transuranic elements Am, Pu, and Cm, there are also reports of its use in chelating patients contaminated with californium (Cf),[17] and berkelium (Bk). The transuranic elements displace the calcium or zinc ion forming a stable DTPA-chelate complex (Fig. A43–1), which is then excreted in urine. DTPA has specific stability coefficients for the various elements that it chelates, which presumably explains the different binding efficacies of the calcium and zinc salts.

DTPA is not recommended or approved for treating patients contaminated with uranium (U) or neptunium (Np) for several reasons. DTPA mobilizes uranium from tissue stores but does not increase urinary elimination.[6,15] Chelating incorporated Np is somewhat dependent on its valence Np^{+4} versus Np^{+5} but because it forms very stable complexes with transferrin it is very difficult to decorporate, and Np currently remains the subject of in vitro experiments combining DTPA with other chelators.[7,14] While a systematic evaluation of all available data on DTPA efficacy for decorporation of transuranics has not been reported, it is nevertheless clear from many case reports that DTPA is very effective.

PHARMACOKINETICS

DTPA is rapidly absorbed via intramuscular, intraperitoneal, and intravenous routes. Animal studies show that DTPA is poorly (less than 5%) absorbed by the gastrointestinal tract. Absorption from the lungs is about 20% to 30%. Its volume of distribution is small (0.14 L/kg

in humans) and is distributed throughout the extracellular space. It does not appear to penetrate well into erythrocytes or other cells. There is no binding of the chelate in the renal parenchyma, which is important to note since animal data showed severe lesions in the kidneys when exposed to 100-fold overdoses.[5] The serum half-life is 20 to 60 minutes, although a small fraction is bound to plasma proteins with a half-life of more than 20 hours. DTPA undergoes minimal, if any, metabolism. Only a minimal release of acetate has been demonstrated, and splitting of ethylene groups was not detected.

Elimination is via glomerular filtration with more than 95% excreted within 12 hours and 99% by 24 hours. There are no data regarding dosing or clearance changes in patients with renal impairment. For patients with renal impairment, hemodialysis increases the rate of elimination of Tc-99m DTPA and Gd-DTPA.[13,21] Less than 3% is excreted via stool.

ADVERSE EFFECTS AND SAFETY

No serious toxicity has been reported among humans after over 4500 Ca-DTPA administrations at recommended doses.[3] Adverse reactions have included nausea, vomiting, diarrhea, chills, fever, pruritus, and muscle cramps. Transient anosmia was observed in one individual after repeated treatments with Ca-DTPA. The specific mechanisms for these adverse reactions remain undefined.

Mice given 60 times the recommended dose of Ca-DTPA developed severe injuries to kidneys, liver, and intestines, and deaths occurred.[5] Toxicity was correlated to the total dose and dosing schedule, where fractionated doses were more fatal than similar doses given as a single injection. The injuries were believed to result from significant depletion of Zn and Mn, since Zn-DTPA did not show the same toxicity at the same dose and schedule. These mouse data were interpreted to suggest that Zn-DTPA is approximately 30-fold less toxic than Ca-DTPA. Acutely lethal doses of Zn-DTPA were estimated to be 10 g/kg in the adult male mouse.

INDICATIONS, DOSING, AND ADMINISTRATION

DTPA is indicated for suspected contamination with Pu, Am, and Cm, and should be strongly considered for contaminations involving californium and berkelium. A registry of persons treated with DTPA was established in 1977 at the Oak Ridge Associated Universities (ORAU), and to date all recipients were contaminated while working with transuranics except for one deliberate overdose of uranium acetate.[15] This is important in that the treated patients were aware of their exposure, whereas a member of the general public exposed to a radiation dispersal device would not necessarily have this knowledge. Additionally, the assessment of the severity of contamination is measured not by mass but in disintegrations (becquerel), which may not be readily available at the time of the patient's initial presentation. Thus, these surreptitiously contaminated patients present the additional challenge of determining if their exposure is severe enough to warrant administration of the chelator, which will require consultation with a radiation safety officer.
FIGURE A43–1. Trisodium zinc diethylenetriaminepentaacetate, where a transuranic element (Am, Pu, Cm) is substituted for Zn forming a stable chelate.

Treatment of contaminated patients includes attention to vital signs and simultaneous superficial decontamination of the radioactive material. Baseline blood and urine samples (for urine radioassay) should be obtained. Administration of DTPA is recommended to begin within the first 24 hours following the exposure, preferably within the first hour. By 24 hours postexposure soluble Pu and Am are deposited in bone, theoretically rendering DTPA ineffective (in the absence of bone remodeling).[8] Historical data concerning contaminated workers at nuclear materials production facilities include those who received both prolonged and delayed treatments and demonstrated greatly increased urinary excretion of radioactive material.[1,10-12,18,19]

If the route of contamination is oral, mixed, or unknown, then Ca-DTPA should be administered intravenously. The intravenous dose of Ca-DTPA is 1 g in adults and 14 mg/kg up to the adult dose in children under 12 years, administered either undiluted over 3 to 4 minutes, or diluted in 100 to 250 mL D_5W, Ringer's lactate, or 0.9% sodium chloride, over 30 minutes. On the basis of animal studies it should not be given more slowly.[5] Maintaining normal volume status and frequent voiding should be encouraged to dilute the radioactive chelate and minimize exposure to the bladder. If contamination occurred only via inhalation, Ca-DTPA may be diluted 1:1 with sterile water and administered via nebulization.[16]

Although Ca-DTPA is recommended as the initial chelator, Zn-DTPA should be used after the first 24 hours. Studies in rodents show a 10-fold increased rate of elimination of Pu with Ca-DTPA compared with Zn-DTPA, and Ca-DTPA has its greatest effect when given within 24 hours of contamination. Additionally, there is concern that trace metals, such as zinc, are excessively removed with continued treatment with Ca-DTPA. After this period, Zn-DTPA given daily at the same dose is recommended for any continuing therapy because of its relatively diminished depletion of trace metals and the absence of liver, kidney, and intestinal injury.

The decision to continue therapy should be based on radioassay data. Historically, about 55% of all patients treated with DTPA required only one dose. This assessment should include collection of 24-hour urine samples, whole body or chest counting, and close consultation with the hospital radiation safety officer. Assistance is also available from the Oak Ridge Institute for Science and Education (ORISE) and its training center, the Radiation Assistance Center/Training Site (REAC/TS) at (865) 576–3131, or (865) 576–1005 after hours. These calculations involve radioassay by alpha spectroscopy for actinides and, using intake retention factors and dose conversion coefficients, one can calculate the residual body activity and resultant committed effective dose to a relevant organ system. Current recommendations are to continue chelation until the deposition of contaminant is less than 5% of the maximum permissible body burden for a given contaminant.[3]

If continued therapy is indicated, a regimen of Zn-DTPA may continue the following day. The FDA recommends daily dosing of 1 g. ORISE recommends 1 g daily for up to 5 days per week, for the first week. If continuing chelation therapy is indicated a two-dose per week

regimen should be initiated until the excretion rate of the contaminant does not increase with Zn-DTPA administration.[4,16,22] For all patients, data regarding vital signs, adverse effects, and bioassay studies should be reported to the drug manufacturer and also to ORAU.

AVAILABILITY

DTPA is available as Ca-DTPA or Zn-DTPA as a sterile solution in 5-mL ampules containing 200 mg/mL (1 g per ampule). It should be stored in a cool, dry place with an ambient temperature of between 15°C and 30°C (59°F–86°F) away from sunlight. The available solution is a clear hyperosmolar solution (1260 mOsm/kg).[16]

USE IN PREGNANCY AND CHILDREN

These chelators do not cross the placental barrier. There are no human pregnancy outcome data from which to draw conclusions regarding the risk of DTPA. Likewise, there are no data regarding safety in lactating women, and data regarding the use in children are extrapolated. Mouse studies involving doses up to 10 times recommended dosage for Ca-DTPA did not produce harmful effects; however, higher doses of greater than 20 times recommended dosage produced teratogenicity and fetal death. Studies have not been conducted on pregnant women or on children. Conversely, these same studies showed only a slight weight reduction in mouse fetuses when given similar overdoses of Zn-DTPA.

SUMMARY

Ca-DTPA, started within the first 24 hours, and Zn-DTPA, which may continue after 24 hours, enhance urinary excretion of Am, Cu, and Pu, and should be considered as chelators for Cf and Bk. Fifty years of experience accompanies the use of these xenobiotics, which have been shown experimentally and historically to be very safe to use in humans. Recommended doses should not be exceeded and adequate hydration is recommended. Dialysis may be considered for contaminated patients with renal insufficiency.

CHAPTER 134

POISON PREVENTION AND EDUCATION

Lauren Schwartz

Unintentional poisonings are a global health concern. According to the World Health Organization (WHO), in 2002 approximately 350,000 people died worldwide from unintentional poisoning. WHO has undertaken initiatives in many countries including China, Trinidad and Tobago, Ghana, the Bahamas, Myanmar, Senegal, and Lebanon to establish Poison Centers (PC) and raise awareness about poison prevention.[28] This chapter focuses on programs in North America that aim to prevent unintentional poisonings and improve access to PC services.

Healthy People 2010 is a US federal program that outlines the health goals for the nation. The goals reflect the input of public health individuals and organizations and consist of 28 areas to reach 2 main goals: increasing quality and years of healthy life, and eliminating health disparities. Two objectives in the Injury and Violence Prevention section relate to poison prevention. Objective 15–7 is to reduce nonfatal poisonings and Objective 15–8 is to reduce deaths caused by poisoning. Objective 1–12 under Access to Quality Health Services recommends establishing a single toll-free telephone number for access to PCs on a 24-hour basis throughout the United States.[26] This objective was achieved in 2002. Community-based public education programs at PCs are designed to help meet these other public health objectives.

LEGISLATION AND POISON PREVENTION

Since the first PC was established in 1953, a number of legislative events have improved poison prevention and awareness efforts and reduced the number of unintentional poisonings in children. Public education programs at PCs have been influenced by these federal measures.[71]

■ NATIONAL POISON PREVENTION WEEK

In 1961, President John F. Kennedy signed Public Law 87–319, designating the third week of March as National Poison Prevention Week (PPW)[6] to raise awareness of the dangers of unintentional poisonings. Each year, during PPW, PCs and other organizations around the country organize events and activities to promote poison prevention.

■ CHILD-RESISTANT PACKAGING ACT

In 1970, the Poison Prevention Packaging Act was passed. This law requires that the Consumer Product Safety Commission (CPSC) mandate the use of child-resistant containers for toxic household substances. In 1974, oral prescription medications were included in this requirement. A review of mortality data in children younger than age 5 shows a significant decrease in deaths after enforcement of the child-resistant packaging legislation.[59,71,74]

■ TASTE-AVERSIVE XENOBIOTICS AND POISON PREVENTION

Nontoxic taste-aversive xenobiotics are frequently added to products such as shampoo, cosmetics, cleaning products, automotive products, and rubbing alcohol to discourage ingestion.[25] Except in the case of rubbing alcohol, this is done primarily to prevent poisoning in children. The most common taste-aversive xenobiotics are the denatonium salts, particularly denatonium benzoate (Bitrex, benzyldiethyl[(2,6-xylylcarbamoyl)methyl] ammonium benzoate), one of the most bitter-tasting xenobiotics known. The bitter taste of denatonium benzoate can be detected at 50 parts per billion (ppb). This aversive xenobiotic is used in concentrations of 6–50 parts per million (ppm), typically 6 ppm in cosmetic products and ethanol and 30–50 ppm in methanol and ethylene glycol.[12,52] Only limited data are available on the usefulness of taste-aversive xenobiotics for prevention of poisoning. Studies using denatonium benzoate added to liquid detergent and orange juice demonstrate that it can decrease the amount ingested by children.[10,67] However, the degree of taste aversion is not universal; in one study, some children were noted to take more than one sip of denatonium benzoate-laced orange juice.[67] Taste aversion is partially a learned response; frequently young children do not find a bitter taste as offensive as do adults.[11] It seems unlikely that taste-aversive xenobiotics will eliminate unintentional ingestions in children, because oral ingestion is required for aversive effects to occur. Taste-aversive xenobiotics may be most beneficial in the prevention of poisoning by toxic and nonaversive xenobiotics, such as ethylene glycol, methanol, paraquat, certain pesticides, acetonitrile, and bromate-containing cosmetics, where more than one or two sips of the product must be ingested to cause toxicity. In 1995, Oregon became the first state to mandate the addition of an aversive xenobiotic to ethylene glycol- or methanol-containing car products in their 1995 Toxic Household Products statute. Analysis on the incidence and severity of ethylene glycol and methanol exposures before and after the mandate could not demonstrate any difference.[48] Taste-aversive xenobiotics are not and cannot be substitutes for other poison prevention modalities.

■ TOLL-FREE ACCESS TO POISON CENTERS

In 2000, the Poison Control Center Enhancement and Awareness Act was enacted with a goal of nationwide access to PCs. A toll-free number (1–800–222–1222) was established in January 2002 for all US

FIGURE 134–1. National toll-free number logo.

PCs. Callers are connected to a regional PC based on the area code and telephone number exchange. Figure 134–1 displays the national logo incorporated into educational efforts.

THE ROLE OF PUBLIC EDUCATORS IN POISON CENTERS

Poison Center educators encompass a range of educational backgrounds including nurses, pharmacists, health educators, and teachers. The role of the public educator is based on social marketing concepts and encompasses two objectives: health promotion to change behavior and marketing the PC.[69] Public education programs at PCs teach poison prevention techniques (primary prevention) and raise awareness about available services should a poisoning occur (secondary prevention). Education programs may utilize primary or secondary teaching or a combination of both.[9,29,36,42] Public educators at PCs provide a range of community-based programs ranging from workshops and health fairs to producing print materials, videos, and awareness campaigns through public service advertising using radio, television, print, and mass transit venues. Additionally, the use of the Internet has provided a new medium for educators to provide information and materials that can be rapidly updated and downloaded without cost.[6] Educators also participate in community health coalitions, working in conjunction with other injury prevention groups such as National Safe Kids, and collaborate with a wide range of community health agencies. Caregivers of children younger than age 6 are often deemed the most important group to reach with education programs. Educators often work with national programs for families including Women, Infant and Children (WIC), Head Start, and the Red Cross. Additionally, programs for grandparents offer an educational opportunity to reach this large high-risk population. Collaborative programs with the American Association of Retired Persons (AARP), senior centers, and Department for the Aging offer an opportunity to provide programs focused on poison prevention for older adults.

The membership of the American Association of Poison Control Center's Public Education Committee (PEC) includes the educators from PCs across the United States and Canada. The mission of the PEC is to provide poison prevention awareness programs in an effort to reduce morbidity and mortality associated with poisoning.[5] Each year, the PEC provides educational sessions at the North American Congress of Clinical Toxicology. PEC workshops focus on program development, evaluation, grant writing, strategic planning, and other topics of interest to PC educators.[6,29]

NEEDS ASSESSMENTS

To develop successful poison education programs, educators must first analyze demographic data, call volume rates, cultural and language issues, and barriers to calling a PC. Geographic information systems (GIS) software offers a way for PCs to visually map demographic data. The use of this type of software is increasing in public health and can be applied to PC efforts. The coordination of data retrieval from various data entry programs and the use of GIS software by PC staff provide access to call rates by zip codes, counties, census tracts, or congressional districts to be used for planning programs. Health and social services for the targeted community may also be presented using GIS maps. Using GIS for population-based programs is recommended for developing social marketing campaigns, health education programs, outreach efforts, and coalition building.[58] The study of geographic areas with low call rates enhances the potential for targeted educational programs.

Focus groups provide a useful qualitative method for PC educators to identify caregivers' and seniors' perceptions about calling the PC. Barriers regarding PC utilization include not knowing the PC number, preference for calling 911 rather than the PC; fear of being reported to child welfare agencies; concerns with regard to confidentiality; language difficulties; lack of direct contact with health providers; low self-efficacy; and concerns regarding the cost of the call.[1,8,13,31,32,64,73] Each of these barriers must be considered and creatively addressed when planning new programs for reaching caregivers of young children. In one study, 51% of caregivers interviewed in a low-income urban pediatric clinic said that they would immediately take their children to the emergency department (ED) after a possible poisoning exposure.[61] In a separate study, focus group participants stated they would not call the PC in the case of a poison emergency. Their responses ranking was (1) call the pediatrician; (2) go to the ED, (3) read the label; and (4) call a friend after a poisoning exposure.[31] Historically, seniors have not been a priority population for PC education resources. However, this group represents the majority of fatalities reported nationally to PCs.[14,29] Focus groups conducted with seniors show that most do not perceive the PC as an appropriate service for their concerns, but rather as a service for children and parents. Additionally, the participants expressed a very narrow view of what was considered a poison such as bleach and household products. Similar to caregivers of children, seniors repeatedly state that they would call 911 in an emergency.[15]

A focus group with parents provided information to refine a telephone survey focusing on hazardous household materials and health risks. Feedback from caregivers resulted in a more concise instrument with more targeted questions. In addition, perceptions of the PC and suggestions for future educational interventions were also gathered from participants.[31]

Followup surveys are an additional way to analyze factors related to PC access. English- and Spanish-speaking caregivers in Texas were contacted after an ED visit related to a child's poisoning exposure. Findings showed that more than half had spoken to PC staff prior to the hospital visit. Of those who did not call the PC, 68% claimed prior knowledge of the PC, yet failed to use it. Significant demographic variables associated with a failure to call the PC were Hispanic (schooled in Mexico) and African American ethnicities.[34] Findings from an ethnographic study of 50 Mexican mothers with children younger than 5 years demonstrated that none had the PC number in their home.[46]

POISON EDUCATION PROGRAMS

Of the two million annual calls to PCs nationally, more than one million involve children younger than age 6.[14] As a result, programs to teach caregivers about primary and secondary prevention techniques have

---

TABLE 134–1. Poison Prevention Tips

- Identify all potential poisons inside and outside the home
- Keep all potential poisons out of reach in a locked cabinet
- Keep all products in their original containers
- Never keep food and nonfood items together
- Install carbon monoxide detectors in all sleeping areas
- Keep plants out of reach of children and pets
- Use child-resistant containers
- Post the poison center number on all telephones and store in cell phones

---

been the focus of education efforts. Typically, these programs focus on teaching poison prevention (Table 134–1) and raising awareness of PC services. Poison education programs designed to reach individuals (caregivers, pediatricians, children, and seniors) through community-wide interventions are reported in the literature. Interventions have reported an increase in knowledge about PC messages and poison prevention.[33,41]

■ INTERVENTIONS TARGETING HEALTH BEHAVIOR

Unintentional poisonings frequently happen when children are left unattended for a brief period of time (<5 minutes) and a toxic product in use or recently purchased is left within reach of the unattended child.[50] A qualitative study conducted with 65 parents, some whose children had experienced an unintentional poisoning, showed that poison prevention strategies were not consistently implemented in the home. Recommendations included ongoing parent education to reemphasize that "child resistant" is not "childproof," and reinforce safe storage of potentially toxic products, particularly those that are often used.[23] When knowledge and behavior were measured through telephone surveys conducted after a poison prevention intervention, caregivers were more likely to have the PC number posted in the home.[33,75]

In the past, syrup of ipecac was distributed as a component of poison prevention programs for parents. However, this has drastically changed since the American Academy of Pediatrics' (AAP) policy statement in 2003. The AAP recommends that healthcare providers disseminate poison prevention information but no longer supports the public's use of syrup of ipecac for poisoning exposures that happen in the home.[3]

The ED presents an opportunity for poison education programs to work with families to prevent further poisoning exposure situations.[19] An injury prevention program provided to caregivers of young children after a home injury was shown to be effective, particularly regarding retention of poison prevention information and the use of safety devices.[54] The use of a computer kiosk in an ED to provide personalized child safety information including poison storage for parents showed increased knowledge scores on followup telephone surveys.[24]

The effectiveness of poison prevention education for families that called the PC following a potential exposure in a young child was also studied. Poison prevention instructions, telephone stickers, and a cabinet lock were sent to the family one week after the initial call. Followup telephone interviews showed that intervention group recipients reported a higher use of the cabinet lock (59%) and were significantly more likely to post the telephone number for the PC (78%) than those in the control group who did not receive any poison prevention materials within 2 weeks of the incident.[75] Similar results were found during followup telephone calls made to WIC participants receiving

a free cabinet lock and telephone stickers following an educational workshop.[63]

Poison education programs developed to address caregiver barriers have also been evaluated. An educational video targeting low-income and Spanish-speaking mothers was developed and evaluated. Results showed increased knowledge about the services, staff, and appropriate use of the PC compared with a control group that attended the regularly scheduled WIC class. After the video intervention, participants reported changes in attitude about calling the PC and comfort level with their recommendations.[33]

Instructor training programs have been designed by a number of PCs to reach leaders or educators of community-based organizations to incorporate poison education into their roles for the general population. An evaluation of the "Be Poison Smart" program showed an increase in knowledge and behavior change among service providers after a standardized training session. These reported changes included having the PC number visibly posted and keeping hazardous products out of reach.[53] Working with community-based services such as WIC presents an opportunity to reach the target population. Pretests and posttests administered to WIC staff and public health nurses showed increased understanding about poison prevention and increased awareness of PC services.[55]

Focus group participants have identified pediatricians as a trusted source of health information for parents.[31,64] The AAP includes a poison prevention counseling recommendation as part of The Injury Prevention Program (TIPP). TIPP is a safety education program for parents of children newborn through age 12. The TIPP Age-Related Safety Sheets include poison prevention advice for parents of children 6–12 month olds, 1–2 years, and 2–4 years.[4] In each, parents are encouraged to call the toll-free number for PCs if the child ingests a potentially poisonous product. It is important that the AAP continues its support for efforts by PCs to prevent childhood poisonings.[42] In another study, family practitioners and pediatricians were surveyed with respect to poison prevention counseling for parents. Although more than 80% of both groups reported that this was an important topic, family practitioners were less likely than pediatricians to provide poison information during a visit.[22]

Education programs are designed for school-age curricula. The effectiveness of MORE HEALTH, a program to teach kindergarten and third-grade students about poison prevention, was studied.[41] Posttests administered 1–2 weeks after the intervention showed increased knowledge in the intervention group of children. Parents of children in the intervention group also reported that their homes were more likely to be "poison-proofed."

The population at highest risk for poisoning fatalities is older adults. As mentioned previously, there is a paucity of poison education research targeting this group. Recommendations have been made to educate older adults, particularly about potential problems with medication use and storage.[29,40,68] Efforts to teach nursing home staff about potential poisoning exposures is also recommended.[40] There has been a shift in the priority of poison education programs to address this target population. An ED study of patients greater than 65 years of age showed that seniors had poor knowledge of their current medications. Also, patients taking more medications were less likely to know the proper dose, name, and purpose of the medications.[17]

■ COMMUNITY-WIDE INTERVENTIONS

In a recent review of pediatric literature focusing on community-based poisoning prevention programs, only four studies could be found using poisoning rates as the outcome measure. Additional creative studies to measure community-based poison prevention efforts will be essential to determine the importance of these efforts.[49]

In general, mass mailing has not been proven to be an effective effort to increase call volume for poison exposure or information requests.[21,38] Likewise, a distribution of textbook covers with the national logo and PC information to elementary and secondary schools in low PC utilization counties was not an effective method for increasing PC calls.[77] However, a few studies have shown an increase in call volume after mass mailing programs. A mailing that combined primary (poison prevention tips) and secondary (telephone stickers) messages and was included in a family health initiative showed increased call volume in areas where at least 5% of the residents received the information.[36] In addition, another study showed that overall call volume increased by 11.2% after more than one million pieces of literature containing the toll-free number were distributed in another mass mailing effort.[37]

An increased number of information calls to the PC was attributed to a campaign developed to raise community awareness.[70] Media provide a venue for conducting educational activities. Direct mail, radio, television, newspapers, and magazines were incorporated into a media campaign developed to raise awareness in a particular Latino community. A telephone survey conducted pre- and postmedia campaign showed an increase in awareness about the PC.[1] Developing this type of program is often costly compared with other education efforts; however, the potential audience is extensive. Mass media campaigns are powerful tools used in health promotion and disease prevention efforts. Research shows that media campaigns combined with community-based interventions and health education materials influence health behaviors and raise awareness. Additional factors that contribute to successful mass media include influencing the information environment to maximize exposure, using social marketing strategies, creating a supportive environment for the target audience to make health changes, and theory-based and process analyses to make changes mid-campaign and assess outcomes.[56] News stations often provide a way to broadcast poison prevention messages through the media during PPW and during periods associated with perceived increased risks to a community. Free and confidential services at poison centers provide caregivers with access to general information or in response to emergencies.

■ MULTILINGUAL POPULATIONS

Language and culture must be addressed when planning community-based programs. Quantitative and qualitative research examining Latino communities and calls to the PC have been conducted. The findings from interviews with 206 Latino parents at a WIC site showed that 62% had not heard of the local PC and 77% did not know the PC services were free and offered in Spanish.[73] Two other studies examined the call rates in communities with significant Latino populations. These areas had lower call rates than comparable areas with high Caucasian populations.[18,72] Furthermore, a number of studies demonstrate that Spanish-speaking caregivers are less likely to call the PC because of concerns including confidentiality and language barriers.[1,8,18,32,46] In a study conducted with 100 Mexican mothers of children younger than age 5, 32% reported that a doctor or nurse would be the initial contact for health advice. Other sources include friends and family (29%), mother, grandmother, mother-in-law (21%), and spouses (17%). The majority of mothers (81%) acknowledged the use of home remedies to treat their children's illnesses.[44] New immigrant families from Mexico and Latin America are at high risk for poisoning exposures. PC education programs should target populations in communities where the impact has the potential to be consequential.[66] Caution should be used when planning programs based on census data for demographic information as this data may not reflect the specific population or characteristic under study in community-based programs. When ethnicity information is not collected from callers who contact the PC, there are severe limitations to the value of the data.[18,65]

Qualitative research can help to identify cultural issues when planning targeted education efforts. Monolingual Spanish mothers were more likely to report poor storage of household products and lack of protective placement of plants.[1] Mexican-born mothers of children younger than 5 were interviewed in their homes about poison prevention techniques. Safe storage was clearly a problem in these homes with 64% of homes having bleach stored within reach of children. Housing made up of multiple families living in the same home further impedes safe storage practices. In this study, families stored all personal products including medications and household cleansing agents with them in their bedrooms rather than in common areas such as the bathroom.[46]

It is important to consider employment of bilingual staff as public educators when attempting to expand public awareness. The benefits of a bilingual educator include the ability to provide programs directly to an audience and eliminate the need for a translator. A lack of bilingual providers was the most significant barrier identified for Latina women interviewed about injury prevention techniques.[27] Recommendations for more effective outreach to Latino populations include television advertisements and distribution of written information at schools, churches, and doctor's offices.[73] Health education programs including mass media campaigns, designed to accurately reflect the cultural identity—language, beliefs, roles—of the targeted population are more likely to be accepted. Field testing concepts and materials are important for the development and distribution of appropriate information for multicultural populations. Further work is needed to examine cultural beliefs related to poison prevention and an individual's use of and access to the PC. It is important to address cultural beliefs related to use of herbal and other complementary medicines.[33] New education programs are needed to reach targeted populations including Latino and Asian communities across the country. Programs may be more successful if individuals trust and view a source as credible, particularly when cultural attitudes and beliefs closely resemble their own.[39]

■ LITERACY/HEALTH LITERACY

Literacy is another area of consideration when designing poison education programs. Health literacy is defined as "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions."[57] This encompasses the ability to read, understand, and discuss medical information.[51] It is estimated that approximately 90 million Americans—half the adult population—have limited literacy skills and are often unable to understand health information and complete the tasks essential for navigating the healthcare system. Older adults, minority groups, immigrants, and low-income individuals are at highest risk for low health literacy.[35] People with low functional health literacy abilities are less likely to understand written and verbal health information, medicine labels, and appointment information.[76] This type of health information is often written at reading levels of at least 10th grade or higher.[20] The recommended reading level for written information is sixth grade. The majority of Americans are able to understand medical information at this level. In addition to reading level, use of graphics, font style, color, type size, and layout are important components when developing print material.[20] Recommendations for nonprint methods for communicating health information include audiotapes, visuals (posters, fotonovelas, pictographs), action-oriented activities (role-play, theater, storytelling), and audiovisuals (videos, CDs).[2,20,51,76]

The inability to read warning labels in English presents a literacy issue for those who are not native English speakers regardless of age.[46] Household product labels are also a concern. Identification of products often includes brand recognition.[45] Instructions for proper use and warnings may not be understood from the label itself.

The effects of health numeracy as a distinct component of health literacy have been presented in the literature.[47,62] Health numeracy involves one's ability to use numeric information to make effective decisions in daily life. This also includes concepts of risk, probability, and the communication of scientific evidence.[47,60,62] Health-related tasks including measuring medications, scheduling appointments, and refilling prescriptions rely on applied numeracy skills.[60,62] Because of their extensive use of medications, older adults are at high risk for medication errors.[68] Working with this population requires educators to understand the importance of interventions that accurately assess numeracy literacy levels and appropriately address health outcomes.

■ APPLYING HEALTH EDUCATION PRINCIPLES TO POISON EDUCATION PROGRAMS

Health education involves planning, implementing, and evaluating programs based on theories and models. These models offer direction for educators with health promotion planning.[43] There is a need to increase the number of poison educational programs incorporating health education principles. This includes educational efforts designed to reach individuals through community-based programs and media campaigns.

Both the Health Belief Model (HBM) and Social Cognitive Theory (SCT) incorporate the concept of "self-efficacy" and are applicable when designing poison prevention interventions and mass media campaigns. Self-efficacy is the individual's belief that he or she will be able to accomplish the task requested.[7,20,30,56] Many health educators believe that self-efficacy is necessary for changing behavior. The SCT suggests that individuals, the environment, and behavior are intimately and inextricably interrelated.[7] The HBM suggests that individuals are more likely to make health behavior changes based on perceived risk susceptibility, severity, potential barriers, and self-efficacy. These decisions are made when actions are seen as potentially more beneficial to the individual than the perceived risks associated with surmounting the current barriers.[30]

In one study, the HBM approach was used as a framework for poison prevention and for the assessment of barriers to PC use. Questions for focus group participants were developed based on the principles of HBM—that is, perceived susceptibility, severity, benefits, barriers, and self-efficacy related to the health action requested. The majority of mothers viewed poisoning as an emergency and felt it was a health concern for their children. Cues to action are also a component of the model and involve discussions about poison prevention or related information. Participants recommended using community-based venues and culturally appropriate information to expand awareness about poison prevention and the poison center.[13]

The HBM and SCT approaches were used to develop the questions for focus groups in both English and Spanish. These questions addressed issues related to poison prevention (severity and susceptibility), the services of the PC (including barriers), and suggestions for education. Focus group participants suggested the use of modeling to reinforce real-life scenarios in which a mother handles the poisoning emergency with the staff at the PC with a positive outcome.[32] As a result, a video was developed addressing these ideas. Two poisoning situations in which a mother calls the center are depicted. One involves home management (ingestion of bleach) and the second involves taking the child to the emergency department (swallowing grandmother's antihypertensive pill). The video and correlated teaching guides are available in English and Spanish.[33]

It is important to develop questionnaires that will be accepted and understood by the target population.[27] A Spanish-language instrument that addresses home safety beliefs using the HBM framework was developed and tested. Low-income monolingual Spanish-speaking mothers of children younger than 4 years of age were interviewed about perceived susceptibility, severity, barriers, and self-efficacy factors affecting unintentional home injuries including poison prevention measures. Barriers identified include literacy skills and access to bilingual health information.[27]

The HBM supports the idea that a "teachable moment" may be the ideal opportunity to present poison prevention interventions.[24,54] People may be more open to health information after experiencing a traumatic experience.[16] Events such as an unintentional poisoning exposure may motivate individuals to behavioral change. Applying HBM principles suggests that individuals will make changes in terms of poison prevention when or if they view the severity and susceptibility of a poisoning to be high in the home.

SUMMARY

Poison center public education efforts encompass needs assessments, program development, implementation, and evaluation. Two populations, children younger than 6 years and older adults, are at highest risk for unintentional poisoning exposures. Focus groups with caregivers of young children conducted across the country have consistently identified barriers to calling poison centers. These include calling 911, fear of being reported to child welfare agencies, and lack of confidence in handling poisoning emergencies. Using health education theories and models, programs should be developed that address these barriers and encourage caregivers to use the services of the PC appropriately. Education programs focusing on the needs of seniors addressing multigenerational living conditions should be designed. Cultural, health literacy, health numeracy and language needs of target populations are important considerations when planning poison education programs.

CHAPTER 135

POISON CENTERS AND POISON EPIDEMIOLOGY

Robert S. Hoffman

Regional poison centers are staffed by highly trained and certified health professionals who are assisted by extensive information systems. Support is provided by 24-hour access to board-certified medical toxicologists and consultants from diverse medical disciplines, the natural sciences, and industry. The American poison center (PC) is charged with maintaining a database, providing information to the public and to health professionals, collecting epidemiologic data on the incidence and severity of poisoning, preventing unnecessary hospitalizations following exposure, and educating healthcare professionals on the diagnosis and treatment of poisoning. This chapter explores some of the critical roles of poison centers and attempts to offer a vision of the future. Unique issues facing poison centers in other countries are discussed in Chap. 136.

HISTORY

In 1950, the American Academy of Pediatrics (AAP) created a Committee on Accident Prevention to explore methods to reduce injuries in young children. A subsequent survey by that committee demonstrated that injuries resulting from unintentional poisoning were a significant cause of childhood morbidity. Simultaneously came the realizations that a source of reliable information on the active ingredients of common household xenobiotics was lacking and that there were few accepted methods for treating poisoned patients. In response to this void, the first PC was created in Chicago in 1953.[72] Although initially designed to provide information to healthcare providers, both the popularity and the success of this center stimulated a PC movement, which rapidly spread across the country. The myriad of new PCs not only offered product content information to healthcare providers, but also began to offer first aid and prevention information to members of the community.

In the 60 years that have since passed, countless achievements have been realized by a relatively small group of remarkably altruistic individuals. Throughout this time, poison services have remained free to the public, highlighting their essential role in the American public health system. Many of the legislative and educational accomplishments, which are chronicled in Chap. 1, have directly reduced the incidence and severity of poisoning in children.[69,77,82] Concurrently, the number, configuration, and specific role of PCs has shifted in response to public and professional needs.[32,90] However, a crucial test of the utility of modern PCs will be their ability help reverse the US current trend of increased adult mortality from poisoning.[16] Additional metrics, such as ICU admissions, length of stay in hospitals, and total healthcare expenditures might serve as other indicators of PC success. The basic functions of PCs are discussed in the following sections.

MAINTAINING A DATABASE ON PRODUCT CONTENTS AND POISON MANAGEMENT

The first toxicology database created in the United States was a set of cumbersome 5″ × 8″ index cards produced in the 1950s by the US National Clearinghouse of Poison Control Centers.[72] When it grew to include more than 16,000 cards, the sheer volume of space required to store this information, and the extensive time necessary to manually search these cards created the necessity of a central repository, such as a PC. As available information grew, a rapid expansion of information technology occurred, and the unwieldy index card database was privatized and transformed into microfiche. Although this resource was physically smaller, specialized equipment was required, and a search was still time-consuming. Numerous encyclopedic and clinical textbooks were written to supplement the database and provide resources for the office or the bedside. With the growth of the computer age and the Internet, the computer product known as POISINDEX was established to replace the microfiche format as the major source of data on the contents of innumerable household and industrial products, drugs, and plant and animal xenobiotics. POISINDEX also provides uniform management strategies for many potentially toxic exposures.

With this evolution of information technology, PCs are no longer perceived as the sole guardians of toxicology information. Although these services are still essential for the public at large, and those professionals away from their computers or mobile phones, a predictable decline in PC utilization has paralleled this growth in availability of information. A 1991 study in Utah demonstrated that 82.6% of emergency physicians who had POISINDEX available in their institutions no longer routinely consulted the PC.[15] A similar 1994 New York State study suggested that 76% of physicians who had POISINDEX in their emergency departments (EDs) perceived that this decreased their own use of their PC.[87]

An initial analysis might suggest that this is an acceptable trend for healthcare professionals in that it both allows physicians to respond more rapidly to patient needs and for PCs to be more available to those individuals, especially nonhealthcare professionals, who do not have access to this information system. However, this practice of "not calling" not only undermines the efforts of PCs to gather epidemiologic data (see later) but also creates an understanding gap. In other words, the interpretation of the data is as essential (or more essential) than the data itself. For example, some commonly used sources of toxicology information such as the Physicians' Desk Reference (PDR) and material safety data sheets (MSDS) occasionally provide information that may be inaccurate, potentially misleading, or severely limited.[35,64] Likewise, two reviews of drug interaction programs designed for mobile devices demonstrated significant variability between individual programs.[2,68] Although POISINDEX routinely provides more accurate information regarding overdose, it cannot be expected to adapt to ongoing epidemiological trends such as regional variations in substance use and is currently updated only periodically.

The best source for essential new information is skilled professionals who specialize in poisoning. Also, because most databases are designed to provide information about known entities, they perform poorly when dealing with unknown and unclear scenarios—especially long and complicated differential diagnoses. For example, consider the case of a clinician caring for a lethargic child whose only medication is Zantac syrup. After the other causes of altered mental status have been excluded, the clinician considers drug toxicity. Consultation with standard references suggests that altered consciousness would not be expected with use of this medication. However, a certified poison specialist at a regional PC recognizes the potential for drug error, has the physician review the syrup bottle in question, and then calls the pharmacy where the drug was provided. The poison specialist learns that although the prescription was written for Zantac (ranitidine), the bottle actually contains Zyrtec syrup (cetirizine) which could account for the child's symptoms.

Thus, although originally designed as providers of information, PCs must now be considered more as valued consultants, with staff who not

only provide content information but also interpret clinical material and link both to appropriate management strategies. This goal can only be achieved through rigorous training and certification and recertification criteria designed to provide valued up-to-date interactions with healthcare professionals. Access to computer programs can never be considered a substitute for a thoughtful human analysis. Computers do not recognize anxiety, inappropriate questions, and other subtle issues that can only be appreciated with human interactions.

Another illustrative example of the value of PCs can be drawn from the use of flumazenil for benzodiazepine overdose (Chap. 74). Although it may easily be determined by anyone capable of using an index that flumazenil is an antidote for benzodiazepine overdoses, many subtle characteristics of the patient or the overdose often contraindicate its use. A prospective study determined that when flumazenil was used before consultation with the PC, contraindications were present in 10 of 14 (71%) cases, resulting in one serious adverse event.[12] In the study mentioned earlier, although physicians with access to POISINDEX were less likely to call the PC, 86.7% still felt that using the PC to gain access to a physician toxicologist was a valued resource.[15] Many PCs are linked with centers for poison treatment (CPT), which are healthcare facilities that can provide both bedside consultation and unique diagnostic and therapeutic interventions for a subset of patients with severe or complex poisoning.[1] The benefits of consultation are discussed later under Health Care Savings.

COLLECTING POISON EPIDEMIOLOGY DATA

Recent data demonstrate that poisoning is the second leading cause of injury-related fatalities, ranking only behind motor vehicle crashes and recently surpassing firearm use.[16] Understanding the evolving trends in poisoning is essential to the development of enhanced surveillance, prevention, and education programs designed to reduce unintentional poisoning. Although data can be analyzed from numerous sources such as death certificates, hospital discharge coding records, and PCs, it is essential to recognize the biases that are inherent in each of these reports. Because not all significant poisonings result in either hospitalization or fatality, data from PCs appear to offer a unique perspective.

Unfortunately, the term "poisoning" is often defined differently and therefore may be confusing. In this text, "poisoning" is used to denote any exposure to any xenobiotic (drug, toxin, chemical, or naturally occurring substance) that results in injury. Yet the data collected and disseminated by PCs are defined by the term "exposures."[10,49,53–57,83–85] Many exposures are of no toxicologic consequence either because of the properties of the xenobiotic involved, the magnitude or duration of the exposure, or the uncertainties regarding whether an actual exposure has occurred; therefore, data collected by PCs represent a limited and ill-defined measure of poisoning.

The situation is further confounded by multiple biases that are introduced by the actual reporting process, which first and foremost is voluntary and passive. Because the majority of calls concern self-reported data that come from the home and are never subsequently confirmed, a significant percentage of the data generated to date may actually represent only potential or possible exposures, potentially resulting in large statistical errors introduced into the database. For example, although a recent study evaluated all children with a history of methanol or ethylene glycol ingestion over more than 2 years, only 21 of 102 children analyzed actually demonstrated the presence of a toxic alcohol concentration.[51] Nevertheless, all 102 of these cases were entered into the database as exposures. If these figures are representative of the rest of the data set, they suggest that ingestion does not actually occur in the vast majority of reported unintentional exposures in children. Also, current events, hoaxes, and media awareness campaigns all may influence

self-reporting rates.[58] Furthermore, in order to report a possible exposure a caller must have a telephone and probably speak English. Although telecommunications devices for the hearing impaired and translation services exist, they are rarely used. Enhancement of technology to facilitate the accurate exchange of information between poison specialists and either hearing impaired callers or those who do not speak English is essential to the success of PCs. Another would be to entertain more active reporting systems automatically triggered directly by hospital laboratory values.

Under the present passive system, when hospitals report exposures to the PC, a comparison of the hospital chart with the PC record shows good agreement, demonstrating an accurate exchange of information.[40] Unfortunately, a reporting bias similar to that described above is well recognized regarding professional utilization of poison centers and has been called the *Pollyanna phenomenon*.[36] For example, in the spring of 1995, PCs in the northeast United States began to receive numerous reports of severe psychomotor agitation and other manifestations of anticholinergic syndrome in heroin users. In the initial phase of the epidemic, most of the callers requested assistance in establishing a diagnosis, determining possible etiologies, and raised questions regarding treatment with physostigmine.[37] Although the epidemic continued for many months, once the media announced that the heroin supply was tainted with scopolamine, and clinicians became familiar with the indications and administration of physostigmine, call volume decreased. Stated simply, healthcare professionals are less likely to call the PC regarding issues with which they are familiar, are of little clinical consequence, or are not recognized as being related to a poison. Thus, a bias is introduced that results in a relative overreporting of new and serious events and a relative underreporting of the familiar or very common, unrecognized poisoning, and those exposures or poisonings that are apparently inconsequential. Numerous comparisons support this contention. Investigators who rely on published data from PCs as a sole source of epidemiological information demonstrate a failure to understand the complexity of poisoning data and the aforementioned consequential limitations of PC-derived data.

■ FATAL POISONING

A 4-year study compared deaths from poisoning reported to the Rhode Island medical examiner with those reported to the area PC.[52] Not surprisingly, the medical examiner reported many more deaths: 369 compared to 45 reported by the PC. Although the majority of the cases not reported to the PC were victims who died at home, were pronounced dead on arrival to the hospital, or those in whom poisoning was not suspected until the postmortem analysis, 79 patients who subsequently became unreported fatalities were actually admitted to the hospital with a suspected poisoning. In 10 of these cases, the authors concluded that a toxicology consultation might have altered the outcome. Examples of interventions that, if recommended and performed, might have resulted in a more favorable outcome included the proper use of antidotes such as naloxone, *N*-acetylcysteine for acetaminophen poisoning, the cyanide antidote kit, sodium bicarbonate for a cyclic antidepressant overdose, hyperbaric oxygen for carbon monoxide poisoning, hemoperfusion for a theophylline overdose, and hemodialysis for a lithium overdose.

Likewise, when medical examiner data were analyzed in Massachusetts, over 47% of poison fatalities had not been reported to the PC.[75] A California study evaluating 358 poisoning fatalities reported to the medical examiner showed that only 10 PC fatalities had been reported over a similar time period, demonstrating an even more consequential reporting gap.[4] Once again in this study, whereas the majority of underreporting was with respect to prehospital deaths (68%), only 5 of 113 hospitalized patients who ultimately died were

reported to the PC. Additionally, a cross-sectional comparison of national mortality data with PC data for agricultural chemical poisoning demonstrated a similar trend of underreporting to PCs of seriously poisoned admitted patients who became fatalities.[46] Furthermore, when data for an entire year from the National Center for Health Statistics (NCHS) were compared to the same year of data from the American Association of Poison Control Centers (AAPCC), it was apparent that the AAPCC data captured only about 5% of annual poison fatalities.[39]

More recent analyses have highlighted a remarkable trend. When 11 states evaluated trends in poison-related mortality from 1990 to 2001, an average increase of 145% was noted.[17] A more comprehensive investigation of the National Vital Statistics System (NVSS) accessed via the Centers for Disease Control and Prevention's (CDC) Web-based Injury Statistics Query and Reporting System (WISQARS) database demonstrated a 5.5% increase in injury related mortality from 1999 to 2004. Mortality from poisoning accounted for 61.95 of the increase in unintentional injury, 28% of the increase in suicide, 81.2% of the increase in death from undetermined intent, and more than half of the total increase injury-related mortality.[16] As of 2004 death from poisoning surpassed firearms and became the second most common cause of injury-related fatality. Focusing on PC data alone would produce the erroneous assumption that poisoning-related fatalities were not a significant public health concern. In actuality, poisoning is a significant concern in that other programs designed to reduce deaths from motor vehicle crashes and firearms have been largely successful.

It is logical to assume that similar disparities exist regarding the reporting of nonfatal poisonings. The resultant gap in public health data needs to be addressed through improved definitions, epidemiology, reporting, and analysis of poison-related data systems. This inequity has developed through a long-standing tradition of PCs to focus attention and concentrate on the largely benign exposures in children. The emphasis needs to be redirected toward seriously ill poisoning, ICU utilization, and other markers of actual poisoning rather than healthcare utilization for benign events.

■ NONFATAL POISONING

An outreach study in Massachusetts determined that hospitals geographically close to a PC reported their cases almost twice as often as hospitals remotely located (46% vs. 27% of total cases).[18] Additionally, the authors noted that private physicians were less likely to report cases than residents in training. A 1-year retrospective review demonstrated that only 26% (123/470) of poisoned patients who were treated in a particular ED were reported to the PC.[38] Interestingly, only 3% of inhalational exposures were reported, compared with 95% of cyclic antidepressant ingestions. The authors also noted, as suggested above, that reporting decreased when comparable exposures occurred over a short period of time. Finally, in the physician survey study cited earlier, physicians reported that they would "almost never" contact the PC for asymptomatic exposures (62.9%), chronic toxicity (50.4%), or simply to assist in establishing a reliable database (90.2%).[15] This statement is most likely accurate even in jurisdictions where reporting of all or select exposures is incorporated into public health laws.

■ OCCUPATIONAL EXPOSURES

Xenobiotic exposure occurs commonly in the workplace. As a result of the long-recognized association between occupational exposure and illness, a number of federal and state government-funded agencies, such as the National Institute for Occupational Safety and Health (NIOSH), Occupational Safety and Health Act (OSHA), and the Agency for Toxic Substances and Disease Registry (ATSDR), exist to prevent occupational illness, to educate the public, and to collect data on exposures to occupational xenobiotics. Legislation provides for mandatory reporting in some instances and offers workers job protection for voluntary reporting. PCs also provide information on occupational exposures and collect data. Once again, there are discrepancies between the poison information data and the data collected by governmental agencies. A 6-month survey in California noted that only 15.9% of the occupational cases reported to the PC were captured by a state occupational reporting system.[6] The most common occupational toxicologic illness—dermatitis—was underrepresented in these cases. A follow-up study by the same authors demonstrated that over a third of calls came directly from the individual worker, 70% of whom were unaware of the link between their occupation and their symptoms.[5] Although these data suggest that PCs can provide substantial assistance following occupational exposures, one author expressed concern, noting in a followup study that the PC failed to provide an adequate epidemiological assessment in that it did not identify an average of 12 other people per workplace who were also potentially exposed in addition to the index case.[9] A 1999 survey of PCs concluded that PCs' "responses to work-related calls are inadequate," and suggested that written protocols might be helpful.[8] Additional efforts need to address the abilities of poison centers to respond to other events that generate multiple patients such as hazardous materials releases, malicious acts, and natural disasters.

■ ADVERSE DRUG EVENTS AND XENOBIOTIC ERRORS

Although the actual numbers are a source of controversy, data suggest that a striking number of adverse drug events (ADEs) occur each year in the United States, with many resulting in death.[23,50] The ease of 24-hour telephone access, combined with the ability to consult with a health professional, make PCs ideal resources for reporting of ADEs.[24] Yet, over 76% of physicians surveyed stated that they would "almost never" contact the PC regarding adverse drug events.[15] Moreover, 30 of 56 (53.6%) PCs surveyed stated that they had not submitted any of their ADE data to the FDA's Med-Watch program.[22] Many of the other centers reported only partial compliance with the MedWatch system.[22]

Prescription drug errors are another source of potential poisoning. Retrospective review of PC data suggests that many of these errors are reported. In one report, the PC provided valuable feedback to pharmacists and physicians about these errors. Ideally, reporting to the state board of pharmacy would ensure that proper surveillance and counseling continue. The PC would seem to be ideally suited to perform this function.[74]

■ DRUGS OF ABUSE

PCs also collect data on exposures to drugs of abuse and misuse. These data consist largely of calls for information from the concerned public and reports of overdose requiring healthcare intervention. Although ethanol, tobacco, and caffeine are the most common xenobiotics used in society, these cases are rarely reflected in poison center data, with the exception of unintentional exposures in children. In fact, because most substance abuse does not result in immediate interactions with the healthcare system, other databases such as the National Institute of Drug Abuse (NIDA) Household Survey (now referred to as the Monitoring the Future Study) might better reflect substance abuse trends.[22] Yet even this database has significant limitations.[3,34] Because PCs are more focused on immediate healthcare effects of exposures, it could be argued that only those cases in which healthcare interaction is required are of value in the database. Whereas PC data are collected passively, the Drug Abuse Warning Network (DAWN) provides an active surveillance system of a sample of hospital visits and deaths that relate to substance misuse. Unfortunately, because DAWN data

use hospital chart "mentions," which are infrequently validated, the data have been significantly criticized.[78] Clearly none of these three systems accurately encompasses the entire scope of the substance abuse problem.

■ GROSSLY UNDERREPORTED XENOBIOTICS

As discussed above, there is little doubt that ethanol and tobacco are the most common xenobiotics intentionally used and misused in our society. Although their toxicologic manifestations can be acute and severe, chronic subclinical poisoning often goes unnoticed for many years. Similarly, more than one million American children have lead concentrations above 10 μg/dL and polychlorinated biphenyls (PCBs) can be found in countless adults and children. We must remain cognizant of these large-scale exposures when we read that plants, cleaning products, and cosmetics comprise the most common exposures to xenobiotics;[10] rather, these are the most common "reported" exposures.

■ USING THE EXISTING DATA

With the current limitations of the PC data, it should be clear that neither the numerator nor the denominator of the actual number of poisonings can be easily appreciated. However, analysis of these data for trends may be more useful because the inherent biases involved in PC reporting are probably consistent over many years. Efforts should be directed to encourage reporting by such enhanced access methods as Web-based forms for passive reporting, a direct interface between laboratory and hospital databases that actively transmits data to PCs and linkages to other agencies that collect reports of poisoning such as state and local health departments. Additional resources should be directed at improved case definitions (distinguishing asymptomatic exposure from poisoning) and integration with other essential databases such as MedWatch, National Vital Statistics System (NVSS), and the National Center for Health Statistics (NCHS).

Despite its limitations, PC data have significant utility. It is often an exposure rather than an actual poisoning that provides the impetus for contact with healthcare. For those exposures that are unlikely to be consequential, the PC can intervene to prevent potentially harmful attempts at home decontamination and costly unnecessary visits to healthcare providers. Interaction with parents at a time of perceived crisis also provides a "teachable moment" (Chap. 134) that may help prevent a more consequential exposure in the future. For those exposures that may result in poisoning, the period of time immediately following exposure is an ideal moment to initiate first aid measures designed to prevent or lessen the severity of poisoning. For both of these reasons the cost, benefits, and efficacy of PCs especially regarding home calls must be measured in terms of exposures and not poisonings.

HEALTHCARE SAVINGS

When visits to pediatric EDs for acute poisoning were analyzed, one study demonstrated that 95% of parents had not contacted the PC before coming to the hospital and 64% of those children required no hospital services.[19] In contrast, when parents called the PC first, fewer than 1% sought emergency services afterward. When 589 callers to one PC were surveyed, 464 (79%) stated that they would have used the emergency care system if the PC were unavailable.[43] In a similar, more recent study 36% of callers would have selected a more costly alternative if the PC were unavailable.[7] Poison center data confirm that approximately 75% of reported exposures that originate outside of healthcare facilities can be safely managed onsite with limited telephone followup. Suggesting simple techniques or reassurance can successfully reduce

hospital visits for patients who typically call PCs which, as defined, may only represent a potential exposure. Unfortunately, this approach is less applicable to adults and the population as a whole. Limited data suggest that direct bedside consultation and care help reduce length of hospital stay and healthcare costs.[26] In a recent assessment, consult with a PC for patients already in hospital is associated with a significant decrease in length of stay and total health care costs.[11,80]

The national average cost to the PC for a single human exposure call is on the order of $35.[90] A federally funded study concluded that in 1 year PCs reduced the number of patients who were treated but not hospitalized by 350,000 and reduced hospitalizations by an additional 40,000 patients.[63] Each call to a PC prevented at least $175 in subsequent medical costs, providing strong theoretical evidence to support the cost efficacy of PCs. In fact, two natural experiments support these calculations: In 1988, Louisiana closed its state-sponsored PC. During the year that followed, the cost of emergency medical services for poisoning in Louisiana increased by more than $1.4 million. This additional expenditure represented a greater than 3-fold increase above the operating cost of that center.[45] Similarly, because of financial disputes in California, direct access to the San Francisco PC was electronically restricted for one major county, with a recording referring callers instead to the 911 system for assistance.[67] The result of each blocked call was to increase healthcare costs by approximately $33. Moreover, these calculations cannot account for the unmeasured benefits to society from PC interventions that reduce waiting times for ambulance availability and hospital treatments because of lower volumes, money saved by the prevention or reduction of injury from early intervention, or lives saved by enhancing access to or utilization of the healthcare system for seriously poisoned patients.

However, many barriers prevent a person from calling a PC, including lack of familiarity with its available services, intellectual and cultural factors, language difficulties, and confidentiality concerns.[25,44,81] Epidemiological studies demonstrate that areas of increased population density with high percentages of minority inhabitants have lower utilization of PC services.[79] Additional barriers include the absence of caregiver comfort with the extensive personal contact provided by the healthcare system and a concern regarding implications of child abuse or neglect when reporting to agencies such as PC, many of which have governmental ties.[73] Data demonstrate that public educators can help overcome some of these barriers.[76] One good example of an effort to overcome reporting barriers was the institution of a single national toll-free number for poisoning (1-800-222-1222). Although it is clear that this intervention improved access and increased total calls to the PC,[48] it has yet to be determined if this has altered the patterns of use.

PROVIDING EDUCATION FOR THE PUBLIC AND HEALTH PROFESSIONALS

Poison center staff work closely with physicians, community health educators, community support groups, and parent–teacher associations to develop poison prevention activities.[59] Table 135–1 lists common strategies advocated to prevent poisoning. PCs are also actively involved in enhancing training programs for paramedics,[31] medical students,[42] pharmacy students,[28] and resident physicians[28,66,88] and are an integral part of postgraduate training programs in medical toxicology fellowships.

As stated previously, there is an inherent risk in both enhanced public and professional education programs. Currently, the decreased telephone utilization of a PC could be both the result of a decrease in the incidence of exposure or poisoning or an enhanced understanding of the prevention, diagnosis, and treatment of poisoning. Although

---

TABLE 135–1. Common Strategies Advocated to Help Prevent Poisoning

All xenobiotics should be kept in their original containers. Food and drink containers should never be used for the excess of a xenobiotic.

Never store xenobiotics in unlocked cabinets under the sink. Apply locks to medicine cabinets that are within the reach of a child.

In the absence of a lock, the more toxic xenobiotics should be stored on the highest shelves.

Xenobiotics should never be left in the glove compartment of the family car.

Parents should buy or accept medication only if it is in a child-resistant container.

Medication should be considered as medicine, not a plaything and certainly not candy.

Adults should not take their medications in front of children:
   This will limit exposure to drug-taking role models that may become objects of imitative behavior.

Unused portions of prescription medications should be discarded.

Activated charcoal should be readily available in the home for use if directed by a poison specialist or clinician.

Children who have ingested a poison will do so again within a year, these children should receive an enhanced level of supervision.

---

education should never be viewed as detrimental, programs must include an emphasis on the continued use of PCs to ensure access to current information in a rapidly changing discipline. In actuality, as a result of the ongoing analysis of incoming calls, the knowledge base has the potential to change as rapidly as the calls are reported. This is far more rapid than can occur in any published literature or electronic database. Thus, additional emphasis should be applied to routine utilization of the PC as a public health tool to improve the accuracy of epidemiological data. Reporting of rare or suspected events can serve as sentinel efforts that help identify consequential adverse drug opportunities long before normal postmarketing surveillance tools identify areas of concern.

On the other hand, outreach programs that advise the public to access free services for inconsequential events can easily overwhelm an already stressed system of responding to incoming calls by demanding an immediate response to the less serious calls in an appropriate time frame. Public education and public health must both be considered to assure that PCs are staffed with the appropriate number of skilled individuals to respond not only to daily events, but also to address surges in calls that may be the result of true epidemics or responses to media announcements. Increasing calls to demonstrate increased utilization offers no public health advantage if the utilization is inappropriate or if seriously ill or potentially ill callers lose access to timely responses.

DEVELOPMENT OF PUBLIC HEALTH INITIATIVES

The initial public health efforts of poison centers focused on attempts to alter product concentration and to enhance product labeling and packaging. These clearly beneficial endeavors should continue and must evolve. However, current events have also increased PC activities in preparedness for disasters resulting from radiological, biological, and chemical terrorism.[33,47] Additional links with governmental agencies

such as the CDC and ATSDR will expand the role of medical toxicology in community health.[86] The need for 24-hour rapid access to centralized information, existing data entry and retrieval systems, and links to experts in medical toxicology and emergency medicine helps to place PCs in critical roles in both local and national initiatives. Important contributions have included development of triage and treatment protocols and assessments of antidote supplies.[13,14,20,21,27,29,30,60–62,65,70,71,89]

SUMMARY

Poison centers provide unique benefits to society. Public education efforts help reduce the likelihood of exposure. Provision of basic management advice helps to diminish the consequences of a poisoning once an exposure has occurred. Reassurance and proper basic management help to curtail unnecessary utilization of expensive healthcare. Interactions with healthcare professionals streamline the care of poisoned patients and improve access to toxicologically specific antidotes and the services of medical toxicologists. Data on exposures are used effectively to create legislation to further limit poisoning by altering contents or improving packaging or labeling.

TABLE 135–2. Goals for Improving Poisoning Epidemiology Data

Identify and remove barriers to reporting

Create multiple methods of reporting:
   Telephone, Facsimile, Internet based or e-mail

Simplify communications devices for the hearing impaired

Allow rapid access to translation services

Enhance awareness of the public health role of PCs

Enhance education of caregivers and healthcare professionals

Establish public health legislation requiring professional reporting of exposures

Distinguish possible exposures from actual exposures to improve the integrity of the database

Create a category for unconfirmed exposures in the database and encourage its use

Divide confirmed exposures by certainty:
   Confirmed by history
   Confirmed by physical examination
   Confirmed by quantitative and qualitative laboratory analysis

Integrate AAPCC database with other databases (such as the ICD and "E" code systems) and utilize a standardized data collection instrument

Automatically interact with hospital and commercial laboratories

Uplink pharmacy ADE reports, hospital discharges, public health department reports (similarly available with lead screening programs), fire departments and hazardous materials responders, industry workplace exposures, death certificates, and drug abuse monitoring systems

Provide real-time analysis of incoming data

Enhance the speed of data collection and reporting

Analyze data as it is reported to identify emerging trends

Mandate the use of accepted epidemiological and statistical analyses of data

Provide rapid and regular feedback to primary reporters

Issue timely analyses and reports

Successes include the establishment of a single nationwide toll-free number to assure easy access to poison services, the development of new databases with enhanced near real-time surveillance system,[10] and the creation of a more stable stream of federal funding. Goals for the continued success of PCs must involve maintaining a uniformly high quality of service, and working to improve the accuracy of the PC database, a shift in emphasis toward active reporting, active involvement in the care of those in need of ICU care and more appropriate utilization of critical services such as ICU admissions and critical resources such as complex and costly antidotes prevention of fatal poisoning, and prevention of medical error. Many experts believe that part of this success will be through development of uniform practice guidelines, which has already begun. Poison centers must publicize the need for reporting all poisonings including ADEs and strive to improve systems of active surveillance. Although mandated reporting may somewhat improve surveillance, barriers to utilization and reporting must be identified and overcome. Poison center reporting must be integrated with other databases so that the true numerators and denominators of poisoning can be understood and so that a concerted response to poisoning and poison prevention can be made. Finally, the causes of the recently identified dramatic rise in poison-related deaths must be identified and addressed. Table 135–2 summarizes these and other initiatives, which are also discussed extensively in a recent report from the Institute of Medicine.[41]

ACKNOWLEDGMENT

CHAPTER 136
INTERNATIONAL PERSPECTIVES ON MEDICAL TOXICOLOGY

Michael Eddleston

Poisoning and envenomations are worldwide problems but the major effects are felt in the developing world. At least 250,000–350,000 people die every year from acute pesticide poisoning[59] and many more suffer from acute or chronic occupational exposure,[38,74] hundreds of thousands of people are affected by groundwater arsenic contamination in Bangladesh and India,[116] and an estimated 20,000–94,000 humans die each year from snake bites.[80] Outbreaks of plant food–derived poisoning affect whole communities,[32] and leaks from poorly regulated chemical plants affect urban areas as the Bhopal disaster did in 1984.[112]

The resources for dealing with these problems are limited. Public health education about poisons and laws limiting access to the most highly toxic chemicals are practically absent in much of the developing world. Rudimentary public health infrastructures make the western model of a toxicology consult service impractical. Clinical toxicology is frequently not a recognized specialty and patients are evaluated by general physicians with little training, although often with great experience. Diagnostic facilities are few, effective treatment options even rarer. Where antidotes exist, there is rarely enough knowledge or experience to know how to use them.[23] Intensive care beds for long-term ventilation are scarce.

Variations in poisoning patterns within any given country may be significant, especially when comparing wealthier urban centers with agrarian, often poorer, rural areas. While the majority of healthcare and academic resources are concentrated in urban centers, it is in the countryside where much of the mortality from acute poisoning occurs. The accessibility of pesticides to rural people, and their lethality, has a profound influence on global poisoning patterns.

EPIDEMIOLOGY OF ACUTE POISONING GLOBALLY

■ PESTICIDES

A systematic review suggested that at least 250,000, and probably 350,000, deaths occur each year from acute pesticide self-poisoning around the world.[59] The annual number of deaths from occupational or unintentional poisoning is unknown but was estimated 20 years ago at 20,000.[73] The majority of self-harm deaths occur in Asia, particularly in China and India.[59] Around 3000–6000 ventilators are required each day for ventilation of pesticide-poisoned patients,[59] with many patients requiring ventilation for weeks.[46] The World Health Organization now considers pesticide poisoning to be the single most important global means of suicide, accounting for more than one-third of all suicides.[17]

While many classes of pesticides are implicated in fatal self-poisonings, organic phosphorous (OP) insecticides appear to be responsible for the majority of pesticide-related deaths.[42] Deliberate self-poisoning with OP insecticides puts a high cost on the healthcare system. In one study examining the experience in Sri Lanka, OP insecticide poisoning was responsible for 943 of 2559 (36%) admissions to a secondary hospital for poisoning.[48] The case fatality for OP poisoning was 21%, and pesticide poisoned patients occupied 41% of all medical intensive care beds. Similar situations have been reported from across the world.[42] In all likelihood, such studies underestimate the mortality associated with intentional pesticide ingestion as most are hospital based and do not include patients who die prior to hospital presentation.[3]

Factors that contribute to the high mortality in self-poisoning with pesticides in the developing world include the intrinsic lethality of many pesticides and healthcare systems that are poorly prepared to handle such critically ill patients (Table 136–1). Pesticides are easily available in highly concentrated preparations in rural communities throughout the developing world. The ease of drinking liquid pesticides is also a factor facilitating massive intentional ingestions.

Inadequate pesticide storage systems are also implicated,[83] particularly in unintentional ingestions in children. Outbreaks of unintentional poisoning from contaminated flour or old pesticide containers used to store food still occur in rural areas.[40] The extraordinarily high human, economic, and social costs of pesticide-related mortality in the developing world reinforce the importance of developing strategies specifically designed to care for acutely poisoned patients in resource-poor environments. Treatment protocols should be simple, economical, and evidence based.[23]

Patients die from other pesticides. Poisoning with organic chlorine insecticides was a common problem in many countries[42] and remains one in Turkey[41,79] (see Chap. 114). However, recent international bans, in particular the *Stockholm Convention on Persistent Organic Pollutants*, have generally reduced their use in agriculture and self-harm. Carbamate insecticides are also a frequent means of fatal self-harm[2,18,78] and may become more common as agricultural use of organic phosphorus insecticides decreases. Avermectin poisoning is reported from Taiwan.[36] The fumigant aluminum phosphide is the most important cause of fatal self-poisoning in Northern India,[115] with a case fatality over 60%.[62] Fatal aluminum phosphide poisoning is also common in children.[117]

Dipyridyl herbicides, particularly paraquat, are common methods of self-harm in some countries, particularly Korea and Sri Lanka.[57,137] Glyphosate-containing herbicides are widely used for agriculture and self-harm;[131] human toxicity appears to relate to the salt and surfactant present in the formulation rather than the actual herbicide itself.[22] Other herbicides reported to be important local self-harm problems include propanil, causing methemoglobinemia and hemolysis anemia,[47] chlorphenoxy compounds, possibly causing oxidative uncoupling in severe cases,[109] and alachlor and butachlor, causing CNS depression[90] (see Chap. 115).

As pesticides are developed[25] and integrated into agricultural practices, their emergence as a means of self-harm is likely to occur. The avermectins and phenylpyrazoles affect the CNS in opposing ways, the former causing coma,[36] the latter seizures.[93] Both have a low case fatality. Other new pesticides, including chitin synthesis inhibitors and neonicotinoids,[25,132] appear to have very low toxicity in overdose compared to the older OP insecticides. Many patients will survive poisoning with only careful supportive care.

■ CAUSTICS

Caustics are common in the developing world in both industry and the home. Poisoning with these chemicals is distinct from other common poisonings in two respects. First, gastric decontamination is generally contraindicated due to direct damage to the oropharynx, esophagus, and stomach. Second, if the acute phase of caustic poisoning is survived, there is a high rate of delayed complications, primarily esophageal strictures. These delayed complications may require surgical

TABLE 136–1. Factors Contributing to High Mortality from Self-Poisoning with Pesticides in the Developing World

1. Ease of access to pesticides in rural, agrarian households
2. Poor storage practices
3. Inadequate labeling of lethal pesticide products
4. High potency of pesticides
5. Lack of evidence-based practice guidelines appropriate for resource poor areas
6. Lack of clear guidelines
7. Distance from and time to health care facilities and resources available at healthcare facilities

intervention, balloon dilatation of the esophagus (bouginage), or feeding tube placement. These treatments are expensive, require significant hospital resources, and have inherent morbidity and mortality. While some patients may die acutely from the original exposure, others die from complications of later reparative surgery (see Chap. 104).

The common form of caustic ingested varies between countries. In Taiwan and Morocco, self-poisoning with hydrochloric or sulfuric acids is a major problem.[4,87,122,139]

Formic and acetic acids are used in the manufacture of rubber, and case series are reported from areas surrounding rubber factories in India and Sri Lanka.[107] In Surinam and Curacao, concentrated acetic acid was an important means of self-harm in the 1970s.[39,100] *Rubigine* is a domestic cleaning product containing hydrofluoric acid and ammonium difluoride that is used for self-harm in the Caribbean.[69] Car battery acid ingestion occurs in Africa, Papua New Guinea, and the Caribbean[138] while ingestion of sodium hydroxide is common in Malaysia.[13] All the caustics have high case fatality, usually well over 10%.

■ INDUSTRIAL PRODUCTS

While many xenobiotics used in industrial processes have been used for self-harm, a complete review of intentional or occupational poisoning is beyond the scope of this chapter. However, two xenobiotics commonly used in self-poisoning require mention. Copper sulfate causes direct damage to the GI tract, hepatorenal failure, and hemolysis[111] (see Chap. 93). Once widely used for self-poisoning in South Asia, there has been a resurgence in cases in Bangladesh in recent years.[8] Cyanide has become a commonly used method in Korea over the last 20 years[88] (see Chap. 126).

Occupational and environmental poisoning from industrial xenobiotics is a significant problem in the developing world. As the world becomes increasingly more industrialized, laws to regulate access to industrial xenobiotics and ensure their safe labeling in developing countries have lagged behind the expansion of exposure. Furthermore, industrial factories are often placed in urban areas, or the areas around factories are rapidly urbanized, placing large numbers of people at risk of poisoning from industrial errors[12] and facilitating easy access to poisons in cases of intentional ingestion.

■ DOMESTIC XENOBIOTICS

Patterns of self-harm using domestic xenobiotics appear to have significant intracountry variability. In one Zimbabwean case series of 1192 cases, the majority of exposures were unintentional ingestions of kerosene in children under the age of 6.[99] However, self-harm was

cited in 19% of cases and was responsible for many deaths. Poor storage of kerosene and paraffin, typically in soda or water containers and in easily accessible locations, is a major factor in the high incidence of poisoning in children[50] (see Chap. 106).

In Hong Kong, significant morbidity is associated with self-poisoning using detergent products such as dettol (4.8% chloroxylenol, pine oil and isopropyl alcohol) and savlon (cetrimide).[26,29,31,37] Common use of potassium permanganate for self-harm has been reported from Hong Kong.[1021,140] While cosmetics are not cited as a major source of poisoning, fatal poisoning with hair dye (paraphenylenediamine) is known in the Middle East and north Africa.[21,49,66,119] Barium sulfide, arsenic sulfide, and calcium oxide are contained in hair removal preparations;[114] ingestion of such preparations has been reported from India and Iran.[6]

■ ANIMAL ENVENOMATION

Snake bites and envenomation by other animals represent a significant cause of morbidity and mortality in the developing world. Venomous snakes are found on all continents, with the exception of Antarctica, although the majority of species are found in equatorial, tropical or subtropical environments.[134,136] The epidemiology of snake bites and therefore the health impact is determined by the species of snake in a given area, lethality of venom from these species, snake behavior, human activities, and access to healthcare. Snakebites from members of the Elapidae and Viperidae families are responsible for the majority of deaths worldwide, although several other families are medically important (Colubridae and Atractaspididae species, in particular)[134,136] (see Chap. 121).

Snakebite is most commonly an occupational hazard in the rural tropics. Victims are just as likely to be women as men, reflecting rural farming practices. Working in large plantations and subsistence farms places rural people in frequent contact with venomous snakes. With simultaneous changes in global climate and expansion of human settlements, it is likely that the range of venomous snakes will enlarge to include urban areas and regions previously considered too temperate to support them.[67,98]

Few countries mandate the reporting of animal bites, making it difficult to estimate snakebite incidence, severity and outcome. Because the majority of rural people in the developing world first consult traditional healers, hospital-based studies of mortality and morbidity associated with snakebites may underestimate the scope of the problem.[33,118] A study of rural Philippine rice farmers found that only 8% of cobra (*Naja philippinensis*) bite victims reached a hospital in the 1980s.[135] However, changes in treatment seeking can occur. Studies over the last decade in Sri Lanka have shown that patients have started going to the hospital rapidly after common krait (*Bungarus caeruleus*) snake bite, bypassing traditional healers.[85]

Taking into account these caveats, a recent study has estimated that 20,000–94,000 deaths occur globally each year from snake bite.[80] The vast majority of deaths and serious envenomations occur in the developing world. In contrast, less than 100 snakebite deaths per year are estimated to occur in Europe, the United States, Canada, and Australia combined.[33,80]

The burden of snake envenomation on local resources can be substantial. During the rainy season in Benin, snakebites account for up to 20% of all hospital admissions.[34] The case fatality is estimated to be 3%–6%. In this region, the annual incidence of snake envenomation ranges from 200–100,000 in rural villagers to 1300–100,000 in sugar cane plantation workers.[34] One study conducted in Nigeria in the late 1970s noted an incidence of 497 per 100,000 and a 12% case fatality (primarily due to envenomation by the carpet viper, *Echis occelatus*).[104] Difficulty with accessing healthcare facilities was responsible in part for the high mortality noted in one Nepalese community study.[113]

The mainstay of effective therapy is antivenom, which must be safe, effective, economical, available, and widely distributed.[130] Currently available antivenoms are prohibitively expensive, ineffective, or have a high rate of adverse reactions. Equally important, some antivenoms must be refrigerated, making them impractical therapies in the developing world. The most important challenge to treating patients with snakebites is this lack of antivenom availability in the developing world.[129] Critical evaluation of existing antivenoms and development of new products are desperately needed.[15,64,87,129,130,1376]

After snakebites, the second most common cause of mortality and morbidity from venomous animals is scorpion stings[70,134] (see Chap. 119). Medically important scorpion species are widely distributed throughout the tropics, being particularly common causes of morbidity in North Africa, Mexico, India, and Brazil.[35] The total number of medically significant scorpion stings that occur annually is unknown; a recent review estimated 1.2 million stings, leading to more than 3250 deaths (case fatality 0.27%).[35] The majority of these deaths occur in children and elderly people in rural areas where access to healthcare and antivenom is limited. The role of antivenom therapy is widely accepted in many countries, although evidence for its efficacy is scant and there is still some debate.[5,58,70,71]

Other venomous insects, such as Arachnida (spiders) and Hymenoptera (bees, ants, and wasps) are rarely sources of significant mortality on a global scale[70] (see Chap. 119). Most deaths are associated with anaphylactic reactions to Hymenoptera venom.[53] Effective antivenom is available to widow spiders (*Lactrodectus* ssp), the Brazilian banana or armed spider (*Phoneutria* ssp), and the Australian funnel spider (*Atrax robustus*).[70]

XENOBIOTICS

In the developing world, the use of pharmaceuticals for self-harm is more common in urban areas where access is easier and more people have the financial means to buy them. The pharmacopeia available in the developing world is smaller than in the industrialized world, with the exception of drugs to treat tropical diseases that may be common in particular areas.

One important medicine for self-harm in the developing world is the antimalarial chloroquine.[42] Chloroquine self-harm was widely reported from west Africa during the 1960s and 1970s;[19,96] recently a rising number of cases have been reported from Zimbabwe[14,105] (see Chap. 58). Cases of intentional and unintentional poisoning with the leprosy drug dapsone, as well as the tuberculosis drug isoniazid, have been reported[102,1265,126,133] (see Chap. 57).

Criminal poisoning of commuters to aid robbery is a common problem across south Asia.[72,97,1043] However, it appears to be particularly common around Dhaka in Bangladesh. In the 1970s and 1980s, drinks containing extracts of *Datura stramonium* were given to unsuspecting commuters, resulting in anticholinergic poisoning.[82] Practice has changed recently so that benzodiazepines are now given to sedate commuters.[90] As many as 300 people are admitted unconscious with this problem to a single university medical unit in Dhaka each year.[90]

HERBAL AND TRADITIONAL MEDICINES

Much is known about the use or the potential toxicity of traditional medicines in the developing world. Large schools of traditional medical theory and practice exist throughout China and India (Ayurvedic medicine). In other countries, traditional medical theory is learned through an apprenticeship process. In Mexico, for example, the National Ethnobotanical herbarium catalogues more than 14,000 different plants used in traditional medical practices.

While traditional medicinal preparations have been tested by generations of practitioners and the concentrations of active ingredients are generally low, both intentional and unintentional poisonings are common.[30,77,121,124] Adulterants are also common in traditional Ayurvedic medicines (particularly steroids[63]) and Asian medicines (particularly synthetic pharmaceuticals and heavy metals[28]) (see Chap. 43). A Taiwanese study of 2609 samples found that 23% were adulterated with pharmaceutical products such as caffeine, NSAIDS, acetaminophen, and diuretics.[68]

PLANTS

Poisonous plants have been used therapeutically and for harm throughout human history. Typically, they are used to induce abortion, for recreational intoxication, in homicidal acts, or for self-harm. Plants have also been the source of unintentional poisoning, either through direct toxicity or due to a toxic contaminant. This section briefly mentions toxic plants that are commonly used in self-poisoning or have caused epidemic poisoning in the developing world.[136]

Self-poisoning with seeds of two plants containing cardioactive steroids are important clinical problems in Asia. Yellow oleander (*Thevetia peruviana*) kills hundreds of people each year in Sri Lanka and India[20,43] (see Chap. 64). Sea mango (*Cerbera manghas*) has killed hundreds of people in Kerala, India,[56] and is a focal problem in eastern Sri Lanka.[44] Oduvan (*Cleistanthus collinus*) leaf contains the glycosides cleistanthin A and B, which produce severe hypokalemia and cardiac dysrhythmias.[11] Self-poisoning has killed hundreds of people in Tamil Nadu, India.[10,123]

Ackee tree fruit (*Blighia sapida*), which contains hypoglycin when unripe, is widely consumed as a food source. Epidemics of fatal poisoning with unripe Ackee fruit have occurred throughout the Caribbean and in Africa.[51,75,91,94] The superb lily (*Gloriosa superba*) contains colchicine alkaloids and has been used for self-harm in south Asia[7,9,92] (see Chap. 37).

Numerous plant species contain atropine like alkaloids, causing an anticholinergic syndrome when ingested. Reports of intentional ingestion of *Datura* species have been reported from Africa, Asia, and Latin America.[65,110,120] Most commonly, the seeds are ingested as a recreational drug for their hallucinatory effects,[55,106] or as part of traditional medical preparations.[27] Poisoning by castor beans (*Ricinus communis*) or other lectin-containing plants such as *Jatropha* spp (African purging nut) has been reported from Africa and South Asia[1,52,65,76] (see Chap. 118).

Unintentional ingestion of *Karwinskia humboldtiana* (buckthorn, coyotillo in Mexico, wild cherry or tullidora) causes a demyelinating polyneuropathy, clinically similar to Guillain-Barré syndrome.[16,24] Contamination of wheat with pyrrolizidine alkaloid-containing *Heliotropium* spp and *Crotalaria* spp in India, Tadjikistan, and Afghanistan has resulted in chronic veno-occlusive liver disease.[32,127,128]

REDUCING POISONING MORTALITY GLOBALLY

Recognition that self-poisoning with pesticides is responsible for the majority of poisoning deaths worldwide compels us to act to reduce the associated mortality. Ironically, some programs to remove the most environmentally persistent and toxic pesticides have inadvertently replaced them with pesticides that are highly toxic to humans, for example, the replacement of persistent organic chlorine compounds with carbamates in malaria control programs. The opposite has also occurred when pyrethroids replaced OP insecticides in an effort to reduce human toxicity.[84] Strategies to reduce the health effects of pesticides should take into account concerns regarding both environmental and human toxicity, and anticipate which xenobiotics will replace the most highly toxic chemicals as they are phased out of use.[108] A strategy

TABLE 136–2. Hierarchical Strategies to Reduce Pesticide Poisoning Mortality in the Developing World[108]

Most	Eliminate the most highly toxic pesticides
	Substitute with less toxic, equally effective alternatives
Efficacy	Reduce use through improved equipment
	Isolate people from the hazard
	Label products and train applicators in safe handling practices
	Promote use of personal protection equipment
Least	Institute administrative controls

based on industrial hygiene models of hierarchy of controls has been proposed by several authors (see Table 136–2).[95,108]

Voluntary interventions include international policy statements and industrial pesticide initiatives. In 1985, the Food and Agriculture Organization (FAO) of the United Nations issued a strongly worded document, the *Code of Conduct on the Distribution and Use of Pesticides*.[54] The pesticide industry has also worked in cooperation with the FAO to remove or destroy large stockpiles of obsolete or banned pesticides in the developing world. CropLife International is an industry-sponsored initiative that aims to reduce the health burden of pesticide poisoning through Safe Use and Integrated Pest Management (IPM) programs (www.croplife.org). The cost effectiveness of industry sponsored Safe Use of Pesticides programs, however, has been questioned.[95] Voluntary initiatives also suffer from a lack of resources, a shortage of political will, and nonexistent enforcement mechanisms.[84]

Restricting access to pesticides is the critical step in reducing the number of cases and the mortality of intentional ingestions. National programs that remove specific WHO-defined high-risk pesticides demonstrate this effect on mortality. The most dramatic illustration of the effectiveness of this approach is provided by Sri Lanka where banning of all WHO high-risk OP insecticides and the organic chlorine endosulfan resulted in an arrest in the previously exponential increase in incidence of pesticide poisoning and a halving of the national suicide rate between 1995 and 2005.[60] The program was estimated to have saved at least 20,000 lives over 10 years.[60]

A minimum pesticide list, based on the WHO essential xenobiotic list initiative, has been proposed.[45] Such a list would provide policy makers and farmers with a source of unbiased information, and remove the most dangerous and obsolete pesticides from everyday use. Programs to restrict the availability of pesticides reduce mortality, although careful consideration of alternative self-harm xenobiotics is necessary to prevent the public from simply switching to another, equally deadly, xenobiotic.[108]

SUMMARY

Poisoning is a common cause of death throughout the developing world. While many different xenobiotics exist in the developing world, pesticides are the most important source of mortality. In particular, organic phosphorous compounds, aluminum phosphide, and paraquat are responsible for a disproportionate number of deaths. Conservative estimates suggest that at least 3 million cases of pesticide poisoning occur annually, resulting in 250,000–350,000 deaths.[59] The majority of deaths occur in the context of acts of deliberate self-poisoning. Envenomation

is another significant problem; an estimated 5 million snakebites occur each year, resulting in 20,000–94,000 additional deaths.[80]

Epidemiologic information about regional and local poisoning patterns is needed to guide public health interventions. At present, poisoning epidemiology represents estimates derived from a minority of developing world countries. Assumptions regarding the generalization of these data may not be true. Efforts to develop epidemiologic surveillance systems and establish harmonized definitions of poisonings will yield a more complete picture of global poisonings.

Lack of evidence to support many treatment interventions hinders public health policy in the developing world. Randomized controlled trials need to be conducted to critically evaluate accepted toxicology dogma.[61] Economic analysis must also be conducted prior to recommending expensive, yet unproven, therapies. Pending the implementation of such studies, proven therapies, such as atropine and pralidoxime for organic phosphorous pesticide poisoning and snake antivenins, should be made available and affordable. In the case of pesticide poisoning, a coordinated international effort to restrict access to the most lethal xenobiotics is of paramount importance.[45]

CHAPTER 137

PRINCIPLES OF EPIDEMIOLOGY AND RESEARCH DESIGN

Kevin C. Osterhoudt

Advances in medical toxicology are achieved through the scientific method using observations, derived from cases of poisoning and nonpoisoning due to xenobiotic exposures, to generate hypotheses. Subsequent research questions are analyzed with epidemiological investigation, and preliminary studies are examined with methodological scrutiny. Initial analytical techniques are improved, and confirmatory studies are performed. Ultimately, models relating cause to effect are formulated.

To optimize patient care, it is useful to grade the quality of available scientific evidence used to justify treatment recommendations. Decisions about how strongly to recommend a medical action will be based upon the careful consideration of the risks of leaving a patient untreated, the potential benefits and harms of treatment, the quality of the guiding evidence, a balanced view of resource utilization, and the values of the person to be treated. The Grading of Recommendations Assessment, Development, and Evaluation (GRADE) Working Group has provided a framework for assessing and communicating levels of scientific evidence (Table 137–1).[15] An understanding of basic principles of research design and epidemiology is required to interpret published studies and to lay the groundwork for future investigation in toxicology.

EPIDEMIOLOGIC TECHNIQUES AVAILABLE TO INVESTIGATE CLINICAL PROBLEMS

Table 137–2 lists different study formats.

■ OBSERVATIONAL DESIGN: DESCRIPTIVE

A staggering array of xenobiotics are able to injure people, necessitating reliance of toxicologists on good descriptive data regarding toxic outcomes. Through 2007, the National Poison Data System (NPDS) of the American Association of Poison Control Centers (AAPCC) has amassed a database of more than 45 million human exposures.[5] Descriptive case reporting serves a valuable purpose in describing the characteristics of a medical condition or procedure and remains a fundamental tool of epidemiological investigation. A *case report* is a clinical description of a single patient or procedure with respect to a situation. Case reports are most useful for hypothesis generation. However, single case reports are not always generalizable, as the reported situation may be atypical. A number of case reports can be grouped, on the basis of similarities, into a *case series*. Case series can be used to characterize an illness or syndrome, but without a control group they are severely limited in proving cause and effect. In 1966, a case series of two patients with "acute liver necrosis following overdose of paracetamol"[12] was accompanied by a case report of "liver damage and impaired glucose tolerance after paracetamol overdosage"[36] which

led to further study and the eventual creation of the Rumack-Matthew nomogram (Chap. 34). Similarly, a 1979 case report of "hypertension and cerebral hemorrhage after trimolets ingestion"[22] led to subsequent animal studies, experimental human studies, and epidemiological studies culminating in the decision by the US Food and Drug administration to remove phenylpropanolamine from nonprescription cold remedies and appetite suppressants. The important role for descriptive data in guiding clinical research, focusing educational efforts, and formulating public policy are often underappreciated.

Cross-sectional studies assess a population for the presence or absence of an exposure and condition simultaneously. Such data often provide estimates of prevalence—the fraction of individuals in a population sharing a characteristic or condition at a point in time. These studies are particularly helpful in public health planning and have been extremely useful in monitoring common environmental exposures, such as childhood lead poisoning, or population-wide drug use, such as occurs with tobacco, marijuana, and alcohol. The US National Health and Nutrition Examination Survey investigations demonstrated that the percentage of children with blood lead concentration greater than 10 μg/dL decreased from 88.2% to 4.4% between 1976 and 1991, with the highest rates of plumbism among African American, low-income, or urban children.[4]

An *analysis of secular trends* is a study type that compares changes in illness over time or geography to changes in risk factors. These analyses often lend circumstantial support to a hypothesis; however, because of the ecological nature of their design, individual data on risk factors are not available to allow exclusion of alternative hypotheses also consistent with the data. A prime example of an analysis of secular trends is the finding that reports of Reye Syndrome declined between 1980 and 1985, coincident with a fall in sales of, or physician recommendations of, children's aspirin products.[3] This investigation suggested an etiologic role of aspirin in the development of Reye Syndrome but could not exclude alternative hypotheses such as a change in viral epidemic patterns.

■ OBSERVATIONAL DESIGN: ANALYTICAL

Hypotheses generated by theoretical reasoning or anecdotal association require analytical testing. Case-control studies and cohort studies are analytical techniques that use observational data, and each technique has its own advantages and disadvantages (Table 137–3). *Case-control studies* compare affected, treated, or diseased patients (cases) to nonaffected patients (controls) and look for a difference in prior risk factors or exposures (Fig. 137–1A). Because subjects are recruited into the study based on prior presence or absence of a particular outcome, case-control studies are always retrospective in nature. They are especially useful when the outcome being studied is rare, and they enable the investigation of any number of potential etiologies for a single disease.

The hypothesis, derived from multiple case reports and case series, that phenylpropanolamine might increase risk for hemorrhagic stroke was well suited to case-control study. Exposure to ingested phenylpropanolamine, as an ingredient in cold remedies and appetite suppressants, was common; but hemorrhagic stroke is rare among children and young adults. Other putative risk factors such as tobacco use, hypertension history, family history, cocaine use, and contraceptive use were identifiable and could be studied simultaneously. In a case-control analysis of 702 subjects with hemorrhagic stroke and 1376 controls, the use of appetite-suppressant doses of phenylpropanolamine were found to be independently associated with the occurrence of hemorrhagic stroke.[21]

Cohort studies compare patients with certain risk factors or exposures to those patients without the exposure, then follow these cohorts to see which subjects develop the outcome of interest (see Fig. 137–1B).

TABLE 137–1. GRADE System for Evaluating Clinical Recommendations[15]

Strength of Recommendation	Quality of Evidence
Strong	High
Weak	Moderate
	Low or very low

TABLE 137–3. Advantages of Case-Control versus Cohort Study Designs

Case-control Study	Cohort Study
Smaller sample required when outcome is rare	Provides more robust evidence of association
Reduced bias in outcome data	Reduced bias in exposure data
Can study many exposures simultaneously	Can study many outcomes simultaneously
Allows estimation of relative risk	Allows direct calculation of incidence
May obviate need for long followup period	Allows direct calculation of relative risk

In this respect, they allow the comparison of *incidence* (the number of new outcomes occurring within a population initially free of disease over a period of time) between populations who share an exposure and populations who do not. They may be retrospective or prospective and enable the study of any number of outcomes from a single exposure. They are particularly well suited to investigations in which the outcome of interest is relatively common. In circumstances when an outcome of interest is very uncommon, such as the case with stroke after phenylpropanolamine use, the large number of study subjects required might make a cohort study impractical. A cohort of 981 acetaminophen overdose subjects was used retrospectively to investigate whether administration of activated charcoal might be beneficial therapy for acetaminophen poisoning.[8] Subjects were separated on the basis of whether or not they were treated with activated charcoal and were subsequently followed to see if they developed concentrations deemed toxic by the Rumack-Matthew nomogram. Perhaps the most famous and ambitious cohort study is the Framingham Heart Study in which 5209 residents of Framingham, MA, ages 30–62 years, were followed for over 50 years. This study provided a useful tool for studying the incidence of lung cancer, stroke, and cardiovascular disease in those exposed to cigarette smoke[13] and other hazardous xenobiotics.

■ EXPERIMENTAL DESIGN

Experimental studies are those in which the treatment, risk factor, or exposure of interest can be controlled by the investigator to study differences in outcome between the groups (Fig. 137–2). The prototype is the randomized, blinded, controlled clinical trial. Among epidemiologic study types, these provide the most convincing demonstration of

causality. Clinical trials are used to measure the *efficacy* (the treatment effect within a controlled experimental setting) of treatment regimens and to draw inferences about the *effectiveness* of a treatment applied to the general population. Unfortunately, interventional studies are the most complex to perform, and several questions must be addressed by investigators before performing a clinical trial (Table 137–4). Human clinical trials have been especially difficult to apply to the practice of toxicology. Table 137–5 lists characteristics of poisoned patients, which hamper attempts at clinical trials. Volunteer studies, using nontoxic xenobiotics or nontoxic doses, are often used to circumvent many of the problems in controlling human poisoning studies; but it is typically difficult to apply results from these studies to the actual physiology of toxic overdose. In an experimental study, activated charcoal was found to result in a 57% reduction in absorption of ampicillin in a nontoxic

[a] Study designs are listed in descending order from the design that offers the best epidemiologic evidence for association to that which offers the least.

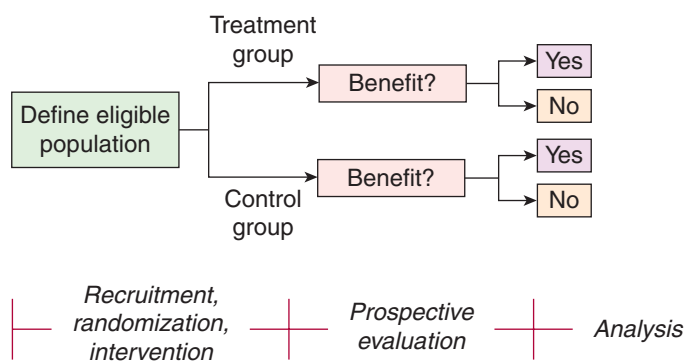
FIGURE 137–1. **A.** Schematic representation of the case-control study design. Subjects with an outcome or condition of interest are selected, along with control subjects, and then are evaluated for previous exposure to a risk factor of interest. **B.** Schematic representation of the cohort study design. Subjects are recruited based on the presence or absence of a risk factor or exposure, then followed to see if they develop an outcome.


FIGURE 137–2. Schematic representation of the design of a randomized clinical trial.

TABLE 137–5. Difficulties in Utilizing Clinical Trials to Study Human Poisoning

It is unethical to intentionally "poison" subjects.

Poisoned patients represent a broad spectrum of demographic patterns.

A wide variety of xenobiotics exist.

Exposures to any single xenobiotic are usually limited.

A limited number of poisoned patients are available at any one study site.

Uncertainty often exists as to type, quantity, and timing of most xenobiotic exposures.

Poisoning typically results in a relatively short course of illness.

model using human volunteers.[35] Taken out of this artificial setting, a trial of single-dose oral activated charcoal was unable to prove benefit to outcome among 1479 heterogenous subjects presenting to an emergency department (ED) for possible poisoning.[26] Neither study was able to answer whether activated charcoal reduces morbidity from ingestion of dangerous xenobiotics if given while the xenobiotic is still in the stomach and amenable to adsorption.

As toxicologists strive to find evidence for, or against, the traditions of clinical practice, several important clinical trials have been published. Among them are many important examples and lessons in epidemiologic study design. One trial attempted to evaluate whether or not corticosteroids might be beneficial in preventing esophageal strictures secondary to circumferential caustic injury of the esophagus.[2] Because of the inherent difficulty in recruiting eligible patients from a single institution, only a small sample of 60 patients with esophageal injury were recruited over an 18-year period. Another study randomized hyperbaric oxygen therapy versus sham (placebo) therapy, among 152 victims of carbon monoxide poisoning, to investigate its effect on the development of neurocognitive injury.[38] Certain concerns with the methodology and analyses of clinical studies are examined later in this chapter to illustrate epidemiologic concepts, and must be carefully considered when trying to apply the results of any clinical trial into the patient care setting.

MEASURES USED TO QUANTIFY THE STRENGTH OF AN EPIDEMIOLOGIC ASSOCIATION

The objective of analytical studies is to define and quantify the degree of statistical dependence between an exposure and an outcome. Such associations are ideally represented by the relative risk of developing an outcome if exposed in comparison to being unexposed. Thus, the *relative risk* can be defined as the incidence of outcome in exposed individuals compared to the incidence of outcome in unexposed individuals. The relative risk can be calculated directly from cohort or interventional studies. However, in a case-control study, an investigator chooses the numbers of cases and controls to be studied, so true incidence data are not obtained. In case-control studies an *odds ratio* can be calculated, and the odds ratio will provide an estimate for relative risk in situations in which the outcome is rare, such as when the outcome occurs in fewer than 10% of exposed individuals. Figure 137–3 demonstrates the calculation of relative risk or odds ratio from analytic studies.

TABLE 137–4. Considerations in Designing a Clinical Trial

What is the question of interest?

What is the target patient population?

How will the safety of subjects be assured?

What is a suitable control group?

How will outcomes be measured?

What difference in outcomes between groups is considered important?

What is the analysis plan?

How many subjects will be required?

How will randomization and blinding be achieved and maintained?

How long a followup period will be required?

How will loss of study subjects be addressed?

How will treatment compliance be evaluated?

Cohort study

$$\text{Relative risk} = \frac{a}{a+b} \bigg/ \frac{c}{c+d}$$

Case control study

$$\text{Odds ratio} = ad/bc$$

FIGURE 137–3. Use of a 2 × 2 table to calculate or estimate relative risk from analytic studies. In cohort studies, study subjects are selected on the basis of exposure. In case-control studies, subjects are selected on the basis of outcome. The letters a, b, c, and d represent the number of subjects either exposed or unexposed to a "risk factor" or treatment, with or without the outcome of interest. The odds ratio estimates the relative risk if the outcome of interest is rare.

A relative risk of 1.0 signifies that an outcome is equally likely to occur whether an individual either is exposed or is not exposed and implies that no association exists between the exposure and the outcome. A relative risk approaching 0 suggests that an exposure is a marker of protection regarding the outcome, and a relative risk approaching infinity suggests the exposure predicts a tendency toward the outcome. Among men and women using phenylpropanolamine appetite suppressants the odds ratio for development of hemorrhagic stroke was 15.9 which suggests a strong association.[21]

MEASURES USED TO QUANTIFY THE SIGNIFICANCE OF AN EPIDEMIOLOGIC ASSOCIATION

Analytical studies are performed to test hypotheses, typically that an exposure is associated with an outcome. The presence of such association in any given study has a number of possible explanations, as detailed in Table 137–6. The goal of statistical analysis is to determine the degree to which chance can be excluded as the true reason the results of the study were obtained. By convention, statistical analysis typically tests the *null hypothesis*—the hypothesis that there is no association between exposure and outcome.

Because analytic studies involve only a sample of the total population, they contain two types of inherent error. *Type I error*, also referred to as alpha (α) error, is the likelihood that an investigator may conclude that an association exists when none truly does. *Type II error*, or beta (β) error, is the possibility that an investigator will be unable to find an association when one is really present. The most commonly reported measures of type I error in published toxicology studies are the *p-value* and the *confidence interval* (CI). Statistical significance has customarily, but not necessarily, been defined as having less than a 1 in 20 chance of conducting a false-positive study. Therefore, a type I error of less than 5%, which corresponds to a *p*-value of less than 0.05, is usually deemed "statistically significant."

Perhaps a more informative description of the significance of an association is provided through the CI. The CI not only provides a test of statistical significance, it also offers information pertaining to the degree (and possible range) of differences observed. In an unbiased study, the 95% CI provides a range between which, if the study could be repeated an infinite number of times, the observed magnitude of effect would lie 95% of the time. One study reported that no toddlers ingesting one or two calcium channel blocker tablets became seriously ill, but a subsequent analysis of the CI around this small set of data

TABLE 137–6. Types of Associations between Exposures and Outcomes That May Be Found with a Clinical Study

No Association	The outcome is independent of exposure.
Artifactual Association	
Chance	The association demonstrated by the study resulted from random error.
Bias	Systematic error in the study led to the noted association.
Indirect Association	The association is real, but not truly cause and effect (confounding).
Causal Association	The outcome is dependent on the exposure.

TABLE 137–7. Considerations in Choice of Sample Size

	Sample Size	
	Large	**Small**
Pros	• Able to detect associations of small magnitude • Less susceptible to some biases • More robust analysis	• Less work • Less cost
Cons	• More work and more cost	• Might not detect associations of small magnitude • More susceptible to biases associated with patient differences

demonstrated that the true incidence could be as high as 18%.[29] A CI around a relative risk or odds ratio is not statistically significant if it includes 1.0, and the narrower the CI the more precise the estimate of the magnitude of effect.

The likelihood that a study will find a difference if one truly exists is termed statistical *power* and relates to the likelihood of a false-negative study (type II error). Power is usually artificially set by an investigator before a study is performed and is typically set at 80% or 90% to practically limit the number of study subjects needed. Table 137–7 lists considerations applicable to choice of sample size. The sample size of a study is determined by the frequency of the exposure and outcome within the study population, the strength of association deemed clinically relevant, and the amount of error deemed acceptable in the study. Because power is often set relatively low, it is difficult to state that an association does not exist. It is more appropriate to state that a study was unable to reject the null hypothesis to find an association.

The finding of a low *p*-value indicates a statistically high level of confidence that a difference between study groups exists but offers no indication that the difference is clinically important. The interpretation of statistical versus clinical significance is often facilitated through calculation of confidence intervals. Small actual differences between two groups can become statistically significant if large numbers of subjects are studied. Likewise, impressive associations of cause and effect can seem trivial if few subjects are in a study. The clinical significance of an association is left to the judgment of the individual interpreting a study. Ideally, a working definition of clinical significance is developed before a study is performed.

METHODOLOGICAL PROBLEMS FOUND WITHIN CLINICAL STUDIES

Calculation of a *p*-value or confidence interval does nothing to assess the adequacy of study design. These measures are used to quantify the influence of random error, or chance, on research findings. Clinical research involving patients is particularly susceptible to *bias*, which can be defined as systematic error in the collection or interpretation of data. Because such error can lead to an inappropriate estimate of the association between an exposure and an outcome, careful evaluation of potential biases affecting a clinical study is of paramount importance.

Selection bias refers to error introduced into a study by the manner in which subjects are selected for inclusion in the study. This type of bias is most problematic for retrospective studies in which exposures and outcomes have both occurred at the time of subject recruitment. Selection bias may be introduced into a prospective clinical study if the study fails to enroll potential subjects, or if potential subjects refuse to participate, on a systematic basis. Selection bias may even influence the results of clinical trials. In a 1995 trial that found no difference in outcome between acutely poisoned patients treated with gastric emptying and patients from whom gastric emptying was withheld, all patients presenting to the ED after acute overdose were enrolled.[32] Because most patients with poisoning exposure are likely to do well with minimal support,[5] selection of patients on this basis might be expected to bias this study to find no effect. Reasoning suggests that the patients most likely to benefit from gastric emptying are those with life-threatening toxic ingestion presenting within the first hour after overdose. Indeed, subgroup review of the results of this paper suggests clinical benefit within this group of patients, but without conclusive power.

Information bias refers to error introduced into a study as a result of systematic differences in the quality of data obtained between exposed and unexposed groups, or between those with and without the outcome of interest. Several distinct types of information bias may exist. Affected and nonaffected individuals may have differential memories regarding exposures, so recall bias is a concern in retrospective studies. The potential for *recall bias* may be cited as criticism of retrospective case-control studies of the association between phenylpropanolamine and hemorrhagic stroke, in which families were asked to recollect phenylpropanolamine use history. Stroke victims and their families might be more vigorous in their recall of exposures than control subjects. Similarly, *interviewer bias* may occur if study personnel differ in how they solicit, record, or interpret information as a result of knowledge of the subjects' status regarding exposures or outcomes.

Prospective studies may be troubled by loss to followup, especially if subjects are lost from the study for reasons relating to either exposure or outcome such as when subjects withdraw from a study because they are feeling better, or are "lost" because they die. *Misclassification bias* occurs when investigators incorrectly categorize subjects with respect to exposure or outcome. In a retrospective study of 378 children regarding the predictability of caustic esophageal injury from clinical signs and symptoms, it was found that 11 of 80 asymptomatic children had significant burns.[14] There is a possibility that these "asymptomatic" children were misclassified because of lack of rigorous written documentation of symptoms or signs within the medical charts.

Bias is best minimized through careful study design. It is important to precisely define the study question and the population at risk and to carefully define rigorous inclusion and exclusion criteria. The outcome should also be defined precisely. During data acquisition the best way to reduce bias may be to keep study personnel gathering exposure data blinded to outcome, and vice versa. Often, it may also be advisable to keep study subjects unaware of their status within a study to the extent that is ethical (thus, "double-blinded"—neither investigators nor subjects are aware of the subjects' status within a study). Use of *placebos* or "sham treatments" is a way to facilitate blinding. One of the strongest criticisms of a 1995 trial of HBO for the prevention of delayed neurologic syndromes after CO poisoning[33] has been the failure to blind patients and investigators to the treatment in question,[28] a flaw that was corrected in a followup study published in 2002.[38] It is inevitable that some degree of potential bias will be present in any clinical study. Such bias should be reviewed in analysis, and estimations of its magnitude and direction (bias toward or away from rejection of the null hypothesis) should be considered.

Unlike selection and information biases, which are errors introduced into studies primarily by the investigators or subjects, *confounding* is a special type of problem that may occur within a study as a result of interrelationships between the exposure of interest and another exposure. Confounding is a bias wherein an observed association is not a product of cause and effect but instead results from linking of the exposure of interest to another associated exposure. Studies pertaining to adverse effects of drugs of abuse are especially prone to confounding by variables such as concomitant caffeine use, alcohol use, tobacco use, nutritional deficiency, and/or psychiatric illness. Analytic studies may restrict characteristics of enrolled subjects or match subject characteristics between comparison groups in an effort to reduce confounding. Accordingly, it has been suggested that future studies on delayed neuropsychiatric manifestations following CO poisoning control for potential confounding from depression and cyanide exposure.[24] Randomization is an important method to assure that unsuspected confounding factors are equally distributed between treatment groups within interventional studies. During data analysis, confounding can often be controlled through stratification of data into subgroups or through multivariate analysis techniques.

In order to improve the reporting of clinical trials, and to improve the recognition and interpretation of biases within them, guidelines referred to as the Consensus Standards of Reporting Trials (CONSORT) have been adopted by many medical journals.[27] The CONSORT guidelines provide a checklist to allow authors to systematically and uniformly report data and limitations. When interpreting published studies, it is also important to consider the potential for *publication bias*. Publication bias refers to the tendency for researchers, editors, and pharmaceutical companies to handle the reporting of studies with positive results differently from those with negative or inconclusive results.[34] Many journals now require that researchers register all planned clinical trials into a registry as a prerequisite for subsequent publication.

BIASES INHERENT IN STUDIES USING THE AMERICAN ASSOCIATION OF POISON CONTROL CENTERS DATABASE

The NPDS database of the AAPCC is an ambitious effort to catalog and describe the epidemiology of poisoning in the United States and Canada. These data serve to help identify new poisoning epidemics, focus prevention and education efforts, guide demographic and economic poisoning analyses, and guide implementation of public health policies. It is a desirable goal to use this database in defining the scope of toxicity for particular xenobiotics and as a clinical research tool. In this regard, it is important to understand the biases inherent in the current database.

It has been suggested that *selection bias* might exist within poison center (PC) data if poisoning is unrecognized as a cause of illness or if a caregiver has no questions pertaining to the management of a recognized poisoning.[16] Indeed, a survey of 170 emergency physicians in Utah found that 53% admitted to using a PC for symptomatic acute overdoses, and only 10% contacted PC for the purposes of reporting cases to the national database.[10] Such selection might result in a bias of PC data toward more severe cases. On the other end of the spectrum, investigation has found selection bias in PC data suggesting that fatal poisonings may be severely underrepresented.[18] It is interesting to note that in a 2004 report of the Institute of Medicine,[20] the estimated range of annual fatal poisonings in the United States was from approximately 1000, derived from AAPCC data, to over 30,000, derived from other databases. A study of potential spectrum bias in PC utilization found that one ED reported 95% of cyclic antidepressant overdoses, 33% of venomous snakebites, and only 3% of inhalation exposures.[17] Further

complicating the interpretation of PC data are the findings that such data may also be biased regarding geographic distribution of callers,[1] age,[31] ethnicity,[1,11,31,37] and socioeconomic status.[37]

Knowledge of *information bias* within NPDS data is less well characterized. Phone interviews of callers, many under duress, are certain to be subject to *recall* and *interviewer bias*. A comparison of rural hospital chart data to the NPDS database demonstrated deficiencies in PC reporting and in clinical information transfer to the NPDS database.[19] Loss to followup remains a problem for many PCs, and misclassification of poisonings by healthcare providers inadequately trained in medical toxicology remains too common. The clinical conundrum of the unwitnessed ingestion frequently becomes an issue in poison center–derived studies designed to create triage policies. Some children having never ingested a xenobiotic of concern may be misclassified as an exposure and may be improperly analyzed.[23]

Despite the large volume of descriptive poisoning data available, it has proven difficult to derive valid, clinically useful conclusions from either the NPDS database or from published case reports.[6] One suggested means through which to minimize information bias in descriptive toxicology is through the use of improved data collection charts.[7] Other researchers have found it useful in clinical studies to transform PC data collection from a passive to an active process through use of specific research instruments.[25] Further efforts are required to reduce and to quantify the impact of selection, interviewer, recall, misclassification, and information biases within PC data to optimize the value of this important resource.

EVIDENTIARY CRITERIA USED TO LINK CAUSE AND EFFECT

As was illustrated in Table 137-6, association of an exposure to an illness does not necessarily equate to cause and effect. In assessing causation it must be determined if bias is present in the selection or measurement of exposure or outcome. If a study is unbiased, the role of chance in the occurrence of the observed association must be explored. If an association is unbiased, unlikely to result from random error, and is not subject to confounding, then assumptions regarding to causation can be derived. Table 137–8 provides a list of evidentiary criteria that are often used to support causation.

TABLE 137–8. Questions to Consider When Determining Causation

Study design	Was the association demonstrated in a well-designed study?
Temporality	Does the cause precede the effect?
Strength	What degree of relative risk was demonstrated in the analysis?
Dose response	Does an increased presence of risk factor correlate to greater or more frequent effect?
Consistency	Does the cause and effect hold true in different studies, locations, and populations?
Plausibility	Is the association in accordance with current scientific knowledge?
Specificity	Does the effect occur without the cause in question, or vice versa?

Many toxicologists deem clinical trials indicating a lack of benefit from gastric emptying, or indicating a therapeutic benefit of HBO therapy for CO intoxication, unconvincing because of the degree of bias present in all relevant published clinical trials. In medical toxicology it is virtually impossible to prove causal relationships beyond any doubt. The goal is to build empiric evidence so that associations can be confirmed or refuted with conviction.

EVALUATION OF DIAGNOSTIC TESTS AND CRITERIA

In clinical practice it is often useful to have a test, which may be a laboratory result or clinical paradigm, to help arrive at a diagnosis or predict an outcome. For instance, historical questionnaires, capillary blood lead concentrations, and venous blood lead concentrations might all be used to identify children at risk of neurocognitive injury from plumbism.[9] However, each of these approaches is likely to have certain disadvantages in terms of effort, cost, discomfort, and/or accuracy. Targeting lead evaluation and therapy at children on the basis of exposure history is expected to be easy and inexpensive, but may not identify some children with significant poisoning; thus, the test may be susceptible to being falsely negative. Capillary blood testing is more costly and uncomfortable and may be susceptible to false-positive test results because of environmental lead dust present on fingertips. The possibility of false-positive or false-negative results must be considered with any diagnostic test (Fig. 137–4).

The utility of diagnostic testing is often described in terms of sensitivity, specificity, predictive value of a positive test (PPV), and predictive value of a negative test (NPV). A cross-sectional design is often

$$\text{Sensitivity} = \frac{a}{a + c} = \frac{\text{True positives}}{\text{True positives} + \text{False negatives}}$$

$$\text{Specificity} = \frac{d}{b + d} = \frac{\text{True negatives}}{\text{False positives} + \text{True negatives}}$$

$$\text{PPV} = \frac{a}{a + b} = \frac{\text{True positives}}{\text{True positives} + \text{False positives}}$$

$$\text{NPV} = \frac{d}{c + d} = \frac{\text{True negatives}}{\text{False negatives} + \text{True negatives}}$$

PPV = Positive predictive value
NPV = Negative predictive value

FIGURE 137–4. Possible results of diagnostic testing and the statistical characteristics used to describe the utility of diagnostic tests. The letters a, b, c, and d represent the numbers of tested individuals with or without the disease of interest.

TABLE 137–9. Questions to Consider When Evaluating a Study

Research objectives
What is the study question?
What is the studied population?

Study design
What type of study was performed?
How were subjects recruited and enrolled? Why were subjects excluded?
What was the nature of the comparison group?

Data accrual
How were the data collected?
Are the exposures and outcomes clearly defined?
Are the observations reliable and reproducible?
Was randomization and/or blinding used?
Were subjects lost to followup?

Analysis
Are the results statistically significant?
Are the results clinically significant?
Are potential confounding variables controlled?
Was the study powered to detect important differences?

Conclusions
Are the conclusions justified by data?

used to study diagnostic tests, as we seek to determine the prevalence of positive tests among the diseased (*sensitivity*), and the prevalence of negative tests among the healthy (*specificity*). A perfect test would be highly sensitive and specific, but this is seldom possible in medical toxicology. A highly sensitive test is often used in screening programs because they rarely lead to false-negative diagnoses. Specific tests are typically used to "rule-in" a diagnosis, as they rarely yield false-positive results. Whereas sensitivity and specificity are inherent properties of a diagnostic test applied to a given population; the probability of disease, based on the results of a test, is highly dependent on the prevalence of disease within the population being tested. *The PPV is the probability of having disease in a patient with a positive test; the NPV is the probability of not having disease when the test result is negative.* A number of studies have tried to examine the utility of vomiting, leukocytosis, hyperglycemia, total iron-binding capacity, and radiographic findings in predicting toxicity after acute iron overdose. In a retrospective assessment of 40 adults with oral iron overdose, vomiting was found to predict a serum iron concentration above 300 μg/dL with a sensitivity of 84%, specificity of 50%, NPV of 44%, and PPV of 87%.[30] This suggested that the presence of vomiting should raise concern for iron toxicity but that the lack of vomiting was not particularly reassuring. Figure 137–4 illustrates the calculation of the sensitivity, specificity, PPV, and NPV. It is important to remember that these calculations, too, are subject to bias and are best presented with confidence intervals.

SUMMARY

Medical toxicology has embraced the vision of incorporating "evidence-based, or literature-based, medicine" into practice. Randomized clinical trials, although a noble goal, are rare and have proven difficult to perform within the discipline. As toxicologists move beyond descriptive data reporting, there remains great potential for scientific advancement in the field of toxicology via observational, hypothesis-testing, clinical research. Clinical investigators are charged with the imperative to perform studies based on sound epidemiologic principles. All studies, by nature of population sampling, are at the mercy of chance, but such random error can be quantified using statistical techniques. Systematic error (bias) can be limited, but not entirely excluded, through careful study design. Clinicians interpreting published toxicologic research need to thoroughly evaluate a study's research objectives, design, data acquisition, analysis, and conclusions before applying the results to patient care (Table 137–9). Future epidemiological investigation should allow more valid conclusions to be drawn regarding the associations between exposures and outcomes, or regarding the value of treatments for poisonings, discussed in the preceding chapters of this text.

Galen, an influential physician from the second century, remarked of his clinical trial, "All who drink of this remedy recover in a short time, except those whom it does not help, who all die. Therefore, it is obvious that it fails only in incurable cases." Unfortunately, error in contemporary clinical investigation of poisoning tends to be more insidious than the error in logic in Galen's conclusion, and skillful scrutiny of published research remains an important endeavor.

CHAPTER 138

ADVERSE DRUG EVENTS AND POSTMARKETING SURVEILLANCE

Louis R. Cantilena

This chapter focuses on drug-induced disease resulting from adverse drug events (ADEs) caused by either inherent drug toxic effects, drug–disease adverse interactions or as a consequence of unintentional drug–drug interactions. Additional topics covered in this chapter include a discussion about the diagnosis of drug-induced disease, an overview of the Food and Drug Administration (FDA) process for drug approval, postmarketing surveillance of ADEs, and the role of the medical toxicologist in the discovery, reporting, and prevention of ADEs.

ADEs are defined as untoward effects or outcomes associated with use of a drug. In this chapter, the word "drug" will be used for a pharmaceutical product and includes prescription and nonprescription medications, and dietary supplements.

In the United States, all new prescription and nonprescription medications must be shown to be both safe and effective in order to achieve approval by the FDA, a prerequisite for marketing and sale. Dietary supplements fall outside of this legal requirement.

HISTORY OF THE UNITED STATES DRUG APPROVAL PROCESS

Prior to 1900, there was no requirement for a drug or medical device manufacturer to demonstrate that the product actually worked (efficacy), was safe when used as directed, or was made to be within precise specifications. In addition, no laws existed that required labeled claims be proven valid. Anyone could sell any product desired and it was left to the consumer or healthcare worker to determine if the products actually worked and were safe. Initiation of medicinal product regulation and the overall evolution of the US drug law and regulations are closely linked to specific medical product disasters that occurred during the 20th century in the United States. Relatively recent changes in US drug approval law further changed drug review timelines and prioritization of drug application reviews.

Examples of the pre-1900 regulation of medicinal products include the lack of a legal requirement for a company to test a product for safety or efficacy or even to make valid claims in the drug label. Products such as aspirin-containing heroin were sold as cough syrup. Wine with cocaine was marketed to enhance sales of the alcoholic beverage. Further, there was no legal requirement for systematic testing of products to determine content or the presence of possible adulterants in product formulations. The Food and Drug Act of 1906 required pharmaceutical manufacturers to meet a standard for the concentration and purity of the drugs they marketed. However, the burden of proof was on the FDA to show that the drug was incorrectly labeled or that the advertising or label was false or misleading.

The Food, Drug and Cosmetic Act of 1938 resulted from a tragedy in which more than 100 patients (mostly children) died from poisoning by an excipient of an oral solution of sulfanilamide. A pharmaceutical

company, in an attempt to improve the palatability of a sulfanilamide product for pediatric formulations, introduced the solvent diethylene glycol into the formulation. Diethylene glycol is a sweet-tasting but nephrotoxic hydrocarbon. Only after almost a full year of marketing were cases of renal failure and death reported in sufficient numbers to alert authorities to the extremely toxic nature of the product. The Food Drug and Cosmetic Act of 1938 accomplished the following:

1. Required companies to list the ingredients of the product on the product label.
2. Required companies to provide the known risks concerning use of the product to physicians or pharmacists.
3. Made illegal the misbranding of food or medical products.
4. For the first time required companies to test their products for safety before being sold.

Drugs already marketed before 1938 were exempt from the requirement (see Chap. 1).

An application in the early 1960s for the approval of α-*N*-phthalylglutaramide (thalidomide), a sedative that had already been marketed in Europe, was submitted to the FDA. The sedative drug had a rapid onset and short duration of action, did not affect ventilation, did not cause a morning-after effect, and was inexpensive. Dr. Frances Kelsey, a medical officer at the FDA, delayed approval by asking the sponsor to clarify several issues in the reportedly poorly organized new drug application (NDA). In the interim, an unusual teratogenic effect, phocomelia, or limb misdevelopment, was linked in Europe to the use of thalidomide. Congressional hearings resulted in the Kefauver-Harris Act of 1968, which required a drug manufacturer or sponsor to do the following:

1. File an investigational new drug application (IND) before beginning a clinical study with a drug in humans.
2. Demonstrate that the drug was effective for the condition that it was being marketed to treat.
3. Provide adequate directions for safe usage of the drug.

Once again, the act was not retroactive and drugs that were already on the market were exempt from these new requirements.

Subsequent US laws that affect FDA review and approval of products include the following:

1. The Orphan Drug Act of 1983, which provides financial incentives to drug manufacturers to develop drugs for the treatment of rare diseases and conditions (see http://www.fda.gov/ orphan/designat/list.htm for a list of drugs that have been approved under the Orphan Drug Act). A rare disease is defined as one in which there are less than 200,000 affected persons in the United States, or one affecting more people, but in which the cost of drug development is likely to exceed any potential sales of the drug (http://www.fda.gov/orphan/oda.htm).
2. The Prescription Drug User Fee Act (PDUFA) of 1992, which required manufacturers to pay user fees to the FDA for NDAs and supplements, to enable the FDA to hire additional reviewers and accelerate the review process. This Act, which has undergone several revisions (the latest in 2007), has proven to be controversial due to the new working relationship it creates between industry and regulators, and the concern that it may force compromises that are not in the best interest of public health.

   The overall question as to whether or not the introduction of user fees and their associated mandate for shorter FDA review times for new drug applications (NDAs) have negatively impacted safety remains controversial.[15,31,39] While some believe that the shorter review times for FDA approval appear to be associated with an

increased likelihood of drug withdrawal and black box label modi-
fication of the drug label postapproval,[2] others have not yet reached
that conclusion.[40] The debate on this issue intensified during the
controversy involving the cyclooxygenase-2 (COX-2) inhibitor anti-
inflammatory drugs. This widely publicized withdrawal and press
coverage of the related litigation resulted in congressional hearings
on the review practices and monitoring of drug safety by the FDA.

3. The Dietary Supplement Health and Education Act (DSHEA amend-
ment) of 1994, which removed from FDA the authority to require
proof of safety or efficacy prior to marketing of products considered
dietary supplements (including herbal remedies). Only when a spe-
cific health claim is made by the manufacturer of a product does the
FDA have premarketing approval authority. Furthermore, rather
than placing on the manufacturers the burden of proof for safety and
efficacy of a product, the FDA is required to determine that a product
is unsafe to prevent sale and distribution in the United States.

4. Section 112 of the FDA Modernization Act of 1997, which allowed
for an accelerated drug approval process for the treatment of life-
threatening illnesses such as AIDS and cancer if the drug has the
potential to address medical needs unmet by currently available
drugs. Many of the accelerated drug approvals rely on efficacy
results derived from surrogate markers linked to the ultimate
indication for the drug. For example, the protease inhibitors were
approved on the accelerated track for the treatment of AIDS because
of their ability to reduce HIV viral load.

5. The Pediatric Research Equity Act of 2003, which requires manu-
facturers to study drugs being submitted for approval for a claimed
indication in children. The FDA provides incentives such as patent
extension and marketing exclusivity for performing these evalu-
ations. As a result more data from children are being provided to
guide therapeutic use of medication in this patient group.

6. Recent FDA funding renewal legislation has added specified dead-
lines for drug application reviews as well as established a priority for
FDA review based on indication and potential benefit of the candi-
date drug for a disease population. In 2007 the United States signed
into law legislation referred to as Food and Drug Administration
Amendments Act (FDAAA) which increased FDA responsibilities
and authorizations primarily aimed at improving product safety.

Four of the provisions of FDAAA reauthorize past legislation: the
Prescription Drug User Fee Act (PDUFA) of 2007, the Medical Device
User Fee Amendments of 2007 (MDUFA), the Pediatric Research
Equity Act of 2007 (PREA), and the Best Pharmaceuticals for Children
Act of 2007 (BPCA).

Other important actions coming from FDAAA include a require-
ment for FDA to ensure that clinical trial information is provided to the
National Institute of Health's ClinicalTrials.gov web site. FDAAA gives
authorization to FDA to require postmarketing studies, primarily of
drug safety, including surveillance and clinical trials as well as to require
that sponsors incorporate Risk Evaluation and Mitigation Strategies
(REMS) in their proposed marketing activities as a prerequisite for
product approval. The goal of these latter components was to enhance
the regulatory authority of the FDA to require active risk surveillance
for newly approved products and make it easier for the FDA to take
regulatory action if safety signals are detected. The elements of REMS
vary considerably among products, and may be applied to both safety
concerns and the potential for misuse, as in the case of prescription
opioids.[38] The impact of these new regulations will be measured and in
time, it should be clear as to whether or not newly approved drugs are
better monitored and by extension, the public health is at less risk for
unintended drug-induced disease from FDA approved medications.

A complete listing of the laws and statutes enforced by the FDA is
found on the FDA Web site.[14]

Recent legislative action suggests that Congress has, for the time
being, chosen to provide FDA with increased postmarketing authority
rather than reconsider PDUFA for new drug applications. The short-
and long-term implications of this decision are not yet fully known.

THE DRUG DEVELOPMENT PROCESS

Figure 138–1 shows a schematic overview of the process for drug
development of a new molecular entity (NME). The process begins
with the preclinical evaluation of the candidate drug. During this evalu-
ation, toxicologic testing is performed in more than one animal species
and other testing includes stability of the product, manufacturing
methods, purity, and initiation of testing for possible carcinogenicity.
Dose–response relationships in animal models and in vitro receptor
binding or surrogate marker effects are often determined at this phase
of the evaluation. Also, this is the time when many manufacturers deter-
mine the metabolism of the drug in animal and in vitro human systems.
Following this preclinical testing, the sponsor submits an IND applica-
tion to the FDA for approval to initiate human testing. This application
contains all relevant data concerning animal and in vitro toxicology
testing, product manufacturing and purity, and a protocol for using
the drug in initial human investigation. Within 30 days, the FDA must
review the IND application and either allow the proposed human study
to proceed or inform the sponsor that additional data or preclinical
work is required before clinical testing of the candidate drug can begin.

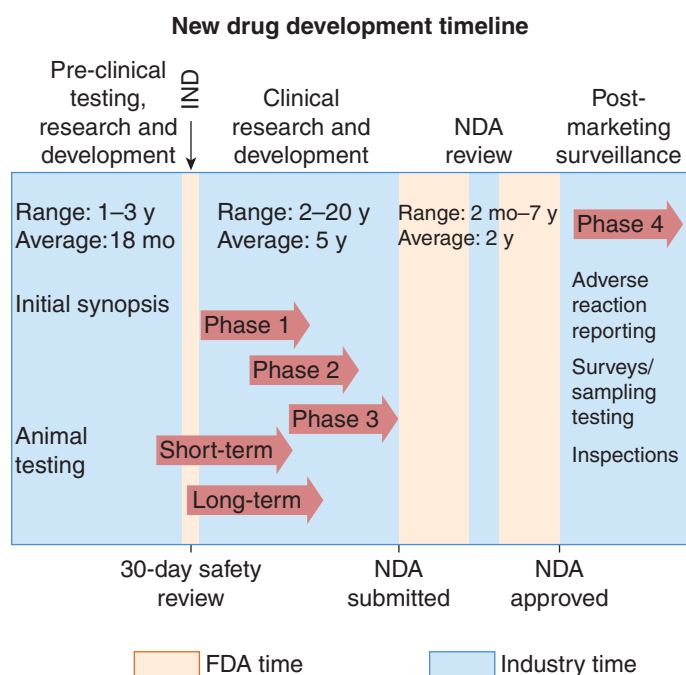
The clinical study of new candidate medications is divided into four
basic phases. Phase 1 clinical testing involves a relatively small number
of subjects with the primary aim of determining the safety and toxic-
ity of the drug. Many phase 1 studies will also determine the human
pharmacokinetics and metabolism of the drug. Phase 1 studies are
normally conducted in 20–100 healthy volunteer subjects with the


FIGURE 138–1. Schematic representation of new drug development. (From www.
fda.gov.) NDA = New Drug Application; IND = Investigational New Drug; FDA = Food
and Drug Administration.

notable exception of phase 1 studies for cancer chemotherapeutics, which enroll only patients with cancer.

Phase 2 clinical testing is designed to determine the potential efficacy of the drug product in humans and sometimes explores the range of effective drug dosages. In this phase, approximately 100–300 subjects are usually studied. In phase 2 clinical trials, subjects generally have the diseases for which the drug is intended or are capable of demonstrating the appropriate, validated, biologic surrogate marker to indicate response to the drug. An example of this would be a drug intended for early treatment of the acute coronary syndrome is tested to show that it can inhibit in vivo platelet function after oral dosing in human study subjects.

Phase 3 clinical drug studies usually involve large-scale clinical trials in the actual population for which the drug use is intended. Typically, this phase of drug development will involve testing a treatment cohort of several hundred to several thousand patients who have the target disease, depending on both the prevalence of the disease and effectiveness of the drug. The primary goal of phase 3 studies is to determine the safety and efficacy of the candidate drug in the actual intended patient population in question, under conditions similar to the anticipated medical use. At the completion of phase 3, an NDA (request for approval to market) is submitted to the FDA. A candidate drug completing phases 1, 2, and 3 can thus be approved for marketing after study in only 2000–4000 patients. In the setting of a fast-track approval or under the Orphan Drug regulations, substantially fewer patients will receive the drug before its approval for marketing. The relatively small number of human exposures to a new chemical or biologic entity prior to approval for marketing is an important factor that limits the sensitivity of the drug approval process to detect uncommon ADEs. There are additional considerations that set a drug review priority based on the PDUFA classification of the candidate drug. This classification also determines the review deadline for FDA. For example, a drug application given a "priority" review status is targeted to complete FDA review in 6 months as compared to the now standard review cycle of 10 months.

The FDA sometimes seeks the external advice of its constituted advisory committees prior to approval, especially in the setting of an uncertain risk–benefit profile of a candidate drug. FDA advisory committees generally are organized by therapeutic areas and are composed of medical professionals, usually from academia, as well as a patient representative and a nonvoting industry representative. These same advisory committees also convene to consider postapproval safety or efficacy data when FDA is considering an important change to a drug label or other postapproval regulatory action. Generally the FDA prepares questions for the committee members and provides an FDA briefing document containing a detailed data analysis and background of the issue from the FDA perspective as well as a briefing document prepared by the manufacturer containing analogous information. Committee members comment and vote on the FDA questions during the proceedings. For a new drug approval one question generally includes a yes or no answer as to whether or not the advisor believes that the drug can be marketed with an adequate risk–benefit profile. The advisory committee vote is technically nonbinding for the FDA, but the FDA generally follows the committee advice. A recent issue of concern is the fact that some members of FDA advisory committees with perceived conflicts of interest are granted waivers by FDA to participate. The appearance of conflict of interest on an advisory committee can have a significant impact on the drug approval process and the FDA has begun to decrease the number of committee member waivers.

At the conclusion of the NDA review and at times an Advisory Committee meeting on the application, the FDA may issue an approval for marketing the new product. On occasion, the FDA issues an "approvable" letter, indicating that the product is potentially approvable but additional data will be needed before final approval can be granted. Examples of additional data required in this setting include further clinical study of a specific drug interaction, use of the drug in a specific patient population, or extension of the submitted drug stability testing. Once approval of the drug is given by FDA, the next phase of drug development begins as discussed separately below.

◼ PHASE 4 DRUG DEVELOPMENT: POSTMARKETING SURVEILLANCE

Every drug, therapeutic biologic product, or medical device carries with it some potential risk.[40] If society required that only "completely" safe drug products were allowed to be marketed, the drug approval process would likely take decades and few if any new drugs would be made available. The FDA and the pharmaceutical industry therefore significantly rely on postmarketing surveillance for further safety information regarding the toxicity of a medical product after approval. A postmarketing surveillance system is in place to monitor postapproval drug safety that is intended to detect instances in which the safety profile appears different following marketing. Individual pharmaceutical manufacturers are responsible for monitoring the safety of their products and regularly reporting any detected ADEs to the FDA. The FDA postmarketing surveillance (MedWatch Program) for all medical products is a parallel system in place to monitor drug and medical device safety.[21] This system relies on spontaneous reports by healthcare professionals or patients regarding the occurrence of deleterious effects associated with the use of a medical product. Because manufacturers are also required by law to report ADEs associated with use of their products to MedWatch, the FDA database contains one complete data set called the Adverse Event Reporting System (AERS database). Because the MedWatch system is passive in nature, the estimated overall rate for adverse event reporting is estimated at only 1%–10%.[17,27,30]

The primary goals of the MedWatch system are the following:

1. To increase awareness of drug- and device-induced disease.

2. To clarify what should (and should not) be reported to the agency.

3. To facilitate reporting of adverse effects by creating a single system for health professionals to use in reporting ADEs and product problems to the agency.

4. To provide regular feedback to the healthcare community about safety issues involving medical products.[24]

Establishing causality for a specific medical product is not required before submission of a MedWatch report. The FDA is primarily interested in the report of a serious adverse event, or an ADE previously not associated with the drug being administered, whether or not a causal relationship is established. Although any potential ADE should be reported, an event is considered serious and should be reported when the patient outcome is one of the following:

1. Death, if the death is suspected to be a direct result of the adverse event.

2. Life threatening, if the patient was considered to be at substantial risk of dying at the time of the adverse event or the use or continued use of the product would result in the patient's death. (Examples include gastrointestinal hemorrhage, bone marrow suppression, pacemaker failure, and infusion pump failure that permits uncontrolled free flow and results in excessive drug dosing.)

3. Hospitalization (initial or prolonged), if admission to the hospital or prolongation of a hospital stay resulted from the adverse event. (Examples include anaphylaxis, pseudomembranous colitis, or bleeding causing or prolonging hospitalization.)

4. Disability, if the adverse event resulted in a significant, persistent, or permanent change, impairment, damage, or disruption in the patient's body function/structure, physical activities, or quality of life. (Examples include cerebrovascular accident caused by drug-induced coagulopathy, toxicity, and peripheral neuropathy.)

5. Congenital anomaly, if there are suspicions that exposure to a medical product before conception or during pregnancy resulted in an adverse effect on the child. (Examples include vaginal cancer in female offspring from exposure to diethylstilbestrol during pregnancy or limb malformations in the offspring from thalidomide use during pregnancy.)

6. Requires intervention to prevent permanent impairment or damage if use of a medical product is suspected to result in a condition requiring medical or surgical intervention to preclude permanent impairment or damage to a patient. (Examples include acetaminophen overdose–induced hepatotoxicity requiring treatment with *N*-acetylcysteine to prevent permanent damage, or burns from radiation equipment requiring drug therapy.[24])

MedWatch reports are easily done through the MedWatch Web site, or by facsimile, telephone, or mail. Physician reports are given priority for review by the FDA in the MedWatch system. A well-documented case of a serious adverse event is a significant and useful contribution to the MedWatch system.

Reports of serious ADEs to the FDA or to the manufacturer can become an epidemiologically detectable signal that can result in more detailed investigations, several examples of which are provided later in this chapter. On occasion serious ADEs detected in the AERS database have led to the withdrawal of products from the US market without conducting additional studies.

Reporting serious ADEs has periodically been encouraged by various healthcare groups in conjunction with the FDA. Currently, the MedWatch program is supported by over 140 organizations, representing health professionals and industry that have agreed to be MedWatch Partners to help achieve these goals. These organizations include medical societies and organizations such as the American Medical Association (AMA), the American College of Medical Toxicology (ACMT), and the American Academy of Pediatrics (AAP) that have encouraged their members to report to the MedWatch system. As a requirement for hospital accreditation, the Joint Commission mandates hospitals to collect, analyze, and report significant and unexpected ADEs to the FDA.

The primary limitation of the MedWatch system is the exclusive reliance on spontaneous reporting of ADEs. The system is passive in nature and therefore has several important limitations. Significant underreporting is known to occur in such systems. The uncertainty about the significance of a signal in the AERS database is aided by the low estimated rate for adverse event reporting and the fact that the true incidence of the reported ADE is almost never precisely known because the denominator, which is the number of actual exposures to the drug, is rarely accurately known.[17,27,30] Despite these limitations, the MedWatch system has detected significant ADEs during the postmarketing period.

Drug regulators must rely on passive surveillance systems like the AERS database to detect potential uncommon or rare but serious ADEs postapproval. This is primarily because a relatively small number of patients or subjects are exposed to the drug during phases 1–3 prior to before approval for marketing. For example, to detect an uncommon ADE occurring in approximately 1 of 5000 individuals exposed to a drug with 95% probability that the ADE resulted from exposure to that drug, approximately 15,000 patients would have to be exposed to the drug.[13] In a balanced (equal numbers of drug and placebo recipients) placebo-controlled clinical trial, 30,000 subjects would need to be enrolled. Premarketing clinical studies (phase 1, 2, and 3) are usually inadequate to detect rare ADEs, ADEs that are incorrectly diagnosed,

or ADEs that result from a drug interaction that may not have been tested in the development program.

An example of a rare ADE not detected until postmarketing involves the drug felbamate, which was approved by the FDA in September 1993 and subsequently found to be associated with aplastic anemia during postmarketing surveillance. Felbamate-induced aplastic anemia had not been detected during the drug development program for the agent. By July 1994, 9 cases had been reported from an estimated 100,000 patients exposed to felbamate in the United States. Most of the aplastic anemia cases occurred in patients who had taken the drug for less than 1 year. The 9 cases represented an approximate 50-fold increase in aplastic anemia over the expected rate in the population with the very low background rate of 2–5 cases per million per previous year[1,34] allowing the FDA to attribute this rare condition to exposure to felbamate.

The primary role of the MedWatch system is to generate a hypothesis for potential association of an ADE with a specific drug. These hypotheses are sometimes further tested in subsequent phase 4 investigations. An example of this "hypothesis generation" function of MedWatch was the question of whether phenylpropanolamine (PPA) caused hemorrhagic stroke in patients using nonprescription diet suppressants or cough and cold preparations containing PPA. In the early 1990s, the Spontaneous Reporting System (SRS, now AERS) detected a potential association of hemorrhagic stroke and nonprescription use of PPA. An industry-sponsored prospective, case-controlled study was designed, to determine if such an association existed. The multicenter study demonstrated that an association did exist, especially for women ages 18–49. The Nonprescription Drug Advisory Committee (NDAC) of FDA reviewed this study and the associated MedWatch data in the fall of 2000 and decided that the evidence supported such an association. The committee advised the FDA to remove PPA from the market, which occurred a short time later. Although the entire process of signal identification from MedWatch to presentation of results from the prospective epidemiologic study required nearly a decade for PPA, the process demonstrates the value of the hypothesis-generating ability of the MedWatch system.

Potential outcomes of a safety signal detection for a marketed drug include dose reduction in all or certain high risk patient populations, restriction of the sale of the specific drug to a more medically supervised environment or with a patient registry to more closely monitor use, and removal of the drug from the market. These are further discussed later in this chapter.

Other types of phase 4 investigations include clinical studies, marketing-type studies, comparative studies with the new drug versus a competitor, or a special population study or drug interaction study when suspicion is raised for a potentially different risk–benefit relationship in certain clinical settings. The enhancement of safety information is the primary goal of most phase 4 studies. Other than the specific prospective study in patient subpopulations, the methods by which phase 4 safety studies are usually conducted are primarily observational and epidemiologic studies. Main sources of data for the postapproval monitoring of the safety of a drug are the spontaneous reports gathered by both the pharmaceutical manufacturer and FDA. The fields of pharmacovigilance and pharmacoepidemiology are typically employed in the conduct of phase 4 studies.[25] Attributing a serious ADE to a drug solely from MedWatch reports does occur but is it much more common for the AERS database to produce a signal suggesting a possible drug-related safety problem.

ESTABLISHING THE DIAGNOSIS OF DRUG-INDUCED DISEASE

The recognition and diagnosis of a drug-induced disease, or an ADE, is an essential skill for all practitioners, and especially for medical toxicologists and clinical pharmacologists. The diagnosis of an ADE is

---

TABLE 138–1. Questions to Consider When Establishing the Diagnosis of an Adverse Drug Event

1. Was the timing of the adverse event appropriate relative to the exposure to the drug?
2. Has the effect noted, which is the suspected ADE, been previously reported?
3. Is there evidence of excessive exposure to the drug?
4. Are there other more likely etiologies responsible for the condition suspected as being an ADE?
5. What is the patient's response to cessation of a suspect drug (dechallenge)?
6. What is the patient's response to rechallenge?

---

typically established as a result of a systematic medical evaluation. One approach to establishing the diagnosis of drug-induced disease involves consideration of six related questions concerning the patient's clinical presentation and available medical data, as shown in Table 138–1.

The first question concerns the timing of the onset of the adverse event in relationship to the reported exposure to the drug. Perhaps because of publicity or word of mouth, ADEs are sometimes reported to the FDA MedWatch system even when the onset of the adverse event occurs before the first exposure to the suspect drug. A careful reconstruction of the time course of drug exposure and onset of adverse effects is extremely important in assessing causality. The time course differs considerably for different adverse clinical events. An anaphylactic reaction to a drug usually occurs within minutes of exposure, whereas renal insufficiency caused by a drug is not likely to be clinically detectable for up to several days after the exposure. A drug that causes cancer (a carcinogen) may not produce a clinically detectable effect for decades. Establishing a time course is an essential first step in the process of making the diagnosis of drug-induced disease.

The second question is whether or not this adverse effect has been reported previously for the suspect drug. An adverse drug effect that occurs commonly is likely to be known before the approval of the drug and therefore is typically found on the initial drug label. For example, respiratory depression and mental status changes were well known before the approval of fentanyl, an opioid agonist. Less common ADEs for drugs that have been on the market for a period of time are sometimes found in case reports in the literature, included in various medical databases, and in some cases will appear in a revised drug label for the medical product. Previous reports linking the observed adverse effect to drug exposure are very helpful to the physician trying to establish a significant level of probability for causality in the setting of an ADE.

However, in the setting of a newly approved drug or a previously unreported possible ADE, neither previous reports/medical literature nor the drug label will help establish causality. In this setting, the clinician must rely more on what is known of the pharmacology, the pharmacokinetics, and the anticipated pharmacodynamics of the suspect drug and the timing of the appearance and observed time course of the adverse event. It is important to put "drug-induced disease" in the differential diagnosis for most patients presenting for medical care. Someone has to be the first to report what is ultimately recognized as an adverse effect. Appropriate vigilance for the possibility of a new ADE significantly increases the probability that a finding can be made early after introduction of a new drug to prevent more widespread drug-induced morbidity or mortality.

The next question to consider is, "Is there evidence of excessive exposure to the drug?" The majority of ADEs that occur are predictable on the basis of the known pharmacology of the specific drug. Such ADEs are referred to as *type A* ADEs.[5] For example, antihistamines such as diphenhydramine are known to cause significant anticholinergic effects. When a patient presents with mental status changes and clinical findings consistent with the anticholinergic toxidrome after significant exposure to an antihistamine-containing product, the observed effects are consistent with an ADE attributable to the antihistamine. Occasionally, proof of drug excess can come from measurement of the drug in serum. In the case of the patient with a history of atrial fibrillation who exhibits nausea, vomiting, vision changes, and ventricular dysrhythmias, the measurement of an elevated serum digoxin concentration supports the diagnosis of digoxin toxicity or an ADE attributable to digoxin perhaps as an inadvertent or intentional overdose, drug interaction, or change in patient renal function resulting in excessive circulating digoxin concentration. In any case, knowing the pharmacology of the drug is important for establishing the diagnosis of an ADE.

When an ADE is caused by an allergic mechanism or another mechanism unrelated to extent of the exposure to the drug, ie, a type B ADE, evidence of drug excess usually does not contribute to the diagnosis. In this setting, other factors such as allergy history or pharmacogenetic background are weighed more heavily to support the diagnosis of an ADE. Patients are usually not aware of their genetically determined ability to metabolize or react to medications but most patients will recall a previously experienced allergic reaction.

The next issue to address in considering possible causality is whether there are other more likely etiologies that could be responsible for the observed effects. Although it is important to be appropriately vigilant for possible ADEs, it is equally important not to miss an alternative cause for the patient's condition. There are certain clinical settings in which establishing an ADE becomes a diagnosis of exclusion. For example, in the case of persistent fever, the assignment of the diagnosis "drug fever" should not be made until a complete search for infectious causes has excluded this etiology.

A very important factor to consider in contemplating a diagnosis of ADE is "What is the patient's response to cessation of a suspect drug (*dechallenge*)?" In this case, the pharmacokinetics of the drug and the timing of resolution of the specific condition must be carefully considered. In some instances, the resolution of a type A ADE closely follows the pharmacokinetics of the suspect drug. For example, in the case of acute β adrenergic antagonist intoxication, cardiac effects resolve in association with decreasing serum concentrations of the drug in question. However, in other instances, onset and resolution of the ADE may not correlate with drug concentrations in the body, for example, in the case of a penicillin rash, which may develop within 1 or 2 days or longer after starting the medication, but may take several days to weeks to completely resolve. In this example of a type B ADE, the resolution of the condition (rash) occurs over a much longer time period than would be predicted by the pharmacokinetics of the drug. When a suspected ADE resolves after discontinuation of exposure to the offending drug, along a predictable time course, the result of this dechallenge would support the diagnosis of ADE.

Lastly, the clinician may have the opportunity or need to *rechallenge* the patient with the suspect agent. If the rechallenge results in the identical response or effect, this would be considered strong evidence to support a causal relationship for the suspect drug and the adverse event. In the setting of a serious or life-threatening adverse event, it is too dangerous to perform a rechallenge with the suspect drug, in which case the response to rechallenge will not be known. In this setting, the weight of evidence previously discussed will then be the only factors available to assign the probability of causality.

FDA REGULATORY ACTIONS REGARDING SAFETY

When new information about a safety issue for an already marketed drug raises concern at FDA, several regulatory options are available to either attempt to improve the safety of the drug or remove the drug from the US market. The most common regulatory action taken by the FDA is modification of the drug label. These modifications can include restrictions as to whom should receive the drug, what doses should be given for which indications or to which patient populations, what type of monitoring should be performed during therapy, and how long treatment should be administered. When potentially life-threatening safety information is discovered, and the FDA believes that the risk–benefit relationship remains in favor of continued availability of the drug, the FDA can require that a "black box" warning be carried in the label. A black box warning is the most serious warning placed in the label of a prescription medication. If a black box warning is established, healthcare professional advertisements regarding product availability are no longer permitted. Additionally, the manufacturer is required in most cases to send a "Dear Doctor" letter to potential prescribers informing them of the new black box warning. Dear Doctor letters may also be required when the FDA requires that prescribers be notified about a significant change in the drug label warning. An example of current medications with recently added black box warnings is antidepressant medication that now must warn about the increased risk of suicidality if children and adolescents are prescribed antidepressants.

Another option sometimes employed by the FDA is the implementation of restricted availability measures to permit continued availability of the drug but only with specified restrictions. For example, use of the drug isotretinoin (Accutane) requires compliance with a multiple component risk evaluation and mitigation program (REMS) program called iPLEDGE that includes informed consent, prescriber and dispensing pharmacy registration, serial pregnancy testing if applicable, documentation of patient education, and completion of risk management programs by patients who will receive the medication.[10] The FDA authority to require companies to submit, prior to drug approval, and execute, postapproval, an effective risk management plan is intended to improve both the monitoring and prevention of postapproval adverse drug events and their consequences.

When the FDA believes that a drug can no longer be safely used despite modification of the drug label or any of the aforementioned restrictions, the regulatory threshold is reached to initiate removal of the drug from the market. This occurs when an acceptable risk–benefit relationship for continued availability of a drug product is no longer possible. Table 117-2 in the seventh edition of *Goldfrank's Toxicologic Emergencies* contains a compilation of products that were withdrawn or removed from the market in the United States for reasons of safety or efficacy. Some recent additions to that list of drugs include valdecoxib (marketed as Bextra) and rofecoxib (marketed as Vioxx), withdrawn because of recognition of elevated cardiovascular risk associated with their use.[15] Table 138–2 contains a listing of drugs that were withdrawn from the US market during the years 2006, 2007, and 2008. In the case of the COX-2 inhibitor withdrawals, the precipitating factor for withdrawal was the findings of a strong safety signal for excess cardiovascular mortality and morbidity during the conduct of efficacy studies for other potential therapeutic indications for these drugs. The postmarketing surveillance system did not serve as the initial, precipitating data set for regulatory action in this instance.[6,11,22,28,29] The manufacturers voluntarily withdrew these COX-2 inhibitors and the majority of the drugs from the United States market. In many cases, the manufacturer ceases marketing the specific drug after notification by the FDA that regulatory action is being initiated to remove their drug

TABLE 138–2. US Drug Withdrawals for Safety Concerns: 2006, 2007, and 2008	
2006	Gatifloxacin–manufacturer discontinued marketing. Hyper/hypoglycemia
2007	Pergolide–manufacturer discontinued marketing. Heart valve damage
	Aprotinin–manufacturer discontinued marketing. Possible increased risk of death
	Tegaserod–manufacturer discontinued marketing. Increased risk of cardiac adverse events
2008	Colchicine (injection)–manufacturer discontinued marketing. Safety concerns and unapproved status
	Papain (topical)–manufacturer discontinued marketing. Safety concerns and unapproved status
	Edetate sodium–manufacturer discontinued marketing. Inappropriate off-label use and name confusion with edetate calcium disodiuim

from the market. Only very rarely has the FDA itself actually removed a drug from the market. One example where the FDA did implement removal is the drug phenformin, which was removed by the FDA after due process was completed. In the case of ephedra-containing dietary supplements, the FDA removed these products from the market based on their analysis of safety data obtained from the medical literature and from analysis of cases reported to the MedWatch system. In some cases, the pharmaceutical manufacturers file suit against the FDA to fight or delay the planned regulatory action against the product. The manufacturer's legal action generally prolongs the time the product remains on the market because the drug usually continues to be sold while the legal proceedings and appeals proceed through the courts.

Some feel that approval of a drug by FDA should preempt legal action for safety issues identified in the drug labeling. However, the FDA decision-making process regarding drug approval is largely reliant on efficacy and safety data provided by the manufacturer or in the publicly available medical literature. Plaintiff actions, taken against drug and device manufacturers, are sometimes a source of significant publicity and confidential disclosures regarding questionable behaviors practiced by companies that market medicinal products. The patient's right to tort action against a product's manufacturer provides an important mechanism to assure drug safety following approval and marketing.[4,16,20] Recent Supreme Court appeals have challenged this position seeking to reinforce the legal position of federal preemption. In the case of *Wyeth v. Levine*, the manufacturer appealed to the US Supreme Court to uphold the federal preemption status for FDA approved drugs. On March 4, 2009, the US Supreme Court ruled that federal law does not preempt this particular plaintiff from seeking and obtaining a judgment from the product manufacturer because the product was approved by the FDA. The case provided the opportunity to debate the extent of protection afforded by the FDA approval status and the issue of product liability litigation as a part of postmarketing surveillance of drug products in the United States. At the current time, medical devices are governed under a distinct statute in which FDA approval does preempt many forms of litigation.

In addition to the highly publicized COX-2 withdrawals, where an elevated risk of cardiovascular ADEs was cited, the past several years

have seen drug withdrawals from the US market because of postmarketing recognition of ADEs in three general areas:

1. Prolongation of the QTc interval
2. Significant drug–drug interactions
3. Hepatotoxicity

■ PROLONGATION OF THE QT INTERVAL

Three significant drug withdrawals in the mid- to late 1990s exemplified a serious drug safety issue with regard to drug-related prolongation of the QT interval when administered alone or as the result of increasing plasma concentrations due to inhibition of its metabolism by other medications. The three examples in this category are terfenadine (Seldane), astemizole (Hismanal),[7] and cisapride (Propulsid).[8,33] Numerous deaths were reported to the MedWatch system for patients taking these medications. The FDA funded small prospective clinical studies to confirm a previously unrecognized ability of terfenadine to dramatically alter cardiac repolarization, which can lead to torsades de pointes. The drug was marketed in 1985, cardiac toxicity detected in clinical use in 1990,[26] the FDA-funded clinical cardiac safety research performed in 1991,[19] and ultimately the drug was withdrawn from the market in 1998. The medicolegal course of the other two is quite similar and these experiences have led to greater rigor by manufacturers and the FDA.

In addition to the drug–drug interactions that led to accumulation of toxic cardiac parent drugs as in the case of terfenadine, astemizole, and cisapride, drugs shown to inhibit multiple metabolic pathways, especially of drugs with narrow therapeutic indices, have been removed from the market. These three drug withdrawals demonstrated that the pre-approval assessment of cardiac repolarization effects at that time was incapable of detecting even the most potent dysrhythmogenic drugs during their respective development and FDA review. Based on this dramatic systematic failure, FDA (as well as the European and Japanese drug regulatory agencies) now requires a thorough QT study (tQT) for all new molecular entities. These studies are designed to detect as little as a 5-millisecond increase in the corrected QT interval in healthy volunteer subjects and must include a positive control to demonstrate the sensitivity of the study to detect this low-level change reliably. Thus far, since this new requirement has been put in place, no newly approved drugs have subsequently been removed from the US market for QT safety reasons.[32]

■ SIGNIFICANT DRUG–DRUG INTERACTIONS

Removal of mibefradil (Posicor) from the US market is an example of drug withdrawn from the US market because of postmarketing discovery of a plethora of drug–drug interactions. Mibefradil, a pharmacologically unique calcium channel blocker, was approved by the FDA for the treatment of patients with hypertension and chronic stable angina. The FDA approved mibefradil for marketing in 1997 with the knowledge that the compound possessed the ability to inhibit certain hepatic CYP isozymes; these facts were included on the drug label. The initial labeling for mibefradil specifically listed three drug–drug interactions: astemizole, cisapride, and terfenadine (CYP3A pathway interactions). During the 1 year that mibefradil was marketed, information accumulated regarding drug–drug interactions with many other drugs and CYP pathways. As the in vitro and in vivo drug interaction data continued to accumulate for mibefradil, the FDA made labeling changes and issued a public warning for these potential drug interactions within 5 months of its initial approval. Additionally, the sponsor distributed a letter to healthcare professionals warning of drug–drug interactions. In the face of a growing and significant list of drug–drug interactions, and a 3-year international study demonstrating no clinical benefit of mibefradil over placebo for congestive heart failure, the FDA initiated

regulatory action. In an unprecedented step for a drug with numerous drug interactions, the FDA requested that it be withdrawn from the market approximately 1 year after it was approved.[12] The FDA felt that the diversity of drug–drug interactions could not be addressed by standard drug label instructions and additional public warnings.[9]

■ DRUG-INDUCED HEPATOTOXICITY

Another category of ADE of recent concern is those drugs that cause hepatotoxicity. In June 1998, the manufacturer of the NSAID bromfenac sodium (Duract) withdrew this agent from the US market. The NDA was submitted for review to the FDA in 1994 and after 28 months of review was approved. The drug was withdrawn approximately 11 months later after postmarketing discovery of significant hepatotoxicity. Although no cases of serious liver injury were reported during premarketing clinical trials, after introduction to the market a higher incidence of liver enzyme elevation was found in patients who were being treated with the drug. Postapproval exposure of patients to bromfenac generally resulted in longer periods of treatment than that of the subjects in the clinical trials. Because of a preapproval concern by the FDA that long-term exposure to bromfenac could cause hepatotoxicity, bromfenac labeling specified that the product was to be used for 10 days or less. This dosing limitation appeared to be inconsistent with the initial approved drug indication for treatment of a chronic condition (eg, osteoarthritis). Information concerning elevated hepatic enzymes was actually included in the original product labeling. The postmarketing surveillance of this product identified rare cases of hepatitis and liver failure, including some patients who required liver transplantation, among those using the drug for more than the 10 days specified on the label. In February 1998, approximately 6 months after approval for marketing, the FDA added a black box warning indicating that the drug should not be taken for more than 10 days. Nonetheless, severe injury and death from long-term use of bromfenac sodium continued to be reported, and ultimately, the sponsor agreed to voluntarily withdraw bromfenac sodium from the market. The withdrawal of bromfenac sodium raised several important questions concerning interpretation of "safety laboratories," such as liver enzymes during the drug development program, and also raised questions concerning the effectiveness of drug labeling.

Another example of a drug withdrawn for safety concerns related to hepatotoxicity is the oral antidiabetic agent troglitazone (Rezulin). It was approved in the mid-1990s and severe liver toxicity was detected by postmarketing surveillance in 1997. Increasingly serious labeling changes and warnings to prescribers recommending close monitoring of liver function tests in patients taking troglitazone were issued over the next 2 years. In March 1999, an FDA advisory committee reviewed the status of troglitazone and its risk of liver toxicity and recommended continued marketing of this drug in patients with type II diabetes who were not well controlled by other drugs. When two newer agents for type II diabetes, rosiglitazone and pioglitazone, became available, the FDA concluded that the risk profile for troglitazone was significantly worse than these newer agents and asked the manufacturer to remove troglitazone from the market.[18] Analogous to the example with mibefradil, this FDA-initiated drug withdrawal was based on a change in the risk–benefit profile for the specific agent in light of new safety information discovered during the postapproval phase for the drug.

■ OTHER EXAMPLES OF POSTMARKETING SAFETY PROBLEMS LEADING TO DRUG WITHDRAWAL

One voluntary withdrawal of two separate drugs used in combination serves as an important example of the discovery and publicizing of an unusual adverse event occurring years after individual drug

approval but after a significant increase in the prescription use of the combination product. The drug fenfluramine was approved in 1973 after an FDA review period of 75 months. A significant increase in prescription use of a combination product of fenfluramine with phentermine, another weight loss agent (referred to as "fen-phen"), began to occur in the 1990s when clinical data suggested that this drug combination was effective in a weight loss program.[35–37] Use of the fen-phen drug combination, however, was never fully approved by the FDA and was therefore considered an "off-label usage" of the product. The number of prescriptions for the drug combination soared in the mid-1990s. In July 1997, research from the Mayo Clinic reported 24 cases[3] of an unusual form of cardiac valvular disease causing aortic and mitral regurgitation in patients using the fen-phen combination. The publicity surrounding the potential linkage of this drug combination to an unusual adverse event led to a significant increase in reports of possible adverse events associated with this drug combination. The FDA issued a public health advisory and initiated further epidemiologic studies to ascertain its prevalence. The FDA also encouraged echocardiographic studies of valvular diseases in patients taking fenfluramine or dexfenfluramine either alone or in combination with phentermine. Although at the onset the FDA, the product manufacturers, and the medical community did not expect valvular lesions to be associated with either fenfluramine or dexfenfluramine, the epidemiologic evidence suggested a possible association, leading the FDA to conclude that these agents should be removed from the US market. The potential association of valvular heart disease with these agents is an example of the use of a case-control study to explore a possible causal relationship between drug exposure and an ADE. In this case, it is unclear what the strength of the MedWatch signal was for the possible association of cardiac valvular disease with exposure to the fen-phen combination. The association between cardiac valvular lesions and exposure to the drug combination serves as an example of elucidation of a rare, unexpected ADE as the result of a dramatic increase in the number of exposed patients using a product.

THE ROLE OF THE TOXICOLOGIST IN THE DETECTION AND PREVENTION OF ADVERSE DRUG EVENTS

Toxicologists can play an extremely important role in ADE diagnosis and prevention, through efforts in patient care, education, and administrative functions. In patient care, it is common for the medical toxicologist to be the first medical specialist to be consulted for a patient with a potential ADE. Perhaps more than any other medical specialty, medical toxicologists are likely to include a thorough medication history that also includes prescription and nonprescription products, as well as dietary supplements. The medical toxicologist's active involvement in the clinical arena, especially in settings in which the initial diagnosis of ADEs can be made, also serves to provide an important role model: the medical toxicologist as an educator to promote the detection and prevention of ADEs often in the academic setting of a medical school and affiliated teaching hospitals. Here, the academic toxicologist can champion the inclusion of education in therapeutics in the curriculum for medical students and house officers and take an active role in the implementation of the instruction. Assuring that the curriculum in therapeutics includes recognition and prevention of ADEs and medical errors that lead to ADEs could have a significant beneficial impact on the ultimate outcome of the education process toward reduction of preventable ADEs. In addition to making sure that quality information is presented in the curriculum

for trainees, the medical toxicologist can often create a special teaching opportunity for this type of education by establishing an elective or, in some cases, required experience in the curriculum for training in therapeutics. Participation in a quality learning experience can significantly impact on the graduates' knowledge of and attitudes toward therapeutics and risk reduction in the practice of medicine. Although the 2000 Institute of Medicine report on medical errors[23] did not focus on education initiatives in its main recommendations for reduction of medical errors in United States, it seems logical that education be considered an important (yet incomplete) tool to improve medication use and prevent ADEs and medical errors with therapeutic agents.

In the private practice setting, medical toxicologists educate fellows in training in the medical specialty and medical staff peers. In this setting, a consistent approach to the patient that includes the listing of drug-induced disease, drug excess, or potential drug–drug interactions in the differential diagnosis as well as incorporating available pharmacologic knowledge about the drugs in question to explain an unexpected drug response can provide an example for medical colleagues.

The administrative functions that the medical toxicologist can perform could have a beneficial impact on detection and prevention of ADEs. Service on hospital or healthcare organization committees, such as the local pharmacy and therapeutics, ADE-monitoring or Medication Safety Committees are important opportunities to impact on the drug-induced disease problem. These committees systematically analyze ADE trends and recommend interventions for medical, nursing, and pharmacy staff to reduce the risk of ADEs. These interventions include targeted education programs, system modifications to reduce error rates, or a limitation of a specific drug usage to certain units of the organization or by certain specialties.

ADEs are known to be significantly underreported in the United States.[17,27,30] Despite efforts to encourage filing of ADE reports, the overall reporting rates do not appear to have changed significantly. A well-documented, complete report to MedWatch made by a healthcare professional is given priority review by the FDA. The toxicologist is likely to encounter a significant number of drug-induced disease cases from a diagnostic and management standpoint, therefore practitioners of the specialty can make a significant impact on ADE reporting. All staff including medical toxicologists and their trainees should always submit an adverse event report locally for appropriate cases they encounter. Hospitals generally do not mandate or request that the reported event be "serious" as a requirement. The FDA MedWatch system requests that reported events be serious in nature or not previously associated with the medication involved. In addition to reporting of the ADE, the medical toxicologist should promote publication of case reports of all new adverse events or adverse events occurring with newly approved products. Such publication often stimulates appropriate reporting of ADEs from other practitioners and generally raises awareness concerning a new ADE.

An additional and very important role for medical toxicologists who work with Poison Centers is to facilitate the accurate reporting of poison center data to the National Poison Data System (NPDS). Poison center data are invariably considered in the overall safety evaluation of approved and marketed drug. This is especially true for drugs with the potential for abuse and misuse. Accurate information and causality assignment for fatalities by the poison centers' medical directors can greatly aid regulatory decisions and guide efforts to improve drug safety at the national and international level. The recent review regarding the safety concerns associated with the use of nonprescription cough and cold preparations in the pediatric age group is an example of an important regulatory use of poison center data in FDA decision making (http://www.fda.gov/cder/drug/advisory/cough_cold_2008).

SUMMARY

Drug-induced disease is common in both inpatient and outpatient settings in the practice of medicine. Despite significant advances in medical science applied to drug development and regulation, ADEs continue to occur and will continue to do so for the foreseeable future. ADEs have a significant impact on patient mortality and morbidity in addition to producing a significant burden on the healthcare system. ADEs caused by newly approved drugs and ADEs resulting from a previously unrecognized association with drugs with a long marketing history continue to be a significant cause of mortality and morbidity. The rapidly expanding number of approved drugs requires that the medical toxicologist and other practitioners have a continuing commitment to reduce the risk for ADEs in medical practice. Active participation in clinical, teaching, and administrative roles that can improve ADE detection, analysis and accurate reporting at the local and national levels by medical toxicologists has led to important advances in patient safety. Maintaining a high level of commitment to these tasks as individuals and as a specialty will ultimately improve patient safety and benefit society.

CHAPTER 139

MEDICATION SAFETY AND ADVERSE DRUG EVENTS

Brenna M. Farmer

A medication error is "any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer."[74] An adverse drug event (ADE) is an untoward event or outcome associated with the use of a drug. The definition of ADEs includes medication errors as well as adverse reaction to a drug, drug interactions, and reactions. A medication error is a preventable ADE and vice versa. An adverse drug reaction is defined as "any noxious, unintended, and undesired effect of a medication, which occurs at doses used for prophylaxis, diagnosis, or therapy, excluding therapeutic failures, intentional and unintentional poisoning, and medication abuse, and also excluding ADEs because of medication administration errors, or noncompliance."[98] Therefore, a medication error is not an adverse drug reaction but both are ADEs. This chapter will address medication errors and ADEs with a focused analysis of the relevant history and epidemiology, special at-risk populations, possible solutions, and the role of the medical toxicologist.

Patient safety is an area of great interest to many regulatory groups, such as the Joint Commission, hospital administrations, healthcare providers, and the general public. The interest has continued to grow since the publication of the Institute of Medicine report in 1999 which focused on the measures necessary to insure a safer healthcare system including medication errors and adverse effects.[52] Medications errors represent up to 25% of all medical errors.[42] The importance of medication errors is highlighted in another Institute of Medicine report that focused solely on medication errors.[4] Many hospitals focus on medication safety through their pharmaceutical and therapeutics committees, patient safety committees, and medication safety committees.

HISTORY AND EPIDEMIOLOGY

Although medication safety developments have occurred throughout history, in the 1990s they became a major cause of concern. Table 139–1 shows a timeline of some important developments for medication safety.

Studies of medical errors and medication are of a highly variable quality as they deal with different populations, the definitions utilized vary, and the methods employed a variety of data collection techniques including observational studies and voluntary reporting.

One recent study estimates that 180,000 people die each year of iatrogenic injury[58] and 60% of these injuries are probably preventable.[16] Another study estimates that an additional 44,000–98,000 people die each year from medical errors.[52] The difference between these studies may be due to variance of populations, inclusion and exclusion criteria, or case definitions. However, despite the statistical differences both studies establish that medical errors cause thousands of deaths each year. Over 1.5 million preventable ADEs (ie, medication errors) may occur each year,[4] with 3% of adverse events occurring in the emergency department (ED).[60] Those ADEs

and medication errors with serious effects lead to 3.1%–6.2% of all hospital admissions.[57]

In 1997, the cost of a single ADE was estimated to be $2000–$5000.[9,21] In the same era, other studies estimated that the annual cost of ADE morbidity and mortality was greater than $77–177 billion in the ambulatory care setting,[29,44] $2 billion in hospitals,[9,21] and $4 billion in nursing homes.[15] Another study estimated that the annual cost of drug-related morbidity and mortality in the United States in 1997 was $76 billion with a significant part being due to hospitalizations.[45] These costs exclude legal or other costs that accrue to the patient or their families.

■ DEATHS FROM MEDICATION ERRORS AND ADES

Although medication errors are the most common cause of iatrogenic patient injury, less than 2% results in injuries. Nevertheless, the incidence of ADEs in hospitalized patients is estimated to range from 2% to 20%[20] resulting in 7000 deaths annually in the United States.[52] A retrospective review of hospital death certificates by ICD 9 and ICD 10 codes from 1983 to 2004 revealed an increase of 361% in fatal medication errors and a 33% increase in deaths from ADEs occurring in a patient's home.[78] It also revealed a 3196% increase in fatal medication errors when prescription medications were combined with alcohol and or illicit drugs.[78] According to voluntary MedWatch reports to the FDA, 17% of ADEs were associated with death, 7% were associated with permanent disability, and many others had serious complications. Women and elderly patients were at the highest risk.[72] Reports suggest that 2.5%–21% of all ED visits are for ADEs.[18,37,79] The patients identified in these studies were typically older, triaged to higher severity/acuity levels, and had increased numbers of drug exposures.[79]

■ NATIONAL COORDINATING COUNCIL FOR MEDICATION ERROR REPORTING AND PREVENTION TAXONOMY

A useful medication error taxonomy, developed by the National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP), classifies medication errors according to severity (Fig. 139–1).[74] Importantly, the categories of least severity (A and B) describe circumstances or events in which the potential to cause error exists, or the error occurs, but does not affect the patient. These "near misses," or "near hits" more correctly, are so frequent that they serve as a critical source of information and education about medication error, but are typically underreported and underappreciated. In one study of 154,816 errors reported by hospitals and health systems to MEDMARX from 1999 to 2001, the majority of the errors were in Category C (47%) and resulted in no patient injury, whereas there were 19 errors in category I, contributing to or resulting in patient death, comprising 0.01%.[84] See Figure 139–1 for definitions of categories. The top four types of the errors were omission (30%), improper dose/quantity (21%), unauthorized medication (13%), and incorrect prescribing (12%). Performance deficit was the most frequently reported cause of error in each of the 3 years of study. It accounted for 43% of all errors, and was more than double nonadherence to established procedures and protocols (20%), the next most frequent cause.[84] See Figure 139–2 for a comparison of errors in the inpatient versus the ED setting. A performance deficit means that the individual making the error had the prerequisite knowledge to avoid the error but failed to do so. There are numerous variables that contribute to performance deficit, including many ergonomic issues such as workload, distractions, resource limitations and staff shortages.[84] Documentation was the third cause of error at 12% and knowledge deficit was fourth at 10%.[84]

TABLE 139–1. Historical Timeline of Medication Safety

1820	United States Pharmacopeia (USP) is established in Washington, DC
1906	The Pure Food and Drugs Act is passed by Congress.
1927	The Bureau of Chemistry is reformed into Food, Drug, and Insecticide Administration and the Bureau of Chemistry and Soils.
1930	The Food, Drug, and Insecticide Administration was renamed the Food and Drug Administration (FDA).
1962	Kefauver-Harris Drug Amendments passed to ensure drug efficacy and greater drug safety.
	President Kennedy proclaims the Consumer Bill of Rights which includes the right to safety, right to be informed, and right to choose.
1963	Representatives from FDA, USP, AMA and American Pharmacists Association form the United States Adopted Names Council to establish drug nomenclature.
1968	The FDA is placed in the Public Health Service after reorganization of the federal government health programs.
1970	The FDA requires the first patient package insert.
1975	The Institute of Safe Medication Practices's (ISMP) work officially begins with a continuing column in *Hospital Pharmacy*.
1987	The first ISMP list of dangerous drug abbreviations is printed in *Nursing '87*.
1989	Agency for Health Care Policy and Research (AHCPR) is established as an agency in the Public Health Service in the Dept. of Health and Human Services.
1991	Institute for Healthcare Improvement is founded as a not-for-profit organization to aid in improvement of healthcare quality.
	USP and ISMP create Medication Error Reporting Program (MERP).
1993	A consolidation of several adverse reaction reporting systems is launched as MedWatch, the FDA voluntary reporting system for problems associated with medical products.
1996	The National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP) is formed.
1997	National Patient Safety Foundation is established with patient safety as its sole purpose.
	ISMP founds a subsidiary, Medical Error Recognition and Revision Strategies (Med. E.R.R.S.), to work with drug companies to predict problems with names, labels, and packaging.
1998	USP launches MEDMARX, an internet-accessible medication errors reporting system for hospitals.
	Founding members of The Leapfrog Group meet to discuss ways to purchase healthcare to influence its quality and affordability.
	ISMP publishes a list of high alert medications.
1999	IOM Report *To Err is Human: Building a Safer Health System*[52] is published.
	The Leapfrog Group founding members establish the reduction of preventable medical errors as their initial focus.
	The National Quality Forum is created as the President's Advisory Commission on Consumer Protection and Quality in the Health Care Industry.
	Agency for Health Care Policy and Research is renamed Agency for Healthcare Research and Quality (AHRQ).
2006	IOM Report *Preventing Medication Errors*[4] is published.
2007	USP and Quantros, a company that collects data on healthcare quality, patient safety and accreditation, partner to run MEDMARX.

MEDICATIONS INVOLVED

FDA reports suggest that opioid analgesics and immune modulators are the commonest medications in which errors resulted in death.[72] The medications most frequently involved in errors and ADEs reported to MEDMARX were insulin, anticoagulants, morphine, and potassium chloride.[84] These medications are considered high alert drugs according to the sentinel event alert system of the Joint Commission. Identifying characteristics of high-risk drugs include low therapeutic index, those with pharmacokinetic interactions, inherent undesirable effects, interactions, classifications as an opioid, newly approved or "off-label" use, and direct-to-consumer promotion.[12] Table 139–2 lists medications commonly reported and their classes of errors.

THE MEDICATION PROCESS

The Medication Process comprises the five stages in the sequence of ordering a medication to its delivery to the patient. The steps are prescribing, transcribing, dispensing, administering, and monitoring.[5] For patients discharged from the ED or hospital, discharging and followup were added.[27] Although the medicating process has only six stages, there are multiple steps within each stage and so the potential for error is high, increasing proportionately as the number of steps and their complexity increases. Figure 139–3 describes typical errors that occur at each stage in the process, along with prevention strategies.

The greatest number of errors resulting in preventable ADEs (medication errors) occurs at the first or prescribing stage.[6] In a study of serious medication errors, 39% were found to occur at the prescribing stage, 12% at transcription, 11% at dispensing, and 38% at administration.[59] In one study of 17,808 inpatient and ED medication orders, 6.2% of orders written involved a prescribing error and 30% of these were likely to harm the patient if they were not discovered.[14] Transcribing errors usually involve poor communication due to illegible handwriting, the use of trailing zeroes, or inappropriate abbreviations. Poor handwriting can lead to confusion, particularly with regard to look-alike and sound-alike medications. The dispensing step is one of the last phases of the medication process where correction and prevention

Definitions

Harm

Impairment of the physical, emotional, or psychological function or structure of the body and/ or pain resulting therefrom.

Monitoring

To observe or record relevant physiological or psychological signs.

Intervention

May include change in therapy or active medical/surgical treatment.

Intervention necessary to sustain life

Includes cardiovascular and respiratory support (e.g. CPR, defibrillation, intubation, etc.)

Category I: An error occurred that may have contributed to or resulted in the patient's death

Category A: Circumstances or events that have the capacity to cause error

Category B: An error occurred but the error did not reach the patient (an "error of omission" does reach the patient)

Category H: An error occurred that required intervention necessary to sustain life

Category G: An error occurred that may have contributed to or resulted in permanent patient harm

Category C: An error occurred that reached the patient but did not cause patient harm

Category F: An error occurred that may have contributed to or resulted in temporary harm to the patient and required initial or prolonged hospitalisation

Category E: An error occurred that may have contributed to or resulted in temporary harm to the patient and required intervention

Category D: An error occurred that reached the patient and required monitoring to confirm that it resulted in no harm to the patient and/or required intervention to preclude harm

No error   Error, no harm   Error, harm   Error, death

of an error can occur.[77] A retrospective review suggests that substitution and labeling errors are the most common pharmacy dispensing errors.[86] Errors at the stage of administering medications include incorrect drug, incorrect dose, incorrect route, and a drug given to the wrong patient.

Monitoring and discharging with followup are associated with fewer errors. This phase involves attention to hepatic and renal function, checking xenobiotic concentrations, and attention to and evaluation of drug interactions and pharmacokinetic interactions.[27] Monitoring must be an ongoing process that begins when the patient receives the medication, wherever the patient is in the healthcare system, and continues as long as the individual continues to have the medication prescribed. In the acute stages of treatment, such as in the hospital or ED, the process is especially important and requires optimal three-way linkage between the pharmacy, laboratory, and

physician.[85] This process must continue throughout the individual's continued relationship with the healthcare system. In the primary care setting, 17 separate tasks were identified from the initial decision to order a laboratory test through to getting the result to the patient.[39]

Communication issues are very important at all stages in this process. All information, whether printed, spoken, or otherwise communicated, must be transmitted in a clear, unambiguous, and timely fashion with avoidance of abbreviations. Physician's handwriting is still an important issue. Furthermore, in its 2004 National Patient Safety Goals, the Joint Commission developed a minimum list of five sets of dangerous abbreviations, acronyms, and symbols that should not be used, and proposed preferred terms.[47] The Institute for Safe Medication Practices (ISMP) also published a comprehensive list.[43] Communication is also especially important between physicians and patients. patients in four primary care practices, patient reports of medication side effects to their physicians led to changed therapies in 76% of cases. A failure to identify medication-related symptoms and change therapy resulted in 21% ameliorable and 2% preventable ADEs. Ameliorable ADEs were defined as those in which "the severity or duration could have been reduced substantially had different actions been taken."[95] The study illustrates the "Swiss Cheese Model of Error."[80] The first error of a preventable ADE is compounded by the second error of failing to identify it.

TABLE 139–2. Medications or Classes Commonly Responsible for Medication Errors

Acetaminophen	Electrolyte replacement:
Albuterol	Potassium chloride
Antibiotics:	Fluid replacement therapies
Amoxicillin	Furosemide
Cefazolin	Insulin, other antidiabetics
Cephalexin	Opioids:
Levofloxacin	Fentanyl
Penicillin	Meperidine
Vancomycin	Methadone
Anticoagulants:	Morphine
Heparin	Opioid-acetaminophen combinations
Warfarin	Oxycodone
Antineoplastics	Sedatives
Aspirin	Benzodiazepines
Cardiovascular:	
Clopidogrel	
Digoxin	
Inotropes	
Vasopressors	

SPECIAL AT-RISK POPULATIONS

Important medication safety issues exist for children and older adults, a problem that is exacerbated by their underrepresentation or exclusion from clinical trials. It is estimated, for example, that only a third of the medications used to treat children have been adequately tested in this population.[24] Similar concerns apply to medications used in older adults.[41]

■ PEDIATRIC CONSIDERATIONS

Adverse exposure to medications may occur during pregnancy and lactation and subsequent errors may occur in all settings: the home, in ambulatory care, the ED, hospital floor, pediatric intensive care unit (PICU), and neonatal intensive care unit (NICU). Approximately 1 in 6.4 pediatric orders results in an error that reaches the patients.[68] In particular, one study showed that 31% of errors in a pediatric population resulted in harm or death compared to 13% in adults.[28] More errors can occur at each stage of the medication process in children and are likely related to calculation requirements and weight-based dosing.[48] Errors occur in the home environment with nonprescription medications, but the true incidence is unknown. In one survey, the errors associated with home antipyretic use were estimated at almost 50%.[69] These errors are typically associated with underdosing, which can be harmless although the converse may be life threatening.[83] In the ambulatory setting, the incidence is unknown but one study identified "numerous" errors in prescription writing in a pediatric clinic.[93] In the ED setting, the error rate was estimated at 10% of all charts.[54] One study showed an increased risk of errors in nonacademic or rural EDs.[51] A retrospective chart review of 177 pediatric charts in 4 rural EDs revealed that 69 of the 135 patients who received medications had 84 different medication errors identified. The outcomes of these errors were in NCCMERP Categories A-D (see Fig. 139–1).[67] Hospitalized children experience up to three times the rate of medication errors and potential ADEs as do adults.[50] The incidence for medication errors of hospitalized children is estimated at about 6% for all orders written; the majority (74%) of these occurred at the prescribing stage and approximately 20% were classified as potentially harmful.[33] Generally, children in the intensive care unit appear to be at higher risk for errors,

Stage	Error producing conditions	Medication error reducing strategies

Prescribing	Incomplete knowledge of medication
	
	Incomplete knowledge of patient
		Readily available medication reference systems
		
		Increased pharmacist availability
		
		Take a thorough medication/medical/allergy history
		Physicians order entry
		Computerized decision support
		Pediatric patients:
		    Determine accurate weight in kilograms
		    Be alert for calculation/decimal point errors
		    Caution with "off-label" prescribing
		Geriatric patients:
		    Consider co-morbidities and drug-drug interactions in
		    particular
		    Consider possibility of falls with new medications
		    Consider renal, hepatic and thyroid function
		    Follow Beers criteria
		Potentially pregnant patients:
		    Rule out pregnancy
		    Careful evaluation of risk:benefit

Transcribing	Verbal orders Poor penmanship Abbreviations, symbols	Avoid verbal orders except in emergencies Write legibly; print if necessary Avoid acronyms or prohibited abbreviations Electronic order transcription Team communication errors Indicate decimal point clearly No trailing zeros Avoid apothecary terms Include physician phone number/pager
Dispensing	Dispensing by nurses Dispensing by physicians Patient ID	Nurses dispense to another nurse and not themselves No dispensing by physicians Automated dispensing Check with physician if any ambiguity in order Check correct placement of decimal points Check weight is correct in kilograms Always check for allergies to medication class Doubly confirm patient indentification; bar-coding Double-check arithmetic
Administration	Multiplicity of medications Potency of medications Multiple patients Parenteral administration Medication incompatabilities Physician administration	Be prepared to challenge orders Clarify any ambiguity or doubt concerning medication order Consistent consultation with reference materials Consultation with hospital pharmacist if available Call back verbal orders Implement systematic safety checks Avoid physician administration of medication whenever possible
Monitoring	Potent medications Parenteral administration Emergent procedures Complex procedures	Ensure adequate monitoring technology Ensure adequate monitoring personnel Clear protocols for conscious sedation or rapid sequence intubation Ensure adequate monitoring time following drug administration
Follow-up	Patients leaving hospital or other healthcare facility, and especially medicated patients	Reconcile all medications No verbal discharge instructions to patients given amnestic drugs Provide written information on any new medication to patient if possible Advise patients of any necessary follow-up Consider effect of medication if patient driving home

FIGURE 139–3. Stages in the ordering and delivery of a medication, and typical errors associated with each stage. (Croskerry P, Shapiro M, Campbell S, et al. Profiles in patient safety: medication errors in the emergency department. *Acad Emerg Med*. 2004;11:298).

presumably reflecting the increased complexity of disease and the medications used.[51] Dosing errors and the intravenous route are the most commonly reported errors with dosing of antimicrobials and intravenous fluids being the most common medications involved.[28,32,50] Errors and discrepancies found in hospital discharge instructions could lead to patient harm[46] (see Chap. 31).

■ GERIATRIC CONSIDERATIONS

Medication errors in older adults occur throughout the healthcare continuum: the home, ambulatory care, in nursing homes, in the assisted-living setting, and in the hospital (Chap. 32). Adults over 65 years of age have a relative risk of 2.37 for drug complications and 4.12 for medication errors compared to patients younger than age 65.[16] The incidence of medication error at home with nonprescription medications is unknown but, for reasons outlined below, would be expected to exceed that of the younger adult population. Using a variety of methodologies, ADEs were evaluated for a 12-month period in a multispeciality ambulatory care practice in a cohort of 27,617 Medicare enrollees, equivalent to over 30,000 person-years of observation. Extrapolating their findings, to the estimated 38 million Medicare enrollees (those 65 or older), would predict nearly 2 million ADEs annually, of which >25% would be considered preventable and about 180,000 fatal or life threatening.[36]

Of the more than 1.5 million nursing home residents in the United States, the average resident uses six different medications, and 20% use ten or more.[13] Extrapolating from the findings of a study of 18 community-based nursing homes in Massachusetts over a 1-year period would predict 350,000 ADEs annually, more than half of which would be preventable.[35] Fatal or life-threatening ADEs would represent 20,000 of these predicted events of which 80% would be preventable. Approximately one million other seniors live in assisted-living facilities, and are vulnerable to medication errors for a variety of reasons including inadequate physician support, inadequately trained staff, and staffing shortages. ADEs cause 10.5% of hospital admissions for geriatric patients and are the most common type of adverse event occurring in hospitalized elderly patients.[60,97] Medications prescribed leading to ADEs and ED visits include oral anticoagulants and antiplatelet medications, antidiabetics, and those medications with narrow therapeutic indexes.[19] These xenobiotics result in nearly 50% of ADE-related visits to the ED but are only prescribed during 9.4% of outpatient visits.[19]

Addressing these issues is becoming increasingly important as the US Census Bureau predicts an increase of 62 million in the number of Americans 65 years or older by the year 2025 and a 68% increase in the 85 or older population that may be at an even higher risk.[3]

Advancing age brings with it several important considerations from the point of view of medication safety:

1. There is an increasing morbidity with age, and therefore an increasing likelihood of receiving medication. Comorbidities and chronic disease increase the number of concurrent medications, and therefore the number of potential interactions.

2. Frailty and cognitive decline in older adults may result in errors following self-administration and may require the assistance of family members or others to achieve proper use.

3. Alterations in medication absorption, metabolism, distribution, and elimination may all affect the efficacy of the medication (see Chaps. 8 and 32).

Criteria were developed in both the United States[10,11,31] and Canada[70] to determine appropriateness of medication prescribing for nursing home residents. Forty-eight medications or classes of medications to avoid, and medications to avoid in the presence of 20 diseases/conditions were

identified.[31] The prevalence of inappropriate medication use in older adults has been and continues to be estimated in the 12%–40% range.[87] Older adult patients medicated with benzodiazepines, for example, have a 4-fold increase in falls. Significant differences within the class of benzodiazepines were found: the risk of injury associated with benzodiazepine use generally appeared to be independent of half-life; there was no increase associated with long-acting diazepam use, nor was there a dose-effect, whereas there was an increased risk associated with the use of the short-acting oxazepam. Flurazepam and chlordiazepoxide (both long-acting) were associated with a 50%–60% increase in risk of injury.[88] There is an alternate approach to develop specific clinical indicators of preventable medication-related morbidity (PMRM) in older adults. The four unique elements of a PMRM include that it be recognizable, foreseeable, identifiable, and controllable as developed by an expert consensus on 52 clinical indicators.[66] In a followup study, the top five indicators were found to account for almost half of all PMRMs.[65] These indicators included four or more diagnoses, four or more prescribers, six or more prescription medications used, antihypertensive drug use, and male gender[65] (see Chap. 32).

RESPONSE TO MEDICATION ERROR

One of the leading causes of medication errors is human performance deficit. Invariably a human action will precede the ADE, and this temporal contiguity of action and consequence inevitably generates a tendency to blame someone; this will usually be the last person to have had contact with the patient. In recent years, however, a consensus has emerged that blaming people for errors is counterproductive. The number of ADEs that result from truly egregious behavior is very small, and more often than not the explanation will be found within the system. Root cause analysis (RCA), a term originally used to investigate major industrial events, is a technique that provides a structured, process-oriented analysis of sentinel events. Its use was mandated by the Joint Commission in accredited hospitals in 1997. It is a time-consuming process requiring multidisciplinary teams with specialized training, and is subject to bias and methodologic limitations.[91] Nevertheless, a judiciously conducted RCA may provide insights into systemic failures underlying the ADE, and identify areas that require change. An alternative approach, a clinical incident analysis protocol, was developed that more appropriately shifts the emphasis from the individual to the system.[90] The clinical incident analysis protocol utilizes seven factors as the basis for an investigation. Some organizations have developed a hybrid combining these two approaches. Both RCA and clinical incident analysis are conducted retrospectively, and therefore subject to retrospective bias.

An alternative approach is failure mode and effect analysis (FMEA), which proactively attempts to identify potential errors, to initiate preventive measures. A multidisciplinary group is utilized in the FMEA approach to identify a process or subprocess that needs analysis to identify the steps of the process and determine the risk/likelihood/severity of failure of each step. Once this phase is accomplished, the team prioritizes a high risk step and conducts a root-cause analysis to make recommendations on redesigning the step. The establishment modifications are analyzed in their performance to determine change and decrease in risk. This process is designed as a quality control and assurance in order to protect the proceedings from legal investigation.[2]

REDUCING ERRORS

In order to reduce medication errors, each hospital should simplify, standardize, and stratify processes and communication. The medication

process should be carefully automated with computer order entry and bar coding as extensively as the system will allow. Limitations of attention and vigilance should be understood and the reporting of errors in a nonpunitive environment should be encouraged.[59] Improving information access, error proofing, reducing reliance on memory, training, and the use of buffers or redundancy to prevent inevitable errors should also be encouraged.[58] Each time a medication is given the focus should be "right drug, right dose, right route, right patient, at the right time." Regulatory agencies such as the US FDA and the European Medicines Agency (EMEA) have developed initiatives to evaluate drug names for their error potentials.

In 2003, the American Academy of Pediatrics Committees on Drugs and on Hospital Care developed a position statement regarding the reduction of medication errors in the pediatric population. The recommendations can be adapted to all hospital settings to patients of all ages. Appropriate staffing was encouraged in addition to dependency on the resources of the pharmacy, standardization of hospital equipment and protocols, and the development of a nonpunitive barrier-free system to report and easily track errors. The committee encouraged improved communication skills and an enhanced team environment such that any member of the team should be able to calculate the dose of a medication and confirm that the dose prescribed is the correct dose for the particular child.[22]

For older adults, prescribers should review medication indications and avoid age bias. Polypharmacy should be limited, but medications should be prescribed as necessary. Dosing should be adjusted as needed based on renal and hepatic function. Computer physician order entry with decision support and bar coded medication administration should be implemented.[81]

HUMAN FACTORS/HUMAN PERFORMANCE DEFICIT

Human factors lead to many medication errors. In fact, it is not surprising that human performance deficits are the primary causes of medication errors in such an extremely complex medical environment. This environment is both burdened and enriched by many inherited properties. Human factors and ergonomics theory draws on a variety of disciplines including industrial engineering, industrial psychology, cognitive psychology, and information technology. Much can be done to optimize the interface between humans and the work environment and to ensure that systems operate more efficiently. As a general principle, it would be preferable if the dominant purpose in designing medical devices and processes was that they fit human users, and not the converse.

Human performance deficits such as diminished memory, sleep deprivation, depression, and distractions contribute to errors. Table 139–3 lists some of the more common human performance deficits. Such errors often manifest as simple slips of action, or execution failures, arising from distraction or attentional capture by something other than the task at hand.[80] Vigilance is better maintained in individuals who are well rested and working without interruption or distraction in a well-designed environment. Fewer medication errors occur in optimally designed environments.[59]

Another factor that contributes to errors is the assignment of a new role to a provider such as asking physicians to dispense or administer medications. Pharmacists are the only professional group formally trained in dispensing medication, and not surprisingly, their presence is associated with a lower medication-dispensing error rate.[61] Nurses administer medications because they receive such training and the administration should be restricted to them except during certain

TABLE 139–3.   Common Factors That may Adversely Affect Human Performance[26,84]
Fatigue
Sleep deprivation/debt
Fragmentation, transitions of care
Interruptions
Distractions
Attentional capture
Diminished motivation/morale
Increased work acuity/cognitive load
Poor workplace ergonomics
Inadequate resource availability (RACQITO)[a]
Inexperience

[a] RACQITO refers to Resource Availability Continuous Quality Improvement Trade-Off.[26]

circumstances such as procedural sedation.[27] Depressed residents made 6.2 times as many medication errors as nondepressed residents.[30] Sleep deprivation and improper supervision, both human performance deficit problems, were highlighted intially after the Libby Zion case, in which a patient on phenelzine developed a fatal serotonin syndrome following the administration of meperidine by a sleep-deprived and inadequately supervised intern. Previous interns working a traditional schedule of call every third night with extended work shifts (36 hours) made 35.9% more serious medical errors than those with the current reduced work schedule.[56] In particular, there were 20.8% more serious medication errors during the older work schedules compared with the current reduced hour schedule.[56] In 2008, an Institute of Medicine study addressed resident work hours and patient safety. This report recommended residents be provided with designated sleep time during each day and rest periods each week in order to decrease the risk of fatigue-related medical errors.[89]

A particularly important goal for human performance deficit is the reduction of cognitive load. Many medication errors originate from cognitive failings because of interruptions, distractions, inexperience, or simple overloading—referred to as performance deficit. Further efforts must be directed at strategies to reduce cognitive failure. The adoption of some very simple strategies based on human factors engineering principles will reduce error, such as simplification of the number of steps involved, reducing reliance on memory, applying cognitive forcing strategies,[26] and using cognitive aids. One particularly useful aid is the color-coded Broselow-Luten system, for pediatric medication dosing.[63] This approach has the potential for further development to improve the safety of nonprescription medications and other potentially dangerous products used in the home. A universal standard color-coding drug labeling system has been proposed in anesthesia to reduce between-class medication errors.[1,76]

KNOWLEDGE DEFICITS

The two most common factors contributing to prescribing errors are related to knowledge deficits. These deficits include lack of knowledge about the drug and lack of knowledge about the patient.[59,62] Knowledge deficits are also likely due to the number of medications that have been introduced to providers. With the large number of medications prescribed and the continuing release of new medications,

it is difficult to know all medication interactions, side effects, and contraindications. References should be contemporaneously available to healthcare providers to assist in decreasing prescribing errors.[77]

Knowledge deficits may also effect dosing calculations and drug ordering. This may be related in part to the lack of formal education regarding the medication process during undergraduate medical training. Only 10% of medical students answered dose calculation questions correctly.[96] However, students in their final year of training performed much better than students in the lower years.[96] It is unclear where the knowledge was obtained by the students in the higher years. Specific training is needed in both of these areas of calculation and order-writing. Improvements have been demonstrated following a short educational intervention,[75] but it is unclear how long this knowledge is retained. Generally, there appears to be a tacit assumption that these skills will be acquired during clinical training, but this study suggested that this knowledge might not be acquired independently and that specific training is indicated.

The prevailing emphasis in physician training is on knowledge acquisition. Less time is spent inculcating critical thinking skills and/or teaching reasoning, the assumption being made that these are passively acquired during the process of training. Although this is partially true it does not exclude opportunities to improve these cognitive faculties by direct intervention.[25]

COMMUNICATION

Improved team communication should result in fewer medication errors. Orders should be written clearly, or computerized physician order entry (CPOE, discussed in detail in Information Technology section) should be used. Orders should optimally include the indications for the medication. Both generic and trade names should be included in orders so that confusion with look-alike/sound-alike drugs may be avoided. Abbreviations should have limited use and trailing zeros should be eliminated. Verbal orders should be used sparingly due to the high risk of sound-alike medications and confusion with dosing.[77] If a verbal order is necessary, it should be restated to the physician prior to administration to ensure that it is correct.

Communication theory should receive more emphasis in healthcare training. Good communication skills both within and among disciplines and especially between practitioners and their patients will limit errors. As patients are admitted, transferred within, and discharged from healthcare facilities it is essential that precise communication as to what medications, strengths, and doses the patient is receiving occurs. Any changes that have occurred must be accurately recorded in the process of medication reconciliation. This effort was adopted by the Joint Commission in 2005 and continues to be an important National Patient Safety Goal. As with other aspects of patient safety, these issues should be formally introduced into the education curriculum.

INFORMATION TECHNOLOGY: COMPUTER PRESCRIBER ORDER ENTRY AND BARCODING

Information technology (IT) in healthcare has been ponderously slow to develop compared with its use in other organizations, but it is now gathering momentum and has obvious potential to improve patient safety.[7] On the other hand, as considerable gains may be made, new technology can also be expected to introduce new types of errors. The US Pharmacopeia announced in 2004 that nearly 20% of 235,159 medication errors reported to MEDMARX involved computerization or automation.[84] One study evaluating CPOE in a tertiary care hospital found that the system actually facilitated a wide variety of medication error risks.[38] Another study identified 24 different types of failures associated with CPOE but suggested that many could be easily corrected, in particular by concentrating on organizational factors.[53] However, more detailed insights have been offered into why process-supporting IT systems fail.[94] Much of the data involved in the medication process are relatively straightforward, amenable to rapid and efficient processing, including cross-checking with patient medication history and evaluating for drug interactions (an example of decision support).

Computerized order entry with decision support has been shown to reduce the incidence of serious medication errors by 50%–55% once the transitional instability has passed.[8,64] This approach mainly reduces errors at the prescribing stage of the medication process and, while likely to prevent 80% of prescribing errors that led to no patient harm, the errors most likely to cause patient harm may not be as amenable to reduction as these errors may be related to dispensation, administration, or monitoring.[14]

In high risk populations, CPOE reduces medication errors. In children, CPOE with substantive decision support reduced ADEs (including medication errors) and potential ADEs in an inpatient pediatrics ward.[40] It also decreased the rate of nonintercepted medication errors by 7% although there was no change in the rate of patient harm.[50,92] In the neonatal ICU, CPOE eliminated all calculation errors as decision support included an automatic dosage calculator.[23] In geriatric medication errors, CPOE resulted in less potentially inappropriate medication prescribing through decision alerts which led to a pharmacist call to the prescriber that offered alternative choices of medications if possible.[71]

Use of barcoding for dispensing and administration of medication ensures that the correct drug is given to the intended patient at the dose intended. Barcoding significantly decreased the relative risk of targeted, preventable ADEs by 47%–50% in a neonatal Intensive Care Unit.[73]

Unit dose dispensing systems, usually in association with CPOE and barcoding of medications, reduced monthly errors from five to none in the inpatient setting.[34] The package sent from pharmacy is prepared to administer to a specific patient at the appropriate dose, eliminating the need for the nurse to draw up medications resulting in fewer errors.

SERVICE-BASED CLINICAL PHARMACISTS

Clinical pharmacists are being stationed in high-risk areas such as the ICUs, the pediatrics services, and EDs to indentify and prevent medication errors. In one ICU study, the input of a clinical pharmacist during rounds saved an estimated $270,000 annually in costs of rehospitalization due to ADEs.[61] The involvement of a clinical pharmacist in work rounds of an adult ICU reduced preventable ADEs by 66%.[61] The introduction of clinical pharmacists in pediatric services has been credited with a 94% reduction of potential ADEs and medication errors.[50] In particular, the addition of pharmacists in the Pediatric Intensive Care Units (PICU) reduced the serious medication error rate by 80%.[49] One study showed that pharmacists in three EDs identified 2200 interventions with an estimated savings of $488,000. This savings came from lower-cost medications, reduced length of stay, and fewer readmissions.[82] Another study showed that there were 16 errors per 100 medication orders in the control group (without a pharmacist) while the intervention group (pharmacist present in the ED) only had 5 errors per 100 medication orders, resulting in a 67% reduction.[17]

However, fiscal restrictions will inevitably mitigate against the expansion of service pharmacists as cost-benefit arguments will be applied. An unintended consequence of having a clinical pharmacist present may be that nurses, residents, and attending physicians will always defer to them and consequently spend less time developing and maintaining their own skills for off-hour periods when such help may not be available.

MEDICAL TOXICOLOGIST IN MEDICATION SAFETY

Medical toxicologists are in a unique position to investigate causes and help decrease the incidence of both medication errors and ADEs in the institutions where they work. With their specialized knowledge and training in pharmacology, poisoning, and clinical medicine, medical toxicologists can also aid in the prediction, identification, and management of ADEs. Medical toxicologists should optimally be involved in Pharmacy and Therapeutics and Medication Safety committees at their institutions. They should educate the providers at their hospitals on ways to reduce errors and encourage diligent reporting of medication errors to the hospital and the national databases such as MedWatch at FDA. They should also encourage drug manufacturers to be diligent in alerting physicians with regard to identified problems.[55]

SUMMARY

Medications are the principal commerce of modern medicine, and medication safety is of paramount importance to healthcare systems. The delivery of medications safely to patients is a more complex process than was originally imagined. It affects patients of all ages but is particularly important in pediatrics and geriatrics. With a new industrywide focus on patient safety, renewed attention and energy has been directed to the problem. Healthcare providers should be aware of why errors occur and how they can be prevented in order to improve patient and medication safety. Many innovations, especially in the field of information technology, hold promise for significant improvement. Focus should be on computerized order entry (CPOE), barcoding, unit dose dispensing, avoidance of look-alike/sound-alike medications, and education. Resource utilization such as use of a clinical pharmacist and reference textbooks or handbooks should be encouraged. Most of all, in order to learn from errors when they occur and to prevent them in the future, communication and nonpunitive local and national reporting must be encouraged.

The process can no longer be perceived as a simple tripartite relationship between the patient, healthcare providers, and pharmacist. Patient safety requires a collaborative effort particularly with the medication manufacturer, but also federal regulation authorities, independent research organizations, error theorists, hospital administrators and managers, information technologists, nurses, cognitive psychologists, human factors ergonomists, and chronobiologists and all of the physicians involved with a patient's care. Input from the medical toxicologist can also improve medication safety. A new multidisciplinary approach may considerably reduce current error rates in the future. In this way tangible and measurable gains can be made in this area of patient safety.

CHAPTER 140

RISK MANAGEMENT AND LEGAL PRINCIPLES

Barbara M. Kirrane and Dainius A. Drukteinis

The number and diversity of toxicologic emergencies faced by emergency department (ED) staff has increased steadily since the early 1970s, and continues to rise today. This chapter discusses the medical-legal management of patients who are intoxicated or exposed to xenobiotics that may affect their thinking. It also addresses the legal and ethical dilemmas routinely encountered by emergency medicine practitioners.

Patients with toxicologic emergencies require immediate care, and yet are often unable to give consent because their impaired consciousness prevents them from making informed decisions. Treating patients who present with an acute organic impairment manifested by confusion, irrational thought, or even dangerous behavior is very challenging. Emergency physicians must recognize the medical-legal problems created when the impaired patient refuses treatment and insists on leaving against medical advice. The issue is further complicated by the variations in relevant laws from state to state. Emergency physicians must become familiar with the legal requirements of informed consent and the essential management necessary to avoid liability for negligence and abandonment within the state that they practice. Of particular concern are the risk management and liability issues that relate to impaired patients attempting to leave the ED before medical care is complete. The legal requirements of informed consent in emergency settings, the duty to treat, medical malpractice, battery, and negligence, are examined here. Guidelines based on generally accepted common law principles are suggested for developing appropriate patient care plans and departmental policies. These issues and principles are best illustrated by case examples.

INFORMED CONSENT

Patient 1 An 18-year-old college student was brought by ambulance to the emergency department (ED) after a friend reported seeing her in the bathroom with slit wrists and an empty bottle of acetaminophen. In the ED, the patient was alert and oriented to person, place, and time. Vital signs were: blood pressure 120/65 mm Hg; pulse 95 beats/min; respiratory rate 16 breaths/min; and temperature 99.1°F (37.3°C). A rapid bedside glucose concentration was 120 mg/dL. The patient stated that she ingested the acetaminophen approximately 5 hours earlier. The healthcare team wished to measure an acetaminophen concentration to determine whether *N*-acetylcysteine should be administered. The patient refused venipuncture and stated that she would refuse any medications. The physicians informed the patient that she might suffer irreparable damage to her liver and possibly die if not treated immediately.

Medically treating patients against their will poses a difficult problem. Forcible treatment violates a patient's autonomy and right to privacy. However, harm may be caused to the patient if the appropriate evaluation and treatment is not performed. As an example, in the case above, the patient gives a history of ingesting a large amount of acetaminophen, which may cause hepatotoxicity and even death if not treated (Chap. 34). Her refusal for this evaluation highlights the important issue of whether a physician is ever justified in performing an assessment of someone who is alert and oriented, yet poisoned, and who refuses treatment. Do most patients suffering from a mental illness such as depression need to be treated against their will? If the harm that faces the patient is not immediate, but certain in the near future, does the physician have the authority to treat? General principles of patient autonomy and informed consent will be elucidated here.

A patient's right to choose the course of medical treatment was first recognized in the early 20th century in a landmark case decided by the NYS Court of Appeals in *Schloendorff v Society of New York Hospital*.[16] Mary Schloendorff was admitted for abdominal pain and was found to have a mass on physical examination. Her physicians offered her a more thorough examination under anesthesia and the option for surgery. She consented only to the exploratory surgery; however, during the procedure the mass was removed. Postoperatively, Schloendorff developed an infection, gangrene and the amputation of several fingers. She sued the hospital. In its decision, the Court upheld Schloendorff's right to self-determination, and the right to refuse treatment. It stated:

> "Every human being of adult years and sound mind has a right to determine what shall be done with his own body and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages, except in cases of emergency in which the patient is unconscious and it is necessary to operate before consent can be obtained."[16]

This decision became the foundation for the "Doctrine of Informed Consent." Informed consent serves to protect a patient's autonomy, the concept that each individual has the right to choose a personal course of medical treatment.[27] This includes the right to refuse care, and the right to terminate care already in process. In a nonemergent situation, it is the physician's responsibility to obtain approval from the patient or surrogate before rendering treatment.

Generally accepted components to the informed consent process consist of (1) an explanation of the treatment/procedure, (2) alternative choices to the proposed intervention, and (3) relevant risks, benefits, and uncertainties associated with each alternative. This discussion must take place whether the patient is consenting to a procedure, or refusing a recommended procedure. A patient does not automatically assume the risks of rejecting a physician's recommendations if the patient has not been fully apprised of the consequences of his or her decision.[29] Furthermore, it is the duty of the physician to assess how well the patient understands the above information. Before a physician may accept a patient's approval or refusal of care the patient must demonstrate adequate understanding of the information discussed.

State courts may apply one of two standards to determine if the information communicated by the physician was sufficient. The reasonable person standard requires a physician to disclose information that a reasonable person in the same position as the patient would need to make an informed decision.[5] The alternative is the reasonable physician standard, which requires a physician to reveal information that a reasonable physician in a similar circumstance would disclose.[5] States vary on which standard they apply.

Courts recognize that the requirement for informed consent is not absolute, and that there are exceptions in which a physician does not need to obtain permission before rendering treatment. In *Schloendorff v. Society of New York Hospital*, the Court recognized that consent is not required in emergency situations. Situations are generally considered emergent if a patient's care would be compromised if there were a delay in treatment. In New York, an emergency is defined as a situation that includes both the immediate endangerment of life or health, or the need for the immediate alleviation of pain.[19] Physicians need to determine the specific requirements of informed consent in their respective states.

Often a physician's well-intended efforts to communicate treatment information to an impaired patient prove ineffectual and present the practitioner with a medical-legal dilemma. The physician may be unable to discuss in a meaningful way the implications of the proposed treatment with the patient; nevertheless, there is a duty to treat the patient who presents with a life-threatening condition or the potential for permanent disability. In these situations, consent is considered to be implied, and emergent treatment should be provided. The principle of implied consent is a general tenet of tort law.[14]

RISK MANAGEMENT CONSIDERATION AND DOCUMENTATION

Patient 2 A 28-year-old woman was brought to the ED by police who believed she might be a "bodystuffer" (an individual who swallows drugs to avoid arrest and prosecution). The triage nurse helped the patient onto a stretcher and brought her to the treatment area and recorded normal vital signs. The patient became combative and uncooperative as the phyisician initiated the examination and he verbally ordered that the patient be restrained. The patient was given 40% oxygen via face mask, cardiac monitoring was begun, and an intravenous line was started with 0.9% sodium chloride at 125 mL/h; a bolus of 100 mL of $D_{50}W$ and 100 mg of thiamine were administered IV. Orogastric lavage was then performed, and 50 g of activated charcoal (AC) was administered.

An hour after arrival the patient's vital signs were: blood pressure 120/70 mmHg; pulse 82 beats/min; and respiratory rate 24 breaths/min. The patient was noted to be stable and transferred to an observation unit. Oxygen and cardiac monitoring were discontinued. No further orders were written, and the patient remained restrained. Three hours later the vital signs were: blood pressure, 110/60 mm Hg; pulse 92 beats/min; and respiratory rate 18 breaths/min. A nurse's note stated the patient was resting comfortably.

Forty-five minutes later, the initial physician completed his shift at midnight and informed his replacement that the patient was stable and resting in the holding area.

At 4:20 am the patient was found unresponsive and hypotensive, with agonal respirations and a weakly palpable pulse. She felt very hot to the touch and had a rectal temperature of 108°F (42.4°C). Resuscitative efforts were initiated but unsuccessful; 30 minutes later the patient was pronounced dead.

Several important risk management questions frequently arise in medical malpractice litigation involving the ED. To prove that a case constitutes medical malpractice, a plaintiff's attorney must show clear and convincing evidence of a departure from good practice by the physician. The attorney must further demonstrate that the negligent act or omission by the physician proximately caused the patient's injury. Courts have held that where "there is substantial probability that the [defendant physician's] negligent conduct caused the resulting injury, that sufficient evidence has been developed against [the] physician."[26]

The problems associated with an improperly documented ED record are numerous, but they can be minimized if the practitioner is cognizant of risk management principles. When the attorney for the patient (plaintiff's attorney) introduces evidence to prove the case, the central document in the medical malpractice trial is likely to be the ED record. Thus, every entry in that record is scrutinized with great care by both parties (plaintiff and defendants), and the importance of completing it with knowledge of risk management implications should be a concern for all healthcare providers.

The physician is required to write a medical record that will amply support the basis for the medical judgments exercised. When a physician chooses to write only a summary statement on the record without noting supporting clinical data or patient history, claims alleging failure to diagnose will be extremely difficult, if not impossible, to defend. One of the basic elements of the defense in a medical malpractice case is that the physician's judgment was appropriate, given the clinical facts and the patient's history available at that time. Therefore, physicians who do not record supporting clinical data and history deprive themselves of a strong "medical judgment" defense.

Inappropriate entries or markings on the medical record can weaken the defense in a liability case. For example, in attempting to correct an error in entering a PO_2 value, if the physician or nurse totally obliterates the number, an attorney representing a patient may suggest to the jury that the obliteration was done intentionally to conceal clinical data harmful to the position of the defense. If a physician must correct a prior entry made on the record, the preferable method is to draw a single line through the value or word to be changed, insert the correct information directly above and initial the correction. Timing and dating the correction also precludes potentially difficult questions of chronology and responsibility in a courtroom setting. By following these suggestions, the physician can avoid any accusations of intentionally concealing an error in judgment (Fig. 140–1).

A frequent claim is that the patient was abandoned or improperly monitored. For the above patient, although the chart appears to document repeated vital signs at appropriate intervals, no temperature is included after the first set until the patient is moribund; nor is any mention made again of the continued use of restraints, the patient's continued need for these restraints, or any adverse effects developing from the use of restraints. Additionally, documentation of physician assessment of the patient's medical condition is incomplete. For example, there is no mention in the physician's notes of the possible cause of the patient's change in mental status. Likewise, there is no documentation regarding the police officers' concerns that the patient was a "body stuffer." Body stuffers quickly ingest a drug to avoid detection, which can result in life-threatening toxicity (see Special Considerations SC-4: Body Packers and Body Stuffers). Documentation of the physician's review of this concern is necessary.

Quality assurance reviews of ED records often demonstrate inadequate charting by physicians and nurses monitoring patients who remain in the department for prolonged periods of time. Under any circumstances, a lapse of documentation of the patient's clinical condition for 4 hours or more after the initial physician and nursing assessment creates a potential risk management problem. In a lawsuit, the plaintiff's attorney would undoubtedly use such a record to develop the theory that no care whatsoever was given to the patient during this time interval, and that the patient was abandoned.

Monitoring notations in the patient's record are considered inadequate when they do not offer insight into the patient's clinical status. Thus, any monitoring note for a patient who must be restrained in the ED for a lengthy period of evaluation, observation, or until an inpatient bed becomes available must include specific clinical data and

FIGURE 140–1. Examples of the preferred and an unacceptable procedure for correcting an error in the medical record.

observations (laboratory results, radiographic findings, hemodynamic changes, and infusion of medications and solutions). All of these deficiencies would undoubtedly be noticed and highlighted at trial by a plaintiff's expert, who frequently is a board-certified physician in the same specialty.

Documentation supporting the restraint of an impaired patient against his will must include a clinical description to support such a forcible impediment to the patient's right to liberty and freedom of movement. Such a clinical description should specifically describe any manifestation of agitation and uncooperative behavior. The record should refer to the specific uncooperative acts of the patient and, most importantly, should comment on the difficulties in providing care to the patient because of the patient's actions.

Physicians who order restraints for patients must exercise extreme caution in the language used to describe such patients. A judgmental physician's note stating that a patient is "a chronic drunk and obnoxious" could undermine the support for the use of restraints. Poorly written physician's notes can become an issue in a medical malpractice action, with the plaintiff's attorney focusing on the derogatory nature of such a statement and suggesting a less-than-caring attitude by the doctor toward the patient. A plaintiff's appeal criticizing the ethical and social consciousness of the physician could very likely be seized upon by a jury and result in a punitive verdict against the physician. As a general rule, all healthcare professionals should depict a compassionate and professional manner when describing patient behavior and life styles in objective and concrete terms. An alternative and more appropriate description of a patient comparable to the one above would note that the patient had a "history of alcohol dependence and was agitated and/or combative."

To summarize, a well-documented ED record consistent with the accepted risk management principles set forth is the best course for the physician managing a difficult overdose situation in which legal principles may appear to present problems in providing proper medical management.

FORCIBLE RESTRAINT OF THE IMPAIRED PATIENT

Patient 3 A 31-year-old woman was found unresponsive on the street and brought to the ED by ambulance. Friends on the scene reported that the patient used methadone. In the ED she was unresponsive and apneic. Oxygen was immediately administered by bag-valve mask and intravenous access was obtained. Naloxone was administered, and shortly thereafter the patient regained consciousness. After 20 minutes of care in the ED, the patient became fully alert and oriented, with no evidence of hypoxia or other clinical signs to suggest impaired judgment. The patient stated that she had taken methadone and demanded to be discharged immediately.

The right of a hospital to retain and physically restrain a person who has an altered level of consciousness for evaluation and emergency intervention is generally well supported by states and case law.[6] Reasonably clear guidelines for the management of such impaired patients have evolved from legal precedents governing appropriate medical assessment, from risk management considerations, and from the predictability of patient injury in the event of premature discharge.

A staff decision to allow a treated or partially treated patient with a drug overdose who subsequently becomes alert to return to the community must be based on an assessment of several factors. The initial concern is the patient's capacity to comprehend. Before the patient can be permitted to leave the hospital, a determination would have to be made that the patient is capable of understanding the information

presented and has neither a medical nor a psychiatric problem preventing such a voluntary decision. The next consideration is that of medical stability. Has the initial process that caused the clinical scenario completed its course? The history of drug use in this patient is cause for concern that the underlying toxic metabolic process is not yet resolved, and alteration in mental status, significant respiratory compromise, or other medical symptoms may recur when the naloxone is metabolized, again placing the patient at risk.

Common ED practice and sound legal principles suggest that both the hospital and its staff have a duty to prevent such a person from leaving if the duration of the effect of the involved xenobiotic is longer than that expected for the antidote. Because the duration of effect for naloxone is considerably shorter than that of methadone, the physician can predict with reasonable certainty that coma or apnea will reoccur in the near future. The physician has the duty to inform the individual of the life-threatening nature of the condition, and then to retain, with restraints if necessary to retain, the patient in the hospital until medically stable.

Liability in this situation is further reduced when the chart substantiates the medical judgment that was the basis for the decision to retain the patient and, if applicable, the use of restraints. Such documentation should specifically note the likely relapse of the patient into a symptomatic state and that this occurrence could place the patient in a life-threatening situation. When documented in a clear manner, legal challenges to the decision to restrain the patient have a limited chance of success. Sound risk management principles support treatment and detainment. Conversely, prematurely releasing a patient with a significant overdose exposes both the physician and the hospital to a claim of negligence on the grounds of failure to foresee a likely and harmful event.

BLOOD ALCOHOL CONCENTRATION AND EVIDENCE COLLECTION

Patient 4 A 41-year-old man who was a driver involved in a motor vehicle collision was taken to the ED by ambulance. Two motorists in another vehicle were killed. The patient had no physical complaints, but was brought to the hospital for medical clearance. On arrival, he was alert and oriented, responded appropriately to all commands, and demonstrated normal motor function and had a normal gait. Police officers suspected that he was driving while intoxicated, but he refused a breath alcohol test at the scene.

The police officers informed the ED staff that he was arrested and might be charged with vehicular homicide. The officers then requested that the emergency physician draw a blood specimen to determine the blood alcohol concentration. The patient stated that he would not allow the ED staff to draw blood for a determination of an alcohol concentration.

In 2005, 16,885 people died in alcohol-related motor vehicle crashes, which was 39% of all traffic-related deaths in the United States.[9] An alcohol-related motor vehicle crash kills someone every 31 minutes and nonfatally injures someone every 2 minutes.[9] Drugs other than alcohol (eg, marijuana and cocaine) are involved in about 18% of motor vehicle driver deaths.[9,10] The judicial system has historically been one of the most effective tools to combat drunk driving, and its effectiveness depends on the ability to identify and punish individuals who violate the law. It is essential, however, that the collection of evidence does not violate the rights afforded by the US Constitution. Does forced phlebotomy for patients suspected of driving while intoxicated violate these protected rights? This has long been debated in the courts, and issues specifically brought into question include the Fourth Amendment,[22] the right against unreasonable search and seizure; the

Fifth Amendment,[23] the right against self-incrimination; and the Due Process clause of the Fourteenth Amendment.[24] Past decisions on these issues help guide current laws and practices.

Every state, and the District of Columbia, has driver "implied consent" laws. When a person obtains a driver's license, he or she consents at the time of acquisition to a chemical alcohol test if suspected of driving while intoxicated. Under implied consent laws, when a person suspected of driving while intoxicated refuses to take an alcohol test, a penalty is imposed. Specific penalties for refusals vary from state to state. At a minimum, the refusal results in suspension or revocation of a driver's license. Some states assign additional fines and penalties for this action. A few states allow the refusal itself to be submitted at trial in support of the prosecution, making it possible to be convicted of an intoxication charge without chemical evidence.[1] Certain states, for example Texas and Illinois, allow blood tests to be performed on patients as ordered by an officer of the law, when there is probable cause of driving while intoxicated resulting in severe injury.[13,21] Other states, such as New York and California, allow forced blood samples with a warrant issued by a judge.[3,11] State laws regarding the approach to this situation vary and it is important that the ED staff be familiar with the specific requirements of the law of that state.

How much force may be used to collect chemical evidence? Does a physician violate human dignity and privacy in obtaining evidence for the State? These issues have been addressed by the United States Supreme Court. In *Rochin v California*,[15] the Court overturned a conviction of drug possession based on violation of the Fourteenth Amendment. In this case, police were informed that Rochin was selling drugs. While entering the defendant's home, the police witnessed the defendant swallow two pills that were lying on the nightstand. When the officers failed to recover the pills on the scene, the officers took Rochin to the ED, where they directed the physician to administer an emetic through a nasogastric tube. The capsules were recovered from the vomit, and *Rochin* was convicted by the trial court for possessing morphine.[1,15] The Supreme Court reversed this decision, based on the Fourteenth Amendment, "nor shall any State deprive any person of life, liberty or property, without due process of law...."[25] The term *due process* is vague, and is defined on a case-by-case basis, but it essentially means that states must use fair legal procedures when depriving an individual of life, liberty, or property. In *Rochin*, the court concluded that forced emesis by a physician was believed to violate Due Process, stating:

> This is conduct that shocks the conscience. Illegally breaking into the privacy of the petitioner, the struggle to open his mouth and remove what was there, the forcible extraction of stomach contents—this course of proceeding by agents of government to obtain evidence is bound to offend even hardened sensibilities. They are methods too close to the rack and the screw to permit constitutional differentiation.[15]

The Supreme Court revisited the issues presented in *Rochin* 4 years later in *Breithaupt v Abram*.[2] Breithaupt was the driver of a truck that killed three occupants of another vehicle. In the ED, a police officer requested that a blood alcohol concentration be drawn. The blood, drawn while the patient was unconscious, was above the legal limit for alcohol and the patient was convicted of involuntary manslaughter. Breithaupt argued that the blood draw, as in forced emesis in *Rochin*, violated due process as he did not consent to its collection. Justice Clark disagreed, stating "the distinction rests on the fact that there is nothing 'brutal' or 'offensive' when done, as in this case, under the protective eye of a physician" and that the "blood test procedure has become routine in our everyday life."[1,2] Phlebotomy while the patient is unconscious and unable to give consent was determined not to violate the due process clause of the Fourteenth Amendment.

The Supreme Court continued to expand the scope of permissible phlebotomy in *Schmerber v California*.[17] Schmerber was involved in a motor vehicle crash in which the police officer suspected he was intoxicated. Unlike in *Breithaupt*, Schmerber was not unconscious, and a physician drew a blood sample at the officer's request despite the patient's verbal refusal. The attorney for Schmerber asserted that forced phlebotomy violated several constitutional rights. Specifically, it violated the Fourth, Fifth, and Fourteenth Amendments of the United States Constitution. He alleged that forced phlebotomy denied him due process of the law, it violated his privilege against self-incrimination, and it violated his right against unreasonable search and seizure.[1,17] The Supreme Court rejected all of these arguments. The phlebotomy did not violate the due process clause because "the extraction was made by a physician in a simple, medically acceptable manner in a hospital environment.... we cannot see that it should make any difference whether one states unequivocally that he objects or resorts to physical violence in protest or is in such condition that he is unable to protest."[17] Furthermore, the forced blood draw did not violate the Fifth Amendment's Privilege Against Self-incrimination because the Fifth Amendment only protects evidence of a "testimonial or communicative nature," such as writings or speech. Finally, there was no violation of the Fourth and Fourteenth Amendments' protections against unreasonable search and seizure:

> The delay necessary to obtain a warrant, under the circumstances, threatened the destruction of evidence.... Similarly, we are satisfied that the test chosen to measure petitioner's blood-alcohol level was a reasonable one. Extraction of blood samples for testing is a highly effective means of determining the degree to which a person is under the influence of alcohol. Such tests are a commonplace in these days of periodic physical examinations and experience with them teaches that the quantity of blood extracted is minimal, and that for most people the procedure involves virtually no risk, trauma, or pain.

To ensure compliance with standards set forth in *Schmerber*, the states have tailored laws and regulations governing the seizure of blood for the purpose of blood alcohol testing. Laws generally require the procedure be (1) done in a reasonable, medically approved manner, (2) incident to a lawful arrest, and (3) based on the belief that the arrestee is intoxicated. It should be remembered that the issues raised by any one case are complex, and the application in real situations is difficult. Laws and regulations governing blood draws for alcohol testing vary from state to state and are the subject of frequent restructuring and amendment. Medical staff should review with hospital counsel the local laws and regulations that pertain to these issues. However, physician and patient safety must always be the priority. The benefits of determining a patient's alcohol concentration must be weighed against the risks of the procedure. For example, drawing blood in an agitated patient may place the staff at risk for a needle stick and the patient at risk of vascular injury.

CONFIDENTIALITY

Patient 5 A 32-year-old woman was fired from her job as a high school mathematics teacher. The school board called for her termination after learning that she had a history of alcohol dependence and had a previous hospitalization for detoxification at the local community hospital. A parent on the school board was also employed as a nurse at the hospital, where the teacher had received therapy. The school board member (and nurse) had inadvertently accessed the teacher's medical record while caring for a patient with the same last name.

The Health Insurance Portability and Accountability Act (HIPAA) was created in 1996. Initially, the purpose of HIPAA was to increase the portability of health insurance, and allow employees to maintain insurance when they changed jobs. The Act called for the establishment

of several provisions, among them an electronic database designed to facilitate the exchange of information between healthcare providers, insurance companies, and those involved in financial and administrative transactions.[8] However, the idea of developing an electronic database brought to light already growing concerns regarding the maintenance of patient privacy. For the first time, patients' medical records would be accessible to an unlimited number of people working in healthcare, from bill processors to pharmacists to clinicians. Could a patient's right to privacy be jeopardized by a system designed to increase efficiency?

Prior to HIPAA, individual hospitals or physician offices designed their own methods for maintaining confidential patient information. Records were maintained on computers in some circumstances and on paper in others. Accessibility to that information was largely regulated by state laws, and supported by some federal regulations and ethical codes of conduct. During the 1990s, however, the weaknesses of the existing systems gained attention as multiple high profile breaches of confidentiality surfaced. For example, the medical records of a congresswoman were released to the media during her campaign, making her history of depression and a past suicide attempt public knowledge.[18] There were also several cases of the medical records of hospital employees being read by staff members not involved in the employees' care, health insurance companies releasing heath care information to employers without permission, and physicians releasing information to pharmaceutical companies that subsequently solicited the patient.[28] These breaches of ethics were each a testament to the fact that a patient's right to privacy needed more stringent regulation. If these examples could occur in the previous systems for recording information, then it could be assumed that further violations would occur with increased access through an electronic database.

The Privacy Rule of HIPAA has become the most well-publicized aspect of this Act among healthcare personnel. The Privacy Rule governs the use and disclosure of protected health information in the hands of healthcare providers, health plans, and healthcare clearinghouses.[8] The terminology used in the Privacy Rule is extensively defined. The following is a brief summary of the terms used:

Protected Health Information: This includes any individually identifiable information concerning the past, present, or future health of an individual; medical information pertaining to assessment and treatment of an individual; in addition to payment and billing information. All forms of information, written, oral, or electronic, are protected by this rule.

Covered Entities: This includes any person or business that provides health-related services or products. All those providing health-related services, for example, clinicians, pharmacists, medical equipment providers, and other healthcare providers, are considered covered entities. Companies that provide disability insurance, car insurance, or casualty insurance are not included in the rule.[8,25]

Healthcare Clearinghouses: These are entities that compile healthcare information, such as billing companies or data processing centers.

Institutions are required to provide all individuals with written notice of their privacy policy when they first seek medical care. Patients must be informed of how the institution may use and disclose information. The notice must also describe patients' rights, including the right to access their medical information and their right to file a complaint if they believe their rights are violated. The notice must be written in plain language, and the patient must be written acknowledgement of receipt of the information in the notice.

The Privacy Rule of HIPAA was not intended to impede healthcare. There are several exceptions to the rule. A covered entity is permitted to use and disclose protected health information for the purposes of evaluation and treatment. Physicians have the freedom to consult with each other, both within and outside their own institution in order to provide clinical care. Additionally, there are several specific exceptions to the Privacy Rule listed within the document—situations in which protected health information may and often must be disclosed, and may be done without an individual's permission. For example, activities related to public health, such as reporting communicable diseases, information necessary to report actual or suspected abuse, neglect or domestic violence, or information pertaining to cadaver organ or tissue donation are specifically exempt from the Privacy Rule.[7]

The HIPAA Privacy Rule specifically addresses consultations with poison centers (PCs). It states: "We consider the counseling and follow-up consultations provided by poison control centers with individual providers regarding patient outcomes to be treatment. Therefore, poison control centers and other healthcare providers can share protected health information about the treatment of an individual without a business associate contract."[7]

Violations of the Privacy Rule are subject to penalties, the severity of which is dependent on the type of infraction. Simple noncompliance may result in financial penalties; however, more significant or intentional disclosures of information may incur steeper fines in addition to criminal charges and potential imprisonment.[28]

OTHER LEGAL CONSIDERATIONS FOR POISON CENTERS AND POISON SPECIALISTS

Patient 6 The Poison Center (PC) received a call from a concerned mother that her daughter might have ingested one of the grandmother's diabetes medications. The mother stated that the child was acting normally all day at the grandmothers' house, but when the family returned home the child had become drowsy. When contacted, the grandmother had confirmed that one pill was missing from her purse although she did not know the name of her medication. The PC advised that the parents give the child juice and closely observe her for the next 6 hours. Approximately 2 hours later, while sleeping, the child had a seizure. The child continued to seize in the hospital, where medical evaluation revealed hypoglycemia. The patient subsequently suffered permanent neurological damage. The medication was later identified as glyburide. Action was brought against the PC, alleging inappropriate advice and failure to recommend transport to a hospital.

As a general rule, any physician who decides to treat a patient enters into a physician–patient relationship that creates well-established legal duties. Courts have ruled that the physician–patient encounter need not be a face-to-face interaction to have legal consequences. For example, the absence of physical contact between a physician and patient as in the practice of radiology and pathology does not preclude a patient from asserting that a duty of care exists.[4] More particularly and quite relevant to the practice of a PC, a New York State court ruled that an initial telephone call from a patient to a physician can be sufficient basis to hold that physician responsible for inappropriate advice or a significant error in judgment.[12] Given the legal precedents previously stated, it is eminently clear that contact with a poison information specialist is a sufficient foundation for a subsequent legal action if inappropriate advice was given.

STANDARDS OF CARE APPLICABLE IN POISON CENTERS

Standards of care applicable to toxicologists are examined under the same legal framework as other medical specialists. The basic medical malpractice concepts are universal with some variations from state to state. Generally, for patients to prevail in medical malpractice cases

they must demonstrate "by a preponderance of the evidence: (1) that the doctor's treatment fell below the ordinary standard of care expected of a physician in his [or her] medical specialty, and (2) the existence of a causal relationship between the alleged negligent treatment and the injury sustained.[30]" While standard of care is recognized not to be one of perfection, what constitutes the "ordinary standard of care" has much room for interpretation.

In the 19th century, courts determined what the "ordinary standard of care" was by introducing testimony from physicians practicing in the community where the event occurred. This was known as the strict locality rule.[31] The strict locality rule was intended to prevent the inequities of comparing rural physicians working with limited resources and under exigent conditions from physicians working in large urban hospital settings.[32] In many jurisdictions, however, the strict locality rule was rejected because: (1) it was difficult to find an expert witness in a small community to testify against another physician in the community, and (2) the strict locality rule permitted some small medical communities to set unacceptably low standards of care.[33] In response, some states adopted the modified locality rule, which compares the physician in question with physicians practicing "in similar localities."[31] Over time, the basis for the modified locality rule was also questioned. Advances in transportation, communication, and education continued to minimize the disparity between rural and urban medical practice. Many states abandoned the locality rule altogether, permitting evidence of nationwide medical practices, as described by one court:

> [A] physician must exercise that degree of care, skill, and proficiency exercised by reasonably careful, skillful, and prudent practitioners in the same class to which he [or she] belongs, acting under the same or similar circumstances. Rather than focusing on different standards for different communities, this standard uses locality as but one of the factors to be considered in determining whether the doctor acted reasonably.[34]

While there is movement toward reviewing nationwide medical practices, depending on the jurisdiction where the event occurs, any one of the above rules may apply. In New York, courts allow evidence from the specific locality where the event occurred, from statewide practice, or from nationwide practice.[35]

A discussion of standard of care for poison control specialists should also mention several operational aspects of poison centers. Poison information specialists are required to have rapid and accurate access to a standard information resource system that contains both basic information and recommendations to deal with most toxic exposures. If a patient were to bring an action, the negligence theory against the poison center might rely on deviations from the standard recommendations in these resources.

It would be inaccurate to suggest, however, that the duty of care owed by a poison information specialist can be measured only by how closely the advice given compares with these standard resources. Frequently, a poison specialist may encounter situations that cannot be managed in accordance with an information system alone, and may seek counsel from a clinical pharmacist or a medical toxicologist working with the poison control center. If this were to occur, any subsequent legal proceeding would also review carefully the content of the information given to the consultant regarding accuracy and appropriateness of treatment for the underlying toxicologic problem.

PRACTICES OF REGIONAL POISON CENTERS THAT CAN REDUCE POTENTIAL LIABILITIES

Clearly there are some inherent risks of potential liability for a PC. To minimize such risk and the risk of civil actions against a PC, quality assurance and risk management programs should be a regular function. Daily audits or monitoring of the advice given by poison

information specialists should be done. Such interactions enhance care and ensure patient safety for the individual and establish a higher general standard.

The medical toxicologists and clinical pharmacists responsible for supervising the poison information specialists must be able to adequately assess the competence and capabilities of the staff and to make recommendations, take corrective actions, and provide suggestions for improvement to involved members. This process is facilitated by such actions as audiotaping calls made to the PC and the subsequent advice given, and reviewing written records maintained by the information specialist on each particular case. Documentation is extremely important, because in the event of a lawsuit, the most likely area of dispute will be what was actually said to the patient.

SUMMARY

The risk management and legal issues of an active ED have implications for many patients. The ability of providers to function responsibly is dependent on an understanding of these constantly evolving principles. Those patients whose consciousness is abnormal because of a xenobiotic represent an acute complex medicolegal emergency. A well-organized hospital is dependent on a close working relationship among the legal, risk management, and medical personnel. Only in this manner can they learn, cooperate, and meet the needs of the ever-evolving clinical dilemmas they confront.
